The **Ruben cell** (Ruben, Balanced Alkaline Dry Cells, *Trans. Electrochem. Soc.,* **92,** 1947) was developed jointly by the Ruben Laboratories and P. R. Mallory & Company during World War II for the operation of radar equipment and other electronic devices which require a high ratio of ampere-hour capacity to the volume of the cell at higher current densities than were considered practicable for the Leclanché type. The anode is of amalgamated zinc, and the cathode is a mercuric oxide depolarizing material intimately mixed with graphite in order to reduce its electrical resistivity. The electrolyte is a solution of potassium hydroxide (KOH) containing potassium zincate. The cell is made in three forms as shown in Fig. 15.1.13, the wound-anode type (*a*), the button type (*b*), and the cylindrical type (*c*).

The no-load emf of the cell is 1.34 V and remains essentially constant irrespective of time and temperature. Advantages of the cell are long shelf life, which enables them to be stored indefinitely; long service life, about four times that of the Leclanché dry cell of equivalent volume; small weight; a flat voltage characteristic which is advantageous for electronic uses in which the characteristics of tubes vary widely with voltage; adaptability to operating at high temperatures without deterioration; high resistance to shock.

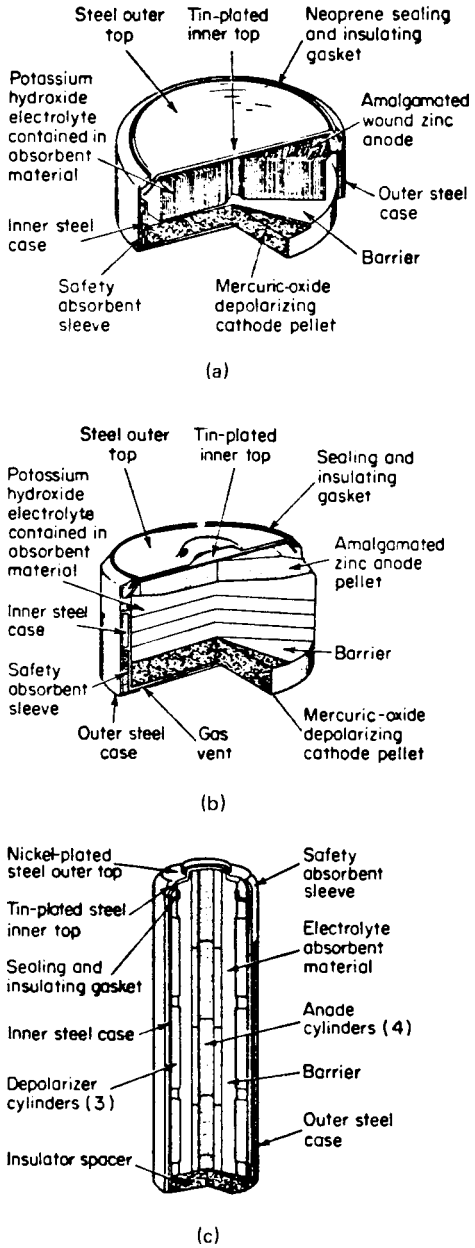

Fig. 15.1.13 Ruben cells. (*a*) Wound-anode; (*b*) button; (*c*) cylindrical. *(From "Standard Handbook for Electrical Engineers," Fink and Carrol, McGraw-Hill, NY, copyright 1968.)*

The **zinc-alkaline-manganese dioxide cell** is a cell especially useful in applications that require a dry cell with relatively heavy or continuous drain. The anode is of amalgamated zinc, and the cathode is a manganese dioxide depolarizing material mixed with graphite for conductivity. The electrolyte is a solution of highly alkaline potassium hydroxide immobilized in cellulosic-type separators. These cells are available in standard-size cylindrical construction and wafer (flat) construction for cassette and tape recorder applications.

Wet Cells The **silver** or **cuprous chloride-magnesium cell** is a one-shot battery with a life of days after the electrolyte is added. A wet cell may

be stored for years in a dry state. The cathode is either compacted copper chloride and graphite or sheet silver chloride, while the cathode is a thin magnesium sheet. The electrolyte is a solution of sodium chloride. The silver chloride cells are more expensive and are available in more and larger ratings.

The **Weston cell** is a primary cell used as a standard of emf. It consists of a glass H tube in the bottom of one leg of which is mercury which forms the cathode; in the bottom of the other leg is cadmium amalgam forming the anode. The electrolytes consist of mercurous sulfate and cadmium sulfate. There are two forms of the Weston cell: the saturated or normal cell and the unsaturated cell. In the normal cell the electrolyte is saturated. This is the official standard since it is more permanent than the unsaturated type and can be reproduced with far greater accuracy. When carefully made, the emfs of cells agree within a few parts per million. There is, however, a small temperature coefficient. Although the unsaturated cell is not so reliable as the normal cell and must be standardized, it has a negligible temperature coefficient and is more convenient for general use. The manufacturers recommend that the temperature be not less than 4°C and not more than 40°C and the current should not exceed 0.0001 A. The emf is between 1.0185 and 1.0190 V. Since no appreciable current can be taken from the cell, a null method must be used to utilize its emf.

Storage (Secondary) Batteries

In a **storage battery** the electrolytic action must be **reversible** to a high degree. There are three types of storage batteries; the lead-lead-acid type, the nickel-iron-alkaline type (**Edison** battery), and the nickel-cadmium-alkali type **(Nicad).** In addition, there are various specialized types of cells for scientific and military purposes, and there is continuous development work in the search for higher capacities.

In the manufacture of the **lead-lead-acid cells** there are three general types of plates, or electrodes. In the **Planté type** the active material is electrically formed of pure lead by repeated reversals of the charging current. In the **Faure,** or **pasted-plate,** type, the positive and negative plates are formed by applying a paste, largely of lead oxides (PbO_2, Pb_3O_4), to lead-antimony or lead calcium supporting grids. A current is passed through the plates while they are immersed in weak sulfuric acid, the positive plates being connected as anodes and the negative ones as cathodes. The paste on the positive plates is converted into lead peroxide while that on the negative plate is reduced to spongy lead. The **tubular plate** (iron-clad) type has lead-alloy rods surrounded by perforated dielectric tubes with powdered-lead oxides packed between the rod and tube for the positive plate.

In order to obtain high capacity per unit weight it is necessary to expose a large plate area to the action of the acid. This is done in the Planté plate by "ploughing" with sharp steel disks, and by using corrugated helical inserts as active positive material (Manchester plate). In the pasted plate a large area of the material is necessarily exposed to the action of the acid.

The chemical reactions in a lead cell may be expressed by the following equation, based on the double sulfation theory:

$$\underbrace{PbO_2}_{\text{positive plate}} + \underbrace{Pb}_{\text{negative plate}} + \underbrace{2H_2SO_4}_{\text{sulfuric acid}} \underset{\text{discharge}}{\overset{\text{charge}}{=}} \underbrace{2PbSO_4}_{\text{positive and negative plates}} + \underbrace{2H_2O}_{\text{water}}$$

Between the extremes of complete charge and discharge, complex combinations of lead and sulfate are formed. After complete discharge a hard insoluble sulfate forms slowly on the plates, and this is reducible only by slow charging. This sulfation is objectionable and should be avoided.

Specific Gravity Water is formed with discharge and sulfuric acid is formed on charge, consequently the specific gravity must decrease on discharge and increase on charge. The variation of the specific gravity for a stationary battery is shown in Fig. 15.1.14. With starting and

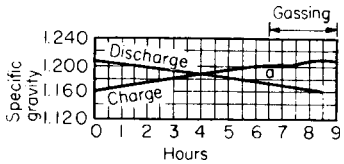

Fig. 15.1.14 Variations of specific gravity in a stationary battery.

vehicle batteries it is necessary to operate the electrolyte from between 1.280 to 1.300 when fully charged to as low as 1.100 when completely discharged. The condition of charge of a battery can be determined by its specific gravity.

Battery electrolyte may be made from concentrated sulfuric acid (oil of vitriol, sp gr 1.84) by **pouring the acid into the water** in the following proportions:

Parts Water to 1 Part Acid

Specific gravity	1.200	1.210	1.240	1.280
Volume	4.3	4.0	3.4	2.75
Weight	2.4	2.2	1.9	1.5

Freezing Temperature of Sulfuric Acid and Water Mixtures

Specific gravity	1.180	1.200	1.240	1.280
Freezing temp, °F	− 6	− 16	− 51	− 90

Voltage The emf of a lead cell when fully charged and idle is 2.05 to 2.10 V. Discharge lowers the voltage in proportion to the current. When charging at constant current and normal rate, the terminal voltage gradually increases from 2.14 to 2.3 V, then increases rapidly to between 2.5 and 2.6 V (Fig. 15.1.15). This latter interval is known as the **gassing period.** When this period is reached, the charging rate should be reduced in order to avoid waste of power and unnecessary erosion of the plates.

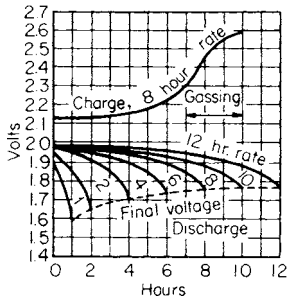

Fig. 15.1.15 Voltage curves on charge and discharge for a lead cell.

Practically all batteries have a **normal rating** based on the 8-h rate of discharge. Thus a 320 A · h battery would have a normal rate of 40 A. The ampere-hour capacity of batteries falls off rapidly with increase in discharge rate.

Effect of Discharge Rate on Battery Capacity

Discharge rate, h	8	5	3	1	⅓	1/10
Percentage of rated capacity,						
Planté type	100	88	75	55.8	37	19.5
Pasted type	100	93	83	63	41	25.5

The following rule may be observed in **charging a lead battery.** The charging rate in amperes should be less than the number of ampere-hours out of the battery. For example, if 200 A · h are out of a battery,

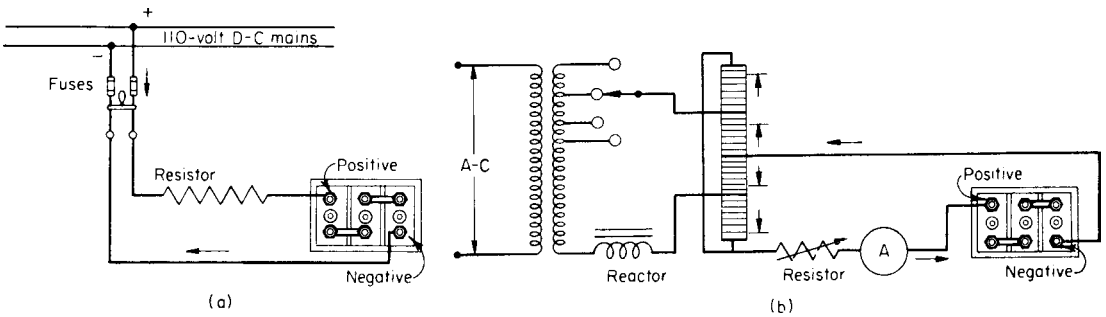

Fig. 15.1.16 Connections for charging a storage battery from (*a*) 110-V dc mains, (*b*) copper oxide rectifier.

a charging rate of 200 A may be used until the ampere-hours out of the battery are reduced appreciably.

There are two common methods of charging: the **constant-current method** and the **constant-potential method.** Figure 15.1.16*a* shows a common method of charging with constant current, provided a low-voltage dc power supply is available. The resistor connected in series may be adjusted to give the required current. Several batteries may be connected in series. Figure 15.1.16*b* shows a more common method, using a copper oxide or silicon rectifier, since ac power supply is more common than dc. The rectifier disks, mounted in a stack, are bridge-connected, the directions of rectification being indicated. The polarity of the two wires can readily be determined by means of a dc voltmeter.

The constant-potential method is to be preferred since the rate automatically tapers off as the cell approaches the charged condition. Without resistance the terminal voltage should be 2.3 V per cell, but it is preferable to use 2.4 to 2.5 V per cell with low resistance in series.

When a battery is being charged, its terminal voltage

$$V = E + Ir \tag{15.1.28}$$

Compare with Eq. (15.1.27).

When a battery is fully charged, any rate will produce gassing, but the rate may be reduced to such a low value that gassing is practically harmless. This is called the **finishing rate.**

Portable batteries for automobile starting and lighting, airplanes, industrial trucks, electric locomotives, train lighting, and power boats employ the pasted-type plates because of their high discharge rates for a given weight and size. The separators are either of treated grooved wood, perforated hard rubber, glass-wool mats, perforated rubber and grooved wood, or ribbed microporous rubber. In low-priced short-lived batteries for automobiles, grooved wood alone is used; in the better types, the wood is reinforced with perforated hard rubber. Containers for the low-priced short-lived automobile-type starting batteries are of asphaltic compound; for other portable types they are usually of hard rubber.

The **Exide iron-clad** battery is a portable type designed for propelling electric vehicles. The positive plate consists of a lead-antimony frame supporting perforated hard-rubber tubes. An irregular lead-antimony core runs down the center of each tube, and the lead peroxide paste is packed into these tubes so that shedding of active material from the positive plate cannot occur. Pasted negative plates are used. The separators are flat microporous rubber.

Stationary Batteries The tanks of stationary batteries are made of hard rubber or plastics. When the battery is used for regulating or cycling duty, the positive plates may be of the Planté type because of their long life. However, in most modern installations thick pasted plates are used. Because of the tight fit of the plate assembly within the container and the resulting pressure of the separator against the plate surfaces, shedding of active material is reduced to a minimum and long life is obtained. Pasted negative plates are used in almost all batteries.

A lead storage battery **removed from service** for less than 9 months should be charged once a month if possible; if not, it should be given a heavy overcharge before discontinuing service. If removed for a longer period, siphon off acid (which may be used again) and fill with fresh water. Allow to stand 15 h and siphon off water. Remove and throw away the wood separators. The battery will now stand indefinitely. To put in service again, install new separators, fill with acid (sp gr 1.210) and charge at normal rate 35 h or until gravity has ceased to rise over a period of 5 h. Charge at a low rate a few hours longer.

The **ampere-hour efficiency** of lead batteries is 85 to 90 percent. The **watthour efficiency** obtained from full charge to discharge at the normal rate and at rated amp-hour is 75 to 80 percent. Batteries which do regulating duty only may have a much higher watthour efficiency.

The **Edison storage cell** when fully charged has a positive plate of nickel pencils filled with a higher nickel oxide and a negative plate of flat nickel-plated-steel stampings containing metallic iron in finely divided form. The active material for the positive plate is nickel hydrate and for the negative plate, iron oxide. The electrolyte is a 21 percent solution of potassium hydrate with lithium hydroxides. The initial emf is about 1.4 V and the average emf about 1.1 V throughout discharge. In Fig. 15.1.17 are shown typical voltage characteristics on charge and discharge for an Edison cell. On account of the higher internal resistance of the cell the battery is not so efficient from the energy standpoint as the lead cell. The jar is welded nickel-plated steel. The battery is compact and extremely light and strong and for these reasons is particularly adapted for propelling electric vehicles and for boat- and train-lighting systems. The battery is rugged, and since there is no opportunity for the growth of active material on the plates or flaking of active material, the battery has long life.

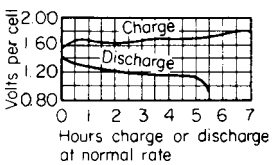

Fig. 15.1.17 Voltage during charge and discharge of an Edison cell.

Nickel-Cadmium-Alkali (Nicad) Battery The positive active material is nickelic (black) hydroxide mixed with graphite to give it high conductivity. The negative active material is cadmium oxide. Both materials are used in powdered form and are contained within flat perforated steel pockets. These pockets are locked into steel plates, the positive and negative being alike in construction. All steel parts are nickel-plated. A complete plate group consists of a number of positive and negative plates assembled on bolts and terminal posts common to plates of the same polarity. The separators are thin strips of polystyrene, and all other battery insulation is also polystyrene. The entire plate assembly is contained within a welded-steel tank. The electrolyte is potassium hydroxide (KOH), specific gravity 1.210 at 72°F (22°C); it does not enter into any chemical reactions with the electrode materials,

and its specific gravity remains constant during charge and discharge, neglecting any slight change due to the small amount of gassing. On charge, the voltage is 1.4 to 1.5 V until near the end when it rises to 1.8 V. On discharge, the voltage is nearly constant at 1.2 V.

Nicad batteries are strong mechanically and are not damaged by overcharge; they hold their charge over long periods of idleness, the active material cannot flake off, the internal resistance is low, there is no corrosion, and the battery has an indefinitely long life. It is a general-purpose battery.

In the **Sonotone** nickel-cadmium battery the positive plates are nickel oxide when the battery is charged, and the negative plates are metallic cadmium. On discharge the positive plates are reduced to a state of lower oxidation, and the negative plates regain oxygen. The electrolyte is a 30 percent solution of potassium hydroxide, the specific gravity of which is 1.29 at room temperature. The case is a transparent plastic. The terminal voltage at the normal discharge rate is 1.2 V per cell.

Rechargeable batteries, exemplified by Gould Nicad cells (Alkaline Battery Division, Gould National Batteries, Inc.), are hermetically sealed nickel-cadmium cells that contain no free alkaline electrolyte. Since there is no spillage or leakage, they can operate in any position, have long life, and require no maintenance or servicing, and their weight is small for their output. They are thus well adapted to power many types of cordless appliances such as tools, hedge shears, cameras, dictating equipment, electric razors, radios, and television sets. The electrodes consist of a plaque of microporous sintered nickel having an extremely high surface area. The electrochemical reactions differ from those of the conventional vented-type alkaline battery, a type which at the end of a charge liberates both oxygen and hydrogen gases as well as electrolytic fumes that must be vented through a valve in the top of the cell. In the sealed nickel-cadmium cell, the negative electrode (at the time that the cell is sealed) never becomes fully charged, and the evolution of hydrogen is completely suppressed. On charging, when the positive electrode has reached its full capacity, the oxygen which has evolved is channeled through the porous separator to the negative electrode and oxidizes the finely divided cadmium of the microporous plate to cadmium hydroxide, which at the same time is reduced to metallic cadmium. The cells are constructed in three different forms: the button type, the cylindrical type, and the prismatic type. Their ratings range from 20 mA · h to 23 A · h. Their average discharge voltage is 1.22 V, and they require 14 h of charge at the normal rate (one-tenth A · h rating), which for a 3.5 A · h cell is 0.35 A.

Precautions in the **care of storage batteries:** An ammeter should not be connected directly across the terminals to test the condition of a cell; a battery should not be left to stand in a discharged condition; a flame should not be brought in the vicinity of a battery that is being charged; the battery should not be allowed to become heated when charging; water should never be added to the concentrated acid—always acid to the water; acid should never be equalized except when the battery is in a charged condition; a battery should never be exposed to the influence of external heat; voltmeter tests should be made when the current is flowing; batteries should always be kept clean. To replace acid lost through slopping, use a solution of 2 parts concentrated sulfuric acid in 5 parts water by weight, unless a hydrometer is at hand to enable the solution to be made up according to the specifications of the makers of the cell.

DIELECTRIC CIRCUITS

Dynamic and Static Electricity Electricity in motion such as an electric current is dynamic electricity; electricity at rest is static electricity. The two are identical physically. Since static electricity is frequently produced at high voltage and small quantity, the two are frequently considered as being two different types of electricity.

Capacitors

Capacitors (formerly condensers) Two conducting bodies, or electrodes, separated by a dielectric constitute a capacitor. If a positive charge is placed on one electrode of a capacitor, an equal negative charge is induced on the other. The medium between the capacitor plates is called a **dielectric.** The dielectric properties of a medium relate to its ability to conduct **dielectric lines.** This is in distinction to its **insulating** properties which relate to its property to conduct **electric current.** For example, air is an excellent insulator but ruptures dielectrically at low voltage. It is not a good dielectric so far as breakdown strength is concerned.

With capacitors

$$Q = CE \tag{15.1.29}$$
$$C = Q/E \tag{15.1.30}$$
$$E = Q/C \tag{15.1.31}$$

where Q = quantity, C; C = capacitance, F; and E = voltage. The unit of capacitance in the practical system is the **farad.** The farad is too large a unit for practical purposes, so that either the **microfarad** (μF) or the **picofarad** (pF) are used. However, in voltage, current, and energy relations the capacitance must be expressed in farads.

The energy stored in a capacitor is

$$W = \tfrac{1}{2}QE = \tfrac{1}{2}CE^2 = \tfrac{1}{2}Q^2/C \quad \text{J} \tag{15.1.32}$$

Capacitance of Capacitors The capacitance of a **parallel-electrode** capacitor (Fig. 15.1.18) is

$$C = \varepsilon_r A/(4\pi d \times 9 \times 10^3) \quad \mu\text{F} \tag{15.1.33}$$

where ε_r = relative capacitivity; A = area of one electrode, m^2; and d = distance between electrodes, m.

Fig. 15.1.18 Parallel-electrode capacitor.

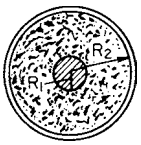

Fig. 15.1.19 Coaxial-cylinder capacitor.

The capacitance of **coaxial cylindrical** capacitors (Fig. 15.1.19) is

$$C = 0.2171\varepsilon_r l/[9 \times 10^5 \log (R_2/R_1)] \quad \mu\text{F} \tag{15.1.34}$$

where ε_r is the relative capacitivity and l the length, m. Also

$$C = 0.03882\varepsilon_r/\log(R_2/R_1) \quad \mu\text{F/mi} \tag{15.1.35}$$

Equation (15.1.35) is useful in that it is applicable to cables.

The capacitance of two **parallel cylindrical conductors** D m between centers and having radii of r m is

$$C = 0.01941/\log (D/r) \quad \mu\text{F/mi} \tag{15.1.36}$$

In practice, the capacitance to neutral or to an infinite conducting plane midway between the conductors and perpendicular to their plane is usually used. The capacitance to neutral is

$$C = 0.03882/\log (D/r) \quad \mu\text{F/mi} \tag{15.1.37}$$

Equations (15.1.36) and (15.1.37) are used for calculating the capacitance of overhead transmission lines. When computing charging current, use voltage between lines in (15.1.36) and to neutral in (15.1.37).

Capacitances in Parallel The equivalent capacitance of capacitances in parallel (Fig. 15.1.20) is

$$C = C_1 + C_2 + C_3 \tag{15.1.38}$$

Capacitances in parallel are all across the same voltage. If the voltage is E, then the total quantity $Q = CE$ and $Q_1 = C_1E$, etc.

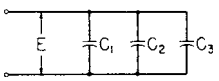

Fig. 15.1.20 Capacitances in parallel.

Capacitances in Series The equivalent capacitance C of capacitances in series (Fig. 15.1.21) is found as follows:

$$1/C = 1/C_1 + 1/C_2 + 1/C_3 \tag{15.1.39}$$

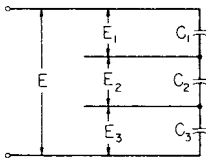

Fig. 15.1.21 Capacitances in series.

If the capacitances are not leaky, the charge Q is the same on each. $Q = CE$, $E_1 = Q/C_1$, $E_2 = Q/C_2$, etc.

Insulators and Dielectrics Insulating materials are applied to electric circuits to prevent the leakage of current. Insulating materials used with high voltage must not only have a high resistance to leakage current, but must also be able to resist dielectric puncture; i.e., in addition to being a good insulator, the material must be a good dielectric. Insulation resistance is usually expressed in MΩ and the resistivity given in MΩ · cm. The dielectric strength is usually given in terms of voltage gradient, common units being V/mil, V/mm, and kV/cm. Insulation resistance decreases very rapidly with increase in temperature. Absorbed moisture reduces the insulation resistance, and moisture and humidity have a large effect on surface leakage. In Table 15.1.8 are given the insulating and dielectric properties of several common insulating materials (see also Sec. 6). Dielectric heating of materials is described in Sec. 7.

TRANSIENTS

Induced EMF If a flux ϕ webers linking N turns of conductor changes, an emf

$$e = -N(d\phi/dt) \qquad \text{V} \qquad (15.1.40)$$

is induced.

Self-inductance Let a flux ϕ link N turns. The linkages of the circuit are $N\phi$ weber-turns. If the permeability of the circuit is assumed constant, the number of these linkages per ampere is the **self-inductance** or **inductance** of the circuit. The unit of inductance is the **henry.** The inductance is

$$L = N\phi/(i) \qquad \text{H} \qquad (15.1.41)$$

If the permeability changes with the current

$$L = N(d\phi/di) \qquad \text{H} \qquad (15.1.42)$$

The energy stored in the magnetic field

$$W = \tfrac{1}{2}Li^2 \qquad \text{J} \qquad (15.1.43)$$

EMF of Self-induction If Eq. (15.1.41) is written $Li = N\phi$ and differentiated with respect to the time t, $L(di/dt) = N(d\phi/dt)$ and from Eq. (15.1.40)

$$e = -L(di/dt) \qquad \text{V} \qquad (15.1.44)$$

e is the emf of self-induction. If a rate of change of current of 1 A/s induces an emf of 1 V, the inductance is then 1 H.

Current in Inductive Circuit If a circuit containing resistance R and inductance L in series is connected across a steady voltage E, the voltage E must supply the iR drop in the circuit and at the same time overcome the emf of self-induction. That is $E = Ri + L\,di/dt$. A solution of this differential equation gives

$$i = (E/R)(1 - e^{-Rt/L}) \qquad \text{A} \qquad (15.1.45)$$

where e is the base of the natural system of logarithms.

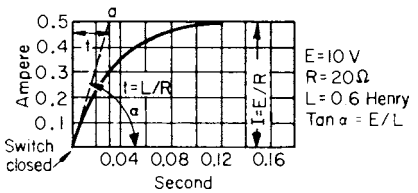

Fig. 15.1.22 Rise of current in an inductive circuit.

Figure 15.1.22 shows this equation plotted when $E = 10$ V, $R = 20\ \Omega$, $L = 0.6$ H. It is to be noted that inductance causes the current to rise slowly to its Ohm's law value, $I_0 = E/R = 10/20 = 0.5$ A. When $t = L/R$, the current has reached 63.2 percent of its Ohm's law value. L/R is the **time constant** of the circuit. In the foregoing circuit, the time constant $L/R = 0.6/20 = 0.03$ s. The initial rate of rise of current is $\tan \alpha = E/L$. If current continued at this rate, it would reach $\alpha = E/R$ in L/R s $[(E/L) \times (L/R) = E/R]$.

Table 15.1.8 Electrical Properties of Insulating Materials

Material	Volume resistivity, MΩ · cm	Dielectric constant, 60 Hz	Dielectric strength V/mil	Dielectric strength V/mm
Asbestos board (ebonized)	10^7		55	2×10^3
Bakelite	$5–30 \times 10^{11}$	4.5–5.5	450–1,400	$(17–55) \times 10^3$
Epoxy	10^{14}	3.5–5	300–400	$(12–16) \times 10^3$
Fluorocarbons:				
Fluorinated ethylene propylene	10^{18}	2.1	500	20×10^3
Polytetrafluoroethylene	10^{18}	2.1	400	16×10^3
Glass	17×10^9	5.4–9.9	760–3,800	$(3–15) \times 10^4$
Magnesium oxide		2.2	300–700	$(12–27) \times 10^3$
Mica	$10^{14}–10^{17}$	4.5–7.5	1,000–4,000	$(4–16) \times 10^4$
Nylon	$10^{14}–10^{17}$	4–7.6	300–400	$(12–16) \times 10^3$
Neoprene		7.5	600	23.5×10^3
Oils:				
Mineral	21×10^6	2–4.7	300–400	$(12–16) \times 10^3$
Paraffin	10^{15}	2.41	410–550	$(16–22) \times 10^3$
Paper		1.7–2.6	110–230	$(4–9) \times 10^3$
Paper, treated		2.5–4	500–750	$(20–30) \times 10^3$
Phenolic (glass filled)	$10^{12}–10^{13}$	5–9	140–400	$(5.5–16) \times 10^3$
Polyethylene	$10^{15}–10^{18}$	2.3	450–1,000	$(17–40) \times 10^3$
Polyimide	$10^{16}–10^{17}$	3.5	400	16×10^3
Polyvinyl chloride (flexible)	$10^{11}–10^{15}$	5–9	300–1,000	$(12–40) \times 10^3$
Porcelain	3×10^8	5.7–6.8	240–300	$(9.5–12) \times 10^3$
Rubber	$10^{14}–10^{16}$	2–3.5	500–700	$(20–27) \times 10^3$
Rubber (butyl)	10^{18}	2.1		

If a circuit containing inductance and resistance in series is short-circuited when the current is I_0, the equation of current becomes

$$i = I_0 e^{-Rt/L} \quad \text{A} \tag{15.1.46}$$

Figure 15.1.23 shows this equation plotted when $I_0 = 0.5$ A, $R = 20\ \Omega$, $L = 0.6$ H. It is seen that inductance opposes the decay of current. Inductance always opposes change of current.

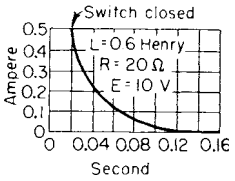

Fig. 15.1.23 Decay of current in an inductive circuit.

Mutual Inductance If two circuits having inductances L_1 and L_2 henrys are so related to each other geometrically that any portion of the flux produced by the current in one circuit links the other circuit, the two circuits possess **mutual inductance**. It follows that a change of current in one circuit causes an emf to be induced in the other. Let e_2 be induced in circuit 2 by a change di_1/dt in circuit 1. Then

$$e_2 = -M\,di_1/dt \quad \text{V} \tag{15.1.47}$$

M is the mutual inductance of the two circuits.

$$M = k\sqrt{L_1 L_2} \tag{15.1.48}$$

where k is the **coefficient of coupling** of the two circuits, or the proportion of the flux in one circuit which links the other. Also a change of current di_2/dt in circuit 2 induces an emf e_1 in circuit 1, $e_1 = -M\,di_2/dt$.

The stored energy is

$$W = \tfrac{1}{2}L_1 I_1^2 + \tfrac{1}{2}L_2 I_2^2 + MI_1 I_2 \quad \text{J} \tag{15.1.49}$$

where I_1 and I_2 are the currents in circuits 1 and 2.

Current in Capacitive Circuit If capacitance C farads and resistance R ohms are connected in series across the steady voltage E, the current is

$$i = (E/R)e^{-t/CR} \quad \text{A} \tag{15.1.50}$$

If a capacitor charged to voltage E is discharged through resistance R, the current is

$$i = -(E/R)e^{-t/CR} \quad \text{A} \tag{15.1.51}$$

Except for sign, these two equations are identical and are of the same form as Eq. (15.1.46).

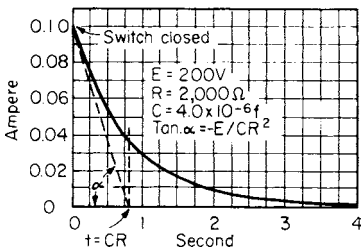

Fig. 15.1.24 Transient current to a capacitor.

In Fig. 15.1.24 is shown the transient current to a capacitor in series with a resistor when $E = 200$ V, $C = 4.0\ \mu$F, $R = 2$ kΩ. When $t = CR$, the current has reached $1/e = 0.368$ its initial value. CR is the **time constant** of the circuit. The initial rate of decrease of current is $\tan\alpha = -E/CR^2$. If the current continued at this rate it would reach zero when the time is CR s. If, in its fully charged condition, the capacitor of Fig. 15.1.24 is discharged through the resistor R, the curve will be the negative of that shown in Fig. 15.1.24.

Resistance, Inductance, and Capacitance in Series If a circuit having resistance, inductance, and capacitance in series is connected across a source of steady voltage, a transient condition results. If $R > \sqrt{4L/C}$, the circuit is nonoscillatory or overdamped.

The current is

$$i = \frac{EC}{\sqrt{R^2C^2 - 4LC}}\left(e^{(-\alpha+\beta)t} - e^{(-\alpha-\beta)t}\right) \quad \text{A} \tag{15.1.52}$$

where $\alpha = R/2L$ and $\beta = (\sqrt{R^2C^2 - 4LC})/2LC$.

In Fig. 15.1.25 is shown the curve corresponding to Eq. (15.1.52). When $R = \sqrt{4L/C}$, the system is **critically damped** and the transient dies out rapidly without oscillation. The current is

$$i = (E/L)te^{-Rt/2L} \quad \text{A} \tag{15.1.53}$$

Figure 15.1.25 shows also the curve corresponding to Eq. (15.1.53).

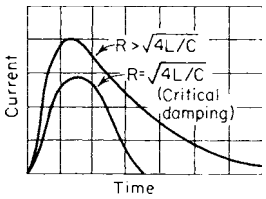

Fig. 15.1.25 Transient current in nonoscillatory circuits.

If $R < \sqrt{4L/C}$ the transient is oscillatory, being a logarithmically damped sine wave. The current is

$$i = \frac{2EC}{\sqrt{4LC - R^2C^2}}e^{-Rt/2L}\sin\frac{\sqrt{4LC - R^2C^2}}{2LC}t \quad \text{A} \tag{15.1.54}$$

The transient oscillates at a frequency very nearly equal to $1/(2\pi\sqrt{LC})$ Hz. This is the **natural frequency** of the circuit.

In Fig. 15.1.26 is shown the curve corresponding to Eq. (15.1.54). If the capacitor, after being charged to E V, is discharged into the foregoing series circuits, the currents are given by Eqs. (15.1.52) to (15.1.54) multiplied by -1. Equations (15.1.52) to (15.1.54) are the same types obtained with dynamic mechanical systems with friction, mass, and elasticity.

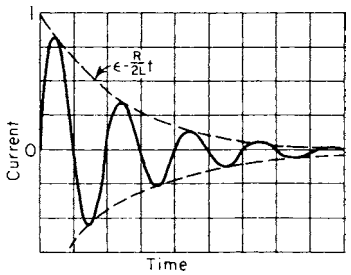

Fig. 15.1.26 Transient current in an oscillatory circuit.

ALTERNATING CURRENTS

Sine Waves In the following discussion of alternating currents, sine waves of voltage and current will be assumed. That is, $e = E_m \sin \omega t$ and $i = I_m \sin(\omega t - \theta)$, where E_m and I_m are maximum values of voltage and current; ω, the angular velocity, in rad/s, is equal to $2\pi f$, where f is the frequency; θ is the angle of phase difference.

Cycle; Frequency When any given armature coil has passed a pair of poles, the emf or current has gone through 360 electrical degrees, or 1 **cycle.** An **alternation** is one-half cycle. The **frequency** of a synchronous machine in cycles per second (hertz) is

$$f = NP/120 \quad \text{Hz} \tag{15.1.55}$$

where N is the speed in r/min and P the number of poles. In the United States and Canada the frequency of 60 Hz is almost universal for general lighting and power. For the ac power supply to dc transit systems,

and for railroad electrification, a frequency of 25 Hz is used in many installations. In most of Europe and Latin America the frequency of 50 Hz is in general use. In aircraft the frequency of 400 Hz has become standard.

Static inverters make it possible to obtain high and variable frequencies to drive motors at greater than the 3,600 r/min limitation on 60-Hz circuits, and to vary speeds. The textile industry has small motors operating at 12,000 r/min (200 Hz), and larger motors have been run at 6,000 r/min (100 Hz). Many large mainframe computers have been powered at 400 Hz.

The **root-mean-square (rms),** or **effective, value of a current wave** produces the same heating in a given resistance as a direct current of the same ampere value. Since the heating effect of a current is proportional to i^2r, the rms value is obtained by squaring the ordinates, finding their average value, and extracting the square root, i.e., the rms value is

$$I = \sqrt{1/T \int_0^T i^2\,dt} \qquad \text{A} \tag{15.1.56}$$

where T is the time of a cycle. The rms value I of a sine wave equals $(1/\sqrt{2})I_m = 0.707I_m$.

Average Value of a Wave The average value of a sine wave over a complete cycle is zero. For a half cycle the average is $(2/\pi)I_m$, or $0.637\,I_m$, where I_m is the maximum value of the sine wave. The average value is of importance only occasionally. A dc measuring instrument gives the average value of a pulsating wave. The average value is of use (1) when the effects of the current are proportional to the number of coulombs, as in electrolytic work and (2) when converting alternating to direct current.

Form Factor The form factor of a wave is the ratio of rms value to average value. For a sine wave this is $\pi/(2\sqrt{2}) = 1.11$. This factor is important in that it enters equations for induced emf.

Inductive reactance, $2\pi fL$ or ωL, opposes an alternating current in inductance L. It is expressed in Ω. Reactance is usually denoted by the symbol X. Inductive reactance is denoted by X_L.

The **current** in an inductive reactance X_L when connected across the voltage E is

$$I = E/X_L = E/(2\pi fL) \qquad \text{A} \tag{15.1.57}$$

This current lags the voltage by 90 electrical degrees. Inductance absorbs no energy. The energy stored in the magnetic field during each half cycle is returned to the source during the same half cycle.

Capacitive reactance is $1/(2\pi fC) = 1/\omega C$ and is denoted by X_C, where C is in F. If C is given in μF, $X_C = 10^6\,2\pi fC$. The current in a capacitive reactance X_C when connected across voltage E is

$$I = E/X_C = 2\pi fCE \qquad \text{A} \tag{15.1.58}$$

This current leads the voltage by 90 electrical degrees. Pure capacitance absorbs no energy. The energy stored in the dielectric field during each half cycle is returned to the source during the same half cycle.

Impedance opposes the flow of alternating current and is expressed in Ω. It is denoted by Z. With resistance and inductance in series

$$Z = \sqrt{R^2 + X_L^2} = \sqrt{R^2 + (2\pi fL)^2} \qquad \Omega \tag{15.1.59}$$

With resistance and capacitance in series

$$Z = \sqrt{R^2 + X_C^2} = \sqrt{R^2 + [1/(2\pi fC)]^2} \qquad \Omega \tag{15.1.60}$$

With resistance, inductance, and capacitance in series

$$Z = \sqrt{R^2 + (X_L - X_C)^2} = \sqrt{R^2 + [2\pi fL - 1/(2\pi fC)]^2} \qquad \Omega \tag{15.1.61}$$

The current is

$$I = E/\sqrt{R^2 + [2\pi fL - 1/(2\pi fC)]^2} \qquad \text{A} \tag{15.1.62}$$

Phasor or Vector Representation Sine waves of voltage and current can be represented by phasors, these phasors being proportional in magnitude to the waves that they represent. The angle between two phasors is also equal to the time angle existing between the two waves that they represent.

Phasors may be combined as forces are combined in mechanics. Both graphical methods and the methods of complex algebra are used. Impedances and also admittances may be similarly combined, either graphically or symbolically. The usual method is to resolve series impedances into their component resistances and reactances, then combine all resistances and all reactances, from which the resultant impedance is obtained. Thus $Z_1 + Z_2 = \sqrt{(r_1 + r_2)^2 + (x_1 + x_2)^2}$, where r_1 and x_1 are the components of Z_1, etc.

Phase Difference With resistance only in the circuit, the current and the voltage are in phase with each other; with inductance only in the circuit, the current lags the voltage by 90 electrical degrees; with capacitance only in the circuit, the current leads the voltage by 90 electrical degrees.

With resistance and inductance in series, the voltage leads the current by angle θ where $\tan\theta = X_L/R$. With resistance and capacitance in series, the voltage lags the current by angle θ where $\tan\theta = -X_C/R$.

With resistance, inductance, and capacitance in series, the voltage may lag, lead, or be in phase with the current.

$$\tan\theta = (X_L - X_C)/R = (2\pi fL - 1/2\pi fC)/R \tag{15.1.63}$$

If $X_L > X_C$ the voltage leads; if $X_L < X_C$ the voltage lags; if $X_L = X_C$ the current and voltage are in phase and the circuit is in resonance.

Power Factor In ac circuits the power $P = I^2R$ where I is the current and R the effective resistance (see below). Also the power

$$P = EI\cos\theta \qquad \text{W} \tag{15.1.64}$$

where θ is the phase angle between E and I. Cos θ is the **power factor** (pf) of the circuit. It can never exceed unity and is usually less than unity.

$$\cos\theta = P/EI \tag{15.1.65}$$

P is often called the true power. The product EI is the volt-amp (V · A) and is often called the apparent power.

Active or **energy** current is the projection of the total current on the voltage phasor. $I_e = I\cos\theta$. Power $= EI_e$.

Reactive, quadrature, or **wattless current** $I_q = I\sin\theta$ and is the component of the current that contributes no power but increases the I^2R losses of the system. In power systems it should ordinarily be made low.

The **vars** (volt-amp-reactive) are equal to the product of the voltage and reactive current. **Vars** $= EI_q$. **Kilovars** $= EI_q/1{,}000$.

Effective Resistance When alternating current flows in a circuit, the losses are ordinarily greater than are given by the losses in the ohmic resistance alone. For example, alternating current tends to flow near the surface of conductors (skin effect). If iron is associated with the circuit, eddy-current and hysteresis losses result. These power losses may be accounted for by increasing the ohmic resistance to a value R, where R is the **effective resistance,** $R = P/I^2$. Since the iron losses vary as $I^{1.8}$ to I^2, little error results from this assumption.

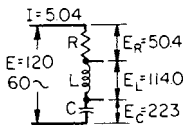

Fig. 15.1.27 Resistor, inductor, and capacitor in series.

SOLUTION OF SERIES-CIRCUIT PROBLEM. Let a resistor R of 10 Ω, an inductor L of 0.06 H, and a capacitor C of 60 μF be connected in series across 120-V 60-Hz mains (Fig. 15.1.27). Determine (1) the impedance, (2) the current, (3) the voltage across the resistance, the inductance, the capacitance, (4) the power factor, (5) the power, and (6) the angle of phase difference.

(1) $\omega = 2\pi 60 = 377$. $X_L = 0.06 \times 377 = 22.6\ \Omega$; $X_C = 1/(377 \times 0.000060) = 44.2\ \Omega$; $Z = \sqrt{(10)^2 + (22.6 - 44.2)^2} = 23.8\ \Omega$; (2) $I = 120/23.8 = 5.04$ A; (3) $E_R = IR = 5.04 \times 10 = 50.4$ V; $E_L = IX_L = 5.04 \times 22.6 = 114.0$ V; $E_C = IX_C = 5.04 \times 44.2 = 223$ V; (4) $\tan\theta = (X_L - X_C)/R = -21.6/10 = -2.16$, $\theta = -65.2°$, $\cos\theta = \text{pf} = 0.420$; (5) $P = 120 \times 5.04 \times 0.420 = 254$ W; $P = I^2R = (5.04)^2 \times 10 = 254$ W (check); (6) from (4) $\theta = -65.2°$. Voltage lags. The phasor diagram to scale of this circuit is shown in Fig. 15.1.28. Since the current is common for all elements of the circuit, its phasor is laid horizontally along the axis of reference.

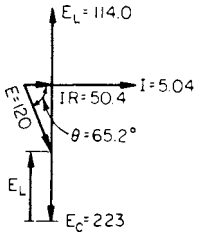

Fig. 15.1.28 Phasor diagram for a series circuit.

Resonance If the voltage E and the resistance R [Eq. (15.1.62)] are fixed, the maximum value of current occurs when $2\pi fL - 1/2\pi fC = 0$. The circuit so far as its terminals are concerned behaves like a noninductive resistor. The current $I = E/R$, the power $P = EI$, and the power factor is unity.

The voltage across the inductor and the voltage across the capacitor are opposite and equal and may be many times greater than the circuit voltage. The frequency

$$f = 1/(2\pi\sqrt{LC}) \quad \text{Hz} \tag{15.1.66}$$

is the **natural frequency** of the circuit and is the frequency at which it will oscillate if the circuit is not acted upon by some external frequency. This is the principle of radio sending and receiving circuits. Resonant conditions of this type should be avoided in power circuits, as the piling up of voltage may endanger apparatus and insulation.

EXAMPLE. For what value of the inductance in the circuit (Fig. 15.1.27) will the circuit be in resonance, and what is the voltage across the inductor and capacitor under these conditions?

From Eq. (15.1.66) $L = 1/(2\pi f)^2C = 0.1173$ H. $I = E/R = 120/10 = 12$ A. $L\omega I = I/C\omega = 0.1173 \times 377 \times 12 = 530$ V. This voltage is over four times the line voltage.

Parallel Circuits Parallel circuits are used for nearly all power distribution. With several series circuits in parallel it is merely necessary to find the current in each and add all the current phasors vectorially to find the total current. Parallel circuits may be solved analytically.

A series circuit has resistance r_1 and **inductive reactance** x_1. **The conductance** is

$$g_1 = r_1/(r_1^2 + x_1^2) = r_1/Z_1^2 \quad \text{S} \tag{15.1.67}$$

and the **susceptance** is

$$b_1 = x_1/(r_1^2 + x_1^2) = x_1/Z_1^2 \quad \text{S} \tag{15.1.68}$$

Conductance is not the reciprocal of resistance unless the reactance is zero; susceptance is not the reciprocal of reactance unless the resistance is zero. With inductive reactance the susceptance is **negative;** with capacitive reactance the susceptance is **positive.**

If a second circuit has resistance r_2 and **capacitive reactance** x_2 in series, $g_2 = r_2/(r_2^2 + x_2^2) = r_2/Z_2^2$; $b_2 = x_2/(r_2^2 + x_2^2) = x_2/Z_2^2$. The total conductance $G = g_1 + g_2$; the total susceptance $B = -b_1 + b_2$. The **admittance** is

$$Y = \sqrt{G^2 + B^2} = 1/Z \quad \text{S} \tag{15.1.69}$$

The energy current is EG; the reactive current is EB; the power is

$$P = E^2G \quad \text{W} \tag{15.1.70}$$
$$\text{vars} = E^2B \quad \text{W} \tag{15.1.71}$$

The power factor is

$$\text{pf} = G/Y \tag{15.1.72}$$

Also the following relations hold:

$$r = g/(g^2 + b^2) = g/Y^2 \quad \Omega \tag{15.1.73}$$
$$x = b/(g^2 + b^2) = b/Y^2 \quad \Omega \tag{15.1.74}$$

SOLUTION OF A PARALLEL-CIRCUIT PROBLEM. In the parallel circuit of Fig. 15.1.29 it is desired to find the joint impedance, the total current, the power in each branch, the total power, and the power factor, when $E = 100$, $f = 60$, $R_1 = 2\ \Omega$, $R_2 = 4\ \Omega$, $L_1 = 0.00795$ H, $X_1 = 2\pi fL_1 = 3\ \Omega$, $C_2 = 1{,}326\ \mu$F, $X_2 = 1/2\pi fC_2 = 2\ \Omega$, $Z_1 = \sqrt{2^2 + 3^2} = 3.6\,\Omega$, and $Y_1 = 1/3.6 = 0.278$ S.

Solution: $g_1 = R_1/(R_1^2 + X_1^2) = 2/13 = 0.154$; $b_1 = -3/13 = -0.231$; $Z_2 = \sqrt{16 + 4} = 4.47$; $Y_2 = 1/4.47 = 0.224$; $g_2 = R_2/(R_2^2 + X_2^2) = 4/(16 + 4) = 0.2$ S; $b_2 = 2/20 = 0.1$ S; $G = g_1 = g_2 = 0.154 + 0.2 = 0.354$ S; $B = b_1 + b_2 = -0.231 + 0.1 = -0.131$ S; $Y = \sqrt{G^2 + B^2} = \sqrt{0.354^2 + (-0.131)^2} = 0.377$ S, and joint impedance $Z = 1/0.377 = 2.65\ \Omega$. Phase angle $\theta = \tan^{-1}(-0.131/0.354) = -20.3°$. $I = EY = 100 \times 0.377 = 37.7$ A; $P_1 = E^2g_1 = 100^2 \times 0.154 = 1{,}540$ W; $P_2 = E^2g_2 = 100^2 \times 0.2 = 2{,}000$ W; total power $= E^2G = 100^2 \times 0.354 = 3{,}540$ W. Power factor $= \cos\theta = 3{,}540/(100 \times 37.7) = 93.8$ percent.

With parallel circuits, unity power factor is obtained when the algebraic sum of the quadrature currents is zero. That is, $b_1 + b_2 + b_3 \cdots = 0$.

Three-Phase Circuits Ac generators are usually wound with three armature circuits which are spaced 120 electrical degrees apart on the armature. Hence these coils generate emfs 120 electrical degrees apart. The coils are connected either in Y (star) or in Δ (mesh) as shown in Fig. 15.1.30. Whether Y- or Δ-connected, with a balanced load, the three coil emfs E_c and the three coil currents I_c are equal. In the Y connection the line and coil currents are equal, but the line emfs E_{AB}, E_{BC}, E_{CA} are $\sqrt{3}$ times in magnitude the coil emfs E_{OA},

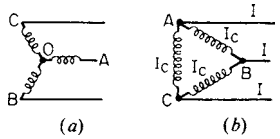

Fig. 15.1.30 Three-phase connections. (*a*) Y connection; (*b*) Δ connection.

E_{OB}, E_{OC}, since each is the phasor difference of two coil emfs. In the delta connection the line and coil emfs are equal, but I, the line current, is $\sqrt{3}I_c$, the coil current, i.e., it is the phasor difference of the currents in the two coils connected to the line. The power of a coil is $E_cI_c \cos\theta$, so that the total power is $3E_cI_c \cos\theta$. If θ is the angle between coil current and coil voltage, the angle between line current and line voltage will be $30° \pm \theta$. In terms of line current and emf, the power is $\sqrt{3}EI\cos\theta$. A fourth or neutral conductor connected to O is frequently used with the Y connection. The neutral point O is frequently grounded in transmission and distribution circuits. The coil

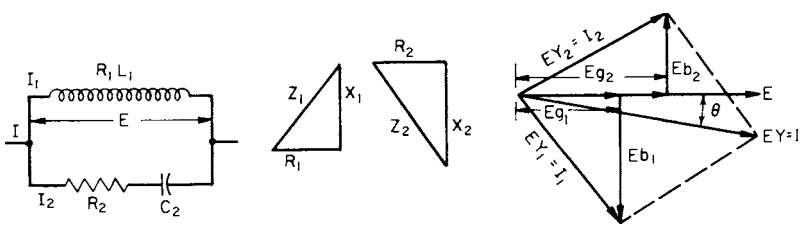

Fig. 15.1.29 Parallel circuit and phasor diagrams.

emfs are assumed to be sine waves. Under these conditions they balance, so that in the delta connection the sum of the two coil emfs at each instant is balanced by the third coil emf. Even though the third, ninth, fifteenth . . . harmonics, $3(2n + 1)f$, where $n = 0$ or an integer, exist in the coil emfs, they cannot appear between the three external line conductors of the three-phase Y-connected circuit. In the delta circuit, the same harmonics $3(2n + 1)f$ cause local currents to circulate around the mesh. This may cause a very appreciable heating. In a three-phase system the power

$$P = \sqrt{3}EI \cos \theta \quad \text{W} \tag{15.1.75}$$

the power factor is

$$P/\sqrt{3}EI \tag{15.1.76}$$

and the kV · A

$$\sqrt{3}EI/1{,}000 \tag{15.1.77}$$

where E and I are line voltages and currents.

Two-Phase Circuits Two-phase generators have two windings spaced 90 electrical degrees apart on the armature. These windings generate emfs differing in time phase by 90°. The two windings may be independent and power transmitted to the receiver though the two single-phase circuits are entirely insulated from each other. The two circuits may be combined into a two-phase three-wire circuit such as is shown in Fig. 15.1.31, where OA and OB are the generator circuits

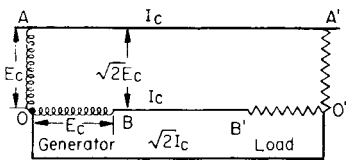

Fig. 15.1.31 Two-phase, three-wire circuit.

(or transformer secondaries) and $A'O'$ and $B'O'$ are the load circuits. The wire OO' is the common wire and under balanced conditions carries a current $\sqrt{2}$ times the current wires AA' and BB'. For example, if I_c is the coil current, $\sqrt{2}\,I_c$ will be the value of the current in the common conductor OO'. If E_c is the voltage across OA or OB, $\sqrt{2}\,E_c$ will be the voltage across AB. The power of a two-phase circuit is twice the power in either coil if the load is balanced. Normally, the voltages OA and OB are equal, and the current is the same in both coils. Owing to nonsymmetry and the high degree of unbalancing of this system even under balanced loads, it is not used at the present time for transmission and is little used for distribution.

Four-Phase Circuit A four-phase or quarter-phase circuit is shown in Fig. 15.1.32. The windings AC and BD may be independent or

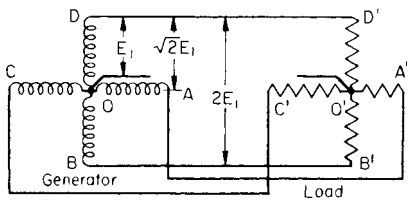

Fig. 15.1.32 Four-phase or quarter-phase circuit.

connected at O. The voltages AC and BD are 90 electrical degrees apart as in two-phase circuits. If a neutral wire O-O' is added, three different voltages can be obtained. Let E_1 = voltage between O-A, O-B, O-C, O-D. Voltages between A-B, B-C, C-D, D-$A = \sqrt{2}\,E_1$. Voltages between A-C, B-$D = 2E_1$. Because of this multiplicity of voltages and the fact that polyphase power apparatus and lamps may be connected at the same time, this system is still used to some extent in distribution.

Advantages of Polyphase Power The advantages of polyphase power over single-phase power are as follows. The output of synchronous generators and most other rotating machinery is from 60 to 90 percent greater when operated polyphase than when operated single phase; pulsating fluxes and corresponding iron losses which occur in many common types of machinery when operated single phase are negligible when operated polyphase; with balanced polyphase loads polyphase power is constant whereas with single phase the power fluctuates over wide limits during the cycle. Because of its minimum number of wires and the fact that it is not easily unbalanced, the three-phase system has for the most part superseded other polyphase systems.

ELECTRICAL INSTRUMENTS AND MEASUREMENTS

Electrical measuring devices that merely indicate, such as ammeters and voltmeters, are called **instruments;** devices that totalize with time such as watthour meters and ampere-hour meters are called **meters.** (See also Sec. 16.) Most types of electrical instruments are available with digital read out.

DC Instruments Direct current and voltage are both measured with an indicating instrument based on the principle of the D'Arsonval galvanometer. A coil with steel pivots and turning in jewel bearings is mounted in a magnetic field produced by permanent magnets. The motion is restrained by two small flat coiled springs, which also serve to conduct the current to the coil. The deflections of the coil are read with a light aluminum pointer attached to the coil and moving over a graduated scale. The same instrument may be used for either current or voltage, but the method of connecting in circuit is different in the two cases. Usually, however, the coil of an instrument to be used as an ammeter is wound with fewer turns of coarser wire than an instrument to be used as a voltmeter and so has lower resistance. The instrument itself is frequently called a **millivoltmeter.** It cannot be used alone to measure voltage of any magnitude since its resistance is so low that it would be burned out if connected across the line. Hence a resistance r' in series with the coil is necessary as indicated in Fig. 15.1.33*a* in which r_c is the resistance of the coil. From 0.2 to 750 V this resistance is usually within the instrument. For higher voltages an external resistance R, called an extension coil or multiplier (Fig. 15.1.33*b*), is necessary. Let e be the reading of the instrument, in volts (Fig. 15.1.33*b*), r the internal resistance of the instrument, including r' and r_c in Eq. (15.1.33*a*), R the resistance of the multiplier. Then the total voltage is

$$E = e(R + r)/r \tag{15.1.78}$$

It is clear that by using suitable values of R a voltmeter can be made to have several scales.

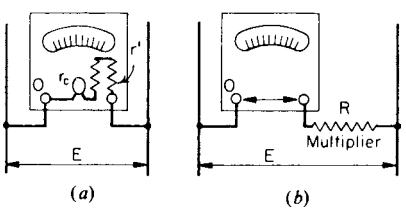

Fig. 15.1.33 Voltmeters. (*a*) Internal resistance; (*b*) with multiplier.

Instruments themselves can only carry currents of the magnitudes of 0.01 to 0.06 A. To measure larger values of current the instrument is provided with a shunt R (Fig. 15.1.34). The current divides inversely as the resistances r and R of the instrument and the shunt. A low resistance r' within the instrument is connected in series with the coil. This permits some adjustment to the deflection so that the instrument can be adapted to its shunt. Usually most of the current flows through the shunt, and the current in the instrument is negligible in comparison. Up to 50 and 75 A the shunt can be incorporated within the instrument. For larger currents it is usually necessary to have the shunt external to

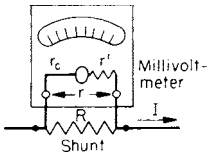

Fig. 15.1.34 Millivoltmeter with shunt.

the instrument and connect the instrument to the potential terminals of the shunt by means of leads. Any given instrument may have any number of ranges by providing it with a sufficient number of shunts. The range of the usual instrument of this type is approximately 50 mV. Although the same instrument may be used for voltmeters or ammeters, the moving coils of voltmeters are usually wound with more turns of finer wire. They take approximately 0.01 A so that their resistance is approximately 100 Ω/V. Instruments used as ammeters alone operate with 0.01 to 0.06 A.

Permanent-magnet moving-coil instruments may be used to measure unidirectional pulsating currents or voltages and in such cases will indicate the average value of the periodically varying current or voltage.

AC Instruments Instruments generally used for alternating currents may be divided into five types: **electrodynamometer, iron-vane, thermocouple, rectifier,** and **electronic.** Instruments of the **electrodynamometer** type, the most precise, operate on the principle of one coil carrying current, turning in the magnetic field produced by a second coil carrying current taken from the same circuit. If these circuits or coils are connected in series, the torque exerted on the moving system for a given relative position of the coil system is proportional to the square of the current and is not dependent on the direction of the current. Consequently, the instrument will have a compressed scale at the lower end and will usually have only the upper two-thirds of the scale range useful for accurate measurement. Instruments of this type ordinarily require 0.04 to 0.08 A or more in the moving-coil circuit for full-scale deflection. They read the rms value of the alternating or pulsating current. The wattmeter operates on the electrodynamometer principle. The fixed coil, however, is energized by the current of the circuit, and the moving coil is connected across the potential in series with high resistance. Unless shielded magnetically the foregoing instruments will not, in general, indicate so accurately on direct as on alternating current because of the effects of external stray magnetic fields. Also reversed readings should be taken. **Iron vane** instruments consist of a fixed coil which actuates magnetically a light movable iron vane mounted on a spindle; they are rugged, inexpensive, and may be had in ranges of 30 to 750 V and 0.05 to 100 A. They measure rms values and tend to have compressed scales as in the case of electrodynamometer instruments.

The compressed part of the scale may, however, be extended by changing the shape of the vanes. Such instruments operate with direct current and are accurate to within 1 percent or so. AC instruments of the **induction type** (Westinghouse Electric Corp.) must be used on ac circuits of the frequency for which they have been designed. They are rugged and relatively inexpensive and are used principally for switchboards where a long-scale range and a strong deflecting torque are of particular advantage. **Thermocouple instruments** operate on the **Seebeck effect.** The current to be measured is conducted through a heater wire, and a thermojunction is either in thermal contact with the heater or is very close to it. The emf developed in the thermojunction is measured by a permanent-magnet dc type of instrument. By controlling the shape of the air gap, a nearly uniform scale is obtained. This type of instrument is well adapted to the measurement of high-frequency currents or voltages, and since it operates on the heating effect of current, it is convenient as a transfer instrument between direct current and alternating current.

In the **rectifier-type instrument** the ac voltage or current is rectified, usually by means of a small copper oxide or a selenium-type rectifier, connected in a bridge circuit to give full-wave rectification (Fig. 15.1.35). The rectified current is measured with a dc permanent-magnet-type instrument *M*. The instrument measures the **average** value of the half waves that have been rectified, and with the sine waves, the average

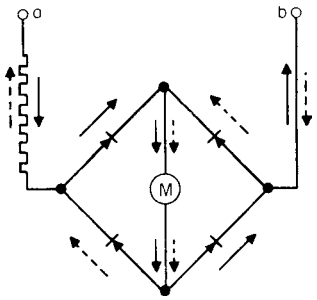

Fig. 15.1.35 Rectifier-type instrument.

value is 0.9 the rms value. The scale is calibrated to indicate rms values. With nonsinusoidal waves the ratio of average to rms may vary considerably from 0.9 so that the instrument may be in error up to ± 5 percent from this cause. This type of instrument is widely used in the measurement of high-frequency voltages and currents. **Electronic voltmeters** operate on the principle of the amplification which can be obtained with a transistor. Since the emf to be measured is applied to the base, the instruments take practically no current and hence are adapted to measure potential differences which would change radically were any appreciable current taken by the measuring device. This type of instrument can measure voltages from a few tenths of a volt to several hundred volts, and with a potential divider, up to thousands of volts. They are also adapted to frequencies up to 100 MHz.

Particular care must be used in selecting instruments for measuring the nonsinusoidal waves of rectifier and controlled rectifier circuits. The **electrodynamic, iron vane,** and **thermocouple** instruments will read rms values. The **rectifier** instrument will read average values, while the **electronic** instrument may read either rms or average value, depending on the type.

Power Measurement in Single-Phase Circuits Wattmeters are not rated primarily in W, but in A and V. For example, with a low power factor the current and voltage coils may be overloaded and yet the needle be well on the scale. The current coil may be carrying several times its rated current, and yet the instrument reads zero because the potential circuit is not closed, etc. Hence it is desirable to use both an ammeter and a voltmeter in conjunction with a wattmeter when measuring power (Fig. 15.1.36*a*). The instruments themselves consume appreciable power, and correction is often necessary unless these losses are negligible compared with the power being measured. For example, in Fig. 15.1.36*a*, the wattmeter measures the $I^2 R$ loss in its own current coil and in the ammeter (1 to 2 W each), as well as the loss in the voltmeter ($=E^2/R$ where R is the resistance of the voltmeter). The losses in the ammeter and voltmeter may be eliminated by short-circuiting the

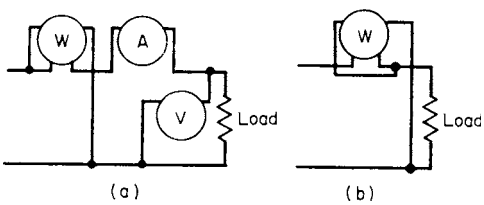

Fig. 15.1.36 Connections of instruments to single-phase load.

ammeter and disconnecting the voltmeter when reading the wattmeter. If the wattmeter is connected as shown in Fig. 15.1.36*b*, it measures the power taken by its own potential coil (E^2/R_p) which at 110 V is 5 to 7 W. (R_p is the resistance of the potential circuit.) Frequently correction must be made for this power.

Power Measurement in Polyphase Circuits; Three-Wattmeter Method Let *ao*, *bo*, and *co* be any Y-connected three-phase load (Fig. 15.1.37). Three wattmeters with their current coils in each line and

their potential circuits connected to neutral measure the total power, since the power in each load is measured by one of the wattmeters. The connection oo' may, however, be broken, and the total power is still the sum of the three readings; i.e., the power $P = P_1 + P_2 + P_3$. This method is applicable to any system of n wires. The current coil of one

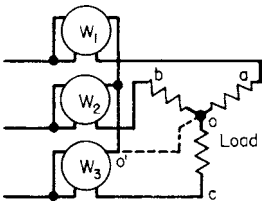

Fig. 15.1.37 Three-wattmeter method.

wattmeter is connected in each of the n wires. The potential circuit of each wattmeter is connected between its own phase wire and a junction in common with all the other potential circuits. The wattmeters must be connected symmetrically, and the readings of any that read negative must be given the negative sign.

In the general case any system of n wires requires at least $n - 1$ wattmeters to measure the power correctly. The $n - 1$ wattmeters are connected in series with $n - 1$ wires. The potential circuit of each is connected between its own phase wire and the wire in which no wattmeter is connected (Fig. 15.1.38).

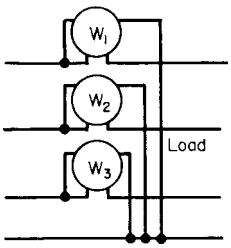

Fig. 15.1.38 Power measurement in an n-wire system.

The thermal watt converter is also used to measure power. This instrument produces a dc voltage proportional to three-phase ac power.

Three-Phase Systems The three-wattmeter method (Fig. 15.1.37) is applicable to any three-phase system. It is commonly used with the three-phase four-wire system. If the loads are balanced, $P_1 = P_2 = P_3$ and the power $P = 3P_1$.

The **two-wattmeter** method is most commonly used with three-phase three-wire systems (Fig. 15.1.39). The current coils may be connected in *any* two wires, the potential circuits being connected to the third. It will be recognized that this is adapting the method of Fig. 15.1.38 to three wires. With balanced loads the readings of the wattmeters are $P_1 = Ei \cos(30° + \theta)$, $P_2 = Ei \cos(30° - \theta)$, and $P = P_2 \pm P_1$. θ is the angle of phase difference between coil voltage and current. Since

$$P_1/P_2 = \cos(30° + \theta)/\cos(30° - \theta) \qquad (15.1.79)$$

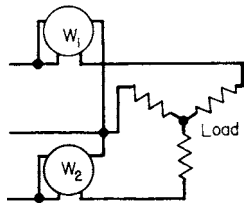

Fig. 15.1.39 Two-wattmeter method.

the power factor is a function of P_1/P_2. Table 15.1.9 gives values of power factor for different ratios of P_1/P_2.

$$P = P_2 + P_1 \text{ when } \theta < 60°.$$

When $\theta = 60°$, pf $= \cos 60° = 0.5$, $P_1 = \cos(30° + 60°) = 0$, $P = P_2$. When $\theta > 60°$, pf < 0.5, $P = P_2 - P_1$. Also,

$$\tan\theta = \sqrt{3}(P_2 - P_1)/(P_2 + P_1) \qquad (15.1.80)$$

In a **polyphase wattmeter** the two single-phase wattmeter elements are combined to act on a single spindle. Hence the adding and subtracting of the individual readings are done automatically. The total power is indicated on one scale. This type of instrument is almost always used on switchboards. The connections of a portable type are shown in Fig. 15.1.40.

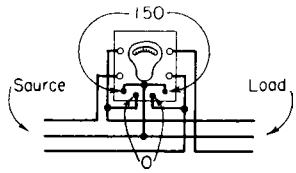

Fig. 15.1.40 Connections for a polyphase wattmeter in a three-phase circuit.

In the foregoing instrument connections, Y-connected loads are shown. These methods are equally applicable to delta-connected loads. The two-wattmeter method (Fig. 15.1.39) is obviously adapted to the two-phase three-wire system (Fig. 15.1.31).

Measurement of Energy

Watthour meters record the energy taken by a circuit over some interval of time. Correct registration occurs if the angular velocity of the rotating element at every instant is proportional to the power. The method of accomplishing this with dc meters is illustrated in Fig. 15.1.41. The meter is in reality a small motor. The field coils *FF* are in series with the line. The armature *A* is connected across the line, usually in series with a resistor *R*. The movable field coil F' is in series with the armature *A* and serves to compensate for friction. *C* is a small commutator, either of copper or of silver, and the two small brushes are usually of silver. An aluminum disk, rotating between the poles of permanent magnets *M*, acts as a magnetic brake the retarding torque of which is proportional to the angular velocity of the disk. A small worm and the gears *G* actuate the recording dials.

Table 15.1.9 Ratio P_1/P_2 and Power Factor

P_1/P_2	Power factor	P_1/P_2	Power factor	P_1/P_2	Power factor	P_1/P_2	Power factor
+1.0	1.000	+0.4	0.804	−0.1	0.427	−0.6	0.142
+0.9	0.996	+0.3	0.732	−0.2	0.360	−0.7	0.102
+0.8	0.982	+0.2	0.656	−0.3	0.296	−0.8	0.064
+0.7	0.956	+0.1	0.576	−0.4	0.240	−0.9	0.030
+0.6	0.918	0.0	0.50	−0.5	0.188	−1.0	0.000
+0.5	0.866						

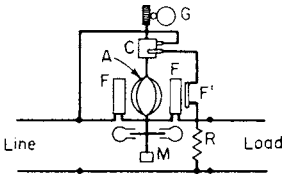

Fig. 15.1.41 DC watthour meter.

The following relation, or an equivalent, holds with most types of meter. With each revolution of the disk, K Wh are recorded, where K is the **meter constant** found usually on the disk. It follows that the average watts P over any period of time t s is

$$P = 3{,}600KN/t \qquad (15.1.81)$$

where N is the revolutions of the disk during that period. Hence, the meter may be calibrated by connecting standardized instruments to measure the average power taken by the load and by counting the revolutions N for t s. Near full load, if the meter registers fast, the magnets M should be moved outward radially; if it registers slow, the magnets should be moved inward. If the meter registers fast at light (5 to 10 percent) load, the starting coil F' should be moved further away from the armature; if it registers slow, F' should be moved nearer the armature. A meter should not register more than 1.5 percent fast or slow, and with calibrated standards it can be made to register to within 1 percent of correct.

The **induction watthour meter** is used with alternating current. Although the dc meter registers correctly with alternating current, it is more expensive than the induction type, the commutator and brushes may cause trouble, and at low power factors compensation is necessary. In the induction watthour meter the driving torque is developed in the aluminum disk by the joint action of the alternating magnetic flux produced by the potential circuit and by the load current. The driving torque and the retarding torque are both developed in the same aluminum disk, hence no commutator and brushes are necessary. The rotating element is very light, and hence the friction torque is small. Equation (15.1.81) applies to this type of meter. When calibrating, the average power W for t s is determined with a calibrated wattmeter. The friction compensation is made at light loads by changing the position of a small hollow stamping with respect to the potential lug. The meter should also be adjusted at low power factor (0.5 is customary). If the meter is slow with lagging current, resistance should be cut out of the compensating circuit; if slow with leading current, resistance should be inserted.

Power-Factor Measurement The usual method of determining power factor is by the use of voltmeter, ammeter, and wattmeter. The wattmeter gives the watts of the circuit, and the product of the voltmeter reading and the ammeter reading gives the volt-amperes. The power factor is the ratio of the two [see Eqs. (15.1.65) and (15.1.76)]. Also single-phase and three-phase power-factor indicators, which can be connected directly in circuit, are on the market.

Instrument Transformers

With voltages higher than 600 V, and even at 600 V, it becomes dangerous and inaccurate to connect instruments and meters directly into power lines. It is also difficult to make potential instruments for voltages in excess of 600 V and ammeters in excess of 60-A ratings. To insulate such instruments from high voltage and at the same time to permit the use of low-range instruments, instrument transformers are used. **Potential transformers** are identical with power transformers except that their volt-ampere rating is low, being 40 to 500 W. Their primaries are wound for line voltage and their secondaries for 110 V. **Current transformers** are designed to go in series with the line, and the rated secondary current is 5 A. The secondary of a current transformer **should always be closed** when current is flowing; it should never be allowed to become open circuited under these conditions. When open-circuited the voltage across the secondary becomes so high as to be dangerous and the flux becomes so large in magnitude that the transformer overheats. Semiconductors that break down at safe voltages and short current-transformer secondaries are available to ensure that the secondary is closed. The secondaries of both potential and current transformers should be well grounded at one point (Figs. 15.1.42 and 15.1.43). Instrument transformers introduce slight errors because of small variations in their ratio with load. Also there is slight phase displacement in both current and potential transformers. The readings of the instruments must be multiplied by the instrument transformer ratios. The scales of switchboard instruments are usually calibrated to take these ratios into account.

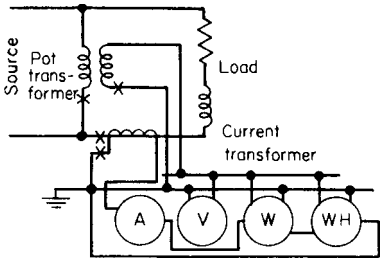

Fig. 15.1.42 Single-phase connections of instruments with transformers.

Figure 15.1.42 shows the use of instrument transformers to measure the voltage, current, power, and kilowatthours of a single-phase load. Figure 15.1.43 shows the connections that would be used to measure the voltage, current, and power of a 26,400-V 600-A three-phase load.

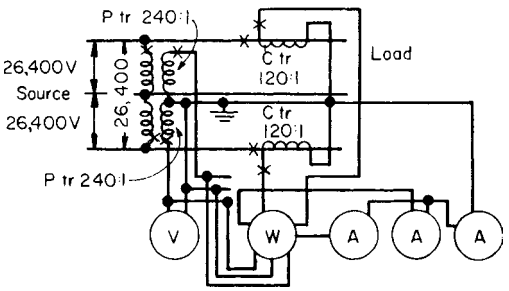

Fig. 15.1.43 Three-phase connections of instruments and instrument transformers.

Measurement of High Voltages Potential transformers such as those shown in Figs. 15.1.42 and 15.1.43 may be used even for very high voltages, but for voltages above 132 kV they become so large and expensive that they are used only sparingly. A convenient method used with testing transformers is the employment of a voltmeter coil, which consists of a coil of a few turns interwoven in the high-voltage winding and insulated from it. The voltage ratio is the ratio of the turns in the high-voltage winding to those in the voltmeter coil. A capacitance voltage divider consists of two or more capacitors connected in series across the high voltage to be measured. A high-impedance voltmeter, such as an electronic one, is connected across the capacitor at the grounded end. The high voltage $V = V_m C_m / C$ V, where V_m is the voltmeter reading, C the capacitance (in μF) of the entire divider, and C_m the equivalent capacitance (in μF) of the capacitor at the grounded end. A bushing potential device consists of a high-voltage-transformer bushing having a capacitance tap brought out from one of the metallic electrodes within the bushing which is near ground potential. This device is obviously a capacitance voltage divider. For testing, **sphere gaps** are used for the very high voltages. Calibration data for sphere gaps are given in the ANSI/IEEE Std. 4-1978 Standard Techniques for High Voltage Testing. Even when it is not being used for the measurement of

voltage, it is frequently advisable to connect a sphere gap in parallel with the specimen being tested so as to prevent overvoltages. The gap is set to a slightly higher voltage than that which is desired.

Measurement of Resistance

Voltmeter-Ammeter Method A common method of measuring resistance, known as the voltmeter-ammeter or fall-in-potential method, makes use of an ammeter and a voltmeter. In Fig. 15.1.44, the resistance to be measured is *R.* The current in the resistor *R* is *I* A, which is measured by the ammeter *A* in series. The drop in potential across the resistor *R* is measured by the voltmeter *V.* The current shunted by the voltmeter is so small that it may generally be neglected. A correction

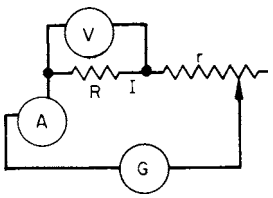

Fig. 15.1.44 Voltmeter-ammeter method for resistance measurement.

may be applied if necessary, for the resistance of the voltmeter is generally given with the instrument. The potential difference divided by the current gives the resistance included between the voltmeter leads. As a check, determinations are generally made with several values of current, which may be varied by means of the controlling resistor *r.* If the resistance to be measured is that of the armature of a dc machine and the voltmeter leads are placed on the brush holders, the resistance determined will include that of the brush contacts. To measure the resistance of the armature alone, the voltmeter leads should be placed directly on the commutator segments on which the brushes rest but not under the brushes.

Insulation Resistance Insulation resistance is so high that it is usually given in megohms (10^6 ohms, MΩ) rather than in ohms. Insulation resistance tests are important, for although they may not be conclusive they frequently reveal flaws in insulation, poor insulating material, presence of moisture, etc. Such tests are applied to the insulation of electrical machinery from the windings to the frame, to underground cables, to insulators, capacitors, etc.

For moderately low resistances, 1 to 10 MΩ, the voltmeter method given in Fig. 15.1.45, which shows insulation measurement to the frame of the field winding of a generator, may be used. To measure the current when a voltage *E* is impressed across the resistor *R,* a high-reading voltmeter *V* is connected in series with *R.* The current under this condition with the switch connecting *S* and *A* is $E/(R + r)$, where *r* is the resistance of the voltmeter. A high-resistance voltmeter is necessary, since the method is in reality a comparison of the unknown insulation resistance *R* with the known resistance *r* of the voltmeter. Hence, the

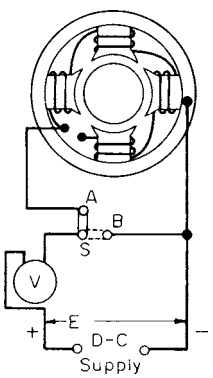

Fig. 15.1.45 Voltmeter method for insulation resistance measurement.

resistance of the voltmeter must be comparable with the unknown resistance, or the deflection of the instrument will be so small that the results will be inaccurate. To determine the impressed voltage *E,* the same voltmeter is used. The switch *S* connects *S* and *B* for this purpose. With these two readings, the unknown resistance is

$$R = r(E - e)/e \qquad (15.1.82)$$

where *e* is the deflection of the voltmeter when in series with the resistance to be measured as when *S* is at *A.* If a special voltmeter, having a resistance of 100 kΩ per 150 V, is available, a resistance of the order of 2 to 3 MΩ may be measured very accurately.

When the insulation resistance is too high to be measured with a voltmeter, a sensitive galvanometer may be used. The connections for measuring the insulation resistance of a cable are shown in Fig. 15.1.46. The battery should have an emf of at least 100 V. Radio B batteries are convenient for this purpose. The method involves comparing the unknown resistance with a standard 0.1 MΩ. To calibrate the galvanometer the cable is short-circuited (dotted line) and the switch *S* is thrown to position (*a*). Let the galvanometer deflection be D_1 and the reading of the

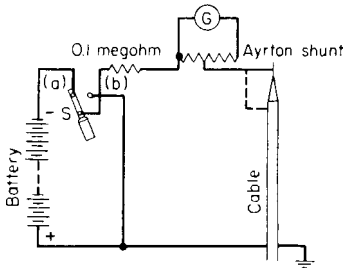

Fig. 15.1.46 Measurement of insulation resistance with a galvanometer.

Ayrton shunt S_1. The short circuit is then removed. The 0.1 MΩ is left in circuit since it is usually negligible in comparison with the unknown resistance *X.* Let the reading of the galvanometer now be D_2 and the reading of the shunt S_2. Then

$$X = 0.1S_2D_1/S_1D_2 \quad \text{MΩ} \qquad (15.1.83)$$

When the switch S is thrown to position (*b*), the cable is short-circuited through the 0.1 MΩ and becomes discharged.

The **Megger** insulation tester is an instrument that indicates insulation resistance directly on a scale. It consists of a small hand or motor-driven generator which generates 500 V, 1,000 V, 2,500 V, or 5,000 V. A clutch slips when the voltage exceeds the rated value. The current through the unknown resistance flows through a moving element consisting of two coils fastened rigidly together, but which move in different portions of the magnetic field. A pointer attached to the spindle of the moving element indicates the insulation resistance directly. These instruments have a range up to 10,000 MΩ and are very convenient where portability and convenience are desirable.

The insulation resistance of electrical machinery may be of doubtful significance as far as dielectric strength is concerned. It varies widely with temperature, humidity, and cleanliness of the parts. When the insulation resistance falls below the prescribed value, it can (in most cases of good design) be brought to the required standard by cleaning and drying the machine. Hence it may be useful in determining whether or not the insulation is in proper condition for a dielectric test. IEEE Std. 62-1978 specifies minimum values of insulation resistance in MΩ = (rated voltage)/(rating in kW + 1,000). If the operating voltage is higher than the rated voltage, the operating voltage should be used. The rule specifies that a dc voltage of 500 be used in testing. If not, the voltage should be specified.

Wheatstone Bridge Resistors from a fraction of an Ω to 100 kΩ and more may be measured with a high degree of precision with the Wheatstone bridge (Fig. 15.1.47). The bridge consists of four resistors

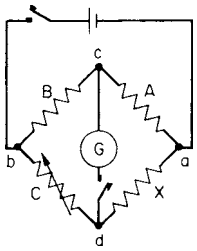

Fig. 15.1.47 Wheatstone bridge.

ABCX connected as shown. *X* is the unknown resistance; *A* and *B* are ratio arms, the resistance units of which are in even decimal Ω as 1, 10, 100, etc. *C* is the rheostat arm. A battery or low-voltage source of direct current is connected across *ab.* A galvanometer *G* of moderate sensitivity is connected across *cd.* The values of *A* and *B* are so chosen that three or four significant figures in the value of *C* are obtained. As a first approximation it is well to make *A* and *B* equal. When the bridge is in balance,

$$X/C = A/B \tag{15.1.84}$$

The positions of the battery and galvanometer are interchangeable. There are many modifications of the bridge which adapt it to measurements of very low resistances and also to ac measurements.

Kelvin Double Bridge The simple Wheatstone bridge is not adapted to measuring very low resistances since the contact resistances of the test specimen become comparable with the specimen resistance. This error is avoided in the Kelvin double bridge, the diagram of which is shown in Fig. 15.1.48. The specimen *X*, which may be a short length of copper wire or bus bar, is connected in series with an adjustable calibrated resistor *R* whose resistance is comparable with that of the specimen. The arms *A* and *B* of the bridge are ratio arms usually with decimal values of 1, 10, 100 Ω. One terminal of the galvanometer is connected to *X* and *R* by means of two resistors *a* and *b.* If these resistors are set so that $a/b = A/B$, the contact resistance *r* between *X* and *R* is eliminated in the measurement. The contact resistances at *c* and *d* have no effect since at balance the galvanometer current is zero. The contact resistances at *f* and *e* need only be negligible compared with the resistances of arms *A* and *B* both of which are reasonably high. By means of the variable resistor *Rh* the value of current, as indicated by ammeter *A,* may be adjusted to give the necessary sensitivity. When the bridge is in balance,

$$X/R = A/B \tag{15.1.85}$$

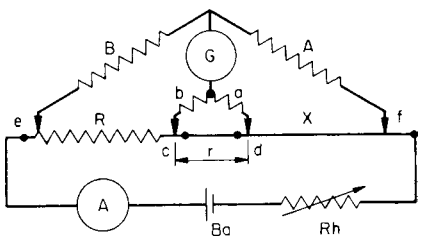

Fig. 15.1.48 Kelvin double bridge.

Potentiometer The principle of the potentiometer is shown in Fig. 15.1.49. *ab* is a slide wire, and *bc* consists of a number of equal individual resistors between contacts. A battery *Ba* the emf of which is approximately 2 V supplies current to this wire through the adjustable rheostat *R.* A slider *m* makes contact with *ab,* and a contactor *m′* connects with the contacts in *bc.* A galvanometer *G* is in series with the wire connecting to *m.* By means of the double-throw double-pole switch *Sw,* either the standard cell or the unknown emf (*EMF*) may

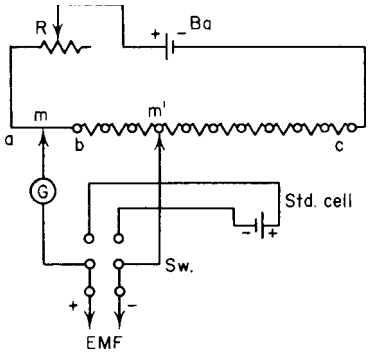

Fig. 15.1.49 Potentiometer principle.

be connected to *mm′* through the galvanometer *G*. The potentiometer is standardized by throwing *Sw* to the standard-cell side, setting *mm′* so that their positions on *ab* and *bc* correspond to the emf of the standard cell. The rheostat *R* is then adjusted until *G* reads zero. (In commercial potentiometers a dial which may be set directly to the emf of the standard cell is usually provided.) The unknown emf is measured by throwing *Sw* to *EMF* and adjusting *m* and *m′* until *G* reads zero. The advantage of this method of measuring emf is that when the potentiometer is in balance no current is taken from either the standard cell or the source of emf. Potentiometers seldom exceed 1.6 V in range. To measure voltage in excess of this, a **volt box** which acts as a multiplier is used. To measure current, the voltage drop across a standard resistor of suitable value is measured with the potentiometer. For example, with 50 A a 0.01-Ω standard resistance gives a voltage drop of 0.5 V which is well within the range of the potentiometer.

Potentiometers of low range are used extensively with thermocouple pyrometers. Figure 15.1.49 merely illustrates the principle of the potentiometer. There are many modifications, conveniences, etc., not shown in Fig. 15.1.49.

DC GENERATORS

All electrical machines are comprised of a magnetic circuit of iron (or steel) and an electric circuit of copper. In a generator the armature conductors are rotated so that they cut the magnetic flux coming from and entering the field poles. In the dc generator (except the unipolar type) the emf induced in the individual conductors is alternating, but this is rectified by the commutator and brushes, so that the current to the external circuit is unidirectional.

The induced emf in a generator (or motor)

$$E = \phi ZNP/60P' \quad \text{V} \tag{15.1.86}$$

where ϕ = flux in webers entering the armature from one north pole; Z = total number of conductors on the armature; N = speed, r/min; P = number of poles; and P' = number of parallel paths through the armature.

Since with a given generator, *Z, P, P′* are fixed, the induced emf

$$E = K\phi N \quad \text{V} \tag{15.1.87}$$

where *K* is a constant. When the armature delivers current, the terminal volts are

$$V = E - I_a R_a \tag{15.1.88}$$

where I_a is the armature current and R_a the armature resistance including the brush and contact resistance, which vary somewhat.

There are three standard types of dc generators: the **shunt generator,** the **series generator,** and the **compound generator.**

Shunt Generator The field of the shunt generator in series with its rheostat is connected directly across the armature as shown in Fig. 15.1.50. This machine maintains approximately constant terminal voltage over its working range of load. An external characteristic of the

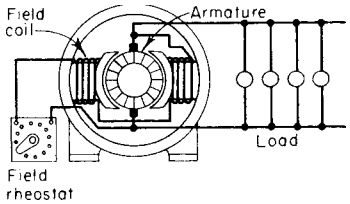

Fig. 15.1.50 Shunt generator.

generator is shown in Fig. 15.1.51. As load is applied the terminal voltage drops owing to the armature-resistance drop [Eq. (15.1.88)] and armature reaction which decreases the flux. The drop in terminal voltage reduces the field current which in turn reduces the flux, hence the induced emf, etc. At some point *B,* usually well above rated current, the foregoing reactions become cumulative and the generator starts to break down. The current reaches a maximum value and then decreases to nearly zero at short circuit. With large machines, point *B* is well above rated current, the operating range being between *O* and *A*. The voltage may be maintained constant by means of the field rheostat. Automatic regulators which operate through field resistance are frequently used to maintain constant voltage.

Shunt generators are used in systems which are all tied together where their stability when in parallel is an advantage. If a generator fails to build up, (1) the load may be connected; (2) the field resistance may be too high; (3) the field circuit may be open; (4) the residual magnetism may be insufficient; (5) the field connection may be reversed.

Series Generator In the series generator (Fig. 15.1.52) the entire load current flows through the field winding, which consists of relatively few turns of wire of sufficient size to carry the entire load current without undue heating. The field excitation, and hence the terminal voltage, depends on the magnitude of the load current. The generator

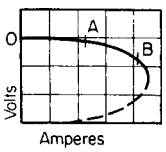

Fig. 15.1.51 Shunt generator characteristic.

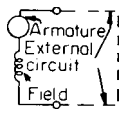

Fig. 15.1.52 Series generator.

supplies an essentially constant current and for years was used to supply series arc lamps for street lighting requiring direct current. Except for some special applications, the series generator is now obsolete.

Compound-Wound Generators By the addition of a series winding to a shunt generator the terminal voltage may be automatically maintained very nearly constant, or, by properly proportioning the series turns, the terminal voltage may be made to increase with load to compensate for loss of voltage in the line, so that approximately constant voltage is maintained at the load. If the shunt field is connected outside the series field (Fig. 15.1.53), the machine is **long shunt;** if the shunt field is connected inside the series field, i.e., directly to the armature terminals, it is **short shunt.** So far as the operating characteristic is concerned, it makes little difference which way a machine is connected. Table 15.1.10 gives performance characteristics.

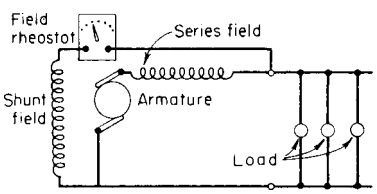

Fig. 15.1.53 Compound-wound dc generator.

Table 15.1.10 Approximate Test Performance of Compound-Wound DC Generators with Commutating Poles

kW	Speed, r/min	Volts	Amperes	Efficiencies, percent ¼ load	½ load	Full load
5	1,750	125	40	77.0	80.5	82.0

SOURCE: Westinghouse Electric Corp.

Compound-wound generators are chiefly used for small isolated plants and for generators supplying a purely motor load subject to rapid fluctuations such as in railway work. When first putting a compound generator in service, the shunt field must be so connected that the machine builds up. The series field is then connected so that it aids the shunt field. Figure 15.1.54 gives the characteristics of an overcompounded 200-kW 600-V compound-wound generator.

Amplidynes The amplidyne is a dc generator in which a small amount of power supplied to a control field controls the generator output, the response being nearly proportional to the control field input. The amplidyne is a dc amplifier which can supply large amounts of power. The amplifier operates on the principle of armature reaction. In Fig. 15.1.55, NN and SS are the conventional north and south poles of a dc generator with central cavities. BB are the usual brushes placed at right angles to the pole axes of NN and SS. A control winding CC of small rating, as low as 100 W, is wound on the field poles. In Fig. 15.1.55, for simplicity, the control winding is shown as being wound on one pole

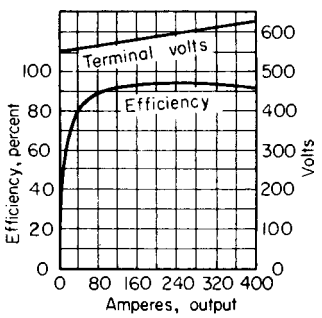

Fig. 15.1.54 Characteristics of a 200-kW compound-wound dc generator.

only. The brushes BB are short-circuited, so that a small excitation mmf in the control field produces a large short-circuit current along the brush axis BB. This large short-circuit current produces a large armature-reaction flux AA along brush axis BB. The armature rotating in this field produces a large voltage along the brush axis B′B′. The load or working current is taken from brushes B′B′ as shown. In Fig. 15.1.55 the working current only is shown by the crosses and dots in the circles. The short-circuit current would be shown by crosses in the conductors to the left of brushes BB and by dots in the conductors to the right of brushes BB.

A small current in the control winding produces a high output voltage and current as a result of the large short-circuit current in brushes BB.

In order that the brushes B′B′ shall not be short-circuiting conductors which are cutting the flux of poles NN and SS, cavities are cut in these poles. Also the load current from brushes B′B′ produces an armature reaction mmf in opposition to flux A′A′ produced by the control field CC. Were this mmf not compensated, the flux A′A′ and the output

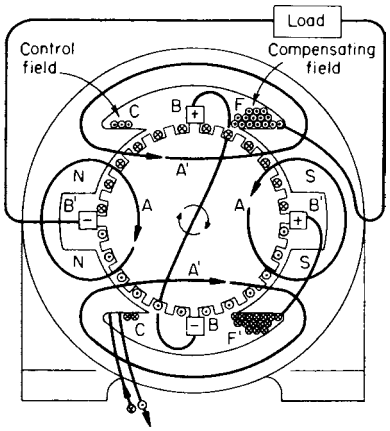

Fig. 15.1.55 Amplidyne.

of the machine would no longer be determined entirely by the control field. Hence there is a compensating field FF′ in series with the armature, which neutralizes the armature-reaction mmf which the load current produces. For simplicity the compensating field is shown on one field pole only.

The amplidyne is capable of controlling and regulating speed, voltage, current, and power with accurate and rapid response. The amplification is from 10,000 to 250,000 times in machines rated from 1 to 50 kW. Amplidynes are frequently used in connection with **selsyns** and are employed for gun and turret control and for accurate controls in many industrial power applications.

Parallel Operation of Shunt Generators It is desirable to operate generators in parallel so that the station capacity can be adapted to the load. Shunt generators, because of their drooping characteristics (Fig. 15.1.51), are inherently stable when in parallel. To connect shunt generators in parallel it is necessary that the switches be so connected that like poles are connected to the same bus bars when the switches are closed. Assume one generator to be in operation; to connect another generator in parallel with it, the incoming generator is first brought up to speed and its terminal voltage adjusted to a value slightly greater than the bus-bar voltage. This generator may then be connected in parallel with the other without difficulty. The proper division of load between them is adjusted by means of the field rheostats and is maintained automatically if the machines have similar voltage-regulation characteristics.

Parallel Operation of Compound Generators As a rule, compound generators have either flat or rising voltage characteristics. Therefore, when connected in parallel, they are inherently unstable. Stability may, however, be obtained by using an equalizer connection, Fig. 15.1.56, which connects the terminals of the generator at the junctions of the series fields. This connection is of low resistance so that any increase of current divides proportionately between the series fields of the two machines. The equalizer switch (E.S.) should be closed first and opened last, if possible. In practice, the equalizer switch is often one blade of a three-pole switch, the other two being the bus switch S, as in Fig. 15.1.56. When compound generators are used on a three-wire system, two series fields—one at each armature terminal—and two equalizers are necessary. It is possible to operate any number of compound generators in parallel provided their characteristics are not too different and the equalizer connection is used.

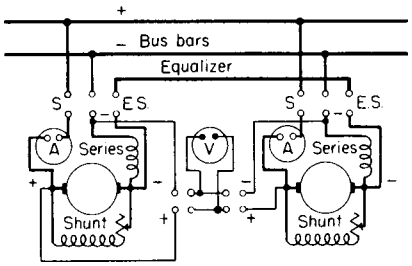

Fig. 15.1.56 Connections for compound-wound generators operating in parallel.

DC MOTORS

Motors operate on the principle that a conductor carrying current in a magnetic field tends to move at right angles to that field (see Fig. 15.1.11). The ordinary dc generator will operate entirely satisfactorily as a motor and will have the same rating. The conductors of the motor rotate in a magnetic field and therefore must generate an emf just as does the generator. The induced emf

$$E = K\phi N \tag{15.1.89}$$

where K = constant, ϕ = flux entering the armature from one north pole, and N = r/min [see Eq. (15.1.87)]. This emf is in opposition to the terminal voltage and tends to oppose current entering the armature. Its value is

$$E = V - I_a R_a \tag{15.1.90}$$

where V = terminal voltage, I_a = armature current, and R_a = armature resistance [compare with Eq. (15.1.88)]. From Eq. (15.1.89) it is seen that the speed

$$N = K_s E/\phi \tag{15.1.91}$$

when $K_s = 1/K$. This is the fundamental speed equation for a motor. By substituting in Eq. (15.1.90)

$$N = K_s(V - 1_a R_a)/\phi \tag{15.1.92}$$

which is the general equation for the speed of a motor.

The internal or electromagnetic torque developed by an armature is proportional to the flux and to the armature current; i.e.,

$$T_t = K_t \phi I_a \tag{15.1.93}$$

when K_t is a constant. The torque at the pulley is slightly less than the internal torque by the torque necessary to overcome the rotational losses, such as friction, windage, eddy-current and hysteresis losses in the armature iron and in the pole faces.

The total mechanical power developed internally

$$P_m = EI_a \quad \text{W} \quad (= EI_a/746 \quad \text{hp}) \tag{15.1.94}$$

The internal torque thus becomes

$$T = EI_a 33{,}000/(2\pi \times 746N) = 7.04EI_a/N \tag{15.1.95}$$

Let VI be the motor input. The output is $VI\eta$ where η is the efficiency. The horsepower is

$$P_H = VI\eta/746 \tag{15.1.96}$$

and the torque is

$$T = 33{,}000P_H/2\pi N = 5{,}260P_H/N \quad \text{lb} \cdot \text{ft} \tag{15.1.97}$$

where N is r/min.

Shunt Motor In the shunt motor (Fig. 15.1.57) the flux is substantially constant and $I_a R_a$ is 2 to 6 percent of V. Hence from Eq. (15.1.92), the speed varies only slightly with load (Fig. 15.1.58), so that the motor is adapted to work requiring constant speed. The speed regulation of constant-speed motors is defined by ANSI/IEEE Std. 100-1992 Standard Dictionary of Electrical and Electronic terms as follows:

> The speed regulation of a constant-speed direct-current motor is the change in speed when the load is reduced gradually from the rated value to zero with constant applied voltage and field rheostat setting expressed as a percent of speed at rated load.

In Fig. 15.1.61 the speed regulation under each condition is $100(ac - bc)/bc$ (Fig. 15.1.58*a*). Also from Eq. (15.1.93) it is seen that the torque

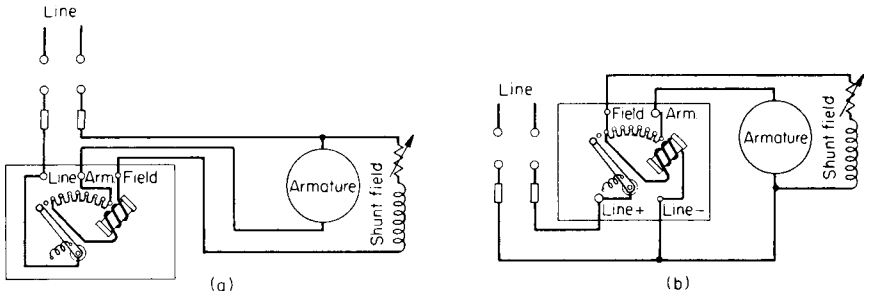

Fig. 15.1.57 Connections for shunt dc motors and starters. (*a*) Three-point box; (*b*) four-point box.

is practically proportional to the armature current (see Fig. 15.1.58*b*). The motor is able to develop full-load torque and more on starting, but the ordinary starter is not designed to carry the current necessary for starting under load. If a motor is to be started under load, the starter

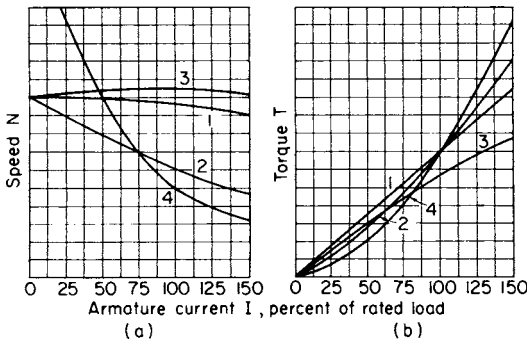

Fig. 15.1.58 Speed and torque characteristics of dc motors. (1) Shunt motor (2) cumulative compound motor; (3) differential compound motor; (4) series motor.

should be provided with resistors adapted to carry the required current without overheating. A controller is also adapted for starting duty under load.

Commutating poles have so improved commutation in dc machines that it is possible to use a much shorter air gap than formerly. Since, with the shorter air gap, fewer field ampere-turns are required, the armature becomes magnetically strong with respect to the field. Hence, a sudden overload might weaken the field through armature reaction, thus causing an increase in speed; the effect may become cumulative and the motor run away. To prevent this, modern shunt motors are usually provided with a **stabilizing winding,** consisting of a few turns of the field in series with the armature and aiding the shunt field. The resulting increase of field ampere-turns with load will more than compensate for any weakening of the field through armature reaction. The series turns are so few that they have no appreciable compounding effect. The shunt motor is used to drive constant-speed line shafting, for machine tools, etc. Since its speed may be efficiently varied, it is very useful when **adjustable speeds** are necessary, such as individual drive for machine tools.

Shunt-Motor Starters At standstill the counter emf of the motor is zero and the armature resistance is very low. Hence, except in motors of very small size, series resistance in the armature circuit is necessary on starting. The field must, however, be connected across the line so that it may obtain full excitation.

Figure 15.1.57 shows the two common types of starting boxes used for starting shunt motors. The armature resistance remains in circuit only during starting. In the **three-point box** (Fig. 15.1.57*a*) the starting lever is held, against the force of a spring, in the running position, by an electromagnet in series with the field circuit, so that, if the field circuit is interrupted or the line voltage becomes too low, the lever is released and the armature circuit is opened automatically. In the **four-point starting box** the electromagnet is connected directly across the line, as shown in Fig. 15.1.57*b*. In this type the arm is released instantly upon failure of the line voltage. In the three-point type some time elapses before the field current drops enough to effect the release. Some starting rheostats are provided with an overload device so that the circuit is automatically interrupted if too large a current is taken by the armature. The four-point box is used where a wide speed range is obtained by means of the field rheostat. The electromagnet is not then affected by changes in field current.

In large motors and in many small motors, automatic starters are widely used. The advantages of the automatic starter are that the current is held between certain maximum and minimum values so that the circuit does not become opened by too rapid starting as may occur with manual operation; the acceleration is smooth and nearly uniform. Since workers can stop and start a motor merely by the pushing of a button, there results considerable saving by the shutting down of the motor when it is not needed. Automatic controls are essential to elevator motors so that smooth rapid acceleration with frequent starting and stopping may be obtained. Also automatic starting is very necessary with multiple-unit operation of electric-railway cars and with rolling-mill motors which are continually subjected to rapid acceleration, stopping, and reversing.

Series Motor In the series motor the armature and field are in series. Hence, if saturation is neglected, the flux is proportional to the current and the torque [Eq. (15.1.93)] varies as the current squared. Therefore any increase in current will produce a much greater proportionate increase in torque (see Fig. 15.1.58*b*). This makes the motor particularly well adapted to traction work, cranes, hoists, fork-lift trucks, and other types of work which require large starting torques. A study of Eq. (15.1.92) shows that with increase in current the numerator changes only slightly, whereas the change in the denominator is nearly proportional to the change in current. Hence the speed of the series motor is practically inversely proportional to the current. With overloads the speed drops to very low values (see Fig. 15.1.58*a*). With decrease in load the speed approaches infinity, theoretically. Hence the series motor should always be connected to its load by a direct drive, such as gears, so that it cannot reach unsafe speeds (see Speed Control of Motors). A series-motor starting box with no-voltage release is shown in Fig. 15.1.59.

Differential Compound Motors The cumulative compound winding of a generator becomes a differential compound winding when the machine is used as a motor. Its speed may be made more nearly constant

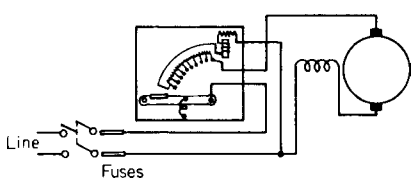

Fig. 15.1.59 Series motor starter, no-voltage release.

SOURCE: Westinghouse Electric Corp.

than that of a shunt motor, or, if desired, it may be adjusted to increase with increasing load.

The speed as a function of armature current is shown in Fig. 15.1.58*a* and the torque as a function of armature current is shown in Fig. 15.1.58*b*.

Since the speed of the shunt motor is sufficiently constant for most purposes and the differential motor tends toward instability, particularly in starting and on overloads, the differential motor is little used.

Cumulative compound motors develop a more rapid increase in torque with load than shunt motors (Fig. 15.1.58*b*); on the other hand, they have much poorer speed regulation (Fig. 15.1.58*a*). Hence they are used where larger starting torque than that developed by the shunt motor is necessary, as in some industrial drives. They are particularly useful where large and intermittent increases of torque occur as in drives for shears, punches, rolling mills, etc. In addition to the sudden increase in torque which the motor develops with sudden applications of load, the fact that it slows down rapidly and hence causes the rotating parts to give up some of their kinetic energy is another important advantage in that it reduces the peaks on the power plant. Performance data for compound motors are given in Table 15.1.11.

Commutation The brushes on the commutator of either a motor or generator should be set in such a position that the induced emf in the armature coils undergoing commutation and hence short-circuited by the brushes, is zero. In practice, this condition can at best be only approximately realized. Frequently conditions are such that it is far from being realized. At no load, the brushes should be set in a position corresponding to the geometrical neutral of the machine, for under these conditions the induced emf in the coils short-circuited by the brushes is zero. As load is applied, two factors cause sparking under the brushes. The mmf of the armature, or **armature reaction,** distorts the flux; when the current in the coils undergoing commutation reverses, an emf of self-induction $-L\,di/dt$ tends to prolong the current flow which produces sparking. In a generator, armature reaction distorts the flux in the direction of rotation and the brushes should be advanced. In order to neutralize the emf of self-induction the brushes should be set a little ahead of the neutral plane so that the emf induced in the short-circuited coils by the cutting of the flux at the fringe of the next pole is opposite to this emf of self-induction. In a motor the brushes are correspondingly moved backward in the direction opposite rotation.

Theoretically, the brushes should be shifted with every change in load. However, practically all dc generators and motors now have **commutating poles** (or **interpoles**) and with these the brushes can remain in the no-load neutral plane, and good commutation can be obtained over the entire range of load. Commutating poles are small poles between the main poles (Fig. 15.1.60) and are excited by a winding in series with the armature. Their function is to neutralize the flux distortion in the **neutral plane** caused by armature reaction and also to supply a flux that will cause an emf to be induced in the conductors undergoing commutation, opposite and equal to the emf of self-induction. Since armature reaction and the emf of self-induction are both proportional to the armature current, saturation being neglected, they are neutralized theoretically at every load. Commutating poles have made possible dc

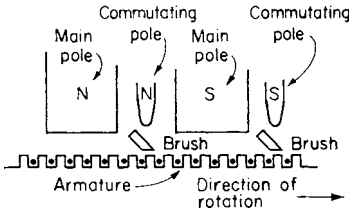

Fig. 15.1.60 Commutating poles in motor.

generators and motors of very much higher voltage, greater speeds, and larger kW ratings than would otherwise be possible.

Occasionally, the commutating poles may be connected incorrectly. In a motor, passing from an N main pole in the direction of rotation of the armature, an N commutating pole should be encountered as shown in Fig. 15.1.60. In a generator under these conditions an *S* commutating pole should be encountered. The test can easily be made with a compass. If poor commutation is caused by too strong interpoles, the winding may be shunted. If the poles are too weak and the shunting cannot be reduced, they may be strengthened by inserting sheet-iron shims between the pole and the yoke thus reducing the air gap.

Although the emfs induced in the coils undergoing commutation are relatively small, the resistance of the coils themselves is low so that unless further resistance is introduced, the short-circuit currents would be large. Hence, with the exception of certain low-voltage generators, carbon brushes that have relatively large contact resistance are almost always used. Moreover, the graphite in the brushes has a lubricating action, and the usual carbon brush does not score the commutator.

Speed Control of Motors

Shunt Motors In Eq. (15.1.91) the speed of a shunt motor $N = K_s E/\phi$, where K_s is a constant involving the design of the motor such as conductors on armature surface and number of poles. Obviously, in order to change the speed of a motor, without changing its construction, two factors may be varied, the counter emf E and the flux ϕ.

Armature-Resistance Control The counter emf $E = V - I_a R_a$, where V is the terminal voltage, assumed constant. R_a must be small so that the armature heating can be maintained within permissible limits. Under these conditions the speed change with load is small. By inserting an external resistor, however, into the armature circuit the counter emf E may be made to decrease rapidly with increase in load; that is, $E = V - I_a(R_a + R)$ [see Eq. (15.1.90)] where R is the resistance of the external resistor. The resistor R must be inserted in the **armature** circuit only. The advantages of this method are its simplicity, the full torque of the motor is developed at any speed, and the method introduces no commutating difficulties. Its disadvantages are the increased speed regulation with change of load (Fig. 15.1.61), the low efficiency, particularly at the lower speeds, and the fact that provision must be made to dissipate the comparatively large power losses in the series resistor. Figure 15.1.61 shows typical speed-load curves without and with series

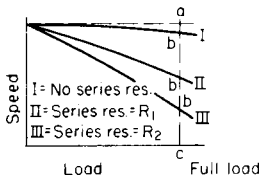

Fig. 15.1.61 Speed-load characteristics with armature resistance control.

resistors in the armature circuit. The armature efficiency is nearly equal to the ratio of the operating speed to the no-load speed. Hence at 25 percent speed the armature efficiency is practically 25 percent. Frequently the controlling and starting resistors are one, and the device is called a **controller.** Starting rheostats themselves are not designed to carry the armature current continuously and must not be used as controllers. The armature-resistance method of speed control is frequently used to regulate the speed of ventilating fans where the power demand diminishes rapidly with decrease in speed.

Control by Changing Impressed Voltage From Eq. (15.1.92) it is evident that the speed of a motor may be changed if V is changed by connecting the armature across different voltages. Speed control by this method is accomplished by having mains (usually four), which are maintained at different voltages, available at the motor.

The shunt field of the motor is generally permanently connected to one pair of mains, and the armature circuit is provided with a controller by means of which the operator can readily connect the armature to any pair of mains. Such a system gives a series of distinct and widely separated speeds and generally necessitates the use of field-resistance control, in combination, to obtain intermediate speeds. This method, known as the **multivoltage method,** has the disadvantage that the system is expensive, for it requires several generating machines, a somewhat complicated switchboard, and a number of service wires. The system is used somewhat in machine shops and is extensively used for dc elevator starting and speed control.

In the **Ward Leonard system,** the variable voltage is obtained from a separately excited generator whose armature terminals are connected directed to the armature terminals of the working motor. The generator is driven at essentially constant speed by a dc shunt motor if the power supply is direct current, or by an induction motor or a synchronous motor if the power supply is alternating current. The field circuit of the generator and that of the motor are connected across a constant-voltage dc supply. The terminal voltage of the generator, and hence the voltage applied to the armature of the motor, is varied by changing the generator-field current with a field rheostat. The rheostat has a wide range of resistance so that the speed of the motor may be varied smoothly from 0 to 100 percent. Since three machines are involved the system is costly, somewhat complicated, and has low power efficiency. However, because the system is flexible and the speed can be smoothly varied over wide ranges, it has been used in many applications, such as elevators, mine hoists, large printing presses, paper machines, and electric locomotives.

The **Ward-Leonard system** has been largely replaced by a **static converter system** where a silicon-controlled-rectifier bridge is used to convert three-phase alternating current, or single-phase on smaller drives, to dc voltage that can be smoothly varied by **phase-angle firing** of the rectifiers from full voltage to zero. This system is smaller, lighter, and less expensive than the motor-generator system. Care must be taken to assure that the dc motor will accept the **harmonics** present in the dc output without overheating.

Control by Changing Field Flux Equation (15.1.91) shows that the speed of a motor is inversely proportional to the flux ϕ. The flux can be changed either by varying the shunt-field current or by varying the reluctance of the magnetic circuit. The variation of the **shunt-field current** is the simplest and most efficient of all the methods of speed control.

With the ordinary motor, speed variation of 1.5 to 1.0 is obtainable with this method. If attempt is made to obtain greater ratios, severe sparking at the brushes results, owing to the field distortion caused by the armature mmf becoming large in comparison with the weakened field of the motor. Speed ratios of 5 : 1 and higher are, however, obtainable with motors which have commutating poles. Since the field current is a small proportion of the total current (1 to 3 percent), the rheostat losses in the field circuit are always small. This method is efficient. Also for any given speed adjustment the speed regulation is excellent, which is another advantage. Because of its simplicity, efficiency, and excellent speed regulation, the control of speed by means of the field current is by far the most common method. Output power remains constant when the field is weakened, so output torque varies inversely with motor speed.

Speed Control of Series Motors The series motor is fundamentally a variable-speed motor, the speed varying widely from light load to full load and more (see Fig. 15.1.58*a*). From Eq. (15.1.92) the speed for any value of ϕ, or current, can be changed by varying the impressed voltage. Hence the speed can be controlled by inserting resistance in series with the motor. This method, which is practically the same as the armature-resistance control method for shunt motors, has the same objections of low efficiency and poor regulation with fluctuating loads. It is extensively used in controlling the speed of hoist and crane motors.

The **series-parallel** system of series-motor speed control is almost universally used in electric traction. At least two motors are necessary. The two motors are first connected in series with each other and with the starting resistor. The starting resistor is gradually cut out and, since each motor then operates at half line voltage, the speed of each is approximately half speed. Both motors take the same current, and each can develop full torque. This condition of operation is efficient since there is no external resistance in circuit. When the controller is moved to the next position, the motors are connected in parallel with each other and each in series with starting resistors. Full speed of the motors is obtained by gradually cutting out these resistors. Connecting the two motors in series on starting reduces the current to one-half the value that would be required for a given torque were both motors connected in parallel on starting. The power taken from the trolley is halved, and an intermediate running speed is efficiently obtained.

In the **multiple-unit** method of speed control which is used for electric railway trains, the starting contactors, reverser, etc., for each car are located under that car. The relays operating these control devices are actuated by energy taken from the train line consisting usually of seven wires. The train line runs the entire length of the train, the connections between the individual cars being made through the couplers. The train line is energized by the action of the motorman operating any one of the small master controllers which are located in each car. Hence corresponding relays, contactors, etc., in every car all operate simultaneously. High accelerations may be reached with this system because of the large tractive effort exerted by the wheels on every car.

SYNCHRONOUS GENERATORS

The synchronous generator is the only type of ac generator now in general use at power stations.

Construction In the usual synchronous generator the armature or stator is the stationary member. This construction has many advantages. It is possible to make the slots any reasonable depth, since the tooth necks increase in cross section with increase in depth of slot; this is not true of the rotor. The large slot section which is thus obtainable gives ample space for copper and insulation. The conductors from the armature to the bus bars can be insulated throughout their entire lengths, since no rotating or sliding contacts are necessary. The insulation in a stationary member does not deteriorate as rapidly as that on a rotating member, for it is not subjected to centrifugal force or to any considerable vibration.

The **rotating member** is ordinarily the field. There are two general types of field construction: the **salient-pole type** and the **cylindrical,** or **nonsalient-pole, type.** The salient-pole type is used almost entirely for slow and moderate-speed generators since this construction is the least expensive and permits ample space for the field ampere-turns.

SOURCE: Westinghouse Electric Corp.

It is not practicable to employ salient poles in high-speed turboalternators because of the excessive windage and the difficulty of obtaining sufficient mechanical strength. The **cylindrical type** consists of a cylindrical steel forging with radial slots in which the field copper, usually in strip form, is placed. The fields are ordinarily excited at low voltage, 125 and 250 V, the current being conducted to the rotating member by means of slip rings and brushes. An ac generator armature to supply **field voltage** can be mounted on the generator shaft and supply dc to the motor field through a static rectifier bridge, also mounted on the shaft, eliminating all slip rings and brushes. The field power is ordinarily only 1.5 percent and less of the rated power of the machine (see Table 15.1.12).

Classes of Synchronous Generators Synchronous generators may be divided into three general classes: (1) the slow-speed engine-driven type; (2) the moderate-speed waterwheel-driven type; and (3) the high-speed turbine-driven type. In (1) a hollow box frame is used as the stator support, and the field consists of a spider to which a larger number of salient poles are attached, usually bolted. The speed seldom exceeds 75 to 90 r/min, although it may run as high as 150 r/min. Waterwheel generators also have salient poles which are usually dovetailed to a cylindrical spider consisting of steel plates riveted together. Their speeds range from 80 to 900 r/min and sometimes higher, although the 9,000-kVA Keokuk synchronous generators rotate at only 58 r/min, operating at a very low head. The speed rating of direct-connected waterwheel generators decreases with decrease in head. It is desirable to operate synchronous generators at the highest permissible speed since the weight and costs diminish with increase in speed. Waterwheel-driven generators must be able to run at double speed, as a precaution against accident, should the governor fail to shut the gate sufficiently rapidly in case the circuit breakers open or should the governing mechanism become inoperative.

Turbine-driven generators operate at speeds of 720 to 3,600 r/min. Direct-connected exciters, belt-driven exciters from the generator shaft, and separately driven exciters are used. In large stations separately driven (usually motor) exciters may supply the excitation energy to excitation bus bars. Steam-driven exciters and storage batteries are frequently held in reserve. With slow-speed synchronous generators, the belt-driven exciter is frequently used because it can be driven at higher speed, thus reducing the cost.

Synchronous-Generator Design At the present time single-phase generators are seldom built. For single-phase service two phases of a standard three-phase Y-connected generator are used. A single-phase load or unbalanced three-phase load produces flux pulsations in the magnetic circuits of synchronous generators, which increase the iron losses and introduce harmonics into the emf wave. Two-phase windings consist of two similar single-phase windings displaced 90 electrical space degrees on the armature and ordinarily occupying all the slots on the armature. The most common type of winding is the three-phase lap-wound two-layer type of winding. In three-phase windings three windings are spaced 120 electrical space degrees apart, the individual phase belts being spaced 60° apart. Usually, all the slots on the armature are occupied. Standard voltages are 550, 1,100, 2,200, 6,600, 13,200, and 20,000 V. It is much more difficult to insulate for 20,000 V than it is for the lower voltages. However, if the power is to be transmitted at this

voltage, its use would be justified by the saving of transformers. In machines of moderate and larger ratings it is common to generate at 6,600 and 13,200 V if transformers must be used. The higher voltage is preferable, particularly for the higher ratings, because it reduces the cross section of the connecting leads and bus bars.

The **standard frequency** in the United States for lighting and power systems is 60 Hz; the few former 50-Hz systems have practically all been converted to 60 Hz. The frequency of 25 Hz is commonly used in street-railway and subway systems to supply power to the synchronous converters and other ac-dc conversion apparatus; it is also commonly used in railroad electrification, particularly for single-phase series-motor locomotives (see Sec. 11). At 25 Hz incandescent lamps have noticeable flicker. In European (and most other) countries 50 Hz is standard. The frequency of a synchronous machine

$$f = P \times \text{r/min}/120 \qquad \text{Hz} \qquad (15.1.98)$$

where P is the number of poles. Synchronous generators are rated in kVA rather than in kW, since heating, which determines the rating, is dependent only on the current and is independent of power factor. If the kilowatt rating is specified, the power factor should also be specified.

Induced EMF The induced emf per phase in synchronous generator is

$$E = 2.22 k_b k_p \Phi f Z \qquad \text{V/phase} \qquad (15.1.99)$$

where k_b = breadth factor or belt factor (usually 0.9 to 1.0), which depends on the number of slots per pole per phase, 0.958 for three-phase, four slots per pole per phase; k_p = pitch factor = 1.0 for full pitch, 0.966 for $\frac{5}{6}$ pitch; Φ = total flux Wb, entering armature from one north pole and is assumed to be sinusoidally distributed along the air gap; f = frequency; and Z = number of series conductors per phase.

Synchronous generators usually are Y-connected. The advantages are that for a given line voltage the voltage per phase is $1/\sqrt{3}$ that of the delta-connected winding; third-harmonic currents and their multiples cannot circulate in the winding as with a delta-connected winding; third-harmonic emfs and their multiples cannot exist in the line emfs; a neutral point is available for grounding.

Regulation The terminal voltage of synchronous generator at constant frequency and field excitation depends not only on the current load but on the power factor as well. This is illustrated in Fig. 15.1.62, which shows the voltage-current characteristics of a synchronous generator with lagging current, leading current and in-phase current (pf = 1.00). With leading current the voltage may actually rise with increase in load;

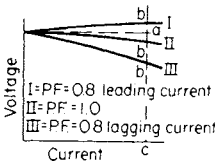

Fig. 15.1.62 Synchronous generator characteristics.

the rate of voltage decrease with load becomes greater as the lag of the current increases. The regulation of a synchronous generator is defined by the ANSI/IEEE Std. 100-1992 Standard Dictionary of Electrical and Electronic Terms as follows:

> The voltage regulation of a synchronous generator is the rise in voltage with constant field current, when, with the synchronous generator operated at rated voltage and rated speed, the specified load at the specified power factor is reduced to zero, expressed as a percent of rated voltage.

For example, in Fig. 15.1.62 the regulation under each condition is

$$100(ac - bc)/bc \qquad (15.1.100)$$

With leading current the regulation may be negative.

Three factors affect the regulation of synchronous generators; the **effective armature resistance,** the **armature leakage reactance,** and the **armature reaction.** With alternating current the armature loss is greater than the value obtained by multiplying the square of the armature current by the ohmic resistance. This is due to hysteresis and eddy-current losses in the iron adjacent to the conductor and to the alternating flux-producing losses in the conductors themselves. Also the current is not distributed uniformly over conductors in the slot, but the current density tends to be greatest in the top of the slot. These factors all have the effect of increasing the resistance. The ratio of effective to ohmic resistance varies from 1.2 to 1.5. The **armature leakage reactance** is due to the flux produced by the armature current linking the conductors in the slots and also the end connections.

The armature mmf reacts on the field to change the value of the flux. With a single-phase generator and with an unbalanced load on a polyphase generator, the armature mmf is pulsating and causes iron losses in the field structure. With polyphase machines under a constant balanced load, the armature mmf is practically constant in magnitude and fixed in its relation to the field poles. Its direction with relation to the field-pole axis is determined by the power factor of the load.

A component of current in phase with the no-load induced emf, or the excitation emf, merely distorts the field by strengthening the trailing pole tip and weakening the leading pole tip. A component of current lagging the excitation emf by 90° weakens the field without distortion. A component of current leading the excitation emf by 90° strengthens the field without distortion. Ordinarily, both cross magnetization and one of the other components are acting simultaneously.

The foregoing effects are called **armature reaction.** Frequently the effects of armature reactance and armature reaction can be combined into a single quantity.

It is difficult to determine the regulation of synchronous generator by actual loading, even when in service, owing to the difficulty of obtaining, controlling, and absorbing the large balanced loads. Hence methods of **predetermining regulation without actually loading** the machine are used.

Synchronous Impedance Method Both armature reactance and armature reaction have the same effect on the terminal voltage. In the synchronous impedance method the generator is considered as having no armature reaction, but the armature reactance is increased a sufficient amount to account for the effect of armature reaction. The phasor diagram for a current I lagging the terminal voltage V by an angle θ is shown in Fig. 15.1.63. In a polyphase generator the phasor diagram is applicable to one phase, a balanced load almost always being assumed.

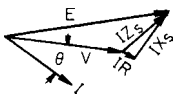

Fig. 15.1.63 Phasor diagram for synchronous impedance method.

The power factor of the load is cos θ; IR is the effective armature resistance drop and is parallel to I; IX_s is the synchronous reactance drop and is at right angles to I and leading it by 90°. IX_s includes both the reactance drop and the drop in voltage due to armature reaction. That part of IX_s which replaces armature reaction is in reality a fictitious quantity. The synchronous impedance drop is given by IZ_s. The no-load or open-circuit (excitation) voltage

$$E = \sqrt{(V\cos\theta + IR)^2 + (V\sin\theta \pm IX_s)^2} \qquad \text{V} \qquad (15.1.101)$$

All quantities are per phase. The negative sign is used with leading current.

$$\text{Regulation} = 100(E - V)/V \qquad (15.1.102)$$

With leading current E may be less than V and a negative regulation results.

The synchronous impedance is determined from an open-circuit and a short-circuit test, made with a weak field. The voltage E' on open circuit is divided by the current I' on short circuit for the same value of field current.

$$Z_s = E'/I' \qquad X_s = \sqrt{Z_s^2 - R^2} \qquad \Omega \qquad (15.1.103)$$

R is so small compared with X_s that for all practical purposes $X_s = Z_s$. R may be determined by measuring the ohmic resistance per phase and multiplying by 1.4 to 1.5 to obtain the effective resistance. This value of R and the value of X_s obtained from Eq. (15.1.103) may then be substituted in Eq. (15.1.101) to obtain E at the specified load and power factor.

Since the synchronous reactance is determined at low saturation of the iron and used at high saturation, the method gives regulations that are too large; hence it is called the **pessimistic method.**

MMF Method In the mmf method the generator is considered as having no armature reactance but the armature reaction is increased by an amount sufficient to include the effect of reactance. That part of armature reaction which replaces the effect of armature reactance is in reality a fictitious quantity. To obtain the data necessary for computing the regulation, the generator is short-circuited and the field adjusted to give rated current in the armature. The corresponding value of field current I_a is read. The field is then adjusted to give voltage E' equal to rated terminal voltage + IR drop (= $V + IR$, as phasors, Fig. 15.1.64) on open circuit and the field current I' read.

I_a is 180° from the current phasor I, and I' leads E' by 90° (Fig. 15.1.64). The angle between I' and I_a is $90 - \theta + \phi$, but since ϕ is small, it can usually be neglected. The phasor sum of I_a and I' is I_o. The open-circuit

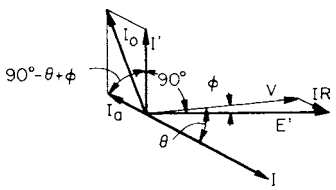

Fig. 15.1.64 Phasor diagram for the mmf method.

voltage E corresponding to I_o is the no-load voltage and can be found on the saturation curve. The regulation is then found from Eq. (15.1.102). This method gives a value of regulation less than the actual value and hence is called the **optimistic method.** The actual regulation lies somewhere between the values obtained by the two methods but is more nearly equal to the value obtained by the mmf method.

ANSI Method The ANSI method (American Standard 50, Rotating Electrical Machinery) which has become the accepted standard for the predetermination of synchronous generator operation, eliminates in large measure the errors due to saturation which are inherent in the synchronous impedance and mmf methods. In Fig. 15.1.65*a* is shown the saturation curve OAF of the generator. The axis OP is not only the field-current axis but also the axis of the current phasor I as well. V the terminal voltage is drawn θ deg from I or OP, where θ is the power factor angle. The effective resistance drop IR and the **leakage reactance** drop IX are drawn parallel and perpendicular to the current phasor. E_a, the phasor sum of V, IR, and IX, is the internal **induced** emf. Arcs are swung with O as the center and V and E_a as radii to intercept the axis of ordinates at B and C. OK, tangent to the straight portion of the saturation curve, is the **air-gap line.** If there is no saturation, I_v is the field current necessary to produce V, and CK is the field current necessary to produce E_a. The field current I_s is the increase in field current necessary to take into account the saturation corresponding to E_a.

The corresponding phasor diagram to a larger scale is shown in Fig. 15.1.65*b*. I'_f, the field current necessary to produce rated current at short circuit, corresponding to I_a (Fig. 15.1.64), is drawn horizontally. The field current I_v is drawn at an angle θ to the right of a perpendicular erected at the right-hand end of I'_f. I_r is the resultant of I'_f and I_v. I_s is added to I_r giving I_f the resultant field current. The no-load emf E is found on the saturation curve, Fig. 15.5.65*a*, corresponding to $I_f = OD$.

Excitation is commonly supplied by a small dc generator driven from the generator shaft. On account of commutation, except in the smaller sizes, the dc generator cannot be driven at 3,600 r/min, the usual speed for turbine generators, and belt or gear drives are necessary. The use of

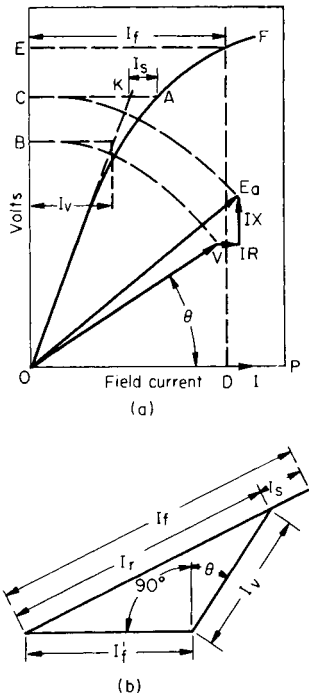

Fig. 15.1.65 ANSI method of synchronous generator regulation.

the silicon rectifier has made possible simpler means of excitation as well as voltage regulation. In one system the exciter consists of a small rotating-armature synchronous generator (which can run at high speed) mounted directly on the main generator shaft. The three-phase armature current is rectified by six silicon rectifiers and is conducted directly to the main generator field without any sliding contacts. The main generator field current is controlled by the current to the stationary field of the exciter generator. In another system there is no rotating exciter, the generator excitation being supplied directly from the generator terminals, the 13,800 V, three-phase, being stepped down to 115 V, three-phase, by small transformers and rectified by silicon rectifiers. Voltage regulation is obtained by saturable reactors actuated by potential transformers connected across the generator terminals.

Most regulators such as the following operate through the field of the exciter. In the **Tirrill regulator** the field resistance of the exciter is short-circuited temporarily by contacts when the bus-bar voltage drops. Actually, the contacts are vibrating continuously, the time that they are closed depending on the value of the bus-bar voltage. The General Electric Co. manufactures a direct-acting regulator in which the regulating rheostat is part of the regulator itself. The rheostat consists of stacks of graphite plates, each plate being pivoted at the center. Tilting the plates changes the path of the current through the rheostat and thus changes the resistance. The plates are tilted by a sensitive torque armature which is actuated by variations of voltage from the normal value (for regulators employing silicon rectifiers).

Parallel Operation of Synchronous Generators The kilowatt division of load between synchronous generators in parallel is determined entirely by the speed-load characteristics of their prime movers and not by the characteristics of the generators themselves. No appreciable adjustment of kilowatt load between synchronous generators in parallel can be made by means of their field rheostats, as with dc generators. Consider Fig. 15.1.66, which gives the speed-load characteristics in terms of frequency, of two synchronous generators, no. 1 and no. 2, these characteristics being the speed-load characteristics of their prime movers. These speed-load characteristics are drooping, which is necessary for stable parallel operation. The total load on the two machines is

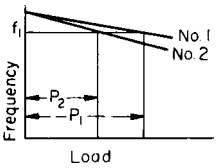

Fig. 15.1.66 Speed-load characteristics of synchronous generators in parallel.

$P_1 + P_2$ kW. Both machines must be operating at the same frequency F_1. Hence generator 1 must be delivering P_1 kW, and generator 2 must be delivering P_2 kW (the small generator losses being neglected). If, under the foregoing conditions, the field of either machine is strengthened, it cannot deliver a greater kilowatt load, for its prime mover can deliver more power only by dropping its speed. This is impossible, for both generators must operate always at the same frequency f_1. For any fixed total power load, the division of kilowatt load between synchronous generators can be changed only by modifying in some manner the speed-load characteristics of their prime movers, such, for example, as changing the tension in the governor spring. Synchronous generators in parallel are of themselves in stable equilibrium. If the driving torque of one machine is increased, the resulting electrical reactions between the machines cause a circulating current to flow between machines. This current puts more electrical load on the machine whose driving torque is increased and tends to produce motor action in the other machines. In an extreme case, the driving torque of one prime mover may be removed entirely, and its generator will operate as a synchronous motor, driving the prime mover mechanically.

Variations in driving torques cause currents to circulate between synchronous generators, transferring power which tends to keep the generators in synchronism. If the power transfer takes the form of recurring pulsations, it is called **hunting,** which may be reduced by building heavy copper grids called **amortisseurs,** or **damper windings,** into the pole faces. Turbine- and waterwheel-driven synchronous generators are much better adapted to parallel operation than are synchronous generators which are driven by reciprocating engines, because of their uniformity of torque.

Increasing the field current of synchronous generators in parallel with others causes it to deliver a greater lagging component of current. Since the character of the load determines the total current delivered by the system, the lagging components of current delivered by the other generators must decrease and may even become leading components. Likewise if the field of one generator is weakened, it delivers a greater leading component of current and the other machines deliver components of current which are more lagging. These leading and lagging currents do not affect appreciably the division of **kilowatt** load between the synchronous generators. They do, however, cause unnecessary heating in their armatures. The fields of all synchronous generators should be so adjusted that the heating due to the quadrature components of currents is a minimum. With two generators having equal armature resistances, this occurs when both deliver equal quadrature currents.

Armature reactance in the armature of machines in parallel is desirable. If not too great, it stabilizes their operation by producing the synchronizing action. Synchronous generators with too little reactance are sensitive, and if connected in parallel with slight phase displacement or inequality of voltage, considerable disturbance results. Armature reactance also reduces the current on short circuit, particularly during the first few cycles when the short-circuit current is a maximum. Frequently, external power-limiting reactances are connected in series to protect the generators and equipment from injury that would result from the tremendous short-circuit currents. For these reasons, poor regulation in large synchronous generators is frequently considered to be an advantage rather than a disadvantage.

Ground Resistors Most power systems operate with a grounded neutral. When the station generators deliver current directly to the system (without intervening transformers), it is customary to ground the neutral (of the Y-connected windings) or one generator in a station; this is usually done through a grounding resistor of from 2 to 6 Ω. If the neutral of more than one generator is grounded, third-harmonic (and multiples thereof) currents can circulate between the generators. The ground resistor reduces the short-circuit currents when faults to ground occur, and hence reduces the violence of the short circuit as well as the duty of the circuit breakers. Grounding reactors are sometimes used but have limited application owing to the danger of high voltages resulting from resonant conditions.

INDUCTION GENERATORS

The **induction generator** is an induction motor driven above synchronous speed. The rotor conductors cut the rotating field in a direction to convert shaft mechanical power to electrical power. Load increases as speed increases, so the generator is self-regulating and can be used without governor control. On short circuits the induction generator will deliver current to the fault for only a few cycles because, unlike the synchronous generator, it is not self-exciting. Since it is not self-excited, an induction generator must always be used in parallel with an electrical system where there are some synchronous machines, or capacitor banks, to deliver lagging current (VARs) to the induction generator for excitation.

Induction generators have found favor in industrial **cogeneration** applications and as **wind-driven** generators where they provide a small part of the total load.

CELLS

Fuel cells convert chemical energy of fuel and oxygen directly to electrical energy. **Solar cells** convert solar radiation to electrical energy. At present, these conversion methods are not economically competitive with historic generating techniques, but they have found applications in isolated areas, such as microwave relaying stations, satellites, and residential lighting, where power requirements are small and costs for transmitting electrical power from more conventional sources is prohibitive. As solar technology continues to improve, many other applications will be evaluated.

TRANSFORMERS

Transformer Theory The transformer is a device that transfers energy from one electric circuit to another without change of frequency and usually, but not always, with a change in voltage. The energy is transferred through the medium of a magnetic field: it is supplied to the transformer through a primary winding and is delivered by means of a secondary winding. Both windings link the same magnetic circuit. With no load on the secondary, a small current, called the exciting current, flows in the primary and produces the alternating flux. This flux links both primary and secondary windings and induces the same volts per turn in each. With a sine wave the emf is

$$E = 4.44\Phi_m nf \quad \text{V} \tag{15.1.104}$$

where Φ_m = maximum instantaneous flux in webers, n = turns on either winding, and f = frequency. Equation (15.1.104) may also be written

$$E = 4.44B_m Anf \quad \text{V} \tag{15.1.105}$$

B_m = maximum instantaneous flux density in iron and A = net cross section of iron. If B_m is in T, A is in m^2; if B_m is in Mx/in^2, A is in in^2.

In English units, Eq. (15.1.104) becomes

$$E = 4.44\Phi_m nf10^{-8} \quad \text{V} \tag{15.1.104a}$$

where Φ_M is in maxwells; Eq. (15.1.105) becomes

$$E = 4.44B_m Anf10^{-8} \quad \text{V} \tag{15.1.105a}$$

where B_m is in Mx/in^2 and A is in in^2.

B_m is practically fixed. In large transformers with silicon steel it varies between 60,000 and 75,000 Mx/in^2 at 60 Hz and between 75,000 and 90,000 Mx/in^2 at 25 Hz. It is desirable to operate the iron at as high

density as possible in order to minimize the weight of iron and copper. On the other hand, with too high densities the eddy-current and hysteresis losses become too great, and with low frequency the exciting current may become excessive. It follows from Eq. (15.1.104) that

$$E_1/E_2 = n_1/n_2 \tag{15.1.106}$$

where E_1 and E_2 are the primary and secondary emfs and n_1 and n_2 are the primary and secondary turns. Since the impedance drops in ordinary transformers are small, the terminal voltages of primary and secondary are also practically proportional to their number of turns. As the change in secondary terminal voltage in the ordinary constant-potential transformer over its range of operation is small (1.5 to 3 percent), the flux must remain substantially constant. Therefore, the added ampere-turns produced by any secondary load must be balanced by opposite and equal primary ampere-turns. Since the exciting current is small compared with the load current (1.5 to 5 percent) and the two are usually out of phase, the exciting current may ordinarily be neglected. Hence,

$$n_1 I_1 = n_2 I_2 \tag{15.1.107}$$
$$I_1/I_2 = n_2/n_1 \tag{15.1.108}$$

where I_1 and I_2 are the primary and secondary currents.

When load is applied to the secondary of a transformer, the secondary ampere-turns reduce the flux slightly. This reduces the counter emf of the primary, permitting more current to enter and thus supply the increased power demanded by the secondary.

Both primary and secondary windings must necessarily have resistance. All the flux produced by the primary does not link the secondary; the counter ampere-turns of the secondary produce some flux which does not link the primary. These **leakage fluxes** produce reactance in each winding. The combined effect of the resistance and reactance produces an impedance drop in each winding when current flows. These impedance drops produce a slight drop in the secondary terminal voltage with load.

Transformer Testing Transformer regulation and losses are so small that it is far more accurate to compute the regulation and efficiency than to determine them by actual measurement. The necessary measurements and computations are comparatively simple, and little power is involved in making the tests. In the **open-circuit** test, the power input to either winding is measured at its rated voltage. Usually it is more convenient to make this test on the low-voltage winding, particularly if it is rated at 110, 220, or 550 V. The open-circuit power practically all goes to supply the core losses, consisting of eddy-current and hysteresis losses. Let this value of power be P_0. The eddy-current loss varies as the square of the voltage and frequency; the hysteresis loss varies as the 1.6 power of the voltage, and directly as the frequency. In the **short-circuit** test one winding is short-circuited, and the current in the other is adjusted to near its rated value. The voltage V_c, the current I_1, and the power input P_c are measured. When one winding of a transformer is short-circuited, the voltage across the other winding is 3 to 4 percent of rated value when rated current flows. Since a voltage range of from 110 to 250 V is best adapted to measuring instruments, that winding whose rated voltage, multiplied by 0.03 or 0.04, is closest to this voltage range should be used for making the short-circuit test, the other winding being short-circuited. Practically all the power on short circuit goes to supply the copper loss of primary and secondary. If the measurements are made on the primary,

$$R_{01} = P_c/I_1^2 \tag{15.1.109}$$
$$Z_{01} = V_c/I_1 \tag{15.1.110}$$
$$X_{01} = \sqrt{Z_{01}^2 - R_{01}^2} \tag{15.1.111}$$

where R_{01}, Z_{01}, and X_{01} are the equivalent resistance, impedance, and reactance referred to the primary. Also $R_{02} = R_{01}(n_2/n_1)^2$; $Z_{02} = Z_{01}(n_2/n_1)^2$; $X_{02} = X_{01}(n_2/n_1)^2$, these quantities being the equivalent resistance, impedance, and reactance referred to the secondary. If the dc resistances R_1 and R_2 of the primary and secondary are measured,

$$R_{01} = R_1 + (n_1/n_2)^2 R_2 \tag{15.1.112}$$
$$R_{02} = R_2 + (n_2/n_1)^2 R_1 \tag{15.1.113}$$

The ac or effective resistances, determined from Eq. (15.1.109), are usually 10 to 15 percent greater than these values.

Regulation The regulation may be computed from the foregoing data as follows:

$$V_1' = \sqrt{(V_1 \cos\theta + I_1 R_{01})^2 + (V_1 \sin\theta \pm I_1 X_{01})^2} \tag{15.1.114}$$
$$\text{Regulation} = 100(V_1' - V_1)V_1 \tag{15.1.115}$$

V_1 = rated primary terminal voltage; cos θ = load power factor; I_1 = rated primary current; R_{01} = equivalent resistance referred to primary [from Eq. (15.1.109)]; X_{01} = equivalent reactance referred to primary. The + sign is used with lagging current and the − sign with leading current. Equations (15.1.114) and (15.1.115) are equally applicable to the secondary if the subscripts are changed.

Efficiency The only two losses in a constant-potential transformer are the core loss in W, P_0, which is practically independent of load, and P_c the copper loss in W, which varies as the load current squared. The efficiency for any current I_1 is

$$\eta = V_1 I_1 \cos\theta/(V_1 I_1 \cos\theta + P_0 + I_1^2 R_{01}) \tag{15.1.116}$$

Equation (15.1.116) applies equally well to the secondary if the subscripts are changed. The maximum efficiency occurs when the core and copper losses are equal.

All-Day Efficiency Since transformers must usually be on the line 24 h/day, part of which time the load may be very light, the all-day efficiency is important. This is equal to the total energy or watthour output divided by the total energy or watthour input for the 24 h. That is,

$$\eta = \frac{(V_1 I_1 \cos\theta_1)t_1 + \cdots}{(V_1 I_1 \cos\theta_1)t_1 + \cdots + (I_1^2 R_{01})t_1 + \cdots + 24P_0} \tag{15.1.117}$$

where t_1 = time in hours that load $V_1 I_1 \cos\theta_1$ is being delivered, etc.

Polyphase Transformer Connections Three-phase transformer banks may be connected Δ-Δ, Δ-Y, Y-Y, and Y-Δ. The Δ-Δ connection is very common, particularly at the lower voltages, and has the important advantage that the bank will operate V-connected if one transformer is disabled. The Δ-Y connection is advantageous for stepping up to high voltages since the secondary of the transformers need be wound only for 58 percent $(1/\sqrt{3})$ of the line voltage; it is also necessary when a four-wire three-phase system is obtained from a three-wire three-phase system since "a floating neutral" on the secondary cannot occur. This connection has found increased application in step-down distribution at 600 V and lower because of the relative ease of applying sensitive fault protection. The Y-Y system may be used for stepping up voltage. It should not be used for obtaining a three-phase four-wire system from a three-phase three-wire system, because of the "floating neutral" on the secondary and the resulting high degree of unbalance of the secondary voltages. The Y-Δ system may be used to step down high voltages, the reverse of the Δ-Y connection. Y-connected windings also preclude third harmonic, and their multiples, circulating currents in the transformer windings. In the Δ-Y and Y-Δ systems the ratio of line voltage is obviously not that of the individual transformers. Because of different phase displacement between primaries and secondaries, a Δ-Δ bank cannot be connected in parallel (on both sides) with a Δ-Y bank, etc., even if they both have the correct voltage ratios between lines.

Three-phase transformers combine the magnetic circuits of three single-phase transformers so that they have parts in common. A material saving in cost, in weight, and in space results, the greatest saving occurring in the core and oil. The advantages of three-phase transformers are often outweighed by their lack of flexibility. The failure of a single phase shuts down the entire transformer. With three single units, one unit may be readily replaced with a single spare. The primaries of single-phase transformers may be connected in Y or Δ at will and the secondaries properly phased. The primaries, as well as the secondaries of three-phase transformers, must be phased.

For the transformation of moderate amounts of power from three-phase to three-phase, two transformers employing either the **open delta** or **T connection** (Fig. 15.1.67) may be used. With each connection the ratio of line voltages is the same as the transformer ratios. In the figure,

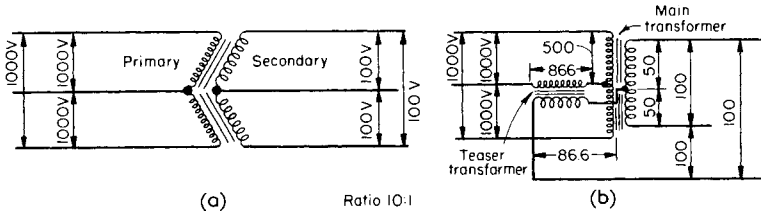

Fig. 15.1.67 Transformer connections for transforming moderate amounts of three-phase power. (*a*) Open delta connection; (*b*) T connection.

ratios 10 : 1 are shown. In the T connection the primary and the secondary of the main transformer must be provided with a center tap to which one end of the teaser transformer is connected. The ratings of these systems are only 58 percent of the rating of the system using three similar transformers, one for each phase. Owing to dissymmetry, the terminal voltages become somewhat unbalanced even with a balanced load.

To transform from two- to three-phase or the reverse, the **T connection** of Fig. 15.1.68 is used. To make the secondary voltages symmetrical a tap (called a **Scott tap**) is brought out at 86.6 percent ($\sqrt{3}/2$) of the primary winding of the teaser transformer as shown in Fig. 15.1.68. With balanced no-load voltages the voltages become slightly unbalanced even under a symmetrical load, owing to unequal phase differences in the individual coils. The three-phase neutral O is one-third the winding of the teaser transformer from the junction. In Fig. 15.1.68*a* the transformation is from three-phase to a two-phase three-wire system. In Fig. 15.1.68*b* the transformation is from three-phase to a four-phase, five-wire system. The voltages are given on the basis of 100-V primaries with 1 : 1 transformer ratios.

An **autotransformer,** also called **compensator,** consists essentially of a single winding linking a magnetic circuit. Part of the energy is transformed, and the remainder flows through conductively. Suitable taps are provided so that, if the primary voltage is applied to two of the taps, a voltage may be taken from any other two taps. The ratio of voltages is equal practically to the ratio of the turns between their taps. An autotransformer should be installed only when the ratio of transformation is not large. The ratio of power transformed to total power is $1 - n$, where n is the ratio of low-voltage to high-voltage emf. This gives the saving over the ordinary transformer and is greatest when the ratio is not far from unity. Figure 15.1.69*a* shows 100 kW being changed from 3,300 to 2,300 V; 30.3 kW only are being actually transformed, and the remainder of the power flows through conductively. Figure 15.1.69*b* shows how an ordinary 10 : 1, 10-kW lighting transformer may be connected to boost 110 kW 10 percent in voltage. In Fig. 15.1.69*b*, however, the 230-V secondary must be insulated for 2,300 V to the core and ground. The voltage may likewise be reduced by reversing the 230-V coil. An autotransformer should never be used when it is desired to keep dangerous primary potentials from the secondary. It is used for starting induction motors (Fig. 15.1.71) and for a number of similar purposes.

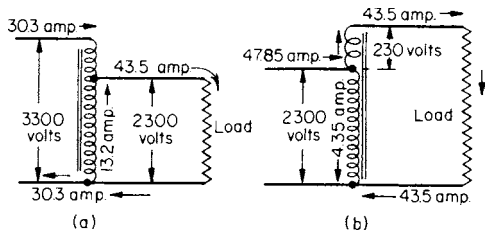

Fig. 15.1.69 Autotransformer.

Data on Transformers Single-phase 55° self-cooled oil-insulated transformers for 2,300-V primaries, 230/115-V secondaries, and in sizes from 5 to 200 kVA for 60(25) Hz have efficiencies from one-half to full load of about 98 (97 to 98.7) percent and regulation of 1.5 (1.1 to 2.1) percent with pf = 1, and 3.5 (2.7 to 4.1) percent with pf = 0.8. Power transformers with 13,200-V primaries and 2,300-V secondaries in sizes from 667 to 5,000 kVA and for both 60 and 25 Hz have efficiencies from one-half to full load of about 99.0 percent and regulation of about 1.0 (4.2) percent with pf = 1 (0.8).

AC MOTORS

Polyphase Induction Motor The polyphase induction motor is the most common type of motor used. It may be classified as squirrel cage or wound rotor and may be single-speed or multispeed type. Squirrel-cage motors are further classified on the basis of torque, speed, and current characteristics as Designs A, B, C, and D and for locked-rotor current in kVA/hp by Codes A to V. It consists ordinarily of a stator which is wound in the same manner as the synchronous-generator stator. If two-phase current is supplied to a two-phase winding or three-phase current to a three-phase winding, a rotating magnetic field is produced in the air gap. The number of poles which this field has is the same as the number of poles that a synchronous generator employing the same stator winding would have. The speed of the rotating field, or the **synchronous speed,**

$$N = 120f/P \quad \text{r/min} \tag{15.1.118}$$

where f = frequency and P = number of poles.

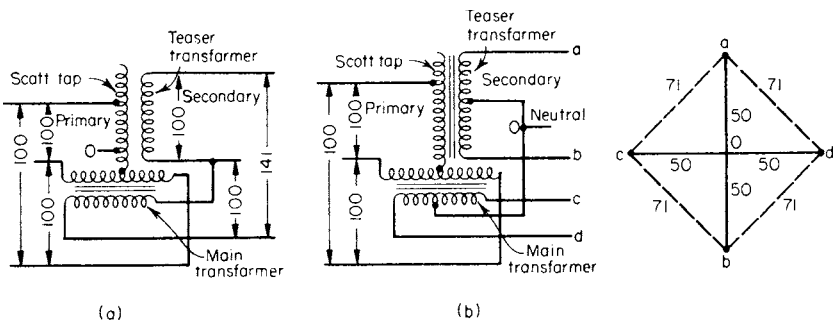

Fig. 15.1.68 Connections for transforming from three-phase to two- and four-phase power.

There are two general types of rotors. The **squirrel-cage type** consists of heavy copper or aluminum bars short-circuited by end rings, or the bars and end rings may be an integral aluminum casting. The **wound rotor** has a polyphase winding of the same number of poles as the stator, and the terminals are brought out to slip rings so that external resistance may be introduced. The rotor conductors must be cut by the rotating field, hence the rotor cannot run at synchronous speed but must slip. The per unit **slip** is

$$s = (N - N_2)/N \tag{15.1.119}$$

where N_2 = the rotor speed, r/min. The rotor frequency

$$f_2 = sf \tag{15.1.120}$$

The torque is proportional to the air-gap flux and the components of rotor current in space phase with it. The rotor currents tend to lag the emfs producing them, because of the rotor-leakage reactance. From Eq. (15.1.120) the rotor frequency and hence the rotor reactance ($X_2 = 2\pi f_2 L_2$) are low when the motor is running near synchronous speed, so that there is a large component of rotor current in space phase with the flux. With large values of slip the increased rotor frequency increases the rotor reactance and hence the lag of the rotor currents behind their emfs, and therefore considerable space-phase difference between these currents and the flux develops. Consequently even with large values of current the torque may be small. The torque of the induction motor increases with slip until it reaches a maximum value called the **breakdown torque,** after which the torque decreases (see Fig. 15.1.72). The breakdown torque varies as the square of the voltage, inversely as the stator impedance and rotor reactance, and is independent of the rotor resistance.

The squirrel-cage motor develops moderate torque on starting ($s = 1.0$) even though the current may be three to seven times rated current. For any value of slip the torque of the induction motor varies as the square of the voltage. The torque of the squirrel-cage motor which, on starting, is only moderate may be reduced in the larger motors because of starting voltage drop from inrush and possible necessity of applying reduced-voltage starting.

Polyphase squirrel-cage motors are used mostly for constant-speed work; however, recent developments in variable-frequency pulse-width modulation (PWM) ac drives have seen these motors used in variable-speed applications where the ratio of maximum to minimum speed does not exceed 4 : 1. They are used widely on account of their rugged construction and the absence of moving electrical contacts, which makes them suitable for operation when exposed to flammable dust or gas. General-purpose squirrel-cage motors have starting torques of 100 to 250 percent of full load torque at rated voltage. The highest torques occur at the higher rated speeds. The locked rotor currents vary between four and seven times full-load current. In the **double-squirrel-cage** type of motor there is a high-resistance winding in the top of the rotor slots and a low-resistance winding in the bottom of the slots. The low-resistance winding is made to have a high leakage reactance, either by separating the windings with a magnetic bridge, Fig. 15.1.70*a*, or by making the slot very narrow in the area between the two windings, Fig. 15.1.70*b*. On starting, because of the high reactance of the low-resistance winding, most of the rotor current will flow in the high-resistance winding, giving the motor a large starting torque. As the rotor approaches the low value of slip at which it normally operates, the rotor frequency and hence the rotor reactance become low and most of the rotor current now flows in the low-resistance winding. Cage bars can be shaped so that one winding gives comparable results. See Fig. 15.1.70*c*. The rotor operates with a low value of slip. The high starting torque of the high-resistance motor and the excellent constant-speed operating characteristics of the low-resistance squirrel-cage rotor are combined in one motor.

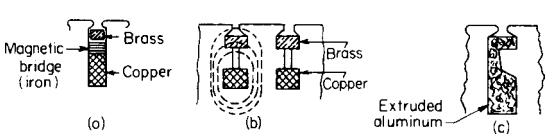

Fig. 15.1.70 Types of slots for squirrel-cage windings.

The **single shaped** cage bar is more economical, and almost any shape for required characteristics can be extruded from aluminum. Single bars also eliminate the problems of differential expansion with double cage bars.

Nameplates of polyphase integral-hp squirrel-cage induction motors carry a *code* letter and a *design* letter. These provide information about motor characteristics, the former on locked rotor or starting inrush current (see Table 15.1.26) and the latter on torque characteristics. National Electrical Manufacturers Association (NEMA) standards publication No. MG1-2006 defines four design letters: A, B, C, and D. In all cases the motors are designed for full voltage starting. Locked rotor current and torque, pull-up torque and breakdown torque are tabulated according to horsepower and speed. Designs A, B, and C have full load slips less than 5 percent and design D more than 5 percent. Design B motors are the most widely used, having starting-torque and line-starting current characteristics suitable for most power systems. The nature of the various designs can be understood by reference to the full voltage values for a 100-hp, 1,800-r/min motor which follow:

	Design			
	A	B	C	D
Locked rotor torque	125*	125*	200*	275*
Pull-up torque	100†	100†	140†	—
Breakdown torque	200†	200†	190†	—
Locked rotor current	—	600*	600*	600*
Full load slip (%)	5§	5§	5§	5‡

NOTE: All quantities, except slip, are percent of full load value.
* Upper limit. [See NEC® Table 430.7(B).]
† Not less than.

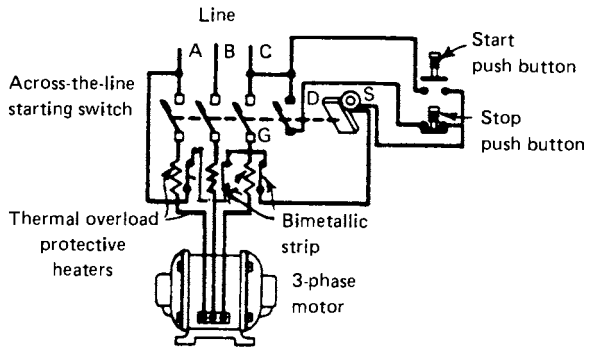
§ Less than.

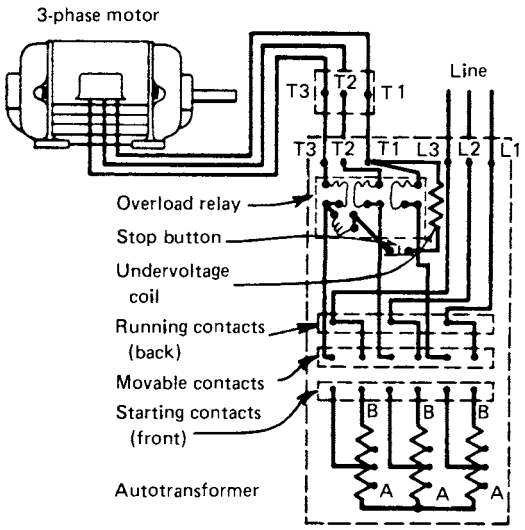
Starting Polyphase induction motor controllers are commonly available for full-voltage (across-the-line) or reduced-voltage starting for single-speed or multispeed applications and may include reversing control. It is desirable to start induction motors by direct connection across the line, since reduced voltage starters are expensive and almost always reduce the starting torque. The capacity of the distribution system dictates when reduced voltage starting must be used to limit voltage dips on the system. On stiff industrial systems 25,000-hp motors have been successfully started **across-the-line.**

In Fig. 15.1.71*a* is shown an **"across-the-line" starter** which may be operated from different push-button stations. The START push button closes the solenoid circuit between phases *C* and *A* through three bimetallic strips in series. This energizes solenoid *S,* which attracts armature *D,* which in turn closes the starting switch and the auxiliary blade *G.* This blade keeps the solenoid circuit closed when the START push button is released. Pressing the STOP push button opens the solenoid circuit, permitting the starting switch to open. A prolonged heavy overload raises the temperature of the heaters by an amount that will cause at least one of the overload sensing elements to open the solenoid circuit, releasing the starting switch.

A common method of applying reduced-voltage start is to use a **compensator** or **autotransformer** or **autostarter** (Fig. 15.1.71*b*). When the switch is in the starting position, the three windings *AB* of the three-phase autotransformer are connected in Y across the line and the motor terminals are connected to the taps which supply reduced voltage. When the switch is in the running position, the starter is entirely disconnected from the line. In modern practice, motors are protected by thermal or magnetic overload relays (Fig. 15.1.71) which operate to trip the circuit breaker. Since a time element is involved in the operation of such relays, they do not respond to large starting currents, because of their short duration. To limit the current to as low a value as possible, the lowest taps that will give the motor sufficient voltage to supply the



(a) Across-the-line-starter



(b) Autostarter

Fig. 15.1.71 Starters for squirrel-cage induction motor. (*a*) Across-the-line starter; (*b*) autostarter.

required starting torque should be used. As the torque of an induction motor varies as the square of the voltage, the compensator produces a very low starting torque.

Resistors in series with the stator may also be used to start squirrel-cage motors. They are inserted in each phase and are gradually cut out as the motor comes up to speed. The resistors are generally made of wire-type resistor units or of graphite disks enclosed within heat-resisting porcelain-lined iron tubes. The disadvantage of resistors is that if the motor is started slowly the resistor becomes very hot and may burn out. Resistor starters are less expensive than autotransformers. Their application is to motors that start with light loads at infrequent intervals.

A **phase-controlled,** silicon-controlled rectifier (SCR) may be used to limit the motor-starting current to any value that will provide sufficient starting torque by reducing voltage to the motors. The SCR can also be used to start and stop the motors. A positive opening device such as a contactor or circuit breaker should be used in series with the SCR to stop the motor in case of a failed SCR, which will normally fail shorted and apply full voltage to the motor. The SCR starter has been combined with a microprocessor to provide gradual motor terminal voltage increases during an adjustable acceleration period. This is commonly called *soft start.* Other features include the ability to limit motor starting current and save energy when the motor is lightly loaded.

By **introducing resistance into the rotor circuit** through slip rings, the rotor currents may be brought nearly into phase with the air-gap flux and, at the same time, any value of torque up to maximum torque obtained. As the rotor develops speed, resistance may be cut out until there is no external resistance in the rotor circuit. The speed may also be controlled by inserting resistance in the rotor circuit. However, like the armature-resistance method of speed control with shunt motors, this method is also inefficient and gives poor speed regulation. Figure 15.1.72 shows graphically the effect on the torque of applying reduced voltage (curves *b, c*) and of inserting resistance in the rotor circuit (curve *d*). As shown by curves *b* and *c*, the torque for any given slip is proportional to the square of the line voltage. The effect of introducing resistance into the rotor circuit is shown by curve *d.* The point of maximum torque is shifted toward higher values of slip. The maximum torque at starting (slip = 1.0) occurs when the

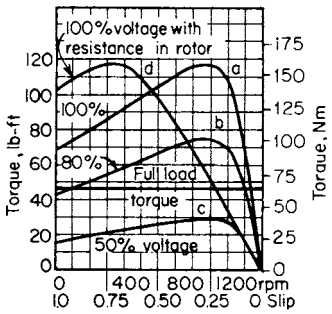


Fig. 15.1.72 Speed-torque curve for 10-hp, 60-Hz, 1,140-r/min induction motor.

rotor resistance is equal to the rotor reactance at standstill. The wound-rotor motor is used where large starting torque is necessary as in railway work, hoists, and cranes. It has better starting characteristics than the squirrel-cage motor, but, because of the necessarily higher resistance of the rotor, it has greater slip even with the rotor resistance all cut out. Obviously, the wound rotor, controller, and external resistance make it more expensive than the squirrel-cage type. See Table 15.1.13 for performance data.

One **disadvantage of induction motors** is that they take lagging current, and the power factor at half load and less is low. The speed- and torque-load characteristics of induction motors are almost identical with those of the shunt motor. The speed decreases slightly to full load, the slip being from 10 percent in small motors to 2 percent in very large motors. The torque is almost proportional to the load nearly up to the breakdown torque. The power factor is 0.8 to 0.9 at full load. The direction of rotation of any three-phase motor may be reversed by interchanging any two stator wires.

Speed Control of Induction Motors The induction motor inherently is a constant-speed motor. From Eqs. (15.1.118) and (15.1.119) the rotor speed is

$$N_2 = 120f(1 - s)/P \qquad (15.1.121)$$

The speed can be changed only by changing the frequency, poles, or slip. By employing two distinct windings or by reconnecting a single winding by switching it is possible to change the number of poles. Complications prevent more than two speeds being readily obtained in this manner. Another objection to changing the number of poles is the fact that the design is a compromise, and sacrifices of desirable characteristics usually are necessary at both speeds. Three-phase, two-speed squirrel-cage motors of either consequent pole or separate winding types are commonly used for applications such as machine tools, fans, blowers, and refrigeration compressors in designs for constant horsepower and for constant or variable torque.

The change of slip by introducing resistance into the rotor circuit has been discussed under the wound-rotor motor.

Solid-state ac drives, also referred to as **adjustable-speed drives (ASDs),** using **pulse-width modulation (PWM)** frequency converters have become widely used for speed control of ac induction motors and are available for powers up to 10,000 horsepower.

AC drives using **line-commutated rectifiers (LCI)** are used for speed control of synchronous motors and, to a lesser degree, induction motors. PWM drives are widely used in industrial applications for pumps, blowers, fans, and compressors. Benefits in energy savings, reduced maintenance, and reduced mechanical and thermal stresses can be realized. Important issues to be considered in applying PWM drives include, but are not limited to: turndown ratio, harmonic effects on electrical networks, impact on the mechanical system, condition of existing motors retrofitted to PWM control, use of insulating bearings to minimize circulating currents in motors, distance from drive to motor, and increased frame size when motors are operated at less than rated speed. AC drive suppliers may have specific installation requirements or recommendations on motor feeder cable type and grounding practices. In many applications the motor/drive combination is engineered and supplied as a system.

Polyphase voltages should be evenly **balanced** to prevent phase current **unbalance.** If voltages are not balanced, the motor must be derated in accordance with National Electrical Manufacturers Association (NEMA), Publication No. MG-1-14.34.

Approximately 5 percent voltage unbalance would cause about 25 percent increase in temperature rise at full load. The input current unbalance at full load would probably be 6 to 10 times the input voltage unbalance.

Single phasing, one phase open, is the ultimate unbalance and will cause overheating and burnout if the motor is not disconnected from the line.

Single-Phase Induction Motor Single-phase induction motors are usually made in fractional horsepower ratings, but they are listed by NEMA in integral ratings up to 10 hp. They have relatively high rotor resistances and can operate in the single-phase mode without overheating. Single-phase induction motors are not self-starting.

However, the single-phase motor runs in the direction in which it is started. There are several methods of starting single-phase induction motors. Short-circuited turns, or **shading coils,** may be placed around the pole tips which retard the time phase of the flux in the pole tip, and thus a weak torque in the direction of rotation is produced. A high-resistance starting winding, displaced 90 electrical degrees from the main winding, produces poles between the main poles and so provides a rotating field which is weak but is sufficient to start the motor. This is called the **split-phase** method. In order to minimize overheating this winding is ordinarily cut out by a centrifugal device when the armature reaches speed. In the larger motors a repulsion-motor start is used. The rotor is wound like an ordinary dc armature with a commutator, but with short-circuited brushes pressing on it axially rather than radially. The motor starts as a repulsion motor, developing high torque. When it nears its synchronous speed, a centrifugal device pushes the brushes away from the commutator, and at the same time causes the segments to be short-circuited, thus converting the motor into a single-phase induction motor.

Capacitor Motors Instead of splitting the phase by means of a high-resistance winding, it has become almost universal practice to connect a capacitor in series with the auxiliary winding (which is displaced 90 electrical degrees from the main winding). With capacitance, it is possible to make the flux produced by the auxiliary winding lead that produced by the main field winding by 90° so that a true two-phase rotating field results and good starting torque develops. However, the 90° phase relation between the two fields is obtainable at only one value of speed (as at starting), and the phase relation changes as the motor comes up to speed. Frequently the auxiliary winding is disconnected either by a centrifugal switch or a relay as the motor approaches full speed, in

which case the motor is called a **capacitor-start** motor. With proper design the auxiliary winding may be left in circuit permanently (frequently with additional capacitance introduced). This improves both the power factor and torque characteristics. Such a motor is called **permanent-split capacitor motor.**

Phase Converter If a polyphase induction motor is operating single-phase, polyphase emfs are generated in its stator by the combination of stator and rotor fluxes. Such a machine can be utilized, therefore, for converting single-phase power into polyphase power and, when so used, is called a **phase converter.** Unless corrective means are utilized, the polyphase emfs at the machine terminals are somewhat unbalanced. The power input, being single-phase and at a power factor less than unity, not only fluctuates but is negative for two periods during each cycle. The power output being polyphase is steady, or nearly so. The cyclic differences between the power output and the power input are accounted for in the kinetic energy stored in the rotating mass of the armature. The armature accelerates and decelerates, but only slightly, in accordance with the difference between output and input. The phase converter is used principally on railway locomotives, since a single trolley wire can be used to deliver single-phase power to the locomotive, and the converter can deliver three-phase power to the three-phase wound-rotor driving motors. PWM-type adjustable-speed drives are also available for small motor applications that can provide variable-speed control of a three-phase motor from a one- or two-phase voltage source.

AC Commutator Motors Inherently simple ac motors are not adapted to high starting torques and variable speed. There are a number of types of commutating motor that have been developed to meet the requirement of high starting torque and adjustable speed, particularly with single phase. These usually have been accompanied by compensating windings, centrifugal switches, etc., in order to overcome low power factors and commutation difficulties. With proper compensation, commutator motors may be designed to operate at a power factor of nearly unity or even to take leading current.

One of the simplest of the **single-phase commutator motors** is the ac series railway motor such as is used on the erstwhile New York, New Haven, and Hartford Railroad. It is based on the principle that the torque of the dc series motor is in the same direction irrespective of the polarity of its line terminals. This type of motor must be used on low frequency, not over 25 Hz, and is much heavier and more costly than an equivalent dc motor. The torque and speed curves are almost identical with those of the dc series motor. Unlike most ac apparatus the power factor is highest at light load and decreased with increasing load. Such motors operate with direct current even better than with alternating current. For example, the New Haven locomotives also operate from the 600-V dc third-rail system (two motors in series) from the New York City line (238th St.) into Grand Central Station. (See also Sec. 11.)

On account of difficulties inherent in ac operation such as commutation and high reactance drops in the windings, it is economical to construct and operate such motors only in sizes adaptable to locomotives, the ratings being of the order of 300 to 400 hp. **Universal motors** are small simple series motors, usually of fractional horsepower, and will operate on either direct or alternating current, even at 60 Hz. They are used for vacuum cleaners, electric drills, and small utility purposes.

Synchronous Motor Just as dc shunt generators operate as motors, a synchronous generator, connected across a suitable ac power supply, will operate as a motor and deliver mechanical power. Each conductor on the stator must be passed by a pole of alternate polarity every half cycle so that at constant frequency the rpm of the motor is constant and is equal to

$$N = 120f/P \qquad \text{r/min} \tag{15.1.122}$$

and the speed is independent of the load.

There are two types of synchronous motors in general use: the **slip-ring** type and the **brushless** type. The motor field current is transmitted to the motor by brushes and slip rings on the slip-ring type. On the brushless type it is generated by a shaft-mounted exciter and rectified and controlled by shaft-mounted static devices. Eliminating the slip rings is advantageous in dirty or hazardous areas.

The synchronous motor has the desirable characteristic that its power factor can be varied over a wide range merely by changing the field excitation. With a weak field the motor takes a lagging current. If the load is kept constant and the excitation increased, the current decreases (Fig. 15.1.73) and the phase difference between voltage and current becomes less until the current is in phase with the voltage and the power factor is unity. The current is then at its minimum value such as I_0, and the corresponding field current is called the **normal excitation.** Further increase in field current causes the armature current to lead and the power factor to decrease. Thus **underexcitation** causes the current to **lag; overexcitation** causes the current to **lead.** The effect of varying the field current at constant values of load is shown by the V curves (Fig. 15.1.73). Unity power factor occurs at the minimum value of armature current, corresponding to normal excitation. The power factor for any point such as P is I_0/I_1, leading current. Because of its adjustable power factor, the motor is frequently run light merely to improve power factor or to control the voltage at some part of a power system. When so used the motor is called a **synchronous condenser.** The motor may, however, deliver mechanical power and at the same time take either leading or lagging current.

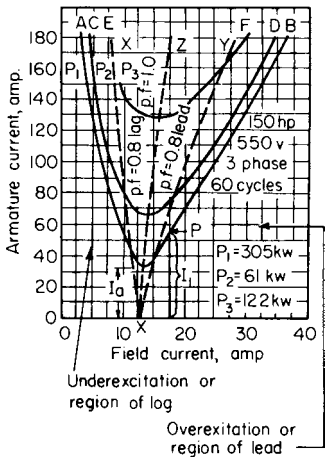

Fig. 15.1.73 V curves of a synchronous motor.

Synchronous motors are used to drive **centrifugal** and **axial compressors,** usually through speed increasers, **pumps, fans,** and other high-horsepower applications where **constant speed, efficiency,** and **power factor** correction are important. **Low-speed** synchronous motors, under 600 r/min, sometimes called **engine** type, are used in driving **reciprocating compressors** and in **ball mills** and in other slow-speed applications. Their low length-to-diameter ratio, because of the need for many poles, gives them a high moment of inertia which is helpful in smoothing the **pulsating torques** of these loads.

If the motor **field current** is separately supported by a **battery** or **constant voltage transformer,** the synchronous motor will maintain speed on a lower voltage dip than will an induction motor because torque is proportional to voltage rather than voltage squared. However, if a synchronous motor drops **out of step,** it will normally not have the ability to reaccelerate the load, unless the driven equipment is automatically unloaded.

The synchronous motor is usually not used in smaller sizes since both the motors and its controls are more expensive than induction motors, and the ability of a small motor to supply VARs to correct power factor is limited.

If situated near an inductive load the motor may be overexcited, and its leading current will neutralize entirely or in part the lagging quadrature current of the load. This reduces the I^2R loss in the transmission

SOURCE: Westinghouse Electric Corp.

lines and also increases the kilowatt ratings of the system apparatus. The **synchronous condenser and motor** can also be used to control voltage and to stabilize power lines. If the condenser or motor is overexcited, its leading current flowing through the line reactance causes a rise in voltage at the motor; if it is underexcited, the lagging current flowing through the line reactance causes a drop in voltage at the motor. Thus within limits it becomes possible to control the voltage at the end of a transmission line by regulating the fields of synchronous condensers or motors. Long 220-kV lines and the 287-kV Hoover Dam–Los Angeles line require several thousand kVa in synchronous condensers floating at their load ends merely for voltage control. If the load becomes small, the voltage would rise to very high values if the synchronous condensers were not underexcited, thus maintaining nearly constant voltage. See Table 15.1.14 for characteristics.

A **salient-pole synchronous motor** may be started as an induction motor. In **laminated-pole** machines conducting bars of copper, copper alloy, or aluminum, **damper** or **amortisseur windings** are inserted in the pole face and short-circuited at the ends, exactly as a squirrel-cage winding in the induction motor is connected. The bars can be designed only for starting purposes since they carry no current at synchronous speed and have no effect on efficiency. In solid-pole motors a block of steel is bolted to the pole and performs the current-carrying function of the damper winding in the laminated-pole motor. At times the pole faces are interconnected to minimize starting-pulsating torques. When the synchronous motor reaches 95 to 98 percent speed as an induction motor, the motor field is applied by a **timer** or **slip frequency** control circuit, and the motor pulls into step at 100 percent speed. While accelerating, the motor field is connected to resistances to minimize induced voltages and currents.

Two-pole motors are built as **turbine** type or **round-rotor motors** for mechanical strength and do not have the thermal capacity or space for starting windings, so they must be started by supplementary means.

One such supplementary starting means is the use of a variable-frequency source, either a **variable-speed generator** or more commonly a static **converter-inverter.** The motor is brought up to speed in synchronism with a slowly increasing frequency. One common application is the starting of the large motor-generators used in **pump-storage** utility systems.

Variable frequency may be used to start salient-pole machines also. Requirements for a start without high torques and pulsations or high voltage drops on small electrical systems may dictate the use of something other than full voltage starting.

The **synchronous reluctance motor** is similar to an induction machine with salient poles machined in the rotors. Under light loads the motor will synchronize on reluctance torque and lock in step with the rotating field at synchronous speed. These motors are used in small sizes with variable-frequency inverters for speed control in the paper and textile industry.

The **synchronous-induction motor** is fundamentally a wound-rotor slip-ring induction motor with an air gap greater than normal, and the rotor slots are larger and fewer. On starting, resistance is inserted in the rotor circuit to produce high torque, and this is cut out as the speed increases. As synchronism is approached, the rotor windings are connected to a dc power source and the motor operates synchronously.

Timing or **clock motors** operate synchronously from ac power systems. Figure 15.1.74*a* illustrates the Warren Telechron motor which operates on the hysteresis principle. The stator consists of a laminated element with an exciting coil, and each pole piece is divided, a short-circuited shading turn being placed on each of the half poles so formed. The rotor consists of two or more hard-steel disks of the shape shown, mounted on a small shaft. The shaded poles produce a 3,600 r/min rotating magnetic field (at 60 Hz), and because of hysteresis loss, the disk follows the field just as the rotor of an induction motor does. When the rotor approaches the synchronous speed of 3,600 r/min, the rotating magnetic field takes a path along the two rotor bars and locks the rotor in with it. The rotor and the necessary train of reducing gears rotate in oil sealed in a small metal can. Figure 15.1.74*b* shows a subsynchronous motor. Six squirrel-cage bars are inserted in six slots of a solid cylindrical iron rotor, and the spaces between the slots form six salient poles. The motor, because of the squirrel cage, starts as an induction motor, attempting to attain

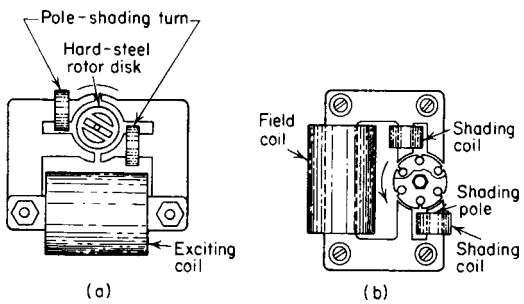

Fig. 15.1.74 Synchronous motors for timing. (*a*) Warren Telechron motor; (*b*) Holtz induction-reluctance subsynchronous motor.

Table 15.1.15 Relationships for AC-DC Conversion Static Devices

Device description	Voltages, %		Currents, %		Ripple, %
	E_{ac}	E_{dc}	I_{ac}	I_{dc}	
1ϕ, half wave	100	45	100	100	121
1ϕ, full wave	100	90	100	90	48
3ϕ, full wave	100	135	100	123	4.2

the speed of the rotating field, or 3,600 r/min (at 60 Hz). However, when the rotor reaches 1,200 r/min, one-third synchronous speed, the salient poles of the rotor lock in with the poles of the stator and hold the rotor at 1,200 r/min.

AC-DC CONVERSION

Static Rectifiers Silicon devices, having replaced gas tubes, are the primary means of ac to dc or dc to ac conversion in modern installations. They are advantageous when compared to synchronous converters or motor generators because of efficiency, cost, size, weight, and reliability. Various bridge configurations for single-phase and three-phase applications are shown in Fig. 15.1.75*a*. Table 15.1.15 shows the relative outputs of rectifier circuits. The use of two three-phase bridges fed from an ac source consisting of a three-winding transformer with both a Δ and Y secondary winding so that output voltages are 30° out of phase will reduce dc ripple to approximately 1 percent.

The use of **silicon-controlled rectifiers** (SCRs) to replace rectifiers in the various bridge configurations allows the output voltages to be varied from rated output voltage to zero. The output voltage wave will not be a sine wave but a series of square waves, which may not be suitable for some applications. Dc to ac conversions are shown in Fig. 15.1.75*b*.

A new technology of ac-to-dc conversion commonly called *switch mode power supplies* (SMPSs) is found in almost all microprocessor-based modern electronic equipment for dc supplies between 3 and 15 V. The supply voltage (120 V ac) is rectified by a single-phase full-wave bridge circuit. See Fig. 15.1.75. The output is stored in a capacitor. A switcher will then switch the dc voltage from the capacitor on and off at a high frequency, usually between 10 and 100 kHz. These high-frequency pulses are stepped down in voltage by a transformer and rectified by diodes. The diodes' output is filtered to the dc supply required. These SMPSs are small in size, have higher efficiency, and are lower in cost. They do create harmonic and power quality problems that have to be addressed.

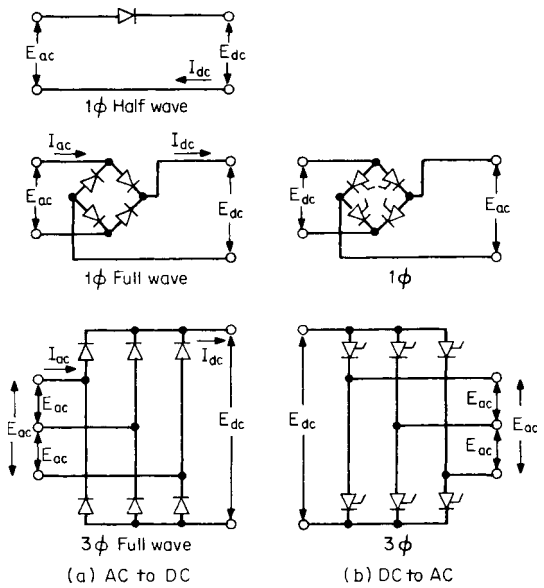

Fig. 15.1.75 AC-DC conversion with static devices.

SYNCHRONOUS CONVERTERS

The synchronous converter is essentially a dc generator with slip rings connected by taps to equidistant points in the armature winding. Alternating current may also be taken from and delivered to the armature. The machine may be single-phase, in which case there are two slip rings and two slip-ring taps per pair of poles; it may be three-phase, in which case there are three slip rings and three slip-ring taps per pair of poles, etc. Converters are usually used to convert alternating to direct current, in which case they are said to be operating **direct;** they may equally well convert direct to alternating current, in which case they are said to be operating **inverted.** A converter will operate satisfactorily as a dc motor, a synchronous motor, a dc generator, a synchronous generator, or it may deliver direct and alternating current simultaneously, when it is called a **double-current generator.**

The rating of a converter increases very rapidly with increase in the number of phases owing, in part, to better utilization of the armature copper and also because of more uniform distribution of armature heating.

Because of the materially increased rating, converters are nearly all operated six-phase. The rating decreases rapidly with decrease in power factor, and hence the converter should operate near unity power factor. The diametrical ac voltage is the ac voltage between two slip-ring taps 180 electrical degrees apart. With a two-pole closed winding, i.e., a winding that closes on itself when the winding is completed, the diametrical ac voltage is the voltage between any two slip-ring taps diametrically opposite each other.

With a sine-voltage wave, the dc voltage is the peak of the diametrical ac voltage wave. The voltage relations for sine waves are as follows: dc volts, 141; single phase, diametrical, 100; three-phase, 87; four-phase, diametrical, 100; four phase, adjacent taps, 71; six phase, diametrical, 100; six phase, adjacent taps, 50. These relations are obtained from the sides of polygons inscribed in a circle having a diameter of 100 V, as shown in Fig. 15.1.76.

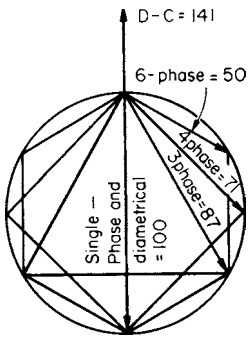

Fig. 15.1.76 EMF relations in a converter.

Selsyns The word **selsyn** is an abbreviation of self-synchronizing and is applied to devices which are connected electrically, and in which an angular displacement of the rotating member of one device produces an equal angular displacement in the rotating member of the second device. There are several types of selsyns and they may be dc or ac, single-phase or polyphase. A simple and common type is shown in Fig. 15.1.77. The two stators S_1, S_2 are phase-wound stators, identical electrically with synchronous-generator or induction-motor stators. For simplicity Gramme-ring windings are shown in Fig. 15.1.77. The two stators are connected three-phase and in parallel. There are

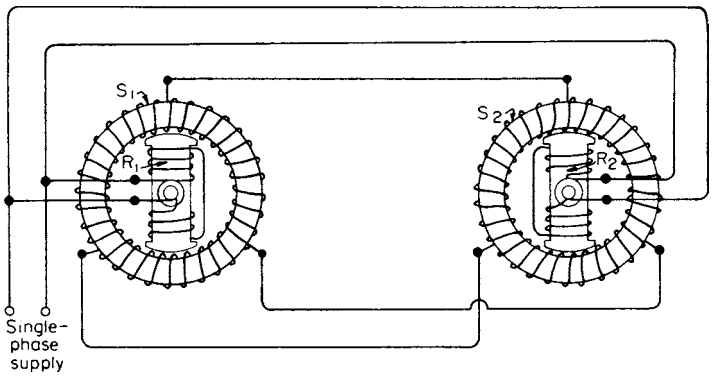

Fig. 15.1.77 Selsyn system.

also two bobbin-type rotors R_1, R_2, with single-phase windings, each connected to a single-phase supply such as 115 V, 60 Hz. When R_1 and R_2 are in the same angular positions, the emfs induced in the two stators by the ac flux of the rotors are equal and opposite, there are no interchange currents between stators, and the system is in equilibrium. However, if the angular displacement of R_1, for example, is changed, the magnitudes of the emfs induced in the stator winding of S_1 are correspondingly changed. The emfs of the two stators then become unbalanced, currents flow from S_1 to S_2, producing torque on R_2. When R_2 attains the same angular position as R_1, the emfs in the two rotors again become equal and opposite, and the system is again in equilibrium.

If there is torque load on either rotor, a resultant current is necessary to sustain the torque, so that there must be an angular displacement between rotors. However, by the use of an auxiliary selsyn a current may be fed into the system which is proportional to the angular difference of the two rotors. This current will continue until the error is corrected. This is called **feedback.** There may be a master selsyn, controlling several secondary units.

Selsyns are used for position indicators, e.g., in bridge–engine-room signal systems. They are also widely used for fire control so that from any desired position all the turrets and guns on battleships can be turned and elevated simultaneously through any desired angle with a high degree of accuracy. The selsyn itself rarely has sufficient power to perform these operations, but it actuates control through power multipliers such as amplidynes.

RATING OF ELECTRICAL MOTORS

Application of Electrical Motors

In addition to motor Design and Code classifications, motors are assigned other classifications to meet specific industry standards and practices such as the **temperature rating** of the motor at which the materials in the machine can be operated for long periods of time without deterioration.

Standard ANSI/IEEE 100-2001 defines seven different **classes** (Class 90, 105, 130, 155, 180, 220, and Class over 220) for **insulating materials** based on a not-to-exceed temperature rating in degrees Celsius. For example, Class 155 insulation includes materials or combinations of materials such as silicone elastomer, mica, glass fiber, and asbestos, with bonding substances suitable for continuous operation at 155°C. Temperature class information would normally be used by wire, motor, or electrical apparatus designers in selecting insulating materials.

A system of motor **insulation classes** is used to establish maximum temperature rise in the motor winding (determined by winding resistance) based on a 40°C ambient, 3,300 ft (1006 m) elevation. In practice the motor manufacturer specifies the ambient temperature and insulation class. The temperature rise shall not exceed the limit for the insulation system when the motor is loaded to its rating or to its service factor load. Temperature rise by insulation class for single and polyphase motors is as follows:

	Class of motor insulation system			
Motor type	A	B	F	H
Integral horsepower				
All motors with 1.15 service factor or higher	70°C	90°C	115°C	—
Totally enclosed fan-cooled motors (TEFC)	60°C	80°C	105°C	125°C
Totally enclosed nonventilated motors (TENV)	65°C	85°C	110°C	135°C
Motors with encapsulated windings, 1.0 service factor	65°C	85°C	110°C	—
All other motors	60°C	80°C	105°C	125°C
Fractional horsepower				
All motors with 1.15 service factor or higher	70°C	90°C	115°C	—
Totally enclosed motors (TEFC and TENV)	65°C	85°C	110°C	135°C
Any motor in frame size smaller than 42 frame	65°C	85°C	110°C	135°C
All other motors	60°C	80°C	105°C	125°C

NOTE: Manufacturers may offer insulation systems that exceed the above classes to provide additional measures of protection—for example, corona-resistant magnet wire for use in PWM ac drive applications.
SOURCE: Table 5-20, *Standard Handbook for Electrical Engineers,* McGraw-Hill.

General-purpose fractional horsepower and integral-horsepower motors are assigned a **service factor,** which allows the motor to be operated above its rated horsepower, when operated at its rated voltage and frequency, without damaging its insulation system. The normal service factors range from 1.40 to 1.25 for fractional to 1-hp motors, 1.15 for motors greater than 1 to 200 hp, and 1.0 for motors from 250 to 500 hp.

The starting kVA of a squirrel-cage motor is indicated by a **locked-rotor indicating code letter** (A to V) included on the motor nameplate (see Table 15.1.16). For additional information refer to NEMA Standard MG-1 or NEC®-2005 Table 430.7(B) for values and application. The locked-rotor current is used for selecting the size of the motor disconnecting means and motor controller (starter).

Required information on the **motor nameplate** includes manufacturer, rated volts, full-load amperes, rated frequency, number of phases if an ac motor, rated full-load speed for each speed, rated temperature rise for the insulation class (A, B, F, or H) at rated ambient temperature, time

Table 15.1.16 Maximum Rating or Setting of Motor Branch-Circuit Protective Devices and Starting-Inrush Code Letters

Type of motor	Percent of full-load current				Code letter	kVA/hp with locked rotor*
	Non-time delay fuse	Dual-element (time delay) fuse	Instantaneous breaker	Inverse time breaker

					K	8.0–8.99
					L	9.0–9.99
					M	10.0–11.19
					N	11.2–12.49
					P	12.5–13.99
					R	14.0–15.99
					S	16.0–17.99
					T	18.0–19.99
					U	20.0–22.39
					V	22.4 and up

* This is a general conversion. Refer to NEC® 2005, Tables 430-251(A) and (B) for conversion tables of single and polyphase motor locked-rotor currents for selection of disconnecting means and controllers as determined by motor horsepower and voltage rating.

SOURCE: NEC 1993, Tables 430-152 and 430-7(*b*). Reprinted with permission from NFPA 70-1993, National Electrical Code®, Copyright © 1992, National Fire Protection Association, Quincy, Massachusetts 02269. This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.

rating (5, 15, 30, 60 minutes, or continuous), rated horsepower for each speed, locked-rotor amperes of code letter (A to V), design letter (B, C, D, or E). Other required information includes identification of secondary volts for wound-rotor motors, field voltage and current for dc-excited synchronous motors, winding type if a dc motor, and whether motor is thermally or impedance protected. Motors are required to be marked with any certifying agency approvals (listing) for hazardous (classified) area use. Large or special motors may also include nominal efficiency, power factor, or other information such as marine or inverter duty, as specified by the manufacturer.

The **motor branch-circuit protection device** provides both short-circuit and ground-fault protection. Once motor hp is known, the approximate motor full load current can be determined from Table 15.1.17 and the maximum setting of motor branch-circuit protection device (fuses, circuit breakers) can be selected using Table 15.1.16. The motor branch-circuit protective device must be capable of carrying the motor locked-rotor current. Where the selected value of the branch-circuit protection device does not correspond to the size of a standard and fuse or nonadjustable circuit breaker, the next standard size (ampere rating) may be used.

Running overload protection is required for each motor unless the motor is impedance protected or provided with an integral thermal protector. A separate overload device is required that is responsive to motor current and selected on the basis of motor nameplate full-load current to trip at no more than 125 percent of the motor nameplate full-load rating for motors with a service factor of 1.15 or greater and motors with a marked temperature rise of 40°C. All other motors are set at 115 percent. Overload devices include electronic current-sensing relays, thermal and eutectic electromechanical relays, and, for motors larger than 1,500 hp, embedded temperature detectors. Thermal and electronic overload relays are supplied with either a fixed or adjustable class of trip curves responsive to motor current. The standard overload trip class is Class 20 and is suitable for most applications of Design B motors. Trip Class 10 is used for quick-trip applications and Class 30 for slow-trip applications.

Motor circuit conductors for a single motor in a continuous duty application are required to have an ampacity of not less than 125 percent of the motor full-load current as determined by Table 15.1.17. Conductors supplying several motors and other loads are sized at 125 percent of the largest load plus the full-load current of other motors, plus ampacity of other loads.

Efficiency of Electrical Motors

Methods of determining efficiency are by **direct measurement** or by **segregated losses**. Methods are outlined in Standard Test Procedure for Polyphase Induction Motors and Generators, ANSI/IEEE Std. 112-1996; Test Procedure for Single-Phase Induction Motors, ANSI/IEEE Std. 114-2001; and Test Procedures for Synchronous Machines, IEEE Std. 115-2002.

Direct measurements can be made by using calibrated **motors, generators,** or **dynamometers** for input to generators and output from motors, and precision electrical motors for input to motors and output from generators.

$$\text{Efficiencies} = \frac{\text{output}}{\text{input}} \tag{15.1.123}$$

The segregated **losses** in motors are classified as follows: (1) Stator I^2R (shunt and series field I^2R for dc); (2) rotor I^2R (armature I^2R for dc); (3) core loss; (4) stray-load loss; (5) friction and windage loss; (6) brush-contact loss (wound rotor and dc); (7) brush-friction loss (wound rotor and dc); (8) exciter loss (synchronous and dc); and (9) ventilating loss (dc). Losses are calculated separately and totaled. Measure the electrical output of the generator; then

$$\text{Efficiency} = \frac{\text{output}}{\text{output} + \text{losses}} \tag{15.1.124}$$

Measure the electrical input of the motors; then

$$\text{Efficiency} = \frac{\text{input} - \text{losses}}{\text{input}} \tag{15.1.125}$$

When testing dc motors, compensation should be made for the **harmonics** associated with rectified ac used to provide the variable dc voltage to the motors. Instrumentation should be chosen to accurately reflect the rms value of currents.

Temperature rise under full-load conditions may be measured by tests as outlined in the IEEE Standards referred to above. Methods of loading

Table 15.1.17 Approximate Full-Load Currents of Motors,* A

* The values of current are for motors running at speeds customary for belted motors and motors having normal torque characteristics. Use name-plate data for low-speed, high-torque, or multispeed motors. For synchronous motors of 0.8 pf multiply the above amperes by 1.25, at 0.9 pf by 1.1. The motor voltages listed are rated voltages. Respective nominal system voltages would be 220 to 240, 440 to 480, and 550 to 600 V. For full-load currents of 208-V motors, multiply the 230-V amperes by 1.10; for 200-V motors, multiply by 1.15.
† Ampere values are for motors running at base speed.
‡ Rated voltage. Nominal system voltages are 120 and 240.

are: (1) Load motor with **dynamometer** or **generator** of similar capacity and run until temperatures stabilize; (2) load generator with **motor-generator** set or **plant** load and run until temperature stabilizes; (3) alternately apply **dual frequencies** to motor until it reaches rated temperature; (4) synchronous motor may be operated as synchronous **condenser** at no load with **zero power factor** at rated current, voltage, and frequency until temperatures stabilize.

Industrial Applications of Motors

Alternating or Direct Current The induction motor, particularly the squirrel-cage type, is preferable to the dc motor for constant-speed work, for the initial cost is less and the absence of a commutator reduces maintenance. Also there is less fire hazard in many industries, such as sawmills, flour mills, textile mills, and powder mills. The use of the induction motor in such places as cement mills is advantageous since with dc motors the grit makes the maintenance of commutators difficult.

For variable-speed work like cranes, hoists, elevators, and for adjustable speeds, the dc motor characteristics are superior to induction-motor characteristics. Even then, it may be desirable to use induction motors since their less desirable characteristics are more than balanced by their simplicity and the fact that ac power is available, and to obtain dc power conversion apparatus is usually necessary. Where both lights and motors are to be supplied from the same ac system, the 208/120-V four-wire three-phase system is now in common use. This gives 208 V three-phase for the motors, and 120 V to neutral for the lights.

Full-load speed, temperature rise, efficiency, and power factor as well as breakdown torque and starting torque have long been parameters of concern in the application and purchase of motors. Another qualification is service factor.

Special enclosures, fittings, seals, ventilation systems, electromagnetic design, etc., are required when the motor is to be operated under unusual service conditions, such as exposure to (1) combustible, explosive, abrasive, or conducting dusts, (2) lint or very dirty conditions where the accumulation of dirt might impede the ventilation, (3) chemical fumes or flammable or explosive gases, (4) nuclear radiation, (5) steam, salt laden air, or oil vapor, (6) damp or very dry locations, radiant heat, vermin infestation, or atmosphere conducive to the growth of fungus, (7) abnormal shock, vibration, or external mechanical loading, (8) abnormal axial thrust or side forces on the motor shaft, (9) excessive departure from rated voltage, (10) deviation factors of the line voltage exceeding 10 percent, (11) line voltage unbalance exceeding 1 percent, (12) situations where low noise levels are required, (13) speeds higher than the highest rated speed, (14) operation in a poorly ventilated room, in a pit, or in an inclined attitude, (15) torsional impact loads, repeated abnormal overloads, reversing or electric braking, (16) operation at standstill with any winding continuously energized, and (17) operation with extremely low structureborne and airborne noise. For dc machines, a further unusual service condition occurs when the average load is less than 50 percent over a 24-h period or the continuous load is less than 50 percent over a 4-h period.

The standard direction of rotation for all nonreversing dc motors, ac single-phase motors, synchronous motors, and universal motors is counterclockwise when facing the end of the machine opposite the drive end. For dc and ac generators, the rotation is clockwise.

Further information may be found in Publication No. MG-1 of the National Electrical Manufacturers Association.

In applying motors the temperature rating of the branch-circuit wiring conductors must be sufficient to meet the operating environment inside the motor terminal box to prevent possible failure of the insulation inside the motor terminal box.

ELECTRIC DRIVES

Cranes and Hoists The dc series motor is best adapted to cranes and hoists. When the load is heavy the motor slows down automatically and develops increased torque thus reducing the peaks on the electrical

system. With light loads, the speed increases rapidly, thus giving a lively crane. The series motor is also well adapted to moving the bridge itself and also the trolley along the bridge. Where alternating current only is available and it is not economical to convert it, the slip-ring type of induction motor, with external-resistance speed control, is the best type of ac motor. Squirrel-cage motors with high resistance end rings to give high starting torque (design D) are used (design D motors; also see Ilgner system).

Constant-Torque Applications **Piston pumps, mills, extruders,** and **agitators** may require constant torque over their complete speed range. They may require high starting torque design C or D squirrel-cage motors to bring them up to speed. Where speed is to be varied while running, a variable armature voltage **dc motor** or a **variable-frequency** squirrel-cage induction-motor drive system may be used.

Centrifugal Pumps Low WK^2 and low starting torques make design B general-purpose squirrel-cage motors the preference for this application. When **variable flow** is required, the use of a **variable-frequency** power supply to vary motor speed will be energy efficient when compared to changing flow by **control-valve** closure to increase head.

Centrifugal Fans High WK^2 may require high starting torque design C or D squirrel-cage motors to bring the fan up to speed in a reasonable period of time. When **variable flow** is required, the use of a **variable-frequency** power supply or a multispeed motor to vary fan speed will be energy efficient when compared to closing **louvers.** For large fans, **synchronous-motor** drives may be considered for high efficiency and improved power factor.

Axial or Centrifugal Compressors For smaller compressors, say, up to 100 hp, the squirrel-cage induction motor is the drive of choice. When the WK^2 is high, a design C or D high-torque motor may be required. For larger compressors, the synchronous motor is more efficient and improves power factor. Where **variable flow** is required, the **variable-frequency** power supply to vary motor speed is more efficient than controlling by **valve** and in some applications may eliminate a **gearbox** by allowing the motor to run at compressor operating speed.

Pulsating-Torque Applications **Reciprocating compressors, rock crushers,** and **hammer mills** experience widely varying torque pulsations during each revolution. They usually have a **flywheel** to store energy, so a high-torque, high-slip design D motor will accelerate the high WK^2 rapidly and allow energy recovery from the flywheel when high torque is demanded. On larger drives a slow-speed, engine-type synchronous motor can be directly connected. The motor itself supplies significant WK^2 to smooth out the torque and current pulsations of the system.

SWITCHBOARDS

Switchboards may, in general, be divided into four classes: direct-control panel type; remote mechanical-control panel type; direct-control truck type; electrically operated. With **direct-control panel-type boards** the switches, rheostats, bus bars, meters, and other apparatus are mounted on or near the board and the switches and rheostats are operated directly, or by operating handles if they are mounted in back of the board. The voltages, for both direct current and alternating current, are usually limited to 600 V and less but may operate up to 2,500 V ac if oil circuit breakers are used. Such panels are not recommended for capacities greater than 3,000 kVA. **Remote mechanical-control panel-type boards** are ac switchboards with the bus bars and connections removed from the panels and mounted separately away from the load. The oil circuit breakers are operated by levers and rods. This type of board is designed for heavier duty than the direct-control type and is used up to 25,000 kVA. **Direct-control truck-type switchboards** for 15,000 V or less consist of equipment enclosed in steel compartments completely assembled by the manufacturers. The high-voltage parts are enclosed, and the equipment is interlocked to prevent mistakes in operation. This equipment is designed for low- and medium-capacity plants and auxiliary power in large generating stations. **Electrically operated switchboards** employ solenoid or motor-operated circuit breakers, rheostats, etc., controlled by small switches mounted on the panels. This makes it possible to locate the high-voltage and other equipment independently of the location of switchboard.

In all large stations the switching equipment and buses are always mounted entirely either in separate buildings or in outdoor enclosures. Such equipment is termed **bus structures** and is electrically operated from the main control board.

Switchboards should be erected at least 3 to 4 ft from the wall. Switchboard frames and structures should be grounded. The only exceptions are effectively insulated frames of single-polarity dc switchboards. For low-potential work, the conductors on the rear of the switchboard are usually made up of flat copper strip, known as **bus-bar** copper. The size required is based upon a current density of about 1,000 A/in^2. Figure 15.1.78 gives the approximate continuous dc carrying capacity of copper bus bars for different arrangements and spacings for 35°C temperature rise.

Switchboards must be individually adapted for each specific electrical system. Space permits the showing of the diagrams of only three boards each for a typical electrical system (Fig. 15.1.79). Aluminum bus bars are also frequently used.

Equipment of Standard Panels Following are enumerated the various parts required in the equipment of standard panels for varying services:

Generator or synchronous-converter panel, dc two-wire system: 1 circuit breaker; 1 ammeter; 1 handwheel for rheostat; 1 voltmeter; 1 main switch (three-pole single throw or double throw) or 2 single-pole switches.

Generator or synchronous-converter panel, dc three-wire system: 2 circuit breakers; 2 ammeters; 2 handwheels for field rheostats; 2 field switches; 2 potential receptacles for use with voltmeter; 3 switches; 1 four-point starting switch.

Generator or synchronous-motor panel, three-phase three-wire system: 3 ammeters; 1 three-phase wattmeter; 1 voltmeter; 1 field ammeter; 1 double-pole field switch; 1 handwheel for field rheostats; 1 synchronizing receptacle (four-point); 1 potential receptacle (eight-point); 1 field

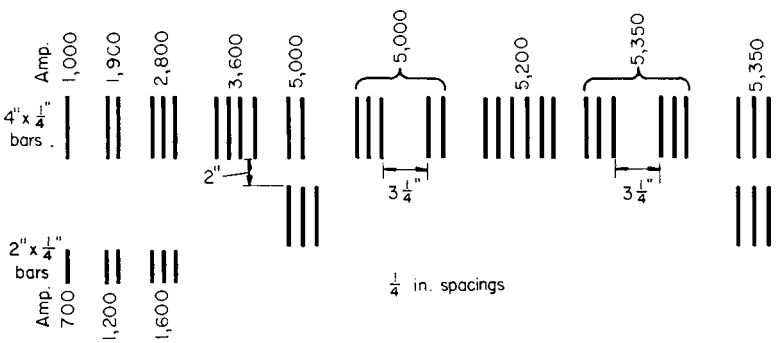

Fig. 15.1.78 Current-carrying capacity of copper bus bars.

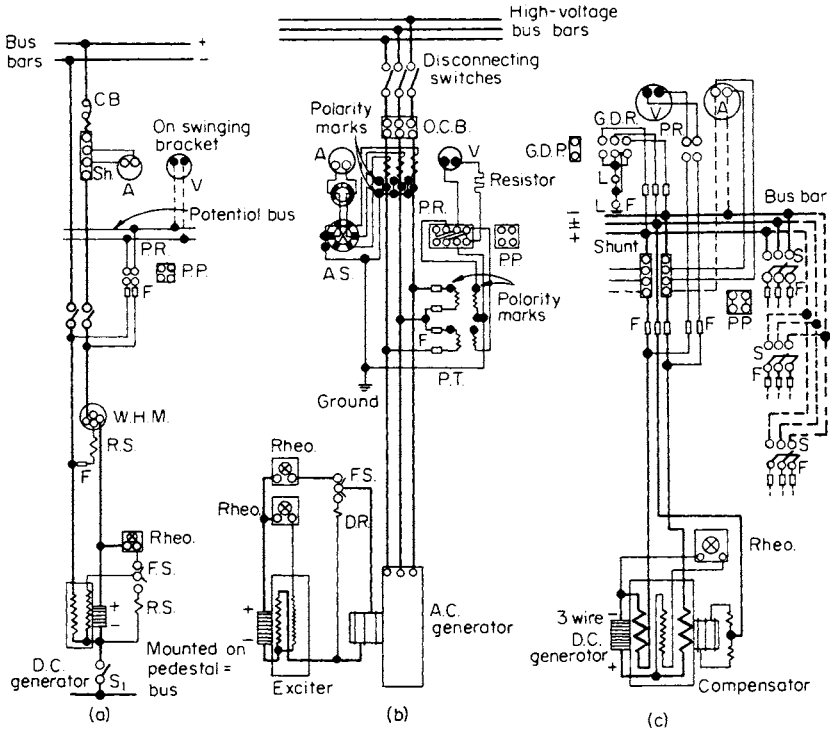

Fig. 15.1.79 Switchboard wiring diagrams for generators. (*a*) 125-V or 250-V dc generator; (*b*) three-phase, synchronous generator and exciter for a small or isolated plant; (*c*) three-wire dc generator for a small or isolated plant. A, ammeter; AS, three-way ammeter switch; CB, circuit breaker, CT, current transformer; DR, ground detector receptacle; L, ground detector lamp; OC, overload coil; OCB, oil circuit breaker; PP, potential ring; PR, potential receptacle; PT, potential transformer; Rheo, rheostat; RS, resistor; S, switch; Sh, shunt; V, voltmeter; WHM, watthour meter.

rheostat; 1 triple-pole oil switch; 1 power-factor indicator; 1 synchronizer; 2 series transformers; 1 governor control switch.

Synchronous-converter panel, three-phase: 1 ammeter; 1 power-factor indicator; 1 synchronizing receptacle; 1 triple-pole oil circuit breaker; 2 current transformers; 1 potential transformer; 1 watthour meter (polyphase); 1 governor control switch.

Induction motor panel, three-phase: 1 ammeter; series transformers; 1 oil switch.

Feeder panel, dc, two-wire and three-wire: 1 single-pole circuit breaker; 1 ammeter; 2 single-pole main switches; potential receptacles (1 four-point for two-wire panel; 1 four-point and 1 eight-point for three-wire panel).

Feeder panel, three-wire, three-phase and single-phase: 3 ammeters; 1 automatic oil switch (three-pole for three-phase, two-pole for single-phase); 2 series transformers; 1 shunt transformer; 1 wattmeter; 1 voltmeter; 1 watthour meter; 1 handwheel for control of potential regulator.

Exciter panel (for 1 or 2 exciters): 1 ammeter (2 for 2 exciters); 1 field rheostat (2 for 2 exciters); 1 four-point receptacle (2 for 2 exciters); 1 equalizing rheostat for regulator.

Switches The current-carrying parts of switches are usually designed for a current density of 1,000 A/in^2. At contact surfaces, the current density should be kept down to about 50 A/in^2.

Circuit Breakers Switches equipped with a tripping device constitutes an elementary load interrupter switch. The difference between a load interrupter switch and a circuit breaker lies in the interrupting capacity. A circuit breaker must open the circuit successfully under short circuit conditions when the current through the contacts may be several orders of magnitude greater than the rated current. As the circuit is being opened, the device must withstand the accompanying mechanical forces and the heat of the ensuing arc until the current is permanently reduced to zero.

The opening of a metallic circuit while carrying electric current causes an electric arc to form between the parting contacts. If the action takes place in air, the air is ionized (a plasma is formed) by the passage of current. When ionized, air becomes an electric conductor. The space between the parting contacts thus has relatively low voltage drop and the region close to the surface of the contacts has relatively high voltage drop. The thermal input to the contact surfaces (VI) is therefore relatively large and can be highly destructive. A major aim in circuit breaker design is to quench the arc rapidly enough to keep the contacts in a reusable state. This is done in several ways: (1) lengthening the arc mechanically, (2) lengthening the arc magnetically by driving the current-carrying plasma sideways with a magnetic field, (3) placing barriers in the arc path to cool the plasma and increase its length, (4) displacing and cooling the plasma by means of a jet of compressed air or inert gas, and (5) separating the contacts in a vacuum chamber.

By a combination of shunt and series coils the circuit breaker can be made to trip when the energy reverses. Circuit breakers may trip unnecessarily when the difficulty has been immediately cleared by a local breaker or fuse. In order that service shall not be thus interrupted unnecessarily, **automatically reclosing breakers** are used. After tripping, an automatic mechanism operates to reclose the breaker. If the short circuit still exists, the breaker cannot reclose. The breaker attempts to reclose two or three times and then if the short circuit still exists it remains permanently locked out.

Metal-clad switch gears are highly developed pieces of equipment that combine buses, circuit breakers, disconnecting devices, controlling devices, current and potential transformers, instruments, meters, and interlocking devices, all assembled at the factory as a single unit in a compact steel enclosing structure. Such equipment may comprise truck-type circuit breakers, assembled as a unit, each housed in a separate steel compartment and mounted on a small truck to facilitate removal for inspection

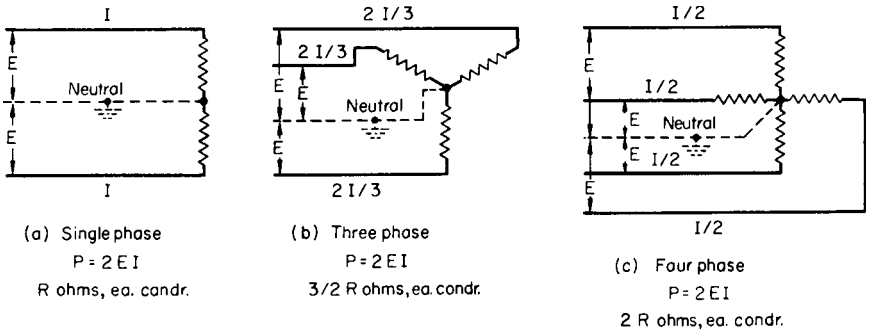

Fig. 15.1.80 Three equivalent symmetrical transmission, or distribution, systems. (*a*) Single-phase; (*b*) three-phase; (*c*) four-phase.

and servicing. The equipment is interlocked to prevent mistakes in operation and in the removal of the unit; the removal of the unit breaks all electrical connections by suitable disconnecting switches in the rear of the compartment, and all metal parts are grounded. This design provides compactness, simplicity, ease of inspection, and safety to the operator.

High-voltage circuit breakers can be oil type, in which the contacts open under **oil, air-blast** type, in which the arc is extinguished by a powerful blast of air directed through an orifice across the arc and into an arc chute, H_2S type, or vacuum contact type. The tripping of high-voltage circuit breakers is initiated by an abnormal current acting through the secondary of a current transformer on an inverse-time relay in which the time of closing the relay contacts is an inverse time function of the current; i.e., the greater the current the shorter the time of closing. The breaker is tripped by a dc tripping coil, the dc circuit being closed by the relay contacts. Modern circuit breakers should open the circuit within 3 cycles from the time of the closing of the relay contacts.

Vacuum circuit breakers have received wide acceptance in all fields in recent years, both for indoor work and for outdoor applications. Indoor breakers are available up to 40 kV and interrupting capacities up to 2.5 GVA. Outdoor breakers are available in ratings up to that of the EHV (extra-high voltage 765-kV three-pole breaker capable of interrupting 55 GVA, or 40,000-A symmetrical current. Its operating rating is 3,000 A, 765 kV. The arc is extinguished in a vacuum. Switching stations, gas-insulated and operating at 550 kV, are also in use.

POWER TRANSMISSION

Power for long-distance transmission is usually generated at 6,600, 13,200, and 18,000 V and is stepped up to the transmission voltage by Δ-Y-connected transformers. The transmission voltage is roughly 1,000 V/mi. Preferred or standard transmission voltages are 22, 33, 44, 66, 110, 132, 154, 220, 287, 330, 500, and 765 kV. High-voltage lines across country are located on private rights of way. When they reach urban areas, the power must be carried underground to the substations which must be located near the load centers in the thickly settled districts. In many cases it is possible to go directly to underground cables since these are now practicable up to 345 kV between three-phase line conductors (200 kV to ground). High-voltage cables are expensive in both first cost and maintenance, and it may be more economical to step down the voltage before transmitting the power by underground cables. Within a city, alternating current may be distributed from a substation at 13,200, 6,600, or 2,300 V, being stepped down to 600, 480, and 240 V, three-phase for power and 240 to 120 V single-phase three-wire for lights, by transformers at the consumers' premises. **Direct current** at 1,200 or 600 V for railways, 230 to 115 V for lighting and power, is supplied by motor-generator sets, synchronous converters, and rectifiers. **Constant current** for series street-lighting systems is obtained through constant-current transformers.

Transmission Systems

Power is almost always transmitted three-phase. The following fundamental relations apply to any transmission system. The weight of conductor required to transmit power by any given system with a given percentage power loss varies directly with the power, directly as the square of the distance, and inversely as the square of the voltage. The cross-sectional area of the conductors with a given percentage power loss varies directly with the power, directly with the distance, and inversely as the square of the voltage.

For two systems of the same length transmitting the same power at different voltages and with the same power loss for both systems, the cross-sectional area and weight of the conductors will vary inversely as the square of the voltages. The foregoing relations between the cross section or weight of the conductor and transmission distance and voltage hold for all systems, whether dc, single-phase, three-phase, or four-phase. With the power, distance, and power loss fixed, all symmetrical systems having equal voltages to neutral require equal weights of conductor. Thus, the three symmetrical systems shown in Fig. 15.1.80 all deliver the same power, have the same power loss and equal voltages to neutral, and the transmission distances are all assumed to be equal. They all require the same weight of conductor since the weights are inversely proportional to all resistances. (No actual neutral conductor is used.) The respective power losses are (1) $2I^2R$ W; (2) $3(2I/3)^2(3R/2) = 2I^2R$ W; (3) $4(I/2)^2(2R) = 2I^2R$ W, which are all equal.

Size of Transmission Conductor Kelvin's law states, "The most economical area of conductor is that for which the annual cost of energy wasted is equal to the interest on that portion of the capital outlay which can be considered proportional to the weight of copper used." In Fig. 15.1.81 are shown the annual interest cost, the annual cost of I^2R loss, and the total cost as functions of circular mils cross section for both typical overhead conductors and three-conductor cables. Note that the total-cost curves have very flat minimums, and usually other

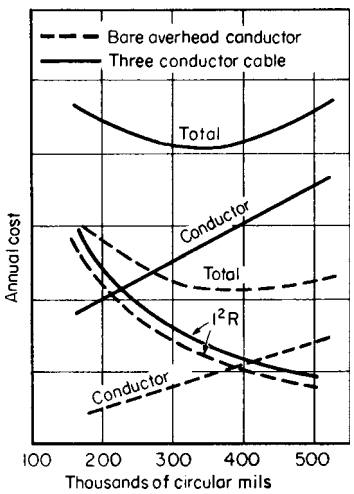

Fig. 15.1.81 Most economical sizes of overhead and underground conductors.

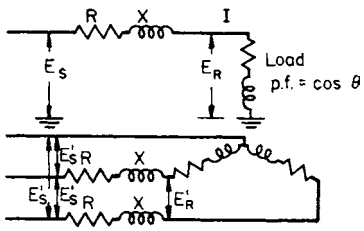

Fig. 15.1.82 Three-phase power system.

factors such as the character of the load and the voltage regulation, are taken into consideration.

In addition to resistance, overhead power lines have inductive reactance to alternating currents. The inductive reactance

$$X = 2\pi f\{80 + 741.1 \log [(D - r)/r]\}10^{-6} \quad \Omega/\text{conductor mile} \quad (15.1.126)$$

where f = frequency, D = distance between centers of conductors (in), and r their radius (in). Table 15.1.18 gives the inductive reactance per mile at 60 Hz and the resistance of stranded and solid copper conductor. (See Table 15.1.22.)

Any **symmetrical system** having n conductors can be divided into n equal single-phase systems, each consisting of one wire and a return circuit of zero impedance and each having as its voltage the system voltage to neutral.

Figure 15.1.82 shows a symmetrical three-phase system, with one phase detached. The load or received voltage between line conductors is E'_R so that the receiver voltage to *neutral* is $E_R = E'_R/\sqrt{3}$ V. The current is IA, the load power factor is cos θ, and the line resistance and reactance are R and X Ω per wire, and the sending-end voltage is E_S. The phasor diagram is shown in Fig. 15.1.83 (compare with Fig. 15.1.63). Its solution is

$$E_S = \sqrt{(E_R \cos\theta + IR)^2 + (E_R \sin\theta + IX)^2} \quad (15.1.127)$$

[see Eq. (15.1.101)].

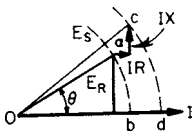

Fig. 15.1.83 Phasor diagram for a power line.

Figure 15.1.84 (Mershon diagram) shows the right-hand portion of Fig. 15.1.83 plotted to large scale, the arc 00 corresponding to the arc *ab* (Fig. 15.1.83). The abscissa 0 (Fig. 15.1.84) corresponds to point *b* (Fig. 15.1.83) and is the load voltage E_R taken as 100 percent. The concentric circular arcs 0–40 are given in percentage of E_R. To find the sending-end voltage E_S for any power factor cos θ, compute first the resistance drop IR and the reactance drop IX in percentage of E_R. Then follow the ordinate corresponding to the load power factor to the inner arc 00 (*a*, Fig. 15.1.83). Lay off the percentage IR drop horizontally to the right, and the percentage IX drop vertically upward. The arc at which the IX drop terminates (*c*, Fig. 15.1.83) when added to 100 percent gives the sending-end voltage E_S in percent of the load voltage E_R.

EXAMPLE. Let it be desired to transmit 20,000 kW three-phase 80 percent power factor lagging current, a distance of 60 mi. The voltage at the receiving end is 66,000 V, 60 Hz and the line loss must not exceed 10 percent of the power delivered. The conductor spacing must be 7 ft (84 in). Determine the sending-end voltage and the actual efficiency. $I = 20{,}000{,}000/(66{,}000 \times 0.80 \times \sqrt{3}) = 218.8$ A. $3 \times 218.8^2 \times R' = 0.10 \times 20{,}000{,}000$. $R' = 13.9\,\Omega = 0.232\,\Omega$/mi. By referring to Table 13.1.18, 250,000 cir mils copper having a resistance of 0.2278

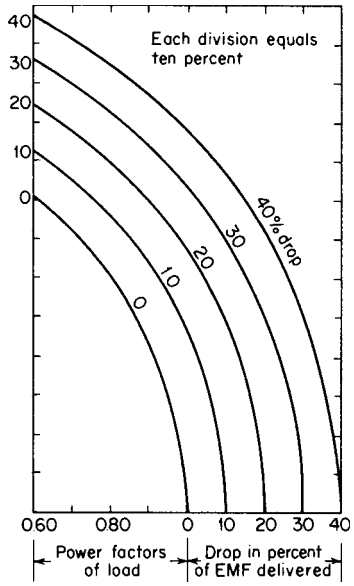

Fig. 15.1.84 Mershon diagram for determining voltage drop in power lines.

Ω/mi may be used. The total resistance $R = 60 \times 0.2278 = 13.67\,\Omega$. The reactance $X = 60 \times 0.723 = 43.38\,\Omega$. The volts to neutral at the load, $E_R = 66{,}000/\sqrt{3} = 38{,}100$ V. cos $\theta = 0.80$; sin $\theta = 0.60$. Using Eq. (15.1.127), $E_S = \{[(38{,}100 \times 0.80) + (218.8 \times 13.67)]^2 + [(38{,}100 \times 0.60) + (218.8 \times 43.38)]^2\}^{1/2} = 46{,}500$ V to neutral or $\sqrt{3} \times 46{,}500 = 80{,}500$ between lines at the sending end. The line loss is $3(218.8)^2 \times 13.67 = 1{,}963$ kW. The efficiency $\eta = 20{,}000/(20{,}000 + 1{,}963) = 0.911$, or 91.1 percent. This same line is solved by means of the Mershon diagram as follows. Let $E_R = 38{,}100$ V = 100 percent. $IR = 218.8 \times 13.67 = 2{,}991$ V = 7.85 percent. $IX = 218.8 \times 43.38 = 9{,}490$ V = 24.9 percent. Follow the 0.80 power-factor ordinate (Fig. 15.1.84) to its intersection with the arc 00; from this point go 7.85 percent horizontally to the right and then 24.9 percent vertically. (These percentages are measured on the horizontal scale.) This last distance terminates on the 22.5 percent arc. The sending-end voltage to neutral is then $1.225 \times 38{,}100 = 46{,}500$ V, so that the sending-end voltage between line conductors is $E'_s = 46{,}500\sqrt{3} = 80{,}530$ V.

In Table 15.1.18 the spacing is the distance between the centers of the two conductors of a single-phase system or the distance between the centers of each pair of conductors of a three-phase system if they are equally spaced. If they are not equally spaced, the geometric mean distance (*GMD*) is used, where $GMD = \sqrt[3]{D_1 D_2 D_3}$ (Fig. 15.1.85*a*). With the flat horizontal spacing shown in Fig. 15.1.85*b*, $GMD = \sqrt[3]{2D^3} = 1.26D$.

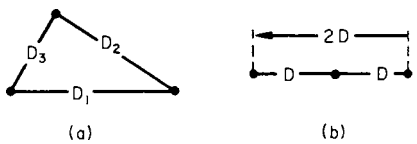

Fig. 15.1.85 Unequal spacing of three-phase conductors. (*a*) GMD = $(D_1 D_2 D_3)^{1/3}$; (*b*) flat horizontal spacing; GMD = 1.26*D*.

In addition to copper, aluminum cable steel-reinforced (ACSR), Table 15.1.19, is used for transmission conductor. For the same resistance it is lighter than copper, and with high voltages the larger diameter reduces corona loss.

Until 1966, 345 kV was the highest operating voltage in the United States. The first 500 kV system put into operation (1966) was a 350-mi

SOURCE: Aluminum Co. of America.

transmission loop of the Virginia Electric and Power Company; the longest transmission distance was 170 mi. The towers, about 94 ft high, are of corrosion-resistant steel, and the conductors are 61-strand cables of aluminum alloy, rather than the usual aluminum cable with a steel core (ACSR). The conductor diameter is 1.65 in with two "bundled" conductors per phase and 18-in spacing. The standard span is 1,600 ft, the conductor spacing is flat with 30-ft spacing between phase-conductor centers, and the minimum clearance to ground is 34 to 39 ft. To maintain a minimum clearance of 11 ft to the towers and 30 ft spacing between phases, vee insulator strings, each consisting of twenty-four 10-in disks, are used with each phase. The highest EHV system in North American is the 765-kV system in the midwest region of the United States. A dc transmission line on the west coast of the United States operating at ± 450 kV is transmitting power in bulk more than 800 miles.

High-voltage dc transmission has a greater potential for savings and a greater ability to transmit large blocks of power longer distances than has three-phase transmission. For the same crest voltage there is a saving of 50 percent in the weight of the conductor. Because of the power stability limit due to inductive and capacitive effects (inherent with ac transmission), the ability to transmit large blocks of power long distances has not kept pace with power developments, even at the present highest ac transmission voltage of 765 kV. With direct current there is no such power stability limit.

Where cables are necessary, as under water, the capacitive charging current may, with alternating current become so large that it absorbs a large proportion, if not all, of the cable-carrying capability. For example, at 132 kV, three-phase (76 kV to ground), with a 500 MCM cable, at 36 mi, the charging current at 60 Hz is equal to the entire cable capability so that no capability remains for the load current. With direct current there is no charging current, only the negligible leakage current, and there are no ac dielectric losses. Furthermore, the dc voltage at which a given cable can operate is twice the ac voltage.

The high dc transmission voltage is obtained by converting the ac power voltage to direct current by means of mercury-arc rectifiers; at the receiving end of the line the dc voltage is inverted back to a power-frequency voltage by means of mercury-arc inverters. The maximum dc transmission voltage in use in the United States, as of 1994, is 500 kV.

Alternating to direct to alternating current is nonsynchronous transmission of electric power. It can be overhead or under the surface. In the early 1970s the problem of bulk electric-power transmission over high-voltage transmission lines above the surface developed the insistent discussion of land use and environmental cost.

While the maximum ac transmission voltage in use in the United States (1994) is 765 kV, ultrahigh voltage (UHV) is under consideration. Transmission voltages of 1,200 to 2,550 kV are being tested presently. The right-of-way requirements for power transmission are significantly reduced at higher voltages. For example, in one study the transmission of 7,500 MVA at 345 kV ac was found to require 14 circuits on a corridor 725 ft (221.5 m) wide, whereas a single 1,200-kV ac circuit of 7,500-MVA capacity would need a corridor 310 ft (91.5 m) wide.

Continuing research and development efforts may result in the development of more economic high-voltage underground transmission links. Sufficient bulk power transmission capability would permit **power wheeling,** i.e., the use of generating capacity to the east and west to serve a given locality as the earth revolves and the area of peak demand glides across the countryside.

Corona is a reddish-blue electrical discharge which occurs when the voltage-gradient in air exceeds 30 kV peak, 21.1 kV rms, at 76 cm pressure. This electrical discharge is caused by ionization of the air and becomes more or less concentrated at irregularities on the conductor surface and on the outer strands of stranded conductors. Corona is accompanied by a hissing sound; it produces ozone and, in the presence of moisture, nitrous acid. On high-voltage lines corona produces a substantial power loss, corrosion of the conductors, and radio and television interference. The fair-weather loss increases as the square of the voltage above a critical value e_0 and is greatly increased by fog, smoke, rainstorms, sleet, and snow (see Fig. 15.1.86). To reduce corona, the diameter of high-voltage conductors is increased to values much greater than would be required for the necessary conductance cross section. This is accomplished by the use of hollow, segmented conductors and by the use of aluminum cable, steel-reinforced (ACSR), which often has inner layers of jute to increase the diameter. In extra-high-voltage lines (400 kV and greater), corona is reduced by the use of bundled conductors in which each phase consists of two or three conductors spaced about 16 in (0.41 m) from one another.

Underground Power Cables

Insulations for power cables include heat-resisting, low-water-absorptive synthetic rubber compounds, varnished cloth, impregnated paper, cross-linked polyethylene thermosetting compounds, and thermoplastics

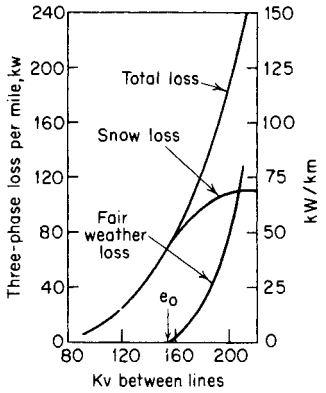

Fig. 15.1.86 Corona loss with snowstorm.

such as polyvinyl chloride (PVC) and polyethylene (PE) compounds (see Sec. 6).

Properly chosen **rubber-insulated cables** may be used in wet locations with a nonmetallic jacket for protective covering instead of a metallic sheath. Commonly used jackets are flame-resisting, such as neoprene and PVC. Such cables are relatively light in weight, easy to train in ducts and manholes, and easily spliced. When distribution voltages exceed 2,000 V phase to phase, an ozone-resisting type of compound is required. Such rubber insulation may be used in cables carrying up to 28,000 V between lines in three-phase grounded systems. The insulation wall will be thicker than with varnished cloth, polyethylene, ethylene propylene rubber, or paper.

Varnished-cloth cables are made by applying varnish-treated closely woven cloth in the form of tapes, helically, to the metallic conductor. Simultaneously a viscous compound is applied between layers which fills in any voids at laps in the taping and imparts flexibility when the cable is bent by permitting movement of one tape upon another. This type of insulation has higher dielectric loss than impregnated paper but is suitable for the transmission of power up to 28,000 V between phases over short distances. Such insulated cables may be used in dry locations with flame-resisting fibrous braid, reinforced neoprene tape, or PVC jacket and are often further protected with an interlocked metallic tape armor; but in wet locations these cables should be protected by a continuous metallic sheath such as lead or aluminum. Since varnish-cloth-insulated cable has high ozone resistance, heat resistance, and impulse strength, it is well adapted for station or powerhouse wiring or for any service where the temperature is high or where there are sudden increases in voltage for short periods. Since the varnish is not affected by mineral oils, such cables make excellent leads for transformers and oil switches.

PVC is readily available in several fast, bright colors and is often chosen for color-coded multiconductor control cables. It has inherent flame and oil resistance, and as single conductor wire and cable with the proper wall thickness for a particular application, it usually does not need any outside protective covering. On account of its high dielectric constant and high power factor, its use is limited to low voltages, i.e., under 1,000 V, except for series lighting circuits.

Polyethylene, because of its excellent electrical characteristics, first found use when it was adapted especially for high-frequency cables used in radio and radar circuits; for certain telephone, communication, and signal cables; and for submarine cables. Submarine telephone cables with built-in repeaters laid first in the Atlantic Ocean and then in the Pacific are insulated with polyethylene. Because of polyethylene's thermal characteristics, the standard maximum conductor operating temperature is 75°C. It is commonly used for power cables (including large use for underground residential distribution), with transmissions up to 15,000 V. Successful installations have been in service at 46 kV and some at 69 kV. The upper limit has not been reached, inasmuch as work is in progress on higher-voltage polyethylene power cables as a result of advancements in the art of compounding.

Cross-linked polyethylene is another insulation which is gaining in favor in the process field. For power cable insulations, the cross-linking process is most commonly obtained chemically. It converts polyethylene from a thermoplastic into a thermosetting material; the result is a compound with a unique combination of properties, including resistance to heat and oxidation, thus permitting an increase in maximum conductor operating temperature to 90°C. The service record with this compound has been good at voltages which have been gradually increased to 35 kV. Another thermosetting material, ethylene propylene rubber (EPR), has found wide acceptance in the 5- to 35-kV range.

Impregnated-paper insulation is used for very-high-voltage cables whose range has been extended to 345 kV. To eliminate the detrimental effects of moisture and to maintain proper impregnation of the paper, such cables must have a continuous metallic sheath such as lead or aluminum or be enclosed within a steel pipe; the operation of the cable depends absolutely on the integrity of that enclosure. In three-conductor belted-type cables the individual insulated conductors are surrounded by a belt or wall of impregnated paper over which the lead sheath is applied. When all three conductors are within one sheath, their inductive effects practically neutralize one another and eddy-current loss in the sheath is negligible. In the type-H cable, each of the individual conductors is surrounded with a perforated metallic covering, either aluminum foil backed with a paper tape or thin perforated metal tapes wound over the paper. All three conductors are then enclosed within the metal sheath. The metallic coverings being grounded electrically, each conductor acts as a single-conductor cable. This construction eliminates "tangential" stresses within the insulation and reduces pockets or voids. When paper tapes are wound on the conductor, impregnated with an oil or a petrolatum compound, and covered with a lead sheath, they are called **solid type.**

Three-conductor cables are now operating at 33,000 V, and single-conductor cables at 66,000 V between phases (38,000 V to ground). In New York and Chicago, special hollow-conductor oil-filled single-conductor cables are operating successfully at 132,000 V (76,000 V to ground). In France, cables are operating at 345 kV between conductors.

Other methods of installing underground cables are to draw them into steel pipes, usually without the sheaths, and to fill the pipes with oil under pressure (**oilstatic**) or **nitrogen** under 200 lb pressure. The ordinary medium-high-voltage underground cables are usually drawn into duct lines. With a straight run and ample clearance the length of cable between manholes may reach 600 to 1,000 ft. Ordinarily, the distance is more nearly 400 to 500 ft. With bends of small radius the distance must be further reduced.

Cable ratings are based on the permissible operating temperatures of the insulation and environmental installation conditions. See Table 15.1.20 for ampacities.

POWER DISTRIBUTION

Distribution Systems The choice of the system of power distribution is determined by the type of power that is available and by the nature of the load. To transmit a given power over a given distance with a given power loss (I^2R), the weight of conductor varies inversely as the square of the voltage. Incandescent lamps will not operate economically at voltages much higher than 120 V; the most suitable voltages for dc motors are 230, 500, and 550 V; for ac motors, standard voltages are 230, 460, and 575 V, three-phase. When power for lighting is to be distributed in a district where the consumers are relatively far apart, alternating current is used, being distributed at high voltage (2,400, 4,160, 4,800, 6,900, and 13,800 V) and transformed at the consumer's premises, or by transformers on poles or located in manholes or vaults under the street or sidewalks, to 240/120 V three-wire for lighting and domestic customers, and to 208, 240, 480, and 600 volts, three-phase, for power.

The first central station power systems were built with dc generation and distribution. The economical transmission distance was short. Densely populated, downtown areas of cities were therefore the first sections to be served. Growth of electric service in the United States

Table 15.1.20 Ampacities of Insulated High-Voltage Cables in Underground Raceways

NOTE: This is a general table. For other temperatures and installation conditions, see NFPA 70, 2005, National Electrical Code®, Tables 310.77, through 310.80 and associated notes.

was phenomenal in the last two decades of the nineteenth century. After 1895 when ac generation was selected for the development of power from Niagara Falls, the expansion of dc distribution diminished. The economics overwhelmingly favored the new ac system.

Direct current service is still available in small pockets in some cities. In those cases, ac power is generated, transmitted, and distributed. The conversion to dc takes place in rectifiers installed in manholes near the load or in the building to be served. Some dc customers resist the change to ac service because of their need for motor speed control. Elevator and printing press drives and some cloth-cutting knives are examples of such needs. (See Low-Voltage AC Network.)

Series Circuits These **constant-current** circuits were widely used for **street lighting.** The voltage was automatically adjusted to match the number of lamps in series and maintain a constant current. With the advent of **HID lamps** and individual **photocells** on street lighting fixtures which require parallel circuitry, this system fell into disuse and is rarely seen.

Parallel Circuits **Power** is usually distributed at **constant potential,** and all the devices or receivers in the circuit are connected in parallel, giving a constant-potential system, Fig. 15.1.87*a*. If conductors of constant cross section are used and all the loads, L_1, L_2, etc., are operating, there will be a greater voltage *IR* drop per unit length of wire in the portion of the circuit *AB* and *CD* than in the other portions; also the voltage will not be the same for the different lamps but will decrease along the mains with distance from the generating end.

Loop Circuits A more nearly equal voltage for each load is obtained in the loop system, Fig. 15.1.87*b*. The electrical distance from one generator terminal to the other through any receiver is the same as that through any other receiver, and the voltage at the receivers may be maintained more nearly equal, but at the expense of additional conductor material.

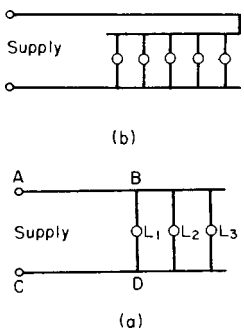

Fig. 15.1.87 (*a*) Parallel circuit; (*b*) loop circuit.

Series-Parallel Circuit For incandescent lamps the power must be at low voltage (115 V) and the voltage variations must be small. If the transmission distance is considerable or the loads are large, a large or perhaps prohibitive investment in conductor material would be necessary. In some special cases, lamps may be operated in groups of two in series as shown in Fig. 15.1.88. The transmitting voltage is thus doubled, and, for a given number of lamps, the current is halved, the permissible voltage drop (*IR*) in conductors doubled, the conductor resistance quadrupled, the weight of conductor material thus being reduced to 25 percent of that necessary for simple parallel operation.

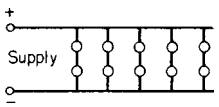

Fig. 15.1.88 Series-parallel system.

Three-Wire System In the series-parallel system the loads must be used in pairs and both units of the pair must have the same power rating. To overcome these objections and at the same time to obtain the economy in conductor material of operating at higher voltage, the three-wire system is used. It consists merely of adding a third wire or neutral to the system of Fig. 15.1.88 as shown in Fig. 15.1.89.

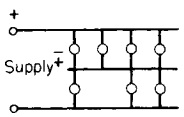

Fig. 15.1.89 Three-wire system.

If the neutral wire is of the same cross section as the two outer wires, this system requires only 37.5 percent of the copper required by an equivalent two-wire system. Since the neutral ordinarily carries less current than the outers, it is usually smaller and the ratio of copper to that of the two-wire system is even less than 37.5 percent (see Table 15.1.21).

When the loads on each half of the system are equal, there will be no current in the middle or neutral wire, and the condition is the same as that shown in Fig. 15.1.88. When the loads on the two sides are unequal,

NOTE: For other frequencies the reactance will be in direct proportion to the frequency.

there will be a current in the neutral wire equal to the difference of the currents in the outside wires.

AC Three-Wire Distribution Practically all energy for lighting and small motor work is distributed at 1,150, 2,300, or 4,160 V ac to transformers which step down the voltage to 240 and 120 V for three-wire domestic and lighting systems as well as 208, 240, 480, and 600 V, three-phase, for power. For the three-wire systems the transformers are so designed that the secondary or low-voltage winding will deliver power at 240 V, and the middle or neutral wire is obtained by connecting to the center or midpoint of this winding (see Figs. 15.1.90 and 15.1.91).

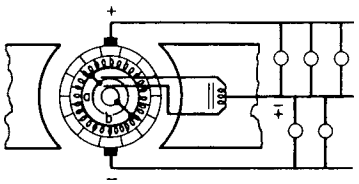

Fig. 15.1.90 Three-wire generator.

Disturbances of utility power have been present since the inception of the electric utility industry; however, in the past equipment was much more forgiving and less affected. Present electronic data processing equipment is microprocessor-based and consequently requires a higher quality of ac power. Although the quality of utility power in the United States is very good, sensitive electronic equipment still needs to be protected against the adverse and damaging effects of transients, surges, and other power-system aberrations.

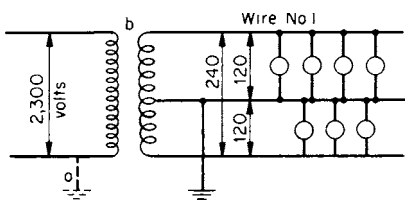

Fig. 15.1.91 Three-wire 230/115-V ac system.

This has led to the development of technologies which condition power for use by this sensitive equipment. Power-enhancing devices (surge suppressors, isolation transformers, and line voltage regulators) modify the incoming waveform to mitigate some aberrations. Power-synthesizing devices (motor-generator sets, magnetic synthesizers, and uninterruptible power supplies) use the incoming power as a source of energy to generate a new, completely isolated waveform. Each type has advantages and limitations.

Grounding The neutral wire of the secondary circuit of the transformer should be grounded on the pole (or in the manhole) and at the service switch in the building supplied. If, as a result of a lightning stroke or a fault in the transformer insulation, the transformer primary circuit becomes grounded at *a* (Fig. 15.1.91) and the transformer insulation between primary and secondary windings is broken down at *b* and if there were no permanent ground connection in the secondary neutral wire, the potential of wire 1 would be raised 2,300 V above ground potential. This constitutes a very serious hazard to life for persons coming in contact with the 120 V system. The National Electrical Code® requires the use of a ground wire not smaller than 8 AWG copper. With the neutral grounded (Fig. 15.1.91), voltages to ground on the secondary system cannot exceed 120 V. (See National Electrical Code® 2005, Art. 250.)

Feeders and Mains Where power is supplied to a large district, improved voltage regulation is obtained by having **centers of distribution.** Power is supplied from the station bus at high voltage to the centers of distribution by large cables known as **feeders.** Power is distributed from the distribution centers to the consumers through the mains and transformed to a usable voltage at the user's site. As there are no loads connected to the feeders between the generating station and centers of distribution, the voltage at the latter points may be maintained constant. **Pilot wires** from the centers of distribution often run back to the station, allowing the operator or automatic controls to maintain constant voltage at the centers of distribution. This system provides a means of maintaining very close **voltage regulation** at the consumer's premises.

A common and economical method of supplying business and thickly settled districts with high load densities is to employ a 208/120-V, three-phase, four-wire **low-voltage ac network.** The network operates

with 208 V between outer wires giving 120 V to neutral (Fig. 15.1.92). Motors are connected across the three outer wires operating at 208 V, three-phase. Lamp loads are connected between outer wires and the grounded neutral. The network is supplied directly from 13,800-V feeders by 13,800/208-V three-phase transformer units, usually located in manholes, vaults, or outdoor enclosures. This system thus eliminates the necessity for transformation in the substation. A large number of such units feed the network, so that the secondaries are all in parallel. Each transformer is provided with an overload reverse-energy circuit breaker (network protector), so that a feeder and its transformer are isolated if trouble develops in either. This system is flexible since units can be easily added or removed in accordance with the rapid changes in local loads that occur particularly in downtown business districts.

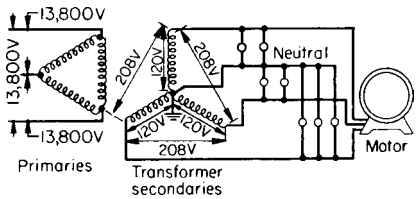

Fig. 15.1.92 208/120-V secondary network (single unit) showing voltages.

Voltage Drops In ac distribution systems the voltage drop from transformer to consumer in lighting mains should not exceed 2 percent in first-class systems, so that the lamps along the mains can all operate at nearly the same voltage and the annoying flicker of lamps may not occur with the switching of appliances. This may require a much larger conductor than the most economical size. In transmission lines and in feeders where there are no intermediate loads and where means of regulating the voltage are provided, the drop is not limited to the low values that are necessary with mains and the matter of economy may be given consideration.

WIRING CALCULATIONS

These calculations can be used for dc, and for ac if the reactance can be neglected. The determination of the proper size of conductor is influenced by a number of factors. Except for short distances, the minimum size of conductor shown in Table 15.1.23, which is based on the maximum permissible current for each type of insulation, cannot be used; the size of conductor must be larger so that the voltage drop IR shall not be too great. With branch circuits supplying an incandescent-lamp load, this drop should not be more than a small percentage of the voltage between wires. The National Electric Code® 2005, Article 215.2, FPN 2 recommends that conductors for feeders, i.e., from the service equipment to the final branch circuit overcurrent device, be sized to prevent (1) a voltage drop of more than 3 percent at the farthest outlet of power, heating, and lighting loads or combinations thereof, and (2) a maximum voltage drop on combined feeders and branch circuits to the farthest outlet of more than 5 percent.

The resistance of 1 cir mil · ft of commercial copper may be taken as 10.8 Ω. The resistance of a copper conductor may be expressed as $R = 10.8l/A$, where l = length, ft and A = area, cir mils. If the length is expressed in terms of the transmission distance d (since the two wires are usually run parallel), the voltage drop IR to the end of the circuit is

$$e = 21.6Id/A \qquad (15.1.128)$$

and the size of conductor in circular mils necessary to give the permissible voltage drop e is

$$A = 21.6Id/e \qquad (15.1.129)$$

If e is expressed as a percentage x of the voltage E between conductors, then

$$A = 2{,}160Id/xE \qquad (15.1.130)$$

EXAMPLE. Determine the size of conductor to supply power to a 10-hp, 220-V dc motor 500 ft from the switchboard with 5 V drop. Assume a motor efficiency of 86 percent. The motor will then require a current of $(10 \times 746)/(0.86 \times 220) = 39.4$ A. From Eq. (15.1.129), $A = 21.6 \times 39.4 \times 500/5 = 85{,}100$ cir mils. The next largest wire is no. 0 AWG.

The calculation of the size conductor for three-wire circuits is made in practically the same manner. With a balanced circuit there is no current in the neutral wire, and the current in each outside wire will be equal to one-half the sum of the currents taken by all the receiving devices connected between neutral and outside wires plus the sum of the currents taken by the receivers connected between the outside wires. Using this total current and neglecting the neutral wire, make calculations for the size of the outside wires by means of Eq. (15.1.129). The neutral wire should have the same cross section as the outside wires in interior wiring.

EXAMPLE. Determine the size wire which should be used for the three-wire main of Fig. 15.1.93. Allowable drop is 3 V and the distance to the load center 40 ft; circuit loaded with two groups of receivers each taking 60 A connected between the neutral and the outside wires, and one group of receivers taking 20 A connected across the outside wires.

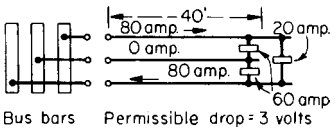

Fig. 15.1.93 Three-wire 230/115-V main.

Solution: load = (60 + 60)/2 + 20 = 80 A. Substituting in Eq. (15.1.129), cir mils = $21.6Id/e = 21.6 \times 80 \times 40/3 = 23{,}030$ cir mils.

From Tables 15.1.21 and 15.1.23, no. 6 wire, which has a cross section of 26,250 cir mils, is the next size larger. This size of wire would satisfy the voltage-drop requirements, but No. 6 wire w/type TW insulation has a safe carrying capacity of 55 A at 60°C. The current in the circuit is 80 A. Therefore, No. 3 wire w/type TW insulation which has a carrying capacity of 85 A should be used. The neutral wire should be the same size as the outside wires.

See also examples in the National Electrical Code® 2005.

Wiring calculations for ac circuits require some consideration of power factor, reactance, and skin effect. Skin effect becomes pronounced only when very large conductors are used for alternating current. For interior wiring, conductors larger than 700,000 cir mils should not be used, and many prefer not to use conductors larger than 300,000 cir mils. Should the required copper cross section exceed these values, a number of conductors may be operated in parallel.

For voltages under 5,000 the effect of line capacitance may be neglected. With ordinary single-phase interior wiring, where the effect of the line reactance may be neglected and where the power factor of the load (incandescent lamps) is nearly 100 percent, the calculations are made the same as for dc circuits. Three-wire ac circuits of ordinary length with incandescent lamp loads are also determined in the same manner. When the load is other than incandescent lamps, it is necessary to know the power factor of the load in order to make calculations. When the exact power factor cannot be accurately determined, the following approximate values may be used: incandescent lamps, 0.95 to 1.00; lamps and motors, 0.75 to 0.85; motors 0.5 to 0.80. Equation (15.1.131) gives the value of current in a single-phase circuit. See also Table 15.1.17.

$$I = (P \times 1{,}000)(E \times \text{pf}) \qquad (15.1.131)$$

where I = current, A; P = kW; E = load voltage; and pf = power factor of the load. The size of conductor is then determined by substituting this value of I in Eq. (15.1.129) or (15.1.130).

For three-phase three-wire ac circuits the current per wire

$$I = 1{,}000P/\sqrt{3}E\text{pf} = 580P/E\text{pf} \qquad (15.1.132)$$

Computations are usually made of voltage drop **per wire** (see Fig. 15.1.94). Hence, if reactance can be neglected, the conductor cross section in cir mils is one-half that given by Eq. (15.1.129). That is,

$$A = 10.8Id/e \quad \text{cir mils} \qquad (15.1.133)$$

where e in Eq. (15.1.133) is the voltage drop per wire. The voltage drop between any two wires is $\sqrt{3}e$. The percent voltage drop should be in terms of the voltage to **neutral**. That is, percent drop = $[e/(E/\sqrt{3})]100 = [\sqrt{3}e/E]100$ (see Fig. 15.1.82).

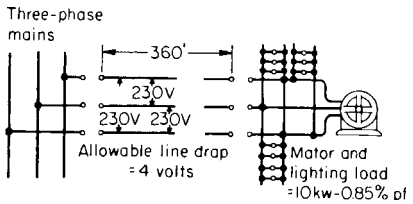

Fig. 15.1.94 Three-phase lamp and induction motor load.

EXAMPLE. In Fig. 15.1.94, load 10 kW; voltage of circuit 230; power factor 0.85; distance 360 ft; allowable drop per wire 4 V. Substituting in Eq. (15.1.132) $I = (580 \times 10)/(230 \times 0.85) = 29.7$ A. Substituting in Eq. (15.1.133), $A = 10.8 \times 29.7 \times 360/4 = 28{,}900$ cir mils.

The next larger commercially available standard-size wire (see Table 15.1.21) is 41,700 cir mils corresponding to AWG no. 4. From Table 15.1.23 the allowable ampacity is 70 A with type TW insulation, and is therefore ample in section for 29.7 A. Three no. 4 wires would be used for this circuit.

From Table 15.1.21 the resistance of 1,000 ft of no. 4 copper wire is 0.249 Ω. Hence, the voltage drop per conductor, $e = 29.7 \times (360/1{,}000)0.249 = 2.66$ V. Percent voltage drop = $\sqrt{3} \times 2.66/230 = 2.00$ percent.

Where all the wires of a circuit, two wires for a single-phase circuit, four wires for a four-phase circuit (see Fig. 15.1.32 and Fig. 15.1.80*c*), and three wires for a three-phase circuit, are carried in the same conduit or where the wires are separated less than 1 in between centers, the effect of line (inductive) reactance may ordinarily be neglected. Where circuit conductors are large and widely separated from one another and the circuits are long, the inductive reactance may increase the voltage drop by a considerable amount over that due to resistance alone. Such problems are treated using IR and IX phasors. Line reactance decreases somewhat as the size of wire increases and decreases as the distance between wires decreases.

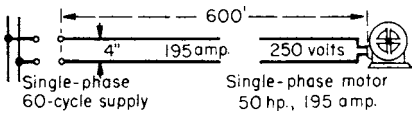

Fig. 15.1.95 Single-phase induction motor load on branch circuit.

EXAMPLE. Determine the size of wire necessary for the branch to the 50-hp, 60-Hz, 250-V single-phase induction motor of Fig. 15.1.95. The name-plate rating of the motor is 195 A, and its full-load power factor is 0.85. The wires are run open and separated 4 in; length of circuit, 600 ft. Assume the line drop must not exceed 7 percent, or $0.07 \times 250 = 17.5$ V. The point made by this example is emphasized by the assumption of an outsize motor.

Solution. To ascertain approximately the size of conductor, substitute in Eq. (15.1.129) giving cir mils = $21.6 \times 195 \times 600/17.5 = 144{,}400$. Referring to Table 15.1.21, the next larger size wire is no. 000 or 167,800 cir mils. This size would be ample if there were no line reactance. In order to allow for reactance drop, a larger conductor is selected and the corresponding voltage drop determined. Inasmuch as this is a motor branch, the code rules require that the carrying capacity be sufficient for a 25 percent overload. Therefore the conductor should be capable of carrying $195 \times 1.25 = 244$ A. From Table 15.1.23, 250,000-cir mil conductor Type THHN insulated cable would be required to carry 255 A at 75°C. Resistance drop (see Table 15.1.21), $IR = 195 \times 0.061 \times 0.6 = 7.14$ V. 7.14/250 = 2.86 percent. From Table 15.1.21, $X = 0.128 \times 0.6 = 0.0768$ Ω. $IX = 195 \times 0.768 = 14.98$ V. 14.98/250 = 5.99 percent. Using the Mershon diagram (Fig. 15.1.84), follow the ordinate corresponding to power factor, 0.85, until it intersects the smallest circle. From this point, lay off horizontally the percentage resistance drop, 2.86. From this last point, lay off vertically the percentage reactance drop 5.99. This last point lies about on the 6.0 percent circle, showing that with 195 amp the difference between the sending-end and receiving-end voltages is $0.06 \times 250 = 15.0$ V, which is within the specified limits.

Also Eq. (15.1.127) may be used. $\cos\theta = 0.85$; $\sin\theta = 0.527$.

$$E_s = \{[(250 \times 0.85) + 7.14]^2 + [(250 \times 0.527) + 14.98]^2\}^{1/2} = 264.3 \text{ V}$$

$$264.3/250 = 105.7 \text{ percent}$$

In the calculation of three-phase three-wire circuits where line reactance must be considered, the method found above under Power Transmission may be used. The system is considered as being three single-phase systems having a ground return the resistance and inductance of which are zero, and the voltages are equal to the line voltages divided by $\sqrt{3}$. When the three conductors are spaced unequally, the value of GMD given in Fig. 15.1.85 should be used in Tables 15.1.18 and 15.1.21. (When the value of resistance or reactance per 1,000 ft of **conductor** is desired, the values in Table 15.1.21 should be divided by 2.)

The National Electrical Code® specifies that the size of conductors for branch circuits should be such that the voltage drop should not exceed 3 percent to the farthest outlet for power, heating, lighting, or combination thereof, requiring further that the total voltage drop for feeders and branch circuits should not exceed 5 percent overall (NEC, Article 210.19, FPN No. 4). For examples of calculations for interior wiring, see National Electrical Code® (Chap. 9).

INTERIOR WIRING

Interior wiring requirements are based, for the most part, on the **National Electrical Code®** (NEC®), which has been adopted by the National Fire Protection Association, American National Standards Institute (ANSI), and the Occupational Safety and Health Act (OSHA).

The Occupational Safety and Health Act of 1970 (OSHA) made the National Electrical Code® a national standard. Conformance with the NEC became a requirement in most commercial, industrial, agricultural, etc., establishments in the United States. Some localities may not accept the latest edition of NEC® standards. In those cases, local rules must be followed.

NEC® authority starts at the point where the connections are made to the conductor of the **service drop** (overhead) or **lateral** (underground) from the electricity supply system. The **service equipment** must have a rating not less than the load to be carried (computed according to NEC® methods). Service equipment is defined as the necessary equipment, such as circuit breakers or fused switches and accompanying accessories. This equipment must be located near the point of entrance of supply conductors to a building or other structure or an otherwise defined area. Service equipment is intended to be the main control and means of cutoff of the supply.

Service-entrance conductors connect the electricity supply to the service equipment. Service-entrance conductors running along the exterior or entering a building or other structure may be installed (1) as separate conductors, (2) in approved cables, (3) as cable bus, or (4) enclosed in rigid conduit. Also, for voltages less than 600 V, the conductors may be installed in electrical metallic tubing; IMC, ENT, and MC cable wireways; auxiliary gutters; or busways. Service-entrance cables which are subject to physical damage from awnings, swinging signs, coal chutes, etc., shall be of the protected type or be protected by conduit, electrical metallic tubing, etc. Service heads must be raintight. Thermoplastic thermoset insulation is required in overhead services. A grounded conductor may be bare. If exposed to the weather or embedded in masonry, raceways must be raintight and arranged to drain. Underground service raceway or duct entering from an underground distribution system must be sealed with a suitable compound (spare ducts, also).

NEC® rules permit **multiple service** to a building for various reasons, such as: (1) fire pumps, (2) emergency light and power, (3) multiple occupancy, (4) when the calculated load is greater than 2,000 A, (5) when the building extends over a large area, and (6) where different voltages, frequencies, number of phases, or classes of use are required.

Ordinary service drops (overhead) and lateral (underground) must be large enough to carry the load but not smaller than no. 8 copper or no. 6 aluminum. As an exception, for installations to supply only limited loads of a single branch circuit, such as small polyphase power, etc., service drops must not be smaller than no. 12 hard-drawn copper or equivalent, and service laterals must be not smaller than no. 12 AWG copper or no. 10 AWG aluminum.

The phrase **large enough to carry the load** requires elaboration. The various conductors of public-utility electric-supply systems are sized according to the calculations and decisions of the personnel of the specific public utility supplying the service drop or lateral. At the load end of the drop or lateral, the NEC® rules apply, and from that point on into the consumer's premises, NEC® rules are the governing authority. There is a discontinuity at this point in the calculation of combined load demand for electricity and allowable current (ampacity) of conductors, cables, etc. This discontinuity in calculations results from the fact that the utility company operates locally, whereas the NEC® is a set of national standards and therefore cannot readily allow for regional differences in electrical coincident demand, ambient temperature, etc. The NEC's aim is the assurance of an electrically "safe" human environment. This will be fostered by following the NEC® rules.

Service-entrance cables are conductor assemblies which bear the type codes SE (for overhead services) and USE (for underground services). Under specified conditions, these cables may also be used for interior feeder and branch-circuit wiring.

The service-entrance equipment must have the **capability of safely interrupting** the current resulting from a short circuit at its terminals. **Available short-circuit current** is the term given to the maximum current that the power system can deliver through a given circuit to any negligible-impedance short circuit applied at a given point. (This value can be in terms of symmetrical or asymmetrical, momentary or clearing current, as specified.)

In most instances, the available short-circuit current is limited by the impedance of the last transformer in the supply system and connecting wiring. **Large power users,** however, must become aware of changes in the electricity supply system which, because of growth of system capacity or any other reason, would increase the short-circuit current available to their service-entrance equipment. If this current is too great, explosive failure can result in a hazard to personnel and equipment.

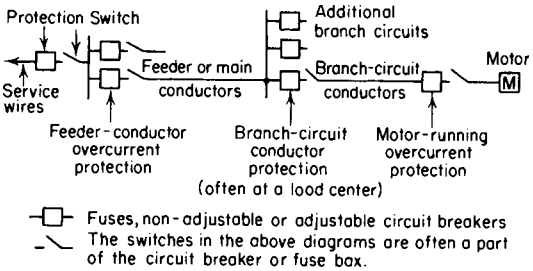

Fig. 15.1.96 Motor and wiring protection.

Kilowatthour and sometimes demand-metering equipment are connected to the service-entrance conductors. Proceeding toward the utilization equipment, the power-supply system fans out into feeders and branch circuits (see Fig. 15.1.96). Each of the feeders, i.e., a run of untapped conductor or cable, is connected to the supply through a switch and fuses or a circuit breaker. At a point, usually near that portion of the electrical loads which are to be supplied, a **panelboard** or perhaps a **load-center assembly** of switching and/or control equipment is installed. From this panel box or load-center assembly, circuits originate; i.e., circuits are installed to extend into the area being served to connect electrical machinery or devices or make available electric receptacles connected to the source of electric power.

Each feeder and each branch circuit will have its own **over-current protection** and **disconnect** means in the form of a fuse and switch combination or a circuit breaker.

Wiring Methods

There is a provision in the NEC® rules for the following types of feeder and branch circuit wiring:

1. Open Wiring on Insulators (NEC® 2005, Art. 398). This wiring method uses approved cleats, knobs, tubes, and flexible tubing for the protection and support of insulated conductors run on or in buildings and not concealed by the building structure. It is permitted only in industrial or agricultural establishments.

2. Concealed Knob-and-Tube Work (NEC® 2005, Art. 394). Concealed knob-and-tube work may be used in the hollow spaces of walls and ceilings. It may be used only for the extension of existing installations.

3. Flat Conductor Cable, Type FCC (NEC® 2005, Art. 324). Type FCC cable may be installed under carpet squares. It may not be used outdoors or in wet locations, in corrosive or hazardous areas, or in residential, school, or hospital buildings.

4. Mineral-Insulated Metal-Sheathed Cable, Type MI (NEC® 2005, Art. 332). Type MI cable contains one or more electrical conductors insulated with a highly compressed refractory mineral insulation and enclosed in a liquid- and gastight continuous copper of steel sheath. Appropriate approved fittings must be used with it. It may be used for services, feeders, and branch circuits either exposed or concealed and dry or wet. It may be used in Class I, II, or III hazardous locations. It may be used for under-plaster extensions and embedded in plaster finish or brick or other masonry. It may be used where exposed to weather or continuous moisture, for underground runs and embedded in masonry, concrete or fill, in buildings in the course of construction or where exposed to oil, gasoline, or other conditions. If the environment would cause destruction of the sheath, it must be protected by suitable materials.

5. Power and Control Tray Cable (NEC® 2005, Art. 336). Type TC cable is a factory assembly of two or more insulated conductors with or without associated bare or covered-grounding conductors under a nonmetallic jacket, approved for installation in cable trays, in raceways, or where supported by messenger wire.

6. Metal-Clad Cable, Type MC and AC Series (NEC® 2005, Art. 320 and 330). These are metal-clad cables, i.e., an assembly of insulated conductors in a flexible metal enclosure. Type **AC cables** are manufactured in sizes 14 AWG through 1 AWG copper and 12 AWG through 1 AWG aluminum conductors. Type **MC cables** are manufactured in sizes 14 AWG and larger copper and 12 AWG and larger aluminum conductors. Optical fibers are permitted in multiconductor-type MC cables. Type AC cables utilize the armor as the path for equipment grounding. Armor of type MC cable is not recognized as the sole grounding path and includes a separate equipment-grounding conductor. Metal-clad cables may generally be installed where not subject to physical damage, for feeders and branch circuits in exposed or concealed work, with qualifications for wet locations, direct burial in concrete, etc. The use of Type AC cable is prohibited (1) in motion-picture studios, (2) in theaters and assembly halls, (3) in hazardous locations, (4) where exposed to corrosive fumes or vapors, (5) on cranes or hoists except where flexible connections to motors, etc., are required, (6) in storage-battery rooms, (7) in hoistways or on elevators except (*i*) between risers and limit switches, interlocks, operating buttons, and similar devices in hoistways and in escalators and moving walkways and (*ii*) short runs on elevator cars, where free from oil, and if securely fastened in place, or (8) in commercial garages in hazardous locations.

7. Nonmetallic-Sheathed Cable, Types NM, NMC, and NMS (NEC® 2005, Art. 334). These are assemblies of two more insulated conductors (nos. 14 through 2 for copper, nos. 12 through 2 for aluminum) having an outer sheath of moisture-resistant, flame-retardant, nonmetallic material. In addition to the insulated conductors, the cable may have an approved size of insulated or bare conductor for equipment grounding purposes only. The outer covering of NMC cable is flame retardant and corrosion resistant. The use of this type of cable, commonly called Romex is permitted in one- or two-family dwellings, multifamily dwellings, and other structures of type III, IV, and V construction. These cables are **not** permitted as open runs in dropped or suspended ceilings, as service entrance cable, in commercial garages

having hazardous (classified) locations, in theaters, motion picture studios, storage battery rooms, hoistways, escalators, or embedded in concrete.

8. Service Entrance Cable, Types SE and USE (NEC® 2005, Art. 338). These cables, containing one or more individually insulated conductors, are primarily used for electric services. Type SE has a flame-retardant, moisture-resistant covering and is not required to have built-in protection against mechanical abuse. Type USE is recognized for use underground. It has a moisture-resistant covering, but not necessarily a flame-retardant one. Like the SE cable, USE cable is not required to have inherent protection against mechanical abuse. Where all circuit conductors are fully insulated, type USE and SE cables can be used for branch circuits or feeders. The equipment grounding conductor is the only conductor permitted to be bare within service entrance cables used for branch circuits.

9. Underground Feeder and Branch-Circuit Cable, Type UF (NEC® 2005, Art. 340). This cable is made in sizes 14 through 4/0, and the insulated conductors are Types TW, RHW, and others approved for the purpose. As in the NM cable, the UF type may contain an approved size of uninsulated or bare conductor for grounding purposes only. The outer jacket of this cable shall be flame-retardant, moisture-resistant, fungus-resistant, corrosion-resistant, and suitable for direct burial in the ground.

10. Other Installation Practices. The NEC® details rules for nonmetallic circuit extensions and underplaster extensions. It also provides detailed rules for installation of electrical wiring in (*a*) rigid metal conduit (which may be used for all atmospheric conditions and locations with due regard to corrosion protection and choice of fittings), (*b*) rigid nonmetallic conduit (which is essentially corrosion-proof), in electrical metallic tubing (which is lighter-weight than rigid metal conduit), (*c*) flexible metal conduit, (*d*) liquidtight flexible metal conduit, (*e*) surface raceways, (*f*) underfloor raceways, (*g*) multioutlet assemblies, (*h*) cellular metal floor raceways, (*i*) structural raceways, (*j*) cellular concrete floor raceways, (*k*) wireways (sheet-metal troughs with hinged or removable covers), (*l*) flat, Type FC (NEC® 2005, Art. 322), cable assemblies installed in a surface metal raceway (Type FC cable contains three or four no. 10 special stranded copper wires), (*m*) busways, and (*n*) cable-bus. Busways and cable-bus installations are permitted for exposed work only.

In all installation work, only approved outlets, switch and junction boxes, fittings, terminal strips, and dead-end caps shall be used, and they are to be used in an approved fashion (see NEC® 2005, Art. 314).

Conductors

Table 15.1.22 relates American wire gage (AWG) AWG wire sizes to metric units. Table 15.1.23 lists the allowable ampacities of copper and aluminum conductors. Table 15.1.24 lists various conductor insulation systems approved by the 2005 NEC® for conductors used in interior wiring. Adjustment factors for number of conductors in a raceway or cable are listed in Table 15.1.25. For installations not covered by the tables presented here, review the NEC®. Estimated full-load currents of motors can be taken from Table 15.1.17.

Table 15.1.22 Wire Table for Standard Annealed Copper at 20°C in SI Units

AWG size	No. wires	Diameter, mm	kg/km	m/Ω	Area, mm²
14	1	1.628	18.50	120.7	2.08
12	1	2.053	29.42	191.9	3.31
10	1	2.588	46.77	305.1	5.261
8	1	3.264	74.37	485.2	8.367
6	7	4.115	118.2	771.5	13.30
4	7	5.189	188.0	1227	21.15
2	7	6.544	299.0	1951	33.62
1	19	7.348	377.0	2460	42.41
0	19	8.252	477.6	3102	53.49
00	19	9.266	599.5	3911	67.43
000	19	10.40	755.7	4932	85.01
0000	19	11.68	935.2	6219	107.2

Protection of conductors Unless excepted by the NEC®, other than fixture cords, flexible cables, and fixture wires, conductors shall be protected against overcurrent according to their rated ampacities (see Table 15.1.23). A fuse or overcurrent trip element of circuit breakers is connected in series with each ungrounded conductor and is normally located at the point where the conductor receives its supply.

Standard ratings for fuses and circuit-breakers (inverse time) are 15, 20, 25, 30, 40, 45, 50, 60, 70, 80, 90, 100, 125, 150, 175, 200, 225, 250, 300, 250, 400, 450, 500, 600, 700, 800, 1,000, 1,200, 1,600, 2,000, 2,500, 3,000, 4,000, 5,000, and 6,000 amperes. Additional standard sizes for fuses are 1, 3, 6, 10, and 601. Listed nonstandard sizes of fuses and circuit-breakers are permitted.

Allowable **conductor ampacities** (Table 15.1.23) are subject to limitations and adjustments that may limit or reduce the initial conductor ampacity. One guiding limitation is that the conductor shall be selected so as not to exceed the lowest temperature rating of any connected termination, conductor, or device. Unless the equipment (termination) is listed for a higher temperature, the following applies:

- Termination provisions for circuits rated 100 A or less, or marked for 14 AWG through 1 AWG conductors, shall be conductors rated for 60°C. Conductors with higher temperature ratings can be used as long as the ampacity is based on the 60°C ampacity.
- Termination provisions for circuits rated over 100 A, or marked for conductors larger than 1 AWG, shall be rated for conductors rated for 75°C. Conductors with higher temperature ratings can be used as long as the ampacity is based on the 75°C ampacity.
- The above temperature limitations are most commonly applied at circuit breakers at motor starter terminals. Listing temperatures are normally identified on each device.
- For additional information see NEC® Article 110.14(C)(1).

Unless the equipment is listed and marked otherwise, conductor ampacities apply after any required derating for ambient temperature or number of conductors in a raceway. Conductor ampacity tables should be carefully checked, since the basis can include ambient temperatures of 20°C, 30°C, or 40°C depending on the application. Refer to Table 15.1.23 for examples of temperature correction factors. For complete ampacity information refer to NEC® Article 310.

Where the number of **current-carrying conductors** in a raceway or cable exceeds three the allowable ampacity in of each conductor in Table 15.1.23 must be reduced. Table 15.1.25 establishes derating factors to be applied to current-carrying conductors after any required derating for ambient temperature. The factors in Table 15.1.25 are based on conductors with no **load diversity,** meaning all conductors are fully loaded. For conductors with **load diversity,** adjustment factors for more than three current-carrying conductors in a raceway or cable are found in NEC® 2005, Annex B, Table B.310.11. For information on ampacity derating of cables in cable trays, refer to NEC® 2005, Article 392.

After the final ampacity is derived, the basic rule for selecting overcurrent protection is that all conductors, other than flexible cords, shall be protected against overcurrent in accordance with their ampacities. For devices rated 800 A or less, the next higher standard overcurrent device rating (above the ampacity of the conductors being protected) is permitted to be used. Refer to NEC® Article 240.4(A) for additional information and exceptions.

The **number and size of conductors in raceways** must not be more than will permit dissipation of heat and ready installation or removal of conductors without damage. Lookup tables for conduit fill by conductor insulation are often used. Because of the large variety of available insulation types, raceway systems, and measurement units (U.S. versus metric), the NEC® approaches fill by several methods. If all of the conductors are the same size and insulation type, conduit fill can be determined by lookup tables based on the type of raceway; refer to NEC® 2005, Annex-C, Tables C1 through C12A. If the conductors are mixed sizes, then the process has two steps:

1. Determine the total area occupied by the conductors (in² or mm²), based on the wire insulation type and size, using NEC®, Chap. 9, Table 5 or 5A.

Table 15.1.23 Allowable Ampacities of Insulated Conductors Rated 0 through 2,000 Volts, 60°C through 90°C (140°F through 194°F), Not More Than Three Current-Carrying Conductors in Raceway, Cable, or Earth (Directly Buried), Based on Ambient Temperature of 30°C (86°F)

Table 15.1.24 Conductor Type and Application

Type letter	Insulation, trade name (see NEC®, Art. 310 for complete information)	Environment	Outer covering[a]
	Max operating temperature = 60°C (140°F)		
TW	Moisture-resistant thermoplastic	Dry and wet	None
TF	Thermoplastic-covered, solid or 7-strand	[c,d]	None
TFF	Thermoplastic-covered, flexible stranding	[c,d]	None
MTW	Moisture-, heat-, and oil-resistant thermoplastic machine-tool wiring (NFPA Stand. 79, NEC 1975, Art. 670)	Wet	None or nylon
UF	Moisture-resistant, underground feeder	Dry and wet	None
	Max operating temperature = 75°C (167°F)		
RHW	Moisture-resistant thermoset	Dry and wet	1,2
THW	Moisture- and heat-resistant thermoplastic	Dry and wet	None
THWN	Moisture- and heat-resistant thermoplastic	Dry and wet	Nylon
XHHW	Moisture-resistant thermoset	Wet	None
RFH-1 and 2	Heat-resistant rubber-covered solid or 7-strand	[b–d]	None
FFH-1 and 2	Heat-resistant rubber-covered flexible stranding	[b–d]	None
UF	Moisture-resistant and heat-resistant	Dry and wet	None
USE	Heat- and moisture-resistant	Dry and wet	4
ZW	Modified ethylene tetrafluoroethylene	Wet	None
	Max operating temperature = 90°C (194°F)		
MI	Mineral-insulated (metal-sheathed)	Dry and wet	Copper or alloy steel
	Max operating temperature = 90°C (194°F)		
RHH	Heat-resistant thermoset	Dry and damp	1,2
THHN	Heat-resistant thermoplastic	Dry and damp	Nylon
THW	Moisture- and heat-resistant thermoplastic	[f]	None
XHHW	Moisture-resistant thermoset	Dry	None
FEP	Fluorinated ethylene propylene	Dry	None
FEPB	Fluorinated ethylene propylene	Dry	3
TFN	Heat-resistant thermoplastic covered, solid or 7-strand	[c,d]	Nylon
TFFN	Heat-resistant thermoplastic flexible stranding		Nylon
MTW	Moisture-, heat-, and oil-resistant thermoplastic machine-tool wiring (NFPA Stand. 79, NEC 1975, Art. 670)	Dry	None or nylon
PFA	Perfluoralkoxy	Dry and damp	None
SA	Silicone	Dry	Glass
	Max operating temperature = 150°C (302°F)		
Z, ZW	Modified ethylene tetrafluoroethylene	Dry	None
	Max operating temperature = 200°C (392°F)		
FEP, FEPB	Fluorinated ethylene propylene	Dry	None
	Special applications		3
PFA	Perfluoralkoxy	Dry	None
PF, PGF	Fluorinated ethylene propylene	[c,d]	None or glass braid
PFA	Perfluoralkoxy	Dry	None
SF-2	Silicone rubber, solid or 7-strand	[c,d]	Nonmetallic
	Max operating temperature = 250°C (482°F)		
MI	Mineral-insulated (metal-sheathed), for special applications	Dry and wet	Copper or alloy steel
TFE	Extruded polytetrafluoroethylene, only for leads within apparatus or within raceways connected to apparatus, or as open wiring (nickel or nickel-coated copper only)	Dry	None
PFAH	Perfluoroalkoxy (special application) (nickel or nickel-coated copper)	Dry	None
PTF	Extruded polytetrafluoroethylene, solid or 7-strand (nickel or nickel-coated copper only)	[c,d]	None

[a] 1: Moisture-resistant, flame-retardant nonmetallic; 2: outer covering not required when thermoset insulation has been specifically approved for the purpose; 3: no. 14-8 glass braid, no. 6-2 asbestos braid; 4: moisture-resistant nonmetallic.
[b] Limited to 300 V.
[c] No. 18 and no. 16 conductor for remote controls, low-energy power, low-voltage power, and signal circuits; NEC® 2005 Sec. 725.27, Sec. 760.27.
[d] Fixture wire no. 18-16.
[e] For over 2,000 V, the insulation shall be ozone-resistant.
[f] Special applications within electric discharge lighting equipment. Limited to 1,000 V open-circuit volts or less.

2. Then, using the appropriate table for the raceway system from NEC® 2005, Table 4, find a raceway equal to or greater than the maximum allowable fill for the number of conductors.

Generally, insulated conductors in premises wiring systems and circuits are required to have a **grounded conductor** (commonly referred to as the *neutral*) identified by a continuous **white or gray finish.** Where the wiring method does not include a white colored conductor, a conductor (other than green) can be identified by three continuous white stripes along its length, or for conductor sizes larger than 6 AWG, white tape or paint can be applied at terminations. Refer to NEC® 2005, Art. 200.6, for additional information.

The insulation color of **ungrounded circuit conductors** is not restricted other than that it be different from a grounded (white) or grounding conductor (green). A common identification practice for circuit conductors in 208Y120-V, three-phase, three-wire systems is black, red, and blue, and for three-phase, four-wire systems is **black, red, blue, and white.** For 480Y277-V, three-phase, three-wire systems, brown, orange, and yellow (BOY) is widely used, and for three-phase, four-wire systems, **brown, orange, yellow, and white** is common practice. Where more than one nominal voltage system exists in a building (or premises), unique identification either by conductor color or tape is required to be applied at each termination.

Switching Arrangements Small quick-break switches must be set in or on an approved box or fitting and may be of the push, tumbler, or rotary type. The following types of switches are used to control lighting circuits: (1) single-pole, (2) double-pole, (3) three-point or three-way, (4) four-way, in combination with three-way switches to control lights from three or more stations.

In all metallic protecting systems, such as conduit, armored cable, or metal raceways, joints and splices in conductors must be made only in junction boxes or other proper fittings; therefore, these fittings can be located only in accessible places and never concealed in partitions. Splices or joints in the wire must never be in the conduit piping, raceway, or metallic tubing itself, for the splices may become a source of trouble as a result of corrosion or grounding if water should enter the conduit.

All conductors of an ac system must be placed in the same metallic casing so that their resultant magnetic field is nearly zero. If this is not done, eddy currents are set up causing heating and excessive loss. With single conductors in a casing, or multiple conductors of the same phase, an excessive reactance drop may result.

Services A **service disconnecting** means is required to disconnect all ungrounded conductors in buildings or other structures from the service entrance conductors. The disconnecting means must be installed at a readily accessible location either outside a building or structure or inside, nearest the point of entrance of the service conductors. The length of **service entrance conductors** should be kept to a minimum inside buildings. Some local jurisdictions have ordinances that limit the distance of service entrance conductors or the location of service equipment inside a building. The service drop or entrance conductors must be insulated or covered, except a grounded conductor is permitted to be bare when part of a service cable, underground lateral, and certain other installations. (Refer to NEC® 2005, Art. 230, for additional information on electrical service requirement.)

The minimum size of service entrance conductors (before any adjustment or correction factors) shall not be less than the sum of the noncontinuous load plus 125 percent of the continuous load. The service disconnecting means shall have a rating of not less than the load to be carried. Calculating the **service size** requires accounting for (1) all fixed loads (motors, appliances, heating devices, etc.), adjusted for any applicable demand factors (ratio of maximum demand to connected load); (2) general lighting load (lights and general-use receptacles) based on type of building (dwelling, hospital, hotel, apartments, warehouse, etc.), adjusted for applicable demand factor; and (3) additional capacity for the future, if applicable. (Refer to NEC® 2005, Art. 220, for additional information and NEC® 2005, Annex D, for examples.)

The computed load of a feeder shall not be less than the sum of all the loads on branch circuits after any applicable demand factors have been applied. In no case shall the service rating be less than 15 A for loads of a single branch circuit, 30 A for loads consisting of two 2-wire circuits, 100 A for a one-family dwelling. For all other installations the service disconnecting means shall be rated for a minimum of 60 A.

Unless specifically excepted, **alternating-current circuits and systems** operating from 50 to 1,000 V supplying premises wiring and premises wiring systems are required to be **grounded.** Also, two-wire **direct-current systems** operating from 50 to 300 V and all three-wire direct-current systems supplying premises wiring are required to be **grounded.** Grounding of electrical systems to earth is done in a manner that will limit the voltage caused by lightning, surges, or unintentional contact with higher voltage sources and acts to stabilize the voltage to earth during normal operation.

System grounding is normally accomplished by connecting a **grounding electrode conductor** from a neutral terminal in the service equipment to a **grounding electrode.** The types of grounding electrodes permitted include driven ground rods, water pipe, metal frames of buildings, ground rings, and others. Refer to NEC® 2005, Art. 250, Part III, for additional information on application and conductor sizing.

Electrical equipment, wiring, and other electrically conductive materials likely to become energized must be installed in a manner that will provide an **effective ground path** capable of carrying the maximum ground-fault current likely in any part of the system where a ground fault may occur to the electrical supply. All non-current-carrying conductive materials enclosing conductors (raceways, wireways, shields, etc.), enclosing equipment, or forming part of electrical equipment (motor frames, etc) are required to be **bonded** (connected together) in a manner that establishes an effective path for ground-fault current.

Equipment grounding conductors are used to provide the grounding of non-current-carrying metal parts likely to become energized for fixed, stationary, or portable equipment served by fixed wiring or cord-and-plug connected. Equipment grounding conductors can be a bare or insulated (green or green/yellow stripe) wire where properly sized, rigid metal or intermediate conduit, copper sheath of MI cables, and cable trays. Under certain conditions electrical metallic tubing, type MC cable, wireways/auxilliary gutters, flexible metal conduit, and liquidtight flexible metal conduit can be used as an equipment-grounding conductor. See NEC® 2005, Art. 250.118, for additional information.

Ground-Fault Protection There are several types of ground-fault protection used for protection of either personnel or equipment.

Ground-fault circuit interrupters (GFCIs) have been required by the NEC® since 1973 to provide personnel protection in certain areas of dwellings, manufactured housing, hotels, swimming pools, health-care facilities, recreational vehicles, and other locations to prevent electrocution. The GFCI monitors the current in the two conductors of a circuit (120 or 240 V, single phase) and automatically trips the circuit breaker on a differential current in excess of 4 to 6 mA (nominally 5 mA). During the time to trip a fault a person can be exposed to a shock sensation that can cause secondary accidents such as falls.

Ground-fault equipment protection (GFEP) is required for **electric heating circuits** as defined by NEC® 2005, Arts. 426 and 427. The requirement can be met by use of a ground-fault equipment protection circuit

interrupter (GFEPCI) with a nominal trip value of 30 mA or a heating controller or ground-fault relay with adjustable trip settings.

Ground-fault protection of equipment has been required since 1971 in **solidly grounded wye systems** of more than 150 V to ground but not exceeding 600 V phase-to-phase at each **service disconnect rated 1,000 A** or more. Adjustable current-sensing relays are commonly used for equipment protections; they monitor either all phase conductors or the main bonding jumper. When the stray current exceeds the setting of the ground-fault relay, a shunt-trip breaker is operated to open all ungrounded circuit conductors.

Arc-fault interrupter protection is designed to detect and interrupt arcing faults. **Arc-fault circuit interrupter (AFCI)** circuit breakers are required in 15- and 20-A, 125-V circuits that supply outlets (receptacles, lighting, etc.) in dwelling-unit bedrooms to provide protection from arcing faults occurring in extension cords or cord-connected lights or appliances.

RESISTOR MATERIALS

For use in rheostats, electric furnaces, ovens, heaters, and many electrical appliances, a resistor material with high melting point and high resistivity which does not disintegrate or corrode at high temperatures is necessary. These requirements are met by the nickel-chromium and nickel-chromium-iron alloys. For electrical instruments and measuring apparatus, the resistor material should have high resistivity, low temperature coefficient, and, for many uses, low thermoelectric power against copper. The properties of resistor materials are given in Table 15.1.26. Most of these materials are available in ribbon as well as in wire form. Cast-iron and steel wire are efficient and economical resistor materials for many uses, such as power-absorbing rheostats and motor starters and controllers. (See also Table 15.1.3.)

Advance has a low temperature coefficient and is useful in many types of measuring instrument and precision equipment. Because of its high thermoelectric power to copper, it is valuable for thermoelements and pyrometers. It is noncorrosive and is used to a large extent in industrial and radio rheostats. **Hytemco** is a nickel-iron alloy characterized by a high temperature coefficient and is used advantageously where self-regulation is required as in immersion heaters and heater pads. **Magno** is a manganese-nickel alloy used in the manufacture of incandescent lamps and radio tubes. **Manganin** is a copper-manganese-nickel alloy which, because of its very low temperature coefficient and its low thermal emf with respect to copper, is very valuable for high-precision electrical measuring apparatus. It is used for the resistance units in bridges, for shunts, multipliers, and similar measuring devices. **Nichrome V** is a nickel-chromium alloy free from iron, is noncorrosive, nonmagnetic, withstands high temperatures, and has high resistivity. It is recommended as material for heating elements in electric furnaces, hot-water heaters, ranges, radiant heaters, and high-grade electrical appliances. **Kanthal** is used for heating applications where higher operating temperatures are required than for Nichrome. Mechanically, it is less workable than Nichrome. **Platinum** is used in specialized heating applications where very high temperatures are required. **Tungsten** may be used in very high temperature ovens with an inert atmosphere. **Pure nickel** is used to satisfy the high requirements in the fabrication of radio tubes, such as the elimination of all gases and impurities in the metal parts. It also has other uses such as in incandescent lamps, for combustion boats, laboratory accessories, and resistance thermometers.

Carbon withstands high temperatures and has high resistance; its temperature coefficient is negative; it will safely carry about 125 A/in^2. Amorphous carbon has a resistivity of 3,800 and 4,100 $\mu\Omega \cdot$ cm, retort carbon about 720 $\mu\Omega \cdot$ cm, and graphite about 812 $\mu\Omega \cdot$ cm. The properties of any particular kind of carbon depend on the temperature at which it was fired. Carbon for rheostats may best be used in the form of compression rheostats. **Silicon carbide** is used to manufacture heating rods that will safely operate at 1,650°C (3,000°F) surface temperature. It has a negative coefficient of resistance up to 650°C, after which it is positive. It must be mechanically protected because of inherent brittleness.

MAGNETS

A **permanent magnet** is one that retains a considerable amount of magnetism indefinitely. Permanent magnets are used in electrical instruments, telephone receivers, loudspeakers, magnetos, tachometers, magnetic chucks, motors, and for many purposes where a constant magnetic field or a constant source of magnetism is desired. The magnetic material should have high retentivity, a high remanence, and a high coercive force (see Fig. 15.1.8). These properties are usually found with hardened steel and its alloys and also in ceramic permanent magnet materials.

Since permanent magnets must operate on the molecular mmf imparted to them when magnetized, they must necessarily operate on the portion *CDO* of the hysteresis loop (see Fig. 15.1.8). The area *CDO* is proportional to the **stored energy** within the magnet and is a criterion of its usefulness as a permanent-magnetic material. In the left half of Fig. 15.1.97 are given the *B-H* characteristics of several permanent-magnetic materials; these include 5 to 6 percent tungsten steel (curve 1); 3½ percent chrome magnet steel (curve 2); cobalt magnet steel, containing 16 to 36 percent cobalt and 5 to 9 percent chromium and in some alloys tungsten (curve 3); and the carbon-free aluminum-nickel-cobalt-steel alloys called Alnico. There are many grades of Alnico; the

characteristics of three of them are shown by curves 4, 5, 6. Their composition is as follows:

Curve	Alnico no.	Composition, percent					
		Al	Ni	Co	Cu	Ti	Fe
4	5	8	14	24	3	. . .	51
5	6	8	14	24	3	1.25	49.75
6	12	6	18	35	. . .	8.0	33

All the Alnicos can be made by the sand or the precision-casting (lost-wax) process, but the most satisfactory method is by the sintering process.

If the alloys are held in a magnetic field during heat-treatment, a **magnet grain** is established and the magnetic properties in the direction of the field are greatly increased. The alloys are hard, can be formed only by casting or sintering, and cannot be machined except by grinding.

The curves in the right half of Fig. 15.1.97 are "external energy" curves and give the product of B and H. The optimum point of operation is at the point of maximum energy as is indicated at A_1 on curve 5.

Considering curve 5, if the magnetic circuit remained closed, the magnet would operate at point B. To utilize the flux, an air gap must be introduced. The air gap acts as a demagnetizing force, H_1 ($= B_1A_1$), and the magnet operates at point A_1 on the HB curve. The line OA_1 is called the *air-gap line* and its slope is given by $\tan \theta_1 = B_1/H_1$ where $H_1 = B_g l_g/l_m$ and $B_1/B_g = A_g/A_m$, where B_g = flux density in gap, T; l_g = length of gap, m; l_m = length of magnet, m; A_g, A_m = areas of the gap and magnet, m^2.

If the air gap is lengthened, the magnet will operate at A_2 corresponding to a lesser flux density B_3 and the new air-gap line is OA_2. If the gap is now closed to its original value, the magnet will not return to operation at point A_1 but will operate at some point C on the line OA_1. If the air gap is varied between the two foregoing values, the magnet will operate along the **minor hysteresis loop** A_2C. Return to point A_1 can be accomplished only by remagnetizing and coming back down the curve from B to A_1.

Alnico magnets corresponding to curves 4 and 5 are best adapted to operation with short air gaps, since the introduction of a long air gap will demagnetize the magnet materially. On the other hand, a magnet with a long air gap will operate most satisfactorily on curve 6 on account of the high coercive force H_2. With change in the length of the air gap, the operation will be essentially along that curve and the magnet will lose little of its original magnetization.

There are several other grades of Alnico with characteristics between curves 4, 5, and 6. Ceramic PM materials have a very large coercive force.

The steels for permanent magnets are cut in strips, heated to a red-hot temperature, and forged into shape, usually in a "bulldozer." If they are to be machined, they are cooled in mica dust to prevent air hardening. They are then ground, tumbled, and tempered. Alnico and ceramic types are cast and then finish-ground.

Permanent magnets are magnetized either by placing them over a bus bar carrying a large direct current, by placing them across the poles of a powerful electromagnet, or by an ampere-turn pulse.

Unless permanent magnets are subjected to artificial aging, they gradually weaken until after a long period they become stabilized usually at from 85 to 90 percent of their initial strength. With magnets for electrical instruments, where a constant field strength is imperative, artificial aging is accomplished by mechanical vibration or by immersion in oil at 250°F for a period of a few hours.

In an **electromagnet** the magnetic field is produced by an electric current. The core is usually made of soft iron or mild steel because, the permeability being higher, a stronger magnetic field may be obtained. Also since the retentivity is low, there is little trouble due to the sticking of armatures when the circuit is opened. Electromagnets may have the form of simple solenoids, iron-clad solenoids, plunger electromagnets, electromagnets with external armatures, and lifting magnets, which are circular in form with a flat holding surface.

A **solenoid** is a winding of insulated conductor and is wound helically; the direction of winding may be either right or left. A **portative electromagnet** is one designed only for holding material brought in contact with it. A **tractive electromagnet** is one designed to exert a force on the load through some distance and thus do work. The **range** of an electromagnet is the distance through which the plunger will perform work when the winding is energized. For long range of operation, the plunger type of tractive magnet is best suited, for the length of core is governed practically by the range of action desired, and the area of the core is

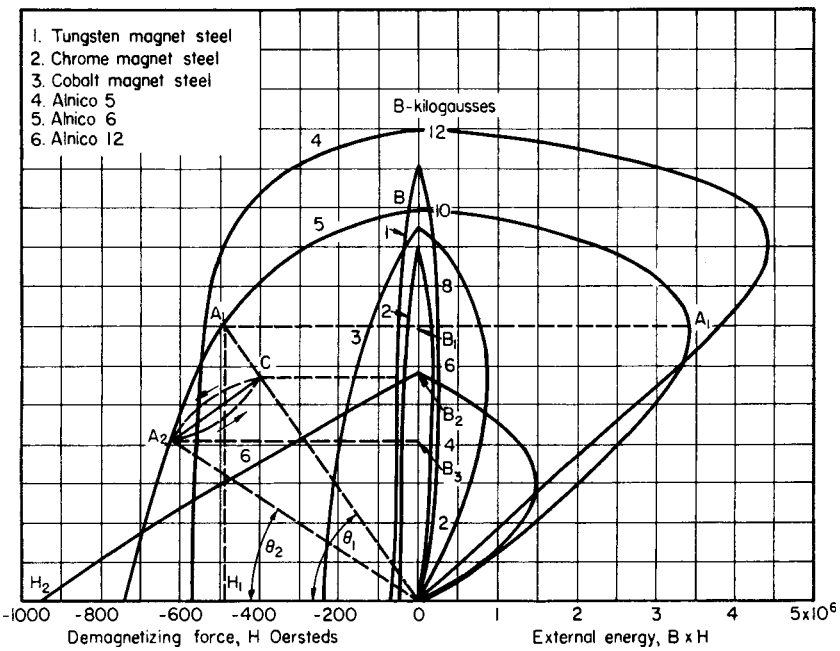

Fig. 15.1.97 Characteristics of permanent magnet materials.

SOURCE: From data by Underhill, *Elec. World,* 45, 1906, pp. 796, 881.

determined by the pull. **Solenoid and plunger** is a solenoid provided with a movable iron rod or bar called a plunger. When the coil is energized, the iron rod becomes magnetized and the mutual action of the field in the solenoid on the poles created on the plunger causes the plunger to move within the solenoid. This force becomes zero only when the magnetic centers of the plunger and solenoid coincide. If the load is attached to the plunger, work will be done until the force to be overcome is equal to the force that the solenoid exerts on the plunger. When the iron of the plunger is not saturated, the strength of magnetic field in the solenoid and the induced poles are both proportional to the exciting current, so that the pull varies as the **current squared**. When the plunger becomes highly saturated, the pull varies almost **directly** with the current.

The **maximum uniform pull** occurs when the end of the plunger is at the center of the solenoid and is equal to

$$F = CAnI/l \qquad \text{lb} \qquad (15.1.134)$$

where A = cross-sectional area of plunger, in^2; n = number of turns; I = current, A; l = length of the solenoid, in; and C = pull, (lb/in^2)/(A-turn/in). C depends on the proportions of the coil, the degree of saturation, the length, and the physical and chemical purity of the plunger. Table 15.1.27 gives values of C for several different solenoids.

Curve 1, Fig. 15.1.98, shows the characteristic pull of an open-magnetic circuit solenoid, 12 in long, having 10,000 A-turns or 833 A-turns/in.

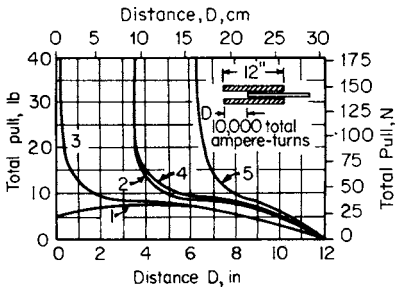

Fig. 15.1.98 Pull on solenoid with plunger. (1) Coil and plunger; (2) coil and plunger with stop; (3) iron-clad coil and plunger; (4) and (5) same as (3) with different lengths of stop.

When a **strong pull** is desired at the end of the stroke, a stop may be used as shown in Fig. 15.1.99. Curve 2, Fig. 15.1.98, shows the pull obtained by adding a stop to the plunger. It will be noted that, except when the end of the plunger is near the stop, the stop adds little to the solenoid pull. The pull is made up of two components: one due to the attraction between plunger and winding, the other to the attraction between plunger and stop. The equation for the pull is

$$P = AIn[(In/l_a^2C_1^2) + (C/l)] \qquad (15.1.135)$$

where A = area of the core, in^2; n = number of turns; l_a = length of gap between core and stop; and C, C_1 = constants. At the beginning of the stroke the second member of the equation is predominant, and at the end

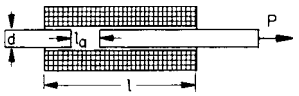

Fig. 15.1.99 Solenoid with stop.

of the stroke the first member represents practically the entire pull. Approximate values of C and C_1 are $C_1 = 2{,}660$ (for l greater than $10d$), $C = 0.0096$, where d is the diameter of the plunger, in. In SI units

$$P = 1.7512AnI\left(\frac{2.54nI}{l_a^2C_1^2} + \frac{C}{l}\right) \qquad \text{N} \qquad (15.1.135a)$$

where A is in cm^2, l and l_a in cm, and the pull P in N. All other quantities are unchanged.

The **range of uniform** pull can be extended by the use of conical ends of stop and plunger, as shown in Fig. 15.1.100. A stronger magnet mechanically can be obtained by using an iron-clad solenoid, Fig. 15.1.101, in which an iron return path is provided for the flux. Except for low flux densities and short air gaps the dimensions of the iron

Fig. 15.1.100 Conical plunger and stop.

return path are of no practical importance, and the fact that an iron return path is used does not affect the pull curve except at short air gaps. This is illustrated in Fig. 15.1.98 where curves 3, 4, and 5 are typical pull curves for this same solenoid when it is made iron-clad, each curve corresponding to a different position of the stop.

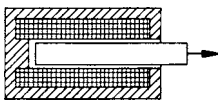

Fig. 15.1.101 Iron-clad solenoid.

Mechanical jar at the end of the stroke may be prevented by leaving the end of the solenoid open. The plunger then comes to equilibrium when its middle is at the middle of the winding, thus providing a magnetic cushion effect. Electromagnets with external armatures are best adapted for **short-range** work, and the best type is the horseshoe magnet. The pull for short-range magnets is expressed by the equation

$$F = B^2A/72{,}134{,}000 \qquad \text{lb} \qquad (15.1.136)$$

where B = flux density, Mx/in^2, and A = area of the core, in^2.

In SI units

$$F = 397{,}840B^2A \qquad \text{N} \qquad (15.1.136a)$$

where the flux density B is in Wb/m^2; A = area, m^2; and F = force, N.

A greater holding power is obtained if the surfaces of the armature and core are not machined to an absolutely smooth contact surface. If the surface is slightly irregular, the area of contact A is reduced but the flux density B is increased approximately in proportion (if the iron is

being operated below saturation) and the pull is increased since it varies as the square of the density B. Nonmagnetic stops should be used if it is desired that the armature may be released readily when the current is interrupted.

Lifting magnets are of the portative type in that their function is merely to hold the load. The actual lifting is performed by the hoisting apparatus. The magnet is almost toroidal in shape. The coil shield is of manganese steel which is very hard and thus resists wear and is practically nonmagnetic. The holding power is given by Eq. (15.1.136), where A = area of holding surface, in^2. It is difficult to calculate accurately the holding force of a lifting magnet for it depends on the magnetic characteristics of the load, the area of contact, and the manner in which the load is applied.

Rapid action in a magnet can be obtained by reducing the time constant of the winding and by subdividing the metal parts to reduce induced currents which have a demagnetizing effect when the circuit is closed. The movement of the plunger through the winding causes the winding and its bobbin to be cut by a magnetic field; if the bobbin is of metal and not slotted longitudinally, it is a short-circuited turn linked by a changing magnetic field and hence currents are induced in it. These currents oppose the flux and hence reduce the pull during the transient period. They also cause some heating. Where it is found impossible to reduce the time constant sufficiently, an electromagnet designed for a voltage much lower than normal is often used. A resistor is connected in series which is short-circuited during the stroke of the plunger. At the completion of the stroke the plunger automatically opens the short circuit, reducing the current to a value which will not overheat the magnet under continuous operation. The extremely short time of overload produces very rapid action but does not injure the winding. The solenoids on many automatic motor-starting panels are designed in this manner.

When **slow action** is desired, it can be obtained by using solid cores and yoke and by using a heavy metallic spool or bobbin for the winding. A separate winding short-circuited on itself is also used to some extent.

Sparking at switch terminals may be reduced or eliminated by neutralizing the inductance of the winding. This is accomplished by winding a separate short-circuited coil with its wires parallel to those of the active winding. (This method can be used with dc magnets only.) This is not economical, since one-half the winding space is wasted. By connecting a capacitor across the switch terminals, the energy of the inductive discharge on opening the circuit may be absorbed. For the purpose of neutralizing the inductive discharge and causing a quick release, a small **reverse current** may be sent through the coil winding automatically on opening the circuit. Sleeves of tin, aluminum, or copper foil placed over the various layers of the winding absorb energy when the circuit is broken and reduce the energy dissipated at the switch terminals. This scheme can be used for dc magnets only. **Sticking** of the parts of the magnetic circuit due to residual magnetism may be prevented by the use of nonmagnetic stops. In the case of lifting magnets subjected to rough usage and hard blows (as in a steel works), these stops usually consist of plates of manganese steel, which are extremely hard and nonmagnetic.

AC Tractive Magnets Because of the iron losses due to eddy currents, the magnetic circuits of ac electromagnets should be composed of laminated iron or steel. The magnetic circuit of large magnets is usually built up of thin sheets of sheet metal held together by means of suitable clamps. Small cores of circular cross section usually consist of a bundle of soft iron wires. Since the iron losses increase with the flux density, it is not advisable to operate at as high a density as with direct current. The current instead of being limited by the resistance of the winding is now determined almost entirely by the inductive reactance as the resistance is small. With the removal of the load the current rises to high values. The pull of ac magnets is nearly constant irrespective of the length of air gap.

In a **single-phase magnet** the pull varies from zero to a maximum and back to zero twice every cycle, which may cause considerable chattering of the armature against the stop. This may be prevented by the use of a spring or, in the case of a solenoid coil, by allowing the plunger to seek its position of equilibrium in the coil. **Chattering** may also be prevented by the use of a short-circuited winding or shading coil around one tip of the pole piece or by the use of polyphase. In a **two-phase magnet** the pull is constant and equal to the maximum instantaneous pull produced by one phase so long as the voltage is a sine function. In a **three-phase magnet** under the same conditions the pull is constant and equal to 1.5 times the maximum instantaneous pull of one phase. Should the load become greater than the minimum instantaneous pull, there will be chattering as in a single-phase magnet.

Heating of Magnets The lifting capacity of an electromagnet is limited by the permissible current-carrying capacity of the winding, which, in turn, is dependent on the amount of heat energy that the winding can dissipate per unit time without exceeding a given temperature rise. **Enamels, synthetic varnishes,** and **thermoplastic wire insulations** are available to allow a wide variety of temperature rises.

Design of Exciting Coil Let n = number of turns, l = mean length of turn, in ($l = 2\pi r$, where r is the mean radius, in), A = cross section of wire, cir mils. The resistance of 1 cir mil · ft of copper is practically 12 Ω at 60°C, or 1 Ω/cir mil · in. Hence the resistance, $R = nl/A$ Ω; the current, $I = EA/nl$; the ampere-turns, $nI = EA/l$; the power to be dissipated, $P = E^2A/nl$ W. From the foregoing equations the cross section of wire and the number of turns can be calculated.

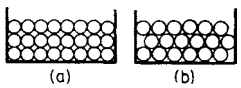

Fig. 15.1.102 Winding space factor.

Space Factor of Winding Space factor of a coil is the ratio of the space occupied by the conductor to the total volume of the coil or winding. Only in the theoretical case of uninsulated square or rectangular conductor may the space factor be 100 percent. For wire of circular section with insulation of negligible thickness, wound as shown in Fig. 15.1.102*a*, the space factor will be 78.5 percent. When the turns of wire are "bedded," as shown in Fig. 15.1.102*b* (the case in most windings, particularly with smaller wires), there is a theoretical gain of about 7 percent in space factor. Experiments have shown that in most cases this gain is about neutralized in practice by the flattening out of the insulation of the wire due to the tension used in winding. When wound in a haphazard manner, the space factors of magnet wires vary according to size, substantially as follows:

	Double covered				Single covered			
Size, AWG	0	5	10	15	20	25	30	35
Space factor, %	60	53.8	45.5	35.1	32.2	32	25.7	16

Magnet wire is usually a soft annealed copper wire of high conductivity. It can be obtained in square, rectangular, and circular conductors. Round or cylindrical wire is almost entirely used in smaller sizes; ribbons are frequently used in the larger sizes. Common round wire sizes for copper magnet wire include No. 42 AWG (0.0025-in bare wire diameter) to 8 AWG (0.1285 in). Common round wire sizes for aluminum magnet wire include No. 26 AWG to No. 4 AWG. For use in very small devices, ultrafine round magnet wire is available in sizes as small as No. 60 AWG copper and No. 52 aluminum.

Magnet wire insulation has evolved to become high in electrical, physical, and thermal performance. Polymers are most commonly used for film-insulated magnet wire and are based on polyvinyl acetates, polyesters, polyamideimides, polyimides, polyamides, and polyurethanes. It is common to use different layers of polymers to obtain the best performance for a specific application. Film-insulated magnet wires are available in temperature classes from 105 to 200°C, each with specific advantages such as solderability, thermal stability, transformer resistance, chemical resistance, windability, and toughness.

Magnet wire is also produced with fabric layers served over bare or conventional film-insulated wire. Fabric materials include fiberglass,

polyester (Dacron), aromatic polyamide (Nomex) paper, and aromatic polyamide film (Kapton). Fibrous insulated magnet wires are available in temperature classes from 105 to 220°C, each with specific advantages such as high dielectric strength, positive separation of conductors, high thermal and chemical stability, physical protection, and high-temperature performance.

AUTOMOBILE SYSTEMS

The evolution of automobile electrical systems toward microprocessors has transformed all aspects of automotive engineering, operation, and repair. Engine operation, emission controls, drive-train control, operator interfaces to vehicle operation and drive controls, entertainment systems, and communication and navigational systems, are commonplace and will continue to evolve. At the heart of understanding the operation of the car/truck for-cycle combustion engine is a basic electrical system that has supported engine operation for generations. The following information describes electrical-based automotive ignition, starting, lighting, and accessory systems commonly used prior to microprocessor-based systems.

Automobile Ignition Systems

The ignition system in an automobile produces the spark which ignites the combustible mixture in the engine cylinders. This is accomplished by a high-voltage, or high-tension, spark between metal points in a spark plug. (A spark plug is an insulated bushing screwed into the cylinder head.) Spark plugs usually have porcelain insulation, but for some special uses, such as in airplane engines, mica may be used. There are two general sources for the energy necessary for ignition; one is the electrical system of the car which is maintained by the generator and the battery **(battery ignition),** and the other is a **magneto.** Battery ignition systems have traditionally operated electromechanically, using a spark coil, a high-voltage distributor, and low-voltage breaker points. Electronic ignition systems, working from the battery, became standard on U.S. cars in 1975. These vary in complexity from the use of a single transistor to reduce the current through the points to pointless systems triggered by magnetic pulses or interrupted light beams. Capacitor discharge into a pulse transformer is used in some systems to obtain the high voltage needed to fire the spark plugs.

Battery ignition is most widely used since it is simple, reliable, and low in cost, and the electrical system is a part of the car equipment. The high voltage for the spark is obtained from an ignition coil which consists of a primary coil of relatively few turns and a secondary coil of a large number of turns, both coils being wound on a common magnetic core consisting of either thin strips of iron or small iron wires. In a 6-V system the resistance of the primary coil is from 0.9 to 2 Ω and the inductance is from 5 to 10 mH. The number of secondary turns varies from 9,000 to 25,000, and the ratio of primary to secondary turns varies from 1 : 40 to 1 : 100.

The coil operates on the following principle. It stores energy in a magnetic field relatively slowly and then releases it suddenly. The power developed ($p = dw/dt$) is thus relatively large (w = stored energy). The high emf e_2 which is required for the spark is induced by the sudden change in the flux ϕ in the core of the coil when the primary current is suddenly interrupted, $e_2 = -n_2(d\phi/dt)$, where n_2 is the number of secondary turns. For satisfactory ignition, peak voltages from 10 to 20 kV are desirable. Figure 15.1.103 shows the relation between the volts required to produce a spark and pressure with compressed air.

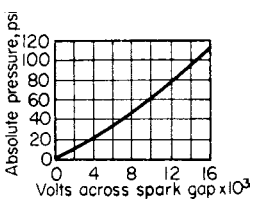

Fig. 15.1.103 Pressure-voltage curve for spark plug.

A battery ignition system for a four-cylinder engine is shown diagrammatically in Fig. 15.1.104. The primary circuit supplied by the battery consists of the primary coil *P* and a set of contacts, or "points" operated by a four-lobe cam, in series. In order to reduce arcing and burning of the contacts and to produce a sharp break in the current, a capacitor *C* is connected across the contacts. The contacts, which are of pure tungsten, are operated by a four-lobe cam which is driven at one-half engine speed. A strong spring tends to keep the contacts closed.

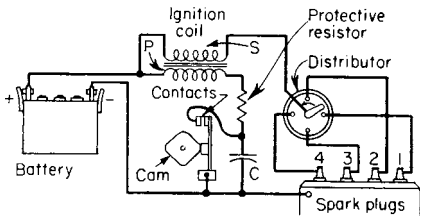

Fig. 15.1.104 Battery-ignition system.

In the Delco-Remy distributor (Fig. 15.1.105) two breaker arms are connected in parallel; one coil and one capacitor are used. One set of contacts is open when the other is just breaking but closes a few degrees after the break occurs. This closes the primary of the ignition coil immediately after the break and increases the time that the primary of the ignition coil is closed and permits the flux in the iron to reach its full value. The interrupter shown in Fig. 15.1.105 is designed for an eight-cylinder engine.

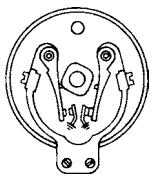

Fig. 15.1.105 Delco-Remy dual-point eight-cylinder interrupter.

Electronic ignition systems have no problem operating at the required speed.

The spark should advance with increase in engine speed so as to allow for the time lag in the explosion. To take care of this automatic timers are equipped with centrifugally operated weights which advance the breaker cam with respect to the engine drive as the speed increases.

Automobile Lighting and Starting Systems

Automobile lighting and starting systems initially operated at 6 V, but at present nearly all cars operate at 12 V because larger engines, particularly V-8s, are now common and require more starting power. With 12 V, for the same power, the starting current is halved, and the effect of resistance in the leads, connections, and brushes is materially reduced. In some systems the positive side of the system is grounded, but more often the negative side is grounded.

A further development is the application of an **ac generator,** or alternator, combined with a rectifier as the generating unit rather than the usual dc generator. One advantage is the elimination of the commutator, made up of segments, which requires some maintenance due to the sparking and wear of the carbon brushes. With the alteraator the dc field rotates, the brushes operating on smooth slip rings require almost no maintenance. Also, the system is greatly simplified by the fact that rectifiers are "one-way" devices, and the battery **cannot** deliver current back to the generator when its voltage drops below that of the battery. Thus, no cutout relay, such as is required with dc generators, is necessary. This ac development is the result of the development of reliable, low-cost germanium and silicon semiconductor rectifiers.

Figure 15.1.106 shows a schematic diagram of the Ford system (adapted initially to trucks). The generator stator is wound three-phase

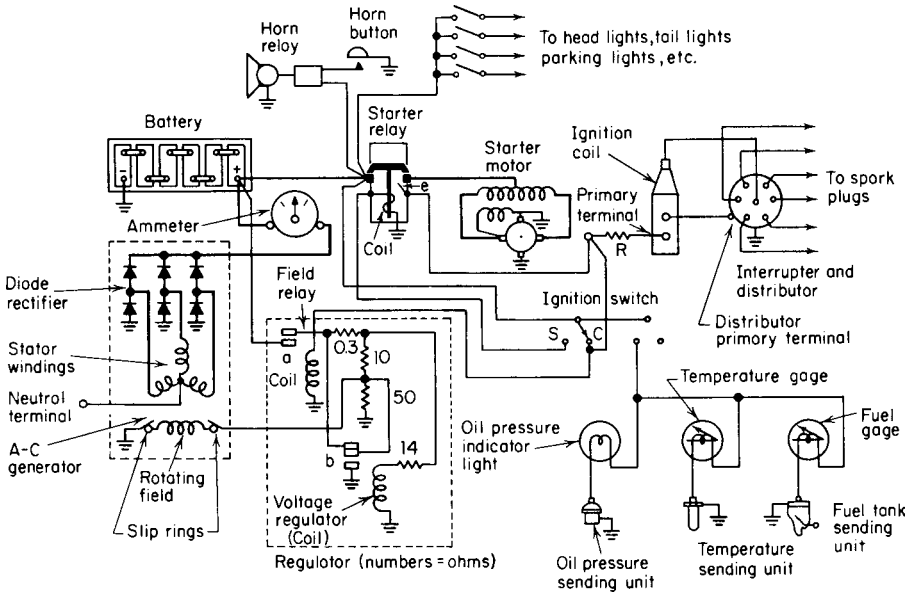

Fig. 15.1.106 Schematic diagram of Ford lighting and starting system.

Y-connected, and the field is bipolar supplied with direct current through slip rings and brushes. The rectifier diodes are connected full-wave bridge circuit to supply the battery through the ammeter.

Regulator The function of the regulator is to control the generator current so that its value is adapted to the battery voltage which is related to the condition of charge of the battery (see Fig. 15.1.15). Thus, when the battery voltage drops (indicating a lowered condition of charge), the current should be increased, and, conversely, when the battery voltage increases (indicating a high condition of charge), the current should be decreased.

Neglecting for the moment the starting procedure, when the ignition switch is thrown to the normal "on" position at *c*, the coil actuating the field relay is connected to the battery + terminal and causes the relay contacts *a* to close. This energizes the regulator circuits, and, if the two upper voltage regulator contacts *b* are closed as shown, the rotating field of the alternator is connected directly to the battery + terminal, and the field current is then at its maximum value and produces a high generator voltage and large output current. At the same time the voltage regulator coil in series with the 0.3- and 14-Ω resistors is connected between the battery + terminal and ground. If the voltage of the battery rises owing to its higher condition of charge, the current to the voltage regulator coil increases, causing it to open the two upper contacts at *b*. Current from the battery now flows through the 0.3-Ω resistor and divides, some going through the 10-Ω resistor and dividing between the field and the 50-Ω resistor, and the remainder going to the voltage regulator coil. The current to the rotating field is thus reduced, causing the alternator output to be reduced. Because of the 0.3 Ω now in circuit, the current to the coil of the voltage regulator is reduced to such a value that it holds the center contact at *b* in the mid, or open, position. If the battery voltage rises to an even higher value, the regulator coil becomes strong enough to close the lower contacts at *b*; this short-circuits the field, reducing its current almost to zero, and thus reducing the alternator output to zero. On the other hand when the battery voltage drops, the foregoing sequence is reversed, and the contacts at *b* operate to increase the current to the alternator field.

As was mentioned earlier, the battery cannot supply current to the alternator because of the "one-way" characteristic of the rectifier. Thus, when the alternator voltage drops below that of the battery and even when the alternator stops running, its current automatically becomes zero. The alternator has a normal rectifier open-circuit voltage of about 14 V and a rating of 20 A.

Starting In most cases, for starting, the ignition key is turned far to the right and held there until the motor starts. Then, when the key is released, the ignition switch contacts assume a normal operating position. Thus, in Fig. 15.1.106, when the ignition-switch contact is in the starting position *S*, the starter relay coil becomes connected by a lead to the battery + terminal and thus becomes energized, closing the relay contacts. The starter motor is then connected to the battery to crank the engine. At the time that the contact closes it makes contact with a small metal brush *e* which connects the battery + terminal to the primary terminal of the ignition coil through the protective resistor *R*. After the motor starts, the ignition switch contacts spring to the normal operating position *C*, and the starter relay switch opens, thereby breaking contact with the small brush *e*. However, when contact *C* is closed, the ignition coil primary terminal is now connected through leads to the battery + terminal. The interrupter, the ignition coil, and the distributor now operate in the manner described earlier (see Fig. 15.1.104); the system shown in Fig. 15.1.106 is that for a six-cylinder engine.

The connection of **accessories** to the electric system is illustrated in Fig. 15.1.106 for the horn, head and other lights, and temperature and fuel gages.

15.2 ELECTRONICS

The subject of electronics can be approached from the standpoint of either the design of devices or the use of devices. The practicing mechanical engineer has little interest in designing devices, so the approach in this article will be to describe devices in terms of their external characteristics.

COMPONENTS

Resistors, capacitors, reactors, and **transformers** are described earlier in this section, along with basic circuit theory. These explanations are equally applicable to electronic circuits and hence are not repeated here. A description of additional components peculiar to electronic circuits follows.

A **rectifier,** or **diode,** is an electronic device which offers unequal resistance to forward and reverse current flow. Figure 15.2.1 shows the schematic symbol for a diode. The arrow beside the diode shows the

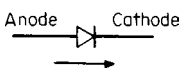

Fig. 15.2.1 Diode schematic symbol.

direction of current flow. Current flow is taken to be the flow of positive charges, i.e., the arrow is counter to electron flow. Figure 15.2.2 shows typical forward and reverse volt-ampere characteristics. Notice that the scales for voltage and current are not the same for the first and third quadrants. This has been done so that both the forward and reverse characteristics can be shown on a single plot even though they differ by several orders of magnitude.

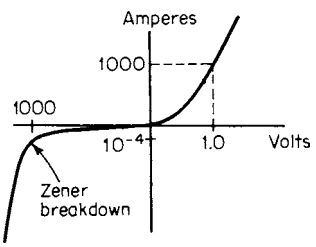

Fig. 15.2.2 Diode forward-reverse characteristic.

Diodes are rated for forward current capacity and reverse voltage breakdown. They are manufactured with maximum current capabilities ranging from 0.05 A to more than 1,000 A. Reverse voltage breakdown varies from 50 V to more than 2,500 V. At rated forward current, the forward voltage drop varies between 0.7 and 1.5 V for silicon diodes. Although other materials are used for special-purpose devices, by far the most common semiconductor material is silicon. With a forward current of 1,000 A and a forward voltage drop of 1 V, there would be a power loss in the diode of 1,000 W (more than 1 hp). The basic diode package shown in Fig. 15.2.3 can dissipate about 20 W. To maintain an acceptable temperature in the diode, it is necessary to mount the diode on a **heat sink.** The manufacturer's recommendation should be followed

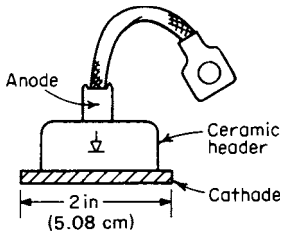

Fig. 15.2.3 Physical diode package.

very carefully to ensure good heat transfer and at the same time avoid fracturing the silicon chip inside the diode package.

The selection of **fuses** or **circuit breakers** for the protection of **rectifiers** and rectifier circuitry requires more care than for other electronic devices. Diode failures as a result of circuit faults occur in a fraction of a millisecond. Special semiconductor fuses have been developed specifically for semiconductor circuits. Proper protective circuits must be provided for the protection of not only semiconductors but also the rest of the circuit and nearby personnel. Diodes and diode fuses have a short-circuit rating in amperes-squared-seconds (I^2t). As long as the I^2t rating of the diode exceeds the I^2t rating of its protective fuse, the diode and its associated circuitry will be protected. Circuit breakers may be used to protect diode circuits, but additional line impedance must be provided to limit the current while the circuit breaker clears. Circuit breakers do not interrupt the current when their contacts open. The fault is not cleared until the line voltage reverses at the end of the cycle of the applied voltage. This means that the **clearing time for a circuit breaker** is about $\frac{1}{2}$ cycle of the ac input voltage. Diodes have a 1-cycle overcurrent rating which indicates the fault current the diode can carry for circuit breaker protection schemes. Line inductance is normally provided to limit fault currents for breaker protection. Often this inductance is in the form of leakage reactance in the transformer which supplies power to the diode circuit.

A **thyristor,** often called a **silicon-controlled rectifier (SCR),** is a rectifier which blocks current in both the forward and reverse directions. Conduction of current in the forward direction will occur when the anode is positive with respect to the cathode and when the gate is pulsed positive with respect to the cathode. Once the thyristor has begun to conduct, the gate pulse can return to 0 V or even go negative and the thyristor will continue to pass current. To stop the cathode-to-anode current, it is necessary to reverse the cathode-to-anode voltage. The thyristor will again be able to block both forward and reverse voltages until current flow is initiated by a gate pulse. The schematic symbol for an SCR is shown in Fig. 15.2.4. The physical packaging of thyristors is

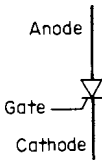

Fig. 15.2.4 Thyristor schematic symbol.

similar to that of rectifiers with similar ratings except, of course, that the thyristor must have an additional gate connection.

The gate pulse required to fire an SCR is quite small compared with the anode voltage and current. Power gains in the range of 10^6 to 10^9 are easily obtained. In addition, the power loss in the thyristor is very low, compared with the power it controls, so that it is a very efficient power-controlling device. Efficiency in a thyristor power supply is usually 97 to 99 percent. When the thyristor blocks either forward or reverse current, the high voltage drop across the thyristor accompanies low current. When the thyristor is conducting forward current after having been fired by its gate pulse, the high anode current occurs with a forward voltage drop of about 1.5 V. Since high voltage and high current never occur simultaneously, the power dissipation in both the on and off states is low.

The thyristor is rated primarily on the basis of its forward-current capacity and its voltage-blocking capability. Devices are manufactured to have equal forward and reverse voltage-blocking capability. Like diodes, thyristors have I^2t ratings and 1-cycle surge current ratings to allow design of protective circuits. In addition to these ratings, which the SCR shares in common with diodes, the SCR has many additional specifications. Because the thyristor is limited in part by its average current and in part by its rms current, forward-current capacity is a function of the duty cycle to which the device is subjected. Since the thyristor cannot regain its blocking ability until its anode voltage is reversed and remains reversed for a short time, this time must be specified. The time to regain blocking ability after the anode voltage has been reversed is called the **turn-off time.** Specifications are also given for minimum and maximum gate drive. If forward blocking voltage is reapplied too quickly, the SCR may fire with no applied gate voltage pulse. The maximum safe value of rate of reapplied voltage is called the *dv/dt* rating of the SCR. When the gate pulse is applied, current begins to flow in the area immediately adjacent to the gate junction. Rather quickly, the current spreads across the entire cathode-junction area. In some circuits associated with the thyristor an extremely fast rate of rise of current may occur. In this event localized heating of the cathode may occur with a resulting immediate failure or in less extreme cases a slow degradation of the thyristor. The maximum rate of change of current for a thyristor is given by its *di/dt* rating. Design for *di/dt* and *dv/dt* limits is not normally a problem at power-line frequencies of 50 and 60 Hz. These ratings become a design factor at frequencies of 500 Hz and greater. Table 15.2.1 lists typical thyristor characteristics.

A **triac** is a bilateral SCR. It blocks current in either direction until it receives a gate pulse. It can be used to control in ac circuits. Triacs are widely used for light dimmers and for the control of small universal ac motors. The triac must regain its blocking ability as the line voltage crosses through zero. This fact limits the use of triacs to 60 Hz and below.

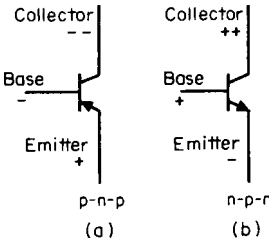

Fig. 15.2.5 Transistor schematic symbol.

A **transistor** is a semiconductor amplifier. The schematic symbol for a transistor is shown in Fig. 15.2.5. There are two types of transistors, *p-n-p* and *n-p-n*. Notice that the polarities of voltage applied to these devices are opposite. In many sizes matched *p-n-p* and *n-p-n* devices are available. The most common transistors have a collector dissipation rating of 150 to 600 mW. Collector to base breakdown voltage is 20 to 50 V. The amplification or gain of a transistor occurs because of two facts: (1) A small change in current in the base circuit causes a large change in current in the collector and emitter leads. This current amplification is designated *hfe* on most transistor specification sheets. (2) A small change in base-to-emitter voltage can cause a large change in either the collector-to-base voltage or the collector-to-emitter voltage. Table 15.2.2 shows basic ratings for some typical transistors. There is a great profusion of transistor types so that the choice of type depends upon availability and cost as well as operating characteristics.

The gain of a transistor is independent of frequency over a wide range. At high frequency, the gain falls off. This cutoff frequency may be as low as 20 kHz for audio transistors or as high as 1 GHz for radio-frequency (rf) transistors.

The schematic symbols for the field effect transistor (FET) is shown in Fig. 15.2.6. The flow of current from source to drain is controlled by an electric field established in the device by the voltage applied between the gate and the drain. The effect of this field is to change the resistance of the transistor by altering its internal current path. The FET has an extremely high gate resistance (10^{12} Ω), and as a consequence, it is used for applications requiring high input impedance. Some FETs have been designed for high-frequency characteristics. The two basic constructions used for FETs are **bipolar junctions** and **metal oxide semiconductors.** The schematic symbols for each of these are shown in Fig. 15.2.6*a* and 15.2.6*b*. These are called JFETs and MOSFETs to distinguish between them. JFETs and MOSFETs are used as stand-alone devices and are also widely used in integrated circuits. (See below, this section.)

A MOSFET with higher current capacity is called a **power MOSFET.** Table 15.2.3 shows some typical characteristics for power MOSFETs. Power MOSFETs are somewhat more limited in maximum power than are thyristors. Circuits with multiple power MOSFETs are limited to about 20 kW. Thyristors are limited to about 1500 kW. As a point of interest, there are electric power applications in the hundreds of megawatts which incorporate massively series and parallel thyristors. An advantage of power MOSFETs is that they can be turned on and turned off by means of the gate-source voltage. Thus low-power electric

control can turn the device on and off. Thyristors can be turned on only by their gate voltage. To turn a thyristor off it is necessary for its high-powered anode-to-cathode voltage to be reversed. This factor adds complication to many thyristor circuits. Another power device which is

similar to the power MOSFET is the **insulated gate-bipolar transistor (IGBT).** This device is a **Darlington** combination of a MOSFET and a bipolar transistor (see Fig. 15.2.13). A low-power MOSFET first transistor drives the base of a second high-power bipolar transistor. These two transistors are integrated in a single case. The IGBT is applied in high-power devices which use high-frequency switching. IGBTs are available in ratings similar to thyristors (see Table 15.2.1), so they are power devices. The advantage of the IGBT is that it can be switched on and off by means of its gate. The advantage of an IGBT over a power MOSFET is that it can be made with higher power ratings.

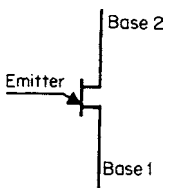

Fig. 15.2.7 Unijunction.

The **unijunction** is a special-purpose semiconductor device. It is a pulse generator and widely used to fire thyristors and triacs as well as in timing circuits and waveshaping circuits. The schematic symbol for a unijunction is shown in Fig. 15.2.7. The device is essentially a silicon resistor. This resistor is connected to base 1 and base 2. The emitter is fastened to this resistor about halfway between bases 1 and 2. If a positive voltage is applied to base 2, and if the emitter and base 1 are at zero, the emitter junction is back-biased and no current flows in the emitter. If the emitter voltage is made increasingly positive, the emitter junction will become forward-biased. When this occurs, the resistance between base 1 and base 2 and between base 2 and the emitter suddenly switches to a very low value. This is a regenerative action, so that very fast and very energetic pulses can be generated with this device.

Before the advent of semiconductors, electronic rectifiers and amplifiers were **vacuum tubes** or **gas-filled tubes**. Some use of these devices still remains. If an electrode is heated in a vacuum, it gives up surface electrons. If an electric field is established between this heated electrode and another electrode so that the electrons are attracted to the other electrode, a current will flow through the vacuum. Electrons flow from the heated cathode to the cold anode. If the polarity is reversed, since there are no free electrons around the anode, no current will flow. This, then, is a vacuum-tube rectifier. If a third electrode, called a **control grid,** is placed between the cathode and the anode, the flow of electrons from the cathode to the anode can be controlled. This is a basic vacuum-tube amplifier. Additional grids have been placed between the cathode and anode to further enhance certain characteristics of the vacuum tube. In addition, multiple anodes and cathodes have been enclosed in a single tube for special applications such as radio signal converters.

If an inert gas, such as neon or argon, is introduced into the vacuum, conduction can be initiated from a cold electrode. The breakdown voltage is relatively stable for given gas and gas pressure and is in the range of 50 to 200 V. The **nixie** display tube is such a device. This tube contains 10 cathodes shaped in the form of the numerals from 0 to 9. If one of these cathodes is made negative with respect to the anode in the tube, the gas in the tube glows around that cathode. In this way each of the 10 numerals can be made to glow when the appropriate electrode is energized.

An **ignitron** is a vapor-filled tube. It has a pool of liquid mercury in the bottom of the tube. Air is exhausted from the enclosure, leaving only mercury vapor, which comes from the pool at the bottom. If no current is flowing, this tube will block voltage whether the anode is plus or minus with respect to the mercury-pool cathode. A small rod called an **ignitor** can form a cathode spot on the pool of mercury when it is withdrawn from the pool. The ignitor is pulled out of the pool by an electromagnet. Once the cathode spot has been formed, electrons will continue to flow from the mercury-pool cathode to the anode until the anode-to-cathode voltage is reversed. The operation of an ignitron is very similar to that of a thyristor. The anode and cathode of each device perform similar functions. The ignitor and gate also perform similar functions. The thyristor is capable of operating at much higher frequencies than the ignitron and is much more efficient since the thyristor has 15 V forward drop and the ignitron has 15 V forward drop. The ignitron has an advantage over the thyristor in that it can carry extremely high overload currents without damage. For this reason ignitrons are often used as electronic "crowbars" which discharge electrical energy when a fault occurs in a circuit.

DISCRETE-COMPONENT CIRCUITS

Several common rectifier circuits are shown in Fig. 15.2.8. The waveforms shown in this figure assume no line reactance. The presence of line reactance will make a slight difference in the waveshapes and the conversion factors shown in Fig. 15.2.8. These waveshapes are equally applicable for loads which are pure resistive or resistive and inductive.

Type	Circuit	Output voltage waveform	E_{dc} (avg)	Ripple fundamental frequency	% ripple	Peak inverse voltage
Half-wave 1φ			0.318 E_M 0.45 E_{ac}	F	121	3.14 E_{dc}
Full-wave 1φ			0.636 E_M 0.9 E_{ac}	2F	48	3.14 E_{dc}
Bridge 1φ			0.636 E_M 0.9 E_{ac}	2F	48	1.57 E_{dc}
Half-wave 3φ			0.827 E_M 1.17 E_{ac}	3F	18	2.09 E_{dc}

E_M = maximum value of e_{ac}
E_{ac} = effective value of e_{ac}
E_{dc} = average value of d-c load voltage
F = line frequency
% ripple = 100 x rms ripple / E_{dc}

Fig. 15.2.8 Comparison of rectifier circuits.

In a resistive load the current flowing in the load has the same waveshape as the voltage applied to it. For inductive loads, the current waveshape will be smoother than the voltage applied. If the inductance is high enough, the ripple in the current may be indeterminantly small. An approximation of the ripple current can be calculated as follows:

$$I = \frac{E_{dc} PCT}{200\pi f N L} \tag{15.2.1}$$

where I = rms ripple current, E_{dc} = dc load voltage, PCT = percent ripple from Fig. 15.2.8, f = line frequency, N = number of cycles of ripple frequency per cycle of line frequency, L = equivalent series inductance in load. Equation (15.2.1) will always give a value of ripple higher than that calculated by more exact means, but this value is normally satisfactory for power-supply design.

Capacitance in the load leads to increased regulation. At light loads, the capacitor will tend to charge up to the peak value of the line voltage and remain there. This means that for either the single full-wave circuit or the single-phase bridge the dc output voltage would be 1.414 times the rms input voltage. As the size of the loading resistor is reduced, or as the size of the parallel load capacitor is reduced, the load voltage will more nearly follow the rectified line voltage and so the dc voltage will approach 0.9 times the rms input voltage for very heavy loads or for very small filter capacitors. One can see then that dc voltage may vary between 1.414 and 0.9 times line voltage due only to waveform changes when **capacitor filtering** is used.

Four different **thyristor rectifier circuits** are shown in Fig. 15.2.9. These circuits are equally suitable for resistive or inductive loads. It will be noted that the half-wave circuit for the thyristor has a rectifier across the load, as in Fig. 15.2.8. This diode is called a **freewheeling diode** because it freewheels and carries inductive load current when the thyristor is not conducting. Without this diode, it would not be possible to build up current in an inductive load. The gate-control circuitry is not shown in Fig. 15.2.9 in order to make the power circuit easier to see. Notice the location of the thyristors and rectifiers in the single-phase full-wave circuit. Constructed this way, the two diodes in series perform the function of a free-wheeling diode. The circuit can be built with a thyristor and rectifier interchanged. This would work for resistive loads but not for inductive loads. For the full three-phase bridge, a freewheeling diode is not required since the carryover from the firing of one SCR to the next does not carry through a large portion of the negative half cycle and therefore current can be built up in an inductive load.

Capacitance must be used with care **in thyristor circuits.** A capacitor directly across any of the circuits in Fig. 15.2.9 will immediately destroy the thyristors. When an SCR is fired directly into a capacitor with no series resistance, the resulting di/dt in the thyristor causes extreme local heating in the device and a resultant failure. A sufficiently high series resistor prevents failure. An inductance in series with a

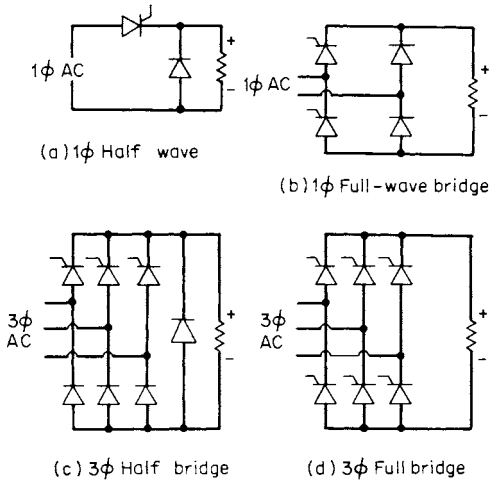

Fig. 15.2.9 Basic thyristor circuits.

capacitor must also be used with caution. The series inductance may cause the capacitor to "ring up." Under this condition, the voltage across the capacitor can approach twice peak line voltage or 2.828 times rms line voltage.

The advantage of the thyristor circuits shown in Fig. 15.2.9 over the rectifier circuits is, of course, that the thyristor circuits provide variable output voltage. The output of the thyristor circuits depends upon the magnitude of the incoming line voltage and the phase angle at which the thyristors are fired. The control characteristic for the thyristor power supply is determined by the waveshape of the output voltage and also by the phase-shifting scheme used in the firing-control means for the thyristor. Practical and economic power supplies usually have control characteristics with some degree of nonlinearity. A representative characteristic is shown in Fig. 15.2.10. This control characteristic is usually given for nominal line voltage with the tacit understanding that variations in line voltage will cause approximately proportional changes in output voltage.

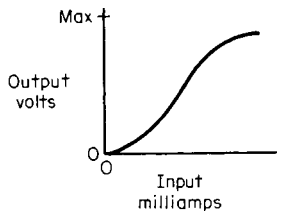

Fig. 15.2.10 Thyristor control characteristic.

Transistor amplifiers can take many different forms. A complete discussion is beyond the scope of this handbook. The circuits described here illustrate basic principles. A basic **single-stage amplifier** is shown in Fig. 15.2.11. The transistor can be cut off by making the input terminal sufficiently negative. It can be saturated by making the input terminal sufficiently positive. In the linear range, the base of an *n-p-n* transistor will be 0.5 to 0.7 V positive with respect to the emitter. The collector voltage will vary from about 0.2 V to V_c (20 V, typically). Note that there is a sign inversion of voltage between the base and the collector; i.e., when the base is made more positive, the collector becomes less positive. The resistors in this circuit serve the following functions. Resistor *R*1 limits the input current to the base of the transistor so that it is not harmed when the input signal overdrives. Resistors *R*2 and *R*3 establish the transistor's operating point with no input signal. Resistors *R*4 and *R*5 determine the voltage gain of the amplifier. Resistor *R*4 also serves to stabilize the zero-signal operating point, as established by resistors *R*2 and *R*3. Usual practice is to design single-stage gains of 10 to 20. Much higher gains are possible to achieve, but low gain levels permit the use of less expensive transistors and increase circuit reliability.

Figure 15.2.12 illustrates a basic **two-stage transistor amplifier** using complementary *n-p-n* and *p-n-p* transistors. Note that the first stage is identical to that shown in Fig. 15.2.11. This *n-p-n* stage drives the following *p-n-p* stage. Additional alternate *n-p-n* and *p-n-p* stages can be added until any desired overall amplifier gain is achieved.

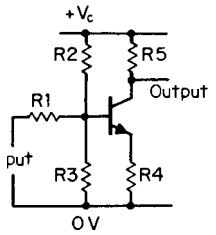

Fig. 15.2.11 Single-stage amplifier.

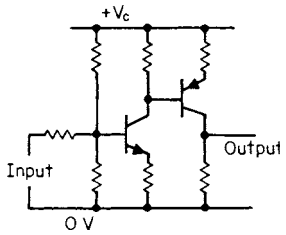

Fig. 15.2.12 Two-stage amplifier.

Figure 15.2.13 shows the **Darlington** connection of transistors. The amplifier is used to obtain maximum current gain from two transistors. Assuming a base-to-collector current gain of 50 times for each transistor, this circuit will give an input-to-output current gain of 2,500. This high level of gain is not very stable if the ambient temperature changes, but in many cases this drift is tolerable.

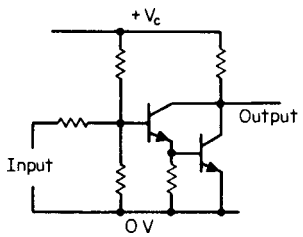

Fig. 15.2.13 Darlington connection.

Figure 15.2.14 shows a circuit developed specifically to minimize temperature drift and drift due to power supply voltage changes. The **differential amplifier** minimizes drift because of the balanced nature of the circuit. Whatever changes in one transistor tend to increase the output are compensated by reverse trends in the second transistor. The input signal does not affect both transistors in compensatory ways, of course, and so it is amplified. One way to look at a differential amplifier is that twice as many transistors are used for each stage of amplification to achieve compensation. For very low drift requirements, matched transistors are available. For the ultimate in differential amplifier performance, two matched transistors are encapsulated in a single unit. **Operational amplifiers** made with discrete components frequently use differential

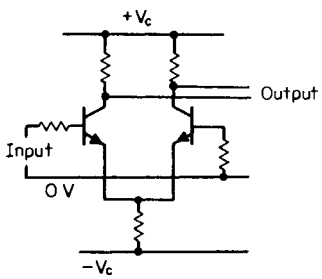

Fig. 15.2.14 Differential amplifier.

amplifiers to minimize drift and offset. The operational amplifier is a low-drift, high-gain amplifier designed for a wide range of control and instrumentation uses.

Oscillators are circuits which provide a frequency output with no signal input. A portion of the collector signal is fed back to the base of the transistor. This feedback is amplified by the transistor and so maintains a sustained oscillation. The frequency of the oscillation is determined by parallel inductance and capacitance. The oscillatory circuit consisting of an inductance and a capacitance in parallel is called an *LC* **tank circuit.**

This frequency is approximately equal to

$$f = 1/2\pi\sqrt{CL} \tag{15.2.2}$$

where f = frequency, Hz; C = capacitance, F; L = inductance, H. A 1-MHz oscillator might typically be designed with a 20-μH inductance in parallel with a 0.05-μF capacitor. The exact frequency will vary from the calculated value because of loading effects and stray inductance and capacitance. The **Colpitts** oscillator shown in Fig. 15.2.15 differs from the **Hartley** oscillator shown in Fig. 15.2.16 only in the way energy is fed back to the emitter. The Colpitts oscillator has a capacitive voltage

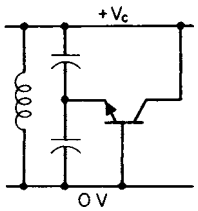

Fig. 15.2.15 Colpitts oscillator.

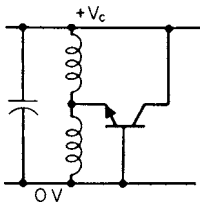

Fig. 15.2.16 Hartley oscillator.

divider in the resonant tank. The Hartley oscillator has an inductive voltage divider in the tank. The **crystal oscillator** shown in Fig. 15.2.17 has much greater frequency stability than the circuits in Figs. 15.2.15 and 15.2.16. Frequency stability of 1 part in 10^7 is easily achieved with a crystal-controlled oscillator. If the oscillator is temperature-controlled by mounting it in a small temperature-controlled oven, the frequency

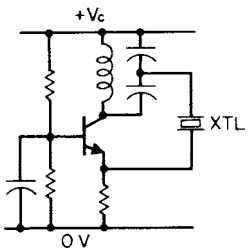

Fig. 15.2.17 Crystal-controlled oscillator.

stability can be increased to 1 part in 10^9. The resonant *LC* tank in the collector circuit is tuned to approximately the crystal frequency. The crystal offers a low impedance at its resonant frequency. This pulls the collector-tank operating frequency to the crystal resonant frequency.

As the desired operating frequency becomes 500 MHz and greater, **resonant cavities** are used as tank circuits instead of discrete capacitors and inductors. A rough guide to the relationship between frequency and resonant-cavity size is the wavelength of the frequency

$$\lambda = 300 \times 10^6/f \tag{15.2.3}$$

where λ = wavelength, m; 300×10^6 = speed of light, m/s; f = frequency, Hz. The resonant cavities will be smaller than indicated by Eq. (15.2.3) because in general the cavity is either one-half or one-fourth wavelength and also, in general, the electromagnetic wave velocity is less in a cavity than in free space.

The operating principles of these devices are beyond the scope of this article. There are many different kinds of **microwave tubes** including **klystrons, magnetrons,** and **traveling-wave** tubes. All these tubes employ moving electrons to excite a resonant cavity. These devices serve as either oscillators or amplifiers at microwave frequencies.

Lasers operate at a frequency of light of approximately 600 THz. This corresponds to a wavelength of 0.5 μm, or, the more usual measure of visual-light wavelength, 5×10^3 Å. Most laser oscillators are basically a variation of the Fabry-Perot etalon, or interferometer.

Most light is disorganized insofar as the axis of vibration and the frequency of vibration are concerned. When radiation along different axes is attenuated, as with a polarizing screen, the light is said to be *polarized*. White light contains all visible frequencies. When white light is filtered, the remaining light is colored, or frequency-limited. A single color of light still contains a broad range of frequencies. Polarized, colored light is still so disorganized that it is difficult to focus the light energy into a narrow beam. Laser light is inherently a single-axis, single-frequency light.

Light-emitting diodes (LEDs) and semiconductor **laser diodes** (LDs) are specialty diodes that emit light and have the same current-voltage characteristic shown in Fig. 15.2.2. These diodes are made from various alloy compositions of compound semiconductor materials of gallium arsenide and indium phosphide that are capable of highly efficient light emission, in contrast to the silicon diodes described previously in this section. The devices are fabricated on 2-, 3-, 4-, and 6-in wafers via a layered deposition technique such as **molecular beam epitaxy** (MBE) or **metalorganic vapor phase epitaxy** (MOVPE) followed by standard semiconductor fabrication processes. Wavelength selection is controlled by engineering the alloy composition and thickness of the diode materials in the deposition process. Typical diode thickness is on the order of a couple of micrometres, with critical wavelength-control layers, known as quantum wells, as thin as a few nanometres. Diodes can be engineered to cover a broad wavelength range from ultraviolet (UV) through infrared (IR). LEDs and lasers have very similar materials, but differ in their fabrication process. For lasers, the fabrication process creates a Fabry-Perot cavity, or gain region, with two highly reflective mirrors, which are required for operation, as described in Section 19, Optics. LEDs have a simpler, yet similar, design that incorporates one or two lower-reflectivity mirrors that enhance the light output, but are not sufficiently reflective to create laser emission. Individual dice, on the order of 500 μm square, are cut from the wafers and then packed in a variety of methods to suit the particular application.

LEDs and lasers have become prevalent in our everyday lives. Early use of LED technology was for indicator lights on industrial electronic equipment. LEDs are now found nearly everywhere, including kitchen appliances, toys, home computers, remote control units, alarm clocks, and solar-powered yard lights. More recently, LEDs have been implemented in vehicle brake lights, traffic signals, and large outdoor video displays, and are starting to break into the overhead lighting market to replace fluorescent lighting. Advantages of LEDs over incandescent or fluorescent technologies are many:

1. Higher electrooptical conversion efficiency results in lower operating cost per lumen.
2. Long life, typically on the order of 10 years, and longer time between replacement, so costs for personnel and equipment for replacement are lower.
3. For transportation applications, improved safety because, with the high number of LEDs used in a stoplight or brake light, about 50 percent can burn out before replacement is required, whereas a single incandescent bulb failure makes the light inoperative.

The semiconductor laser has also become part of our everyday lives, and is more of an enabling technology, as opposed to the LED, which replaced incandescent technology in many of its applications. The laser diode has enabled novel products and services such as:

1. Fiber-optic communications
2. Read/write optical disk technology (CD/DVD)
3. Portable handheld bar code scanners
4. Laser pointers
5. Laser printers

Additionally, arrays of laser diodes are used for replacing older solid-state lasers in high-power applications such as industrial cutting, machining, and marking, with advantages of much smaller footprint and lower power consumption.

A radio wave consists of two parts, a **carrier** and an information signal. The carrier is a steady high frequency. The information signal may be a voice signal, a video signal, or telemetry information. The carrier wave can be modulated by varying its amplitude or by varying its frequency. **Modulators** are circuits which impress the information signal onto the carrier. A **demodulator** is a circuit in the receiving apparatus which separates the information signal from the carrier. A simple amplitude modulator is shown in Fig. 15.2.18. The transistor is base-driven with the carrier input and emitter driven with the information signal. The modulated carrier wave appears at the collector of the transistor.

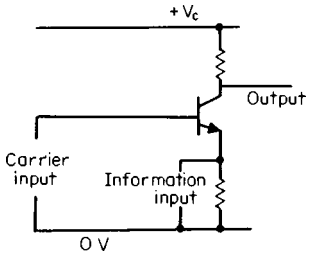

Fig. 15.2.18 AM modulator.

An FM modulator is shown in Fig. 15.2.19. The carrier must be changed in frequency in response to the information signal input. This is accomplished by using a saturable ferrite core in the inductance of a Colpitts oscillator which is tuned to the carrier frequency. As the collector current in transistor $T1$ varies with the information signal, the saturation level in the ferrite core changes, which in turn varies the inductance of the winding in the tank circuit and alters the operating frequency of the oscillator.

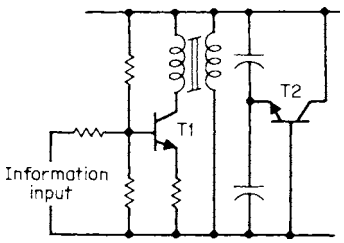

Fig. 15.2.19 FM modulator.

The **demodulator** for an AM signal is shown in Fig. 15.2.20. The diode rectifies the carrier plus information signal so that the filtered voltage appearing across the capacitor is the information signal. Resistor $R2$ blocks the carrier signal so that the output contains only the information signal. An FM **demodulator** is shown in Fig. 15.2.21. In this circuit, the carrier plus information signal has a constant amplitude. The information is in the form of varying frequency in the carrier wave. If inductor $L1$ and capacitor $C1$ are tuned to near the carrier frequency but

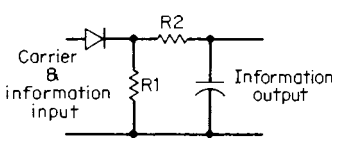

Fig. 15.2.20 AM demodulator.

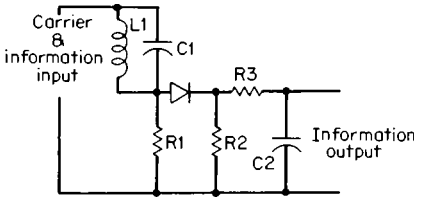

Fig. 15.2.21 FM discriminator.

not exactly at resonance, the current through resistor $R1$ will vary as the carrier frequency shifts up and down. This will create an AM signal across resistor $R1$. The diode, resistors $R2$ and $R3$, and capacitor $C2$ demodulate this signal as in the circuit in Fig. 15.2.20.

The waveform of the basic **electronic timing circuit** is shown in Fig. 15.2.22 along with a basic timing circuit. Switch $S1$ is closed from time $t1$ until time $t3$. During this time, the transistor shorts the capacitor and holds the capacitor at 0.2 V. When switch $S1$ is opened at time $t3$, the transistor ceases to conduct and the capacitor charges exponentially due to the current flow through resistor $R1$. Delay time can be measured to any point along this exponential charge. If the time is measured until time $t6$, the timing may vary due to small shifts in supply voltage or slight changes in the voltage-level detecting circuit. If time is

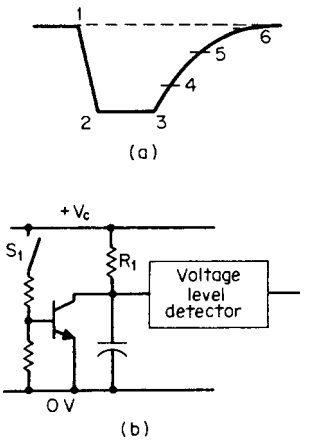

Fig. 15.2.22 Basic timing circuit.

measured until time $t4$, the voltage level will be easy to detect, but the obtainable time delay from time $t3$ to time $t4$ may not be large enough compared with the reset time $t1$ to $t2$. Considerations like these usually dictate detecting at time $t4$. If this time is at a voltage level which is 63 percent of V_c, the time from $t3$ to $t4$ is one time constant of $R1$ and C. This time can be calculated by

$$t = RC \tag{15.2.4}$$

where t = time, s; R = resistance, Ω; C = capacitance, F. A timing circuit with a 0.1-s delay can be constructed using a 0.1-μF capacitor and a 1.0-MΩ resistor.

An improved timing circuit is shown in Fig. 15.2.23. In this circuit, the unijunction is used as a level detector, a pulse generator, and a reset means for the capacitor. The transistor is used as a constant current source for charging the timing capacitor. The current through the transistor is determined by resistors $R1$, $R2$, and $R3$. This current is adjustable by means of $R1$. When the charge on the capacitor reaches approximately 50 percent of V_c, the unijunction fires, discharging the capacitor and generating a pulse at the output. The discharged capacitor is then recharged by the transistor, and the cycle continues to repeat. The pulse rate of this circuit can be varied from one pulse per minute to many thousands of pulses per second.

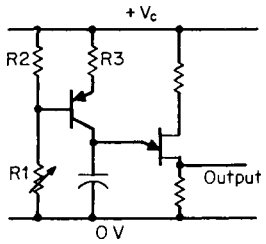

Fig. 15.2.23 Improved timing circuit.

INTEGRATED CIRCUITS

Table 15.2.4 lists some of the more common physical packages for discrete component and integrated semiconductor devices. Although discrete components are still used for electronic design, **integrated circuits (ICs)** are becoming predominant in almost all types of electronic equipment. Dimensions of common dual in-line pin (DIP) integrated-circuit devices are shown in Fig. 15.2.24. An IC costs far less than circuits made with discrete components. Integrated circuits can be classified in several different ways. One way to classify them is by complexity. **Small-scale integration (SSI), medium-scale integration (MSI), large-scale integration (LSI),** and **very large scale integration (VLSI)** refer to this kind of classification. The cost and availability of a particular IC are more dependent upon the size of the market for that device than on the level of its internal complexity. For this reason, the classification by circuit complexity is not as meaningful today as it once was. The literature still refers to these classifications, however. For the purpose of this text, ICs will be separated into two broad classes: linear ICs and digital ICs.

Flat pack	
Chip carrier (50-mil centers)	

The trend in IC development has been toward greatly increased complexity at significantly reduced cost. Present-day ICs are manufactured with internal spacings as low as 0.5 μm. The limitation of the contents of a single device is more often controlled by external connections than by internal space. For this reason, more and more complex combinations of circuits are being interconnected within a single device. There is also a tendency to accomplish functions digitally that were formerly done by analog means. Although these digital circuits are much more complex than their analog counterparts, the cost and reliability of ICs make the resulting digital circuit the preferred design. One can expect these trends will continue based on current technology. One can also anticipate further declines in price versus performance. It has been demonstrated again and again that digital IC designs are much more stable and reliable than analog designs.

Number of pins	*W*	*P*	*L*	Approximate height
64	0.8	0.1	3.3	0.24
40	0.6	0.1	2.0	0.2

8	0.3	0.1	0.4	0.2

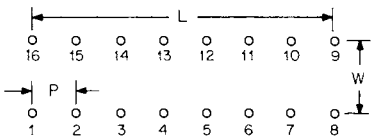

Fig. 15.2.24 Approximate physical dimensions of dual in-line pin (DIP) integrated circuits. All dimensions are in inches. Dual in-line packages are made in three different constructions—molded plastic, cerdip, and ceramic.

For years, the complexity of large-scale integrated circuits doubled each year. This meant that, over a 10-year period, the complexity of a single device increased by 2^{10} times, or over 1,000 times, and, over the period from 1960 to 1980 grew from one transistor on a chip to one million transistors on a chip. More recently the complexity increase has fallen off to only 1.7 times, or 1.7^{10}, or over 200 times in a 10-year period. Manufacturers also have developed application-specific integrated circuits (ASICs). These devices allow a circuit designer to design integrated circuits almost as easily as printed board circuits.

LINEAR INTEGRATED CIRCUITS

The basic building block for many linear ICs is the **operational amplifier.** Table 15.2.5 lists the basic characteristics for a few representative IC operational amplifiers. In most instances, an adequate design for an operational amplifier circuit can be made assuming an "ideal" operational amplifier. For an ideal operational amplifier, one assumes that it has infinite gain and no voltage drop across its input terminals. In most designs, feedback is used to limit the gain of each operational amplifier. As long as the resulting closed-loop gain is much less than the open-loop gain of the operational amplifier, this assumption yields results that are within acceptable engineering accuracy. Operational amplifiers use a balanced input circuit which minimizes input voltage offset. Furthermore, specially designed operational amplifiers are available which have extremely low input offset voltage. The input voltage must be kept low because of temperature drift considerations. For these reasons, the assumption of zero input voltage, sometimes called a "virtual ground," is justified. Figure 15.2.25 shows three operational amplifier circuits and the equations which describe their behavior. In this figure *S*

Table 15.2.5 Operational Amplifiers

Type	Purpose	Input bias current, nA	Input res., Ω	Supply voltage, V	Voltage gain	Unity-gain bandwidth, MHz
LM741	General purpose	500	2×10^6	+ 20	25,000	1.0

LM255	FET input	0.1	10^{12}	+ 22	50,000	2.5
LM444A	Quad FET input	0.005	10^{12}	+ 22	50,000	1.0

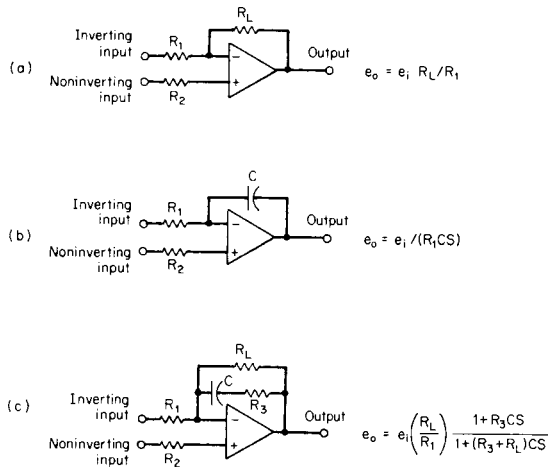

Fig. 15.2.25 Operational amplifier circuits.

is the **Laplace transform** variable. In these equations the input and output voltages are functions of S. The equations are written in the frequency domain. A simple transformation to steady variable-frequency behavior can be obtained by simply substituting cos ωt for the variable S wherever it appears in the equation. By varying ω, the frequency in radians per second, one can obtain the steady-state frequency response of the circuit.

The operational amplifier circuits shown in Figs. 15.2.25, 15.2.26, 15.2.27, and 15.2.28, show only the signal wires. There are additional connections to a dc power supply, and in some instances, to stabilizing circuits and guard circuits. These connections have been omitted for conceptual clarity.

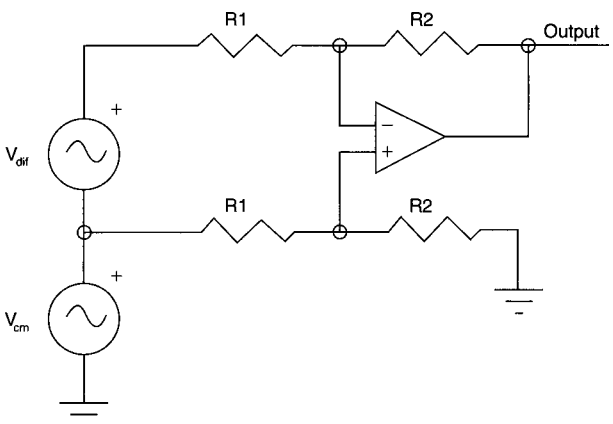

Fig. 15.2.26 Difference amplifier.

One of the most useful analog integrated circuits is the **difference amplifier.** This is a balanced input amplifier that is a fundamental component in instrumentation and control applications. The difference amplifier is shown in Fig. 15.2.26. This amplifier maximizes the voltage gain for V_{output}/V_{dif}, the **difference gain,** and minimizes the voltage gain for V_{output}/V_{CM}, the **common-mode gain**. There are two resistors in the circuit shown as $R1$ and two resistors shown as $R2$. The resistance values of the two $R1$ resistors are equal, and similarly the resistance values of the two $R2$ resistors are equal. The difference gain is given by

$$\frac{V_{output}}{V_{dif}} = -\frac{R2}{R1} \tag{15.2.5}$$

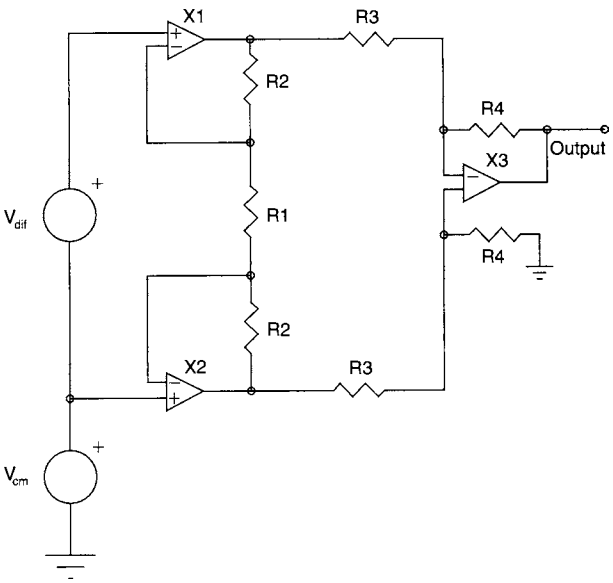

Fig. 15.2.27 Instrumentation amplifier.

The ratio of the common-mode gain to the difference gain is called the **common-mode rejection ratio (CMRR)**. In a well-designed difference amplifier, the CMRR is −80 dB. Stated another way, the common-mode gain is 10,000 times smaller than the difference gain. The difference amplifier is the most common input to instrumentation amplifiers and analog-to-digital converter circuits. Bridge-connected transducers have a common-mode voltage that is 100 times the difference voltage, or more. Such transducers require a difference amplifier. The common-mode gain is highly dependent on the matching of the $R1$ resistors and the $R2$ resistors. A 1 percent difference in these resistors causes the CMRR to be degraded to −30 or −40 dB.

An **instrumentation amplifier** is a high-grade difference amplifier. Although there are many implementations of the instrumentation amplifier, the three op-amp circuit is quite common, and will illustrate this device. Figure 15.2.27 shows the three op-amp instrumentation amplifier. This is a two-stage amplifier. The first stage is composed of amplifiers $X1$ and $X2$ and resistors $R1$, $R2$, and $R2$. The second stage is composed of amplifier $X3$ and resistors $R3$, $R3$, $R4$, and $R4$. The CMRR is usually much lower for the instrumentation amplifier, typically −120 dB. The differential mode gain is much higher for the instrumentation amplifier. For stability and frequency response considerations, the difference gain of a normal difference amplifier is usually 10 or less. For the instrumentation amplifier, the difference gain is typically 1,000. In the circuit shown in Fig. 15.2.27, the difference gain of the first stage is given by

$$\frac{V_{internal}}{V_{dif}} = \frac{2 \times R2 + R1}{R1} \tag{15.2.6}$$

The difference gain of the second is given by

$$\frac{V_{output}}{V_{internal}} = -\frac{R4}{R3} \tag{15.2.7}$$

The overall gain for the amplifier is the product of the individual stage gains. In the typical case the gain of the first stage is 100, and for the second stage is 10, giving an overall gain of 1,000. Integrated circuit instrumentation amplifiers are available which include all of the circuitry in Fig. 15.2.27. The resistors are matched so that the circuit designer does not have to contend with component matching.

A word about cost is in order. In 1994, high-grade operational amplifiers cost $0.50 for four op-amps in a single IC chip, or about $0.125 for each amplifier. The instrumentation amplifier is somewhat more expensive, but can be obtained for less than $5.00.

Filtering of electronic signals is often required. A filter passes some frequencies and suppresses others. Filters may be classed as low pass, high pass, band pass, or band stop. Figure 15.2.28 shows a low-pass active filter circuit which is a modification of the Sallen-Key circuit. In this circuit, the two resistors labeled R are matched and the two capacitors labeled C are matched. The frequency response of this circuit is given by its transfer function:

$$\frac{V_{\text{output}}}{V_{\text{input}}} = \frac{1}{S^2 + \frac{\omega_N}{Q}S + \omega_N^2} \tag{15.2.8}$$

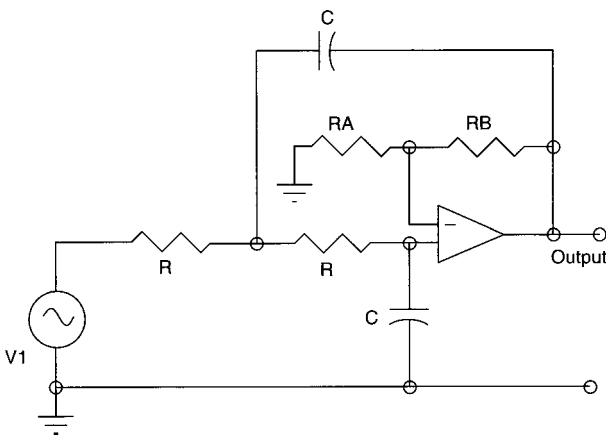

Fig. 15.2.28 Modified Sallen-Key filter circuit.

In this equation, ω_N is the resonant frequency of this circuit, in radians per second, and Q is a quality factor that indicates the amount of amplitude increase at the resonant frequency. For the circuit shown in Fig. 15.2.28, ω_N is given by

$$\omega_N = \frac{1}{RC} \tag{15.2.9}$$

and Q is given by

$$Q = \frac{1}{2 - (\text{RB/RA})} \tag{15.2.10}$$

The filter shown in Fig. 15.2.28 is a two-pole low-pass filter. Higher-order filters—four pole, six, etc.—can be constructed by cascading sections of two-pole filters. Thus, a six-pole low-pass filter would consist of three circuits of the configuration shown in the figure. The components R, R, C, C, RA, and RB would vary in each filter section.

Continuing with the low-pass filter, there are three common variations in filter response: Butterworth response, Chebychev response, and elliptical response. The Butterworth filter has no ripple in either the pass band or the stop band. The Chebychev filter has equal ripple variations in the pass band, but is flat in the stop band, and the elliptical filter has equal ripple variations in both the pass band and the stop band. There is a transition band of frequencies between the pass band and the stop band. The Butterworth filter has the greatest transition band. The Chebychev response has a sharper cutoff frequency characteristic than the Butterworth response, and the elliptical response has the sharpest transition from pass band to stop band. The circuits shown in Figs. 15.2.27 and 15.2.28 can be used to realize Butterworth and Chebychev filters. The elliptical filter requires a more complex circuit.

The high-pass filter can be formulated by substituting $1/S$ for S in Eq. (15.2.8). The circuit configuration for a high-pass filter is shown in Fig. 15.2.29. Notice that only the position of the Rs and Cs have changed. In general, the values of Rs, Cs, RA, and RB will change for the high-frequency filter, so it would be inappropriate to design a low-pass filter and simply reverse the positions of the Rs and Cs.

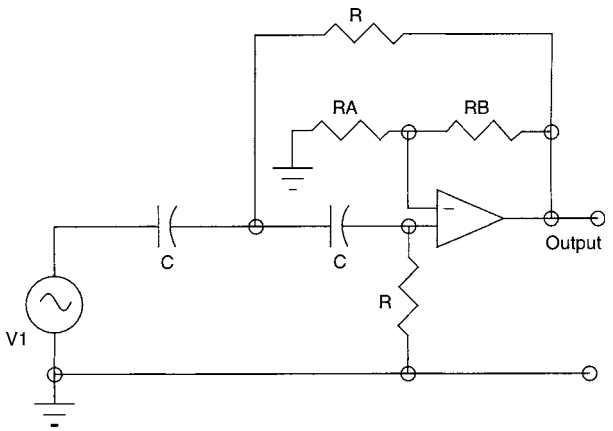

Fig. 15.2.29 High-pass filter section.

Band-pass and band-stop filters can be made by combinations of low-pass and high-pass filter sections. Figure 15.2.30*a* shows the diagram configuration of filters to realize a band-pass filter. The low-pass filter would be designed for the high-frequency transition, and the high-pass filter would be designed for the low-frequency transition. Figure 15.2.30*b* shows the block diagram configuration for a band-stop filter. The band-stop filter and the low-pass filter would be designed for the low-frequency transition, and the high-pass filter would be designed for the high-frequency transition. Band-pass and band-stop filters may also be realized by means of special high-Q circuits. A more complete discussion of filter technology can be found in the references at the beginning of this section.

Table 15.2.6 lists some typical linear ICs, most of which contain operational amplifiers with additional circuitry. The **voltage comparator** is an operational amplifier that compares two input voltages, $V1$ and $V2$. Its output voltage is positive when $V1$ is greater than $V2$, and negative when $V2$ is greater than $V1$. The **sample-and-hold** circuit samples an analog input voltage at prescribed intervals, which are determined by an input clock pulse. Between clock pulses the circuit holds the sample voltage level. This circuit is useful in converting from an analog voltage to a digital number whose value is proportional to the analog voltage. An **analog-to-digital (A/D) converter** is a signal-converting device which changes several analog signals into digital signals. It consists of an input difference amplifier, an analog time multiplexer, a sample-and-hold amplifier, a digital decoder, and the necessary logic to interface with a digital computer. The A/D converter is programmable, in that a computer can set up the device for the requisite number of input channels and whether these input channels are differential inputs or single-ended inputs. The A/D converter typically takes eight differential analog input signals and converts them to 10-, 12-, or 16-bit digital signals. Typical A/D converters convert signals at a rate of 200,000 samples per second. Other types of A/D converters, such as flash converters, can convert over 10,000,000 samples per second.

A companion circuit to the A/D converter is the **digital-to-analog (D/A) converter,** which is used to convert from digital signals to analog signals. This is also a programmable device, but in general the D/A converter is less complex than is the A/D converter. **Voltage-regulators** and **voltage references** are electronic circuits which create precision dc voltage sources. The voltage reference is more precise than the voltage regulator. The **voltage-controlled oscillator** is a circuit which converts from a dc signal to a proportional ac frequency. The output of a voltage-controlled oscillator is usually a rectangular ac wave rather than a sine wave. The **NE555 timer/oscillator** is a general-purpose timer/oscillator which has been integrated into a single IC chip. It can function as a **monostable multivibrator,** a **free-running multivibrator,** or as a **synchronized multivibrator**. It can also be used as a **linear ramp generator,** or for time delay or sequential timing applications.

Table 15.2.7 lists linear ICs that are used in audio, radio, and television circuits. The degree of complexity that can be incorporated in a single device is illustrated by the fact that a complete AM-FM radio circuit is available in a single IC device. The **phase-locked loop** is a device that is widely utilized for accurate frequency control. This device produces an output frequency that is set by a digital input. It is a highly accurate and stable circuit. This circuit is often used to demodulate FM radio waves.

Table 15.2.8 lists linear IC circuits that are used in telecommunications. These circuits include digital circuits within them and/or are used with digital devices. Whether these should be classed as linear ICs or digital ICs may be questioned. Several manufacturers include them in their linear device listings and not with their digital devices, and for this reason, they are listed here as linear devices. The radio-control **transmitter-encoder** and **receiver-decoder** provide a means of sending up to four control signals on a single radio-control frequency link. Each of the four channels can be either an on-off channel or a **pulse-width-modulated (PWM)** proportional channel. The **pulse-code modulator–coder-decoder (PWM CODEC)** is typical of a series of IC devices that have been designed to facilitate the design of digital-switched telephone circuits.

Integrated circuits are normally divided into two classes: linear or analog ICs and digital ICs. There are a few hybrid circuits which have both analog and digital characteristics. Some representative hybrid integrated circuits are listed in Table 15.2.9, and shown in Fig. 15.2.31. In the **superdiode,** there are two modes of operation. When the input signal is positive, the output of the op-amp is negative, causing diode *D*2 to conduct and diode *D*1 to block current flow. When the input is negative, diode *D*2 blocks and diode *D*1 conducts. The output of the circuit is zero when the input is negative, and the output is proportional to the input when the input is positive. A normal diode has 0.5 to 1.0 V of forward voltage drop. This circuit is called a super diode because its switching point is at zero volts. There is a voltage inversion from input to output, but this can be reversed by means of an additional op-amp inverter following the super diode. The action of the circuit can be reversed by reversing diodes *D*1 and *D*2. The **limiter** circuit, shown in Fig. 15.2.31*b*, provides linear operation at low output voltages, either positive or negative, and neither diode is conducting. When the input voltage goes sufficiently negative, diode *D*1 begins to conduct, limiting the negative output of the op-amp. Similarly when the input goes sufficiently positive, diode *D*2 begins to conduct, limiting the positive

Table 15.2.9 Hybrid Circuits

Superdiode	Limiters
Schmitt trigger circuits	Dead-band circuits
Switched-capacitor filters	Logarithmic amplifiers

output of the op-amp. The **Schmitt trigger** circuit, shown in Fig. 15.2.31*c*, has positive feedback to the op-amp, through resistors *R*1 and *R*2. If the amplifier output is initially negative, the output will not change until the input becomes as negative as the noninverting terminal of the op-amp. When the input becomes slightly more negative, the op-amp output will suddenly switch from negative to positive due to the positive feedback. The op-amp will remain in this condition until the input becomes sufficiently positive, causing the op-amp to switch to a negative output.

The **dead-band** circuit is similar to the limiter circuit except that for input voltages around zero, there is no output voltage. Above a threshold input voltage, the output voltage is proportional to the input voltage. The logarithmic amplifier relies upon the fact that the voltage drop across a diode causes logarithmically varying current to flow through the diode. This relationship is remarkably true for current changes of 10^6 to 1. The logarithmic amplifiers can have their outputs added together to effect a multiplication of the input signals.

DIGITAL INTEGRATED CIRCUITS

The basic circuit building block for digital ICs is the gate circuit. A gate is a switching amplifier that is designed to be either on or off. (By contrast, an operational amplifier is a proportional amplifier.) For 5-V logic levels, the gate switches to a 0 whenever its input falls below 0.8 V and to a 1 whenever its input exceeds 2.8 V. This arrangement ensures immunity to spurious noise impulses in both the 0 and the 1 state.

Several representative **transistor-transistor-logic (TTL) gates** are listed in Table 15.2.10. Gates can be combined to form logic devices of two fundamental kinds: combinational and sequential. In **combinational logic,** the output of a device changes whenever its input conditions change. The basic gate exemplifies this behavior.

Table 15.2.10 Digital Integrated-Circuit Devices

Type 54/74*	No. circuits per device	No. inputs per device	Function
00	4	2	NAND gate
02	4	2	NOR gate
04	6	1	Inverter
06	6	1	Buffer
08	4	2	AND gate
10	3	3	NAND gate
11	3	3	AND gate
13	2	4	Schmitt trigger
14	6	1	Schmitt trigger
20	2	4	NAND gate
21	2	4	AND gate
30	1	8	NAND gate
74	2		D flip-flop
76	2		JK flip-flop
77	4		Latch
86	4	2	EXCLUSIVE OR gate
174	6		D flip-flop
373	8		Latch
374	8		D flip-flop

NOTE: Example of device numbers are 74LS04, 54L04, 5477, and 74H10. The letters after the series number denote the speed and loading of the device.

* 54 series devices are rated for temperatures from − 55 to 125°C. 74 series devices are rated for temperatures from 0 to 70°C.

A number of gates can be interconnected to form a **flip-flop** circuit. This is a bistable circuit that stays in a particular state, a 0 or a 1 state, until its "clock" input goes to a 1. At this time its output will stay in its present state or change to a new state depending upon its input just prior to the clock pulse. Its output will retain this information until the next time the clock goes to a 1. The flip-flop has memory, because it retains its output from one clock pulse to another. By connecting several flip-flops together, several sequential states can be defined permitting the design of a **sequential logic** circuit.

Table 15.2.11 shows three common flip-flops. The **truth table,** sometimes called a **state table,** shows the specification for the behavior of each circuit. The present output state of the flip-flop is designated $Q(t)$. The next output state is designated $Q(t + 1)$. In addition to the truth table, the Boolean algebra equations in Table 15.2.11 are another way to describe the behavior of the circuits. The **JK flip-flop** is the most versatile of these three flip-flops because of its separate J and K inputs. The **T flip-flop** is called a *toggle*. When its T input is a 1, its output toggles, from 0 to 1 or from 1 to 0, at each clock pulse. The **D flip-flop** is called a *data cell*. The output of the D flip-flop assumes the state of its input at each clock pulse and holds this data until the next clock pulse. The JK flip-flop can be made to function as a T flip-flop by applying the T input to both the J and K input terminals. The JK flip-flop can be made to function as a D flip-flop by applying the data signal to the J input and applying the inverted data signal to the K input. Some common IC flip-flops are listed in Table 15.2.10.

Table 15.2.11 Flip-Flop Sequential Devices

Name	Graphic symbol	Algebraic function	Truth table
JK flip-flop	Clock: J, K, S, R, Q, $\overline{Q}$	$Q(t+1) = JQ'(t) + K'Q(t)$	J K $Q(t)$ | $Q(t+1)$ 0 X 0 | 0 1 X 0 | 1 X 0 1 | 1 X 1 1 | 0
T flip-flop	Clock: T, Q, $\overline{Q}$	$Q(t+1) = TQ'(t) + T'Q(t)$	T $Q(t)$ | $Q(t+1)$ 0 0 | 0 0 1 | 1 1 0 | 1 1 1 | 0
D flip-flop	Clock: D, Q, $\overline{Q}$	$Q(t+1) = D$	D $Q(t)$ | $Q(t+1)$ 0 0 | 0 0 1 | 0 1 0 | 1 1 1 | 1

Various types of gates are shown in Table 15.2.12. Combinational logic defined by means of these various gates is used to define the input to flip-flops, which serve as memory devices. At each clock pulse, these flip-flops change state in accordance with their respective inputs. These new states are retained in the flip-flop and also applied to the gates. The output of the gates change (with only a small delay due to propagation time), and at the next clock pulse the flip-flops will change to the next state as directed by the gates.

The gates shown in Table 15.2.12 have only two inputs. As was seen in Table 15.2.10, gates may have as many as eight inputs. In the case of an AND **gate**, all its inputs must be 1 in order for its output to be a 1. For an OR gate, if any of its inputs become a 1, then its output will become a 1. The NAND and NOR gates function in a similar way.

Table 15.2.12 Combinational Gate Logic

Name	Graphic symbol	Algebraic function	Truth table
AND		$Q = xy$	x y | Q 0 0 | 0 0 1 | 0 1 0 | 0 1 1 | 1
OR		$Q = x + y$	x y | Q 0 0 | 0 0 1 | 1 1 0 | 1 1 1 | 1
Inverter		$Q = x'$	x | Q 0 | 1 1 | 0
Buffer		$Q = x$	x | Q 0 | 0 1 | 1
NAND		$Q = (xy)'$	x y | Q 0 0 | 1 0 1 | 1 1 0 | 1 1 1 | 0
NOR		$Q = (x + y)'$	x y | Q 0 0 | 1 0 1 | 0 1 0 | 0 1 1 | 0
EXCLUSIVE-OR		$Q = xy' + x'y$ $= x + y$	x y | Q 0 0 | 0 0 1 | 1 1 0 | 1 1 1 | 0

To facilitate the analysis of digital circuits and to aid in the application of the rules given in Table 15.2.13, **Karnaugh maps** are used. Typical two-variable and four-variable Karnaugh maps are shown in Fig. 15.2.32 along with the algebraic expressions represented by each map.

Boolean algebra is the branch of mathematics used to analyze logic circuits. Boolean algebra has two operators: $\cdot$, which indicates an AND operation, and $+$, which indicates an OR operation: The $=$ has the same meaning in Boolean algebra as in ordinary algebra. The symbol for "X not" is X' (or sometimes $\overline{X}$). The identity element for the AND operation is 0; the identity element for the OR operation is 1. The rules for Boolean algebra can be derived from set theory applied to a system in which only two numbers exist, i.e., zero and one. These rules are summarized in Huntington's postulates and DeMorgan's theorem and are listed in Table 15.2.13.

Table 15.2.13 Rules for Boolean Algebra

$X + 0 = X$	$X \cdot 1 = X$
$X + 1 = 1$	$X \cdot X' = 0$
$X + X' = 1$	$X \cdot X = X$
$(X')' = X$	$X \cdot 0 = 0$
$X + Y = Y + X$	$X \cdot Y = Y \cdot X$
$X + (Y + Z) = (X + Y) + Z$	$X \cdot (YZ) = (X \cdot Y)Z$
$X + X \cdot Y = X$	$X \cdot (X + Y) = X$
DeMorgan's theorem:	
$(X + Y)' = X' \cdot Y'$	$(X \cdot Y)' = X' + Y'$

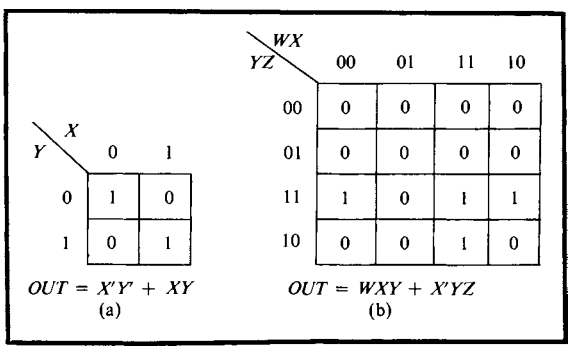

Fig. 15.2.32 Karnaugh maps of typical logic functions.

Table 15.2.14 Large-Scale Digital Integrated Circuits

Adder	Accumulator
Arithmetic logic unit	Parity generator-checker
Shift register	Encoder
Multiplexer	Decoder
Demultiplexer	Counters
Display controller-driver	

Looking at Fig. 15.2.32*b* and realizing each of the ones individually would lead to the Boolean expression:

$$\text{OUT} = \text{W}'\text{X}'\text{YZ} + \text{WXYZ} + \text{WX}'\text{YZ} + \text{WXYZ}' \quad (15.2.11)$$

Realizing this expression directly would require four four-input AND gates, and one four-input OR gate. The reduced expression

$$\text{OUT} = \text{WXY} + \text{X}'\text{YZ} \quad (15.2.12)$$

requires only two three-input AND gates and one two-input OR gate, a simpler and less expensive logic circuit.

Some of the more common large-scale integrated circuits are listed in Table 15.2.14. The adder can add two binary numbers together and output the result. For a single bit adder which adds a bit from word A, a bit from word B, and a carry bit, C, the Boolean expressions for the two outputs of the adder are

$$\text{SUM} = \text{AB}'\text{C}' + \text{A}'\text{BC}' + \text{A}'\text{B}'\text{C} + \text{ABC} \quad (15.2.13)$$

$$\text{CO} = \text{AB} + \text{BC} + \text{AC} \quad (15.2.14)$$

Adders are available, not for a single bit, but rather for 4 bits, 8 bits, or 16 bits. There is only one carry bit for the whole device. The devices in Table 15.2.14 will be described in words, but the specifications for each of these devices has a truth table as a part of the product description. An arithmetic logic unit (ALU) or accumulator can perform several simple logical or arithmetic operations, such as add, complement, shift left, and shift right. In addition, the set of instructions which command these operations will also be decoded by the ALU. As one might expect, the Boolean expression for a 16-bit or 32-bit ALU can be formidable. A parity generator/checker is a circuit that can make a cyclic redundancy code which can be used to check the accurate transmission of data. Shift registers perform only the shifting functions of ALUs. Counters are made in many configurations—up-down counters, binary-coded-decimal counters, Johnson counters, etc. A decoder can best be explained by a simple example. A three- to eight-line decoder will be described. The three input lines can have eight binary variations, 000, 001, 010, 011, 100, 101, 110, and 111. For each of these input conditions one, and only one, of the output lines will be set. The input signal is said to have been decoded. The encoder performs the related operation of encoding from eight to three lines. Depending on which one input line is set, an appropriate output bit pattern is set. Encoders and decoders are available in 2 to 4, 3 to 8, and 4 to 16 line configurations. The multiplexer/demultiplexer performs a similar function. The multiplexer has a data input terminal and control input terminal and several data output terminals. It switches a single train of information, ones and zeros, on an input line, and routes this information to one of many output lines depending on the bit pattern placed on a control input. The demultiplexer performs the reverse operation. Multiplexers/demultiplexers are also configured in 2 to 4, 3 to 8, and 4 to 16 line devices.

There are a wide variety of display controllers and drivers. These are devices which interface between digital circuits and displays which humans can use. Light-emitting diodes, liquid crystals, and fluorescent displays have different drive requirements. The digital device may perform in binary, but the display requires decimal. In many cases, the display driver is separate from the display itself, but more recently the display driver has been incorporated in the display.

The complexity of integrated circuits is growing continually. The simple gates and flip-flops discussed so far are still used to some extent. Logically, these gates and flip-flops can be integrated into larger single-chip circuits called *large-scale integrated circuits* **(LSI)**. Combinations of these circuits are grouped together on single chips called *very large scale integrated circuits* **(VLSI)**. VLSI chips contain 500,000 to more than 2,000,000 gates. VLSI chips have enabled the explosive growth of personal computers, by allowing ever-increasing functionality at lower cost. These circuits are custom-designed VLSI circuits which are developed for large-volume applications. Bridging the gap between LSI and custom VLSI circuits are a series of linear and digital user-designed circuits.

The first of these user-designed circuits is called programmable logic arrays **(PLAs)** or programmable array logic **(PAL)**. The PLA grew out of the programmable read-only memory **(PROM)**. A programmable read-only memory is a computer memory which can be programmed one time, and then can be read many times. The PROM consists of a series of gates, initially all ones, each of which can be electrically altered to be a zero. A PROM might be logically organized to be 1 bit wide by 64K bits long, or 4 bits by 16K bits, 8 bits by 8K bits. The example just given is a series of 64K-bit PROMs. PROMs are available up to 4M bits on a single chip. The PLA is also field programmable, but has a more limited programming capability than the PROM. The limited capability makes it less costly to program. The PLA is adaptable to replacing Boolean functions in both combinational logic and sequential logic circuits. The PLA can replace 10 to 40 gate and flip-flop chips, resulting in a simpler, more reliable, less costly design.

There are two other approaches to application-specific integrated circuits **(ASICs)**. These are field-programmable gate arrays **(FPGAs)** and standard cells. The FPGA is sometimes referred to as a "sea of gates." The chip is designed with a series of identical gates, but without any interconnections between them. The user specifies the interconnections, and thus makes the chip specific to the application. The manufacture of the chip cannot be completed until the interconnections have been specified, however. There was initially some concern that the circuit designer would be losing design control, but this has largely disappeared now that alternative sources of supply are available. The customizing production drawings and specifications can be pulled from one manufacturer, and sent to another. The standard cell device is similar to an FPGA, except that some interconnections are specified to connect gates to form subcircuits. The design by the user consists of selecting the individual cells, AND gates, OR gates, flip-flops, etc. and specifying the interconnections of these standard cells. The standard cells may be as simple as an AND gate or as complex as a 16K-bit memory or a microprocessor. The standard cell also allows the user to specify light-current cells or heavy-current cells. The standard cell gives the user much more flexibility in the design. Standard cells have also been extended to include linear circuits, op-amps, difference amplifiers, limiters, etc. Some standard cell chips are suitable for hybrid digital and linear circuits on a single chip.

Two problems arise as more complex circuitry is incorporated in ASICs, and also in microprocessors (which will be discussed in the next section). These devices require more input and output data pins than are available in dual in-line packages (see Fig. 15.2.24), and they generate more heat on the chip. One solution to the pin problem is the pin array package, shown in Fig. 15.2.33. These packages still maintain 0.1-in spacing between pins, but the pin count has been increased to 132 and 208 in the examples shown. The package size has increased from dual in-line packages, and the force necessary to install and remove the package is not appreciably greater than for dual in-line packages. There are additional microcircuit packages at various stages of development and standardization that have up to 500 pins and 0.05-in pin spacing.

Higher-speed and higher-density digital electronics lead to higher heat dissipation in devices. One solution is to provide heat sinks and fans to remove heat. A more recent development is the **heat pipe**. The heat pipe consists of boiling fluid/vapor refrigerant in a closed chamber. The semiconductor boils the fluid to change it to the vapor state. A pipe conducts the vapor to a vapor-to-air heat exchanger, where the vapor is condensed. The heat pipe also provides a return path for the fluid to return to the semiconductor. An attractive feature of the heat pipe is that there is no requirement for a mechanical compressor.

A further problem for complex electronic circuits is proof of design and proof of manufacture testing. To adequately test a device, it is

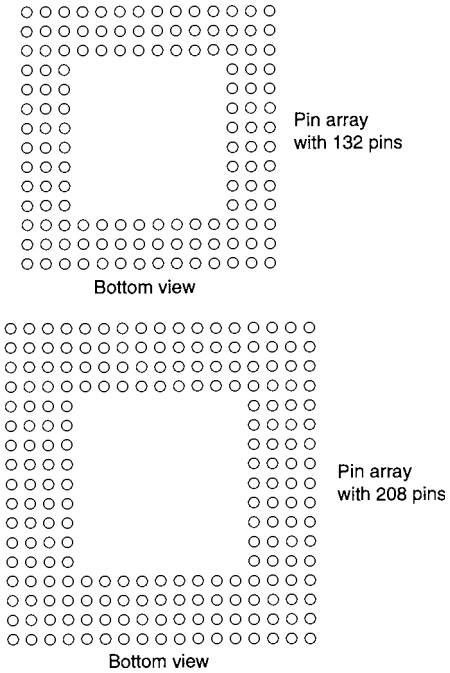

Fig. 15.2.33 Typical pin grid array packages. (All pins are on a 0.1 in grid.)

necessary to have access to additional test points in the circuit, beyond those needed to interface in actual operation. With a limited number of output pins and highly complex internal logic, the design of the circuit must include a fairly long test vector that will excite the various circuit functions. In addition, a fairly long results vector will be generated by the circuit. One approach to test design is called **boundary scan** design, described in specification IEEE 1149.1 of the Institute of Electrical and Electronics Engineers. This specification outlines a four- or five-wire test circuit, and the internal circuitry, which allows a test vector to be entered serially onto the chip, and allows a results vector to be serially unloaded from the chip. Internal circuitry is required to accept each bit of the input test vector and to generate each bit of the results vector. The serial transfer is a tradeoff between the time required to enter and retrieve the test vectors and the cost of additional input/output pins for the device. Serial transfer would be unacceptable for normal operations, but is all right for test purposes.

COMPUTER INTEGRATED CIRCUITS

One of the devices which has become feasible as a result of VLSI is the **microprocessor.** A complete computer can be built in a single IC device. In most cases, however, several devices are employed to build a complete computer system. In most computers, the cost of the microprocessor is negligible compared with the total system cost. Not long ago, the **central processing unit (CPU)** was the most expensive part of a computer. The microprocessor provides the total CPU function at a fraction of the earlier cost.

The power of a microprocessor is a function of its clock speed and the size and number of its registers. Clock rates vary from 1 to 200 MHz. Common register sizes are 8, 16, 24, 32, and 64 bits. Most personal computers currently use 32-bit registers. Commonly microprocessors have 12 to 16 registers. Other factors affect processor power and speed. Most microprocessors have a data bus, an address bus, and a set of control and power supply terminals. The number of each of these buses may vary. A small inexpensive microprocessor might have 8 data lines, 16 address lines, and 8 control/power supply lines. A large sophisticated microprocessor might have 64 data lines, 24 address lines, and 20 control/power supply lines. Some microprocessors have 32-bit internal registers and only 16 data bit terminals. The 16 data terminals are time-multiplexed to allow the complete 32-bit word to be entered onto the microprocessor chip in two read cycles. Once in the microprocessor, the 32-bit registers communicate with each other over a data bus which is a full 32 bits wide. This scheme reduces the number of terminals on the microprocessor, and reduces its cost, with a slight timing penalty.

Clock speed is limited by clock skew and parasitic capacitance. There is a finite time required for electric pulses to move along wires and for gates to change state. Typically electric pulses move along wires at about half the speed of light. Gates change state in a few nanoseconds. Parasitic capacitance is the stray capacitance that exists between any circuit and ground. When the gate changes state, this capacitance must be charged. The charging current increases linearly with switching rate and voltage. Because of the small circuit components and short wire lengths, the parasitic capacitance is much smaller for circuits on a chip compared with circuits on printed boards. Modern microprocessors use an on-chip clock rate that is 3 times as fast as the off-chip clock.

The **microcontroller** is a device similar to the microprocessor, in that it is also a CPU. Microcontrollers are configured for controlling applications. In general, they have greater input and output capability. It is very easy to control a single output bit for turning on an electric relay. With a microprocessor, 8 bits are switched together, but with a microcontroller individual bits can be switched. Some microcontrollers have 256 internal registers, rather than the 15 to 20 of a microprocessor. Microcontrollers are often stand-alone single-chip devices, and are a less expensive system than a microcomputer. Typical applications for microcontrollers are microwave oven controllers, washer and dryer controls, and automobile engine controls.

Memory is an important part of a computer system. Memory can be divided into two broad classes: volatile and nonvolatile. Volatile memory forgets what it contains when the power is removed from it. Nonvolatile memory retains its contents when power is removed. Random-access memory **(RAM)** is volatile memory that is sometimes called *main memory.* This is the memory that the CPU uses for most of its operations. RAM is a semiconductor memory. RAM may be dynamic memory or static. In a static RAM the memory elements are flip-flops, and retain their memory for as long as power is applied. Dynamic RAMs are also semiconductor memories, but hold the information as charges on capacitors. This charge will leak off even though the power is still applied to the memory. To retain the memory in a dynamic RAM, it is necessary to continually refresh the memory. This is typically done every 10 ms. Dynamic RAMs are much cheaper and have less loss than static RAMs. Large banks of memory are made with dynamic RAMs. Small memories, or memories with special requirements, are made with static RAMs. Typical dynamic RAMs are 256K, 1M, and 4M bytes. Typical static RAM may be as small as 1K bytes and can be as large as 1M bytes.

Nonvolatile memory can take several forms: ROMs, disk storage, compact disks, and tapes. A read-only memory (ROM) is a set of flip-flops which are programmed to take a particular state. This programming may be installed at the time of manufacture. Some devices are programmable by the user **(PROMs).** A PROM is typically all ones as shipped. The individual memory cells may be programmed to a zero or left a one. Programming memory cell is done by applying a high voltage to a programming pin when that cell's address is set. Normally the ROM or PROM is written once and read many times. An **EPROM** is an erasable, programmable read-only memory. The EPROM is programmed in the same way as a PROM. To erase the memory, the EPROM is placed under a high-intensity ultraviolet light. When the EPROM is erased, all of the memory is lost, so the entire program must be reentered.

Disks and tapes are magnetic storage devices. When power is removed from these devices, the memory is retained due to magnetic retentivity. Magnetic memory can only be read (or written) by moving the magnetic medium under a read/write head. **Compact disks** are a form of read-only memory. In the compact disk, the information is stored optically rather than magnetically.

The magnetic tape is a removable nonvolatile memory device. Hard disks are usually not removable. Floppy disks are removable, but for large quantities of data, the tape medium is cheaper and more convenient. Tape

is either in a cartridge or on a reel. Newer tape cartridges have large volumes, 50M bytes to 1,000M bytes. The trend is that cartridge tape is replacing reel tape as a storage means. Magnetic tape can store computer data for over a year, and with a periodic refreshing can store data indefinitely.

In addition to the CPU and storage devices, other integrated circuits have been designed for computer systems. These are listed in Table 15.2.15. The **tristate buffer** is a switching amplifier which can be a zero, a one, or high impedance. When a computer bus line can be driven by several devices, all of the devices are high impedance except the one which is controlling the bus line at that time. Typically eight tristate buffers are contained in one IC package. The **tristate transceiver** is similar to the tristate buffer except that it allows the bus signal to be

Table 15.2.15 Digital Computer Integrated-Circuit Devices

Tristate buffer	Tristate transceiver
Parallel interface adapter	Programmable peripheral interface
Universal asynchronous transmitter-receiver	Floppy/hard disk controller
Analog-to-digital converter	Digital-to-analog converter
Programmable timer	Direct memory access controller
Programmable interrupt controller	

received as well as written. The **parallel interface adapter** is a device that permits a parallel output device, such as a printer, to be connected to a computer bus. There are several variations of the parallel interface adapter. Some control two, three, four, or more parallel devices. Some have been designed to work with Intel microprocessors, others to work with Motorola microprocessors. The **programmable peripheral interface** is a parallel interface adapter designed for use with Intel computers. The **universal asynchronous receiver-transmitter (UART)** is a device which will allow a serial output device to be connected to a computer bus. The UART has a parallel connection to the computer bus, but provides a serial output to the peripheral device. The UART is programmable, so that it can be set for 7-bit or 8-bit transmission. It can be set for even or odd parity checking, and the transmitting/receiving speed can be set. The **floppy/hard disk controller** is a programmable device which can handle the interfacing requirements for floppy and/or hard disks. Analog-to-digital and digital-to-analog converters allow the digital computer to interface with analog signals. The **programmable timer** is a timing circuit which can be programmed by the computer either to generate an interrupt periodically, or to generate an interrupt after a programmed time. An interrupt is a signal on one of the control lines of the computer bus. The **direct memory access controller (DMA)** is a CPU type of device which can control the computer bus. The direct memory access controller generates a DMA request signal on a computer control line. The main CPU will complete the portion of the instruction that it is executing, and generate a DMA grant signal. The DMA controller then transfers data into or out of main memory or disk memory. Since the CPU is not involved in the memory transfer, it can proceed with the instruction it is executing, as long as that instruction does not require the computer bus that the DMA controller is using. DMA controllers can off-load the CPU, allowing the overall system to have more power. The **programmable interrupt controller** is a general-purpose semiconductor which can be used in various types of computer printed boards to service interrupts.

COMPUTER APPLICATIONS

The computer is universally used, and a complete discussion of computer usage is beyond the scope of this section. Computer techniques are used in electronic design so extensively that some description of these electronic applications of computers are necessary in order to understand modern electronic design.

Computers can be used as control devices. The computer might be a controlling device to simply turn a pump on and off. On the other hand, a variable displacement pump might incorporate a microcontroller in its feedback control loop in place of pilot hydraulic circuits. Entire processes may be controlled by computers. For example, modern paper machines use computers throughout for control purposes. Computer terminals at various locations show the operation conditions throughout the machine. Entire chemical-producing plants are under computer control.

Some automotive applications include control of air, fuel mixture, and spark timing in an automobile engine. This is typical of an application in which there are several input variables that must be measured, and several controlled outputs. The input variables that must be measured are air temperature, manifold temperature, crankcase temperature, engine speed, fuel flow, etc. The outputs which are controlled by the computer are ignition timing and fuel/air mixture. Automobile brakes, transmissions, and suspensions are automotive subsystems that incorporate microcontrollers for improved automobile performance. Microcomputers may also be used to reduce the complexity of automobile wiring. In such a system, battery power is distributed to all parts of the car along a single wire. Intelligence for the control of lights and accessories flows along a single control wire. Relays are provided at each lamp, switch, etc. to interface between the control and battery wire. Messages along the control wire are time-multiplexed so that all devices share the same control wire.

Testing, data acquisition, and analysis is another use of computers. Modern testing systems make extensive use of computers. Either digital or analog signals can be incorporated into a test system. Analog-to-digital converters convert analog signals into digital signals which the computer can use. Within the computer, a model of the process being tested can be constructed, and monitored by the test data being accumulated. Within the computer, signals can be generated which are not being actually measured. For example, the velocity of a mass may be measured, but the acceleration or the position of the mass may be calculated within the computer. Highly reliable systems can be developed using electronic control and computers, if redundancy is incorporated into the measuring and computer systems. In the aerospace industry, these systems are called **fly-by-wire** control systems. The space shuttle and supersonic fighters are examples of craft using fly-by-wire. In such systems, failure of a computer, a controller, or a sensor must not cause a failure of the craft.

Data acquisition systems give the user much greater insight into the data being taken. Limitations and anomalies of the measured data become much more apparent than with analog data. The need for signal conditioning becomes imperative in a digital data acquisition system. Signal processing is an integral part of any digital data system. Analog signals can be filtered as a part of signal conditioning, but after the signal has been converted to digital data, digital filtering may also be used. Digital filters can be broken into two classes: **finite impulse response (FIR)** and **infinite impulse response (IIR)** filters. As can be seen in Fig 15.2.34, the FIR filter does not have any feedback from a later part of the filter to a previous part. The IIR filter incorporates feedback from a later part of the filter to an earlier part. The FIR filter normally requires a greater length to accomplish the filtering objective than does the IIR filter. Because the IIR filter incorporates feedback, it is possible for it to be unstable. The FIR filter cannot be unstable. Both FIR and IIR filters employ a clock to generate a fixed delay from point to point in the filter. The clock delays are shown as ΔT in the figure. Each delay is a clock period. FIR filters are often 45 to 75 delays long. IIR filters are usually 8 to 10 delays long. The effective delay for an IIR filter is longer than the actual number of delays, because of the feedback in these filters. Although the infinite response suggests that the filter never completes its response, in a practical sense the IIR filter response is finite. The design approach for FIR filters and IIR filters is quite different. For an FIR filter, the filter coefficients A_0 through A_n are designed to optimally fit a desired filter response curve. The response of this optimal filter often has excessive sidebands, that is, high output in the nonpass frequency range. The sidebands can be reduced by applying a window function, which modifies the filter coefficients. The effect of the window function is to broaden the transition region between the passband and the stopband, and reduce the magnitude of the sidebands. The response equation, or transfer function, for the FIR filter with even symmetry is

$$H(\omega) = \sum_{i=0}^{i=n} A_i \cos\ (\omega i) \qquad (15.2.15)$$

In this equation, the frequency ω is a continuous variable in radians per second. Although the filter is a discrete device, its frequency response

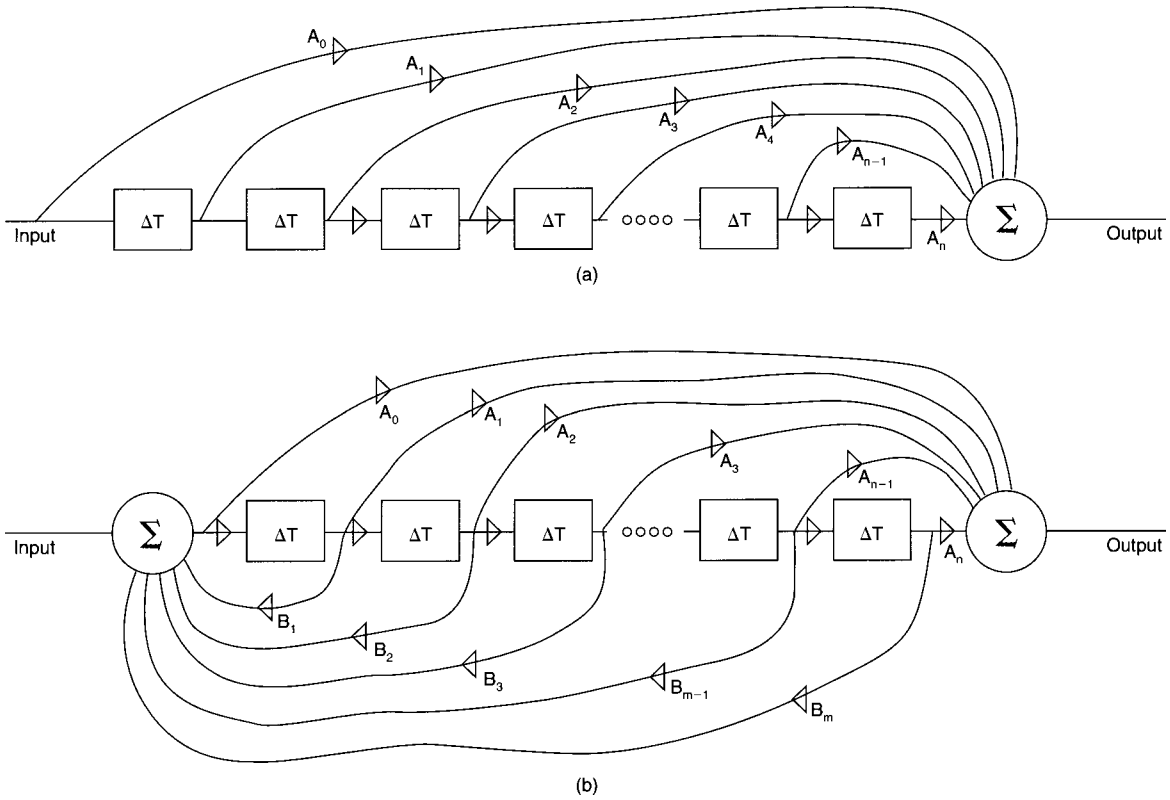

Fig. 15.2.34 (*a*) Finite impulse response (FIR) and (*b*) infinite impulse response (IIR) digital filters.

can be viewed as continuous. The digital signal is discrete, and when a signal is converted from digital to analog, this conversion adds its own modification of the signal.

The design approach for an IIR filter is quite different. For an IIR filter, the first step is to design a low-pass analog filter for a particular filter response, such as a Butterworth, Chebychev, or Cauer response. The analog filter can then be converted to a low-pass digital filter using the bilinear transform. Finally, the low-pass digital filter can be converted to a high-pass, band-pass, or band-stop filter. The resulting filter has a transfer function given by

$$H(\omega) = \frac{\sum_{i=0}^{i=n} A_i \cos(\omega i)}{1 - \sum_{i=1}^{i=m} B_i \cos(\omega i)} \qquad (15.2.16)$$

A more complete discussion of digital filter technology can be found in the references at the beginning of this section. Further help in digital filter design can be obtained by using a computer program, such as MATLAB.

Digital filter calculations consist of a series of mathematical operations which follow a consistent pattern. Each calculation is performed by retrieving a number, multiplying it by a coefficient, adding it to another number, and storing the result. This is the operation at each of the summation points in the FIR and the IIR. A microprocessor called a **digital signal processor (DSP)** has been developed for this purpose. DSPs complete a retrieve, multiply, add, and store in a single clock pulse (30 ns), several times faster than a general-purpose microprocessor. DSP microprocessors are widely used in test equipment, telephone equipment, television, and military equipment. Because of the wide usage, DSP microprocessors are quite inexpensive. DSPs were developed in order to increase the bandwidth of digital signal processing. It should be further noted that digital filters can employ parallel processing, in which several DSP chips can operate in parallel to further increase bandwidth.

Digital signal processing is not limited to analog and digital filtering. Digital data may also be improved by using smoothing algorithms, or by removing inconsistent data points, such as outliers. Insight into data content can also be obtained by statistical analysis. Digital signal processing is also used to improve the quality of voice signals, and to enhance video signals.

DIGITAL COMMUNICATIONS

The bandwidth required to transmit information depends on the digital pulse rate. A fundamental relationship exists for the bandwidth required for the transmission of digital or analog information. For analog signals, the bandwidth depends on the highest frequency component in the signal. For digital circuits, the bandwidth depends on the maximum pulse rate. The relationship between the two is known as the Nyquist criterion. The minimum pulse rate pr necessary to transmit an analog signal digitally must be twice the highest frequency f:

$$\text{pr} = 2f \qquad (15.2.17)$$

This is a bilateral relationship. The frequency bandwidth BW of a transmission system must be equal to at least half the pulse rate:

$$\text{BW} = \text{pr}/2 \qquad (15.2.18)$$

These conditions are minimum requirements. A transmission system that has greater bandwidth can support slower pulse rates, and similarly, a high-pulse-rate system can be used to pass a low-frequency signal. A higher pulse rate than the Nyquist criterion will approximate an analog signal waveform more accurately, but is not necessary to pass the information. Voice-grade lines have a bandwidth of 4,000 Hz, and will pass 8,000 bits per second (bps). Twisted-pair cable, properly terminated, can pass about 1 MHz or 2 Mbps. Coaxial cable can pass 100 to 200 MHz.

To obtain greater bandwidths, light is being used to transmit information, rather than electricity. Inexpensive fiber-optic devices can be used for distances up to several hundred feet. For longer distances, phase-locked lasers and single-mode fiber-optic cable is being employed. Single-mode fiber is quite small and somewhat hard to terminate. Tooling to facilitate connecting single-mode cable is becoming more readily available.

Electric instrumentation has several communication standards which facilitate the connection of measuring systems. A low-speed instrument bus, IGIB, has been developed and described in a standard, IEEE 488. For higher communication rates, a CAMAC crate has been standardized. These standards give physical characteristics, such as connectors and plugs, mounting dimensions, printed board sizes, etc. These standards also define communications protocol, bus timing, and connector pin assignment.

In most computers, the interconnection of computer printed boards is accomplished using a "mother board." The mother board may contain the CPU, semiconductor memory, and several input/output devices. While these devices are somewhat arbitrary, it is essential that the mother board contain a computer bus structure. The computer bus is defined by a standard which defines the type connector, the connector circuit configuration, and the computer communication protocol. There are several agencies which define computer bus standards in the United States and around the world. Some of the more common IEEE bus standards are listed in Table 15.2.16.

Table 15.2.16 IEEE Computer Bus Standards

Identifier	Common name	Description
IEEE 488	GPIB	General-purpose instrument bus
IEEE 796	Multibus	General-purpose computer bus
IEEE 961	STD bus	Standard computer bus
IEEE 1014	VMEBUS	European computer bus
IEEE Proposal	VXIBUS	Instrumentation adaptation of VMEBUS
IEEE Proposal	MXIBUS	Extension of VXIBUS

POWER ELECTRONICS

Power electronics can be divided into three major groups: motor drives, power supplies, and power amplifiers. Motor drives can be divided into dc motor drives and ac motor drives. Power supplies include power supplies for electronic circuits, battery back-up systems, electric power applications, and induction/dielectric heating supplies. Power amplifiers cover other power conditioning topics.

The power for dc motor armatures can be derived from thyristor circuits like those shown in Fig. 15.2.9. Single-phase bridge circuits are used for 5-hp drives and smaller. Three-phase bridge circuits are used for drives larger than 5 hp. A single set of six thyristors can supply power for about 300 hp. Above 300 hp, multiple sets of thyristors must be used in parallel. Mill drives have been built with more than 10,000 hp provided by thyristors.

The control of dc motors whether powered by thyristors or by dc generators is accomplished electronically. Control of individual drives can be accomplished by tachometer feedback or by armature voltage feedback. The speed-regulation accuracy for armature feedback is 5 percent; for tachometer feedback speed-regulation accuracy is from 0.1 to 1.0 percent. When two drives must be coordinated with each other, as in a continuous-web processing machine, they can be regulated to control torque, speed, position, draw, or a combination of these parameters. Torque controls can be achieved using dc motor armature current for a feedback signal. Speed-control signals are derived as for single motors. Position or draw control can be accomplished by using selsyn ties or dancer rolls. A **dancer roll** is a weight- or spring-loaded roll that rides on the web. It is free to move up and down, and as it does, a signal is taken from its position to serve as a feedback for the drive regulator before the dancer or after it.

Coordination of the motions of two or more drives requires tracking of the drives in both steady-state and transient conditions. Linearity of the control and feedback signals determine steady-state tracking. Provision must be made for both low-speed and high-speed matching signals. Transient matching requires that signals not only be the right magnitude but also arrive at the right time. An example will serve to illustrate this point. Suppose it is desired to have two drives with tachometer feedback which have a continuous web between them. One way to accomplish this would be to designate one drive as a master and the other as a slave. The tachometer on the master drive would serve as its own feedback signal and as the reference or command signal for the slave drive. The slave drive would have its own feedback from its own tachometer and so its regulator would try to minimize the difference between the two tachometer signals. On a transient basis the master drive will always start before the slave. An alternate and more common arrangement is to provide a common reference for both drives and let each drive receive its command signals at the same instant.

Digital computers are being used on-line in mills and continuous processing industries. DC motors can be controlled by either analog or digital regulators. With the greatly reduced cost of integrated circuits, digital regulators are being increasingly used.

For digital speed control, feedback is taken from a digital tachometer, which generates a pulse frequency proportional to motor speed. An adjustable frequency reference is compared with the feedback, and the difference is applied to an up/down counter. The output of the counter is converted to a dc control signal for the motor controller. In this system the dc drive functions as a form of phase-locked loop, and in fact, a phase-locked loop can be substituted for the up/down counter in digital speed control. For digital position control, a shaft encoder is used for feedback. In a shaft encoder, a single turn of the motor shaft is encoded in a binary code. For example, an eight-track shaft encoder can define 2^8, or 256, parts of a revolution. The output of the shaft encoder is compared with a digitally derived reference code. The difference between the feedback and the reference is converted into a dc signal which controls the motor, and holds the desired position. Sometimes the position encoder is mounted on the driven machine. The accuracy of sensing the machine position is improved. Accurate milling machines have feedback from machine position, rather than from the drive motor. Computers can be used to derive a speed reference or a position reference for several motors, and thus, an entire process line can be controlled. Modern high-speed paper making machines are one example of coordinated computer control of several motors. Graphic terminals, which display the entire paper making machine, are located at various positions allowing several operators to coordinate the operation of the machine.

DC motors can also be supplied from a fixed dc voltage such as a battery or a fixed dc power supply. Inherently, fixed voltage on the field and on the armature of a dc motor implies constant-speed operation. The armature voltage can be controlled by a proportional device such as a transistor. Proportional devices are limited to low-power applications. At low speeds, the dc motor requires low voltage and full current to produce full torque. The losses in the control device are proportional to the product of voltage and current. The full battery voltage is applied to the control device and the motor in series. Thus, the control device has a high voltage drop across it at low motor armature voltages and low motor speeds. To reduce controller losses, a **chopper** may be used. The chopper is thyristor, power MOSFET, or IGBT circuit which can rapidly switch on and off. When the chopper is on, the loss in the control device is low because the voltage drop is small. When the chopper is off, the loss in the control device is small because the current through the device is very small. Large amounts of power can be controlled with low losses by means of a switching controller. For large dc motors, the switching rate of the chopper is made high enough that the inherent inductance of the motor armature maintains a nearly constant motor current.

The speed range of a variable-speed dc motor is limited by its armature resistance, which produces *IR* drop. For a very small motor, the *IR* drop can be as much as 20 percent of rated armature voltage. The resistance-to-inductance ratio of small motors is much greater than for large motors. To extend the speed range of small motors, a low-frequency chopper can be used which will cause the armature current to be

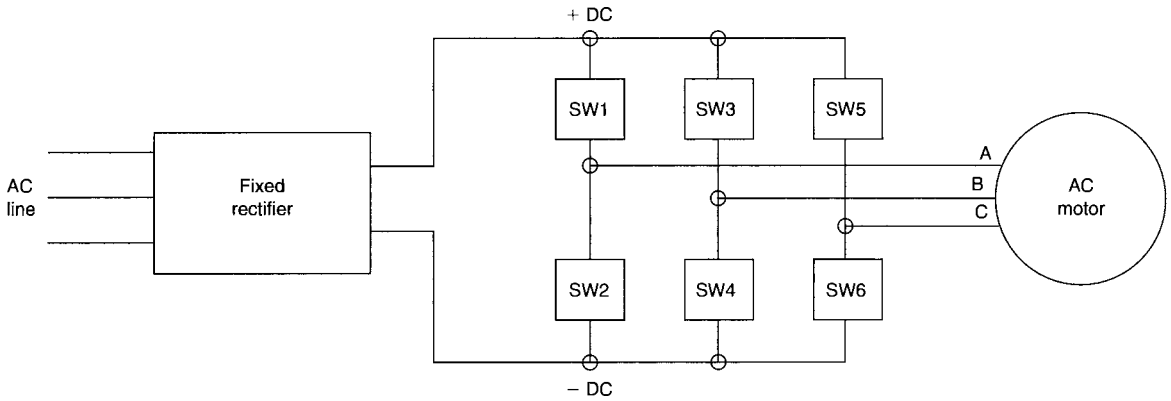

Fig. 15.2.35 Pulse width modulation inverter.

discontinuous. Discontinuous conduction reduces the effective *IR* drop for the motor allowing its speed range to be extended.

DC motors have been widely used for variable-speed applications because of their excellent characteristics. AC motors have been used primarily for constant-speed applications. The control schemes described above are equally applicable to ac motors (except of course for armature voltage and armature current feedback). If power circuitry is properly handled, the control of an ac motor is just as flexible and versatile as that of a dc motor.

AC motors can be supplied either from **phase-controlled circuits** or from **inverter circuits**. Phase control uses a simpler electronic circuit than the inverter, but it results in high loss in the ac motor. The phase control switches at line frequency, and so the frequency applied to the motor is constant. This means that the synchronous speed of the induction motor is constant. The difference between the operating speed of the motor and synchronous speed produces losses in the rotor of the motor proportional to the torque demanded of the motor. For this reason, phase-controlled ac motor drives are limited to applications with slight speed change requirements or to loads that require much lower torque at low speed, such as pumps or fans. Inverters are used for ac motor drives which require constant torque operation over a wide speed range. Several different schemes have been used for ac motor inverters. Some of these are **pulse width modulation (PWM), six-step inverters,** and **current link inverters**. Most modern drives are PWM inverters. In a PWM inverter, the ac line voltage is converted into a fixed dc voltage, and then this dc voltage is inverted into a variable frequency and a variable voltage. Figure 15.2.35 shows a block diagram of PWM inverter. Since the motor is an ac motor, both positive and negative voltages must be applied to each motor phase. The motor shown in Fig. 15.2.35 has three phases. Consider the operating conditions at only one of the phases of the motor. To apply a positive voltage to phase A-B of the motor, switches SW1 and SW4 are turned on. To apply a negative voltage to phase A-B, SW2 and SW3 are turned on. To apply zero volts to phase A-B, either SW2 and SW4 or SW1 and SW3 are turned on. A similar operation takes place for phase B-C and phase C-A of the motor. The dc voltage in the PWM inverter is constant. To generate an approximate sine wave of voltage, the inverter must produce a low voltage during part of the cycle and high voltage during another part of the cycle, and it must do this on both the positive half of the sine wave as well as the negative half. On the positive half-cycle, switching occurs alternately between switches SW1 and SW4 and switches SW1 and SW3. To control the speed of the ac motor and keep its losses low, one must vary both the frequency of the motor voltage and its magnitude. The motor requires an approximately constant volts per hertz rate for full torque and low losses. Although this control scheme seems very complicated, PWM inverter drives have been developed which are far more dependable than dc drives. The commutator and brushes required for a dc motor limit its reliability. The motor frequency for an ac motor inverter drive varies from nearly zero to a maximum of 120 Hz typically. To reverse the rotation of the ac motor, the phase sequence applied to the motor is reversed. The actual switching frequency of the inverter is approximately 10,000 Hz, allowing the inverter switch on and off several times during a cycle applied to the motor. The pulse width is varied or modulated, to change the output voltage, hence the name pulse-width-modulated inverter. The inductance of the motor keeps the current variations in the motor from being too great.

Switching power supplies use technology similar to ac motor inverters. In Fig. 15.2.35, SW1 and SW2 are called an *inverter leg*. The inverter leg is fundamental to switching power supplies. The dc chopper described earlier could be made with a single inverter leg. Regulated dc power supplies are also made using an inverter leg. A higher intermediate voltage is produced in an ac-to-dc rectifier. This voltage is then chopped to make a lower output voltage. Feedback is taken from the load point of the power supply to control the pulse width of the inverter leg, or chopper. Precise computer power supplies are often switching power supplies of this type. They maintain precise dc output voltage under changing load conditions and changing supply voltage. Because the power supplies switch, the loss in these power supplies is much lower than for proportionally controlled power supplies.

The switching behavior of the inverter leg is actually more complex than simply turning on one switch and turning off another. Each switching action involves a resonant transient. At each switching point an *R-L-C* circuit rings from one voltage to another. At very high switching rates, a second transient starts before the first transient is over. This leads to a power supply with a parade of transients. Such power supplies are called *resonant converters*. These power supplies may be used for dc-to-dc, dc-to-ac, ac-to-dc, and ac-to-ac conversions. By using the ring-up inherent in resonant circuits, voltage levels can be increased as well as decreased. Induction heating power supplies are typical of these kinds of circuits. Induction heating is produced by the magnetic losses generated in nonmagnetic and magnetic metals. If the frequency and voltage are increased sufficiently, dielectric heating may also be produced in high-frequency power supplies. High-frequency, high-voltage power supplies are also used to produce a corona discharge to treat the surface of plastic materials. Plastics which are normally hydrophobic can be made hydrophilic by corona discharge treatment.

COMMUNICATIONS

The Federal Communications Commission (FCC) regulates the use of radio-frequency transmission in the United States. This regulation is necessary to prevent interfering transmissions of radio signals. Some of the frequency allocations are given in Table 15.2.17. The frequency bands are also classified as shown in Table 15.2.18. Very low frequencies are used for long-distance communications across the surface of the earth. Higher frequencies are limited to line-of-sight transmission. Because of bandwidth considerations, high frequencies are used for high-density

Table 15.2.17 Partial Table of Frequency Allocations
(For a complete listing of frequency allocations, see "Reference Data for Radio Engineers," published by Howard Sams & Co.)

Frequency, MHz	Utilization
0.535−1.605	Commercial broadcast band
27.255	Citizen's personal radio
54–72	Television channels 2–4
76–88	Television channels 5–6
88–108	Frequency-modulation broadcasting
174–216	Television channels 7–13
460–470	Citizens' personal radio
470–890	Television channels 14–83

Table 15.2.18 Frequency Bands

Designation	Frequency	Wavelength
VLF, very low frequency	3–30 kHz	100–10 km
LF, low frequency	30–300 kHz	10–1 km
MF, medium frequency	300–3,000 kHz	1,000–100 m
HF, high frequency	3–30 MHz	100–10 m
VHF, very high frequency	30–300 MHz	10–1 m
UHF, ultra-high frequency	300–3,000 MHz	100–10 cm
SHF, super-high frequency	3,000–30,000 MHz	10–1 cm
EHF, extremely high frequency	30,000–300,000 MHz	10–1 mm

NOTE: Wavelength in metres = 300/*f*, where *f* is in megahertz.

communication links. Orbiting **satellites** allow the use of high-frequency transmission for long-distance high-density communications.

A radio transmitter is shown in Fig. 15.2.36. It consists of four basic parts: an rf oscillator tuned to the carrier frequency, an information-input device (microphone), a modulator to impress the input signal on the carrier, and an antenna to radiate the modulated carrier wave.

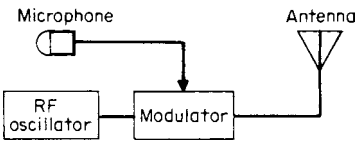

Fig. 15.2.36 Radio transmitter.

A radio wave can be modulated in several ways. It can be amplitude-, frequency-, or phase-modulated. These are examples of analog signal modulation. A radio wave may also be digitally modulated. Examples of digital modulation include on-off, binary phase-shift keying (BPSK), frequency-shift keying (FSK), quadrature phase-shift keying (QPSK), and quadrature amplitude modulation. Regardless of which method of modulation is used, the frequency content in the signal requires a bandwidth of frequencies to support the transmission. If a 10-kHz signal is to be broadcast, the transmitted radio wave will consist of a center frequency, called the *carrier frequency,* and an upper and lower sideband, for a frequency bandwidth of 2 times 10 kHz, or 20 kHz. It is possible to suppress the upper or lower sideband leading to single-sideband transmission, but this is a special case. Regardless of the modulation scheme, the bandwidth required for signal transmission is the same for a given signal bandwidth. Higher frequencies or higher digital pulse rates require greater bandwidth for transmission.

A radio receiver is shown in Fig. 15.2.37. This is called a **superheterodyne** receiver because it utilizes a frequency-mixing scheme. The tuned radio-frequency amplifier is tuned to receive the desired radio signal. The local oscillator is adjusted by the same tuning control to a lower frequency. The mixer produces an output frequency which is the difference between the incoming radio-signal frequency and the local-oscillator frequency. Since this difference frequency is constant for all tuning positions, the intermediate-frequency amplifier always operates

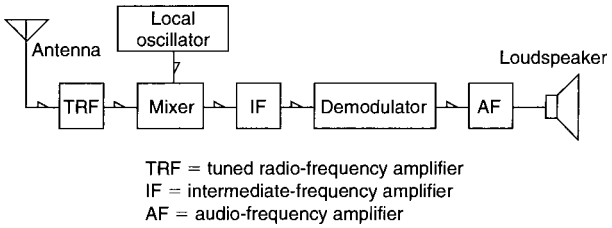

Fig. 15.2.37 Superheterodyne radio receiver.

with a constant frequency. This allows optimum design of the intermediate-frequency (IF) amplifiers since they are constant-frequency amplifiers. The IF frequency signal is modulated in just the same way as the radio signal. The demodulator separates this audio signal, which is then amplified so that the loudspeaker can be driven.

The term **radar** is **derived** from the first letters of the words "*ra*dio *d*etection *a*nd *r*anging." It is essentially an echo system in which the location of an object is determined by sending out short pulses of radio waves and observing and measuring the time required for their reflections or echoes to return to the sending point. The time interval is a measure of the distance of the object from the transmitter. The velocity of radio waves is the same as the velocity of light, or 984 ft/μs, so that each microsecond interval corresponds to a distance of 492 ft. The direction of an object can be determined by the position of the directional transmitting and receiving antenna. Radio waves penetrate darkness, fog, and clouds, and hence are able to detect objects that otherwise would remain concealed. Radar can be used for the automatic "tracking" of objects such as airplanes.

A block diagram of a radar system is shown in Fig. 15.2.38. The transmitting system consists of an rf oscillator which is controlled by a modulator, or pulser, so that it sends to the antenna intermittent trains of rf waves of relatively high power but of very short duration, corresponding to the pulses received by the modulator. The energy of the

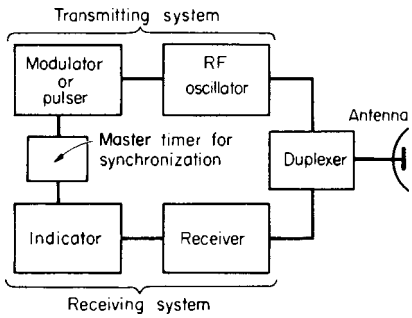

Fig. 15.2.38 Block diagram of radar system.

oscillator is transmitted through the duplexer and to the antenna through either coaxial cable or waveguides. The **receiver** is an ordinary heterodyne-type radio receiver which has high sensitivity in the band width corresponding to the frequency of the oscillator. For low frequencies the local oscillator is an ordinary oscillator for frequencies of 2,000 MHz; and higher a reflex **klystron** (hf cavity oscillator) is used. A common intermediate frequency is 30 MHz but 15 and 60 MHz are also frequently used.

In most radar systems the same antenna is used for receiving as for transmitting. This requires the use of a **duplexer** which cuts off the receiver during the intervals when the oscillator is sending out pulses and disconnects the transmitter during the periods between these pulses when the echo is being received.

The antenna is highly directional. By noting its angular position, the direction of the object may be determined. In the PPI (plan position indicator), the angle of the sweep of the cathode-ray beam on the screen

of the oscilloscope is made to correspond to the azimuth angle of the antenna.

The receiver output is delivered to the indicator which consists of a cathode-ray tube or oscilloscope. The pulses which are received, corresponding to echoes from the target, must be synchronized with the sending pulses in order that the distance to the target may be determined. This is accomplished by synchronization of the sweep circuit of the oscilloscope with the pulses by the master timer.

Displays Conversion of the received radar signals to usable display is accomplished by a cathode-ray oscilloscope. The simplest type, called the **A presentation,** is shown in Fig. 15.2.39*a*. When the pulser operates, a sawtoothed wave produces a linear sweep voltage (Fig. 15.2.39*b*) across the sweep plates of the cathode-ray tube; at the same time a transmitter pulse is impressed on the deflection plates and the return echoes appear as AM pulses, or "pips," on the screen, as shown in Fig. 15.2.39*a*. The distance on the screen between the transmitter pulse and the pip caused by the echo is proportional to the distance to the target, and the screen can be calibrated in distance such as miles.

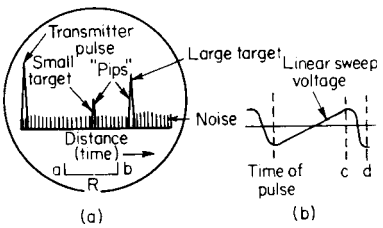

Fig. 15.2.39 Type A presentation.

[The return of the spot to its initial starting position, produced by the sweep interval *cd* (Fig. 15.2.39*b*), is so rapid that it is not detectable by the eye.] The direction of the target may be determined by the angular position of the antenna, which can be transmitted to the operator by means of a selsyn. Different objects, such as airplanes, ships, islands, and land approaches, have characteristic pips, and operators become skilled in their interpretation. A bird in flight can be recognized on the screen. Also a portion of the scale such as *ab* can be segregated and amplified for close study of the characteristics of the pips.

Plan Position Indicator (PPI) In the PPI (Fig. 15.2.40) the direction of a radial sweep of the electron beam is synchronized with the azimuth sweep of the antenna. The sweep of the beam is rotated continuously in synchronism with the antenna, and the received signals intensity-modulate the electron beam as it sweeps from the center of the oscilloscope screen radially outward. In this way the direction and range position of an object can be determined from the pattern on the screen of the oscilloscope, as shown in Fig. 15.2.40.

There are two methods by which the angular direction of the cathode spot is made to correspond with the angular position of the antenna. In one method, used on board ship, two magnetic deflecting coils are rotated around the neck of the tube in synchronism with the antenna, by means of a selsyn. In the other method, used on aircraft, two fixed magnetic deflecting coils at right angles to each other and placed at the neck of the tube are supplied with current from a small two-phase synchronous generator whose rotor is driven by the antenna. Thus a rotating field, similar to that produced by the stator of an induction motor, is produced by the magnetic deflecting coils. These two rotating fields, although produced by different means, are equivalent and cause the cathode beam to sweep radially in synchronism with the antenna. Circular coordinates spaced radially corresponding to distance are obtained by impressing on the control electrode short positive pulses synchronized with the transmitted pulse but delayed by time values corresponding to the desired distances. These coordinates appear as circles on the screen. Since the time of rotation of the antenna is relatively slow, it is necessary that a persistent screen be used in order that the operator may view the entire pattern. In Fig. 15.2.32 is shown a line drawing of a PPI presentation of Cape Cod, Mass., on a radar screen, taken from an airplane.

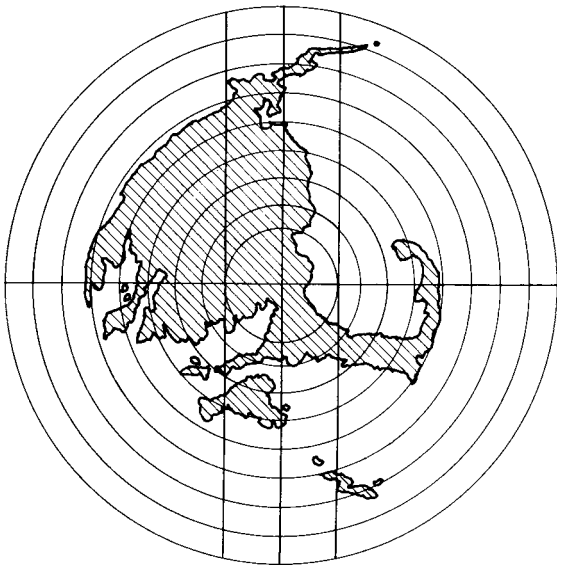

Fig. 15.2.40 Plan position indicator (PPI) of southeastern Massachusetts.

The applications of radar to war purposes are well known, such as detecting enemy ships and planes, aiming guns at them, and locating cities, rivers, mountains, and other landmarks in bombing operations. In peacetime, radar is used to navigate ships in darkness and poor visibility by locating navigational aids such as buoys and lighthouses, as well as protruding ledges, islands, and other landmarks. It can be similarly used in air navigation, as well as to operate altimeters for determining the height of the plane above ground. It is also used for aerial mapping.

Sonar is closely related to radar. The difference is that sound is used as the transmitting signal. Since the velocity of sound in water is so much slower than radio waves in free space, the timing for sonar signals is much slower than for radar signals. A 1-s delay of a sonar return echo implies that the target is 2,500 ft away. A 1-s delay of a radar return echo would imply that the target is 193,000 miles away. Although A displays and PPI displays are used with sonar signals, much reliance is placed on hearing. Transmitting a sonar pulse is an excellent way of disclosing your presence to an enemy vessel. Today more reliance is placed on passive detection of enemy vessels, by **signature analysis**. Signature analysis is signal analysis using fast Fourier transforms and filters.

Television is accomplished by systematically scanning a scene or the image of a scene to be reproduced and transmitting at each instant a current or a voltage which is proportional to the light intensity of the elementary area of the scene which at the instant is being scanned. The varying voltage or current is amplified, modulated on a carrier wave, and then transmitted as a radio wave. At the receiver the radio wave enters the antenna, is amplified, and demodulated to give a voltage or a current wave similar to the original wave. This voltage or current wave is then used to control the intensity of a cathode-ray beam which is focused on a fluorescent screen in a cathode-ray reproducing tube. The cathode-ray beam is caused to move over the screen in the same pattern as the scanning beam at the transmitter and in synchronism with it. Thus each small area of the receiver screen is illuminated instantaneously with light intensity corresponding to that of a similarly placed area in the original scene. This process is conducted so rapidly that owing to persistence of vision of the eye, the reproduction of each instantaneous scene appears to be a complete picture and the effect with successive scenes is similar to that produced by the projection of successive frames of a motion picture.

Scanning and Blanking In the United States the ratio of width to height of a standard television picture is 4 : 3, and the picture is composed of 525 lines repeated 30 times a second, this last factor being one-half 60, the prevalent electric power frequency in the United States. The scanning sequence along the individual lines is from left to right and the

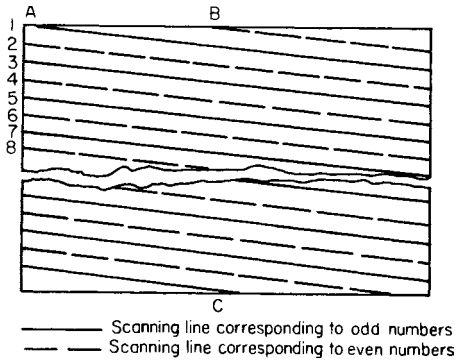

Fig. 15.2.41 Pattern of interlaced scanning.

sequence of the lines is from top to bottom. Also, interlacing is employed, the general method of which is shown in Fig. 15.2.41. The cathode-ray spot starts at 1 in the upper left-hand corner and is swept rapidly from left to right either by a sawtooth emf wave applied to the sweep plates or by the sawtooth current wave applied to the sweep coils of the tube. When the spot arrives at the right-hand side of the picture, the sawtooth wave of either emf or current in the sweep circuit acts to return the cathode-ray spot rapidly to point 3 at the left-hand side of the picture. However, during this period the cathode-ray is blanked, or entirely eliminated, by the application of a negative potential to the control grid of the tube. At the end of the return period, the blanking effect ceases and the spot appears at point 3, from which it again is swept across the picture and this process is repeated for 262.5 lines until the spot reaches a midpoint *C* at the bottom of the picture. It is then carried vertically and rapidly to *B,* the midpoint of the top of the picture, the beam also being blanked during this period. This process of scanning is then repeated, a second set of lines corresponding to the even numbers 2, 4, 6 being established between the lines designated by the odd numbers. These lines are shown dashed in Fig. 15.2.41. This method or pattern of scanning is called **interlacing**. The two sets of lines taken together produce a frame of 525 lines, which are repeated 30 times each second. However, owing to interlacing, the flicker frequency is 60 Hz which is not noticeable, 50 Hz having been determined as the threshold of flicker noticeable to the average eye. In Fig. 15.2.41, for the sake of clarity, the distances between horizontal lines are greatly exaggerated and no attempt is made to maintain proportions.

Frequency Band In order to obtain the necessary resolution of pictures, television frequencies must be high. In the United States, VHF frequencies from 54 to 88 MHz (omitting 72 to 76 MHz) and 174 to 216 MHz are assigned for television broadcasting. A UHF band of frequencies for commercial television use is also allocated and consists of the frequencies from 470 to 890 MHz (see also Tables 15.2.17 and 15.2.18).

In order to obtain the 525 lines repeated 30 times per second, a bandwidth of 6 MHz is necessary. The video, or picture, signal with the superimposed scanning and blanking pulses is amplitude-modulated, amplified, and transmitted. The carrier frequency associated with the sound transmitter is 4.5 MHz higher than the video carrier frequency and is frequency-modulated with a maximum frequency deviation of 25 kHz.

In scanning motion-picture films a complication arises because standard film rate is 24 frames per second, while the television rate is 30 frames per second. This difficulty is overcome by scanning the first of two successive film frames twice and the second frame three times at the 60-Hz rate, making the total time for the two frames $\frac{1}{12}$ ($\frac{2}{60} + \frac{3}{60}$) or $\frac{1}{24}$ s average per frame.

Kinescope The kinescope (Fig. 15.2.42) is the terminal tube in which the televised picture is reproduced. It is relatively simple, being not unlike the cathode-ray oscilloscope tube. It has an electric gun operating at 8,000 to 20,000 V which produces an electron beam focused on a fluorescent surface within the front wall of the tube. The picture is viewed at the front wall. The horizontal and vertical deflections of the beam are normally controlled by deflection coils, as shown in Fig. 15.2.42.

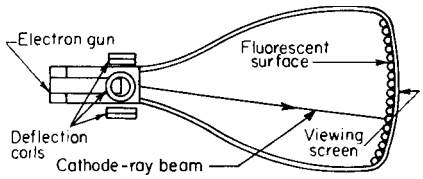

Fig. 15.2.42 Kinescope for television receiver.

Television Receivers A block diagram for a television receiver is given in Fig. 15.2.43. It is in reality a superheterodyne receiver with tuned rf amplification, the separating of the sound and video or picture channels taking place at the intermediate frequency in the mixer. The sound channel is then conventional, a discriminator being used to demodulate the FM wave (Fig. 15.2.21). The object of the dc restorer is to make the picture reproduction always positive, and it consists of applying a dc voltage at least equal in magnitude to the maximum values of the negative loops of the ac waves. The synchronizing pulses for both the vertical and the horizontal deflections are delivered by the dc restorer to an amplifier and the two pulses are then divided into the V and H components. The integrating and differentiating circuits are necessary to separate horizontal and vertical synchronizing signals.

As stated earlier, at any instant the magnitude of the current from the pickup tube varies in accordance with the light intensity of the part of the scene being scanned at that instant. This current is amplified and, together with the sound and synchronizing current, is broadcast and received by the circuit shown in Fig. 15.2.43. The video current is detected by rectification, is amplified, and is then made to control the intensity of the kinescope electron beam. Tubes produce a scanning pattern, identical with that in the pickup tube, and these tubes are triggered by the synchronizing pulses which are transmitted in the broadcast wave. Hence, the original televised scene is reproduced on the fluorescent screen of the kinescope.

Color-television transmission is similar to black-and-white television, and the two signals must be compatible with each other. The kinescope for color TV has three electron guns, one for each primary color. The fluorescent screen has a matrix of three different colors of phosphor and a mask with many small holes in it. The intensity signals for each color are phase-shifted from each other so that the proper phosphors are excited by each electron stream at each mask point over the entire screen. A black-and-white signal does not have the same synchronizing signal as a color signal. The color receiver has circuits which recognize this state and switch it to black and white reception.

TELEPHONE COMMUNICATIONS

Telephone communications is an important aspect of electronics because it provides a source of low-cost electronic devices which can be adapted for electronic circuit design. One of the big problems in telephone system design is switching. Each long-distance phone call requires that several circuits be joined together, and thousands of phone calls take place simultaneously. Older telephone exchange buildings had rack upon rack of telephone relays. These are being replaced by semiconductor switching. Older trunk lines were coaxial cable or microwave radio links. These are being replaced by fiber-optic cables. Fiber-optic cables have a tremendous bandwidth. A telephone voice circuit has a bandwidth of 4 kHz. Thousands of these circuits can be routed through one fiber-optic cable. Separating these voice circuits into communication channels by frequency separation and filtering is not feasible. Communication on fiber-optic cables is done digitally, and in packets. Each packet is a few hundred bytes long, and includes a header with an address and other control information, the message, and a trailer with error-correcting codes. The address is a session address to identify where the packet is from and

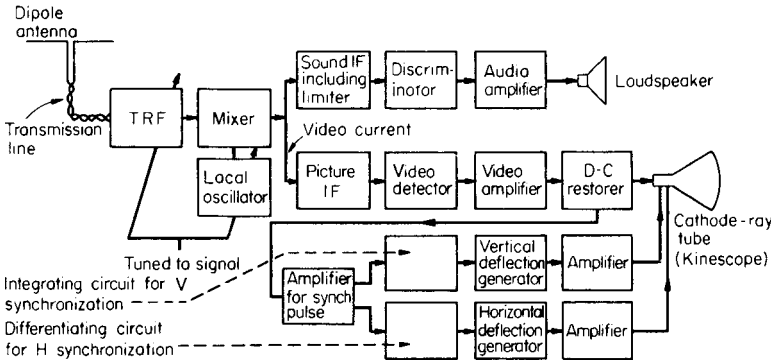

Fig. 15.2.43 Block diagram for television receiver. TRF: tuned radio frequency; IF: intermediate frequency.

where it is going. Users time-share the fiber-optic cable, and all of this signal processing must be done at a high enough rate to appear to be instantaneous to the subscriber.

Any form of signal modulation can be considered to be data encryption. The information is coded or encrypted onto the transmitting medium. At the transmitting end, a clear signal with no noise is sent, but at the receiving end of the medium, the signal contains the signal plus unwanted noise. Since the coding method is known, and since the noise is known to be random, separation of signal and noise is possible. This process of separating signal from noise will be repeated several times for long-distance communications. Each time, the noise is discarded and only the signal is sent on. Such a scheme of data encryption, or modulation, is also warranted in data telemetry, in order to allow noise to be removed from the desired signal.

Long-distance communications takes several different forms. Historically, cables with hundreds of twisted-pair circuits were used for long-distance communication. These are used for local subscriber service today. The next step was a cable made up of many wideband microwave coaxial cables. The coaxial cables were replaced by microwave radio links. Then, fiber-optic cables replaced microwave links. Wireless communication, using laser-generated signals, is the latest form of high volume data transmission. In a telephone system, all of these systems must coexist and work together.

Two technologies are replacing traditional telephone communications: **cellular communication** and **voice over Internet protocol** (VOIP).

The first **cell phones** used analog voice transmission technology, which consumed a lot of power. The cost and lack of versatility limited wide acceptance of the technology. Early cell phones were powered by the electrical system in a car, and the first batteries were bigger than the phone and thus were not an integrated handset but a collection of individual parts (handset, keypad, battery, and antenna all separate) with antennas mounted on the exterior of the vehicle. Evolution of several technologies allowed widespread use. Digital encoding technologies such as code division multiple access (CDMA), time division multiple access (TDMA), and global system for mobile communications (GSM) reduced the power consumption dramatically, as did the use of gallium arsenide compound semiconductor materials for the power amplifier that sends the signal to the cell tower. Improvements in nickel metal hydride (NiMH) and lithium ion technologies enabled smaller and more powerful batteries that could be integrated directly into the handset. These developments enabled ubiquitous mobile cellular communications. You could take your phone anywhere and not be tethered to a vehicle or large power source. Additionally, expansion of cellular communications is lower in cost and faster compared to the traditional copper or optical lines, which has enabled communication in remote and underprivileged areas of the world.

VOIP, also referred to as Internet telephony, is another replacement technology for traditional telephone communications. This technology is piggybacked onto a high-speed Internet connection, such as a digital subscriber line (DSL) or high-speed cable modem. This convergence of data and voice enables a single connection to the home that allows multiple concurrent users. By bundling voice with the Internet, companies are able to offer very attractive flat-fee rates for nationwide calling, email, and Internet access.

WIRELESS TECHNOLOGY

In addition to cellular phones, many other applications are taking advantage of wireless technology. Two standards have gained broad acceptance: **Bluetooth (IEEE 802.15)** and **WiFi (IEEE 802.11).** Bluetooth is finding its niche in **personal area networking (PAN),** whereas WiFi is making its mark in **local area networking (LAN).** Bluetooth enables wireless interconnection of devices, such as hands-free headsets and cell phones, while WiFi replaces wired computer networks such as Ethernet. Another emerging standard is **WiMax/EV-DO (IEEE 802.16),** an enabling technology for wireless broadband access, which would allow computers Internet access analogous to the current cell phone system.

WiFi is becoming ubiquitous, with deployment branching out from universities and businesses, now into homes, hotels, airports, coffee shops, and restaurants. Laptop computers rival their desktop counterparts for performance, and prices have dropped considerably, such that the demand for mobile Internet access is driving the rapid acceptance of WiFi. The IEEE 802.11 standard has three "flavors"—a, b, and g—with respective peak speeds of 11 Mbps, 22 Mbps, and 108 Mbps and ranges of 330 ft indoors and 1,300 ft line-of-sight. While these speeds are slower than those of wired Ethernet, they are fast enough, and the desire for mobility outweighs the need for speed. Peripherals such as wireless cameras and integrated video phones are just a couple of examples of the limitless additional capabilities that can be attached to WiFi networks. As demand increases, WiMax, which has a 30-mi range and 1.5-Mbps speed, is seeing initial deployment in some small cities, and speeds will increase as the technology is accepted and evolves.

While WiFi and WiMax enable multiple computers and peripherals to communicate on a network, Bluetooth, on the other hand, is a device-to-device direct interconnect technology which enables such applications as hands-free cell phone use in vehicles. It is a close-range wireless connection technology that enables a myriad of personal devices to intercommunicate, e.g., cell phones and laptop computers, laptop computers and digital cameras, or personal digital assistants and cell phones.

Other wireless applications, while not as cutting edge, are still benefitting from technology advancements that provide one- or two-chip designs for low-cost consumer-level products. Two-way radios with ranges up to 3 mi that do not require an amateur radio license are in wide use today, and wireless intercom systems for the home can be installed without the need to pull wires through walls. Commuters in high-traffic areas are benefitting from wireless RF identification (**RFID**), as tollways implement systems whereby commuters have an RFID device in their vehicle that allows them to proceed through a

special **EZPass** lane at a tollbooth without stopping. The RFID is linked to an account, and the toll is debited each time the vehicle passes through the system. Additional RFID applications are to implant a chip containing critical medical information into a chronically ill person's arm. This can be extended to all people, which of course has extreme privacy concerns, which are being debated. Other more mundane uses of RFID are retail product tagging and automated inventory tracking.

DISPLAY TECHNOLOGY

Display technology has evolved beyond the curved monitor cathode-ray tube (CRT), with emphasis on **flat-screen technology,** wide viewing angles, large screens, and outdoor capability.

While CRT flat screens are widely available at reasonable prices, the tube still means a distinct depth of several inches. Other technologies, such as LCD, LED and plasma, are enabling displays to converge toward being truly flat, almost two-dimensional, by shrinking the depth of the display to about an inch. Each of these technologies has its strengths and weaknesses, all are relatively immature display technologies, and as a result all are currently very expensive. Plasma is the technology leader for brightness and large screen size; however, leading CRT manufacturers are dropping production of smaller (less than 20-in) CRTs in favor of LCD displays, which will help drive down price and increase production, leading to new technology developments that will enable wider availability of LCD flat-screen displays. For outdoor displays, LED technology is the best solution for its outstanding brightness capability, simple scalability to larger screens, and robustness in all weather conditions.

GLOBAL POSITIONING INFORMATION

Navigational aids take several different forms. **Shoran** (short-range navigation) and **loran** (long-range navigation) are methods by which ships or planes can locate their position. A loran station consists of a master transmitter and slave transmitter located about 200 mi apart. A pulse is broadcast from the master transmitter and, when received by the slave transmitter, causes it to also broadcast a pulse. The loran receiver, located on a ship or airplane, receives both the master and the slave pulses. The receiver allows the user to measure the delay between receiving the master and slave pulses. The delay defines a line across the surface of the earth. By picking three loran stations, determining the delay of each of the transmitter pairs, and using loran charts, three lines can be defined, allowing the user to determine the triangle which defines the receiver's position. **Very high frequency omnirange (VOR)** is used for short-range aircraft navigation, often in conjunction with **direction measuring equipment (DME).** VOR stations are located approximately 100 mi apart. The receiver in the aircraft receives a signal from the VOR transmitter with two pieces of information, which allows the pilot to determine the bearing from the VOR station. The first piece of information is a 30-Hz amplitude-modulated signal which is broadcast from a rotating directional antenna. The antenna rotates 30 times per second, and broadcasts in the 108- to 112-MHz range. The second piece of information is a frequency-modulated signal which varies between 9,480 and 10,440 Hz. This FM signal changes frequency at 30 Hz, and forms a reference for the VOR system. A receiver on the aircraft compares the 30-Hz amplitude-modulated signal and the 30-Hz frequency-modulated reference, and translates the difference in phase between the FM signal and the AM signal to give the airplane its bearing. The VOR also broadcasts station identification information in the 112- to 118-MHz range. Most VOR stations can also broadcast a **distance measuring equipment (DME).** The aircraft has a DME transmitter which broadcasts a pulse which activates a ground mounted transponder. The aircraft sends an FM signal in the 1,025- to 1,150-MHz range. The DME ground station responds with a delayed signal in the 962- to 1,024-MHz or 1,151- to 1,213-MHz range. Distance is determined by the time delay required for the propagation of the signals. The depressed, straight line distance from the aircraft is measured by the DME equipment. To relieve the pilot of the job of correcting for altitude in the DME signal and to allow the pilot to fly any heading, a computer system called RNAV was introduced. RNAV uses the VOR and DME information, plus wind velocity and airspeed, to calculate the required aircraft heading and the estimated time of arrival at the destination.

Most major airports have an **instrument low approach system (ILS).** This produces a set of signals in the 108- to 112-MHz region. There a right-hand antenna lobe, relative to the aircraft, which is modulated at 150 Hz, and a left-hand lobe modulated at 90 Hz. In addition, in the 329- to 335-MHz range there is a vertical set of antenna lobes, with the upper lobe modulated at 90 Hz and lower lobe at 150 Hz. The display on the aircraft is an azimuth needle and a glide path needle. The pilot simply flies the aircraft to center the needles to determine a correct landing approach. There are also ILS marker beacons to tell the pilot how close the aircraft is to the airport. Other aircraft navigation systems are based on ground-operated radar systems. Still others are based on aircraft-mounted Doppler radar. Doppler radar is a velocity measuring system.

Satellite positioning systems are the newest development for long-range and short-range navigation. The **Global Positioning System (GPS)** is a system of 24 satellites that broadcast accurate time marks from a known position in space, which enable accurate positioning determination by triangulation. GPS was initially developed for military applications, for which it is still in use. By knowing which satellite has broadcast the time mark, and measuring its delay, a spherical surface in space centered on the satellite is determined. By determining the delay from four satellites, four spherical surfaces in space can be determined, with the intersection providing positioning accuracy to within a meter. Technologically advanced GPS electronics can determine position within a centimetre. Technology advancements have lowered the cost of GPS receivers, enabling widespread consumer use. GPS receivers have been miniaturized to just a few integrated circuits and are now used in cars, boats, planes, construction equipment, movie-making gear, farm machinery, laptop computers, and most recently cell phones. The lower cost has enabled an increase in the complexity and integration of GPS systems, by including significant memory and simple microprocessors for a variety of applications including integrated traffic maps and real-time driving instructions. Farmers combine laboratory-analyzed soil samples that are mapped into a GPS system with a fertilizer delivery system for efficient, economic, and ecologically sound soil treatments. By introducing GPS into cell phones, the 911 emergency system can be utilized by anyone, anytime, anywhere. Fishermen and hunters use GPS receivers with integrated memory to archive their favorite locations so they can return time and time again. Vehicle tracking and control is another interesting application, not only for commercial vehicle fleets, but for private citizens as well. Service providers offer the ability to track a vehicle's location and speed, and make the information available via the Internet, with parents of teens being the largest target market. Typical prices for these integrated GPS products start at around $300, making them widely available to consumers.

INTRODUCTION TO MEASUREMENT

An **instrument,** as referred to in the following discussion, is a device for determining the value or magnitude of a quantity or variable. The variables of interest are those which help describe or define an object, system, or process. Thus, in a manufacturing operation, product quality is related to measurements of its various dimensions and physical properties such as hardness and surface finish. In an industrial process, measurement and control of temperature, pressure, flow rates, etc., determine quality and efficiency of production.

Measurements may be direct, e.g., using a micrometer to measure a dimension, or indirect, e.g., determining moisture in steam by measuring the temperature in a throttling calorimeter.

Because of physical limitations of the measuring device and the system under study, practical measurements always have some error. The **accuracy** of an instrument is the closeness with which its reading approaches the true value of the variable being measured. Accuracy is commonly expressed as a percentage of measurement span, measurement value, or full-scale value. Span is the difference between the full-scale and the zero-scale value. **Uncertainty,** the sum of the errors at work to make the measured value different from the true value, is the accuracy of measurement standards. Uncertainty is expressed in parts per million (ppm) of a measurement value. **Precision** refers to the reproducibility of the measurements, i.e., with a fixed value of the variable, how much successive readings differ from one another. **Sensitivity** is the ratio of output signal or response of the instrument to a change in input or measured variable. **Resolution** relates to the smallest change in measured value to which the instrument will respond.

Error may be classified as systematic or random. Systematic errors are those due to assignable causes. These may be static or dynamic. Static errors are caused by limitations of the measuring device or the physical laws governing its behavior. Dynamic errors are caused by the instrument not responding fast enough to follow the changes in measured variable. Random errors are those due to causes which cannot be directly established because of random variations in the system.

Standards for measurement are established by the National Institute of Standards and Technology. Secondary standards are prepared by very precise comparison with these primary standards and, in turn, form the basis for calibrating instruments in use. A well-known example is the use of precision gage blocks for the calibration of measuring instruments and machine tools.

There are three essential parts to an instrument: the **sensing element,** the **transmitting means,** and the **output** or **indicating element.** The sensing element responds directly to the measured quantity, producing a related motion, pressure, or electrical signal. This is transmitted by linkage, tubing, wiring, etc., to a device for display, recording, and/or control. Displays include motion of a pointer or pen on a calibrated scale, chart, oscilloscope screen, or direct numerical indication. Recording forms include writing on a chart and storage on magnetic tape or disk. The instrument may be actuated by mechanical, hydraulic, pneumatic, electrical, optical, or other energy medium. Often a combination of several energy modes is employed to obtain the accuracy, sensitivity, or form of output desired.

The transmission of measurements to distant indicators and controls is industrially accomplished by using the standardized electrical current signal of 4 to 20 mA; 4 mA represents the zero-scale value and 20 mA the full-scale value of the measurement range. A pressure of 3 to 15 lb/in^2 is commonly used for pneumatic transmission of signals.

COUNTING EVENTS

Event counters are used to measure the number of items passing on a conveyor line, the number of operations of a machine, etc. Coupled with time measurements, they yield measures of average rate or frequency. They find important application, therefore, in inventory control, production analysis, and in the sequencing control of automatic machines.

Choice of the proper counting device depends on the kind of events being counted, the necessary counting speed, and the disposition of the measurement; i.e., whether it is to be indicated remotely, used to actuate a machine, etc. Errors in the total count may be introduced by events being too close together or by too much nonuniformity in the items being counted.

The **mechanical counter** is shown in Fig. 16.1.1. Motion of the event being counted deflects the arm, which through an appropriate linkage

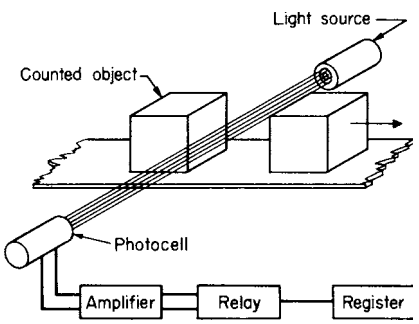

Fig. 16.1.1 Mechanical counter.

advances the count register one unit. Alternatively, motion of the actuating arm may close an electrical switch which energizes a relay coil to advance the count register one step.

Where there is a desire to avoid contact or close proximity with the object being counted, the photoelectric cell or diode, in conjunction with a lamp, a light-emitting diode (LED), or a laser light source, is employed in the transmitted or reflected light mode (Fig. 16.1.2). A signal to a counter is generated whenever the received light level is altered by the passing objects. Objects may be very small and very high counting speeds may be achieved with electronic counters.

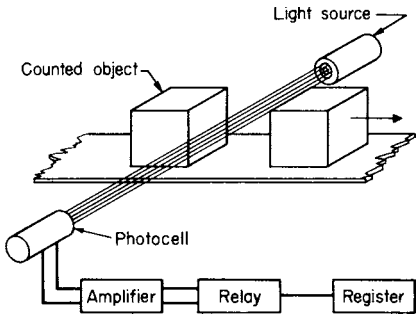

Fig. 16.1.2 Photoelectric counter.

Sensing methods based on electrical capacitance, magnetic, and eddy-current effects are extremely sensitive and fast acting, and are suitable for objects in close proximity to the sensor. The capacitive probe senses dielectrics other than air, such as glass and plastic parts. The magnetic pickup, by induction, responds to the motion of iron and nickel. The eddy-current sensor, by energy absorption, detects nonmagnetic conductors. All are suitable for counting machine operations.

The count is displayed by either a mechanical register as in Fig. 16.1.1, a dial-type register (as on the household watthour meter), or an electronic pulse counter with either number indicators or digital printing output. **Electronic counters** can operate accurately at rates exceeding 1 million counts per second.

TIME AND FREQUENCY MEASUREMENT

Measurement of time is basic to time and motion studies, time program controls, and the measurements of velocity, frequency, and flow rate. (See also Sec. 1.)

Mechanical clocks, chronometers, and stopwatches measure time in terms of the natural oscillation period of a system such as a pendulum, or hairspring balance-wheel combination. The minimum resolution is one-half period. Since this period is somewhat affected by temperature, precise timepieces employ a compensating element to maintain timing accuracies over long periods. Stopwatches may be obtained to read to better than 0.1 s. The major limitation, however, is in the response time of the user.

Electric timers are simple, inexpensive, and readily adaptable to remote-control operations. The majority of these are ac synchronous motors geared in the proper ratio to the indicator. These depend for their accuracy on the frequency of the line voltage. Consequently, care must be exercised in using such devices for precise short-time measurements.

Electronic timers are started and stopped by electrical pulses and hence are not limited by the observer's reaction time. They may be made extremely accurate and capable of measuring to less than 1 μs. These measure time by counting the number of cycles in a high-frequency signal generated internally by means of a quartz crystal. Stopwatch versions read at 0.01 s. Commercial instruments offer one or more functions: counting, measurement of frequency, period, and time intervals. Microprocessor-equipped versions increase versatility.

There are a variety of timing devices designed to indicate or control to a fixed time. These include timers based on the charging time of a condenser (e.g., type 555 integrated circuit), and the flow of oil or other fluid through a restriction. Most of these timing devices are now obsolete in favor of solid-state timing devices, but some mechanical or electromechanical timing devices are still in use.

Timing devices can be **calibrated** by comparison with a standard instrument, or by reference to the National Institute of Standards and Technology (NIST) timed radio signals (stations WWV, WWVB, and WWVH), telephone modem synchronization system (ACTS), or Internet Time Service (ITS). The most up-to-date information on time standards can be found on the Internet at www.boulder.nist.gov/timefreq/index.html. Frequency devices can also be calibrated by referring to the information on that page. The GOES Time Service, using geostationary satellites, was ended on January 1, 2005. See the References section at the beginning of this chapter for information on ACTS and ITS services.

Fast-moving, repetitive motions may be timed and studied by the use of stroboscopes which generate brilliant, very brief flashes of light at an adjustable rate.

The frequency of the observed motion is measured by adjusting the stroboscopic frequency until the system appears to stand still. The frequency of the motion is then equal to the stroboscope frequency or an integer multiple of it.

Many other means exist for **measuring vibrational or rotational frequencies.** These include timing a fixed number of rotations or oscillations of the moving member. Contact sensing can be done by an attached switch, or noncontact sensing can be done by magnetic or optical means. The pulses can be counted by an electronic counter or displayed on an oscilloscope or recorder and compared with a known frequency. Also used are reeds which vibrate when the measured oscillation excites their natural frequencies, flyball devices which respond directly to angular velocity, and generator-type tachometers which generate a voltage proportional to the speed.

MASS AND WEIGHT MEASUREMENT

Mass is the measure of the quantity of matter. The fundamental unit is the kilogram. The U.S. customary unit is the pound; 1 lb = 0.4536 kg (see Sec. 1.2, "Measuring Units"). Weight is a measure of the force of gravity acting on a mass (see "Units of Force and Mass" in Sec. 4).

A general equation relating weight W and mass M is $W/g = M/g_c$, where g is the local acceleration of gravity, and $g_c = 32.174$ lbm · ft/(lbf) (s^2) [(1 kg · m/(N) (s^2)] is a property of the unit system. Then $W = Mg/g_c$. The specific weight w and the mass density p are related by $w = pg/g_c$. Masses are conveniently compared by comparing their weights, and masses are often loosely referred to as weights. Indeed, almost all practical measures of mass are based on weight.

Weighing devices fall into two major categories: balances and force-deflection systems. The device may be batch or continuous weighing, automatic or manual. Accuracies are expected to be of the order of 0.1 to better than 0.0001 percent, depending on the type and application of the scale. Calibration is normally performed by use of standard weights (masses) with calibrations traceable to the National Institute of Standards and Technology.

The **equal arm balance** compares the weight of an object with a set of standard weights. The laboratory balance shown in Fig. 16.1.3 is used

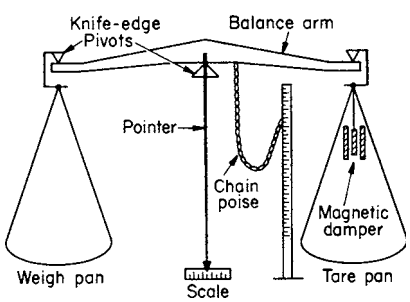

Fig. 16.1.3 Laboratory balance.

for extreme precision and sensitivity. A chain poise provides fine adjustment of the final balance weight. The magnetic damper causes the balance to come to equilibrium quickly.

Large weighing scales operate on the same principle; however, the arms are unequal to allow multiplication between the tare and the measured weights. In this group are platform, track, hopper, and tank scales. Here balance is achieved by adjusting the position of one or more balance weights along a beam directly calibrated in weight units. In dial-indicating-type scales, balance is achieved automatically through the deflection of calibrated pendulum weights from the vertical. The deflection is greatly magnified by the pointer-actuating mechanism, providing a direct-reading weight indication on the dial.

Since the deflection of a spring (within its design range) is directly proportional to the applied force, a calibrated spring serves as a simple and inexpensive weighing device. Applications include the **spring scale** and **torsion balance.** These are subject to hysteresis and temperature errors and are not used for precise work.

Other force-sensing elements are adaptable to weight measurement. Strain-gage load cells eliminate pivot maintenance and moving parts and provide an electrical output which can be used for direct recording and control purposes. Pneumatic pressure cells are also used with similar advantages.

In production processes, **continuous and automatic operating scales** are employed. In one type, the balancing weight is positioned by a reversible electric motor. Deflection of the beam makes an electrical contact which drives the motor in the proper direction to restore balance. The final balance position is translated by means of a potentiometer or digital encoding disk into a signal which is used for recording or control purposes.

The **batch-type scale** (Fig. 16.1.4) is adaptable to continuous flow streams of either liquids or solid particles. Material flows from the feed hopper through an adjustable gate into the scale hopper. When the

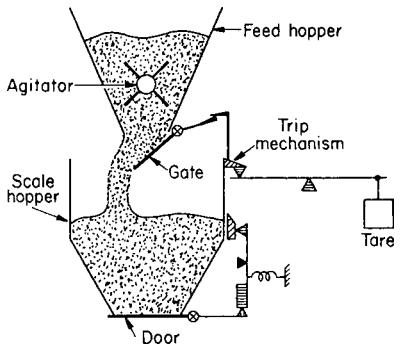

Fig. 16.1.4 Automatic batch-weighing scale.

weight in the scale hopper reaches that of the tare, the trip mechanism operates, closing the gate and opening the door. As soon as the scale hopper is empty, the weight of the tare forces the door closed again, resets the trip, and opens the gate to repeat the cycle. The agitator rotates while the gate is open, to prevent the solids from packing. Also, a "dribble" (partial closing of the gate just before the mechanism trips) is employed to minimize the error from the falling column of material at the instant balance is achieved. Since each dump of the scale represents a fixed weight, a counter yields the total weight of material passing through the scale.

In **continuous weighers,** a section of conveyor belt is balanced on a weigh beam (Fig. 16.1.5). The belt is driven at a constant speed; hence, if the total weight is held constant, the weight rate of material fed through the scale is fixed. Unbalance of the weight beam causes the rate of material flow onto the belt to be changed in the direction of restoring balance. This is accomplished by a mechanical adjustment of the feed gate or by varying the speed of a belt or screw feeder drive.

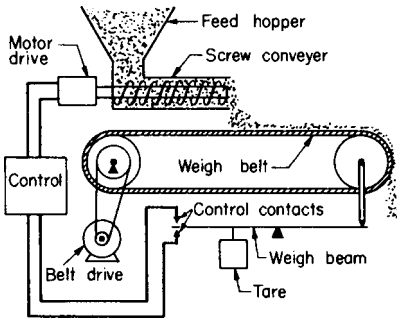

Fig. 16.1.5 Continuous-weighing scale.

If the density of the material is constant, **volume measurements** may be used to determine the mass. Thus, calibrated tanks are frequently used for liquids and vane and screw-type feeders for solids. Though often simpler to apply, these are not generally capable of as high accuracies as are common in weighing.

MEASUREMENT OF LINEAR AND ANGULAR DISPLACEMENT

Displacement-measuring devices are employed to measure dimension, distances between points, and some derived quantities such as velocity, area, etc. These devices fall into two major categories: those based on comparison with a known or reference length and those based on some fixed physical relationship.

The **measurement of angles** is closely related to displacement measurements, and indeed, one is often converted into the other in the process of measurement. The common unit is the degree, which represents $^1/_{360}$ of an entire rotation. The radian is used in mathematics and is related to the degree by π rad = 180°; 1 rad = 57.3°. The grad is an angle unit = $^1/_{400}$ rotation.

Figure 16.1.6 illustrates some methods of **rotary to linear conversion.** Figure 16.1.6*a* is a simple link and lever, Fig. 16.1.6*b* is a flexible link and sector, and Fig. 16.1.6*c* is a rack-and-pinion mechanism. These can be used to convert in either direction according to the relationship $D = RA/57.3$, where R = mean radius of the rotating element, in; D = displacement, in; and A = rotation, deg. (This equation holds for the link and lever of Fig. 16.1.6*a* only if the angle change from the perpendicular is small.)

Comparative devices are generally of the indicating type and include ruled or graduated devices such as the machinist's scale, folding rule, tape measure, digital caliper (Fig. 16.1.7), digital micrometer (Fig. 16.1.8), etc. These vary widely in their accuracy, resolution, and measuring span, according to their intended application. The manual readings depend for their accuracy on the skill and care of the operator.

The digital caliper and digital micrometer provide increased sensitivity and precision of reading. The stem of the digital caliper carries an embedded encoded distance scale. That scale is read by the slider. The distance so found shows on the digital display. The device is battery-operated and capable of displaying in inches or millimetres. Typical resolution is 0.0005 in or 0.01 mm.

The **digital micrometre,** employing rotation and translation to stretch the effective encoded scale length, provides resolution to 0.0001 in or 0.003 mm.

Dial gages are also used to magnify motion. A rack and pinion (Fig. 16.1.6*c*) converts linear into rotary motion, and a pointer moves over a calibrated scale.

Various modifications of the above-mentioned devices are available for making special kinds of measurements; e.g., **depth gages** for measuring the depth of a hole or cavity, **inside and outside calipers** (Fig. 16.1.7) for measuring the internal and external dimensions, respectively, of an object, **protractors** for angular measurement, etc.

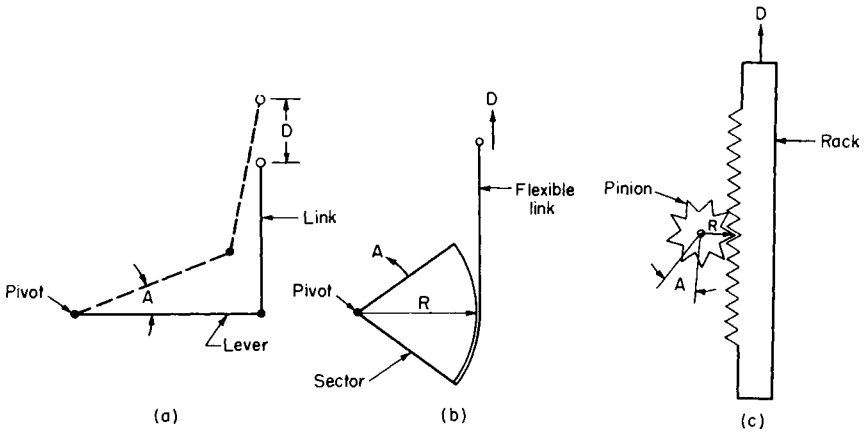

Fig. 16.1.6 Linear-rotary conversion mechanisms.

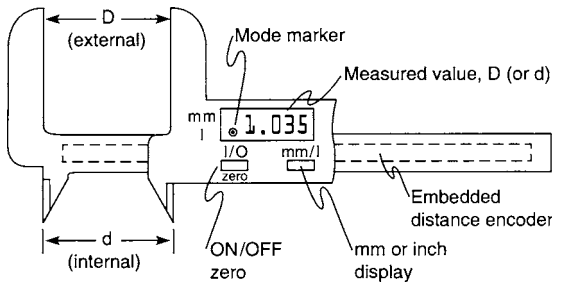

Fig. 16.1.7 Digital caliper.

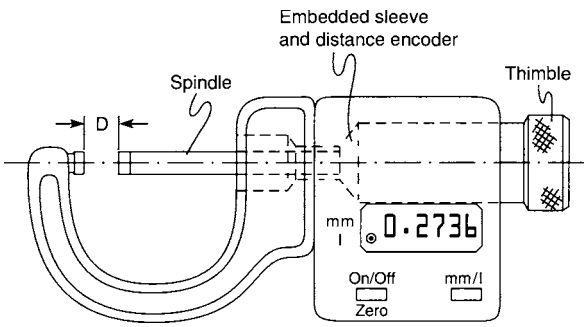

Fig. 16.1.8 Digital micrometer.

For line production and inspection work, **go no-go gages** provide a rapid and accurate means of dimension measurement and control. Since the measured values are fixed, the dependence on the operator's skill is considerably reduced. Such gages can be very complex in form to embrace a multidimensional object. They can also take the more general forms of the **feeler, wire, or thread-gage** sets. Of particular importance are **precision gage blocks,** which are used as standards for calibrating other measuring devices.

Displacement can be measured electrically through its effect on the resistance, inductance, reluctance, or capacitance of an appropriate sensing element.

The **potentiometer** is comparatively inexpensive, accurate, and flexible in application. It consists of a fixed linear resistance over which slides a rotating contact keyed to the input shaft (Fig. 16.1.9). The resistance or voltage (assuming constant voltage across terminals 1 and 3) measured across terminals 1 and 2 is directly proportional to the angle *A*. For straight-line motion, a mechanism of the type shown in Fig. 16.1.6 converts to rotary motion (or a rectilinear-type potentiometer can be used directly). (See also Sec. 15.) Versions with multiturns, straight-line motion, and special nonlinear resistance vs. motion are available.

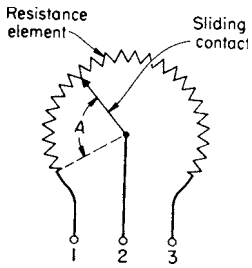

Fig. 16.1.9 Potentiometer.

The **synchro,** the **linear variable differential transformer (LVDT),** and the **E transformer** are devices in which the input motion changes the inductive coupling between primary and secondary coils. These avoid the limitations of wear, friction, and resolution of the potentiometer, but they require an ac supply and usually an electronic amplifier for the output. (See also Sec. 15.)

The **synchro** is a rotating device which is used to transmit rotary motions to a remote location for indication or control action. It is particularly useful where the rotation is continuous or covers a wide range. They are used in pairs, one transmitter and one receiver. For measurement of difference in angular position, the **control-transmitter** and **control-transformer** synchros generate an electrical error signal useful in control systems. A synchro differential added to the pair serves the same purpose as a gear differential.

The **linear variable differential transformer (LVDT)** consists of a primary and two secondary coils wound around a common core (Fig. 16.1.10). An armature (iron) is free to move vertically along the axis of the coils. An ac voltage is applied to the primary. A voltage is

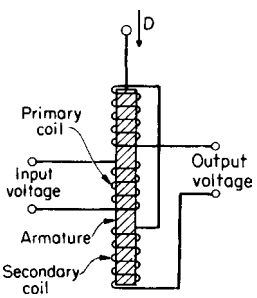

Fig. 16.1.10 Linear variable differential transformer (LVDT).

induced in each secondary coil proportional to the relative length of armature linking it with the primary. The secondaries are connected to oppose each other so that when the armature is centered, the output voltage is zero. When the armature is displaced off center by an amount D, the output will be proportional to D (and phased to show whether D is above or below the center). These devices are very linear near the centered position, require negligible actuating force, and have spans ranging from 0.1 to several inches (0.25 cm to several centimetres).

The **E transformer** is very similar to the above except that the coils are wound around a laminated iron core in the shape of an E (with the primary and secondaries occupying the center and outside legs respectively). The magnetic path is completed through an armature whose motion, either rotary or translational, varies the induced voltage in the secondaries, as in the device of Fig. 16.1.10. This, too, is sensitive to extremely small motions.

A method that is readily applied, if a strain-gage analyzer is handy, is to measure the deflection of a cantilever spring with strain gages bonded to its surface (see Strain Gages, Sec. 5).

The **change of capacitance** with the displacement of the capacitor plates is extremely sensitive and suitable to very small displacements or large rotation. Often, one plate is fixed within the instrument; the other is formed or rotated by the object being measured. The capacitance can be measured by an impedance bridge, by determining the resonant frequency of a tuned circuit or using a relaxation oscillator.

Many optical instruments are available for obtaining precise measurements. The **transit and level** are used in surveying for measuring angles and vertical distances (see Sec. 16.3). A telescope with fine cross hairs permits accurate sighting. The angle scales are generally equipped with verniers. The **measuring microscope** permits measurement of very small displacements and dimensions. The microscope table is equipped with micrometer screws for sensitive adjustment. In addition, templates of scales, angles, etc., are available to permit measurement by comparison. The **optical comparator** projects a magnified shadow image of an object on a screen where it can readily be compared with a reference template.

Light can be used as a standard for the measurement of distance, straightness, and related properties. The wavelength of light in a medium is the velocity of light in vacuum divided by the index of refraction n of the medium. For dry air $n - 1$ is closely proportional to air density and is about 0.000277 at 1 atm and 15°C for 550-nm green light. Since the wavelength changes about + 1 ppm/°C, and about −0.36 ppm/mmHg, density gradients bend light slightly. A temperature gradient of 1°C/m (0.5°F/ft) will cause a deviation from a tangent line of about 0.05 mm (0.002 in) at 10 m (33 ft).

Optical equipment to establish and test alignment, plumb lines, squareness, and flatness includes **jig transits, alignment telescopes, collimators,** optical squares, mirrors, targets, and scales.

Interference principles can be used for distance measurements. An optical flat placed in close contact with a polished surface and illuminated perpendicular to the surface with a monochromatic light will show interference bands which are contours of constant separation distance between the surfaces. Adjacent bands correspond to separation differences of one-half wavelength. For 550-nm wavelength this is 275 nm (10.8 μin). This test is useful in examining surfaces for flatness and in length comparisons with gage blocks.

Laser beams can be used over great distances. Surveying instruments are available for measurements up to 40 mi (60 km). Accuracy is stated to be about 5 mm (0.02 ft) + 1 ppm. These instruments take several measurements which are processed automatically to display the distance directly. Momentary interruptions of the light beam can be tolerated.

A laser system for machine tools, measurement tables, and the like is available in modular form (Agilent Corp.). It can serve up to eight axes by using beam splitters with a combined range of 200 ft (60 m). Normal resolution of length is about one-fourth wavelength, with a digital display least count of 10 μin (0.1 μm). Angle-measurement display resolves 0.1 s of arc. Accuracy with proper environmental compensation is stated to be better than 1 ppm + 1 count in length measurement. Velocities up to 720 in/min (0.3 m/s) can be followed. Accessories are available for measuring straightness, parallelism, squareness, and flatness and for automatic temperature compensation. Various output options include displays and automatic computation and plots. The system can be used directly in measurement and control or to calibrate lead screws and other conventional measuring devices.

Pneumatic gaging previously found an important place in line inspection and quality control and is still seen. The device (Fig. 16.1.11) consists of a nozzle fixed in position relative to a stop or jig. Air at constant supply pressure passes through a restriction and discharges through the

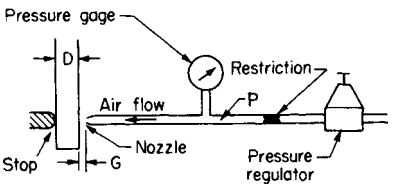

Fig. 16.1.11 Pneumatic gage.

nozzle. The nozzle back pressure P depends on the gap G between the measured surface and the nozzle opening. If the measured dimension D increases, then G decreases, restricting the discharge of air, increasing P. Conversely, when D decreases, P decreases. Thus, the pressure gage indicates deviation of the dimension from some normal value. With proper design, this pressure is directly proportional to the deviation, limited, however, to a few thousandths of an inch span. The device is extremely sensitive [better than 0.0001 in (0.003 mm)], rugged, and, with periodic calibration against a standard, quite accurate. The gage is adaptable to automatic line operation where the pressure signal is recorded or used to actuate **"reject"** or **"accept"** controls. Further, any number of nozzles can be used in a jig to check a multiplicity of dimensions. In another form of this device, the flow of air is measured with a rotameter in place of the back pressure. The linear-variable differential transformer (LVDT) is also applicable.

The advent of automatically controlled machine tools has brought about the need for very accurate displacement measurement over a wide range. Most commonly applied for this purpose is the calibrated **lead screw** which measures linear displacement in terms of its angular rotation. **Digital** systems greatly extend the resolution and accuracy limitations of the lead screw. In these, a uniformly spaced optical or inductive grid is displaced relative to a sensing element. The number of grid lines counted is a direct measure of the displacement (see discussion of lasers above).

Measurement of strip thickness or coating thickness is achieved by **X-ray** or **beta-radiation**-type gages (Fig. 16.1.12). A constant radiation source (X-ray tube or radioisotope) provides an incident intensity I_0; the radiation intensity I after passing through the absorbing material is measured by an appropriate device (scintillation counter, Geiger-Müller tube, etc.). The thickness t is determined by the equation $I = I_0 e^{-kt}$, where k is a constant dependent on the material and the measuring device. The major advantage here is that measurements are continuous

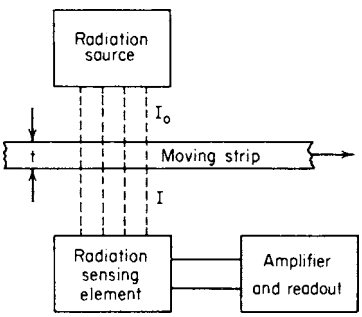

Fig. 16.1.12 Radiation-type thickness gage.

and nondestructive and require no contact. The method is extended to measure liquid level and density.

MEASUREMENT OF AREA

Area measurements are made for the purpose of determining surface area of an object or area inside a closed curve relating to some desired physical quantity. Dimensions are expressed as a length squared; e.g., in^2 or m^2. The areas of simple forms are readily obtained by formula. The area of a complex form can be determined by subdividing into simple forms of known area. In addition, various numerical methods are available (see **Simpson's rule,** Sec. 2) for estimating the area under irregular curves.

Area measuring devices include various mechanical, electrical, or electronic **flow integrators** (used with flowmeters) and the **polar planimeter.** The latter consists of two arms pivoted to each other. A tracer at the end of one arm is guided around the boundary curve of the area, causing rotation of a recorder wheel proportional to the area enclosed.

MEASUREMENT OF FLUID VOLUME

For a liquid of known density, volume is a quick and simple means of measuring the amount (or mass) of liquid present. Conversely, measuring the weight and volume of a given quantity of material permits calculation of its density. Volume has the dimensions of length cubed; e.g., cubic metres, cubic feet. The volume of simple forms can be obtained by formula.

A volumetric device is any container which has a known and fixed calibration of volume contained vs. the level of liquid. The device may be calibrated at only one point **(pipette, volumetric flask)** or may be graduated over its entire volume **(burette, graduated cylinder, volumetric tank).** In the case of the tank, a sight glass may be calibrated directly in liquid volume.

Volumetric measure of continuous flow streams is obtained with the **displacement meter.** This is available in various forms: the nutating disk, reciprocating piston, rotating vane, etc. The **nutating-disk meter** (Fig. 16.1.13) is relatively inexpensive and hence is widely used (water meters, etc.). Liquid entering the meter causes the disk to nutate or "roll" as the liquid makes its way around the chamber to the outlet. A

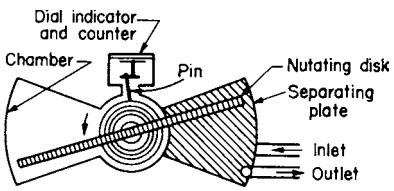

Fig. 16.1.13 Nutating-disk meter.

pin on the disk causes a counter to rotate, thereby counting the total number of rolls of the disk. Meter accuracy is limited by leakage past the disk and friction. The **piston meter** is like a piston pump operated backward. It is used for more precise measure (available to 0.1 percent accuracy).

Volumetric gas measurement is commonly made with a **bellows meter.** Two bellows are alternately filled and exhausted with the gas. Motion of the bellows actuates a register to indicate the total flow. Various liquid-sealed displacement meters are also available for this purpose. Recent innovations in gas flow measurement have made possible the use of Coriolis mass flowmeters, transit time ultrasonic flowmeters, and thermal mass flowmeters for volumetric gas measurements. It is likely that one or more of these methods will replace the bellows meter for many applications within the life of this edition.

For precise volume measurements, corrections for temperature must be made (because of expansion of both the material being measured and the volumetric device). In the case of gases, the pressure also must be noted.

FORCE AND TORQUE MEASUREMENT

Force may be measured by the deflection of an elastic element, by balancing against a known force, by the acceleration produced in an object of known mass, or by its effects on the electrical or other properties of a stress-sensitive material. The common unit of force is the pound (newton). **Torque** is the product of a force and the perpendicular distance to the axis of rotation. Thus, torque tends to produce rotational motion and is expressed in units of pound feet (newton metres). Torque can be measured by the angular deflection of an elastic element or, where the moment arm is known, by any of the force measuring methods.

Since weight is the force of gravity acting on a mass, any of the weight-measuring devices already discussed can be used to measure force. Common methods employ the deflection of springs or cantilever beams.

The strain gage is an element whose electrical resistance changes with applied strain (see Sec. 5). Combined with an element of known force-strain, motion-strain, or other input-strain relationship it is a transducer for the corresponding input. The relation of gage-resistance change to input variable can be found by analysis and calibration. Measure of the resistance change can be translated into a measure of the force applied. The gage may be bonded or unbonded. In the bonded case, the gage is cemented to the surface of an elastic member and measures the strain of the member. Since the gage is very sensitive to temperature, the readings must be compensated. For this purpose, four gages are connected in a Wheatstone-bridge circuit such that the temperature effect cancels itself. A four-element unbonded gage is shown in Fig. 16.1.14. Note that as the applied force increases, the tension on two of the elements increases while that on the other two decreases. Gages subject to strain change of the same sign are put in opposite arms of the bridge. The zero adjustment permits balancing the bridge for zero output at any desired input. The e_1 and e_2 terminal pairs may be used interchangeably for the input excitation and the signal output.

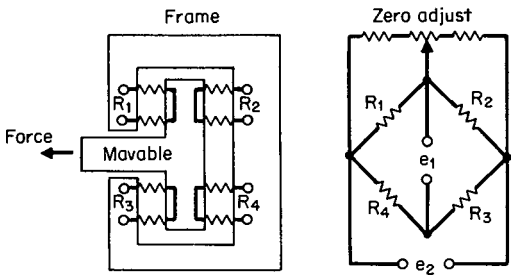

Fig. 16.1.14 Unbonded strain-gage board.

The **piezoelectric** effect is useful in measuring rapidly varying forces because of its high-frequency response and negligible displacement characteristics. Quartz rochelle salt, and barium titanate are common piezoelectric materials. They have the property of varying an output charge in direct proportion to the stress applied. This produces a voltage inversely proportional to the circuit capacitance. Charge leakage produces drifting at a rate depending on the circuit time constant. The voltage must be measured with a device having a very high input resistance. Accuracy is limited because of temperature dependence and some hysteresis effect.

Forces may also be measured with any of the pressure devices described in the next section by balancing against a fluid pressure acting on a fixed area.

PRESSURE AND VACUUM MEASUREMENT

Pressure is defined as the force per unit area exerted by a fluid. Pressure devices normally measure with respect to atmospheric pressure (mean value = 14.7 lb/in^2), $p_a = p_g + 14.7$, where p_a = total or **absolute** pressure and p_g = **gage** pressure, both lb/in^2. Conventionally, gage pressure and vacuum refer to pressures above and below atmospheric, respectively.

Common units are lb/in^2, in Hg, ftH_2O, kg/cm^2, bars, and mmHg. The mean SI atmosphere is 1.013 bar.

Pressure devices are based on (1) measure of an equivalent height of liquid column; (2) measure of the force exerted on a fixed area; (3) measure of some change in electrical or physical characteristics of the fluid.

The manometer measures pressure according to the relationship $p = wh = \rho gh/g_c$, where h = height of liquid of density ρ and specific weight w (assumed constants) supported by a pressure p. Thus, pressures are often expressed directly in terms of the equivalent height (head) of manometer liquid, e.g., inH_2O or inHg. Usual manometer fluids are water or mercury, although other fluids are available for special ranges.

The **U-tube manometer** (Fig. 16.1.15*a*) expresses the pressure difference $p_1 - p_2$ as the difference in levels h. If p_2 is exposed to the atmosphere, the manometer reads the gage pressure of p_1. If the p_2 tube is evacuated and sealed ($p_2 = 0$), the absolute value of p_1 is indicated. A common modification is the **well-type manometer** (Fig. 16.1.15*b*). The scale is specially calibrated to take into account changes of level inside the well so that only a single tube reading is required. In particular, Fig. 16.1.15*b* illustrates the form usually applied to measurement of atmospheric pressure **(mercury barometer).**

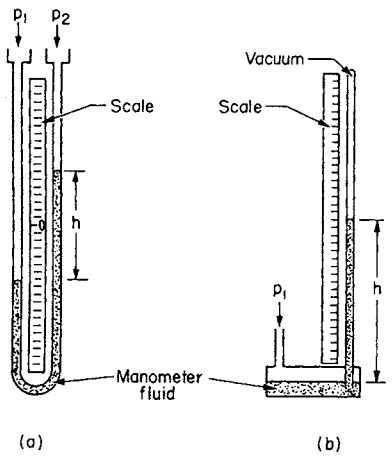

Fig. 16.1.15 Manometers. (*a*) U tube; (*b*) well type.

The sensitivity of readings can be increased by inclining the manometer tubes to the vertical **(inclined manometer),** by use of low-specific-gravity manometer fluids, or by application of optical-magnification or level-sensing devices. Accuracy is influenced by surface-tension effects (reading of the meniscus) and changes in fluid density (due to temperature changes and impurities).

By definition, pressure times the area acted upon equals the force exerted. The pressure may act on a diaphragm, bellows, or other element of fixed area. The force is then measured with any force-measuring device, e.g., spring deflection, strain gage, or weight balance. Very commonly, the unknown pressure is balanced against an air or hydraulic pressure, which in turn is measured with a gage. By use of unequal-area diaphragms, the pressure can thus be amplified or attenuated as required. Further, it permits isolating the process fluid which may be corrosive, viscous, etc.

The **Bourdon-tube gage** (Fig. 16.1.16) is the most commonly used pressure device. It consists of a flattened tube of spring bronze or steel bent into a circle. Pressure inside the tube tends to straighten it. Since one end of the tube is fixed to the pressure inlet, the other end moves proportionally to the pressure difference existing between the inside and outside of the tube. The motion rotates the pointer through a pinion-and-sector mechanism. For amplification of the motion, the tube may be bent through several turns to form spiral or helical elements as are used in pressure recorders.

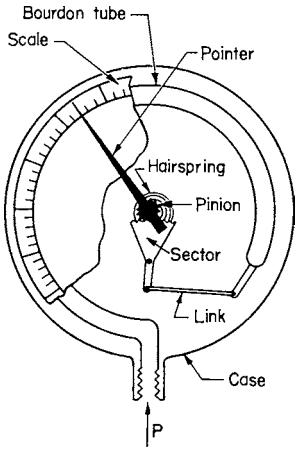

Fig. 16.1.16 Bourdon-tube gage.

In the **diaphragm gage,** the pressure acts on a diaphragm in opposition to a spring or other elastic member. The deflection of the diaphragm is therefore proportional to the pressure. Since the force increases with the area of the diaphragm, very small pressures can be measured by the use of large diaphragms. The diaphragm may be metallic (brass, stainless steel) for strength and corrosion resistance, or nonmetallic (leather, neoprene, silicon, rubber) for high sensitivity and large deflection. With a stiff diaphragm, the total motion must be very small to maintain linearity.

The **bellows gage** (Fig. 16.1.17) is somewhat similar to the diaphragm gage, with the advantage, however, of providing a much wider range of motion. The force acting on the bottom of the bellows is balanced by the deflection of the spring. This motion is transmitted to the output arm, which then actuates a pointer or recorder pen.

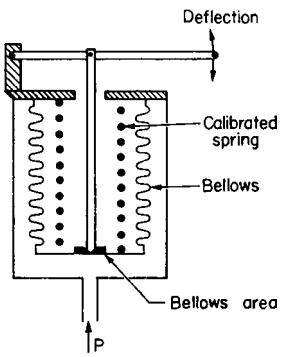

Fig. 16.1.17 Bellows gage.

The motion (or force) of the pressure element can be converted into an electrical signal by use of a differential transformer or strain-gage element or into an air-pressure signal through the action of a nozzle and pilot. The signal is then used for transmission, recording, or control.

The **dead-weight tester** is used as a standard for calibrating gages. Known hydraulic or gas pressures are generated by means of weights loaded on a calibrated piston. The useful range is from 5 to 5,000 lb/in^2 (0.3 to 350 bar). For low pressures, the water or mercury manometer serves as a reference.

For many applications (fluid flow, liquid level), it is important to measure the **difference between two pressures.** This can be done directly with the manometer. Other pressure devices are available as differential devices where (1) the case is made pressure-tight so that the second pressure can be applied external to the pressure element; (2)

two identical pressure elements are mounted so that their outputs oppose each other.

Similar devices to those discussed are used to measure **vacuum,** the only difference being a shift in range or at most a relocation of the zeroing spring. When the vacuum is high (absolute pressure near zero) variations in atmospheric pressure become an important source of error. It is here that absolute-pressure devices are employed.

Any of the differential-pressure elements can be converted to an **absolute-pressure device** by sealing one pressure side to a perfect vacuum. A common instrument for the range 0 to 30 inHg employs two bellows of equal area set back to back. One bellows is completely evacuated and sealed; the other is connected to the measured pressure. The output is a bellows displacement, as in Fig. 16.1.17.

There are many instruments for high-vacuum work (0.001 to 10,000 μm range). These kinds of devices are based on the characteristic properties of gases at low pressures. The **McLeod gage** amplifies the pressure to be measured by compressing the gas a known amount and then measuring its pressure with a mercury manometer. The ratio of initial to final pressure is equal to the ratio of final to initial volume (for common gases). This gage serves as a standard for low pressures.

The **Pirani gage** (Fig. 16.1.18) is based on the change of heat conductivity of a gas with pressure and the change of electrical resistance of a wire with temperature. The wire is electrically heated with a constant current. Its temperature changes with pressure, producing a voltage across the bridge network. The compensating cell corrects for room-temperature changes.

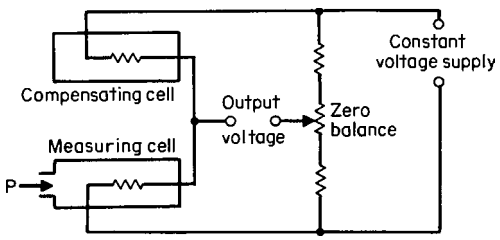

Fig. 16.1.18 Pirani gage.

The **thermocouple gage** is similar to the Pirani gage, except that a thermocouple is used to measure the temperature difference between the resistance elements in the measuring and compensating cells, respectively.

The **ionization gage** measures the ion current generated by bombardment of the molecules of the gas by the electron stream in a triode-type tube. This gage is limited to pressures below 1 μm. It is, however, extremely sensitive.

LIQUID-LEVEL MEASUREMENT

The past 30 years have seen significant advancement in the measurement of liquid level. Level instruments are used for determining or controlling the height of liquid in a vessel, or finding the location of the interface between two liquids of different specific gravity. Liquid level measurement can be made both continuously, or as a point level measurement (or switch).

In process measurement, typical level devices include differential pressure and hydrostatic pressure transmitters of various types; capacitance and radio-frequency (RF) admittance device; a wide variety of floats and other mechanical level measurement systems; magnetostrictive gages; ultrasonic level sensors; pulse and continuous wave radar level sensors; guided wave radar sensors; laser level sensors; and nuclear level gages. Typically, the applications for these devices fit along a continuum from very easy to measure (water) to very hard to measure (molten plastic inside a jacketed reactor).

Each of these level measurement techniques has advantages and limitations, dependent on the application. For example, a mechanical gage is not advisable in an application where the fluid is sticky or viscous.

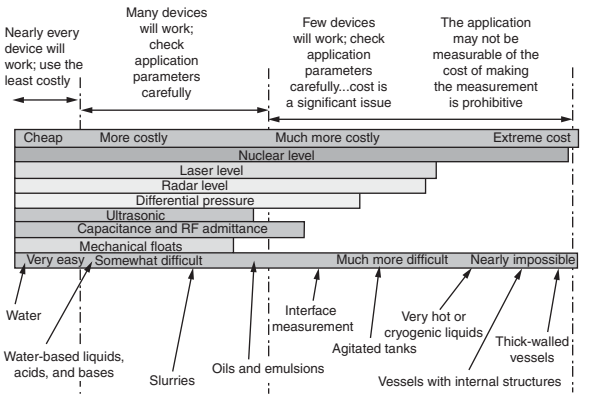

Fig. 16.1.19 Level measurement continuum.

Ultrasonic level meters are extremely sensitive to temperature changes in the vapor space and to density changes of the vapor, and should normally only be used at atmospheric pressure. Capacitance or RF admittance–type gages may be used in a wide variety of applications, although long measurement spans make them expensive. Radar level gages of either type can be used in pressurized vessels, since the changing dielectric of the vapor space is usually too small a change to affect the measurement. Nuclear level gages are the "last resort" in part because of their expense, but also because of the licensing and training required to operate them and the disposal and storage requirements of the nuclear source.

Differential pressure measurement is still used as a common means of measuring level in vessels, although the use of this technique is declining. As indicated in the discussion on manometers, the pressure difference is the height times the specific weight of the liquid.

Ultrasonic and pulse radar level devices operate by measuring the transit time of a signal reflected off the liquid surface and converting that signal into a level measurement. Continuous-wave and guided-wave radar instruments measure the signal return from the largest peak of the reflected signals in the vessel. Ultrasonic level devices are also commonly used as open-channel flowmeters when combined with a physical primary device such as a weir or flume.

Capacitive or RF admittance level devices measure the change in dielectric that occurs at the level surface or at the interface between two liquids. Like ultrasonics, these can be supplied as either point or continuous level transmitters, and like ultrasonics, they have applications in bulk solids and powders as well as liquid level.

Nuclear level gages are also available in point or continuous level designs. These instruments work by the attenuation of a beam of gamma energy by the surface of the liquid (which is much more dense than the vapor phase in the vessel). The point at which the measured radiation drops to near zero is the level.

TEMPERATURE MEASUREMENT

The common temperature scales (Fahrenheit and Celsius) are based on the freezing and boiling points of water (see Sec. 4 for discussion of temperature standards, units, and conversion equations).

Temperature is measured in a number of different ways. Some of the more useful are as follows.

1. *Thermal expansion of a gas* **(gas thermometer).** At constant volume, the pressure p of an (ideal) gas is directly proportional to its absolute temperature T. Thus, $p = (p_0/T_0)T$, where p_0 is the pressure at some known temperature T_0.

2. *Thermal expansion of a liquid or solid* **(mercury thermometer, bimetallic element).** Substances tend to expand with temperature. Thus, a change in temperature $t_2 - t_1$ causes a change in length $l_2 - l_1$ or a change in volume $V_2 - V_1$, according to the expressions.

$$l_2 - l_1 = a'(t_2 - t_1)l_1 \quad \text{or} \quad V_2 - V_1 = a'''(t_2 - t_1)V_1$$

where a' and a''' = linear and volumetric coefficients of thermal expansion, respectively (see Sec. 4). For many substances, a' and a''' are reasonably constant over a limited temperature range. For solids, $a''' = 3a'$. For mercury at room temperature, a''' is approximately $0.00018°C^{-1}$ ($0.00010°F^{-1}$).

3. *Vapor pressure of a liquid* **(vapor-bulb thermometer).** The vapor pressure of all liquids increases with temperature. The Clapeyron equation permits calculation of the rate of change of vapor pressure with temperature.

4. *Thermoelectric potential* **(thermocouple).** When two dissimilar metals are brought into intimate contact, a voltage is developed which depends on the temperature of the junction and the particular metals used. If two such junctions are connected in series with a voltage-measuring device, the measured voltage will be very nearly proportional to the temperature difference of the two junctions.

5. *Variation of electrical resistance* **(resistance thermometer, thermistor).** Electrical conductors experience a change in resistance with temperature which can be measured with a Wheatstone- or Mueller-bridge circuit, or a digital ohmmeter. The platinum resistance thermometer (PRT) can be very stable and is used as the temperature scale interpolation standard from −160 to 660°C. Commercial resistance temperature detectors (RTD) using copper, nickel, and platinum conductors are in use and are characterized by a polynomial resistance-temperature relationship, such as

$$t = A + B \times R_t + C \times R_t^2 + D \times R_t^3 + E \times R_t^4$$

where R_t = resistance at prevailing temperature t in °C. *A, B, C, D,* and *E* are range- and material-dependent coefficients listed in Table 16.1.1. R_0, also shown in the table, is the base resistance at 0°C used in the identification of the sensor.

The thermistor has a large, negative temperature coefficient of resistance, typically −3 to −6 percent/°C, decreasing as temperature increases. The temperature-resistance relation is approximated (to perhaps 0.01° in range 0 to 100°C) by:

$$R_t = \exp\left(A_0 + A_1/t + \frac{A_2}{t^2} + \frac{A_3}{t^3}\right)$$

and

$$\frac{1}{t} = a_0 + a_1 \ln R_t + a_2(\ln R_t)^2 + a_3(\ln R_t)^3$$

with the constants chosen to fit four calibration points. Often a simpler form is given:

$$R = R_0 \exp\left\{\beta\left[\left(\frac{1}{t}\right) - \left(\frac{1}{t_0}\right)\right]\right\}$$

Typically β varies in the range of 3,000 to 5,000 K. The reference temperature t_0 is usually 298 K(= 25°C, 77°F), and R_0 is the resistance at that temperature. The error may be as small as 0.3°C in the range of 0° to 50°C. Thermistors are available in many forms and sizes for use from −196 to +450°C with various tolerances on interchangeability and matching. (See "Catalog of Thermistors," Thermometrics, Inc.) The AD590 and AD592 integrated circuit (Analog Devices, Inc.) passes a current of 1 μA/K very nearly proportional to absolute temperature. All these sensors are subject to self-heating error.

6. *Change in radiation* **(radiation and optical pyrometers).** A body radiates energy proportional to the fourth power of its absolute temperature. This principle is particularly adaptable to the measurement of very high temperatures where either the total quantity of radiation or its intensity within a narrow wavelength band may be measured. In the former type (radiation pyrometer), the radiation is focused on a heat-sensitive element, e.g., a thermocouple, and its rise in temperature is measured. In the latter type (optical pyrometer) the intensity of the radiation is compared optically with a heated filament. Either the filament brightness is varied by a control calibrated in temperature or a fixed brightness filament is compared with the source viewed through a calibrated optical wedge.

The infrared thermometer accepts radiation from an object seen in a definite field of view, filters it to select a portion of the infrared spectrum, and focuses it on a sensor such as a blackened thermistor flake, which warms and changes resistance. Electronic amplification and signal processing produce a digital display of temperature. Correct calibration requires consideration of source emissivity, reflection, and transmission from other radiation sources, atmospheric absorption between the source object and the sensor, and compensation for temperature variation at the sensor's immediate surroundings.

Electrical nonconductors generally have fairly high (about 0.95) emissivities, while good conductors (especially smooth, reflective metal surfaces), do not; special calibration or surface conditioning is then needed. Very wide band (0.7 to 20 μm) instruments gather relatively large amounts of energy but include atmospheric absorption bands which reduce the energy received from a distance. The band 8 to 14 μm is substantially free from atmospheric absorption and is popular for general use with source objects in the range 32 to 1,000°F (0 to 540°C). Other bands and two-color instruments are used in some cases. See Bonkowski, Infrared Thermometry, *Measurements and Control,* Feb. 1984, pp. 152–162.

Fiber-optic probes extend the use of radiation methods to hard-to-reach places.

Important relationships used in the design of these instruments are the Wien and Stefan-Boltzmann laws (in modified form):

$$\lambda_m = k_1/T \qquad q = k_2 \varepsilon A(T_2^4 - T_1^4)$$

where λ_m = wavelength of maximum intensity, μm (nm); q = radiant energy flux, Btu/h (W); A = radiation surface, ft^2 (m^2); ε = mean emissivity of the surfaces; T_2, T_1 = absolute temperatures of radiating and receiving surfaces, respectively, °R (K); $k_1 = 5{,}215$ μm, °R (2,898 μm · K); $k_2 = 0.173 \times 10^{-8}$ Btu/(h · ft^2 · $°R^4$) [5.73×10^{-8} W/(m^2 · K^4)]. The emissivity depends on the material and form of the surfaces involved (see Sec. 4). Radiation sensors with scanning capability can produce maps, photographs, and television displays showing temperature-distribution patterns. They can operate with resolutions to under 1°C and at temperatures below room temperature.

7. *Change in physical or chemical state* **(Seger cones, Tempilsticks).** The temperatures at which substances melt or initiate chemical reaction are often known and reproducible characteristics. Commercial products are available which cover the temperature range from about 120 to 3,600°F (50 to 2,000°C) in intervals ranging from 3 to 70°F (2 to 40°C).

Table 16.1.1 Polynomial Coefficients for Resistance Temperature Detectors

Material of conductor	ID R_0, Ω	Useful range, °C	Polynomial coefficients					Typical accuracy,* °C
			A, °C	*B*, °C/Ω	*C*, °C/Ω²	*D*, °C/Ω³	*E*, °C/Ω⁴	
Copper	9.042	−70 to 0	−225.64	23.30735	+0.246864	−0.00715		1.5
10Ω @ 25°C		0 to 150	−234.69	25.95508				1.5
Nickel	120	−80 to 320	−199.47	1.955336	−0.00266	1.88E − 6		1
Platinum	100	−200 to 0	−241.86	2.213927	0.002867	−9.8E − 6	1.64E − 8	1
DIN/IEC		0 to 850	−236.06	2.215142	0.001455			0.5
α = 0.00385/°C								

* For higher accuracy consult the table or equation furnished by the manufacturer of the specific RTD being used. Temperatures per ITS-90, resistances per SI-90.

The temperature-sensing element may be used as a solid which softens and changes shape at the critical temperature, or it may be applied as a paint, crayon, or stick-on label which changes color or surface appearance. For most the change is permanent; for some it is reversible. Liquid crystals are available in sheet and liquid form: these change reversibly through a range of colors over a relatively narrow temperature range. They are suitable for showing surface-temperature patterns in the range 20 to 50°C (68 to 122°F).

An often used temperature device is the **mercury-in-glass thermometer.** As the temperature increases, the mercury in the bulb expands and rises through a fine capillary in the graduated thermometer stem. Useful range extends from − 30 to 900°F (− 35 to 500°C). In many applications of the mercury thermometer, the stem is not exposed to the measured temperature; hence a correction is required (except where the thermometer has been calibrated for **partial immersion).** Recommended formula for the correction K to be added to the thermometer reading is $K = 0.00009D(t_1 - t_2)$, where D = number of degrees of exposed mercury filament, °F; t_1 = thermometer reading, °F; t_2 = the temperature at about middle of the exposed portion of stem, °F. For Celsius thermometers the constant 0.00009 becomes 0.00016.

For **industrial applications** the thermometer or other sensor is encased in a metal or ceramic protective well and case (Fig. 16.1.20). A threaded union fitting is provided so that the thermometer can be installed in a line or vessel under pressure. Ideally the sensor should have the same

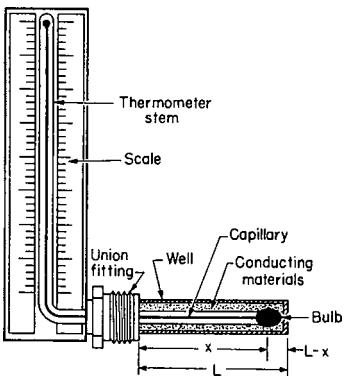

Fig. 16.1.20 Industrial thermometer.

temperature as the fluid into which the well is inserted. However, heat conduction to or from the pipe or vessel wall and radiation heat transfer may also influence the sensor temperature (see ASME PTC 19.3-1974 Temperature Measurement, on well design). An approximation of the conduction error effect is

$$T_{sensor} - T_{fluid} = (T_{wall} - T_{fluid})E$$

For a sensor inserted to a distance $L - x$ from the tip of a well of insertion length L, $E = \cosh[m(L - x)]/\cosh mL$, where $m = (h/kt)^{0.5}$; x and L are in ft (m); h = fluid-to-well conductance, Btu/(h) (ft^2)(°F) [J/(h)(m^2)(°C)]; k = thermal conductivity of the well-wall material. Btu/(h)(ft)(°F) [J/(h)(m)(°C)]; and t = well-wall thickness, ft (m). Good thermal contact between the sensor and the well wall is assumed. For $(L - x)/L = 0.25$:

mL	1	2	3	4	5	6	7
E	0.67	0.30	0.13	0.057	0.025	0.012	0.005

Radiation effects can be reduced by a polished, low-emissivity surface on the well and by radiation shields around the well. Concern with mercury contamination has made the bimetal thermometer the most commonly used expansion-based temperature measuring device. Differential thermal expansion of a solid is employed in the simple **bimetal** (used in thermostats) and the bimetallic helix (Fig. 16.1.21). The bimetallic

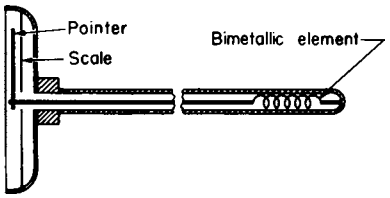

Fig. 16.1.21 Bimetallic temperature gage.

element is made by welding together two strips of metal having different coefficients of expansion. A change in temperature then causes the element to bend or twist an amount proportional to the temperature. A common bimetallic pair consists of invar (iron-nickel alloy) and brass.

For control or alarm indications at fixed temperatures, thermometers may be equipped with electrical contacts such that when the temperature matches the contact point, an external relay circuit is energized.

A popular industrial-type instrument employs the deflection of a **pressure-spring** to indicate (or record) the temperature (Fig. 16.1.22). The sensing element is a metal bulb containing some specific gas or liquid. The bulb connects with the pressure spring (in the form of a spiral or helix) through a capillary tube which is usually enclosed in a protective sheath or armor. Increasing temperature causes the fluid in the bulb to expand in volume or increase in pressure. This forces the pressure spring to unwind and move the pen or pointer an appropriate distance upscale.

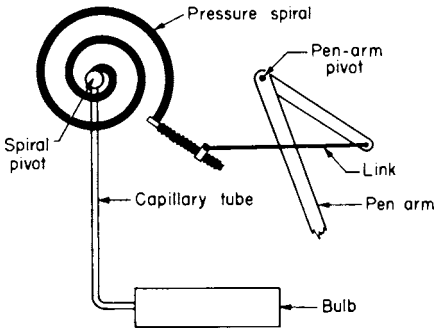

Fig. 16.1.22 Pressure-spring element.

The **bulb fluid** may be mercury (mercury system), nitrogen under pressure (gas system), or a volatile liquid (vapor-pressure system). Mercury and gas systems have linear scales; however, they must be compensated to avoid ambient temperature errors. The capillary may range up to 200 ft in length with, however, considerable reduction in speed of response. The use of mercury is being phased out due to environmental and health concerns over the use of the metal.

The **pneumatic transmitter** (Fig. 16.1.23) was at one time the standard for long-distance transmission of temperature. Although its place has been taken by various electronic means, it is still commonly used in many parts of the world, especially in refining and other hydrocarbon processing applications. The bulb is filled with gas under pressure, which acts on the diaphragm. An increase in bulb temperature increases the upward force acting on the main beam, tending to rotate it clockwise. This causes the baffle or flapper to move closer to the nozzle, increasing the nozzle back pressure. This acts on the pilot, producing an increase in output pressure, which increases the force exerted by the feedback bellows. The system returns to equilibrium when the increase in bellows pressure exactly balances the effect of the increased diaphragm pressure. Since the lever ratios are fixed, this results in a direct proportionality between bulb temperature and output air pressure. For precision, compensating elements are built into the instrument to correct for the effects of changes in barometric pressure and ambient temperature.

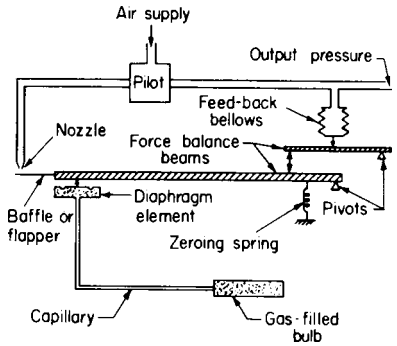

Fig. 16.1.23 Pneumatic temperature transmitter.

Electrical systems based on the thermocouple or resistance thermometer are particularly applicable where many different temperatures are to be measured, where transmission distances are large, or where high sensitivity and rapid response are required. The thermocouple is used with high temperatures; the resistance thermometer for low temperatures and high accuracy requirements.

The **choice of thermocouple** depends on the temperature range, desired accuracy, and the nature of the atmosphere to which it is to be exposed. The temperature-voltage relationships for the more common of these are given by the curves of Fig. 16.1.24. Table 16.1.2 gives the recommended temperature limits, for each kind of couple. Table 16.1.3 gives polynomials for converting thermocouple millivolts to temperature. The thermocouple voltage is measured by a digital or deflection millivoltmeter or null-balance type of potentiometer. Completion of the thermocouple circuit through the instrument immediately introduces one or more additional junctions. Common practice is to connect the thermocouple (hot junction) to the instrument with special lead wire (which may be of the

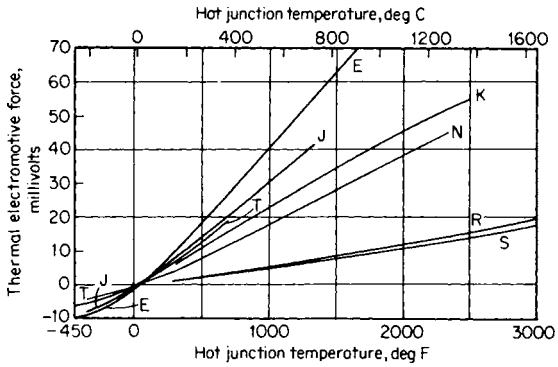

Fig. 16.1.24 Thermocouple voltage-temperature characteristics [reference junction at 32°F (0°C)].

Table 16.1.2 Limits of Error on Standard Wires without Selection*†

All temperatures are ITS-1990 and all voltages are SI-1990 values. Maximum deviation is that from the ITS-1990 tables; thermocouple wire error is additional. Computed temperature deviates greatly outside of given ranges. Consult source for thermocouple types B and R and for other millivolt ranges.

SOURCE: NIST Monograph 175, April 1993.

same materials as the thermocouple itself). This assures that the **cold junction** will be inside the instrument case, where compensation can be effectively applied. Cold junction compensation is typically achieved by measuring the temperature of the thermocouple wire to copper wire junctions or terminals with a resistive or semiconductor thermometer and correcting the measured terminal voltage by a derived equivalent millivolt cold junction value. Figure 16.1.25 shows a digital temperature indicator with correction for different ANSI types of thermocouple voltage to temperature nonlinearities being stored in and applied to the analog-to-digital converter (A/D) by a read-only memory (ROM) chip.

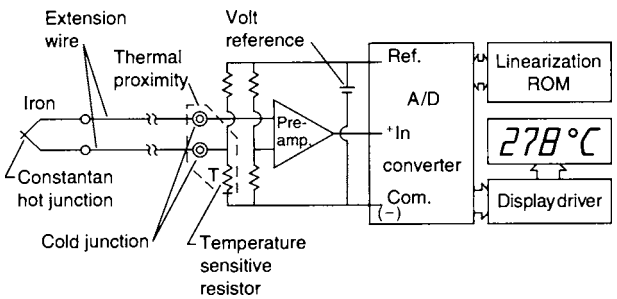

Fig. 16.1.25 Temperature measurement with thermocouple and digital millivoltmeter.

The **resistance thermometer** employs the same circuitry as described above, with the resistance element (RTD) being placed external to the instrument and the cold junction being omitted (Fig. 16.1.26). Three types of RTD connections are in use: two wire, three wire, and four wire. The two-wire connection makes the measurement sensitive to lead wire temperature changes. The three-wire connection, preferred in industrial applications, eliminates the lead wire effect provided the leads are of the same gage and length, and subject to the same environment. The four-wire arrangement makes no demands on the lead wires and is preferred for scientific measurements.

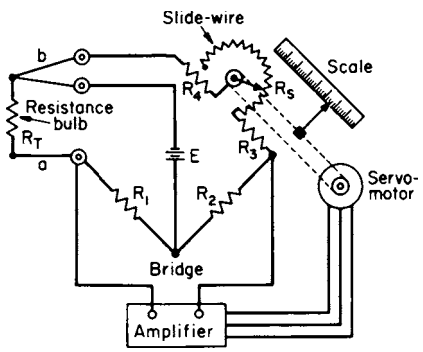

Fig. 16.1.26 Three-wire resistance thermometer with self-balancing potentiometer recorder.

The resistance bulb consists of a copper or platinum wire coil sealed in a protective metal tube. The **thermistor** has a very large temperature coefficient of resistance and may be substituted in low-accuracy, low-cost applications.

By use of a **selector switch,** any number of temperatures may be measured with the same instrument. The switch connects in order each thermocouple (or resistance bulb) to the potentiometer (or bridge circuit) or digital voltmeter. When balance is achieved, the recorder prints the temperature value, then the switch advances on to the next position.

Optical pyrometers are applied to high-temperature measurement in the range 1,000 to 5,000°F (540 to 2,760°C). One type is shown in Fig. 16.1.27. The surface whose temperature is to be measured (target) is focused by the lens onto the filament of a calibrated tungsten lamp.

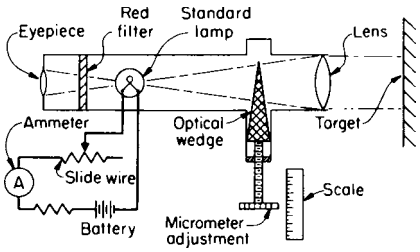

Fig. 16.1.27 Optical pyrometer.

The light intensity of the filament is kept constant by maintaining a constant current flow. The intensity of the target image is adjusted by positioning the optical wedge until the image intensity appears exactly equal to that of the filament. A scale attached to the wedge is calibrated directly in temperature. The red filter is employed so that the comparison is made at a specific wavelength (color) of light to make the calibration more reproducible. In another type of optical pyrometer, comparison is made by adjusting the current through the filament of the standard lamp. Here, an ammeter in series is calibrated to read temperature directly. **Automatic operation** may be had by comparing filament with image intensities with a pair of photoelectric cells arranged in a bridge network. A difference in intensity produces a voltage, which is amplified to drive the slide wire or optical wedge in the direction to restore zero difference.

The **radiation pyrometer** is normally applied to temperature measurements above 1,000°F. Basically, there is no upper limit; however, the lower limit is determined by the sensitivity and cold-junction compensation of the instrument. It has been used down to almost room temperature. A common type of radiation receiver is shown in Fig. 16.1.28. A lens focuses the radiation onto a thermal sensing element. The temperature rise of this element depends on the total radiation received and the

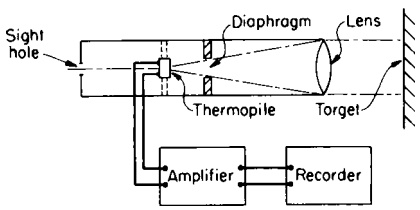

Fig. 16.1.28 Radiation pyrometer.

conduction of heat away from the element. The radiation relates to the temperature of the target; the conduction depends on the temperature of the pyrometer housing. In normal applications the latter factor is not very great; however, for improved accuracy a compensating coil is added to the circuit. The sensing element may be a thermopile, vacuum thermocouple, or bolometer. The **thermopile** consists of a number of thermocouples connected in series, arranged so that all the hot junctions lie in the field of the incoming radiation; all of the cold junctions are in thermal contact with the pyrometer housing so that they remain at ambient temperature. The **vacuum thermocouple** is a single thermocouple whose hot junction is enclosed in an evacuated glass envelope. The **bolometer** consists of a very thin strip of blackened nickel or platinum foil which responds to temperature in the same manner as the resistance thermometer. The **thermal sensing element** is connected to a potentiometer or bridge network of the same type as described for the self-balance thermocouple and resistance-thermometer instruments. Because of the nature of the radiation law, the scale is nonlinear.

Accuracy of the optical- and radiation-type pyrometers depends on:

1. *Emissivity of the surface being sighted on.* For closed furnace applications, blackbody conditions can be assumed (emissivity = 1). For other applications corrections for the actual emissivity of the surface must be made (correction tables are available for each pyrometer model).

Multiple color or wavelength sensing is used to reduce sensitivity to hot object emissivity. For measuring hot fluids, a target tube immersed in the fluid provides a target of known emissivity.

2. *Radiation absorption between target and instrument.* Smoke, gases, and glass lenses absorb some of the radiation and reduce the incoming signal. Use of an enclosed (or purged) target tube or direct calibration will correct this.

3. *Focusing of the target on the sensing element.*

MEASUREMENT OF FLUID FLOW RATE

(See also Secs. 3 and 4.)

Flow is expressed in volumetric or mass units per unit time. Thus gases are generally measured in ft^3/min (m^3/min) or ft^3/h (m^3/h), steam in lb/h (kg/h), and liquid in gal/min (L/min) or gal/h (L/h). Conversion between volumetric flow Q and mass flow m is given by $m = K\rho Q$, where ρ = density of the fluid and K is a constant depending on the units of m, Q, and ρ. Flow rate can be measured directly by attaching a rate device to a volumetric meter of the types previously described, e.g., a tachometer connected to the rotating shaft of the nutating-disk meter (Fig. 16.1.13).

There are many kinds of flow instruments that serve in different applications. Depending on the application, the engineer may choose from a dozen different technologies. Issues, such as accuracy, repeatability, and cost, as well as suitability for the service, make selecting a flowmeter a demanding exercise. The basic flowmeter technologies include:

Positive displacement
Differential pressure
Variable area and rotameter
Turbine
Electromagnetic
Ultrasonic
Coriolis mass flowmeter
Vortex shedding and other fluidic
Thermal dispersion
Open-channel primary elements

Because of their use in domestic water systems worldwide, positive displacement meters (nutating disk, rotary piston, multijet) are the most widely used method of measurement of flow rate and total. They are, as the name implies, a means of measuring volumetric flow rate directly, one small volume at a time. Positive displacement meters are limited in the materials of construction, pressure, amount of air entrained, and the amount and size of solids they can pass.

They must be compensated for temperature and viscosity changes. Typically, they are used for totalization of clean fluids from water to petroleum byproducts. Differential pressure flowmeters operate by the conversion of fluid velocity to pressure (head). Thus, if the fluid is forced to change its velocity from V_1 to V_2, its pressure will change from p_1 to p_2 according to the equation (neglecting friction, expansion, and turbulence effects):

$$V_2^2 - V_1^2 = \frac{2g_c}{\rho}(p_1 - p_2) \qquad (16.1.1)$$

where g = acceleration due to gravity, ρ = fluid density, and g_c = 32.184 lbm · ft/(lbf)(s^2) [1.0 kg · m/(N)(s^2)]. **Caution:** If the flow pulsates, the average value of $p_1 - p_2$ will be greater than that for steady flow of the same average flow.

See "ASME Pipeline Flowmeters," and "Pitot Tubes" in Sec. 3 for coverage of venturi tubes, flow nozzles, compressible flow, orifice meters, ASME orifices, and Pitot tubes.

The tabulation orifice coefficients apply only for **straight pipe** upstream and downstream from the orifice. In most cases, satisfactory results are obtained if there are no fittings closer than 25 pipe diameters upstream and 5 diameters downstream from the orifice. The upstream limitation can be reduced a bit by employing **straightening vanes.** Reciprocating pumps in the line may introduce serious errors and require special efforts for their correction.

A wide variety of differential pressure meters is available for measuring the orifice (or other primary element) pressure drop.

Figure 16.1.29 shows an orifice plate and differential-pressure flow transmitter. An electronic device is shown, but in relatively old plants, and in some very special cases in the refinery industry, pneumatic devices still are present. The differential across the orifice plate produces a pressure differential on either side of the diaphragm, thus causing an electrical signal to be transmitted. Modem differential-pressure flow transmitters generally include a microprocessor, which permits temperature compensation, pressure compensation, and the conversion of the differential pressure (the square root of flow) to a linear flow rate. The absolute accuracy of a differential pressure flow device is fixed by the accuracy of the primary device.

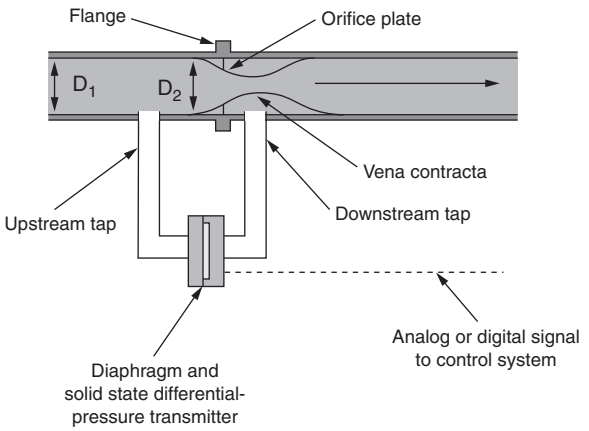

Fig. 16.1.29 Orifice plate and differential-pressure transmitter.

The meters described thus far are termed **variable-head** because the pressure drop varies with the flow, orifice ratio being fixed. In contrast, the **variable-area** meter maintains a constant pressure differential but varies the orifice area with flow.

The **rotameter** (Fig. 16.1.30) consists of a float positioned inside a tapered tube by action of the fluid flowing up through the tube. The flow restriction is now the annular area between the float and the tube (area increases as the float rises). The pressure differential is fixed, determined by the weight of the float and the buoyant forces. To satisfy

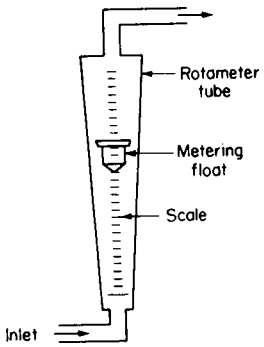

Fig. 16.1.30 Rotameter.

the volumetric flow equation then, the annular area (hence the float level) must increase with flow rate. Thus the rotameter may be calibrated for direct flow reading by etching an appropriate scale on the surface of the glass tube. The calibration depends on the float dimensions, tube taper, and fluid properties. The equation for volumetric flow is

$$Q = C_R(A_T - A_F)\left[\frac{2gV_F}{\rho A_F}(\rho_F - \rho)\right]^{1/2}$$

where A_T = cross-sectional area of tube (at float position), A_F = effective float area, V_F = float volume, $\rho_{F\ =}$ float density, ρ = fluid density, and C_R = rotameter coefficient (usually between 0.6 and 0.8). The coefficient varies with the fluid viscosity; however, special float designs are available which are relatively insensitive to viscosity effects. Also, fluid density compensation can be obtained.

The **rotameter reading may be transmitted** for recording and control purposes by affixing to the float a stem which connects to an armature or permanent magnet. The armature forms part of an inductance bridge whose signal is amplified electronically to drive a pen-positioning motor. For pneumatic transmission, the magnet provides magnet coupling to a pneumatic motion transmitter external to the rotameter tube. This generates an air pressure proportional to the height of the float.

The **area meter** is similar to the rotameter in operation. Flow area is varied by motion of a piston in a straight cylinder with openings cut into the wall. The piston position is transmitted as above by an armature and inductance bridge circuit.

Turbine, propeller, and paddlewheel flowmeters operate by converting velocity into rotational energy by means of a flighted rotor. These flowmeters are primarily used to measure water, and water-based liquids, and come in a very wide variety of designs, styles, and materials of construction. Some of these devices are mechanical, using gears and cams to convert the rotation of the rotor to increment an electromechanical counter. Others use solid-state pickups such as magnetic induction coils and Hall effect sensors to sense the speed of rotation of the rotor.

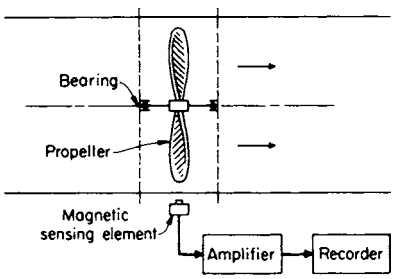

Fig. 16.1.31 Propeller-type flowmeter.

These flowmeters are limited by the velocity of the fluid (they can be overdriven, with disastrous results), by the size and composition of solids they can pass, and by temperature and viscosity changes, and they are subject to significant wear in operation. Some turbine meters can be calibrated to be very highly accurate and are often used to meter expensive additives and blends.

One of the most widely used flowmeter types is the electromagnetic flowmeter, often called a **magmeter**. The device operates by means of Faraday's law, converting velocity of a conductive fluid to a proportional current signal by passing the fluid at right angles to an electromagnetic field. Magmeters are inherently the most accurate of the velocimetric flow technologies, because the current signal is directly proportional to the average velocity of the conductive fluid. Magmeters are therefore restricted to conductive fluids (generally above 5 microsiemens). Magmeters are supplied in a very wide range of sizes (generally from 1 to 2,000 mm), and the larger meters are among the most economical devices. Magmeters also have the advantage that they can be made out of a wide variety of materials, including ones suitable for ultrapure service and highly corrosive or abrasive service as well. Their final large advantage over other flowmeter types is that they are obstructionless, having no moving parts in the flow stream, and therefore do not increase the pressure drop to the system over the pressure drop of an equivalent length of pipe.

Four different types of flowmeter using ultrasonic technology are in common use. These are Doppler flowmeters, transit time flowmeters, sonar flowmeters, and ultrasonic level devices used in conjunction with open-channel primary flow devices such as weirs and flumes.

Doppler flowmeters operate by means of the Doppler effect. A signal of known frequency (typically 660 kHz) is beamed into a pipe. The return echo is frequency-shifted proportionally to the velocity of the fluid in the pipe. Because homogenous fluids generally do not reflect the signal well, Doppler flowmeters are restricted to fluids with relatively large quantities of entrained particulate (usually a minimum of 100 mg/L of plus-100-μm solids). They are commonly used in mining, dredging, and wastewater sludge applications.

Transit time flowmeters operate by beaming an ultrasonic signal into the pipe in the direction of flow, and a duplicate signal downstream. The difference in time for the transmitted signal to reach the receiver between the upstream and downstream signals is proportional to the velocity of the fluid. The difference in transit time is $2vl/(c^2 + v^2)$, where l is the path length. For $v \ll c$, the factor $(c^2 + v^2)$ is nearly constant. Like magmeters, transit time flowmeters have no pressure drop. Transit time flowmeters can be provided in similar sizes to magmeters, and are used in all types of fluids, except slurries. Transit time flowmeters can be used in gas flow measurement. Increasing the number of paths of signal transmission can increase the accuracy of the flowmeter, and transit time flowmeters are increasingly used for transmission and custody transfer of petroleum products and gas.

Sonar flowmeters are acoustic, rather than strictly ultrasonic, and operate by "listening" to the sonic properties of the fluid and determining velocity from the sonic profile.

Ultrasonic open-channel flowmeters are actually ultrasonic level transmitters used at the measurement point of a flume or weir, and supplied with electronic conversion from measured height to flow rate. Because of their noncontacting nature, ultrasonic open-channel flowmeters have become the standard technology for this measurement, replacing floats and other mechanical devices. The limiting accuracy of these devices is not the accuracy of the sensor, but rather the accuracy of the primary device.

Coriolis mass flowmeters are now common in many process industries. Generally available from fractional inch to 4 in (100 mm), at least one manufacturer produces up to 12-in sizes. Using the principle of measurement of the Coriolis force, these devices natively measure mass flow, and can be used to compute volumetric flow rate and total, and fluid density. Recent advances in Coriolis mass flowmeter design have permitted the device to also be used for measurement of gases.

Another extremely common measurement devices is the **fluidic flowmeter**, of which the best known examples are the vortex-shedding, the vortex-precession (or swirlmeter), and the Coanda effect flowmeter. The **vortex-shedding flowmeter** operates by sensing in a variety of ways the vortices shed by a bluff body in the flow stream. The frequency of the shed vortices is proportional to the fluid velocity. The **swirlmeter**, an ancestor of the vortex-shedder, uses the combination of a stationary turbine rotor to impart a twist and a flow restriction to produce a standing wave, the frequency of which is proportional to velocity. The **Coanda effect flowmeter** uses the Coanda effect to produce a hydraulic switch. The frequency of the switching operation is proportional to the velocity of the fluid. Vortex-shedding flowmeters and swirlmeters are commonly used in chemical and steam applications, while Coanda effect flowmeters are normally found in district heating and gas applications in relatively small sizes. Vortex-shedding flowmeters are limited in turndown at low velocities, and should not be used in applications with large-diameter solids such as wastewater or mining.

Thermal dispersion flowmeters operate by measuring the temperature differential caused by the passage of a fluid between two sensors. One sensor is heated to a constant temperature, and imparts heat to the fluid. The other sensor measures the temperature of the fluid. The temperature differential produces a power demand on the heater circuit that is proportional to the mass flow of the fluid. Thermal dispersion flowmeters are commonly used in gas flow measurement, but can also be used in some liquid flow measurements, generally as switches. These devices can be extremely accurate, and at least one manufacturer produces ultralow-flow thermal dispersion flowmeters that measure in the millilitre per hour range.

The most common open-channel primary flow elements in current usage are the **v-notch** and rectangular **weirs**, and the **Parshall** and

Palmer-Bowlus flumes. All of these devices produce a flow restriction that raises the fluid behind the restriction to a predictable height. The change in height H produces a measurement of flow rate by the formula $Q = K/n$, where K is a constant related to flow rate units and n is a constant related to the design of the specific primary element. The constant n is often written as a fraction, as in $^3/_2$. Other forms of primary elements for open-channel flow exist, and sometimes the **Manning formula** and its derivatives are used to measure the flow in open conduits without a primary device. Manning's formula is: $v = K/n\ R^{2/3}\ S^{1/2}$ (English units) [SI units], where v = fluid velocity (ft/s) or [m/s], $K = 1.486$ (English), $K = 1.00$ [SI], R = hydraulic radius (ft) or [m] = A/P_w, A = cross-sectional area of flow (ft^2) or [m^2], P_w = wetted perimeter (ft) or [m], S = channel slope, and n = Manning's roughness coefficient. Then $Q = vA$.

Most flowmeters measure rate of flow. To measure the total quantity of fluid flowing during a specific time interval, it is necessary to integrate the flow rate over that interval. The integration, prior to the advent of microprocessor-based flow transmitters, was often done manually, or with the use of specially shaped cams. Almost all flow transmitters now integrate mathematically, and display total flow on an electronic or electromechanical register.

POWER MEASUREMENT

Power is defined as the rate of doing work. Common units are the horsepower and the kilowatt: 1 hp = 33,000 ft · lb/min = 0.746 kW. The power input to a rotating machine in hp (W) = $2\pi nT/k$, where n = r/min of the shaft where the torque T is measured in lbf · ft (N · m), and k = 33,000 ft · lbf/hp · min [60 N · m/(W · min)]. The same equation applies to the power output of an engine or motor, where n and T refer to the output shaft. Mechanical power-measuring devices **(dynamometers)** are of two types: (1) those absorbing the power and dissipating it as heat and (2) those transmitting the measured power. As indicated by the above equation, two measurements are involved: shaft speed and torque. The speed is measured directly by means of a tachometer. Torque is usually measured by balancing against weights applied to a fixed lever arm; however, other force measuring methods are also used. In the **transmission dynamometer,** the torque is measured by means of strain-gage elements bonded to the transmission shaft.

There are several kinds of **absorption dynamometers.** The **Prony brake** applies a friction load to the output shaft by means of wood blocks, flexible band, or other friction surface. The **fan brake** absorbs power by "fan" action of rotating plates on surrounding air. The **water brake** acts as an inefficient centrifugal pump to convert mechanical energy into heat. The pump casing is mounted on antifriction bearings so that the developed turning moment can be measured. In the **magnetic-drag** or **eddy-current brake,** rotation of a metal disk in a magnetic field induces eddy currents in the disk which dissipate as heat. The field assembly is mounted in bearings in order to measure the torque.

One type of **Prony brake** is illustrated in Fig. 16.1.32. The torque developed is given by $L(W - W_0)$, where L is the length of the brake arm, ft; W and W_0 are the scale loads with the brake operating and with the brake free, respectively. The brake horsepower then equals $2\pi nL(W - W_0)/33{,}000$, where n is shaft speed, r/min.

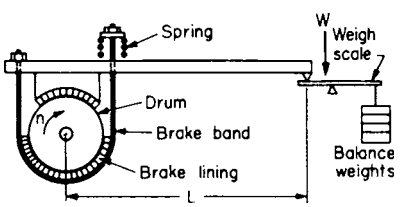

Fig. 16.1.32 Prony brake.

In addition to eddy-current brakes, **electric dynamometers** include calibrated generators and motors and cradle-mounted generators and motors. In calibrated machines, the efficiency is determined over a range of operating conditions and plotted. Mechanical power measurement can then be made by measuring the electrical power input (or output) to the machine. In the electric-cradle dynamometer, the motor or generator stator is mounted in trannion bearing so that the torque can be measured by suitable scales.

The **engine indicator** is a device for plotting cylinder pressure as a function of piston (or volume) displacement. The resulting p-v diagram (Fig. 16.1.33) provides both a measure of the work done in a reciprocating engine, pump, or compressor and a means for analyzing its performance (see Secs. 4, 9, and 14). If A_d is the area inside the closed curve drawn by the indicator, then the indicated horsepower for the cylinder under test = KnA_pA_d where K is a proportionality factor determined by the scale factors of the indicator diagram, n = engine speed, r/min, A_p = piston area.

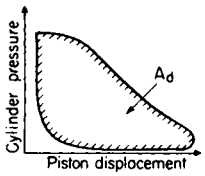

Fig. 16.1.33 Indicator diagram.

Completely mechanical indicators can be used only for low-speed machines. They have largely been superseded by electrical transducers using strain gages, variable capacitance, piezoresistive, and piezoelectric principles which are suitable for **high-speed** as well as low-speed pressure changes (the piezoelectric principle has low-speed limitations). The usual diagram is produced on an oscilloscope display as pressure vs. time, with a marker to indicate some reference event such as spark timing or top dead center. Special transducers can be coupled to a crank or cam shaft to give an electrical signal representing piston motion so that a p-v diagram can be shown on an oscilloscope.

ELECTRICAL MEASUREMENTS

(See also Sec. 15.)

Electrical measurements serve two purposes: (1) to measure the electrical quantities themselves, e.g., line voltage, power consumption, and (2) to measure other physical quantities which have been converted into electrical variables, e.g., temperature measurement in terms of thermocouple voltage.

In general, there is a sharp distinction between ac and dc devices used in measurements. Consequently, it is often desirable to transform an ac signal to an equivalent dc value, and vice versa. An ac signal is converted to dc (rectified) by use of **selenium rectifiers, silicon or germanium diodes, or electron-tube diodes.** Full-wave rectification is accomplished by the **diode bridge,** shown in Fig. 16.1.34. The rectified signal may be passed through one or more low-pass filter stages to smooth the waveform to its average value. Similarly, there are many ways of modulating a dc signal (converting it to alternating current). The most common method used in instrument applications is a solid-state oscillator.

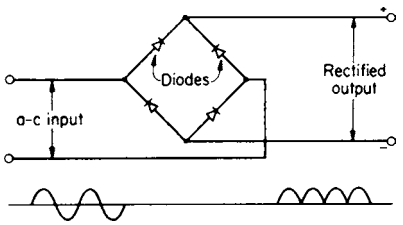

Fig. 16.1.34 Full-wave rectifier.

The **galvanometer** (Fig. 16.1.35), recently supplanted by the direct-reading **digital voltmeter** (DVM), is basic to dc measurement. The input signal is applied across a coil mounted in jeweled bearings or on a taut-band suspension so that it is free to rotate between the poles of a

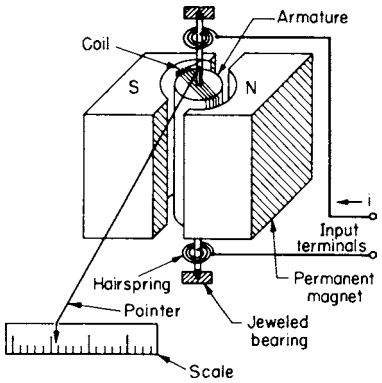

Fig. 16.1.35 D'Arsonval galvanometer.

permanent magnet. Current in the coil produces a magnetic moment which tends to rotate the coil. The rotation is limited, however, by the restraining torque of the hairsprings. The resulting deflection of the coil θ is proportional to the current I:

$$\theta = \frac{NBWL}{K} I$$

where N = number of turns in coil; W, L = coil width and length, respectively; B = magnetic field intensity; K = spring constant of the hairsprings. Galvanometer deflection is indicated by a balanced pointer attached to the coil. In very sensitive elements, the pointer is replaced by a mirror reflecting a spot of light onto a ground-glass scale; the bearings and hairspring are replaced by a torsion-wire suspension.

The galvanometer can be converted into a **dc voltmeter, ammeter, or ohmmeter** by application of Ohm's law, $IR = E$, where I = current, A; E = electrical potential, V; and R = resistance, Ω.

For a **voltmeter,** a fixed resistance R is placed in series with the galvanometer (Fig. 16.1.36*a*). The current i through the galvanometer is proportional to the applied voltage E: $i = E/(r + R)$, where r = coil resistance. Different voltage ranges are obtained by changing the series resistance.

An **ammeter** is produced by placing the resistance in parallel with the galvanometer or DVM (Fig. 16.1.36*b*). The current then divides between the galvanometer coil or DVM and the resistor in inverse ratio to their resistance values (r and R, respectively); thus, $i = IR/(r + R)$, where i = current through coil and I = total current to be measured. Different current ranges are obtained by using different shunt resistances.

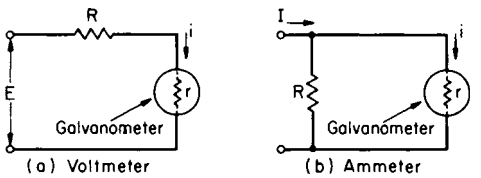

Fig. 16.1.36 (*a*) Voltmeter; (*b*) ammeter.

The common ohmmeter consists of a battery, a galvanometer with a shunt rheostat, and resistance in series to total Ri Ω. The shunt is adjusted to give a full-scale (0 Ω) reading with the test terminals shorted. When an unknown resistance R is connected, the deflection is $Ri/(Ri + R)$ fraction of full scale. The scale is calibrated to read R directly. A half-scale deflection indicates $R = Ri$. Alternatively, the galvanometer is connected to read voltage drop across the unknown R while a known current flows through it. This principle is used for low-value resistances and in digital ohmmeters.

Digital instruments are available for all these applications and often offer higher resolution and accuracy with less circuit loading. Fluctuating readings are difficult to follow, however.

Alternating current and voltage must be measured by special means. A dc instrument with a rectifier input is commonly used in applications requiring high input impedance and wide frequency range. For precise measurement at power-line frequencies, the electrodynamic instrument is used. This is similar to the galvanometer except that the permanent magnet is replaced by an electromagnet. The movable coil and field coils are connected in series; hence they respond simultaneously to the same current and voltage alternations. The pointer deflection is proportional to the square of the input signal. The moving-iron-type instruments consist of a soft-iron vane or armature which moves in response to current flowing through a stationary coil. The pointer is attached to the iron to indicate the deflection on a calibrated nonlinear scale. For measuring at very high frequencies, the **thermocouple voltmeter or ammeter** is used. This is based on the heating effect of the current passing through a fixed resistance R. Heat is liberated at the rate of E^2/R or $I^2 R$ W.

DC **electrical power** is the product of the current through the load and the voltage across the load. Thus it can be simply measured using a voltmeter and ammeter. AC power is directly indicated by the wattmeter, which is similar to the electrodynamic instrument described above. Here the field coils are connected in series with the load, and the movable coil is connected across the load (to measure its voltage). The deflection of the movable coil is then proportional to the effective load power.

Precise voltage measurement (direct current) can be made by balancing the unknown voltage against a measured fraction of a known reference voltage with a **potentiometer** (Fig. 16.1.9). Balance is indicated by means of a sensitive current detector placed in series with the unknown voltage. The potentiometer is calibrated for angular position vs. fractional voltage output. Accuracies to 0.05 percent are attainable, dependent on the linearity of the potentiometer and the accuracy of the reference source. The reference standard may be a Weston standard cell or a regulated voltage supply (based on diode characteristics). The balance detector may be a galvanometer or electronic amplifier.

Precision resistance and general impedance measurements are made with bridge circuits (Fig. 16.1.37) which are adjusted until no signal is detected by the null detector (bridge is balanced). Then $Z_1Z_3 = Z_2Z_4$. The basic Wheatstone bridge is used for resistance measurement where all the impedances (Z's) are resistances (R's). If R_1 is to be measured, $R_1 = R_2R_4/R_3$, when balanced. A sensitive galvanometer for the null detector and dc voltage excitation is usual. All R_2, R_3, R_4 must be calibrated, and some adjustable. For general impedance measurement, ac voltage excitation of suitable frequency is used. The null detector may be a sensitive ac meter, oscilloscope, or, for audio frequencies, simple earphones. The basic balance equation is still valid, but it now requires also that the sum of the phase angles of Z_1 and Z_3 equal the sum of the phase angles of Z_2 and Z_4. As an example, if Z_1 is a capacitor, the bridge can be balanced if Z_2 is a known capacitor while Z_3 and Z_4 are resistances. The phase-angle condition is met, and $Z_1Z_3 = Z_2Z_4$ becomes $(1/2\pi fC_1)R_3 = (1/2\pi fC_2)R_4$ and $C_1 = C_2R_3/R_4$. Variations on the basic

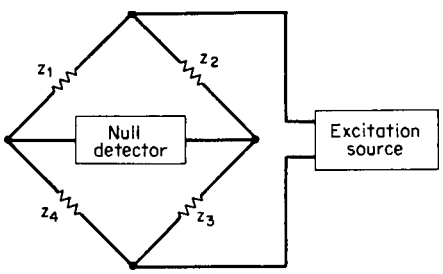

Fig. 16.1.37 Impedance bridge.

principle include the Kelvin bridge for measurement of low resistance, and the Mueller bridge for platinum resistance thermometers.

Voltage measurement requires a meter of substantially higher impedance than the impedance of the source being measured. The vacuum-tube cathode follower and the field-effect transistor are suitable for high-impedance inputs. The following circuitry may be a simple amplifier to drive a pointer-type meter, or may use a digital technique to produce a digital output and display. Digital counting circuits are capable of great precision and are widely adapted to measurements of time, frequency, voltage, and resistance. Transducers are available to convert temperature, pressure, flow, length and other variables into signals suitable for these instruments.

The charge amplifier is an example of an operational amplifier application (Fig. 16.1.38). It is used for outputs of piezoelectric transducers in which the output is a charge proportional to input force or other input converted to a force. Several capacitors switchable across the feedback path provide a range of full-scale values. The output is a voltage.

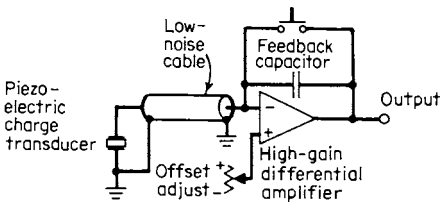

Fig. 16.1.38 Charge amplifier application.

The **cathode-ray oscilloscope** (Fig. 16.1.39) is an extremely useful and versatile device characterized by high input impedance and wide frequency range. An electron beam is focused on the phosphor-coated face of the cathode-ray tube, producing a visible spot of light at the point of impingement. The beam is deflected by applying voltages to vertical

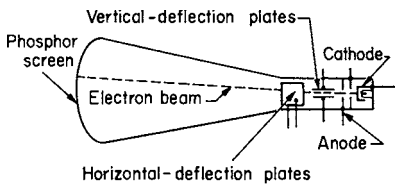

Fig. 16.1.39 Cathode-ray tube.

and horizontal deflector plates. Thus, the relationship between two varying voltages can be observed by applying them to the vertical and horizontal plates. The horizontal axis is commonly used for a linear time base generated by an internal sawtooth-wave generator. Virtually any desired sweep speed is obtainable as a calibrated sweep. Sweeps which change value part way across the screen are available to provide localized time magnification. As an alternative to the time base, any arbitrary voltage can be applied to drive the horizontal axis. The vertical axis is usually used to display a dependent variable voltage. **Dual-beam** and **dual-trace** instruments show two waveforms simultaneously. Special long-persistence and storage screens can hold transient waveforms for from seconds to hours. Greater versatility and unique capabilities are afforded by use of **digital-storage** oscilloscope. Each input signal is sampled, digitized, and stored in a first-in–first-out memory. Since a record of the recent signal is in memory when a trigger pulse is received, the timing of the end of storing new data into memory determines how much of the stored signal was before, and how much after, the trigger. Unlike storage screens, the stored signal can be amplified and shifted on the screen for detailed analysis, accompanied by numerical display of voltage and time for any point. Care must be taken that enough samples are taken in any waveform; otherwise aliasing results in a false view of the waveform.

The stored data can be processed mathematically in the oscilloscope or transferred to a computer for further study. Accessories for microcomputers allow them to function as digital oscilloscopes and other specialized tasks.

VELOCITY AND ACCELERATION MEASUREMENT

Velocity or speed is the time rate of change of displacement. Consequently, if the displacement measuring device provides an output signal which is a continuous (and smooth) function of time, the velocity can be measured by **differentiating** this signal either graphically or by use of a differentiating circuit. The accuracy may be very limited by noise (high-frequency fluctuations), however. More commonly, the output of an accelerometer is integrated to yield the velocity of the moving member. **Average speed** over a time interval can be determined by measuring the time required for the moving body to pass two fixed points a known distance apart. Here photoelectric or other rapid sensing devices may be used to trigger the start and stop of the timer. **Rotational speed** may be similarly measured by counting the number of rotations in a fixed time interval.

The **tachometer** provides a direct measure of angular velocity. One form is essentially a small permanent-magnet-type generator coupled to the rotating element; the voltage induced in the armature coil is directly proportional to the speed. The principle is also extended to rectilinear motions (restricted to small displacements) by using a straight coil moving in a fixed magnetic field.

Angular velocity can also be measured by magnetic drag-cup and **centrifugal-force** devices (flyball governor). The force may be balanced against a spring with the resulting deflection calibrated in terms of the shaft speed. Alternatively, the force may be balanced against the air pressure generated by a pneumatic nozzle-baffle assembly (similar to Fig. 16.1.23).

Vibration velocity pickups may use a coil which moves relative to a magnet. The voltage generated in the coil has the same frequency as the vibration and, for sine motion, a magnitude proportional to the product of vibration frequency and amplitude. Vibration **acceleration pickups** commonly use strain-gage, piezoresistive, or piezoelectric elements to sense a force $F = Ma/g_c$. The maximum usable frequency of an accelerometer is about one-fifth of the pickup's natural frequency (see Sec. 3.4). The minimum usable frequency depends on the type of pickup and the associated circuitry. The output of an accelerometer can be integrated to obtain a velocity signal; a velocity signal can be integrated to obtain a displacement signal. The **operational amplifier** is a versatile element which can be connected as an integrator for this use.

Holography is being applied to the study of surface vibration patterns.

MEASUREMENT OF PHYSICAL AND CHEMICAL PROPERTIES

Physical and chemical measurements are important in the control of product quality and composition. In the case of manufactured items, such properties as color, hardness, surface, roughness, etc., are of interest. Color is measured by means of a **colorimeter,** which provides comparison with color standards, or by means of a **spectrophotometer,** which analyzes the color spectrum. The **Brinell and Rockwell testers** measure surface hardness in terms of the depth of penetration of a hardened steel ball or special stylus. Testing machines with **strain-gage** elements provide measurement of the strength and elastic properties of materials. **Profilometers** are used to measure surface characteristics. In one type, the surface contour is magnified optically and the image projected onto a screen or viewer; in another, a stylus is employed to translate the surface irregularities into an electrical signal which may be recorded in the form of a highly magnified profile of the surface or presented as an averaged roughness-factor reading.

For liquids, attributes such as density, viscosity, melting point, boiling point, transparency, etc., are important. Density measurements have already been discussed. **Viscosity** is measured with a **viscosimeter,** of which there are three main types: flow through an orifice or capillary

(Saybolt), viscous drag on a cylinder rotating in the fluid (MacMichael), damping of a vibrating reed (Ultrasonic) (see Secs. 3 and 4). **Plasticity** and consistency are related properties which are determined with special apparatus for heating or cooling the material and observing the temperature-time curve. The **photometer, reflectometer, and turbidimeter** are devices for measuring transparency or turbidity of nonopaque liquids and solids.

A variety of properties can be measured for determining chemical composition. **Electrical properties** include pH, conductivity, dielectric constant, oxidation potential, etc. **Physical properties** include density, refractive index, thermal conductivity, vapor pressure, melting and boiling points, etc. Of increasing industrial application are **spectroscopic measurements: infrared absorption spectra, ultraviolet and visible emission spectra, mass spectrometry,** and **gas chromatography.** These are specific to particular types of compounds and molecular configurations and hence are very powerful in the analysis of complex mixtures. As examples, infrared analyzers are in use to measure low-concentration contaminants in engine oils resulting from wear and in hydraulic oils to detect deterioration. **X-ray diffraction** has many applications in the analysis of crystalline solids, metals, and solid solutions.

Of special importance in the realm of composition measurements is the determination of **moisture content.** A common laboratory procedure measures the loss of weight of the oven-dried sample. More rapid methods employ electrical conductance or capacitance measurements, based on the relatively high conductivity and dielectric constant values for ordinary water.

Water vapor in air (humidity) is measured in terms of its physical properties or effects on materials (see also Secs. 4 and 12). (1) The **psychrometer** is based on the cooling effect of water evaporating into the airstream. It consists of two thermal elements exposed to a steady airflow; one is dry, the other is kept moist. See Sec. 4 for psychrometric charts. (2) The **dew-point recorder** measures the temperature at which water just starts to condense out of the air. (3) The **hygrometer** measures the change in length of such humidity-sensitive elements as hair and wood. (4) **Electric sensing elements** employ a wire-wound coil impregnated with a hygroscopic salt (one that maintains an equilibrium between its moisture content and the air humidity) such that the resistance of the coil is related to the humidity.

The **throttling calorimeter** (Fig. 16.1.40) is most commonly used for determining the moisture in steam. A sampling nozzle is located preferably in a vertical section of steampipe far removed from any fittings. Steam enters the calorimeter through a throttling orifice and into a well-insulated expansion chamber. The steam quality x (fraction dry steam) is determined from the equation $x = (h_c - h_f) / h_{fg}$, where h_c is the enthalpy of superheated steam at the temperature and pressure measured in the calorimeter; h_f and h_{fg} are, respectively, the liquid enthalpy and the heat of vaporization corresponding to line pressure. The chamber is conveniently exhausted to atmospheric pressure; then only line pressure and temperature of the throttled steam need be measured. The range of the throttling calorimeter is limited to small percentages of moisture; a **separating calorimeter** may be employed for larger moisture contents.

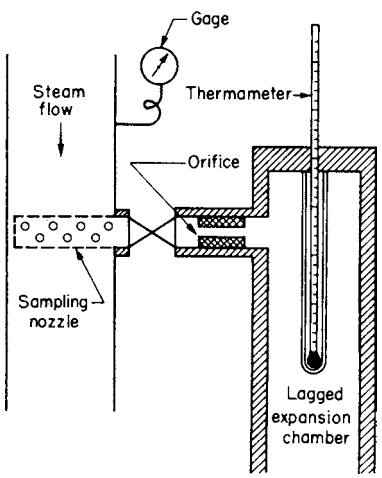

Fig. 16.1.40 Throttling calorimeter.

The **Orsat** apparatus is generally used for chemical analysis of flue gases. It consists of a graduated tube or burette designed to receive and measure volumes of gas (at constant temperature). The gas is analyzed for CO_2, O_2, CO, and N_2 by bubbling through appropriate absorbing reagents and measuring the resulting change in volume. The reagents normally employed are KOH solution for CO_2, pyrogallic acid and KOH mixture for O_2, and cuprous chloride (Cu_2Cl_2) for CO. The final remaining unabsorbed gas is assumed to be N_2. The most common errors in the Orsat analysis are due to **leakage** and poor **sampling.** The former can be checked by simple test; the latter factor can only be minimized by careful sampling procedure. Recommended procedure is the taking of several simultaneous samples from different points in the cross-sectional area of the flue-gas stream, analyzing these separately, and averaging the results.

There are many instruments for **measuring CO_2 (and other gases) automatically.** In one type, the CO_2 is absorbed in KOH, and the change in volume determined automatically. The more common type, however, is based on the difference in **thermal conductivity** of CO_2 compared with air. Two thermal conductivity cells are set into opposing arms of a Wheatstone-bridge circuit. Air is sealed into one cell (reference), and the CO_2-containing gas is passed through the other. The cell contains an electrically heated resistance element; the temperature of the element (and therefore its resistance) depends on the thermal conductivity of the gaseous atmosphere. As a result, the unbalance of the bridge provides a measure of the CO_2 content of the gas sample.

The same principle can be employed for analyzing other constituents of gas mixtures where there is a significant thermal-conductivity difference. A modification of this principle is also used for determining CO or other combustible gases by mixing the gas sample with air or oxygen. The combustible gas then burns on the heated wire of the test cell, producing a temperature rise which is measured as above.

Many other physical properties are employed in the determination of specific components of gaseous mixtures. An interesting example is the **oxygen analyzer,** based on the unique paramagnetic properties of oxygen.

NUCLEAR RADIATION INSTRUMENTS

(See also Sec. 9.)

Nuclear radiation instrumentation is increasing in importance with two main areas of application: (1) measurement and control of radiation variables in nuclear reactor-based processes, such as nuclear power plants and (2) measurement of other physical variables based on radioactive excitation and tracer techniques. The instruments respond in general to electromagnetic radiation in the gamma and perhaps X-ray regions and to beta particles (electrons), neutrons, and alpha particles (helium nuclei).

Gas Ionization Tubes The **ion chamber, proportional counter,** and **Geiger counter** are common instruments for radiation detection and measurement. These are different applications of the gas-ionization tube distinguished primarily by the amount of applied voltage.

A simple and very common form of the instrument consists of a gas-filled cylinder with a fine wire along the axis forming the anode and the cylinder wall itself (at ground potential) forming the cathode, as shown in Fig. 16.1.41. When a radiation particle enters the tube, its collision with gas molecules causes an ionization consisting of electrons (negatively charged) and positive ions. The electrons move very rapidly toward the positively charged wire; the heavier positive ions move relatively slowly toward the cathode. The above activity is detected by the resulting current flow in the external circuitry.

When the voltage applied across the tube is relatively low, the number of electrons collected at the anode is essentially equal to that produced by the incident radiation. In this voltage range, the device is

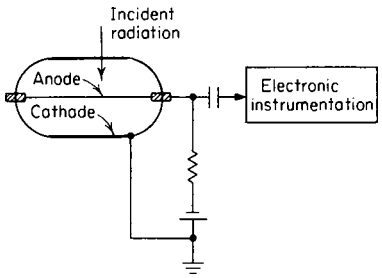

Fig. 16.1.41 Gas-ionization tube.

called an **ion chamber.** The device may be used to count the number of radiation particles when the frequency is low; when the frequency is high, an external integrating circuit yields an output current proportional to the radiation intensity. Since the amplification factor of the ion chamber is low, high-gain electronic amplification of the current signal is necessary.

If the applied voltage is increased, a point is reached where the radiation-produced ions have enough energy to collide with other gas molecules and produce more ions which also enter into collisions so that an "avalanche" of electrons is collected at the anode. Thus, there is a very considerable amplification of the output signal. In this region, the device is called a **proportional counter** and is characterized by the voltage or current pulse being proportional to the energy content of the incident radiation signal.

With still further increase in the applied voltage, a point of saturation is reached wherein the output pulses have a constant amplitude independent of the incident radiation level. The resulting **Geiger counter** is capable of producing output pulses up to 10 V in amplitude, thus greatly reducing the requirements on the external circuitry and instrumentation. This advantage is offset somewhat by a lower maximum counting rate and more limited ability to differentiate among the various types of radiation as compared with the proportional counter.

The **scintillation counter** is based on the excitation of a phosphor by incident radiation to produce light radiation which is in turn detected by a photomultiplier tube to yield an output voltage. The signal output is greatly amplified and nearly proportional to the energy of the initial radiation. The device may be applied to a wide range of radiations, it has a very fast response, and, by choice of phosphor material, it offers a large degree of flexibility in applications.

Applications to the Measurement of Physical Variables The ready availability of radioactive isotopes of long half-life, such as cobalt 60, make possible a variety of industrial and laboratory measuring techniques based on radiation instruments of the type described above. Most applications are based on (1) radiation absorption, (2) tracer identification, and (3) other properties. These techniques often have the advantages of isolation of the measuring device from the system, access to a variable not observable by conventional means, or measurement without destruction or modification of the system.

In the utilization of **absorption** properties, a radioactive source is separated from the radiation-measuring device by that part of the system to be measured. The measured radiation intensity will depend on the fraction of radiation absorbed, which in turn will depend on the distance traveled through the absorbing medium and the density and nature of the material. Thus, the instrument can be adapted to measuring thickness (see Fig. 16.1.12), coating weight, density, liquid or solids level, or concentration (of certain components).

Tracer techniques are effectively used in measuring flow rates or velocities, residence time distributions, and flow patterns. In flow measurement, a sharp pulse of radioactive material may be injected into the flow stream; with two detectors placed downstream from the injection point and a known distance apart, the velocity of the pulse is readily measured. Alternatively, if a known constant flow rate of tracer is injected into the flow stream, a measure of the radiation downstream is easily converted into a measure of the desired flow rate. Other applications of tracer techniques involve the use of tagged molecules embedded in the process to provide measures of wear, chemical reactions, etc.

Other applications of radiation phenomena include level measurements based on a floating radioactive source, level measurements based on the back-scattering effect of the medium, pressure measurements in the high-vacuum region based on the amount of ionization caused by alpha rays, location of interface in pipeline transmission applications, and certain chemical analysis applications.

INDICATING, RECORDING, AND LOGGING

Rapid change has overtaken the ways in which process information is presented and stored. The control panel of the 1970s, with banks of analog pointer indicators and circular and strip chart recorders, has given way to digital indicators, dataloggers, and recorder simulations that are entirely software based. Some industrial sectors continue the use of paper chart recorders, so typical strip and circular chart recorders are shown here.

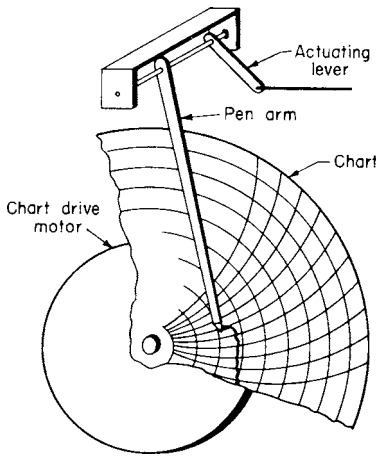

Fig. 16.1.42 Circular-chart recorder.

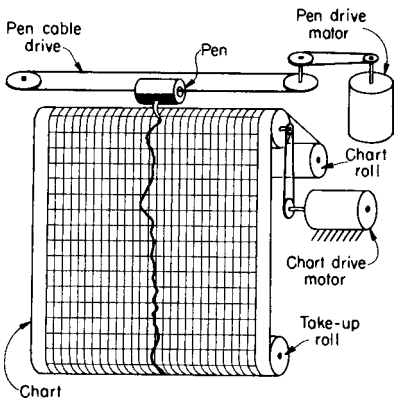

Fig. 16.1.43 Strip-chart recorder.

These include the nuclear power, food, and pharmaceuticals industry sectors. However, even these last holdouts are now moving to more modem means of indicating and recording information about measured variables.

With the advent of liquid crystal displays (LCDs) that can display graphical elements, even field instruments now have digital displays, some of which mimic analog indicators with "dials" or "bargraphs" or other even more sophisticated displays.

Replacing recorders in most applications now are digital dataloggers with cathode-ray tube (CRT) or LCD displays that simulate the visual aspect of an analog trend recorder. These are designed with the same form factor as older mechanical recorders so that they can be inserted into precut holes in existing control panels.

Most HMI packages for control systems contain a software system called a "data historian," which provides for logging and display of large amounts of process measurement data. Data historian software is often used to provide data to advanced process control software packages and to enterprise software systems for quality control and supply chain integration.

Field dataloggers have become small and are operated by very low power internal batteries, and can even be inserted into, for example, a single carton of food for long-term monitoring. These dataloggers can be accessed by connection to a laptop, another type of host computer, or remotely by means of wireless connections such as Bluetooth, Zigbee, and the various IEEE 802.11 standards.

INFORMATION TRANSMISSION

In the process plant, information is transmitted from field devices and control elements to control stations and the process control computer system by means of either analog or digital signals.

With the exception of some refinery and petrochemical applications, where pneumatic instrumentation, using a 3 to 15 lb/in^2 variable pressure range, is still used, the vast majority of analog information transmission is by means of either variable voltage, current, or frequency.

ANSI/ISA50 standardized the analog transmission protocol to be 4 to 20 mA dc (1 to 5 V dc) into 1,000 ohms resistive as equal to 0 to 100 percent scale. Another transmission protocol in less common use is 0 to 20 mA dc, 10 to 50 V dc, among many others. Two-wire instruments receive their operational power as well as transmit their signal on the "current output loop." Four-wire instruments require separate power supplies for operation.

ANSI/ISA50 chose a "live zero" at 4 mA dc so that a reading of 0 mA would indicate a diagnostic failure condition. Numerous manufacturers provide field converters to take voltages and frequencies and convert them to current loop outputs, and vice versa.

While many field sensors continue to have analog outputs (voltage, current, frequency, or pressure), many field instruments are now supplied with digital communications systems built into the device. The most ubiquitous in process automation is the **HART protocol** (www.hartcomm.org), which is a digital communications system carried on existing 4- to 20-mA dc current loop outputs. The HART protocol permits remote readout, calibration, diagnostics, and reprogramming of many field instruments and control valves.

Other bus systems are in use, some relatively old, such as IEEE 488 GPIB (or BPIB), developed as a general-purpose interface bus. Other buses such as Modbus are often found in machine control applications in discrete automation. Another digital communications bus, BACNet, has found wide acceptance in building automation systems worldwide.

Growing reliance is being placed, at least in new plant construction, on two other, more fully featured communications methods, known by the common name of **fieldbuses. Profibus** (www.profibus.com) and **Foundation Fieldbus** (www.fieldbus.org) provide complete bidirectional communications and control between field instruments and final control elements and the process control system. The design of fieldbuses is beginning to converge with the design of enterprise LAN and WAN (local- and wide-area networks) using TCP/EP protocols over Ethernet configured networks. Recently, IEEE released a standard for power over Ethernet, but it is not yet workable for field instruments.

Despite intellectual property challenges, the use of embedded web servers in field instruments and controllers is proliferating. This permits the use of standard Internet-based communication protocols by even a pressure transmitter or flowmeter. The control system then is a virtual control system architected as a series of World Wide Web pages, rather than a physical hardware set.

INTRODUCTION

The purpose of an **automatic control** on a system is to produce a desired output when inputs to the system are changed. Inputs are in the form of commands, which the output is expected to follow, and disturbances, which the automatic control is expected to minimize. The usual form of an automatic control is a **closed-loop feedback control** which Ahrendt defines as "an operation which, in the presence of a disturbing influence, tends to reduce the difference between the actual state of a system

and an arbitrarily varied desired state and which does so on the basis of this difference." The general theories and definitions of automatic control have been developed to aid the designer to meet primarily three basic specifications for the performance of the control system, namely, stability, accuracy, and speed of response.

The **terminology** of automatic control is being constantly updated by the ASME, IEEE, and ISA. Redundant terms, such as *rate, preact,* and *derivative,* for the same controller action are being standardized. Common terminology is still evolving. The introduction of the digital computer as a control device has necessitated the introduction of a whole new subset of terminology. The following terms and definitions have been selected to serve as a reference to a complex area of technology whose breadth crosses several professional disciplines.

Adaptive control system: A control system within which automatic means are used to change the system parameters in a way intended to improve the performance of the system.

Amplification: The ratio of output to input, in a device intended to increase this ratio. A gain greater than 1.

Attenuation: A decrease in signal magnitude between two points, or a gain of less than 1.

Automatic-control system: A system in which deliberate guidance or manipulation is used to achieve a prescribed value of a variable and which operates without human intervention.

Automatic controller: A device, or combination of devices, which measures the value of a variable, quantity, or condition and operates to correct or limit deviation of this measured value from a selected command (set-point) reference.

Bode diagram: A plot of log-gain and phase-angle values on a log-frequency base, for an element, loop, or output transfer function.

Capacitance: A property expressible by the ratio of the time integral of the flow rate of a quantity (heat, electric charge) to or from a storage, divided by the related potential charge.

Command: An input variable established by means external to, and independent of, the automatic-control system, which sets the ideal value of the controlled variable. See *set point.*

Control action: Of a control element or controlling system, the nature of the change of the output affected by the input.

Control action, derivative: That component of control action for which the output is proportional to the rate of change of input.

Control action, floating: A control system in which the rate of change of the manipulated variable is a continuous function of the actuating signal.

Control action, integral (reset): Control action in which the output is proportional to the time integral of the input.

Control action, proportional: Control action in which there is a continuous linear relationship between the output and the input.

Control system, sampling: Control using intermittently observed values of signals such as the feedback signal or the actuating signal.

Damping: The progressive reduction or suppression of the oscillation of a system.

Deviation: Any departure from a desired or expected value or pattern. Steady-state deviation is known as *offset.*

Disturbance: An undesired variable applied to a system which tends to affect adversely the value of the controlled variable.

Error: The difference between the indicated value and the accepted standard value.

Gain: For a linear system or element, the ratio of the change in output to the causal change in input.

Load: The material, force, torque, energy, or power applied to or removed from a system or element.

Nyquist diagram: A polar plot of the loop transfer function.

Nichols diagram: A plot of magnitude and phase contours using ordinates of logarithmic loop gain and abscissas of loop phase angle.

Offset: The steady-state deviation when the command is fixed.

Peak time: The time for the system output to reach its first maximum in responding to a disturbance.

Proportional band: The reciprocal of gain expressed as a percentage.

Resistance: An opposition to flow that results in dissipation of energy and limitation of flow.

Response time: The time for the output of an element or system to change from an initial value to a specified percentage of the steady-state.

Rise time: The time for the output of a system to increase from a small specified percentage of the steady-state increment to a large specified percentage of the increment.

Self-regulation: The property of a process or a machine to settle out at equilibrium at a disturbance, without the intervention of a controller.

Set point: A fixed or constant command given to the controller designating the desired value of the controlled variable.

Settling time: The time required, after a disturbance, for the output to enter and remain within a specified narrow band centered on the steady-state value.

Time constant: The time required for the response of a first-order system to reach 63.2 percent of the total change when disturbed by a step function.

Transfer function: A mathematical statement of the influence which a system or element has on a signal or action compared at input and output terminals.

BASIC AUTOMATIC-CONTROL SYSTEM

A **closed-loop control system** consists of a process, a measurement of the controlled variable, and a controller which compares the actual measurement with the desired value and uses the difference between them to automatically adjust one of the inputs to the process. The **physical system** to be controlled can be electrical, thermal, hydraulic, pneumatic, gaseous, mechanical, or described by any other physical or chemical process. Generally, the control system will be designed to meet one of two **objectives.** A **servomechanism** is designed to follow changes in set point as closely as possible. Many electrical and mechanical control systems are servomechanisms. A **regulator** is designed to keep output constant despite changes in load or disturbances. Regulatory controls are widely used on chemical processes. Both objectives are shown in Fig. 16.2.1.

The **control components** can be actuated pneumatically, hydraulically, electronically, or digitally. Only in very few applications does actuation affect controllability. **Actuation** is chosen on the basis of economics.

The **purpose** of the control system must be defined. A large capacity or inertia will make the system sluggish for servo operation but will help to minimize the error for regulator operation.

PROCESS AS PART OF THE SYSTEM

Figure 16.2.1 shows the **process** to be part of the control system either as load on the servo or process to be controlled. Thus the process must be designed as part of the system. The process is **modeled** in terms of its static and dynamic gains in order that it be incorporated into the system diagram. Modeling uses Ohm's and Kirchhoff's laws for electrical systems, Newton's laws for mechanical systems, mass balances for fluid-flow systems, and energy balances for thermal systems.

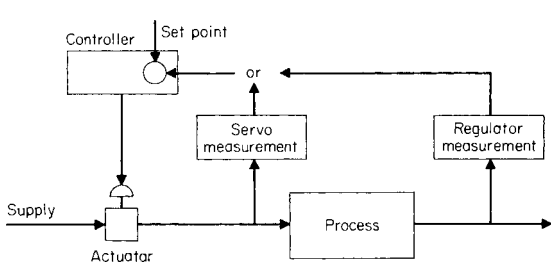

Fig. 16.2.1 Feedback control loop showing operation as servomechanism or regulator.

Consider the **electrical system** in Fig. 16.2.2

$$i = \frac{E_1 - E_2}{R}$$
$$i = C\frac{dE_2}{dt} \tag{16.2.1}$$

Combining

$$RC\frac{dE_2}{dt} + E_2 = E_1 \tag{16.2.2}$$

where $\left(R\,\frac{\text{volt-second}}{\text{coulomb}}\right)\left(C\,\frac{\text{coulomb}}{\text{volt}}\right) = \tau\text{ s} = \text{time constant}$

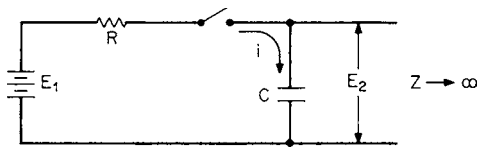

Fig. 16.2.2 Electrical system where current flows upon closing switch.

Consider the **mass balance** of the vessels shown in Figs. 16.2.3 and 16.2.4:

$$\text{Accumulation} = \text{input} - \text{output}$$
$$\frac{d(\rho V)}{dt} = w_1 - w_2 \quad \text{lb/min} \tag{16.2.3}$$

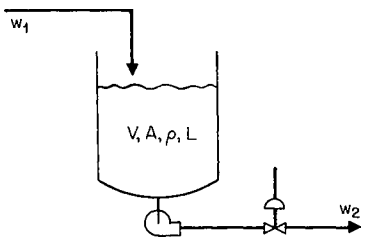

Fig. 16.2.3 Liquid level process.

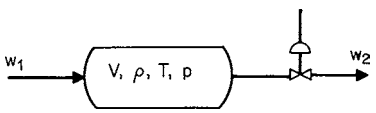

Fig. 16.2.4 Gas pressure process.

For the liquid level process (Fig. 16.2.3):

$$V = AL \tag{16.2.4}$$

Linearizing

$$w_2 = \left.\frac{w_2}{x}\right|_{ss} x$$

Substituting

$$\rho A\frac{dL}{dt} = w_1 - \left.\frac{w_2}{x}\right|_{ss} x \tag{16.2.5}$$

where ρA = analogous capacitance.

For the **gas pressure process** (Fig. 16.2.4):

$$V\frac{d\rho}{dt} = w_1 - w_2 \tag{16.2.6}$$

From thermodynamics

$$\left(\frac{\rho}{p}\right)^n = \text{constant} \tag{16.2.7}$$

Linearizing

$$w_2 = \left.\frac{w_2}{x}\right|_{ss} x + \left.\frac{w_2}{2(p - p_2)}\right|_{ss} p - p_2 \tag{16.2.8}$$

Substituting

$$RC\frac{dp}{dt} + p = \left.\frac{2(p - p_2)}{x}\right|_{ss} x + p_2 \tag{16.2.9}$$

where $C = \dfrac{V}{nRT}$ $R = \dfrac{2(p - p_2)}{w_2}$ $RC = \tau\,\text{min}$

and the terms are defined: V = volume, ft^3 (m^3); A = cross-sectional area, ft^2 (m^2); L = level, ft (m); ρ = density, lb/ft^3 (g/ml); x = valve stem position (normalized 0 to 1); T = temperature, °F (°C); p = pressure, lb/in^2 (kPa); and w = mass flow, lb/min (kg/min).

The **thermal process** of Fig. 16.2.5 is modeled by a heat balance (Shinskey, "Process Control Systems," McGraw-Hill):

$$Mc\frac{dT}{dt} = wc(T_0 - T) - UA(T - T_w) \tag{16.2.10}$$

$$\frac{Mc}{wc + UA}\frac{dT}{dt} + T = \frac{wc}{wc + UA}T_0 + \frac{UA}{wc + UA}T_w \tag{16.2.11}$$

where $C = Mc$ $R = \dfrac{1}{wc + UA}$ $RC = \tau\,\text{min}$

$$RC\frac{dT}{dt} + T = \frac{wc}{wc + UA}T_0 + \frac{UA}{wc + UA}T_w \tag{16.2.12}$$

The terms are defined: M = weight of process fluid in vessel, lb (kg); c = specific heat, Btu/lb · °F (J/kg · °C); U = overall heat-transfer coefficient, Btu/ft^2 · min · °F (W/m^2 · °C); and A = heat-transfer area, ft^2 (m^2).

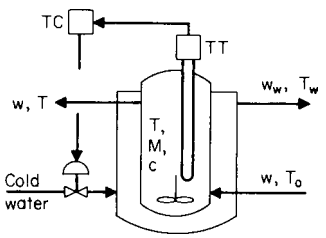

Fig. 16.2.5 Thermal process with heat from vessel being removed by cold water in jacket.

Newton's laws can be applied to the manometer shown in Fig. 16.2.6.

$$\text{Inertia force} = \text{restoring force} - \text{flow resistance}$$
$$\frac{Al\rho}{g_c}\frac{d^2h}{dt^2} = A\left(p - 2h\rho\frac{g}{g_c}\right) - RA\frac{dh}{dt} \tag{16.2.13}$$

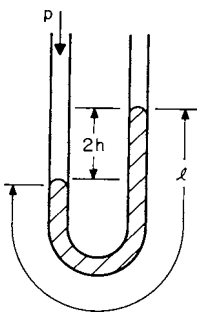

Fig. 16.2.6 Filled manometer measuring pressure P.

Flow resistance for laminar flow is given by the Hagen-Poiseuille equation:

$$R = \frac{\text{driving force}}{\text{rate of transfer}} = \frac{321\mu}{d^2 g_c} \tag{16.2.14}$$

Substituting

$$\frac{1}{2g}\frac{d^2h}{dt^2} + \frac{161\mu}{\rho d g^2}\frac{dh}{dt} + h = h_i \tag{16.2.15}$$

In standard form

$$\tau_c^2 \frac{d^2h}{dt^2} + 2\tau_c\zeta\frac{dh}{dt} + h = h_i \tag{16.2.16}$$

where τ_c = characteristic response time, min, = $1/[(60)(2\pi)\omega_n]$ where ω_n = natural frequency, Hz; and ζ = damping coefficient (ratio), dimensionless.

The variables τ_c and ζ are very valuable design aids since they define **system response** and **stability** in terms of system parameters.

TRANSIENT ANALYSIS OF A CONTROL SYSTEM

The stability, accuracy, and speed of response of a control system are determined by analyzing the **steady-state** and the **transient** performance. It is desirable to achieve the steady state in the shortest possible time, while maintaining the output within specified limits. Steady-state performance is evaluated in terms of the accuracy with which the output is controlled for a specified input. The transient performance, i.e., the behavior of the output variable as the system changes from one steady-state condition to another, is evaluated in terms of such quantities as maximum overshoot, rise time, and response time (Fig. 16.2.7).

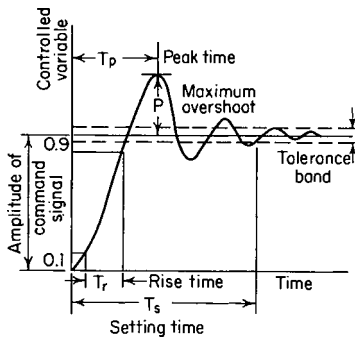

Fig. 16.2.7 System response to a unit step-function command.

Transient-Producing Disturbances A number of factors affect the **quality of control,** among them **disturbances** caused by set-point changes and process-load changes. Both set point and process load may be defined in terms of the setting of the final control element to maintain the controlled variable at the set point. Thus both cause the final control element to reposition. For a purely mechanical system the disturbance may take the form of a vibration, a displacement, a velocity, or an acceleration. A process-load change can be caused by variations in the rate of energy supply or variations in the rate at which work flows through the process. Reference to Fig. 16.2.5 and Eq. (16.2.12) shows disturbances to be variations in inlet process fluid temperature and cooling-water temperature. Further linearization would show variations in process flow and the overall heat-transfer coefficient to also be disturbances.

The Basic Closed-Loop Control To illustrate some characteristics of a basic closed-loop control, consider a mechanical, rotational system composed of a prime mover or motor, a total system inertia J, and a viscous friction f. To control the system's output variable θ_o, a command signal θ_i must be supplied, the output variable measured and compared to the input, and the resulting signal difference used to control the flow of energy to the load. The basic control system is represented schematically in Fig. 16.2.8.

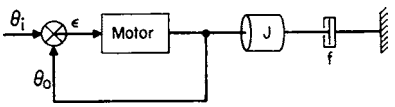

Fig. 16.2.8 A basic closed-loop control system.

The differential equation of this basic system is readily obtained from the idealized equations

$$\text{Load torque } T_L = J\frac{d^2\theta_o}{dt^2} + f\frac{d\theta_o}{dt} \tag{16.2.17}$$

$$\text{Developed torque } T_D = K\varepsilon \tag{16.2.18}$$

$$\text{Error } \varepsilon = \theta_i - \theta_o \tag{16.2.19}$$

The above equations combine to yield the system differential equation:

$$J\frac{d^2\theta_o}{dt^2} + f\frac{d\theta_o}{dt} + K\theta_o = K\theta_i \tag{16.2.20}$$

Step-Input Response of a Viscous-Damped Control If the control system described in Fig. 16.2.8 by Eq. (16.2.20) is subjected to a step change in the input variable θ_i, a solution $\theta_o = \theta_o(t)$ can be obtained as follows. (1) Let the ratio $\sqrt{K/J}$ be designated by the symbol ω_n and be called the **natural frequency**. (2) Let the quantity $2\sqrt{JK}$ be designated by the symbol f_c and be called the **friction coefficient** required for critical damping. (3) Let f/f_c be designated by the symbol ζ and be called the **damping ratio.** Equation (16.2.20) can then be written as

$$\frac{d^2\theta_o}{dt^2} + 2\zeta\omega_n\frac{d\theta_o}{dt} + \omega_n^2\theta_o = \omega_n^2\theta_i \tag{16.2.21}$$

For $\theta_i = 1$:

$$\theta_o = 0 \quad \text{and} \quad \frac{d\theta_o}{dt} = 0 \text{ at } t = 0$$

The complete solution of Eq. (16.2.21) is

$$\theta_o = 1 - \frac{\exp(-\zeta\omega_n t)}{\sqrt{1-\zeta^2}} \sin\left(\sqrt{1-\zeta^2}\,\omega_n t + \tan^{-1}\frac{\sqrt{1-\zeta^2}}{\zeta}\right) \tag{16.2.22}$$

Equation (16.2.22) is plotted in dimensionless form for various values of damping ratio in Fig. 16.2.9. The curves for $\zeta = 0.1$, 2, and 1 illustrate the underdamped, overdamped, and critically damped case, where any further decrease in system damping would result in overshoot.

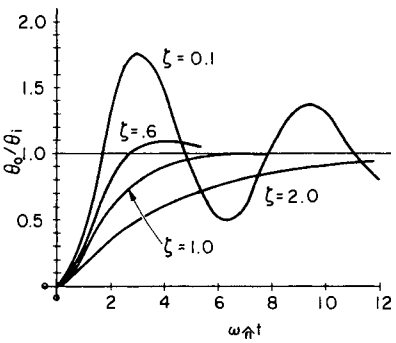

Fig. 16.2.9 Transient response of a second-order viscous-damped control to unit-step input displacement.

Damping is a property of the system which opposes a change in the output variable.

The immediately apparent features of an observed transient performance are (1) the existence and magnitude of the maximum overshoot, (2) the frequency of the transient oscillation, and (3) the response time.

Maximum Overshoot When an automatic-control system is underdamped, the output variable overshoots its desired steady-state condition and a transient oscillation occurs. The first overshoot is the greatest, and it is the effect of its amplitude which must concern the control designer. The primary considerations for limiting this maximum overshoot are (1) to avoid damage to the process or machine due to excessive excursions of the controlled variable beyond that specified by the command signal, and (2) to avoid the excessive settling time associated with highly underdamped systems. Obviously, exact quantitative limits cannot generally be specified for the magnitude of this overshoot. However, experience indicates that satisfactory performance can generally be obtained if the overshoot is limited to 30 percent or less.

Transient Frequency An undamped system oscillates about the final steady-state condition with a frequency of oscillation which should be as high as possible in order to minimize the response time. The designer must, however, avoid resonance conditions where the frequency of the transient oscillation is near the natural frequency of the system or its component parts.

Rise Time T_n, Peak Overshoot P, Peak Time T_p These quantities are related to ζ and ω_n in Figs. 16.2.10 and 16.2.11. Some useful formulas are listed below:

$$\omega_n T_n \approx 1.02 + 0.48\zeta + 1.15\zeta^2 + 0.76\zeta^3 \qquad 0 \le \zeta \le 1$$

$$\omega_n T_s = \begin{cases} 17.6 - 19.2\zeta & 0.2 \le \zeta \le 0.75 \\ -3.8 + 9.4\zeta & 0.75 \le \zeta \le 1 \end{cases} \quad 2\% \text{ tolerance band}$$

$$P = \exp\left(\frac{-\pi\zeta}{\sqrt{1-\zeta^2}}\right) \qquad T_p = \frac{\pi}{\omega_n\sqrt{1-\zeta^2}}$$

Although these quantities are defined for a second-order system, they may be useful in the early design states of higher-order systems if the response of the higher-order system is dominated by roots of the characteristic equation near the imaginary axis.

Derivative and Integral Compensation (Thaler) Four common compensation methods for improving the steady-state performance of a proportional-error control without damaging its transient response are shown in Fig. 16.2.12. They are (1) error derivative compensation, (2) input derivative compensation, (3) output derivative compensation, (4) error integral compensation.

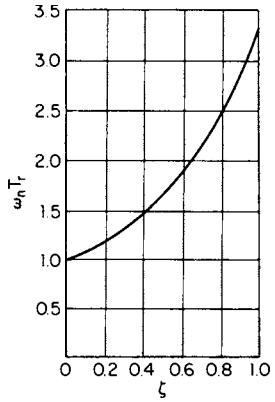

Fig. 16.2.10 Rise time T_r as a function of ζ and ω_n.

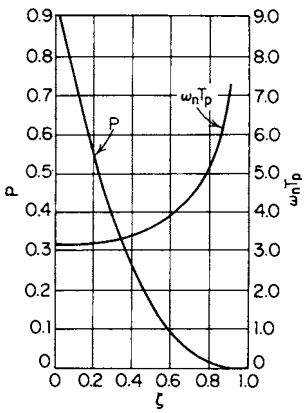

Fig. 16.2.11 Peak overshoot P and peak time T_p as functions of ζ and ω_n.

Error Derivative Compensation The torque equilibrium equation is

$$J\frac{d^2\theta_o}{dt^2} + f\frac{d\theta_o}{dt} = K_2\varepsilon + K_1\frac{d\varepsilon}{dt} \tag{16.2.23}$$

Writing Eq. (16.2.23) in terms of the input and output variables yields

$$J\frac{d^2\theta_o}{dt^2} + (f + K_1)\frac{d\theta_o}{dt} + K_2\theta_o = K_2\theta_i + K_1\frac{d\theta_i}{dt} \tag{16.2.24}$$

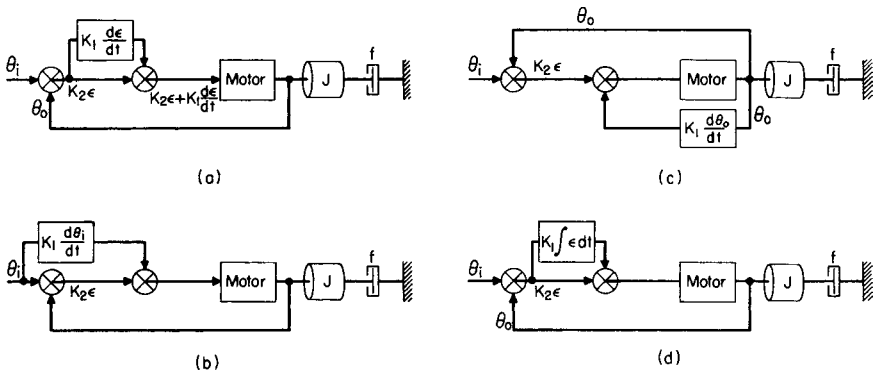

Fig. 16.2.12 Derivative and integral compensation of a basic closed-loop system. (*a*) Error derivative compensation; (*b*) input derivative compensation; (*c*) output derivative compensation; (*d*) error integral compensation. *(Thaler.)*

By adjusting K_1 and reducing f so that the quantity $f + K_1$ is equal to f in the uncompensated system, the system performance is affected as follows: (1) ε resulting from a constant-first-derivative input is reduced because of the reduction in viscous friction; (2) the transient performance of the uncompensated system is preserved unchanged.

Derivative Input Compensation The torque equilibrium equation is

$$J\frac{d^2\theta_o}{dt^2} + f\frac{d\theta_o}{dt} = K_2\varepsilon + K_1\frac{d\theta_i}{dt} \tag{16.2.25}$$

Writing Eq. (16.2.25) in terms of the input and output variables yields

$$J\frac{d^2\theta_o}{dt^2} + f\frac{d^2\theta_o}{dt} + K_2\theta_o = \theta_i + K_1\frac{d\theta_i}{dt} \tag{16.2.26}$$

Examination of Eq. (16.2.26) yields the following information about the compensated system's performance: (1) since the characteristic equation is unchanged from that of the uncompensated system, the transient performance is unaltered; (2) the steady-state solution to Eq. (16.2.26) is

$$\theta_o = \theta_i - \frac{f}{K_2}\left(1 - \frac{K_1}{K_2}\right)\frac{d\theta_i}{dt} \tag{16.2.27}$$

Therefore the input derivative signal can reduce the steady-state error by adjusting K_1 to equal K_2.

Derivative Output Compensation The torque equilibrium equation is

$$J\frac{d^2\theta_o}{dt^2} + f\frac{d^2\theta_o}{dt} = K_2\varepsilon \pm K_1\frac{d\theta_o}{dt} \tag{16.2.28}$$

Writing Eq. (16.2.28) in terms of the input and output variables yields

$$J\frac{d^2\theta_o}{dt^2} + (f \pm K_1)\frac{d\theta_o}{dt} + K_2\theta_o = K_2\theta_i \tag{16.2.29}$$

Examination of Eq. (16.2.29) yields the following information about the compensated system's performance. (1) Output derivative feedback produces the same system effect as the viscous friction does. This compensation therefore damps the transient performance. (2) Under conditions where $\theta_i = ct$, the steady-state error is increased.

Error Integral Compensation Error integral compensation is used where it is necessary to eliminate steady-state errors resulting from input signals with constant first derivatives or under conditions of externally applied loads. The torque equilibrium equation is

$$J\frac{d^2\theta_o}{dt^2} + f\frac{d\theta_o}{dt} \pm \text{external load torque} = K_2\varepsilon + K_1\int_0^t \varepsilon\,dt \tag{16.2.30}$$

Writing Eq. (16.2.30) in terms of the input variable and the error yields

$$\text{External load torque} + J\frac{d^2\theta_i}{dt^2} + f\frac{d\theta_i}{dt}$$

$$= J\frac{d^2\varepsilon}{dt^2} + f\frac{d\varepsilon}{dt} + K_2\varepsilon + K_1\int_0^t \varepsilon\,dt \tag{16.2.31}$$

At steady state for $t \gg 0$ and with a step change in the input derivative

$$\frac{d^2\theta_i}{dt^2} = \frac{d\varepsilon}{dt} = \frac{d^2\varepsilon}{dt^2} = 0 \qquad \frac{d\theta_i}{dt} = \text{const} \tag{16.2.32}$$

Equation (16.2.31) assumes the form

$$\pm\,\text{External load torque} + f\frac{d\theta_i}{dt} = K_2\varepsilon + K_1\int_0^t \varepsilon\,dt \tag{16.2.33}$$

Since the sum of the load torque and the term $f(d\theta_i/dt)$ is finite, $\varepsilon = 0$ for

$$\int_0^\infty \varepsilon\,dt \to \infty \tag{16.2.34}$$

If the integrating coefficient is a small number, additional torque produced by the integration action is developed very slowly, and, although the steady-state error is eventually eliminated, the transient performance is essentially unchanged. However, if K_1 is a large value, a large torque is produced in a short period of time, increasing the effect T/J ratio, and thereby decreasing the damping. The general effects of error integral compensation within its useful range are (1) steady-state error is eliminated; and (2) transient response is adversely effected, resulting in increased overshoot and the attendant increase in response time.

TIME CONSTANTS

The **time constant** τ, the **characteristic response time** (τ_c), and the **damping coefficient** are combined with operational calculus to design a control system without solving the classical differential equations. Note that the electrical, Eq. (16.2.2), mass, Eq. (16.2.9), and energy, Eq. (16.2.12) processes are all described by analogous first-order differential equations of the form

$$\tau\frac{dc}{dt} + c = Ka \tag{16.2.35}$$

Solving with initial conditions equal to zero, the **time-domain response** to a step disturbance is

$$c = Ka(1 - e^{t/\tau}) \tag{16.2.36}$$

Plotting is shown in Fig. 16.2.13.

Figure 16.2.13 shows the **time constant** to be defined by the point at 63.2 percent of the response, while response is essentially complete at three time constants (95 percent).

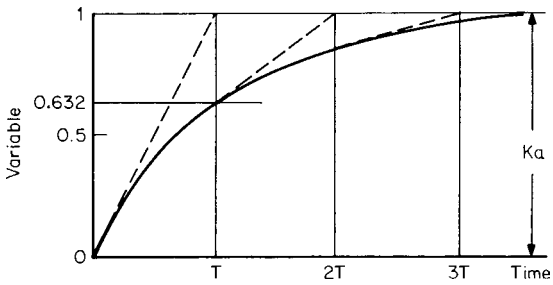

Fig. 16.2.13 Response of first-order system showing time constant relationship.

Operational calculus provides a systematic and simple method for handling linear differential equations with constant coefficients. The **Laplace operator** is used in control system analysis because of the straightforward transformation among the domains of interest:

Time domain	Complex domain	Frequency domain
$\frac{d}{dt}$	s	$j\omega$

Extensive tables of transforms are available for converting between the time and complex domains and back again. Transformation from the **complex** or **frequency domains** to **time** is difficult, and it is seldom attempted. Time-domain solutions are obtained only from computer simulations, which can solve the finite difference equations fast enough to serve as a design tool. Control system analysis and design proceed with a number of analytical and graphical techniques which do not require a time-domain solution.

The **root locus method** is a graphical technique used in the complex domain which provides substantial insight into the system. It has the weaknesses of handling dead time poorly and of the graph's being very tedious to plot. It is used only when computerized plotting is available.

BLOCK DIAGRAMS

The **physical diagram** of the system is converted to a **block diagram** in order that the different components of the system (all the way from a steam boiler to a thermocouple) can be placed on a common mathematical footing for analysis as a system. The block diagram shows the

functional relationship among the parts of the system by depicting the action of the variables in the system. The circle represents an algebraic function of addition. Each system component is represented by a **block** which has one input and one output. The block represents a dynamic function such that the output is a function of time and also of the input. The dynamic function is called a **transfer function**—the ratio of the Laplace transform of the output variable to the input variable with all initial conditions equal to zero. The input and output variables are considered as signals, and the blocks are connected by arrows to show the flow of information in the system.

Rewriting Eq. (16.2.12) for the thermal system,

$$RC\frac{dT}{dt} + T = K_1T_0 + K_2T_w \tag{16.2.37}$$

Transforming

$$(\tau s + 1)T = K_1T_0 + K_2T_w \tag{16.2.38}$$

for which the block diagram is shown in Fig. 16.2.14. Two conditions are specified: (1) the components must be described by linear differential equations (or nonlinear equations linearized by suitable approximations), and (2) each block is unilateral. What occurs in one component may not affect the components preceding.

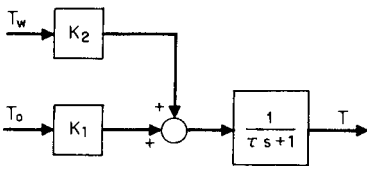

Fig. 16.2.14 Block diagram of thermal process.

Block-Diagram Algebra

The block diagram of a single-loop feedback-control system subjected to a command input $R(s)$ and a disturbance $U(s)$ is shown in Fig. 16.2.15.

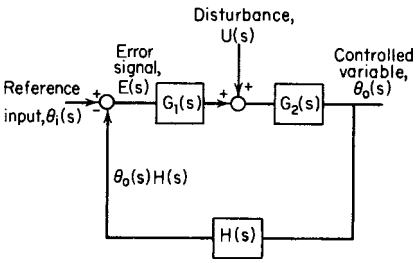

Fig. 16.2.15 Single-loop feedback control system.

When $U(s) = 0$ and the input is a reference change, the system may be reduced as follows:

$$E(s) = -\theta_o(s)H(s)$$
$$\theta_o(s) = E(s)[G_1(s)G_2(s)]$$

Therefore

$$\frac{\theta_o(s)}{\theta_i(s)} = \frac{G_1(s)G(s)}{1 + G_1(s)G_2(s)H(s)} \tag{16.2.39}$$

When $\theta_i(s) = 0$ and the input is a disturbance, the system may be reduced as follows:

$$E(s) = -\theta_o(s)H(s)$$
$$[E(s)\,G_1(s) + U(s)]G_2(s) = \theta_o(s)$$
$$\frac{\theta_o(s)}{U(s)} = \frac{G_2(s)}{1 + G_1(s)G_2(s)H(s)} \tag{16.2.40}$$

Closed-loop transfer function Eq. (16.2.40) can be determined by observation from

$$\frac{\theta_o(s)}{U(s)} = \frac{\text{feedforward functions}}{1 + \text{complete-loop functions}}$$

The denominator of Eq. (16.2.40) is the **characteristic equation** which determines **stability.** Most systems are designed on the basis of the characteristic equation since it sets both response time τ_c and damping ζ. The equation is undefined (unstable) if $G_1(s)G_2(s)H(s)$ equals -1. But -1 is a vector of magnitude 1 and a phase of $-180°$. This fact is used to determine stable parameter adjustments in the graphical techniques to be discussed later.

The input disturbance $[U(s)]$ can be any time function in actual operation. The **step input** is widely used for analysis and testing since it is easily implemented; it results in a simple Laplace transform; it is the most severe type of disturbance; and the response to a step change shows the maximum error that could occur.

In many complex control systems, especially in the nonmechanical process-control field, auxiliary feedback paths are provided in order to adjust the system's performance. Figure 16.2.16*a* illustrates such a condition. In analyzing such a system it is usually best to combine secondary loops into the main control loop to form an equivalent series block and transfer function. The system of Fig. 16.2.16*a* might be reduced in the following sequence.

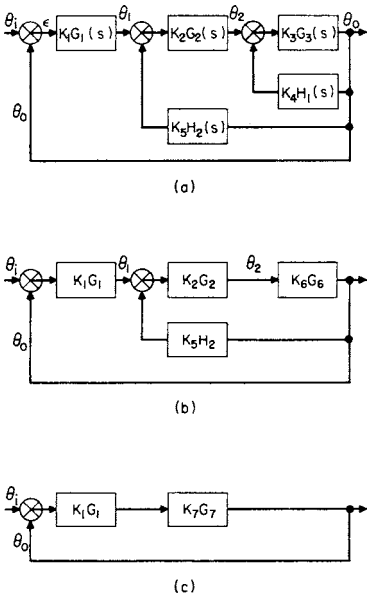

Fig. 16.2.16 Reduction of a closed-loop control system with multiple secondary loops.

1. Replace $K_3G_3(s)$ and $K_4H_1(s)$ with a single equivalent element

$$\frac{\theta_o}{\theta_2} = \frac{K_3G_3(s)}{1 + K_4H_1(s)K_3G_3(s)} = K_6G_6 \tag{16.2.41}$$

The result of this first reduction is shown in Fig. 16.2.16*b*:

2. Figure 16.2.16*b* can be treated in a similar fashion and a single block used to replace K_2G_2, K_6G_6, and K_5H_2

$$\frac{\theta_o}{\theta_1} = \frac{K_2G_2K_6G_6(s)}{1 + K_5H_2K_2G_2K_6G_6(s)} = K_7G_7 \tag{16.2.42}$$

The result of this second reduction is shown in Fig. 16.2.16*c*. The resulting open-loop transfer function is

$$\theta_o/\varepsilon = K_1G_1K_7G_7(s) \tag{16.2.43}$$

The closed-loop or frequency response function is

$$\frac{\theta_o}{\theta_i} = \frac{K_1G_1K_7G_7(s)}{1 + K_1G_1K_7G_7(s)} \tag{16.2.44}$$

Equation (16.2.44) can, of course, be expanded to include the terms of the system's secondary loops.

SIGNAL-FLOW REPRESENTATION

An alternate graphical representation of the mathematical relationships is the signal-flow graph. For complicated systems it allows a more compact representation and more rapid reduction techniques than the block diagram.

In Fig. 16.2.17, the nodes represent the variables θ_i, ε, θ_1, . . . , θ_o, and the branches the relationships between the nodes, of the system shown in Fig. 16.2.16. For example,

$$\theta_1(s) = \varepsilon K_1G_1(s) - K_5H_2(s)\theta_o(s) \tag{16.2.45a}$$

and

$$\varepsilon = \theta_i - \theta_o \tag{16.2.45b}$$

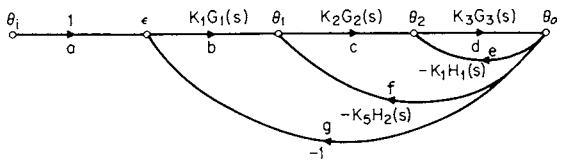

Fig. 16.2.17 Signal flow graph of the closed-loop control system shown in Fig. 16.2.16.

Signal-flow terminology follows:

Source: node having only outgoing branches, for example, θ_i
Sink: node having only incoming branches, θ_o
Path: series of branches with the same sense of direction, for example, *abcd, cdf*
Forward path: path originating at a source and ending at a sink, with no node encountered more than once, for example, *abcd*
Path gain: product of the coefficients along a path, for example, 1 $[K_1G_2(s)][K_2G_2(s)][K_3G_3(s)]$
Feedback loop: path starting at a node and ending at the same node, for example, *bcdg*
Loop gain: product of coefficients along a feedback loop, for example, $[K_1G_2(s)][K_2G_2(s)][K_3G_3(s)]$ (-1)

The overall gain of the system can be calculated from

$$G = \frac{\Sigma_i G_i\Delta_i}{\Delta} \tag{16.2.46}$$

where G_i = gain of ith forward path and

$$\Delta = 1 - \Sigma L_1 + \Sigma L_2 - \Sigma L_3 + \cdots + (-1)^k\Sigma L_k$$

where ΣL_1 = sum of the gains of each forward loop; ΣL_2 = sum of products of loop gains for nontouching loops (no node is common), taken two at a time; ΣL_3 = sum of products of loop gains for nontouching loops taken three at a time; Δ_i = value of Δ for signal flow graph resulting when ith path is removed.

From Fig. 16.2.17 there is only one forward path, *abcd.*

$$\therefore G_1 = K_1G_1(s)K_2G_2(s)K_3G_3(s)$$

Closed loops are *de, cdf,* and *bcdg,* with gains $-K_1H_1(s)K_3G_3(s)$, $-K_2G_2(s)K_3G_3(s)K_5H_2(s)$, and $-K_1G_1(s)K_2G_2(s)K_3G_3(s)$.

There are no nontouching closed loops;

$$\therefore \Delta = 1 + K_1H_1(s)K_3G_3(s) + K_2G_2(s)K_3G_3(s)K_5H_2(s) + K_1G_1(s)K_2G_2(s)K_3G_3(s)$$

There are no loops remaining if the forward path *abcd* is removed;

$$\therefore \Delta_1 = 1$$

Thus

$$\theta_o/\theta_1 = K_1G_1(s)K_2G_2(s)K_3G_3/[1 + K_1H_1(s)K_3G_3(s) + K_2G_2(s)K_3G_3(s)K_5H_2(s) + K_1G_1(s)K_2G_2(s)K_3G_3(s)] \tag{16.2.47}$$

which is identical with Eq. (16.2.44).

CONTROLLER MECHANISMS

The **controller** modifies the error signal in a desired manner to produce an output pressure which is used to actuate the valve motor. The several controller modes used singly or in combination are (1) the proportional mode in which $P_{out}(t) = K_cE(t)$, (2) the integral mode, in which $P_{out}(t) = 1/T_1 \int E(t)\,dt$, and (3) the rate mode, in which $P_{out}(t) = T_2\,dE(t)/dt$. In these expressions $P_{out}(t)$ = controller output pressure, $E(t)$ = input error signal, K_c = proportional gain, $1/T_1$ = reset rate, and T_2 = rate time.

A **pneumatic controller** consists of an **error-detecting mechanism, control modes** made up of proportional (P), integral (I), and derivative (D) actions in almost any combination, and a **pneumatic amplifier** to provide output capacity. The error-detecting mechanism is a differential link, one end of which is positioned by the signal proportional to the controlled variable, and the other end of which is positioned to correspond to the command set point. The proportional action is provided by a flapper nozzle (Fig. 16.2.18), where the flapper is positioned by the error signal. A motion of 0.0015 in by the flapper is sufficient for nearly full output range. Nozzle back pressure is inversely proportional to the distance between nozzle opening and flapper.

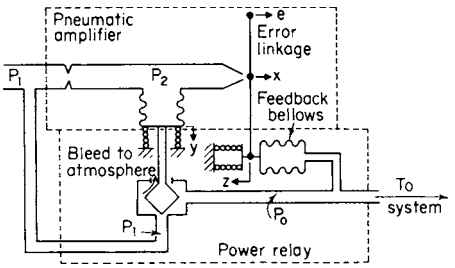

Fig. 16.2.18 Gain reduction of pneumatic amplifier by means of feedback bellows. *(Raven, "Automatic Control Engineering," McGraw-Hill.)*

The controller employs a power-amplifying pilot for providing a larger quantity of air than could be provided through the small restriction shown in Fig. 16.2.18. The nozzle back pressure, instead of operating the final control element directly, is transmitted to a bellows chamber where it positions the pilot valve.

The combination of flapper-nozzle amplifier and power relay shown in Fig. 16.2.18 has a very high gain since small flapper displacements can result in the output traversing the full range of output pressure. Negative feedback is employed to reduce the gain. Controller output is connected to a feedback bellows which operates to reposition the flapper. With the feedback bellows, a movement of the flapper toward the nozzle increases back pressure, causing output pressure to decrease and the feedback bellows to move the flapper away from the nozzle. Thus the mechanism is stabilized. Figure 16.2.19 shows controller gain being varied by adjusting the point at which the feedback bellows bears on the flapper.

The **rate mode**, called "anticipatory," can take large corrective action when errors are small but have a high rate of change. The mode resists not only departures from the set point but also returns and so provides a stabilizing action. Since the rate mode cannot control to a set point, it is not used alone. When used with the proportional mode, its stabilizing influence (90° phase lead; see Table 16.2.3) may allow an increase in gain K_c and a consequent decrease in steady-state error.

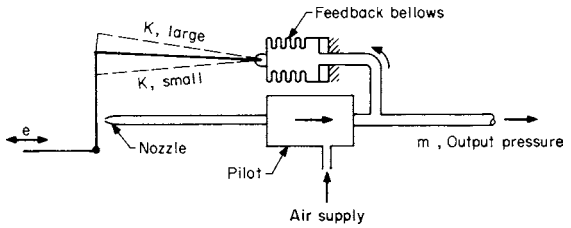

Fig. 16.2.19 Proportional controller with negative feedback. *(Reproduced by permission. Copyright © John Wiley & Sons, Inc. Publishers, 1958. From D. P. Eckman, "Automatic Process Control.")*

Proportional-derivative (PD) control is obtained by adding an adjustable feedback restriction as shown in Fig. 16.2.20. This results in delayed negative feedback. The restriction delays and reduces the feedback, and, since the feedback is negative, the output pressure is momentarily higher and leads, instead of lags, the error signal.

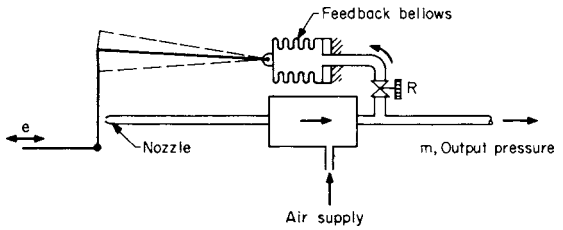

Fig. 16.2.20 Proportional-derivative controller. *(Reproduced by permission. Copyright © John Wiley & Sons, Inc. Publishers, 1958. From D. P. Eckman, "Automatic Process Control.")*

Since the proportional mode requires an error signal to change output pressure, set point and load changes in a proportionally controlled system are accompanied by a steady-state error inversely proportional to the gain. For systems which, because of stability considerations, cannot tolerate high gains, the integral mode added to the proportional will eliminate the steady-state error since the output from this mode is continually varying so long as an error exists. The addition of the integral mode to a proportional controller has an adverse effect on the relative stability of the control because of the 90° phase lag introduced.

Proportional-integral (PI) control is obtained by adding a positive feedback bellows and an adjustable restriction (Fig. 16.2.21). The addition of the positive feedback bellows cancels the gain reduction brought about by the negative feedback bellows at a rate determined by the adjustable restriction.

Electronic controllers which are analogous to the pneumatic controller have been developed. They have the advantages of elimination of time lags; compatability with computers; being less expensive to install (although more expensive to purchase); being more energy efficient; and being immune to low temperatures (water in pneumatic lines freezes).

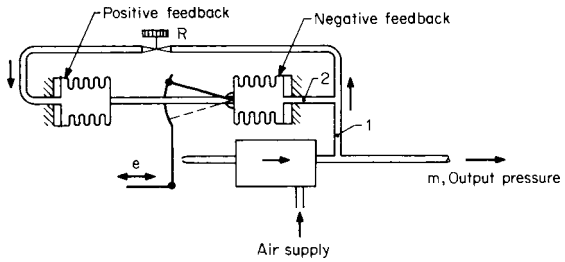

Fig. 16.2.21 Proportional-integral controller. *(Reproduced by permission. Copyright © John Wiley & Sons, Inc. Publishers, 1958. From D. P. Eckman, "Automatic Process Control.")*

The heart of the electronic controller is the **high-gain operational amplifier** with passive elements at the input and in the feedback. Figure 16.2.22 shows the classical control elements, though circuits in commercially available controllers are far more sophisticated. The current drawn by the dc amplifier is negligible, and the amplifier gain is around 1,000, so that the junction point is essentially at ground potential. The reset amplifier has delayed negative feedback, similar to the pneumatic circuit in Fig. 16.2.21. The derivative amplifier has advanced negative feedback, similar to Fig. 16.2.20. Gains are adjusted by changing the ratios of resistors or capacitors, while adjustable time constants are made up of a variable resistor and a capacitor *(RC)*.

Regardless of actuation, the commonly applied **controller modes** are as follows:

Designation	*Transform*	*Symbol*
Proportional	K (gain)	P
Reset	$1 + \frac{1}{\tau_i s}$	I
Derivative	$\frac{\tau_d s + 1}{(t_d/\alpha)s + 1}$	D
Floating	$\frac{1}{\tau_F s}$	F

The modes are combined as needed into P, PI, PID, PD, and F. Choice depends on the application and can be made from the Bode diagram. The block diagram for a PID controller is shown in Fig. 16.2.23.

The **derivative mode** can be placed on the measured variable signal (as shown), on the error, or on the controller output. The arrangement of Fig. 16.2.23 is preferred for regulation since the derivative does not affect set-point changes, and the derivative acts to reduce overshoot on start-up (Zoss, "Applied Instrumentation in the Process Industries," Vol. IV, Gulf Publishing Co.). Regardless of a sequence, the block diagram of a PID controller is commonly drawn as shown in Fig. 16.2.24.

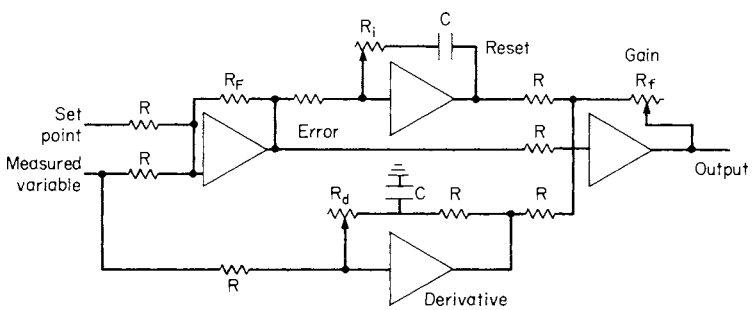

Fig. 16.2.22 Simplified circuit for a typical electronic controller.

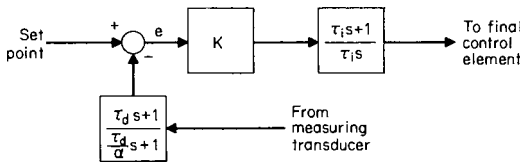

Fig. 16.2.23 Block diagram of PID controller.

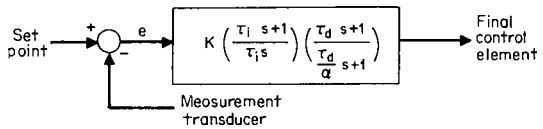

Fig. 16.2.24 Combined controller block diagram.

FINAL CONTROL ELEMENTS

The **final control element** is a mechanism which alters the value of the **manipulated variable** in response to an output signal from the automatic-control device. It will typically receive a signal from the controller and manipulate a flow of material or energy to the process. The final control element can be a control valve, an electrical motor, a servovalve, or a damper. Servovalves are discussed in the next section, "Hydraulic-Control Systems."

The final control element often consists of two parts: first, an **actuator** which translates the controller signal into a command for the manipulating device, and, second, a **mechanism** to adjust the manipulated variable. Figure 16.2.25 shows a control valve made up of an actuator and an adjustable orifice.

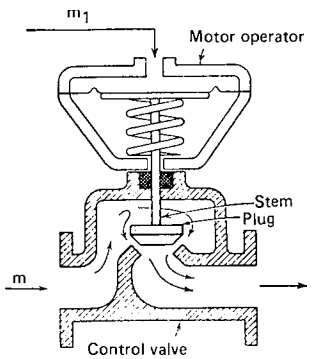

Fig. 16.2.25 Control valve and pneumatic actuator. *(Reproduced by permission. Copyright © John Wiley & Sons, Inc. Publishers, 1958. From D. P. Eckman, "Automatic Process Control.")*

The most commonly used **actuator** is a diaphragm motor in which the output pressure from the controller is counteracted not only by the spring but also by fluid forces in the valve body. The latter may cause serious deviation from linear static behavior with deleterious control effects. High friction at the valve stem or large unbalanced fluid forces at the plug can be overcome by valve positioners, which are essentially proportional controllers.

A **control valve** in liquid service is described by Eq. (16.2.48):

$$q = C_v \sqrt{\frac{\Delta p}{G}} \tag{16.2.48}$$

And C_v is described by its relationship to stem lift x, which is called the **valve-flow characteristic.**

The linear characteristic is

$$C_v = C_v|_{\max} x \tag{16.2.49}$$

and the equal-percentage characteristic is

$$C_v = C_v|_{\max} (r)^{x-1} \tag{16.2.50}$$

where q = flow, gpm (m^3/min); $C_v|_{\max}$ = valve sizing coefficient; Δp = pressure drop across valve, lb/in^2 (kPa); G = specific gravity (density, g/ml); r = valve rangeability; and x = stem position, normalized to 0 to 1.

The flow characteristic relationship is not necessarily the lift-flow characteristic of the valve when installed since the valve is but one component in a piping system in which pressure drops vary with the flow rate. The change in characteristic as less percentage of total system drop is taken across the control valve is shown in Fig. 16.2.26.

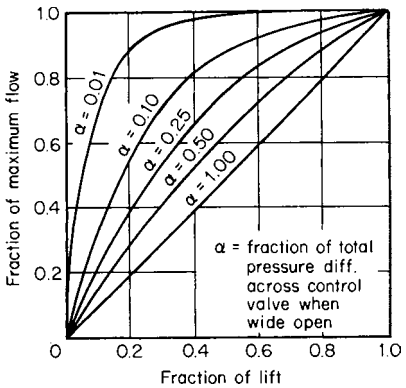

Fig. 16.2.26 Control valve linear flow characteristic. *(Reproduced by permission. Copyright © John Wiley & Sons, Inc. Publishers, 1958. From D. P. Eckman, "Automatic Process Control.")*

Valve characteristics are generally selected according to their ability to compensate for nonlinearities in the system. Nonlinearities typically represent a change in gain which in turn changes the character of the control response for a given controller setting when load- or set-point changes occur or when there is a variable overall pressure drop across the system. Equal-percentage valves, for example, tend to control over widely varying operating conditions, since the change in flow is always proportional to flow rate. The selection of the proper valve therefore depends on study of the particular system.

HYDRAULIC-CONTROL SYSTEMS

Hydraulic systems are used for rapid-response servomechanisms at high power levels. Operating system pressures are from 50 to 100 lb/in^2 for slower-acting systems and up to 5,000 lb/in^2 where lightweight and fast responses are required. Compared with **electrical systems** the major advantages are a rapid response in the large horsepower ranges and the capability of operating at high power-density levels since the fluid can transmit dissipated energy from the point of generation. Compared with **pneumatic systems,** hydraulic systems are faster because the fluid is essentially incompressible. Major disadvantages are vulnerability to dirt, since the components generally require close machining tolerances, and the danger of fire and explosion resulting from the flammability of the hydraulic fluids used.

The direction and volume of flow are controlled by **servo valves** in the system. They may be single-stage (pilot-operated) and mechanically or electrically actuated. A schematic of a spool-type four-way single-stage control piston and inertia load is shown in Fig. 16.2.27. Hydraulic fluid at constant pressure enters at the supply port. With displacement of the spool valve downward, for example, inflow to the top side of the piston moves the piston downward. Because of machining tolerances the spool dimensions are either large (overlapped) or smaller (underlapped) than the port dimension. Underlapped valves permit leakage to the piston in the centered position; overlapped valves result in a dead zone, where motion x results in no flow until a port is opened.

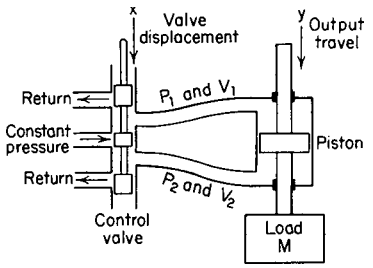

Fig. 16.2.27 Four-way valve-piston circuit. *(Truxal, "Control Engineer's Handbook," McGraw-Hill.)*

The transfer function of this circuit is given as (Truxal, "Control Engineers' Handbook")

$$\frac{y}{x} = \frac{C_1 \dfrac{1}{1 + \alpha(C_1/C_2)}}{s\left[\dfrac{VM}{2BA^2}\dfrac{1}{1 + \alpha(C_1/C_2)}s^2 + \dfrac{C_1 m/C_2 + V\alpha/2BA^2}{1 + \alpha(C_1/C_2)}s + 1\right]}$$

where C_1 = servo velocity gradient, in/(s)(in), C_2 = servo force gradient, lb/in, α = viscous friction of load and piston, lb/(in)(s), B = bulk modulus of fluid, lb/in^2 M = mass of load and piston, lb/(in)(s^2), A = piston area, in^2, and V = effective entrained fluid volume, in^3 (one-half of total entrained volume between valve and piston).

The velocity of the output is proportional to the input resulting in a **velocity-control** servo. To convert this system to a **position-control** servo, mechanical, hydraulic, or electrical feedback may be employed. A valve-piston position servo with **mechanical feedback** is shown in Fig. 16.2.28. Any difference between the input D and the piston position y causes a motion x, which causes the piston to move in a direction opposite to D, that is, in a direction to reduce x. The lever ratio establishes the relationship between y and D.

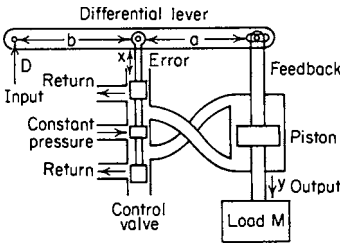

Fig. 16.2.28 Valve-piston position servomechanical feedback. *(Truxal, "Control Engineer's Handbook," McGraw-Hill.)*

Most commercially available servo valves are two stages, permitting electrohydraulic action. The pilot stage can be operated by a low-power, short-travel electrical device, with a concomitant increase in flexibility. A typical pilot-operated servo valve is shown in Fig. 16.2.29. In this case the pilot is a double-flapper valve rather than a spool valve. (In general, small, accurate low-leakage spool valves are costly.) Upward movement of the flapper by the actuating motor results in increased pressure to the right end of the power spool. Hydraulic feedback occurs because of the increased flow across restrictor *a*. The power spool moves to the left until the unbalanced pressure is matched by the spring resistance. The disadvantage of this valve is the continual leakage flow through the flapper nozzle, but the torque motor has a low-power requirement and is inexpensive.

The major disadvantages of spool-type valves are (1) high cost, because of high-tolerance requirements between the valve lands, (2) high static friction and inertia, and (3) susceptibility to dirt. The **flapper** valve is less expensive to manufacture than a spool valve of equivalent characteristics and is not so susceptible to damage by dirt particles.

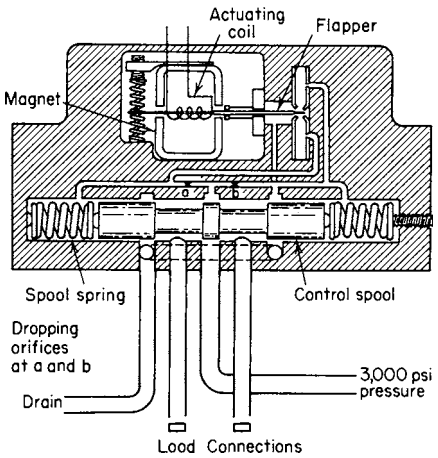

Fig. 16.2.29 Two-stage electrohydraulic servo valve. The first-stage is a four-way flapper valve with a calibrated pressure output driving a second-stage, spring-loaded, four-way spool valve. *(Moog Servocontrols, Inc.)*

In Fig. 16.2.30, P_1, the supply pressure, is constant. Input motion of the flapper toward the nozzle increases P_2 and drives the piston toward the right. The steady-state characteristic P_2 vs. x is shown in Fig. 16.2.31.

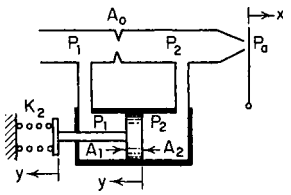

Fig. 16.2.30 Flapper valve. *(Raven.)*

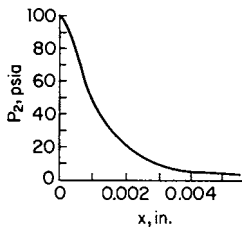

Fig. 16.2.31 Equilibrium curve of P_2 versus x for a flapper valve. *(Raven, "Automatic Control Engineering," McGraw-Hill.)*

STEADY-STATE PERFORMANCE

The steady-state error of a control system can be determined by using the final value theorem (see Laplace Transforms, Sec. 2) in which

$$\theta_o(t) \underset{t\to\infty}{=} s\theta_o(s) \underset{s\to 0}{\quad} \text{provided } \theta_o(t) \text{ is stable}$$

The classification of control systems according to the form of the open-loop transfer function facilitates the determination of the steady-state errors when the system is subjected to various inputs.

The open-loop transfer function $\theta_o(s)/\varepsilon(s) = KG(s)$ may be written

$$KG(s) = \frac{\theta_o(s)}{\varepsilon(s)} = \frac{K(1 + \tau_a s)(1 + \tau_a s)(1 + \tau_o s)\cdots}{s^N(1 + \tau_1 s)(1 + \tau_2 s)(1 + \tau_3 s)\cdots} \qquad (16.2.51a)$$

The **system type** is given according to the value of N as

$$\begin{aligned} &\text{Type 0 system} \quad N = 0 \\ &\text{Type 1 system} \quad N = 1 \\ &\text{Type 2 system} \quad N = 2 \\ &\text{Type 3 system} \quad N = 3 \end{aligned} \tag{16.2.51b}$$

Error coefficients, based on a system with unity feedback [$H(s) = 1$], are defined as

$$\text{Positional error constant} = K_o = \lim_{s\to 0} KG(s) \tag{16.2.52a}$$

$$\text{Velocity error constant} = K_v = \lim_{s\to 0} sKG(s) \tag{16.2.52b}$$

$$\text{Acceleration error constant} = K_a = \lim_{s\to 0} s^2KG(s) \tag{16.2.52c}$$

A summary of error coefficients for systems of different types is given in Table 16.2.1.

Table 16.2.1 Summary of Error Coefficients

N	K_o	K_v	K_a
0	const	0	0
1	∞	const	0
2	∞	∞	const

A summary of the errors for types 0, 1, and 2 systems, when subjected to various inputs is given in Table 16.2.2.

Table 16.2.2 Summary of Errors

Input error	$\theta_i(t) = A$ ε_0/A	$\theta_i(t) = vt$ ε_v/v	$\theta_i(t) = at^2$ ε_a/a
$N = 0$	$1/(1 + K_0)$	∞	∞
1	0	$1/K_v$	∞
2	0	0	$1/K_a$

The higher the system type, the better is the output able to follow the higher degrees of input. Higher-type systems, however, are more difficult to stabilize, and a compromise must be made between the steady-state error and the settling time of the response.

CLOSED-LOOP BLOCK DIAGRAM

The **transfer functions** of the process, controller, and final control element can be combined with the measuring transducer into a **block diagram** of the complete control loop. Consider the thermal system of Fig. 16.2.5 and the heat balance on the vessel jacket:

$$M_j c \frac{dT_w}{dt} = w_w c(T_{w1} - T_w) \tag{16.2.53}$$

Linearizing and rearranging:

$$\frac{M_j}{w_w} T_w s + T_w = \left[\frac{T_{w1} - T_w}{w_w}\right]\left[\frac{w_w}{x}\right] x \tag{16.2.54}$$

where M_j = weight of cooling water in jacket, lb (kg); c = specific heat of water, Btu/lb · °F (J/kg · °C); T = temperature, °F; x = valve stem position (normalized 0 to 1); and w_w = water flow, lb/min (kg/min).

For simplicity, let the jacket time constant M_j/w_w be so small as to be negligible (not typically the case). The block diagram of Fig. 16.2.32 then represents process diagram Fig. 16.2.5. The **gain** K in each case is an incremental change in output divided by an incremental change in input. For example, if the temperature transmitter has a temperature span of 100°F and an output of 4 to 20 mA, the gain would be

$$K_\tau = \frac{20 - 4}{100} = \frac{16}{100} = 0.16 \text{ mA/°F}$$

The **open-loop gain** is defined as the product of all the gains in the control loop:

$$K_o = K_c K_v K_T \left(\frac{T_{w1} - T_w}{x}\right)\left(\frac{UA}{wc + UA}\right)$$

Combining the **closed-loop system** of Fig. 16.2.32 results in the closed-loop equation

$$T = \frac{\left(\dfrac{wc}{wc + UA}\right)\left(\dfrac{1}{\tau s + 1}\right) T_0}{1 + \dfrac{K_o(\tau_i s + 1)(\tau_d s + 1)}{\tau_i s(\tau s + 1)\left(\dfrac{\tau_d}{\alpha} s + 1\right)\left(\tau_T s + 1\right)}} \tag{16.2.55}$$

The time-dependent modes on the controller have been designed to compensate for the dynamics of the rest of the loop. Let

$$\tau_i = \tau \quad \text{and} \quad \tau_d = \tau_T$$

After cancellation, Eq. (16.2.55) becomes

$$T = \frac{\left(\dfrac{wc}{wc + UA}\right) T_0}{(\tau s + 1)\left[1 + \dfrac{K_c}{\tau_i s\left(\dfrac{\tau_d}{\alpha} s + 1\right)}\right]} \tag{16.2.56}$$

Equation (16.2.56) can be multiplied out to become

$$T = \frac{\left(\dfrac{wc}{wc + UA}\right)(\tau_i s)\left(\dfrac{\tau_d}{\alpha} s + 1\right) T_0}{(\tau s + 1)\left(\dfrac{\tau_i \tau_d}{\alpha} s^2 + \tau_i s + K_c\right)} \tag{16.2.57}$$

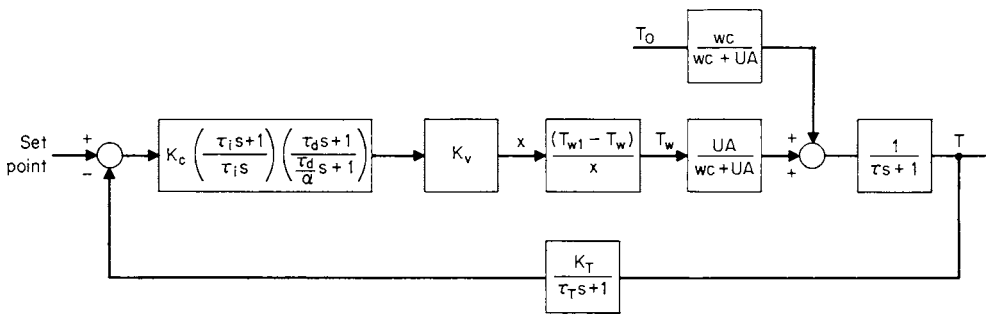

Fig. 16.2.32 Block diagram of a thermal system.

Table 16.2.3 Process Characteristics versus Mode of Control

Number of process capacities	Process reaction rate	Process time lags		Load changes		Suitable mode of control
		Resistance-capacitance *(RC)*	Dead time (transportation)	Size	Speed	
Single	Slow	Moderate to large	Small	Any Moderate	Any Slow	Two-position. Two-position with differential gap Multiposition. Proportional input
Single (self-regulating)	Fast	Small	Small	Any	Slow Moderate	Floating modes: Single-speed Multispeed Proportional-speed floating
Multiple	Slow to moderate	Moderate	Small	Small	Moderate	Proportional position
Multiple	Moderate	Any	Small	Small	Any	Proportional plus rate
Multiple	Any	Any	Small to moderate	Large	Slow to moderate	Proportional plus reset
Multiple	Any	Any	Small	Large	Fast	Proportional plus reset plus rate
Any	Faster than that of the control system	Small or nearly zero	Small to moderate	Any	Any	Wideband proportional plus fast reset

SOURCE: Considine, "Process Instruments and Controls Handbook," McGraw-Hill.

Equation (16.2.57) can be written in the standard form of Eqs. (16.2.16) and (16.2.21):

$$T = \frac{\left(\frac{wc}{wc + UA}\right)(\tau_i s)\left(\frac{\tau_d}{\alpha}s + 1\right)T_0}{K_c(\tau s + 1)(\tau_c^2 s^2 + 2\tau_c\zeta s + 1)} \qquad (16.2.58)$$

Controller gain K_c can then be chosen to give the best response τ_c with stability ζ. More rigorous techniques for determining controller parameter values are shown under Bode diagrams and Routh's criterion. Table 16.2.3 provides preliminary guidance for the selection of control modes.

FREQUENCY RESPONSE

Although it is the time response of the control system that is of major importance, study of the effect on transient response of changes in system parameters, either in the process or controller, is more conveniently made from a **frequency-response** analysis of the system. The **frequency response** of a system is the steady-state output of the system to input sinusoids of varying frequency. The output for a linear system can be completely described in terms of the amplitude ratio of the output sinusoid to the input sinusoid. The amplitude ratio or gain, and phase, are functions of the frequency of the input sinusoid.

The use of **sinusoidal methods** to analyze and test dynamic systems has gained widespread popularity because system response is obtained easily from the response of the individual elements, no matter how many elements are included. By contrast, transient analysis is quite tedious, with only three dynamic components in the system, and is too difficult to be worthwhile for four or more components.

Frequency-response analysis provides quantitative information concerning the system on maximum gain K_o for stability, time response τ_c, ω_n, and the controller parameter adjustments τ_i, τ_d. In most cases, this information is adequate for assurance of stability, for comparing alternatives, or for judging the merits of a proposed control system. System parameters are generally obtained from open-loop frequency response, which is the response with the loop broken between the controller and the final control element (Fig. 16.2.32).

Frequency response also lends itself to system identification by testing for systems not readily amenable to mathematical analysis by subjecting the system to input sinusoids of varying frequency.

The shift from the **complex domain** to the **frequency domain** (linear systems, zero initial conditions) is accomplished by simply substituting $j\omega$ for s. Consider Eq. (16.2.38).

$$(\tau s + 1)T = K_1 T_0 \qquad (16.2.59)$$

Substituting

$$\frac{T}{T_0} = \frac{K_1}{\tau j\omega + 1}$$

Multiply by the complex conjugate

$$\frac{T}{T_0} = \frac{K_1}{\tau j\omega + 1}\frac{\tau j\omega - 1}{\tau j\omega - 1}$$

Collecting terms

$$\frac{T}{T_0} = K_1\left[\frac{1}{\tau^2\omega^2 + 1} - j\frac{\tau\omega}{\tau^2\omega^2 + 1}\right] \qquad (16.2.60)$$

The first term is the real part of the solution, and the second term, the imaginary part. These terms define a vector, shown in Fig. 16.2.33,

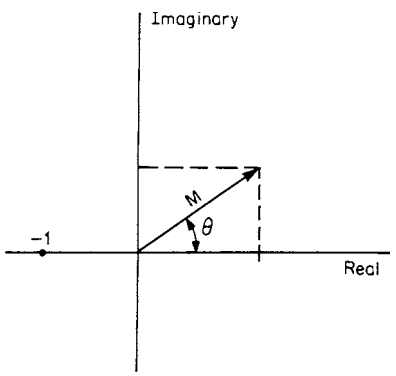

Fig. 16.2.33 Polar plot showing vector.

which has magnitude M and phase angle θ as determined either graphically or by the Pythagorean theorem.

$$M = \left[\frac{1}{\tau^2\omega^2 + 1}\right]^{1/2} \tag{16.2.61}$$

$$\theta = \tan^{-1}\left(\frac{-\zeta\omega}{1}\right) \tag{16.2.62}$$

GRAPHICAL DISPLAY OF FREQUENCY RESPONSE

Sinusoidal response is **plotted** in three different ways: (1) the rectangular plot with the log of the amplitude versus the log of the frequency, called a **Bode plot;** (2) a phase-margin plot with magnitude shown versus a function of phase with frequency as a parameter, called a **Nichols plot;** and (3) a polar plot with magnitude and phase shown in vector form with frequency as a parameter, called a **Nyquist plot.** The Nichols plot is actually a plot of phase margin ($180° - \theta$) versus frequency and is used to define system performance. The polar plot enables the absolute stability of the system to be determined without the need for obtaining the roots of the characteristic equation. The logarithmic (Bode) plot has the advantage of ease in plotting, especially in design, since the individual effects of cascaded elements can be gaged by superposition. All the graphical procedures use the "minus 1" point [discussed with Eq. (16.2.38)] as the criterion for stability (magnitude = 1, phase = $-180°$).

NYQUIST PLOT

The **Nyquist diagram** is a graphical method of determining stability. The diagram is essentially a mapping into the $G(s)$ plane of a contour enclosing the major portion of the right half of the s plane. Figure 16.2.34 shows the Nyquist plot of a typical system.

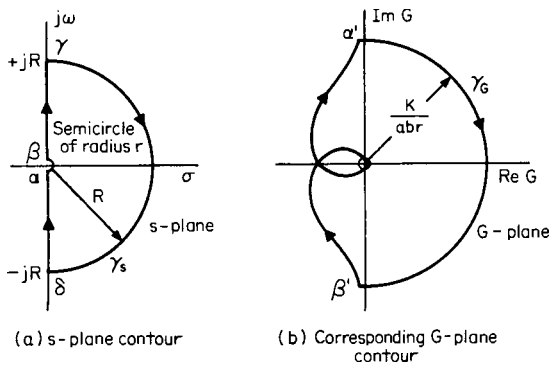

Fig. 16.2.34 Nyquist diagram for $G(s) = 1/[s(s + a)(s + b)]$. *(Truxal, "Control System Synthesis," McGraw-Hill.)*

The frequency response of a closed-loop system can also be derived from the **polar plot** of the direct transfer function $KG(s)$. Systems with dynamic elements in the feedback can be transformed into direct systems by block-diagram manipulation. In Fig. 16.2.35, the amplitude ratio θ_o/θ_i at any frequency ω is the ratio of the lengths of the vectors $O\beta$ and $\alpha\beta$. The angle formed by the vectors $\alpha\beta$ and $O\beta$ is the phase angle of the frequency response $\angle\theta_o/\theta_i(j\omega)$. The numerator of the transfer function is a constant representing the closed-loop gain. Changing the gain proportionately changes the length of the vector $O\beta$. Figure 16.2.36 shows another typical Nyquist plot.

The Nyquist diagram is widely used in the design of electrical systems, but plots are very tedious to make and are generated via computer programs.

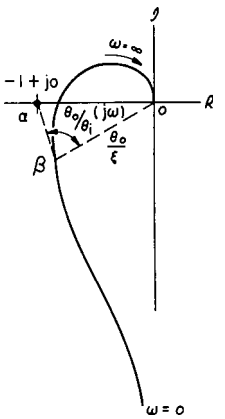

Fig. 16.2.35 Typical $(\theta_o/\varepsilon)/(j\omega)$ plot.

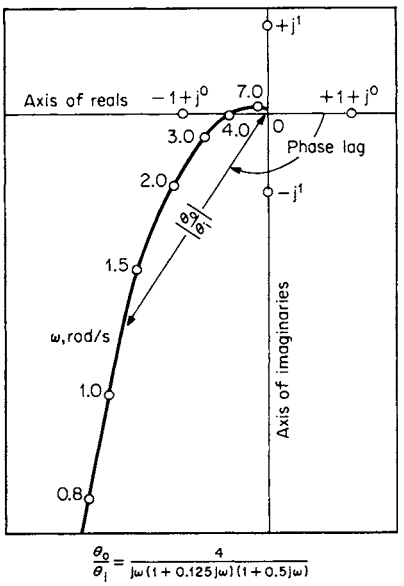

Fig. 16.2.36 Typical Nyquist diagram showing loop transfer function $|\theta_o/\theta_i|$. *(ASME, "Terminology for Automatic Control," Pub. ASA C85.1-1963.)*

BODE DIAGRAM

The most common method of presenting the **response data at various frequencies** is to use the log-log plot for amplitude ratios, accompanied by a semilog plot for phase angles. These rectangular plots are called **Bode diagrams,** after H. W. Bode, who did basic work on the theory of feedback amplifiers. A major advantage of this method is that the numerical computation of points on the curve is simplified by the fact that log magnitude versus log frequency can be approximated to engineering accuracy with straight-line approximations. In the **sinusoidal testing** of a system, the system dynamics will be faster than a very low frequency test signal, and the output amplitude has time to recover fully to the input amplitude. Thus the magnitude ratio is 1. Conversely, at high frequency, the system does not have time to reach equilibrium, and output amplitude will decrease. Magnitude ratio goes to a very small value under this condition. Thus the system will show a decrease in magnitude ratio as frequency increases. By similar reasoning, the difference

between input and output phase angles becomes progressively more negative as frequency increases.

Consider the equations for magnitude, Eq. (16.2.61), and phase, Eq. (16.2.62). If $\tau_w \ll 1$,

$$M = \left(\frac{1}{1}\right)^{1/2} = 1 \qquad \theta = \tan^{-1}(0) = 0$$

and if $\tau_w \gg 1$,

$$M = \left(\frac{1}{\tau^2\omega^2}\right)^{1/2} = \frac{1}{\tau\omega} \approx 0 \qquad \theta = \tan^{-1}\left(\frac{-\tau_w}{1}\right) \approx -90°$$

The two **straight-line asymptotes** of magnitude, if extended, would intersect at $\tau\omega = 1$. Thus a relationship between frequency and time constant is established. The point at which $\tau\omega = 1$ is called the *corner frequency,* or the *break frequency.* The asymptote past the break frequency is easily plotted from a point at the break frequency $\omega = 1/\tau$ and a point at 10 times the frequency and 0.1 times the magnitude ratio.

The frequency response of systems containing different dynamic elements may be calculated by suitably employing the magnitude and phase characteristics of each element separately. Combined magnitudes are calculated

$$|M_1M_2| = |M_1| \times |M_2|$$

Or, on the log-log Bode diagram,

$$\log |M_1M_2| = \log |M_1| + \log |M_2|$$

The logarithmic scale permits **multiplication** by adding vertical distances. For phase

$$\angle\theta_1\theta_2 = \angle\theta_1 + \angle\theta_2$$

Thus **phase addition** is also made by adding vertical distances. Figure 16.2.37 shows the combination of the straight-line asymptotes for the following transfer function:

$$G(s) = \frac{1}{\tau s(\tau s + 1)} \tag{16.2.63}$$

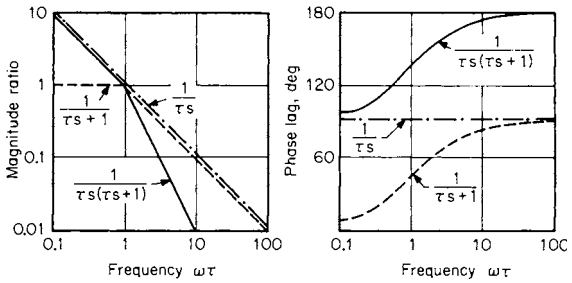

Fig. 16.2.37 Combined transfer functions. *(Reproduced by permission. Copyright © John Wiley & Sons, Inc. Publishers, 1958. From D. P. Eckman, "Automatic Process Control.")*

Table 16.2.4 lists additional frequency-response relationships for system elements. The noninteracting controller, item 8, has the advantage of no interaction among tuning parameters but has the disadvantages of being more difficult to plot on the Bode diagram and of not offering the direct compensation of the controller shown in Fig. 16.2.24.

Figure 16.2.38 shows a typical combined Bode diagram. The ordinate has a scale in decibels in addition to the magnitude ratio scale. Decibels (dB) are sometimes used to provide a linear scale. They are defined

$$\text{dB} = -20 \log M$$

The discontinuity at the break frequency due to the meeting of the straight-line asymptotes will not be found in actual test data. Instead, the corner will be rounded, as shown dotted in Fig. 16.2.39. The error due to the approximation is some 3 dB at the break frequency, as shown in the figure.

Quadratic terms (Table 16.2.4) also lend themselves to asymptotic approximation, but the form of the magnitude and phase plots around the break frequency depends on the damping coefficient ζ. The slope of the magnitude ratio attenuation past the break point is twice that of the first-order system.

Table 16.2.4 Frequency-Response Equations for Some Common Control-System Elements

Description	Transfer function $G(s)$	Frequency response $G(j\omega)$	Magnitude ratio	Phase angle
1. Dead time	$\varepsilon^{-T_L s}$	$\varepsilon^{-j\omega T_L}$	1	$-\omega T_L$ radians
2. First-order lag	$\dfrac{1}{Ts+1}$	$\dfrac{1}{j\omega T+1}$	$\dfrac{1}{\sqrt{\omega^2T^2+1}}$	$-\tan^{-1}(\omega T)$
3. Second-order lag	$\dfrac{1}{(Ts+1)(aTs+1)}$	$\dfrac{1}{-a\omega^2T^2+j(1+a)\omega T+1}$	$\dfrac{1}{\sqrt{(1-a\omega^2T^2)^2+(1+a)^2\omega^2T^2}}$	$-\tan^{-1}\left[\dfrac{(1+a)\,\omega T}{1-aT^2\omega^2}\right]$
4. Quadratic (underdamped)	$\dfrac{1}{\left(\dfrac{s}{\omega_n}\right)^2+\dfrac{2\zeta}{\omega_n}s+1}$	$\dfrac{1}{-\left(\dfrac{\omega}{\omega_n}\right)^2+j2\zeta\dfrac{\omega}{\omega_n}+1}$	$\dfrac{1}{\sqrt{\left(1-\dfrac{\omega^2}{\omega_n^2}\right)^2+4\zeta^2\left(\dfrac{\omega}{\omega_n}\right)^2}}$	$-\tan^{-1}\left[\dfrac{2\zeta\dfrac{\omega}{\omega_n}}{1-\left(\dfrac{\omega}{\omega_n}\right)^2}\right]$
5. Ideal proportional controller	K	K	K	0
6. Ideal proportional-plus-reset controller $T_i=\dfrac{1}{r}$ r = reset rate	$K\left(1+\dfrac{1}{T_i s}\right)$ or $K\dfrac{T_i s+1}{T_i s}$	$K\left(1+\dfrac{1}{j\omega T_i}\right)$ or $K\dfrac{j\omega T_i+1}{j\omega T_i}$	$K\sqrt{1+\left(\dfrac{1}{\omega T_i}\right)^2}$	$-\tan^{-1}\left(\dfrac{1}{\omega T_i}\right)$
7. Ideal proportional-plus-rate controller	$K(1+T_d s)$	$K(1+j\omega T_d)$	$K\sqrt{1+\omega^2T_d^2}$	$\tan^{-1}(\omega T_d)$
8. Ideal proportional-plus-reset-plus-rate controller	$K\left(1+T_d s+\dfrac{1}{T_i s}\right)$	$K\left(1+j\omega T_d+\dfrac{1}{j\omega T_i}\right)$ or $K\dfrac{j\omega T_i-\omega^2T_dT_i+1}{j\omega T_i}$	$K\sqrt{(\omega T_i)^2+(1-\omega^2T_dT_i)^2}$	$\tan^{-1}\left(\omega T_d-\dfrac{1}{\omega T_i}\right)$

CONTROLLERS ON THE BODE PLOT

Controller modes, gain, reset, and derivative are plotted individually (in the form of Fig. 16.2.24) on the Bode diagram and summed as required. The functions for reset (integral) and derivative modes are moved horizontally on the diagram to determine proper parameter adjustment. The combined magnitude ratio curve for the whole system is moved vertically to determine open-loop gain.

After all the dynamic elements of the system are plotted and combined, reset and derivative are set in accordance with the following **criteria:**

Reset: The reset phase curve is positioned horizontally so that it contributes 10° of phase lag where the system phase lag is 170°.

Derivative: The derivative phase curve is positioned horizontally so that it contributes 60° of phase lead where the system phase lag is 180°.

The magnitude ratio curves are positioned with the phase-angle curves, and parameter values for reset and derivative can be read at the break points.

STABILITY AND PERFORMANCE OF AN AUTOMATIC CONTROL

An automatic-control system is stable if the amplitude of transient oscillations decreases with time and the system reaches a steady state. The stability of a system can be evaluated by examining the roots of the differential equation describing the system. The presence of positive real roots or complex roots with positive real parts dictates an unstable system. Any stability test utilizing the open-loop transfer function or its plot must utilize this fact as the basis of the test.

The Nyquist Stability Criterion The $KG(j\omega)$ locus for a typical single-loop automatic-control system plotted for all positive and negative frequencies is shown in Fig. 16.2.40. The locus for negative values of ω is the mirror image of the positive ω locus in the real axis. To complete the diagram, a semicircle (or full circle if the locus approaches $-\infty$ on the real axis) of infinite radius is assumed to connect in a positive sense, the + locus at $\omega \to 0$ with the negative locus at $\omega \to -0$. If this locus is traced in a positive sense from $\omega \to \infty$ to $\omega \to 0$, around the circle at ∞, and then along the negative-frequency locus the following may be concluded: (1) if the locus **does not** enclose the $-1 + j0$ point, the system is stable; (2) if the locus **does** enclose the $-1 + j0$ point, the system is unstable. The Nyquist criterion can also be applied to the log magnitude of $KG(j\omega)$ and phase-vs.-log ω diagrams. In this method of display, the criterion for stability reduces to the requirement that the log magnitude of $KG(j\omega)$ must cross the 0-dB axis at a frequency less than the frequency at which the phase curve crosses the $-180°$ line. Two stability conditions are illustrated in Fig. 16.2.41. The Nyquist criterion not only provides a simple test for the stability of an automatic-control system but also indicates the degree of stability of the system by indicating the degree to which $KG(j\omega)$ locus avoids the $-1 + j0$ point.

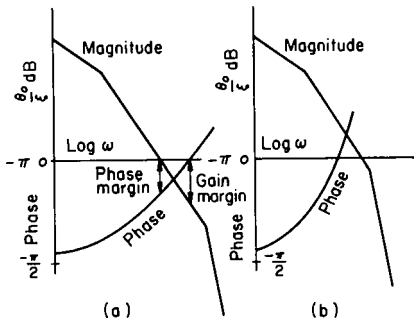

Fig. 16.2.41 Nyquist stability criterion in terms of log magnitude $KG(j\omega)$ diagrams. (*a*) Stable; (*b*) unstable. *(Porter, "An Introduction to Servomechanism," Wiley.)*

The concepts of **phase margin** and **gain margin** are employed to give this quantitative indication of the degree of stability of an automatic-control system. **Phase margin** is defined as the additional negative phase shift necessary to make the phase angle of the transfer function $-180°$ at the frequency where the magnitude of the $KG(j\omega)$ vector is unity. Physically, phase margin can be interpreted as the amount by which the unity KG vector has to be shifted to make a stable system unstable.

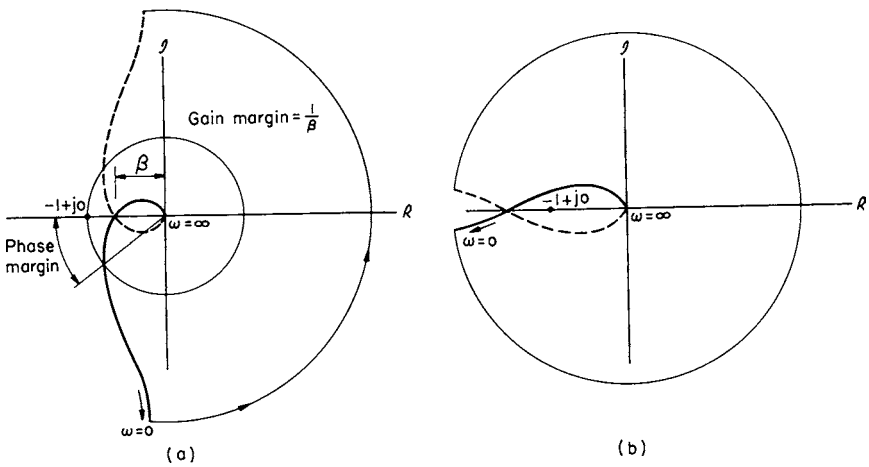

Fig. 16.2.40 Typical $KG(j\omega)$ loci illustrating application of Nyquist's stability criterion. (*a*) Stable; (*b*) unstable.

In a similar manner, **gain margin** is defined as the reciprocal of the magnitude of the KG vector at $-180°$. Physically, gain margin is the number by which the gain must be multiplied to put the system to the limit of stability. Thaler suggests satisfactory results can be obtained in most control applications if the phase margin is between 40 and 60° while the gain margin is between 3 and 10 (10 to 20 dB). These values will ensure a small transient overshoot with a single cycle in the transient. The margin concepts are qualitatively illustrated in Figs. 16.2.40 and 16.2.41.

Routh's Stability Criterion The frequency-response equation of a closed-loop automatic control is

$$\frac{\theta_o}{\theta_i} = \frac{KG(j\omega)}{1 + KG(j\omega)} \tag{16.2.64}$$

The characteristic equation obtained therefrom has the algebraic form

$$A(j\omega)^n + B(j\omega)^{n-1} + C(j\omega)^{n-2} + \cdots = 0 \tag{16.2.65}$$

The purpose of Routh's method is to determine the existence of roots of this equation which are positive or which are complex with positive real parts and thus identify the resulting instability. To apply the criterion the coefficients are written alternately in two rows as

$$\begin{array}{cccc} A & C & E & G \\ B & D & F & H \end{array}$$

This array is then expanded to

$$\begin{array}{ccccc} A & C & E & G & \\ B & D & F & H & \\ \alpha_1 & \alpha_2 & \alpha_3 & & \\ \beta_1 & \beta_2 & \beta_3 & & \\ \gamma_1 & \gamma_2 & & & \end{array}$$

where α_1, α_2, α_3, β_1, β_2, β_3, γ_1 and γ_2 are computed as

$$\alpha_1 = \frac{BC - AD}{B} \qquad \beta_1 = \frac{D\alpha_1 - B\alpha_2}{\alpha_1}$$

$$\alpha_2 = \frac{BE - AF}{B} \qquad \beta_2 = \frac{F\alpha_1 - B\alpha_3}{\alpha_1} \qquad \gamma_1 = \frac{\beta_1\alpha_2 - \alpha_1\beta_2}{\beta_1}$$

$$\alpha_3 = \frac{BG - AH}{B} \qquad \beta_3 = \frac{H\alpha_1 - B_o}{\alpha_1} \qquad \gamma_2 = \frac{\beta_1\alpha_3 - \alpha_1\beta_3}{\beta_1}$$

When the array has been computed, the left-hand column $(A, B, \alpha_1, \beta_1, \gamma_1)$ is examined. If the signs of all the numbers in the left-hand column are the same, there are no positive real roots. If there are changes in sign, the number of positive real roots is equal to the number of changes in sign. It should be recognized that this is a test for instability; the absence of sign changes does not guarantee stability.

SAMPLED-DATA CONTROL SYSTEMS

Definition Sampled-data control systems are those in which continuous information is transformed at one or more points of the control system into a series of pulses. This transformation may be performed intentionally, e.g., the flow of information over long distances to preserve the accuracy of the data during the transmission, or it may be inherent in the generation of the information flow, e.g., radiating energy from a radar antenna which is in the form of a train of pulses, or the signals developed by a digital computer during a direct digital control of machine-tool operation.

Methods of analysis analogous to those for continuous-data systems have been developed for the sampled-data systems. Discussed herein are (1) sampling, (2) the z transformation, (3) the z-transfer function, and (4) stability of sampled data systems.

Sampling The ideal sampler is a simple switch (Fig. 16.2.42) which is closed only instantaneously and opens and closes at a constant frequency. The switch, which may or may not be a physical component in a sampled-data feedback system, indicates a sampled signal. Such a sampled-data feedback system is shown in Fig. 16.2.43. The error signal in continuous form is $\epsilon(t)$, and the sampled error signal is $\epsilon^*(t)$. Figure 16.2.42 shows the relationship between these signals in a graphical form.

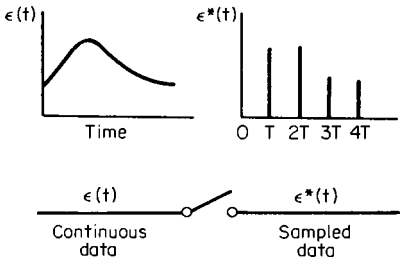

Fig. 16.2.42 Ideal sampler, showing continuous input and sampled output.

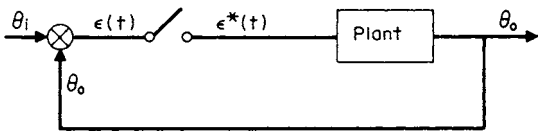

Fig. 16.2.43 Sampled data feedback system.

***z* Transformation** In the analysis of continuous-data systems, it has been shown that the Laplace transformation can be used to reduce ordinary differential equations to algebraic equations. For sampled-data systems, an operational calculus, the z transform, can be used to simplify the analysis of such systems.

Consider the sampler as an impulse modulator; i.e., the sampling modulates an infinite train of unit impulses with the continuous-data variable. Then the Laplace transformation can be shown to be

$$F^*(s) = \sum_{n=0}^{\infty} f(nT)e^{-nTs} \tag{16.2.66}$$

(See A. W. Langill, "Automatic Control Systems Engineering.")

In terms of the z transform, this becomes

$$F^*(s) = F(z) = \sum_{n=0}^{\infty} f(nT)z^{-n} \tag{16.2.67}$$

where $z^{-n} = e^{-nTs}$.

Tables in Sec. 2 list the Laplace transforms for a number of continuous time functions. Table 16.2.5 lists the z transforms for some of these functions.

It should be noted that unlike the Laplace transforms, the z-transform method imposes the restriction that the sampled-data-system response can be determined only at the sampling instant. The same z transform may apply to different time functions which may have the same value at

Table 16.2.5 Laplace and *z* Transforms

Time function	$f(t)$	$F(s) = \mathcal{L}[f(t)]$	$F^*(z) = F(z)$
Unit ramp function	t	$\frac{1}{s^2}$	$\frac{Tz}{(z-1)^2}$
Unit acceleration function	$\frac{t^2}{2}$	$\frac{1}{s^3}$	$\frac{1}{2}T^2\frac{z(z+1)}{(z-1)^3}$
Exponential function	$e^{-\alpha t}$	$\frac{1}{s+\alpha}$	$\frac{z}{z-e^{-\alpha T}}$
Sinusoidal function	$\sin \beta t$	$\frac{\beta}{s^2+\beta^2}$	$\frac{z \sin \beta T}{z^2 - 2z\cos \beta T + 1}$
Cosinusoidal function	$\cos \beta t$	$\frac{s}{s^2+\beta^2}$	$\frac{z(z-\cos \beta T)}{z^2 - 2z\cos \beta T + 1}$

Table 16.2.6 Typical Block Diagrams of Sampled-Data Control Systems and Their Transforms

System	Laplace transform of the output, $C(s)$	z-transform of the output, $C^*(z)$
1. 	$\dfrac{G_1(s)}{1 + G_1G_2^*(z)}R^*(z)$	$\dfrac{G_1^*(z)}{1 + G_1G_2^*(z)}R^*(z)$
2. 	$\dfrac{G_1(s)}{1 + G_1(s)G_2(s)}R^*(z)$	$\left[\dfrac{G_1(s)}{1 + G_1(s)G_2(s)}\right]^* R^*(z)$
3. 		$\dfrac{G_1^*(z)}{1 + G_1^*(z)G_2^*(z)}R^*(z)$
4. 	$G_1(s)\left[R(s) - G_2(s)\dfrac{RG_1^*(z)}{1 + G_1G_2^*(z)}\right]$	$\dfrac{RG_1^*(s)}{1 + G_1G_2^*(s)}$
5. 	$G_1(s)\left[R^*(z) - \dfrac{G_1^*(z)G_2^*(z)R^*(z)}{1 + G_1^*(z)G_2^*(z)}\right]$	$\dfrac{G_1^*(z)}{1 + G_1^*(z)G_2^*(z)}R^*(z)$
6. 	$G_1(s)\left[R^*(z) - G_2(s)\dfrac{R^*(z)G_1^*(z)}{1 + G_1G_2^*(z)}\right]$	$\dfrac{G_1^*(z)}{1 + G_1G_2^*(z)}R^*(z)$
7. 	$\dfrac{G_2(s)}{1 + G_1G_2G_3^*(z)}RG_1^*(z)$	$\dfrac{G_2^*(z)}{1 + G_1G_2G_3^*(z)}RG_1^*(z)$
8. 	$\dfrac{G_2(s)}{1 + G_2^*(z) + G_1G_2^*(z)}RG_1^*(z)$	$\dfrac{G_2^*(z)}{1 + G_2^*(z) + G_1G_2^*(z)}RG_1^*(z)$

SOURCE: John G. Truxal (ed.), "Control Engineers' Handbook," McGraw-Hill.

the instant of sampling. The z-transform function is not defined, therefore, in a continuous sense, and the inverse z transform is not unique.

***z*-Transfer Function** The ratio of the sampled output function of a discrete network to the sampled input function is the z-transfer function. A discrete network is one which has both a sampled input and output. A table of block diagrams of a number of sampled-data control systems with their associated transfer functions is presented in Table 16.2.6.

Stability of Sampled-Data Systems The stability of sampled-data systems can be demonstrated utilizing frequency-response methods which have been discussed in this section. See "Stability and Performance of an Automatic Control." The Nyquist stability criterion again applies with the same conclusions relative to the -1 point, and the methods of generalizing the open- and closed-loop frequency response plots remain the same.

MODERN CONTROL TECHNIQUES

Many engineers and researchers have been actively pursuing the application and development of advanced control strategies. In recent years this effort has included extensive work in the area of robust control theory. One of the primary attractions of this theory is that it generalizes the **single input-single system output (SISO)** concept of gain and phase margins, and its effect on system sensitivity to multivariable control system.

In this section the design technique for a **linear quadratic gaussian with loop transfer recovery (LQG/LTR)** robust controller design method will be summarized. The concepts required to understand this method will be reviewed. A linearized model of a simple process has been chosen to illustrate this technique. The simple process has three state variables, one input, and one output. Three control system design methods are compared: LQG, a LQG/LTR, and a proportional plus integral controller (PI).

Previous Work and Results

Most applications of modern control techniques to process control have appeared in the form of **optimal control strategies** which were in the form of full-state feedback control with and without state estimation [linear quadratic regulator (LQR)]. The regulator problem, coupled with a state estimation problem, was shown not to have desirable robustness properties. Doyle and Stein (Doyle and Stein, 1979) proposed the multivariable robust design philosophy known as LQG/LTR to eliminate the

shortcomings of the LQR and LQG design techniques. The LQG/LTR design technique has been applied to control submersible vehicles, engine speed, helicopters, ship steering, and large, flexible space structures.

The LQG/LTR method requires the plant to be **minimum phase,** which cannot be guaranteed in a plant process. Typically **nonminimum phase** conditions in a plant process are due to time delay. The LQG/LTR design procedure offers no guarantees when a nonminimum-phase plant is used. However recent work develops a method to obtain a robust controller design for plants with time delay (Murphy and Bailey, IEEE 1989 and IECON 1990).

The LQG/LTR synthesis method for minimum phase plants achieves desired loop shapes and maximum robustness properties in the design of feedback control systems. The LQG/LTR design procedure uses **singular value analysis** and design procedures to obtain the desired performance and stability robustness. The use of singular values yields a frequency-domain design and analysis method generally expected by control engineers to determine system robustness. The LQG/LTR synthesis method is applicable to both **multiple-input/multiple-output (MIMO)** and SISO control systems. The performance limitations of this design method are analogous to those of a SISO system.

Definition of Robustness

A system is considered to be robust and have **good robustness properties** if it has a large stability margin, good disturbance attenuation, and/or low sensitivity to parameter variations. The term **stability margin** refers to the gain margin and the phase margin, which are quantitative measures of stability. A proven method of obtaining good robustness properties is the use of a feedback control system, which can be designed to allow for variations in the system dynamics. Some causes of **variation** in system dynamics are

Modeling and data errors in the nominal plant and system.

Changes in environmental conditions, manufacturing tolerances, wear due to aging, and noncritical material failures.

Errors due to calibration, installation, and adjustments.

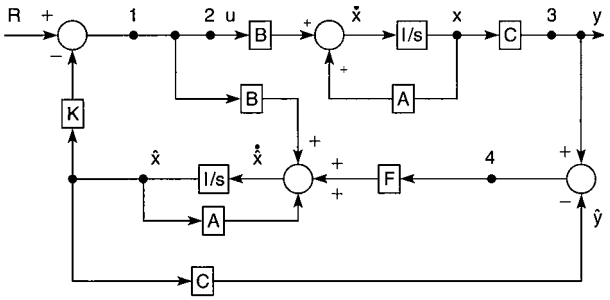
Feedback control systems with good feedback properties have been synthesized for SISO systems. Classical frequency domain techniques such as Nyquist, root-locus, Bode, and Nichols plots have been used to obtain the feedback control system for the SISO system. These design techniques have allowed the synthesis of feedback control systems yielding **insensitivity** to bounded parameter variations and a large stability margin. The success of the feedback control system for the SISO system has led to the direct extension of the classical frequency domain technique to the design of a multivariable feedback control system. This extension to the multivariable design problem examines an individual feedback loop as the phase and gain margins are varied, while the nominal phase and gain values in the remaining feedback paths are held constant. This technique, however, fails to consider the results of simultaneous variation of gain and phase in all paths, which is a real-world possibility and needs to be considered. A method of obtaining a feedback control system with good robustness properties that takes into consideration simultaneous gain and phase variation is the LQG/LTR.

The LQG/LTR technique can be applied to MIMO systems or SISO systems. The LQG/LTR technique not only has the good robustness properties of the classical frequency domain techniques but also is capable of minimizing the effects of unmodeled high-frequency dynamics, neglected nonlinearities, and a reduced-order model. **Computer control system design tools,** for instance, developed by Integrated Systems Incorporated (ISI) and The MathWorks can be used in synthesizing the LQG/LTR technique and other controller design techniques. The use of computer-aided design tools eliminates the numerical programming burden of programming the complex LQG/LTR algorithm.

In what follows, the needed concepts are defined and the LQG/LTR procedure for development of a **model-based compensator** (MBC) is described. A unity-feedback MBC is selected for the controller structure, because of its similarity to the SISO unity-feedback control system well known to classical control designers. The MBC closed-loop control system has proven to offer great practical considerations in the design of automatic control systems.

Robustness Concepts of the LQG and LQG/LTR Control Systems

The LQG/LTR design procedure is based on the system configuration of the LQG controller shown in Fig. 16.2.44. The LQG controller consists of a Kalman filter state estimator and a linear quadratic regulator. The Kalman filter state estimator has good robustness properties for plant perturbations at the plant output. The linear quadratic regulator (LQR) has good robustness properties for perturbations at the plant input. Even though its components separately have good robustness properties, the LQG controller is found to have no guaranteed robustness properties at either the input (point 2) or the output (point 3) of the plant.



- LQG guaranteed no robustness properties at the input or output of the plant.
- Point 1 has the good robustness properties of the full-state feedback system.
- Point 4 has the good robustness properties of the Kalman filter.
- Point 2 has no guaranteed robustness properties.
- Point 3 has no guaranteed robustness properties.
- The LQG/LTR design method permits recovery of the robustness properties of point 1 at point 2 or the robustness properties of point 4 at point 3.

Fig. 16.2.44 Summary of the robustness properties of the LQG block diagram.

The LQG/LTR design procedure allows us to recover robustness properties at either the input or the output of the plant. If robustness is desired at the input to the plant, first a nominal robust LQR design is made to satisfy the design constraints. Next, an LTR step is made to design a Kalman filter gain that recovers the robustness at the input to the plant of the LQG controller that is approximately that of the nominal LQR design. This implies from Fig. 16.2.44 that the robustness properties at points 1 and 2 are approximately the same.

If robustness is desired at the **output of the plant,** first a nominal robust Kalman filter design is made to satisfy the performance constraints. Next, an LTR step is made to design an LQR gain that recovers the robustness at the output of the plant that is approximately that of the nominal Kalman filter design. This implies from Fig. 16.2.44 that the robustness properties at points 3 and 4 are approximately the same.

The block diagram of the unity-feedback MBC is shown in Fig. 16.2.45. This control system structure allows tracking and regulation of a reference input at the output of the plant. The filter and regulator gains used in the controller $R(s)$ are obtained appropriately, depending on whether robustness is desired at the input or the output of the plant. Note that the robustness properties of the **unity-feedback MBC** (UFMBC) are the same as those of the LQG system, since the UFMBC is just an alternative structure of the LQG system.

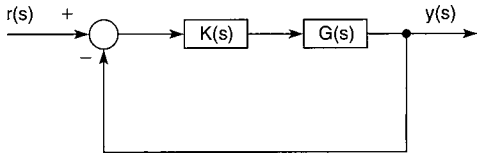


Fig. 16.2.45 Unity feedback model-based compensator (UFMBC).

MATHEMATICS AND CONTROL BACKGROUND

The use of **matrix algebra** is very important in the study of MIMO control system design methods. Some MIMO control system design methods use matrix algebra to decouple the system so that the plant matrix transfer function consists only of individual **decoupled transfer functions,** each represented conventionally as the ratio of two polynomials. This simplification then allows the use of conventional methods such as the Bode plot, Nyquist plot, and Nichols chart as a means of designing a controller for each loop of the MIMO plant. The LQG/LTR control system design method, however, does not require **decoupling** of the plant but rather preserves the coupling between the individual loops of the MIMO plant. Each step of the LQG/LTR design technique therefore requires the use of some matrix algebra, vector and matrix norms, and singular values during the control system design procedure. For instance, matrix algebra is used to derive a suitable representation of the closed-loop system for stability and robustness analysis. Matrix norms and singular values are used to examine the matrix magnitude of the MIMO transfer function. The **matrix magnitude** or **singular values** of a system allows preservation of the coupling between the various loops of the MIMO control system.

The concepts of matrix norm, singular values, controllability, observability, stabilizability, and detectability are very important in applying MIMO design procedures. It is therefore important that these concepts be well understood.

The purpose of this section is to provide **background material** in mathematics and control systems that has proved useful in deriving the procedures and analysis required to implement the control system design procedure.

Matrix Norm and Singular Values

The matrix norm of $||\mathbf{A}||_2$ is defined for the $m \times n$ matrix **A.** The matrix **A** defines a linear transformation from the vector space *V,* called the domain to a vector space *W,* which is called the range. Thus the linear transformation

$$\mathbf{A}(x) = \mathbf{A}x \tag{16.2.68}$$

transforms a vector x in $V \in C^n$ into a vector $\mathbf{A}(x)$ in $W \in C^m$. The matrix norm of $||\mathbf{A}||_2$ is defined as

$$||\mathbf{A}||_2 = \max_{x \neq 0} \frac{||\mathbf{A}||_2}{||x||_2} = l_2 \text{ norm} \tag{16.2.69}$$

Since the l_2 **norm** is a useful tool in control system analysis, further insight into its definition is given. The l_2 norm of Eq. (16.2.69) can be written as

$$||\mathbf{A}||_2 = \max_i [\lambda_i (\mathbf{A}^H \mathbf{A})]^{1/2} \qquad i = 1, 2, \ldots, n \tag{16.2.70}$$

$$||\mathbf{A}||_2 = \max_i [\lambda_i (\mathbf{A}\mathbf{A}^H)]^{1/2} \qquad i = 1, 2, \ldots, n \tag{16.2.71}$$

The matrices $\mathbf{A}^H\mathbf{A}$ and $\mathbf{A}\mathbf{A}^H$ are Hermitian and positive semidefinite. The eigenvalues of these matrices are real and nonnegative. The definition of the **singular value** of a complex matrix $\mathbf{A} \in \mathbf{C}^{n \times n}$ is

$$\begin{aligned} \sigma_i(\mathbf{A}) &= [\lambda_i(\mathbf{A}^H\mathbf{A})]^{1/2} \\ &= [\lambda_i(\mathbf{A}\mathbf{A}^H)]^{1/2} \geq 0 \qquad i = 1, 2, \ldots, n \end{aligned} \tag{16.2.72}$$

If $\mathbf{A} \in \mathbf{C}^{m \times n}$, which indicates that **A** is a nonsquare matrix, then

$$\sigma_i(\mathbf{A}) = [\lambda_i(\mathbf{A}^H\mathbf{A})]^{1/2} = [\lambda_i(\mathbf{A}\mathbf{A}^H)]^{1/2} \tag{16.2.73}$$

for $1 \leq i \leq k$, where k is the number of singular values = min (m, n). The maximum and minimum singular values are defined, respectively, as

$$\overline{\sigma}(\mathbf{A}) = ||\mathbf{A}||_2 \tag{16.2.74}$$

and

$$\underline{\sigma}(\mathbf{A}) = \max_{x \neq 0} \frac{||\mathbf{A}x||}{||x||_2} = \frac{\mathbf{1}}{||\mathbf{A}^{-1}||_2} \tag{16.2.75}$$

provided **A** has an inverse.

Controllability, Observability, Stabilizability, and Detectability

The LQG/LTR control system design method has a certain **requirement** of the plant for which the controller is being designed: the plant must be at least stabilizable and detectable. Therefore it is important that the conditions of controllability, observability, and the less restricted conditions of stabilizability and detectability be understood. A description of these concepts follows.

Given the state equation for the linear time invariant (LTI) system described as $\dot{x}(t) = \mathbf{A}x(t) + \mathbf{B}u(t)$ and $y(t) = \mathbf{C}x(t)$. The matrices **A, B,** and **C** are constant. Note that $x \in R^n$, $n \in R^p$, and $y \in R^p$ are, respectively, the state, input, and output vectors. Variables n and p are the dimensions of the states and the input and output vectors. The input and output vectors are of the same dimension.

A system is said to be controllable if it is possible to transfer the system from any initial state x_0 in state space to any other state x_F using the input in a finite period of time. The system is said to be uncontrollable otherwise. The condition of controllability places **no constraint** on the input in the system.

The algebraic test for controllability of the LTI system state equation uses the controllability matrix

$$\mathbf{Q} = [\mathbf{B}\ \mathbf{A}\mathbf{B} \cdots \mathbf{A}^{n-1}\mathbf{B}] \tag{16.2.76}$$

where n is the **number of states.** The LTI system is controllable if the rank of **Q** is equal to n. If the rank of **Q** is less than n, the system is not controllable. An uncontrollable system indicates that some modes or poles are not affected by the control input. Uncontrollable systems with **unstable modes** imply that a controller design is not possible to ensure system stability. If the uncontrollable modes of the uncontrollable system are stable, then the system is stabilizable.

An LTI system is considered **observable** at initial time t_0 if there exists a finite time t_1 greater than t_0 such that for any initial state x_0 in state space using knowledge of the input u and output y over the time interval $t_0 < t > t_1$, the state x_0 can be determined. The system is said to be unobservable otherwise.

The algebraic test for observability of the LTI system uses the observability matrix

$$\mathbf{N} = [\mathbf{C}^T\ \mathbf{A}^T\mathbf{C}^T \cdots (\mathbf{A}^T)^{n-1}\mathbf{C}^T] \tag{16.2.77}$$

The LTI system is observable if the rank of **N** is equal to n, where n is the number of states. If the rank of **N** is less than n, the system is unobservable. An unobservable system indicates that not all system modes contribute to the output of the system. If the **unobservable modes** (states) are stable, then the system is considered to be detectable.

EVALUATING MULTIVARIABLE PERFORMANCE AND STABILITY ROBUSTNESS OF A CONTROL SYSTEM USING SINGULAR VALUES

Performance Robustness

The requirements for the control system design are formulated by placing certain restrictions on the singular values of the **return ratio, return difference,** and **inverse return difference** of the control system. The block diagram in Fig. 16.2.46 shows the controller $K(s)$ and plant $G(s)$ with input $d_i(s)$ and output $d_o(s)$ disturbances and sensor noise $n(s)$.

Using Fig. 16.2.46, a **frequency-domain transfer function** representation for the plant output is first obtained. These transfer function representations, used in conjunction with concepts of singular values, allow the formulation of requirements in the frequency domain to obtain a control system with good performance and stability robustness.

In this design, performance robustness is of concern at the output of the plant. Therefore it is required that the plant output transfer function be derived in order to analyze and assist in obtaining a control system design to meet certain performance robustness requirements. Using Fig. 16.2.46,

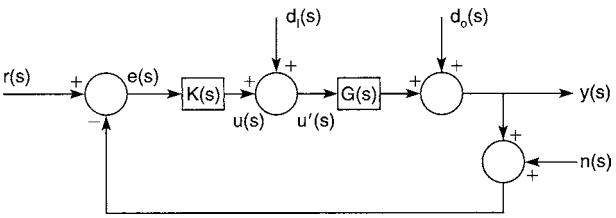

Fig. 16.2.46 Model-based unity feedback MIMO control system.

the plant output transfer function is derived and performance robustness requirements established. From Fig. 16.2.46 it can be shown that

$$y(s) = d_o(s) + G(s)u'(s) \tag{16.2.78}$$

$$e(s) = r(s) - y(s) - n(s) \tag{16.2.79}$$

and

$$u'(s) = d_o(s) + u(s) = d_I(s) + K(s)e(s). \tag{16.2.80}$$

where $G(s) = \mathbf{C}[s\mathbf{I} - \mathbf{A}]^{-1}\mathbf{B}$ is the plant transfer function and **A**, **B**, and **C** are system matrices. The transfer functions $y(s)$, $d_o(s)$, $e(s)$, $r(s)$, $n(s)$, $u(s)$, $d_I(s)$, and $K(s)$ are, respectively, the output, output disturbance, error, reference, noise, input, input disturbance, and controller transfer functions.

Using Eqs. (16.2.79) and (16.2.80) it can be shown that Eq. (16.2.78) becomes

$$\begin{aligned} y(s) &= [G(s)K(s)][r(s) - y(s) - n(s)] \\ &\quad + d_o(s) + G(s)d_I(s) \\ &= G(s)K(s)r(s) - G(s)K(s)y(s) - G(s)K(s)n(s) \\ &\quad + d_o(s) + G(s)d_I(s) \end{aligned} \tag{16.2.81}$$

Therefore,

$$\begin{aligned} y(s) &= [\mathbf{I} + G(s)K(s)]^{-1}[G(s)K(s)r(s) - G(s)K(s)n(s) \\ &\qquad + d_o(s) + G(s)d_I(s)] \\ &= [\mathbf{I} + G(s)K(s)]^{-1}\{G(s)K(s)[r(s) - n(s)]\} \\ &\quad + [\mathbf{I} + G(s)K(s)]^{-1}[d_o(s) + G(s)d_I(s)] \\ &= y_r(s) + y_{d_I}(s) + y_{d_o}(s) + y_n(s) \end{aligned} \tag{16.2.82}$$

where $y_r(s)$, $y_{d_I}(s)$, $y_{d_o}(s)$, and $y_n(s)$ are, respectively, the contributions to the plant output due to the reference input, input disturbance, output disturbance, and noise input to the system. The requirements for good command following, disturbance rejection, and insensitivity to sensor noise are defined by using singular values to characterize the magnitude of MIMO transfer functions. These requirements are also **applicable to SISO systems** (Kazerooni and Narayan; Murphy and Bailey, April 1989).

Command Following The conditions required to obtain a MIMO control system design with good command following is described. Good command following of the reference input $r(s)$ by the plant output $y(s)$ implies that

$$y(s) \approx r(s) \qquad \forall\, s \in s_R \tag{16.2.83}$$

where $s = j\omega$ and $s_R = j\omega_R$ and ω_R is the frequency range of the input $r(s)$. Letting $d_o(s) = d_I(s) = n(s) = 0$ in Eq. (16.2.82) results in

$$\begin{aligned} y_r(s) &= [\mathbf{I} + G(j\omega)K(j\omega)]^{-1}G(j\omega)K(j\omega)r(j\omega) \qquad \forall\, \omega \in \omega_R \\ &= \{\mathbf{I} + [G(j\omega)K(j\omega)]^{-1}\}^{-1}r(j\omega) \qquad \forall\, \omega \in \omega_R \end{aligned} \tag{16.2.84}$$

where $G(j\omega)K(j\omega)$ is defined as the return ratio. Therefore, to obtain good command following, the system **inverse return difference** $\mathbf{I} + [G(j\omega)K(j\omega)]^{-1}$ must have the property such that

$$\mathbf{I} + [G(j\omega)K(j\omega)]^{-1} \approx \mathbf{I} \qquad \forall\, \omega \in \omega_R \tag{16.2.85}$$

which implies that

$$\underline{\sigma}[G(j\omega)K(j\omega)] \gg 1 \qquad \forall\, \omega \in \omega_R \tag{16.2.86}$$

Thus the magnitude of the minimum singular value of the **return ratio** $\underline{\sigma}[G(j\omega)K(j\omega)]$ must be large over the frequency range of the input to obtain good command following of the control system.

Disturbance Rejection To minimize the effect of the output disturbance, $y_{d_o}(s)$, on the output signal $y(s)$, Eq. (16.2.82) is used with $n(s) = r(s) = d_I(s) = 0$, which results in

$$y_{d_o}(s) = [\mathbf{I} + G(s)K(s)]^{-1}d_o(s) \tag{16.2.87}$$

Rejection of this output disturbance at the plant output requires that the magnitude of the **return difference** $\mathbf{I} + G(s)K(s)$ to meet the following condition

$$\underline{\sigma}\,[\mathbf{I} + G(j\omega)K(j\omega)] \gg 1 \qquad \forall\, \omega \in \omega_{d_o} \tag{16.2.88}$$

which implies

$$\underline{\sigma}\,[G(j\omega)K(j\omega)] \gg 1 \qquad \forall\, \omega \in \omega_{d_o} \tag{16.2.89}$$

where y_{d_o} is the frequency range of the output disturbance $d_o(s)$.

With $n(s) = r(s) = d_o(s) = 0$ in Eq. (16.2.82), the effect of input disturbance on the plant output is examined. This effect is seen to be

$$y_{d_I}(s) = [\mathbf{I} + G(j\omega)K(j\omega)]^{-1}[G(j\omega)d_I(j\omega)] \qquad \forall\, \omega \in \omega_{d_I} \tag{16.2.90}$$

where ω_{d_I} is the frequency range of the input disturbance $d_I(s)$. To minimize the effect of $y_{d_I}(s)$ on the plant output requires that the magnitude of the return difference be large (in general, the larger the better). This requirement implies that

$$\underline{\sigma}\,[G(j\omega)K(j\omega)] \gg 1 \qquad \forall\, \omega \in \omega_{d_I} \tag{16.2.91}$$

to reject the input disturbance. It should be noted that this equation gives only general conditions for rejection. The control engineer must determine how much greater than 1 the return ratio magnitude must be.

Noise Rejection The requirements to minimize the effects of sensor noise on the plant output must be determined. First letting $n(s) = d_I(s) = d_o(s) = 0$ in Eq. (16.2.82) results in

$$\begin{aligned} y_n(s) &= [\mathbf{I} + G(s)K(s)]^{-1}[G(s)K(s)]n(s) \qquad \forall\, s \in s_n \\ &= \{\mathbf{I} + [G(s)K(s)]^{-1}\}^{-1}n(s) \qquad \forall\, s \in s_n \end{aligned} \tag{16.2.92}$$

where $s_n = j\omega_n$ and ω_n is the frequency range of the sensor noise. Thus to minimize the effects of sensor noise on the plant output it is desired to have the magnitude of $y_n(s)$ small over the frequency range of the noise. Thus

$$\overline{\sigma}\,[G(j\omega)K(j\omega)] \gg 1 \qquad \forall\, \omega \in \omega_n \tag{16.2.93}$$

is required to minimize the effect of noise on the plant output.

Any overlapping of any of the frequency ranges ω_R, ω_{d_I}, ω_{d_o}, ω_n will require system design specification tradeoffs to be made. This will definitely occur when the lower frequency ranges of ω_R and/or ω_{d_I} and ω_{d_o} overlap the higher frequency range ω_n.

Stability Robustness

All linear control system design methods are based on a linear model of the plant. Because this design model only approximates the actual plant, an error exists between the design model and the actual plant. This error can be evaluated as **absolute** or **relative.** The method of evaluation of this error (model uncertainty) depends on the nature of the differences between the actual design model and the actual plant. The evaluation of an absolute error defines an additive model uncertainty, whereas the evaluation of a relative error defines a multiplicative model uncertainty. The **additive** and multiplicative model uncertainties can be further classified as either structured or unstructured model uncertainties (Murphy and Bailey, ORNL 1989).

A **structured model uncertainty** is usually a low-frequency phenomenon characterized by variations in the parameters of the linear time-invariant plant design model. These parameter variations are caused by changes in the plant operating conditions, wear due to aging, and environmental conditions. A structured uncertainty also indicates that the gain and phase information concerning the uncertainty is known. Additive model uncertainties are generally considered structured uncertainties.

An **unstructured uncertainty** is typically a high-frequency phenomenon in which the only information known about the uncertainty is its magnitude. Unstructured uncertainties usually have the characteristic of becoming significant at high frequencies. Multiplicative uncertainties are characterized as unstructured. Unstructured uncertainties are usually caused by the truncation of high-frequency plant dynamics or modes due to the linearization process, and the neglect of plant dynamics such as actuators and sensors. Some plant dynamics that characterize unstructured uncertainty are flexible-body dynamics, electrical and mechanical resonances, and transport delays. Most linear control-system design methods neglect these high-frequency plant dynamics. The result is that if a high-frequency bandwidth controller is implemented, the high-frequency modes could be excited, resulting in an unstable control system.

Model uncertainty clearly is seen to impose limitations on the achievable performance of a feedback control system design. Hence this section will focus on the limitations imposed by uncertainty, not on the difficult problem of exact representation of the system uncertainty.

Multiplicative Uncertainty Multiplicative uncertainty (perturbation) can be represented at the input or output of the plant, and is called respectively the input multiplicative uncertainty or the **output multiplicative uncertainty.** The model uncertainty due to actuator and sensor dynamics is modeled, respectively, as an input or output multiplicative perturbation. A reduced-order model of an already **linearized model** results in a multiplicative model uncertainty. **Time delay** at the input or output of a plant yields, respectively, input and output multiplicative uncertainties in the plant. Even though other multiplicative model uncertainties exist among various types of control system design problems, the model uncertainties mentioned above are a common consideration in most control problems.

Output Multiplicative Uncertainty

The output multiplicative uncertainty $\Delta G(s)$ is defined as

$$\Delta G(s) = [G'(s) - G(s)]G^{-1}(s) \tag{16.2.94}$$

where

$$G'(s) = L(s)G(s) \tag{16.2.95}$$

is the perturbed transfer function, $L(s)$ represents dynamics not included in the nominal plant $G(s)$. Thus resulting in

$$\Delta G(s) = [L(s) - \mathbf{I}] \tag{16.2.96}$$

A block diagram of a control system with output multiplicative perturbation is shown in Fig. 16.2.47. The conditions of stability for a control system with output multiplicative uncertainty require that

$$\underline{\sigma}\{\mathbf{I} + [G(j\omega)K(j\omega)]^{-1}\} > \overline{\sigma}[\Delta G(j\omega)] \qquad \forall\, \omega > 0 \tag{16.2.97}$$

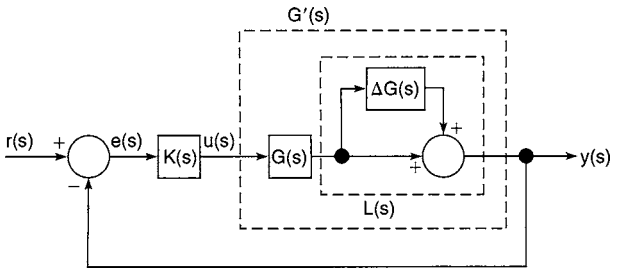

Fig. 16.2.47 Control system with output multiplicative perturbation.

Additive Uncertainty The block diagram of a control system with a plant additive model uncertainty is shown in Fig. 16.2.48. The representation of the additive model uncertainty using an absolute error criterion is defined as

$$\Delta G(s) = G'(s) - G(s) \tag{16.2.98}$$

where in this case the perturbed transfer function $G'(s)$ is

$$G'(s) = [\mathbf{C} + \Delta\mathbf{C}]\{s\mathbf{I} - [\mathbf{A} + \Delta\mathbf{A}]\}^{-1}[\mathbf{B} + \Delta\mathbf{B}] \tag{16.2.99}$$

and the nominal plant transfer function $G(s)$ is

$$G(s) = \mathbf{C}[s\mathbf{I} - \mathbf{A}]^{-1}\mathbf{B} \tag{16.2.100}$$

and where $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ are the nominal system matrices and $\mathbf{\Delta A}$, $\mathbf{\Delta B}$, and $\mathbf{\Delta C}$ are the perturbation matrices that indicate the respective deviations from the nominal system matrices. The condition for stability of the additively perturbed control system requires that

$$\underline{\sigma}[G(j\omega)K(j\omega)] > \overline{\sigma}[\Delta G(j\omega)K(j\omega)] \qquad \forall\, \omega > 0 \tag{16.2.101}$$

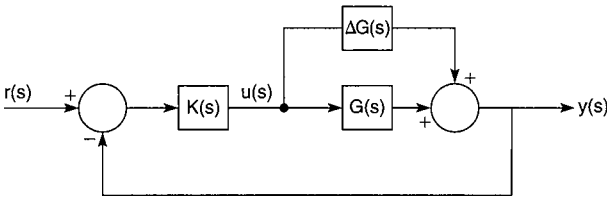

Fig. 16.2.48 Control system with additive perturbation.

Table 16.2.7 contains a summary of the general design requirements presented in this section to obtain a control system with good performance and stability robustness.

REVIEW OF OPTIMAL CONTROL THEORY

Linear Quadratic Regulator

Consider the linear time-invariant state-space system, first-order vector differential equation model

$$\dot{\mathbf{x}}(t) = \mathbf{A}x(t) + \mathbf{B}u(t) \tag{16.2.102}$$

$$y(t) = \mathbf{C}x(t) \tag{16.2.103}$$

where $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ are constant system matrices, and $x(t)$, $u(t)$, and $y(t)$ are, respectively, the system state, input, and output vectors. The system is stabilizable and controllable. The goal of this procedure is to minimize the finite performance index

$$\begin{aligned} J &= \int^{\infty} [x^{\mathrm{T}}(t)\mathbf{Q}x(t) + u^{\mathrm{T}}(t)\mathbf{R}u(t)]\,dt \\ &= \int_0^{\infty} [x^{\mathrm{T}}\mathbf{C}^{\mathrm{T}}\mathbf{C}x + u^{\mathrm{T}}\mathbf{R}u]\,dt \\ &= \int^{\infty} [y^{\mathrm{T}}y + u^{\mathrm{T}}\mathbf{R}u]\,dt \end{aligned} \tag{16.2.104}$$

where $\mathbf{Q}$ is a symmetric positive semidefinite matrix and $\mathbf{R}$ is positive definite.

Table 16.2.7 General System Design Specifications

System requirements	Range	
Good command-following	$\underline{\sigma}[G(j\omega)K(j\omega)] \gg 0$ dB	$\forall\, \omega \in \omega_R$
Good disturbance rejection	$\underline{\sigma}[G(j\omega)K(j\omega)] \gg 0$ dB	$\forall\, \omega \in \omega_d$
Good immunity to noise	$\overline{\sigma}[G(j\omega)K(j\omega)] \ll 0$ dB	$\forall\, \omega \in \omega_n$
Good system response to high-frequency modeling error*	$\underline{\sigma}\{I + [G(j\omega)K(j\omega)]^{-1}\} > \|\|\Delta G(j\omega)\|\|$	$\forall\, \omega > 0$ rad/s
Good insensitivity to parameter variations at low frequencies*	$\underline{\sigma}[G(j\omega)K(j\omega)] > \overline{\sigma}[\Delta G(j\omega)K(j\omega)]$	

* The $\Delta G(j\omega)$ indicated corresponds to the applicable multiplicative or additive model uncertainty.

The **performance index** J, referred to as the quadratic performance index, implies that a control $u(t)$ is sought to facilitate the minimization of J. The weighting matrices $\mathbf{Q}$ and $\mathbf{R}$ are selected to reflect the importance of particular states and control inputs. In general the weighting of the diagonal elements of $\mathbf{Q}$ can be determined by the importance of the state, as observed by the $\mathbf{C}$ matrix of the output equation. The effect of $\mathbf{Q}$ is the ability to control the **transient response** of the LQR. The effect of $\mathbf{R}$ is the ability to **control** the **energy** resulting from u.

Therefore a linear control law that minimizes J is defined as

$$u(t) = -\mathbf{K}x(t) \tag{16.2.105}$$

where

$$\mathbf{K} = \mathbf{R}^{-1}\mathbf{B}^{\mathrm{T}}\mathbf{S} \tag{16.2.106}$$

where, in turn, $\mathbf{S}$ is a constant symmetric positive semidefinite matrix that satisfies the algebraic Riccati equation

$$\mathbf{Q} - \mathbf{S}\mathbf{B}\mathbf{R}^{-1}\mathbf{B}^{\mathrm{T}}\mathbf{S} + \mathbf{A}^{\mathrm{T}}\mathbf{S} + \mathbf{S}\mathbf{A} = 0 \tag{16.2.107}$$

The closed-loop regulator is given by

$$\dot{\mathbf{x}}(t) = [\mathbf{A} - \mathbf{B}\mathbf{K}]x(t) = [\mathbf{A} - \mathbf{B}\mathbf{R}^{-1}\mathbf{B}^{\mathrm{T}}\mathbf{S}]x(t) \tag{16.2.108}$$

and is asymptotically stable provided the state equation (16.2.102) and the output equation (16.2.103) are detectable.

Kalman Filter

What follows is a method of reconstructing an estimate of the states using only the output measurements of the system. The method of reconstruction must be applicable when **process noise** and **measurement noise,** respectively, corrupt the plant state equations and the output measurement equations.

Let us consider the stochastic linear system state space vector differential equation model

$$\dot{\mathbf{x}}(t) = \mathbf{A}x(t) + \mathbf{B}u(t) + \Gamma d(t) \tag{16.2.109}$$

$$y(t) = \mathbf{C}x(t) + n(t) \tag{16.2.110}$$

where $\mathbf{A, B, C,}$ and Γ are constant system matrices. Vectors $s(t)$, $u(t)$, and $y(t)$ are, respectively, the state, input, and output vectors. Vector $d(t)$ is a process noise random vector and vector $n(t)$ is a measurement noise random vector. Assuming that $d(t)$ and $n(t)$ are zero-mean, uncorrelated, gaussian white noises,

$$E[d(t)E[n(t)] = 0 \qquad \text{for all } t \tag{16.2.111}$$

$$E[d(t)d^{\mathrm{T}}(\tau)] = \mathbf{D}_o\delta(t - \tau) \tag{16.2.112}$$

$$E[n(t)n^{\mathrm{T}}(\tau)] = \mathbf{N}\delta(t - \tau) \qquad \text{for all } t < \tau \tag{16.2.113}$$

$$E[d(t)n^{\mathrm{T}}(\tau)] = 0 \tag{16.2.114}$$

where τ is the difference between two points in time, $E[\ ]$ is mean value, δ is an impulse function, and $\mathbf{N}$ and $\mathbf{D}_o$ are constant symmetric, positive definite, and positive semidefinite matrices, respectively. Note that $\mathbf{N}$ and $\mathbf{D}_o$ are constant because it is assumed that $d(t)$ and $n(t)$ are wide-sense stationary.

The **state estimate $\hat{\mathbf{x}}$ of the actual measured state** x is obtained from the noisy measurement y. Therefore we can define a state error vector

$$e(t) = x(t) - \hat{\mathbf{x}}(t) \tag{16.2.115}$$

where we desire to minimize the mean square error

$$\bar{\mathbf{e}} = E[e^{\mathrm{T}}(t)e(t)] \tag{16.2.116}$$

The estimator can thus be shown to take the form

$$\dot{\hat{\mathbf{x}}} = \mathbf{A}x(t) + \mathbf{B}u(t) + \mathbf{F}[y(t) - \mathbf{C}x(t)] \tag{16.2.117}$$

where $\mathbf{F}$ is the filter gain which minimizes Eq. (16.2.116); $\mathbf{F}$ is defined as

$$\mathbf{F} = \Sigma\mathbf{C}^{\mathrm{T}}\mathbf{N}^{-1} \tag{16.2.118}$$

where Σ is a constant-variance matrix of the error $e(t)$. It is assumed here that $e(t)$ is wide-sense stationary. The matrix Σ is obtained by solving the algebraic variance Riccati equation

$$\mathbf{D} - \Sigma\mathbf{C}^{\mathrm{T}}\mathbf{N}^{-1}\mathbf{C}\Sigma + \mathbf{A}\Sigma + \Sigma\mathbf{A}^{\mathrm{T}} = 0 \tag{16.2.119}$$

where

$$\mathbf{D} = \Gamma\mathbf{D}_o\Gamma \tag{16.2.120}$$

A sufficient condition to obtain a unique and positive definite Σ from Eq. (16.2.117) requires that $[\mathbf{A, C}]$ be completely observable. However, if the pair $[\mathbf{A, C}]$ is required to be detectable, then Σ can be positive semidefinite.

The **reconstruction error** $e(t)$ satisfies the differential equation

$$\dot{e}(t) = [\mathbf{A} - \mathbf{F}\mathbf{C}]e(t) + [\Gamma - \mathbf{F}]\begin{bmatrix} d(t) \\ n(t) \end{bmatrix} \tag{16.2.121}$$

such that

$$e(t) \to 0 \quad \text{as} \quad t \to \infty \quad \forall\, t \geq t_0$$

if and only if the **observer** is asymptotically stable. The poles of the observer (filter) are found by using the closed-loop dynamics matrix $[\mathbf{A} - \mathbf{F}\mathbf{C}]$. To obtain asymptotic stability of the filter, it is required that the pair $[\mathbf{A}, \Gamma]$ be completely controllable. The necessary and sufficient condition of **stabilizability** of the pair $[\mathbf{A}, \Gamma]$ will ensure **stability** also.

PROCEDURE FOR LQG/LTR COMPENSATOR DESIGN

An LQG/LTR compensator will be designed for a **minimum phase plant (no right half plane zeroes).** The control system so designed will be guaranteed to be stable and will be robust at the plant output.

First, it is assumed that if **zero steady-state error** is desired in the control system design, the plant inputs will be augmented to obtain the desired **integral action.** In some cases the dynamics of the plant may have poles that are nearly zero, which establishes a **near integral action** in the plant. In such a case the addition of integrals at the plant input causes a much greater than **20-dB/decade roll-off,** thus yielding unreasonable plant dynamics characterized by the return ratio singular-value plots. Therefore caution is required in deciding how or whether to augment the plant dynamics. In the following description of the compensator design it is assumed that the nominal plant transfer function $G(s)$ has been augmented as required by the control engineers' desires.

Step 1 The first step requires selecting the appropriate transfer function $[G_{\mathrm{FOL}}(s)]$ that satisfies the desired **performance and stability robustness** of the final control system. Therefore, the appropriate scalar $\mu > 0$ and a constant matrix $\mathbf{L}$ such that the singular values of

$$G_{\mathrm{FOL}}(s) = (1/\sqrt{\mu})[\mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{L}] \tag{16.2.122}$$

approximately meet the desired control system requirements. The system matrices $\mathbf{C}$ and $\mathbf{A}$ of the minimum phase component are assumed to have been augmented already to obtain the necessary integral action. The selection of $\mathbf{L}$ is made so that at low frequencies $(s = j\omega \to 0)$, high frequencies $(s = j\omega \to j\omega)$, or intermediate frequencies $(s = j\omega \to j\omega_I)$ the singular values of $G_{\mathrm{FOL}}(s)$ are approximately the same. After $\mathbf{L}$ is selected, then μ is adjusted to obtain the desired crossover frequency $\sigma[G_{\mathrm{FOL}}(j\omega)]$; therefore μ functions as a gain parameter of the transfer function. It should be noted that it is desired to balance the singular values of $G_{\mathrm{FOL}}(s)$ in the region of the crossover frequency in order to obtain similar responses for each loop of the system. Also, typically it is desired to have the return ratio singular values roll off at a rate no greater than -20 dB/decade in the region of gain crossover.

Step 2 In this step the Kalman filter transfer function is defined as

$$G_{\mathrm{KF}}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{F} \tag{16.2.123}$$

where $\mathbf{F}$ is the Kalman filter gain and $\mathbf{C}$ and $\mathbf{A}$ are the system matrices of the linear time-invariant state-space system.

To compute the **filter gain F,** first the following Kalman filter **algebraic Riccati equation (ARE)** is solved

$$\mathbf{L}\mathbf{L}^{\mathrm{T}} - (1/\sqrt{\mu})\Sigma\mathbf{C}^{\mathrm{T}}\mathbf{C} + \mathbf{A}\Sigma + \Sigma\mathbf{A}^{\mathrm{T}} = 0 \tag{16.2.124}$$

where $\mathbf{L}$ and μ are as obtained in step 1 and Σ (the covariance matrix) is the solution to the equation. The filter gain is thus computed to be

$$\mathbf{F} = (1/\sqrt{\mu})\Sigma\mathbf{C}^{\mathrm{T}} \tag{16.2.125}$$

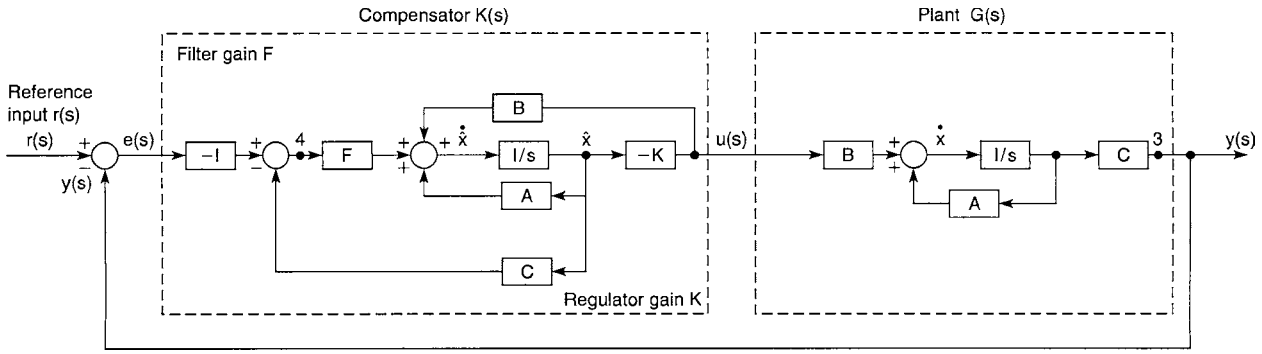

Fig. 16.2.49 Block diagram of unity-feedback LQG/LTR control system.

Thus as seen above, $\mathbf{L}$ and μ are tunable parameters used to produce the necessary filter gain $\mathbf{F}$ to meet the desired system performance and stability robustness constraints. This step completes the LQG/LTR design requirement of designing the target Kalman filter transfer function matrix with the desired properties which will be recovered at the plant output during the loop transfer recovery step. The general block diagram of the LQG/LTR control system is shown in Fig. 16.2.49.

Step 3 The transfer function of the LQG/LTR controller is defined as

$$K(s) = \mathbf{K}[s\mathbf{I} - (\mathbf{A} - \mathbf{BK} - \mathbf{FC})]\mathbf{F} \qquad (16.2.126)$$

where $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ are the system matrices of Eqs. (16.2.102) and (16.2.103). The filter gain $\mathbf{F}$ is as stated in Eq. (16.2.125). The **regulator gain K** will be computed in this step to achieve loop transfer recovery. The selection of $\mathbf{K}$ will yield a return ratio at the plant output such that

$$G(s)K(s) \to G_{\mathrm{KF}}(s) \qquad (16.2.127)$$

where $G(s)$ is the plant transfer function, and $K(s)$ is the controller transfer function.

The first step in selecting $\mathbf{K}$ requires solving the LQR problem, which has the following ARE:

$$\mathbf{Q}(q) - \mathbf{SBR}_0^{-1}\mathbf{B}^{\mathrm{T}}\mathbf{S} + \mathbf{SA} + \mathbf{A}^{\mathrm{T}}\mathbf{S} = 0 \qquad (16.2.128)$$

where $\mathbf{R}_0 = \mathbf{I}$ is the control weighting matrix and $\mathbf{Q}(q) = \mathbf{Q}_0 + q^2\mathbf{CC}^{\mathrm{T}}$ is the modified state weighting matrix. The scalar q is a free design parameter. The resulting regulator gain $\mathbf{K}$ is computed as

$$\mathbf{K} = \mathbf{B}^{\mathrm{T}}\mathbf{S} \qquad (16.2.129)$$

As $q \to 0$ Eq. (16.2.128) becomes the ARE to the optimal regulator problem. As $q \to \infty$ the LQG/LTR technique guarantees that, since the design model $G(s) = (\mathbf{C}(s)\mathbf{I} - \mathbf{A})^{-1}\mathbf{B}$ has no nonminimum phase zeroes, then pointwise in s

$$\lim_{q\to\infty} G(s)K(s) \to G_{\mathrm{KF}}(s) \qquad (16.2.130)$$

$$\lim_{q\to\infty} \{\mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{BK}[s\mathbf{I} - (\mathbf{A} - \mathbf{BK} - \mathbf{FC})]^{-1}\mathbf{F}\} \to \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{F} \qquad (16.2.131)$$

This completes the LQG/LTR design procedure. Now that the loop transfer recovery step is complete, the singular-value plots of the return ratio, return difference, and inverse return difference must be examined to verify that the desirable loop shape has been obtained.

EXAMPLE CONTROLLER DESIGN FOR A DEAERATOR

In this section, three linear control methods are used to obtain a level-control system design for a deaerator. The **three linear control system design methods** that will be used are proportional plus integral, linear quadratic gaussian, and linear quadratic gaussian with loop transfer recovery. In this investigation, the dual of the procedure developed for the LQG/LTR design at the plant input will be used to obtain a **robust control system design** at the **plant output** (Murphy and Bailey, ORNL 1989).

The **Bode gain** and **phase plots** of the resulting control system design will be presented for each controller. Also, the singular-value plots of the **return ratio, return difference,** and **inverse return difference** for opening the loop at the plant output (point 3 in Fig. 16.2.50) will be presented.

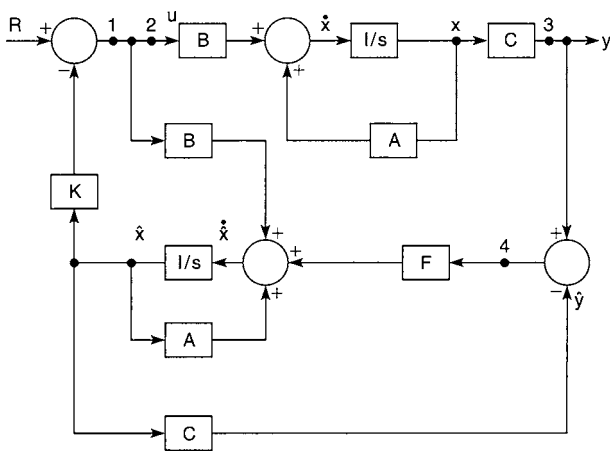

Fig. 16.2.50 Block diagram of LQG system.

The deaerator was chosen because of its **simple mathematical structure;** one input, one output, and three state variables. Thus the model is easy to follow but complex enough to illustrate the design technique.

The Linearized Model

The mathematical model of the deaerator is **nonlinear,** with a process flow diagram as shown in Fig. 16.2.51. This nonlinear plant is **linearized** about a nominal operating condition, and the resulting linearized plant

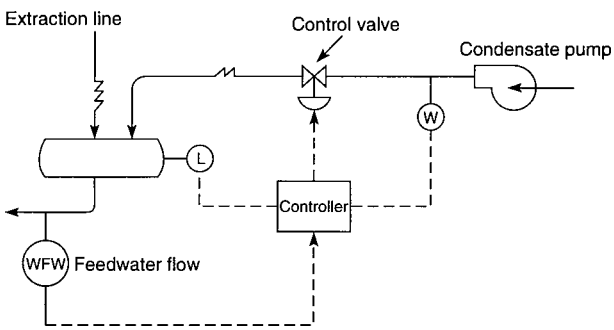

Fig. 16.2.51 General process flow diagram of the deaerator.

model will be used to obtain the controller design. The linear **deaerator model** is described by the state space linear time-invariant (LTI) differential equation

$$\dot{x}(t) = \mathbf{A}x(t) + \mathbf{B}u(t) \qquad (16.2.132)$$

$$y(t) = \mathbf{C}x(t) \qquad (16.2.133)$$

where **A**, **B**, and **C** are the system matrices given, respectively, as

$$\mathbf{A} = \begin{bmatrix} -53.802 & 1.7093 & 9.92677 \\ 0.0001761 & -0.0009245 & -0.0053004 \\ -0.001124 & -0.0243636 & -0.139635 \end{bmatrix}$$

$$\mathbf{B} = \begin{bmatrix} -9526.25 \\ 0.265148 \\ -1.72463 \end{bmatrix}$$

$$\mathbf{C} = [0.0 \quad 3.2833 \quad 0.06373]$$

The system states are defined as

$$x = \begin{bmatrix} \delta P \\ \delta \rho \\ \delta H \end{bmatrix}$$

where δP is operating pressure between the pump and the extraction line, $\delta\rho$ is fluid density, and δH is internal energy of the tank level. Plant output y = change in deaerator tank level, and the plant input u = change in control valve.

LQG Controller Design

The design considerations for the tracking LQG control system will first be discussed. The block diagram of the LQG control system is shown in Fig. 16.2.50. It is apparent that output tracking of a reference input will not occur with the present LQG controller configuration. An alternative compensator structure, shown in Fig. 16.2.52, is therefore used to obtain a tracking LQG controller. The controller $K(s)$ uses the same filter gain **F** and regulator gain **K** computed by the LQG design procedure. The detailed block diagram is the same structure that will be used for the LQG/LTR controller shown in Fig. 16.2.49.

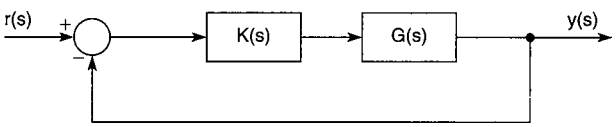

Fig. 16.2.52 Alternative compensator structure.

Using a **control system design package** MATRIX$_X$, the regulator gain **K** and filter gain **F** are computed as

$$\mathbf{K} = 10^5 \times [0.0233 \quad 3.145 \quad -0.1024]$$

and

$$\mathbf{F} = \begin{bmatrix} 0.1962 \\ 9.9998 \\ -0.0083 \end{bmatrix}$$

given **user-defined weighting matrices.** The frequency response of the open-loop transfer function of the closed-loop compensated system

$$\frac{y(s)}{r(s)} = \frac{\text{tank level}}{\text{reference input}}$$

where $y(s)$ is the **tank level** and $r(s)$ is the **reference input,** as shown in Fig. 16.2.53.

LQG/LTR Controller Design

This LQG/LTR control system has the structure shown in Fig. 16.2.52. This LQG/LTR control system design is a two-step process. First, a Kalman filter (KBF) is designed to obtain **good command following** and **disturbance rejection** over a specified low-frequency range. Also, the KBF design is made to meet the required robustness criteria with system

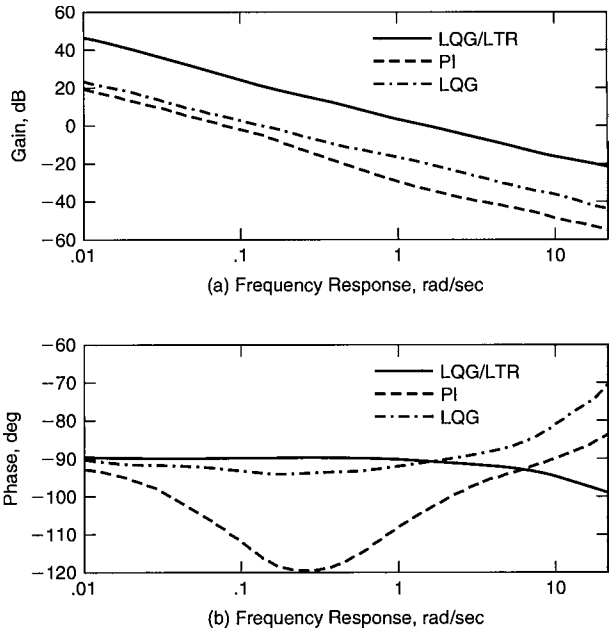

Fig. 16.2.53 Open-loop frequency response of the PI, LQG, LQG/LTR control system. (*a*) Frequency response of system gain; (*b*) frequency response of system phase.

uncertainty of $\Delta G(s)$ at the system's output. To obtain good command following and disturbance rejection requires that

$$\underline{\sigma}(G_4(s)) \geq 20 \text{ dB} \qquad \forall\, \omega < 0.1 \text{ rad/s} \qquad (16.2.134)$$

where $G_4(s)$ is the loop transfer function at the output of the KBF (point 4 of Fig. 16.2.50). Assuming the **high-frequency uncertainty** $\Delta G(s)$ for this system becomes significant at 5 rad/s, then for robustness

$$\underline{\sigma}\{\mathbf{I} + [G_4(s)]^{-1}\} \geq ||\Delta G(j\omega)|| = 5 \text{ dB}$$

$$\forall\, \omega \geq 5 \text{ rad/s} \qquad (16.2.135)$$

In this application, the frequency at which system uncertainty becomes significant, 5 rad/s, and the magnitude of the uncertainty, 5 dB at 5 rad/s, are assumed values. This assumption is required because of the lack of information on the high-frequency modeling errors of the process being studied.

The **second step** is to **recover the good robustness properties** of the loop transfer function $G_4(s)$ of point 4 at the output node y (point 3). This will be accomplished by applying the loop transfer recovery (LTR) step at the output node (point 3). The LTR step requires the computation of a regulator gain (**K**) to obtain the robustness properties of the loop transfer function $G_4(s)$ at the output node y.

The tool used to obtain the LQG/LTR design for this system, considering the low- and high-frequency bound requirements is CASCADE, a computer-aided system and control analysis and design environment that synthesizes the LQG/LTR design procedure (Birdwell et al.). Note that more recent computer-aided control system design tools synthesize this design procedure.

The resulting filter gain **F** and regulator **K** gain for this system are, respectively,

$$\mathbf{F} = \begin{bmatrix} -0.0107 \\ 0.472 \\ -0.02299 \end{bmatrix}$$

and

$$\mathbf{K} = [0.660 \quad 27703.397 \quad 589.4521]$$

The resulting open-loop frequency response of the compensated system is shown in Fig. 16.2.53.

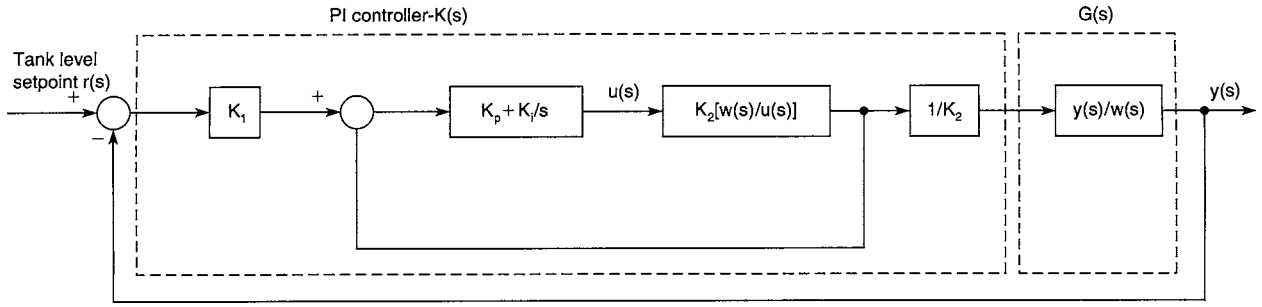

Fig. 16.2.54 Block diagram of a PI control system.

PI Controller Design

The PI controller for this system design takes on a structure similar to the three-element controller prevalent in process control. Therefore the PI control system structure takes the form shown in Fig. 16.2.54. The classical design details of the deaerator are shown in Murphy and Bailey, ORNL 1989.

The transfer functions used in this control structure are defined as

$$\frac{w(s)}{u(s)} = \frac{\text{condensate flow}}{\text{controller output}} \tag{16.2.136}$$

$$= 4.5227 \times 10^{8} \times \frac{s + 0.142}{(s + 0.1405)(s + 53.8015)}$$

and

$$\frac{y(s)}{w(s)} = \frac{\text{tank level}}{\text{condensate}} \tag{16.2.137}$$

$$= 1.6804 \times 10^{-9} \times \frac{(s + 0.1986)(s + 47.458)}{s(s + 0.142)}$$

The constants K_1 and K_2 are used for unit conversion and defined, respectively, as 1.0 and 10^{-6}. The terms K_p and K_i are defined, respectively, as the proportional gain and the integral gain.

Using the practical experience of a prior three-element controller design, the proportional and integral gains are selected to be $K_p = 0.1$ and $K_i = 0.05$. The resulting open-loop frequency response plot of the compensated system $y(s)/r(s)$ is shown in Fig. 16.2.54.

Precompensator Design

The transient responses of the PI, LQG, and LQG/LTR control systems are shown in Fig. 16.2.55. The transient response of the LQG/LTR controller is seen to have a faster time to peak than the LQG and PI transient responses. Considering the practical physical limitations of the plant, it appears unlikely that the required rise time dictated by the transient response of the LQG/LTR control system is possible. The obvious solution would be to redesign the LQG/LTR control system to obtain a slower, more practical response. In the case of the LQG/LTR control system, the possibility of a redesign is eliminated, because the control system was designed to meet certain command-tracking, disturbance-rejection, and stability-robustness requirements.

Therefore, to eliminate this difficulty, a second-order precompensator will be placed in the forward path of the reference input signal. This precompensator will shape the output transient response of the system, since the control system design requires the output to follow the reference input. The precompensator in this investigation will be required to have a time to peak of 30 s with a maximum overshoot of about 3 percent. The requirements are selected to emulate somewhat the transient response of the PI controller.

The transfer function of the second-order precompensator used is as follows:

$$\frac{r(s)}{r_i(s)} = \frac{\omega_n^2}{s^2 + 2\xi\omega_n s + \omega_n^2} \tag{16.2.138}$$

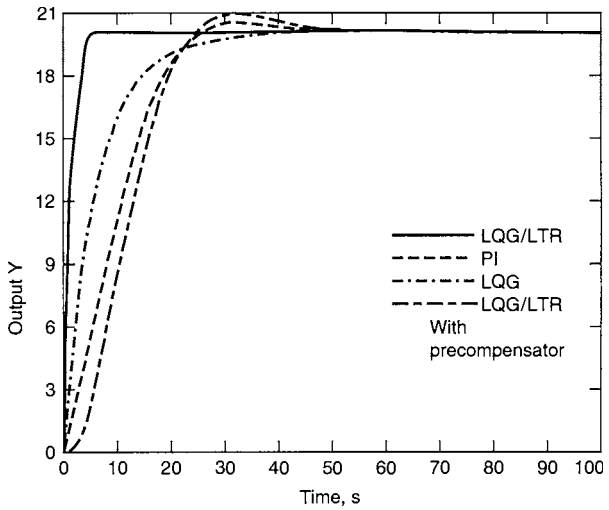

Fig. 16.2.55 PI, LQG, LQG/LTR, LQG/LTR (with precompensator) control system closed-loop transient responses.

where ξ is the damping ratio, ω_n is the natural frequency, $r(s)$ is the output of the precompensator, and $r_i(s)$ is the actual reference input. The precompensator Eq. (16.2.138) can be represented in state equation form as follows:

$$\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\omega_n^2 & -\zeta\omega_n \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} r_i(t) \tag{16.2.139}$$

and

$$r(t) = [\omega_n^2 \;\; 0] \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} \tag{16.2.140}$$

where $r_i(t)$ is the time-domain representation of the reference input signal and $r(t)$ is the time-domain signal at the output of the precompensator.

Considering the 3 percent overshoot requirement, then ξ must be 0.7. Using the expression

$$t_{\max} = \frac{\pi}{\omega_n\sqrt{1 - (0.7)^2}} \tag{16.2.141}$$

where $t_{\max}$ must be 30 s, gives

$$\omega_n = \frac{\pi}{30\sqrt{1 - (0.7)^2}} \tag{16.2.142}$$

The complete state equation of the precompensator is

$$\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -0.0215 & -0.2052 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} r_i(t) \tag{16.2.143}$$

and

$$r(t) = [0.0215 \;\; 0] \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} \tag{16.2.144}$$

The resulting transient response of the LQG/LTR control system using the precompensator is shown in Fig. 16.2.55.

ANALYSIS OF SINGULAR-VALUE PLOTS

Systems with large stability margins, good disturbance rejection/command following, low sensitivity to plant parameter variations, and stability in the presence of model uncertainties are described as being robust and having good robustness properties. The singular-value plots for the PI, LQG, and LQG/LTR control systems are examined to evaluate the robustness properties. The singular-value plots of the return ratio, return difference, and the inverse return difference are shown in Figs. 16.2.56, 16.2.57, and 16.2.58.

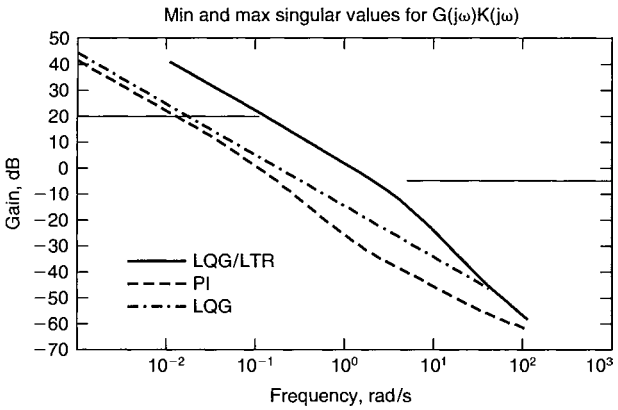

Fig. 16.2.56 Singular-value plots of return ratio.

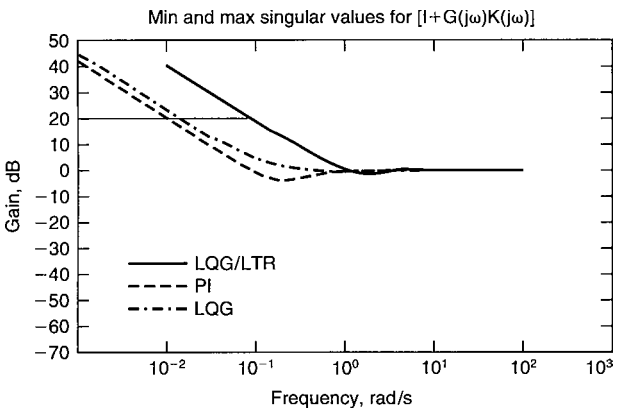

Fig. 16.2.57 Singular-value plots of return difference.

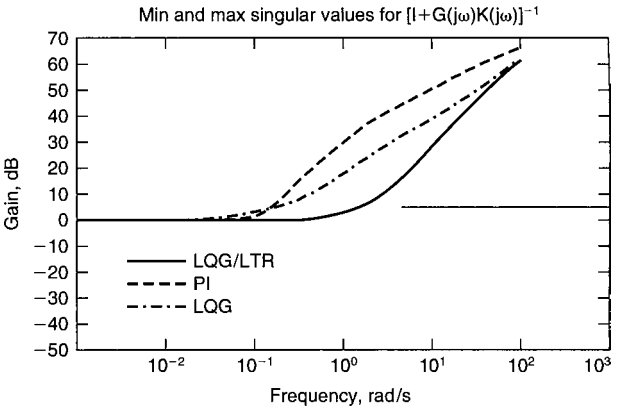

Fig. 16.2.58 Singular-value plots of inverse return difference.

Deaerator Study Summary and Conclusions

Summary of Control System Analysis The design criteria used for analysis in this system is defined as shown in Table 16.2.8. The performance and robustness results summarized from the analysis using the singular-value plots are shown in Table 16.2.9, from which it appears that the LQG/LTR control system has the widest low-frequency range of disturbance rejection and insensitivity to parameter variations. The PI control system has the worst disturbance rejection property and the most sensitivity to parameter variations.

All of the control systems are capable of maintaining a stable robust system in the presence of high-frequency modeling errors, but the PI control system is best. Though all the control systems also have good immunity to noise at frequencies significantly greater than 5 rad/s, the PI control system has the best immunity.

Unlike the other systems, the LQG/LTR control system meets all the design criteria. Its design was obtained in a systematic manner, in contrast to the trial-and-error method used for the LQG control system. The LQG controller design was obtained by shaping the output transient response using the system state weighting matrix, then examining the system's singular-value plots. The PI control system used is simply a

Table 16.2.8 System Design Specifications

System requirements	Range
Good command-following/ disturbance rejection	$\underline{\sigma}[L(j\omega)] > 20$ dB $\forall\, \omega \le 0.1$ rad/s
Good system response to high-frequency modeling error	$\underline{\sigma}(I + [L(j\omega)]^{-1}) \ge \|\|\Delta L\|\| = 5$ dB $\forall\, \omega \le 5$ rad/s
Good insensitivity to parameter variations at low frequencies	$\underline{\sigma}[I + L(j\omega)] \ge 26$ dB for low frequencies
Good immunity to noise, $\omega \ge 5$ rad/s	$\overline{\sigma}(L(j\omega)] \ll 0$ dB for high frequencies

Table 16.2.9 Performance and Robustness Results

System properties	PI control system	LQG control system	LQG/LTR control system
Command following/disturbance	$\underline{\sigma}[L(j\omega)] \ge 20$ dB $\forall\, \omega \le 0.01$ rad/s	$\underline{\sigma}[L(j\omega)] \ge 20$ dB $\forall\, \omega \le 0.017$ rad/s	$\underline{\sigma}[L(j\omega)] \ge 20$ dB $\forall\, \omega \le 0.1$ rad/s
System response to high-frequency modeling error ($\omega \ge 5$ rad/s)	$\underline{\sigma}(I + [L(j\omega)]^{-1}) \ge 43.0$ dB	$\underline{\sigma}(I + [L(j\omega)]^{-1}) \ge 30$ dB	$\underline{\sigma}(I + [L(j\omega)]^{-1}) \ge 16.7$ dB
Insensitivity to parameter variations at low frequencies	$\underline{\sigma}[I + L(j\omega)] \ge 26$ dB $\forall\, \omega \le 0.0055$ rad/s	$\underline{\sigma}[I + L(j\omega)] \ge 26$ dB $\forall\, \omega \le 0.008$ rad/s	$\underline{\sigma}[I + L(j\omega)] \ge 26$ dB $\forall\, \omega \le 0.0055$ rad/s
Immunity to noise ($\omega \ge 5$ rad/s)	$\overline{\sigma}[L(j\omega)] \le -42.5$ dB	$\overline{\sigma}[L(j\omega)] \le -30$ dB	$\overline{\sigma}[L(j\omega)] \le -16$ dB

three-element control system strategy that has previously been used in the simulation study of the deaerator flow control system.

Conclusions It should be evident that performance characteristics such as a suitable transient response do not imply that the system will have good robustness properties. Obtaining suitable performance characteristics and a stable robust system are two separate goals. Classical unity-feedback design methods have been used for transient response shaping, with little consideration for robustness properties. The main advantage of a closed-loop feedback system is that good performance and stability robustness properties are obtainable. As has been shown, transient response shaping can be obtained easily using a precompensator. Therefore it appears that the goal of the control system designer is first to design a stable robust system and then use prefiltering to obtain the desired transient response.

Optimal control methods as demonstrated by the LQG control system do not guarantee good robustness properties when applied systematically to meet minimization requirements of a performance index. Methods such as **pole placement** emphasize transient response characteristics without regard to robustness, which could be detrimental to the system integrity in the presence of model uncertainties.

Classical and Modern Representation of Process Models

A dynamic unsteady state model will be developed for a heated stirred-tank process shown in Fig. 16.2.59. This process is common to the chemical and other industries. This process will be used to show that the classical frequency domain models (Buckley, "Techniques of Process Control," Wiley) presently and previously used in classical control design can also easily be represented in a state differential equation form common for use with the modern control techniques.

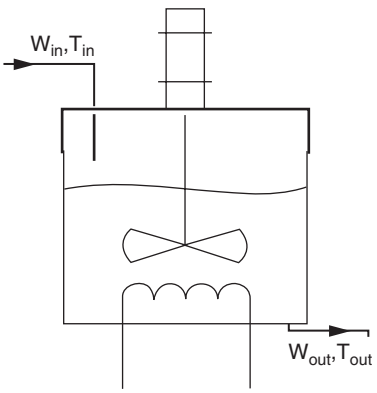

Fig. 16.2.59 Process diagram of heated stirred-tank.

The first step in developing the model is to obtain the system dynamic energy balance as follows

$$C\frac{d[V\rho(T_{out} - T_{tank})]}{dt} = w_{in}C(T_{in} - T_{tank}) - w_{out}C(T_{out} - T_{tank}) + Q \qquad (16.2.145)$$

where T_{in}, T_{out}, and T_{tank} are, respectively, the liquid temperatures in the inlet and outlet lines and the tank for enthalpy calculations (assumed constant). The terms w_{in}, w_{out}, C, V, ρ, and Q are, respectively, the inlet and outlet mass flow rate, the specific heat of the liquid, the tank liquid volume, density, and the heat input to the tank from the electrical heating unit. Equation (16.2.145) defines the rate of energy accumulation for the tank contents.

The dynamic unsteady-state mass balance for the tank contents will now be defined as

$$\frac{d(V\rho)}{dt} = w_{in} - w_{out} \qquad (16.2.146)$$

Equation (16.2.146) gives the rate of mass accumulation of liquid in the tank (Seborg, Edgar, Mellichamp, "Process Dynamics and Control," Prentice-Hall). The simplifying assumptions for this model are that ρ and C are constants for Eqs. (16.2.145) and (16.2.146). Thus it follows that Eq. (16.2.146) becomes

$$\frac{\rho\, dV}{dt} = w_{in} - w_{out} \qquad (16.2.147)$$

and the differentiation of the left-hand side of Eq. (16.2.145) yields

$$C\frac{d[V\rho(T_{out} - T_{tank})]}{dt} = \rho C(T_{out} - T_{tank})\frac{dV}{dt} + V\rho C\frac{d(T_{out} - T_{tank})}{dt} \qquad (16.2.148)$$

Substituting the mass balance relation of Eq. (16.2.147) into Eq. (16.2.148) yields

$$C\frac{d[V\rho(T_{out} - T_{tank})]}{dt} = V\rho C\frac{dT_{out}}{dt} + C(T_{out} - T_{tank})(w_{in} - w_{out}) \qquad (16.2.149)$$

where $dT_{tank}/dt = 0$. Now substituting the right-hand side of Eq. (16.2.149) into the left-hand side of Eq. (16.2.145) yields with simplification

$$V\rho C\frac{dT_{out}}{dt} = C(T_{in} - T_{out})w_{in} + Q \qquad (16.2.150)$$

The resulting equations of the heated stirred-tank process model are

$$\frac{dV}{dt} = (w_{in} - w_{out})/\rho \qquad (16.2.151)$$

$$V\rho C\frac{dT_{out}}{dt} = C(T_{in} - T_{out})w_{in} + Q \qquad (16.2.152)$$

where Eq. (16.2.152) is nonlinear.

This set of equations gives the flexibility to define various operating conditions for the heated stirred-tank process. Next we will formulate the classical and modern representation for the process model that can be used for control system design.

Linearization of the Nonlinear Model

Typical classical and more of the popular modern control techniques of control system design use linear process models. Equation (16.2.152) above is nonlinear. We must make some assumptions to obtain a linear equation model. The assumptions are: the process has a constant liquid volume and the inlet and outlet flow rates are equal and constant ($w = w_{in} = w_{out}$). The initial steady-state conditions of the heated stirred-tank process at time $t = 0$ are assumed as follows: $T_{outi} = T_{out}(0)$, $T_{ini} = T_{in}(0)$, and $Q_{int} = Q(0)$.

Considering that the dynamic components of the system variables are more important for the control system designer, the initial steady-state component will be subtracted from the process variables. Applying this normalization to Eq. (16.2.152) yields the following perturbation model equation

$$V\rho C\frac{d(T_{out} - T_{outi})}{dt} = C[(T_{in} - T_{ini}) - (T_{out} - T_{outi})]w_{in} + (Q - Q_{int}) \qquad (16.2.153)$$

Let us define $\delta T_{in} = T_{in} - T_{ini}$, $\delta T_{out} = T_{out} - T_{outi}$, and $\delta Q = Q - Q_{int}$. Therefore Eq. (16.2.153) becomes

$$\tau\frac{d(\delta T_{out})}{dt} = \delta T_{in} - \delta T_{out} + \delta Q/Cw \qquad (16.2.154)$$

where $\tau = V\rho/w$ and Eq. (16.2.154) is a linear perturbed differential equation describing the dynamics of the heated stirred-tank process.

Classical Transfer Function Model

Equation (16.2.154) can be used to obtain the frequency domain process transfer function. Let's assume that at time $t = 0$, $\delta T_{out} = 0$, and the inlet temperature is constant [$\delta T_{in}(t) = T_{in}(t) - T_{ini}(0) = 0$, for $t \geq 0$]. Thus Eq. (16.2.154) becomes

$$\tau \frac{d(\delta T_{out})}{dt} = -\delta T_{out} + \frac{\delta Q}{Cw} \tag{16.2.155}$$

and, taking the Laplace transform and simplifying, the heated stirred-tank transfer function is found to be

$$\frac{\delta T_{out}(s)}{dQ(s)} = \frac{1}{Cw(\tau s + 1)} \tag{16.2.156}$$

Assuming δQ, the input heat, makes a step change from $\delta Q = Q - Q_{int}$, where $Q = Q_{int}$, to $\delta Q = Q - Q_{int}$, where $Q = \Delta Q + Q_{int}$ at $t = 0$, then for $t \geq 0$, $\delta Q = \Delta Q$. For these conditions the heated stirred-tank transfer function now becomes

$$\delta T_{out}(s) = \frac{\Delta Q}{Cw(\tau s + 1)(s)} \tag{16.2.157}$$

A general block diagram of the perturbed transfer function process model using Eq. (16.2.156) with closed-loop feedback to control the output temperature is shown in Fig. 16.2.60.

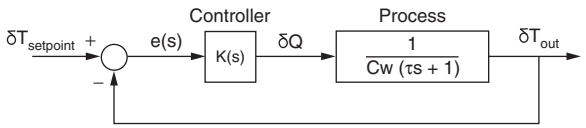

Fig. 16.2.60 Block diagram for heated stirred-tank closed-loop temperature feedback control using process transfer function.

Modern State Differential Equation Process Model

The state differential equation typically used in modern control for the process model takes the general form of

$$\dot{\boldsymbol{x}}(t) = \mathbf{A}x(t) + \mathbf{B}u(t) \tag{16.2.158}$$

$$\boldsymbol{y}(t) = \boldsymbol{C}x(t) \tag{16.2.159}$$

The perturbed state differential equation is easily obtained for the heated stirred-tank process by using Eq. (16.2.155), resulting in

$$\dot{\delta}T_{out} = [-1/\tau]\delta T_{out} + [1/\tau Cw]\delta Q \tag{16.2.160}$$

where $\mathbf{A} = -1/\tau$, $\mathbf{B} = 1/\tau Cw$, $\dot{\boldsymbol{x}} = \dot{\delta}T_{out}$, $\boldsymbol{x} = \delta T_{out}$, $\boldsymbol{u} = \delta Q$, $\boldsymbol{C} = 1$, and $\boldsymbol{y} = \delta T_{out}$. A block diagram of the process model using Eq. (16.2.160) with closed-loop feedback to control the output temperature is shown in Fig. 16.2.61.

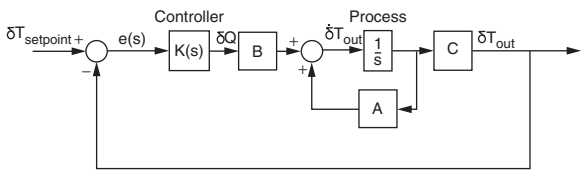

Fig. 16.2.61 Block diagram for heated stirred-tank closed-loop temperature feedback control using state differential equations.

Conclusion

This heated stirred-tank example provides a detailed look at the derivation of the process transfer function and the process differential equation that would be used, respectively, for the frequency domain classical and modern control system design methods. It is clear that obtaining the linearized process model is a crucial step in this process. It should be noted that obtaining the transfer function model is an easy step from the state differential equation used in modern control system design. Finally, it should be observed that the time constant obtained during this example is directly related to the design properties of the process. Therefore it is clear that the best control engineer cannot overcome any inherent characteristic of the process that limits, for instance, the desire for a fast process response. This makes a clear argument for the need to include the control engineer in the initial design efforts for a new process or the modification of an existing process to ensure the desired system performance is obtained in the final process.

TECHNOLOGY REVIEW

Fuzzy Control

Fuzzy controllers are a popular method for construction of simple control systems from **intuitive knowledge of a process.** They generally take the form of a set of IF . . . **THEN** . . . rules, where the conditional parts of the rules have the structure "Variable *i* is <fuzzy value 1> AND Variable *j* is <fuzzy value 2> . . . . " Here the <fuzzy value> refers to a **membership function,** which defines a range of values in which the variable may lie and a number between zero and one for each element of that range specifying the possibility (where certainty is one) that the variable takes that value. Most fuzzy control applications use an **error signal** and the rate of change of an error signal as the two variables to be tested in the conditionals.

The actions of the rules, specified after THEN, take a similar form. Because only a finite collection of membership functions is used, they can be named by mnemonics which convey meaning to the designer. For **example,** a fuzzy controller's rule base might contain the following rules:

IF temperature-error is high and temperature-error-rate is slow
THEN fuel-rate is negative.
IF temperature-error is zero and temperature-error-rate is slow
THEN fuel-rate is zero.

Fuzzy controllers are an attractive control design approach because of the ease with which fuzzy rules can be interpreted and can be made to follow a designer's **intuitive knowledge** regarding the control structure. They are inherently nonlinear, so it is easy to incorporate effects which mimic variable gains by adjusting either the rules or the definitions of the membership functions. Fuzzy controller technology is attractive, in part because of its intuitive appeal and its **nonlinear nature,** but also because of the frequent claim that fuzzy rules can be utilized to approximate arbitrary continuous functional relationships. While this is true, in fact it would require substantial complexity to construct a fuzzy rule base to mimic a desired function sufficiently well for most engineers to label it an approximation. Herein also lie the potential liabilities of fuzzy controller technology: there is very little theoretical guidance on how rules and membership functions should be specified. Fuzzy controller design is an **intuitive process;** if intuition fails the designer, one is left with very little beyond trial and error.

One remedy for this situation is the use of machine, or **automated learning technology** to **infer** fuzzy controller **rules** from either collected data or simulation of a process model. This process is inference, rather than deductive reasoning, in that proper operation of the controller is **learning by example,** so if the examples do not adequately describe the process, problems can occur. This inference process, however, is quite similar to the methods of system identification, which also infer model structure from examples, and which is an accepted method of model construction. Machine learning technology enables utilization of more complex controller structures as well, which introduce additional degrees of freedom in the design process but also enhance the capabilities of the controller. One **example** of this approach is the **Fuzzy PID controller** structure (Wang and Birdwell), which utilizes a fuzzy rule base to generate gains for a PID controller. Other similar approaches have been reported in the literature. An advantage of this approach is the ability to establish theoretical results on closed-loop stability, which are otherwise lacking for fuzzy controllers.

Signal Validation Technology

Continuous monitoring of instrument channels in a process industry facility serves many purposes during plant operation. In order to achieve the desired operating condition, the system states must be measured accurately. This may be accomplished by implementing a **reliable signal validation procedure** during both normal and transient operations. Such a system would help reduce challenges on control systems, **minimize plant downtime,** and help plan maintenance tasks. Examples of measurements include pressure, temperature, flow, liquid level, electrical parameters, machinery vibration, and many others. The performance of control, safety, and plant monitoring systems depends on the accuracy of signals being used in these systems. Signal validation is defined as the detection, isolation, and characterization of faulty signals. This technique must be applicable to systems with redundant or single sensor configuration.

Various methods have been developed for signal validation in aerospace, power, chemical, metals, and other process industries. Most of the early development was in the aerospace industry. The signal validation techniques vary in complexity depending on the level of information to be extracted. Both **model-based** and **direct data-based techniques** are now available. The following is a list of **techniques** often implemented for signal validation:

Consistency checking of redundant sensors
Sequential probability ratio testing for incipient fault detection
Process empirical modeling (static and dynamic) for state estimation
Computational neural networks for state estimation
Kalman filtering technique for state estimation in both linear and nonlinear systems
Time-series modeling techniques for sensor response time estimation and frequency bandwidth monitoring

PC-based signal validation systems (Upadhyaya, 1989) are now available and are being implemented on-line in various industries. The computer software system consists of one or more of the above signal processing modules, with a decision maker that provides sensor status information to the operator.

An example of **signal validation** (Upadhyaya and Eryurek) in a power plant is the monitoring of water level in a steam generator. The objective is to estimate the water level using other related measurements and compare this with the measured level. An empirical model, a neural network model, or the Kalman filtering technique may be used. For example, the inputs to an empirical model consist of steam generator main feedwater flow rate, steam generator pressure, and inlet and outlet temperatures of the primary water through the steam generator. Such a model would be developed during normal plant operation, and is generally referred to as the *training phase.* The signal estimation models should be updated according to the plant operational status. The use of multiple signal validation modules provides a high degree of confidence in the results.

Chaos

Recent advances in dynamical process analysis have revealed that nonlinear interactions in simple deterministic processes can often result in highly complex, aperiodic, sometimes apparently "random" behavior. Processes which exhibit such behavior are said to be exhibit *deterministic chaos.* The term *chaos* is perhaps unfortunate for describing this behavior. It evokes images of purely erratic behavior, but this phenomenon actually involves highly structured patterns. It is now recognized that deterministic chaos dominates many engineering systems of practical interest, and that, in many cases, it may be possible to exploit previously unrecognized deterministic structure for improved understanding and control.

Deterministic chaos and nonlinear dynamics both apply to phenomena that arise in process equipment, motors, machinery, and even control systems as a result of nonlinear components. Since nonlinearities are almost always present to some extent, nonlinear dynamics and chaos are the rule rather than the exception, although they may sometimes occur to such a small degree that they can be safely ignored. In many cases, however, nonlinearities are sufficiently large to cause significant changes in process operation. The effects are typically seen as unstable operation and/or apparent noise that is difficult to diagnose and control with conventional linear methods. These instabilities and noise can cause reduced operating range, poor quality, excessive downtime and maintenance, and, in worst cases, catastrophic process failure.

The apparent erratic behavior in chaotic processes is caused by the extreme sensitivity to initial conditions in the system, introduced by nonlinear components. Though the system is deterministic, this sensitivity and the inherent uncertainty in the initial conditions make long-term predictions impossible. In addition, small external disturbances can cause the process to behave in unexpected ways if this sensitivity has not been considered. Conversely, if one can learn how the process reacts to small perturbations, this inherent sensitivity can be taken advantage of. Once the system dynamics are known, small changes in system parameters can be used to drive the system to a desired state and to keep it there. Thus, great effects can be achieved through minimal input. Various control algorithms have been developed that use this principle to achieve their goals. A recent example from engineering is the control of a slugging fluidized bed by Vasadevan et al.

The following example illustrates the use of chaos analysis and control which involves a laboratory fluidized-bed experiment. Several recent studies have recognized that some modes of fluidization in fluidized beds can be classified as deterministic chaos. These modes involve large-scale cyclic motions where the mass of particles move in a pistonlike manner up and down in the bed. This mode is usually referred to as *slugging* and is usually considered undesirable because of its inferior transfer properties. Slugging is notoriously difficult to eradicate by conventional control techniques. Vasadevan et al. have shown that the inherent sensitivity to small perturbations can be exploited to alleviate the slugging problem. They did this by adding an extra small nozzle in the bed wall at the bottom of the bed. The small nozzle injected small pulses of process gas into the bed, thus disrupting the "normal" gas flow. The timing of the pulses was shown to be crucial to achieve the desired effect. Different injection timing caused the slugging behavior to be either enhanced or destroyed.

16.3 SURVEYING

by W. David Teter

Kissam, "Surveying for Civil Engineers," McGraw-Hill. Anderson and Mikhail, "Introduction to Surveying," McGraw-Hill. McCormac, "Surveying Fundamentals," Prentice-Hall.

INTRODUCTION

Surveying is often defined as the art and science of measurement for location or establishment of position above, on, or beneath the earth's surface. The principles of surveying practice have remained consistent from their earliest inception, but in recent years the equipment and technology have changed rapidly. The emergence of the total station device, electronic distance measurements (EDM), Global Positioning System (GPS), and geographic information systems (GIS) is of significance in comparing modern surveying to past practice.

The information required by a surveyor remains basically the same and consists of the measurement of direction (angle) and distance, both horizontally and vertically. This requirement holds regardless of the type of survey such as land boundary description, topographic, construction, route, or hydrographic.

HORIZONTAL DISTANCE

Most surveying and engineering measurements of distance are horizontal or vertical. Land measurement referenced to a map or plat is reduced to horizontal distance regardless of the manner in which the field measurements are made.

The methods and devices used by the surveyor to measure distance include pacing, odometers, tachometry (stadia), steel tape, and electronic distance measurement. These methods produce expected precision ranging from ±2 percent for pacing to +0.0003 percent for EDM. The surveyor must be aware of the necessary precision for the given application.

Tapes

Until the advent of EDM technology, the primary distance-measuring instrument was the steel tape, usually 100 ft or 30 m (or multiples) in length, with 1 ft or 1 dm on the end graduated to read with high precision (0.01 ft or 1 mm). Cloth tapes can be used when low precision is acceptable.

Corrections Measurements with a steel tape are subject to variations that normally must be corrected for when high precision is required. Tapes are manufactured to a standard length at usually 68°F (20°C), for a standard pull of between 10 and 20 lb (4.5 and 9 kg), and supported over the entire length. The specifications for the tape are provided by the manufacturer. If any of the conditions vary during field measurement, corrections for temperature, pull, and sag will have to be made according to the manufacturer's instructions.

Tape Use Most surveying measurements are made with reference to the horizontal, and if the terrain is level, involves little more than laying down the tape in a sequential manner to establish the total distance. Care should be taken to measure in a straight line and to apply constant tension. When measuring on a slope, either of two methods may be employed. In the first method, the tape is held horizontal by raising the low end and employing a plumb bob for location over the point. In cases of steep terrain a technique known as *breaking tape* is used, where only a portion of the total tape length is used. With the second method, the slope distance is measured and converted by trigonometry to the horizontal distance. In Fig. 16.3.1 the horizontal distance $D = S \cos(\alpha)$ where S is the slope distance and α is the slope angle which must be estimated or determined.

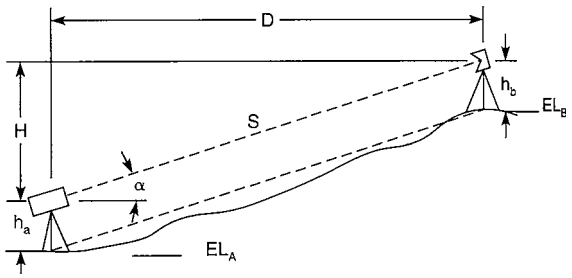

Fig. 16.3.1 Slope-reduction measurements used with EDM devices.

Electronic Distance Measurement

Modern surveying practice employs EDM technology for precise and rapid distance measurement. A representation of an EDM device is shown in Fig 16.3.2. The principle of EDM is based on the comparison of the modulated wavelength of an electromagnetic energy source (beam) to the time required for the beam to travel to and return from a

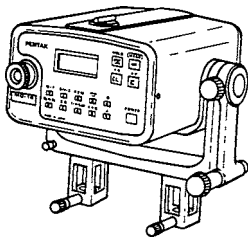

Fig. 16.3.2 Electronic distance meter (EDM). *(PENTAX Corp.)*

point at an unknown distance. The EDM devices may be of two types: (1) electrooptical devices employing light transmission within or just beyond the visible region or (2) devices transmitting in the microwave spectrum. Electrooptical devices require an active transmitter and a passive reflector, while microwave devices require an active transmitter and an identical unit for reception and retransmission at the endpoint of the measured line. Ideally the EDM beam would propagate at the velocity of light; however, the actual velocity of propagation is affected by the index of refraction of the atmosphere. As a result, the atmospheric conditions of temperature, pressure, and humidity must be monitored in order to apply corrections to the measurements. Advances in electrooptical technology have made microwave devices, which are highly sensitive to atmospheric relative humidity, nearly obsolete.

Atmospheric Corrections EDM devices built prior to about 1982 require a manual computation for atmospheric correction; however, the more modern instruments allow for keystroke entry of values for temperature and pressure which are processed and applied automatically as a correction for error to the output reading of distance. The relationships between temperature, pressure, and error are shown in Fig. 16.3.3. Microwave devices require an additional correction for relative humidity. A psychrometer wet-dry bulb temperature difference of 3°F (2°C) causes an error of about 0.001 percent in distance measurement.

Instrument Corrections Electrooptical devices may also be subject to error attributed to *reflector constant.* This results from the physical center of the reflector not being coincident with the effective or optical center. The error can range to 30 or 40 mm and is unique, but is usually known, for each reflector. The older EDM devices required this value to

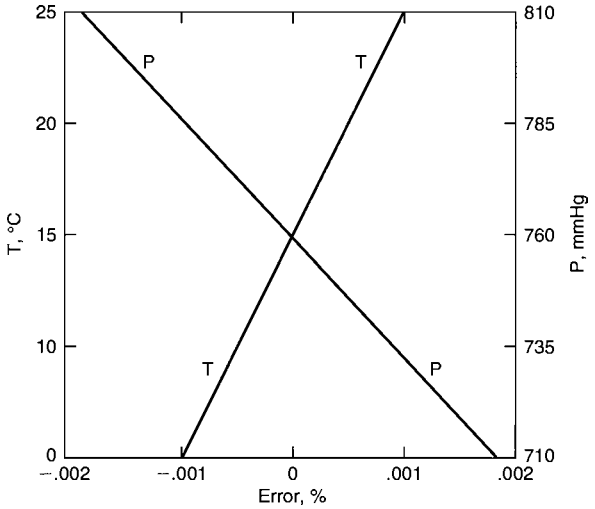

Fig. 16.3.3 Relationship of error to atmospheric pressure and temperature.

be subtracted from each reading, but in more modern devices the reflector constant can be preset into the instrument and the compensation occurs automatically. Finally, microwave EDM devices are subject to error from ground reflection which is known as *ground swing.* Care must be taken to minimize this effect by deploying the devices as high as possible and averaging multiple measurements.

EDM Field Practice Practitioners have developed many variations in employing EDM devices. Generally the field procedures are governed by the fact that the distance readout from the device is a slope measurement which must be reduced to the horizontal equivalent. Newer EDM devices may allow for automatic reduction by keystroke input of the vertical angle, if known, as would be the case when the EDM device is employed with a theodolite or if the device is a total station (see later in the section). Otherwise the slope reduction can be accomplished by using elevation differences. With reference to Fig. 16.3.1, it is seen that $H = (\mathrm{EL}_A + h_a) - (\mathrm{EL}_B + h_b)$ and that the horizontal distance $D = (S^2 - H^2)^{1/2}$. EDM devices are sometimes mounted on a conventional theodolite. In such cases the vertical angle as measured by the theodolite must be adjusted to be equivalent to the angle seen by the EDM device. It is common to sight the theodolite at a point below the reflector equal to the vertical distance between the optical centers of the theodolite and the EDM device.

VERTICAL DISTANCE

The acquisition of data for vertical distance is also called **leveling.** Methods for the determination of vertical distance include direct measurement, tachometry or stadia leveling, trigonometric leveling, and differential leveling. Direct measurement is obvious, and stadia leveling is discussed later.

Trigonometric Leveling This method requires the measurement of the vertical angle and slope distance between two points and is illustrated in Fig. 16.3.1. The vertical distance $H = S \sin(\alpha)$. A precise value for the vertical angle and slope distance will not be obtained if the EDM device is mounted on the theodolite or the instrument heights h_a and h_b are not equal. See "EDM Field Practice," above. Before the emergence of EDM devices, the slope distance was simply taped and the vertical angle measured with a theodolite or transit.

If the elevation of an inaccessible point is required, the EDM reflector cannot be placed there and a procedure employing two setups of a transit or theodolite may be used, as shown in Fig. 16.3.4. Angle $Z_3 = Z_1 - Z_2$, and the application of the law of sines shows that distance $A/\sin Z_2 = C/\sin Z_3$. C is the measured distance between the two instrument setups. The vertical distance $H = A \sin Z_1$. The height of the stack above

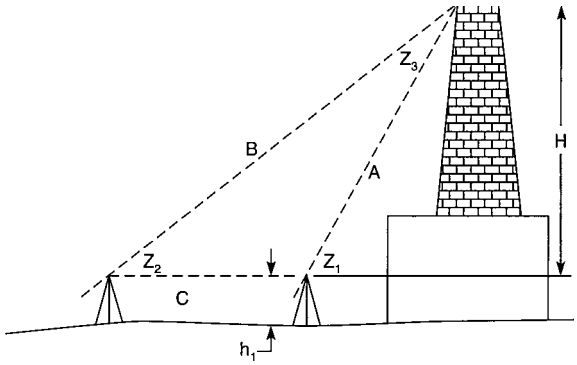

Fig. 16.3.4 Determination of elevation of an inaccessible point.

the instrument point is equal to $H + h_1$, where h_1 is the height of the instrument.

Differential Leveling This method requires the use of an instrument called a **level,** a device that provides a horizontal line of sight to a rod graduated in feet or metres. Figure 16.3.5 shows a vintage level, and Fig. 16.3.6 shows a modern "automatic" level. The difference is that with the older device, four leveling screws are used to center the spirit-level bubble in two directions so that the instrument is aligned with the horizontal. The modern device adjusts its own optics for precise levelness once the three leveling screws have been used to center the rough-leveling/circular level bubble within the scribed circle. The instrument legs should be planted on a firm footing. The eyepiece is checked and adjusted to the user's eye for clear focus on the crosshairs, and the objective-lens focus knob is used to obtain a clear image of the graduated rod.

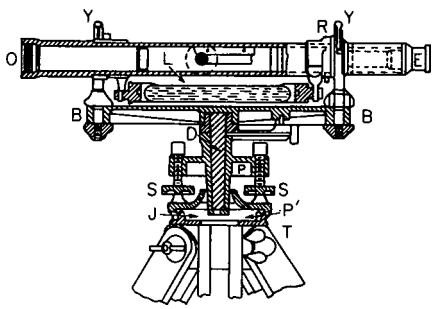

Fig. 16.3.5 Y level.

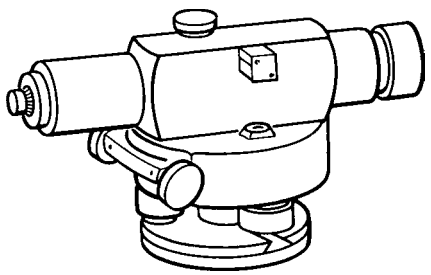

Fig. 16.3.6 Automatic (self-adjusting) level.

To determine the difference in elevation between two points, set the level nearly midway between the points, hold a rod on one, look through the level and see where the line of sight, as defined by the eye and horizontal cross wire, cuts the rod, called **rod reading.** Move the rod to the second point and read. The difference of the readings is the difference in level of the two points. If it is impossible to see both points from a single setting of the level, one or more intermediate points, called

turning points, are used. The readings taken on points of known or assumed elevation are called **plus sights,** those taken on points whose elevations are to be determined are called **minus sights.** The elevation of a point plus the rod readings on it gives the elevation of the line of sight; the elevation of the line of sight minus the rod reading on a point of unknown elevation gives that elevation. In Fig. 16.3.7, I_1 and I_2 are intermediate points between *A* and *B*. The setups are numbered. Assuming *A* to be of known elevation, the reading on *A* is a + sight; the reading on I_1 from 1 is a – sight; the reading on I_1 from 2 is a + sight and on I_2 is a – sight. The algebraic sum of the plus and minus sights is the difference of elevation between *A* and *B*. Target rods can usually be

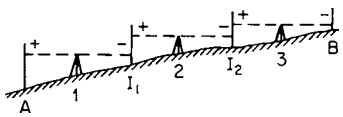

Fig. 16.3.7 Determining elevation difference with intermediate points.

read by vernier to thousandths of a foot. In grading work the nearest tenth of a foot is good; in lining shafting the finest possible reading is none too good. It is desirable that the sum of the distances to the plus sights approximately equal the sum of the distances to the minus sights to ensure compensation of errors of adjustment. On a side hill this can be accomplished by zigzagging. When the direction of pointing is changed, the position of the level bubble should be checked. In the case of a vintage instrument, the bubble should be adjusted back to a centered position along the spirit level. An automatic level requires the bubble to be repositioned within the centering circle.

To Make a Profile of a Line **A benchmark** is a point of reasonably permanent character whose elevation above some surface—such as sea level—is known or assumed and used as a reference point for elevation. The level is set up either on or a little off the line some distance—not more than about 300 ft (90 m)—from the starting point or a convenient benchmark (BM), as at *K* in Fig. 16.3.8. A reading is taken on the BM and added to the known or assumed elevation to get the height of the instrument, called HI. Readings are then taken at regular intervals (or **stations**) along the line and at such irregular points as may be necessary to show change of slope, as at *B* and C between the regular points. The regular points are marked by stakes previously set "on line" at distances of 100 ft (30 m), 50 ft (15 m), or other distance suitable to the character of

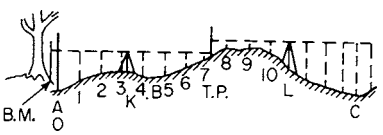

Fig. 16.3.8 Making a profile.

the ground and purpose of the work. When the work has proceeded as far as possible—not more than about 300 ft (90 m) from the instrument for good work—a **turning point** (TP) is taken at a regular point or other convenient place, the instrument moved ahead and the operation continued. The first reading on the BM and the first reading on a TP after a new setup are plus sights (+S); readings to points along the line and the first reading on a TP to be established are minus sights (−S).

The **notes** are taken in the form shown in Fig. 16.3.9. The elevation of a given point, both sights taken on it, and the HI determined from it all appear on a line with its station (Sta) designation. In plotting the **profile,** the vertical scale is usually exaggerated from 10 to 20 times.

Inspection and Adjustment of Levels Leveling instruments are subject to maladjustment through use and should be checked from time to time. Vintage instruments require much more attention than modern devices. Generally, the devices should be checked for verticality of the crosshair, proper orientation of the leveling bubble, and the optical line of sight. The casual user would normally not attempt to physically adjust an instrument, but should be familiar with methods for inspection for maladjustment as follows.

1. *Verticality of crosshair.* Set up the level and check for coincidence of the vertical crosshair on a suspended plumb line or vertical corner of a building. The crosshair ring must be rotated if this condition is not satisfied. This test applies to all types of instruments.

2. *Alignment of the bubble tube.* This check applies to older instruments having a spirit level. In the case of a Y level, the instrument is carefully leveled and the telescope removed from the Ys and turned end for end. In the case of a dumpy level, the instrument is carefully leveled and then rotated 180°. In each case, if the bubble does not remain centered in the new position, the bubble tube requires adjustment.

3. *Alignment of the circular level.* This check applies to tilting levels and modern automatic levels equipped with a circular level consisting of a bubble to be centered within a scribed circle. The instrument is carefully adjusted to center the bubble within the leveling circle and then rotated through 180°. If the bubble does not remain centered, adjustment is required.

4. *Line of sight coincident with the optical axis.* This check (commonly called the *two-peg* test) applies to all instruments regardless of construction. The check is performed by setting the instrument midway between two graduated rods and taking readings on both. The instrument is then moved to within 6 ft of one of the rods, and again readings are taken on both. The difference in readings should agree with the first set. If they do not, an adjustment to raise or lower the crosshair is necessary.

ANGULAR MEASUREMENT

The instruments used for measurement of angle include the transit (Fig. 16.3.10), the optical theodolite, and the electronic total station (Fig. 16.3.11). Angular measurements in both horizontal and vertical planes are obtained with the quantitative value derived in one of three

ways depending on the era in which the instrument was manufactured. In principle, the effective manner in which these devices operate is shown in Fig. 16.3.12. The graduated outer circle is aligned at zero with the inner-circle arrow, and an initial point *A* is sighted on. Then, with the outer circle held fixed by means of clamps on the instrument, the

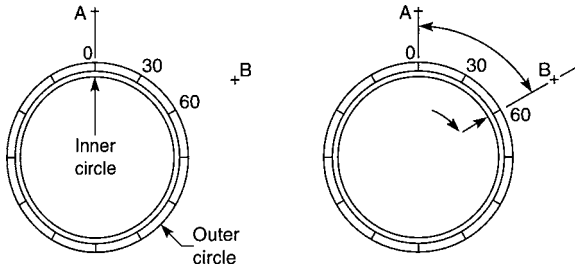

Fig. 16.3.12 Use of graduated circles to measure the angles between points.

inner circle (with pointer and moving with the telescope) is rotated to a position for sighting on point *B*. The relative motion between the two circles describes the direction angle which is read to precision with the aid of the scale's vernier. In the actual case, only the transit operates in the mechanical manner described. The operation of an optical theodolite occurs internally with the user viewing internal scales that move relative to each other. Many optical theodolites have scale microscopes or scale micrometres for precise reading. The electronic total station (discussed later) is also dependent on internal optics, but in addition it gives its angle values in the form of a digital display.

Examination of these devices reveals the presence of an *upper clamp* (controlling the movement of the inner circle described before) and a *lower clamp* (controlling the movement of the outer circle). Both clamps have associated with them a *tangent* screw for very fine adjustment. Setting up the instrument involves leveling the device and, unlike the procedure with a level, locating the instrument exactly over a particular point (the apex of the angle). This is accomplished with a suspended plumb (in the case of older transits) or an optical (line-of-sight) plummet in modern instruments. Prior to any measurement the clamps are manipulated so as to zero the initial angular reading prior to turning the angle to be read. In the case of the digital output total station, the initial angular reading is zeroed by pushing the zero button on the display. A total station, in effect, has only one motion clamp.

Angle Specification Figure 16.3.13 shows several ways in which direction angles are expressed. The angle describing the direction of a line may be expressed as a **bearing,** which is the angle measured east or west from the north or south line and not exceeding 90°, e.g.: N45°E, S78°E, N89°W. Another system for specifying direction is by **azimuth** angle. Azimuths are measured clockwise from north (usually) up to 360°. Still other systems exist where direction is expressed by angle to the right (or left), deflection angles, or interior angles.

To Produce a Straight Line Set up the instrument over one end of the line; with the lower motion clamp and tangent screw bring the telescopic line of sight to the other end of the line marked by a flag, a pencil, a pin, or other object; transit the telescope, i.e., plunge it by revolving on its horizontal axis, and set a point (drive a stake and "center" it with a tack or otherwise) a desired distance ahead in line with the telescopic line of sight; loosen the lower motion clamp and turn the instrument in azimuth until the line of sight can be again pointed to the other end of the line; again transit and set a point beside the first point set. If the instrument is in adjustment, the two points will coincide; if not, the point marking the projection of the line lies midway between the two established points.

To Measure a Horizontal Angle Set up the instrument over the apex of the angle; with the lower motion bring the line of sight to a distant point in one side of the angle; unclamp the upper motion and bring the line of sight to a distant point in the second side of the angle, clamp and set exactly with the tangent screw; read the angle as displayed using scale micrometre or vernier if required.

To Measure a Vertical Angle Set up the instrument over a point marking the apex of the angle *A* (see Fig. 16.3.14) by the lower motion and the motion of the telescope on its horizontal axis, bring the intersection of the vertical and horizontal wires of the telescope in line with a point as much above the point defining the lower side of the angle as

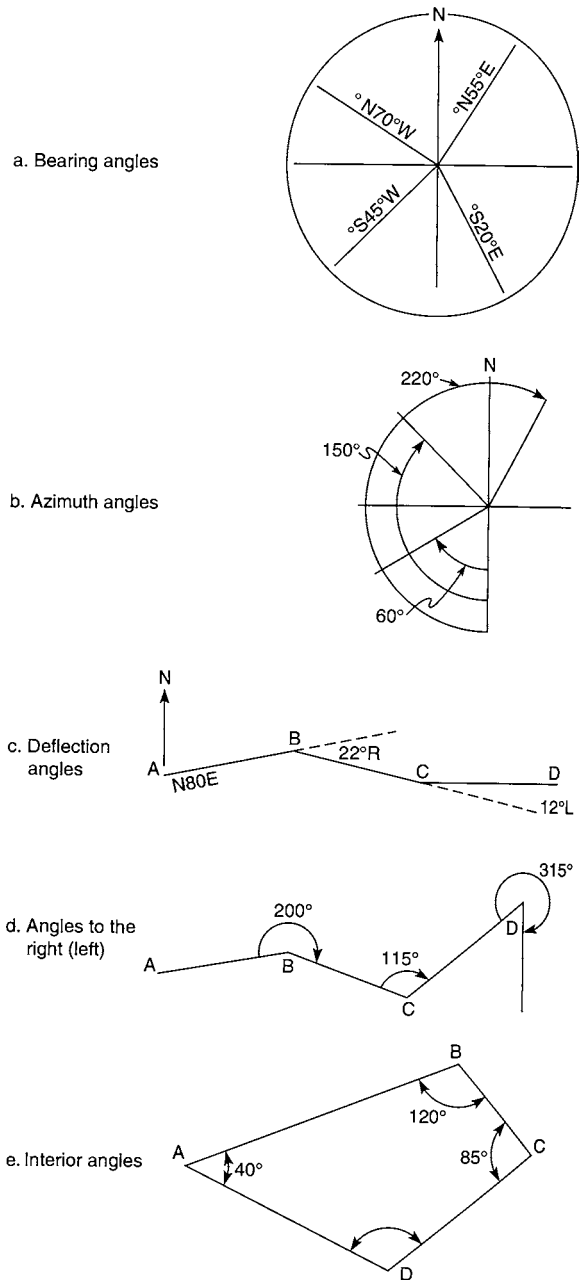

Fig. 16.3.13 Diagram showing various methods of specifying direction angles.

the telescope is above the apex; read the vertical angle, turn the telescope to a point which is the height of the instrument above the point marking the upper side of the angle and read the vertical angle. How to combine the readings to find the angle will be obvious.

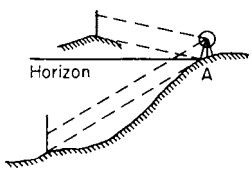

Fig. 16.3.14 Measuring a vertical angle.

To Run a Traverse A traverse is a broken line marking the line of a road, bank of a stream, fence, ridge, or valley, or it may be the boundary of a piece of land. The bearing or azimuth and length of each portion of the line are determined, and this constitutes "running the traverse."

To Establish Bearing The bearing of a line may be specified relative to a north-south line (meridian) that is true, magnetic, or assumed, and whose angle is less than 90°. Whatever the reference meridian, the instrument is set over one end of the line, and the horizontal angle readout is set to zero with the instrument pointing in the direction of the north-south meridian. This is shown in Fig. 16.3.12 when point *A* is in the direction of the meridian (north). Using appropriate clamps, the angle is turned by pointing the telescope to the other end of the desired line. In Fig. 16.3.12 the bearing angle would be N60°E. Note that modern electron total stations generally do not have a magnetic needle and, as a result, the bearings or azimuths are typically measured relative to an arbitrary (assumed) meridian.

To establish azimuth the same procedure as described for the determination of bearing may be used. An azimuth may have values up to 360°. When the preceding line of a traverse is used to orient the instrument, the azimuth of this line is known as the **back azimuth** and its value should be set into the instrument as it is pointed along the preceding line of the traverse. The telescope is turned clockwise to the next line of the traverse to establish the **forward azimuth.**

In traverse work, azimuths and bearings are not usually measured except for occasional checks. Instead, deflection angles or angles to the right from one course to the next are measured. The initial line (course) is taken as an assumed meridian, and the bearings or azimuths of the other courses with respect to the initial course are calculated. The calculations are derived from the measured deflection angles or angles to the right. If the magnetic or true meridian for the initial course is determined, then the derived bearings or azimuths can likewise be adjusted.

In Fig. 16.3.15, the bearing of *a* is N40°E, of *b* is N88° 30′E, of *c* is S49°20′E = 180° − (40° + 48°30′ + 42°10′), of *d* is S36°40′W = 86° − 49°20′, or 40° + 48°30′ + 42°10′ + 86° − 180°, of *e* is N81°20′W = 180° − (36°40′ + 62°). No azimuths are shown in Fig. 16.3.15, but note that the azimuth of *a* is 40° and the back azimuth of *a* is 220° (40° + 180°). The azimuths of *b* and *c* are 88°30′ and 130°40′ respectively.

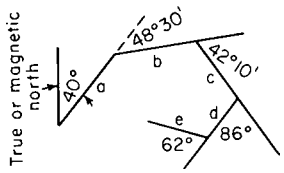

Fig. 16.3.15 Bearings derived from measured angles.

Inspection and Adjustment of the Instrument The transit, optical theodolite, and total station devices are subject to maladjustment through use and should be checked from time to time. Regardless of the type of instrument, the basic relationships that should exist are (1) the plate level-bubble tubes must be horizontal, (2) the line of sight must be perpendicular to the horizontal axis, (3) the line of sight must move in the vertical plane, (4) the bubble (if there is one) of the telescope tube must be centered when the scope is horizontal, and (5) the reading of vertical angles must be zero when the instrument is level and the telescope is level.

All modern devices are subject to the following checks: (1) adjustment of the plate levels, (2) verticality of the crosshair, (3) line of sight perpendicular to the horizontal axis of the telescope, (4) the line of sight must move in a vertical plane, (5) the telescope bubble must be centered (two-peg test), (6) the vertical circle must be indexed, (7) the circular level must be centered, (8) the optical plummet must be vertical, (9) the reflector constant should be verified, (10) the EDM beam axis and the line of sight must be closely coincident, and (11) the vertical and horizontal zero points should be checked.

To Measure Distances with the Stadia In the transit and optical theodolite telescope are two extra horizontal wires so spaced (when fixed by the maker) that they are 1/100 of the focal length of the objective apart. When looking through the telescope at a rod held in a vertical position, 100 times the rod length S intercepted between the two extra horizontal wires plus an instrumental constant C is the distance D from the center of the instrument to the rod if the line of sight is horizontal, or $D = 100S + C$ (see Fig. 16.3.16). If the line of sight is inclined by a vertical angle A, as in Fig. 16.3.17, then if S is the space intercepted on the rod and C is the instrumental constant, the distance is given by the formula $D = 100S \cos^2 A + C \cos A$. For angles less than 5 or 6°, the distance is given with sufficient exactness by $D = 100S$. Although theory would indicate that distances can thus be determined to within 0.2 ft, in practice it is not well to rely on a precision greater than the nearest foot for distances of 500 ft or less.

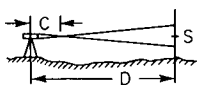

Fig. 16.3.16 Horizontal stadia measurement.

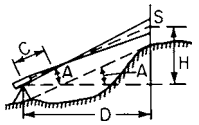

Fig. 16.3.17 Sloping stadia measurement.

Only the oldest transits, known as *external-focusing devices,* have an instrument constant. They can be recognized by noting that the objective lens will physically move as the focus knob is turned. Such devices have not been manufactured for at least 50 years, and therefore it is most probable that, for stadia applications, the value of $C = 0$ should be used in the equations. Likewise, it is certain that the stadia interval factor K in the following equation will be exactly 100. Stadia surveying falls into the category of low-precision work, but in certain cases where low precision is acceptable, the speed and efficiency of stadia methods is advantageous.

Stadia Leveling This method is related to the previously described trigonometric leveling. The elevation of the instrument is determined by sighting on a point of known elevation with the center crosshair positioned at the height of the instrument (HI) at the setup position. Record the elevation angle A from the setup point to the distant point of known elevation, read the rod intercept S, and apply the following equation to determine the difference in elevation H between the known point and the instrument:

$$H = KS \cos A \sin A + C \sin A$$

Since K is sure to be equal to 100 and that the stadia constant C for most existing instruments will be equal to zero, the value of H is easily determined and the elevation of the instrument HI is known. With known HI, sights can now be performed on other points and the above equation applied to determine the elevation differences between the instrument and the selected points. Note also that the horizontal distance D can be determined by a similar equation:

$$D = \tfrac{1}{2} KS \sin 2A + C \cos A$$

Stadia Traverse A stadia traverse of low precision can be quickly performed by recording the stadia data for rod intercept S and vertical angle A plus the horizontal direction angle (or deflection angle, angle to the right, or azimuth) for each occupied point defining a traverse. Application of the equation for distance D eliminates the need for laborious taping of a distance. Note that modern surveying with EDM devices makes stadia surveying obsolete.

Topography Low-precision location of topographic details is also quickly performed by stadia methods. From a known instrument setup position, the direction angle to the landmark features, along with the necessary values of rod intercept S and vertical angle A, allows computation of the vertical and horizontal location of the landmark position from the foregoing equations for H and D. If sights are made in a regular pattern as described in the next paragraph, a contour map can be developed.

Contour Maps A contour map is one on which the configuration of the surface is shown by lines of equal elevation called **contour lines.** In Fig. 16.3.18, contour lines varying by 10 ft in elevation are shown. *H, H* are hill peaks, *R, R* ravines, *S, S* saddles or low places in the ridge *HSHSH*. The horizontal distance between adjacent contours shows the distance for a fall or rise of the contour interval—10 ft in the figure. A profile of any line as *AB* can be made from the contour map as shown in the lower part of the figure. Conversely, a contour map may be made from a series of profiles, properly chosen. Thus, a profile line run along the ridge *HSHSH* and radiating profile lines from the peaks down the hills and from the saddles down the ravines would give data for projecting points of equal elevation which could be connected for contour lines. This is the best method for making contour maps of very limited areas, such as city squares, or very small parks. If the ground is not too much broken, the small tract is divided into squares and elevations are taken at each square, corner, and between two corners on some lines if necessary to get correct profiles.

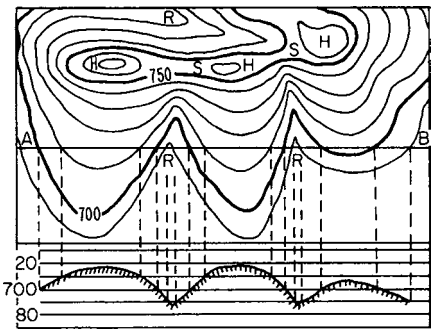

Fig. 16.3.18 Contour map.

SPECIAL PROBLEMS IN SURVEYING AND MENSURATION

Volume of Earth in Foundation and Area Grading The volume of earth removed from a foundation pit or in grading an area can be computed in several ways, of which two follow.

1. The area (Fig. 16.3.19) is divided into squares or rectangles, elevations are taken at each corner before and after grading, and the volumes are computed as a series of prisms. If A is the area (ft^2) of one of the squares or rectangles—all being equal—and b_1, b_2, b_3, b_4 are corner heights (ft) equal to the differences of elevation before and after grading, the subscripts referring to the number of prisms of which b is a corner, then the volume in cubic yards is

$$Q = A(\Sigma h_1 + 2\Sigma h_2 + 3\Sigma h_3 + 4\Sigma h_4)/(4 \times 27)$$

In Fig. 16.3.19 the h's at A_0, D_0, D_3, C_5, and A_5, would be h_1's; those at B_0, C_0, D_1, D_2, C_4, B_5, A_4, A_3, A_2, and A_1 would be h_2's; that at C_3 an h_3; and the rest h_4's. The rectangles or squares should be of such size that their tops and bottoms are practically planes.

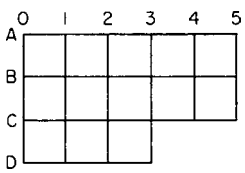

Fig. 16.3.19 Estimating volume of earth by squares.

2. A large-scale profile of each line one way across the area is carefully made, as the *A, B, C,* and *D* lines of Fig. 16.3.19, the final grade line is drawn on it, and the areas in excavation and embankment are separately measured with a planimeter or by estimation from the drawing. The excavation area of profile *A* is averaged with that of profile *B,* and the result multiplied by the distance *AB* and divided by 27 to reduce to cubic yards. Similarly, the material between *B* and *C* is found.

To Pass an Obstacle Four cases are shown in Fig. 16.3.20. If the obstacle is large, as a building, (1) turn right angles at *B, C, D,* and *E,* making $BC = DE$ when $CD = BE$. All distances should be long enough to ensure sufficiently accurate sighting. (2) At *B* turn the angle *K* and measure *BC* to a convenient point. At *C* turn left $= 360° - 2K$; measure $CD = BC$. At *D* turn *K* for line *DE*. $BD = 2BC \cos (180° - K)$. (3) At *B* lay off a right angle and measure *BC*. At *C* measure any angle to clear object and measure $CD = BC/\cos C$. At *D* lay off $K = 90° + C$ for the line *DE*. $BC = BC \times \tan C$. If the obstacle is small, as a tree. (4) at *A*, some distance back, turn the small angle *a* necessary to pass the obstacle and measure *AB*. At *B* turn the angle $2a$ and measure $BC = AB$. At *C* turn the small angle *a* for the line *AC*, and transit, or turn the large angle $K = 180° - a$. If *a* is but a few minutes of arc, $AC = AB + BC$ with sufficient exactness. If only a tape is available, the right-angle method (1) above given may be used, or an equilateral triangle, *ABC* (Fig. 16.3.21) may be laid out, *AC* produced a convenient distance to *F,* the similar triangle *DEF* laid out, *FE* produced to *H* making $FH = AF$, and the similar triangle *GHI* then laid out for the line *GH*. $AH = AF$.

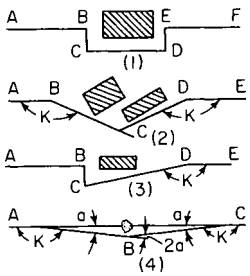

Fig. 16.3.20 Surveying past an obstacle.

To Measure the Distance across a Stream To measure *AB,* Fig. 16.3.22, *B* being any established point, tree, stake, or building corner: (1) Set the instrument over *A*; turn a right angle from *AB* and measure any distance *AC*; set over *C* and measure the angle *ACB*. $AB = AC \tan ACB$. (2) Set over *A,* turn any convenient angle *BAC′* and measure *AC′;* set over *C′* and measure *AC′B*. Angle $ABC' = 180° - AC'B - BAC''$. $BA = AC' \times \sin AC'B/\sin ABC'$. (3) Set up on *A* and produce *BA* any measured distance to *D*; establish a convenient point *C* about opposite *A* and measure *BAC* and *CAD;* set over *D* and measure *ADC;* set over *C*, and measure *DCA* and *ACB;* solve *ACD* for *AC*, and *ABC* for *AB*. For best results the acute angles of either method should lie between 30 and 60°.

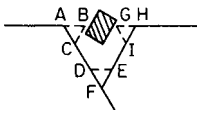

Fig. 16.3.21 Surveying past an obstacle by using an equilateral triangle.

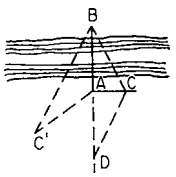

Fig. 16.3.22 Measuring across a stream.

To Measure a Visible but Inaccessible Distance (as *AB* in Fig. 16.3.23) Measure *CD*. Set the instrument at *C* and measure angles *ACB* and *BCD;* set at *D* and measure angles *CDA* and *ADB*. $CAD = 180° - (ACB + BCD + CDA)$. $AD = CD \times \sin ACD/\sin CAD$. $CBD = 180° - (BCD + CDA + ADB)$. $BD = CD \times \sin BCD/\sin CBD$. In the triangle *ABD,* $\frac{1}{2}(B + A) = 90° - \frac{1}{2} D$, where *A, B,* and *D* are the angles of the triangle; $\tan \frac{1}{2}(B - A) = \cot \frac{1}{2} D(AD - BD) / (AD + BD)$; $AB = BD \sin D/\sin A = AD \sin D/\sin B$.

Random Line On many surveys it is necessary to run a random line from point *A* to a nonvisible point *B* which is a known distance away. On the basis of compass bearings, a line such as *AB* is run. The distances *AB* and *BC* are measured, and the angle *BAC* is found from its calculated tangent (see Fig. 16.3.24).

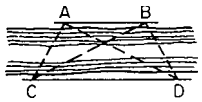

Fig. 16.3.23 Measuring an inaccessible distance.

Fig. 16.3.24 Running a random line.

To Stake Out a Simple Horizontal Curve A simple horizontal curve is composed of a single arc. Usually the curve must be laid out so that it joins two straight lines called tangents, which are marked on the ground by PT (points on tangent). These tangents are run to intersection, thus locating the PI (point of intersection). The plus of the PI and the angle *I* are measured (see Fig. 16.3.25). With these values and any given value of *R* (the radius desired for the curve), the data required for staking out the curve can be computed.

$$R = \frac{5{,}729.58}{D} \qquad L = 100\,\frac{\Delta}{D} \qquad T = R \tan \frac{\Delta}{2}$$

where R = radius, T = tan distance, L = curve length, C = long chord. In a sample computation, assume that $\Delta = 8°24'$ and a 2° curve is required. $R = 5{,}729.58/2 = 2{,}864.79$ ft (873 m); $L = (100)\,(8.40/2) = 420.0$ ft (128 m); $T = 2{,}864.79 \times 0.07344 = 210.39$ ft (64 m). The degree of the curve is always twice as great as the deflection angle for a chord of 100 ft (30 m).

Setting Stakes for Trenching A common way to give line and grade for trenching (see Fig. 16.3.26) is to set stakes *K* ft from the center line, driving them so that the near face is the measuring point and the top is some whole inch or tenth of a foot above the bottom grade or grade of the center or top of the pipe to be laid. The top of the pipe barrel is perhaps the better line of reference. If preferred, two stakes can be driven on opposite sides and a board nailed across, on which the centerline is marked and the depth to pipeline given. When only one stake is used, a graduated pole sliding on one end of a level board at right angles is convenient for workmen and inspectors. On long grades, the grade stakes are set by "shooting in." Two grade stakes are set, one at each end of the grade, the instrument is set over one, its height above grade determined, and a rod reading calculated for the distance stake such as to make the line of sight parallel to the grade line; the line of sight is then set at this rod reading; when the rod is taken to any intermediate stake, the height of instrument above grade less the rod reading will be the height of the top of the stake above grade. If the ground is uniform, the stakes may all be set at the same height above grade by driving them so as to give the same rod readings throughout.

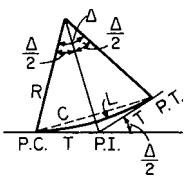

Fig. 16.3.25 Staking out a horizontal curve.

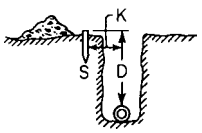

Fig. 16.3.26 Setting stakes for trenching.

To Reference a Point The point *P* (Fig. 16.3.27), which must be disturbed during construction operations and will be again required as a line point in a railway, pipeline, or other survey, is referenced as follows: (1) Set the instrument over it and set four points, *A, B,* and *C, D* on two intersecting lines. When *P* is again required, the transit is set over *B* and, with foresight on *A,* two temporary points close together near *P* but on opposite sides of the line *DC* are set; the instrument is then set on *D* and, with foresight on *C*, a point is set in the lines *DC* and *BA* by setting it in *DC* under a string stretched between the two temporary points on *BA*. (2) Points *A* and *E* and *C* and *F* may be established instead of *A, B, C, D*. (3) If the ground is fairly level and is not to be much disturbed, only points *A* and *C* need be located, and these by simple tape measurement from *P*. They should be less than a tape length from

P. When *P* is wanted, arcs struck from *A* and *C* with the measured distance for radii will give *P* at their intersection.

Foundations The corners and lines of a foundation are preserved by setting stakes outside the area to be disturbed, as in Fig. 16.3.28. Cords stretched around nails in the stakes marking the reference points will give the referenced corners at their intersections and the main lines of the building. These corners can be plumbed down to the level desired if the height of the stakes above grade is given. It is well to nail boards across the stakes at *AB,* putting nails in the top edge of the board to mark the points *A* and *B,* and if the ground permits, to put all the boards at the same level.

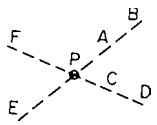

Fig. 16.3.27 Referencing a point which will be disturbed.

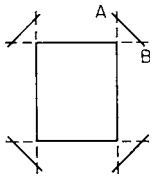

Fig. 16.3.28 Reference points for foundation corners.

To Test the Alignment and Level of a Shaft Having placed the shaft hangers as closely in line as possible by the use of a chalk line, the shaft is finally adjusted for line by hanging plumb lines over one side of the shaft at each hanger and bringing these lines into a line found by stretching a cord or wire or by setting a theodolite at one end and adjusting at each hanger till its plumb line is in the line of sight. The position of the line will be known either on the floor or on the ceiling rafters or beams to which the hangers are attached. If the latter, the instrument may be centered over a point found by plumbing down, and sighted to a plumb line at the farther end.

To level the shaft, an ordinary carpenter's level may be used near each hanger, or, better, a pole with an improvised sliding target may be hung over the shaft at each hanger by a hook in one end. The target is brought to the line of sight of a leveling instrument set preferably about under the middle of the shaft, by adjusting the hanger.

When the hangers are attached to inclined roof rafters, the two extreme hangers can be put in a line at right angles to the vertical planes of the rafters by the use of a square and cord. The other hangers will then be put as nearly as possible without instrumental test in the same line. The shaft being hung, the two extreme hangers, which have been attached to the rafters about midway between their limits of adjustment, are brought to line and level by trial, using an instrument with a well-adjusted telescope bubble, a plumb line, and inverted level rod or target pole. Each intermediate hanger is then tested and may be adjusted by trial.

To Determine the Verticality of a Stack If the stack is not in use and its top is accessible, a board can be fitted across the top, the center of the opening found, and a plumb line suspended to the bottom, where its deviation from the center will show any leaning. If the stack is in use or its top not accessible and its sides are battered, the following procedure may be followed. Referring to Fig. 16.3.29, set up an instrument at any point *T* and measure the horizontal angles between vertical planes tangent, respectively, to both sides of the top and the base and also the angle *a* to a second point T_1. On a line through *T* approximately at right angles to the chimney diameter, set the transit at T_1 and perform the same operations as at T_1, measuring also *K* and the angle *b.* On the drawing board, lay off *K* to as large a scale as convenient, and from the plotted *T* and T_1 lay off the several angles shown in the figure. By trial, draw circumferences tangent to the two quadrilaterals formed by the intersecting tangents of the base and top, respectively. The line joining the centers of these circumferences will be the deviation from the vertical in direction and amount. If the base is square, *T* and T_1 should be established opposite the middle points of two adjacent sides, as in Fig. 16.3.30.

To Determine Land Area and Boundaries Two procedures may be followed to gather data to establish and define land area and boundaries. Generally the data is gathered by the traverse method or the radial/radiation-survey method.

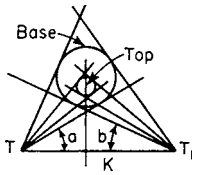

Fig. 16.3.29 Determining the verticality of a stack.

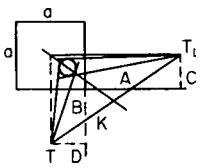

Fig. 16.3.30 Determining the verticality of a stack.

The **traverse** method entails the occupation of each end point on the boundary lines for a land area. The length of each boundary is measured (in more recent times with EDM) and the direction is measured by deflection angle or angle to the right. Reference sources explain how direction angles and boundary lengths are converted to **latitudes** and **departures** (north-south and east-west change along a boundary). The latitudes and departures of each course/boundary allow for a simple computation of double meridian distance (DMD), which in turn is directly related by computation to land area. In Fig. 16.3.31 each of the points 1 through 4 would be occupied by the instrument for direction and distance measurement.

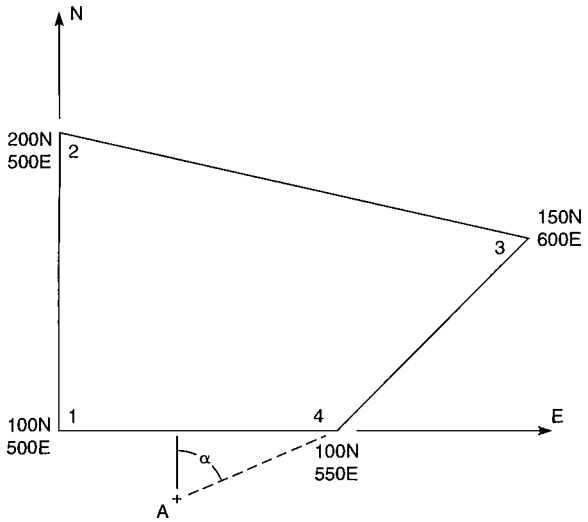

Fig. 16.3.31 Land area survey points.

The **radial** method requires, ideally, only a single instrument setup. In Fig. 16.3.31 the setup point might be at *A* or any boundary corner with known or assumed coordinates and with line of sight available to all other corners. This method relies on gathering data to permit computation of boundary corners relative to the instrument coordinates. The data required is the usual direction angle from the instrument to the point (e.g., angle α in Fig. 16.3.31) and the distance to the point. The references detail the computation of the coordinates of each corner and the computation of land area by the **coordinate method.** The coordinate method used with the radial survey technique lends itself to the use of modern EDM and total station equipment. In very low precision work (approximation) the older methods might be used.

Stream flow estimates may be obtained by using leveling methods to determine depth along a stream cross section and then measuring current velocity at each depth location with a current meter. As shown in Fig. 16.3.32, the total stream flow *Q* will be the sum of the products of area *A* and velocity *V* for each (say) 10-ft-wide division of the cross section.

To define limits of cut and fill once the route alignment for the roadway has been established (see Fig. 16.3.15), the surveyor uses leveling methods to define transverse ground profiles. From this information and the required elevation of the roadbed, the distance outward from the roadway

center is determined, thus defining the limits of cut and fill. The surveyor then implants slope stakes to guide the earthmoving equipment operators. See Fig. 16.3.33.

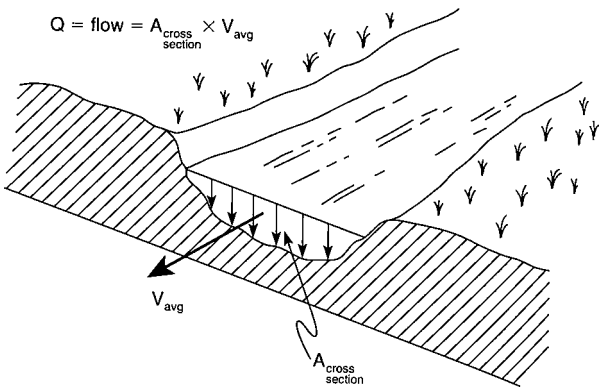

Fig. 16.3.32 Determination of stream flow.

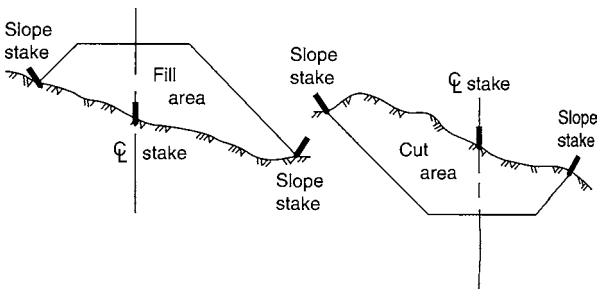

Fig. 16.3.33 Stakes showing limits of roadway cut and fill.

Datum of Reference The establishment of horizontal position, elevation, and direction is meaningless unless a known reference or datum is specified. It is fundamentally the question of "where is the point?," "which way is north?," and "what is the basis for specified latitude, longitude, and direction?" Plane surveying is based on the concept that all distances and directions are as projected upon a horizontal plane which at a single point is tangent to the earth spheroid. This practice serves nicely for local surveys but as the survey expands, the distances and angles measured on the earth spheroid will depart more from the corresponding data as projected upon the horizontal plane. The deviation can become unacceptable as the limits of plane surveying are reached and the accuracy of geodetic surveying is required. However, the methods of geodetic surveying (dealing with spherical angles and coordinates) are complex and require difficult computations, expense, and expertise.

Mapping of coordinates and direction to establish geodetic points has been carried out by the U.S. Coast and Geodetic Survey (USCGS, now NGS and NOAA), originating many years ago. The mapping of geodetic position is represented on the Lambert conformal projection or the transverse Mercator projection. The Lambert projection is appropriate in most states and areas having their long dimension in the east-west direction, while the Mercator projection is best used in places having their longer extents in the north-south direction. The Lambert projection utilizes a developed conic surface and the Mercator projection uses a developed cylinder. The methods to produce the flat/developed cone or cylinder are found in the references.

Simplification has been accomplished through evolution of the **State Plane Coordinate System** (SPCS), which is a rectangular coordinate definition. The USCGS has developed the SPCS for every state, providing a common reference for all points lying in the state plane. On the SPCS, grid points are located by *x*-*y* values and all longitudinal lines are parallel to a central meridian (unlike converging true geodetic meridians). Thus the traditional thinking of azimuth direction as (*a*) geographic north-south, (*b*) magnetic north-south, and (*c*) assumed north-south is now expanded to include grid north-south. Low-order surveys can be conducted throughout the state plane with no adjustment in distance. For higher-order surveys, however, a *grid factor* (1.000 or very close to 1.000) is used. The *grid factor* is the product of a *scale factor* and an *elevation factor*. These values are available in tables for each state.

The adoption of SPCS within a state or region is gaining support within the profession. Lawmakers and the courts have been slow to incorporate the principles of SPCS. Among the advantages of the system are the following:

1. When the SPCS (*x* and *y*) coordinates of a point are lost they may be regained from relationship to nearby known SPCS points within a degree of accuracy of its original specification.
2. Lengthy statewide surveys (right-of-way for highways, railroads, utilities) may be conducted without loop closure and with near geodetic accuracy.
3. Maps referenced to SPCS will always "fit" when joined regardless of the agency producing the map.
4. There is a common *grid north* direction definition (see Resurvey and Retracement below).

Resurvey and Retracement On occasion it may become necessary to verify and reestablish boundaries described in a deed description dating from many years ago. At least two problems arise in the effort to find the original monuments, corners, and ties referenced in the original survey. Equipment used in the older surveys does not approach the precision of that used in recent times and the basic measurements of angle and distance must be examined and interpreted carefully.

Angles are almost always based upon a magnetic reference and usually specified to about 15′ to 30′, consistent with the precision of the compass box of the era. Subsequent measured angles are limited to the refinement of the graduated circle of the transit often specified to no better than 30′. The magnetic reference is subject to adjustment to current declination which is arguably an inexact process.

Additionally, distance measurement may be subject to the diligence of the original crew of chain men and the surveyor. The possibility also exists that the distances were measured on the slope and not converted to horizontal equivalent. It is known that often the early chain men were paid "by the foot" or "by the chain," which is a practice that does not lend itself to due diligence.

A resurvey/retracement requires the consideration of several quantities. Research is required to determine all the relevant information from deeds, legal records, historic documents, etc. The research goal is to identify references that include monuments (natural or artificial), identification of corner markers, established lines (fence lines, stone walls, trails, streams), acreage, and referenced angles and distances.

After the thorough research, the subsequent visit to the field is likely to reveal that features and data required for definition of the survey may be missing or conflicting. In the case of conflict there is an accepted order of preference to be applied. Courts tend to follow precedence, as listed, in the absence of intent that is contrary. Priorities are as follows:

1. Natural monuments or landmarks. These are objects of specific reference or set by the early surveyor and found along the boundary.
2. Secondary or artificial monuments which are references documented by other maps or deeds and established by other previous surveyors.
3. Boundaries or lines of record to adjoining tracts documented by maps, plats, or deeds.
4. Bearing or distance references (ties) to on-site or off-site objects.
5. Distances are deemed to be more reliable than angle bearing references.
6. Angle measurement related to direction of a line.
7. Quantity or area may be cited in the old survey but is inferior to all the above cited items.

With the continued development of the State Plane Coordinate System, many surveying groups argue for the inclusion of coordinates in the hierarchy of calls listed above.

GLOBAL POSITIONING SYSTEM

The GPS concept is based on a system of 24 satellites in six orbital planes with four satellites per orbit. Two elements of data support the underlying principle of GPS surveying. First, radio-frequency signals are transmitted from the satellites and received by GPS receiver units at or near the earth's surface. The signal transmission time is combined with the velocity of propagation (approximately the speed of light) to result in a pseudodistance $d = Vt$, where V is the velocity of propagation and t is the time interval from source to receiver. A second requirement is the precise location of the satellites as published in satellite ephemerides.

The satellite data (ephemeride and time) is transmitted on two frequencies referred to as L1 (1,575.42 MHz) and L2 (1,227.60 MHz). The transmissions are band-modulated with codes that can be interpreted by the GPS receiver-signal processor. The L1 frequency modulation results in two signals: the precise positioning service (PPS) P code and the C/A or standard positioning service (SPS) code. The L2 frequency contains the P code only. The most recent GPS receivers use dual-frequency receiving and process the C/A code from L1 and the P code from L2.

Single-Receiver Positioning A single point position can be established using one GPS receiver where C/A or SPS code is processed from several satellites (at least four for both horizontal and vertical position). The reliability depends on the uncertainty of the satellite position, which is +15 m in the ephemeride data transmitted. This handicap can be circumvented through the application of Loran C technology. The surveyor may also obtain high precision through the use of two receivers and differential positioning. The U.S. government reserves the right to degrade ephemeride data for reasons of national security.

Differential Positioning Multiple GPS receivers may be used to attain submeter accuracy. This is done by placing one receiver at a known location and multiple receivers at locations to be determined. Virtually all error inherent in the transmissions is eliminated or cancels out, since the difference in coordinates from the known position is being determined. By averaging data taken over time and postprocessing, the precision of this technique can approach millimetre precision.

Field Practice A procedure, sometimes called *leapfrogging,* can be used with three GPS receivers (R1, R2, and R3) operating simultaneously (see Fig. 16.3.34). Receiver R1 is placed at a known control point *P,* while R2 and R3 are placed at *L* and *M*. The three units are operated for a minimum of 15 min to obtain time and position data from at least four satellites. The R1 at *P* and R2 at *L* are leapfrogged to *N* and *O*, respectively. This procedure is repeated until all points have been occupied. It is also desirable to include a partial leapfrog to obtain data for the *OP* line if a closed traverse is wanted.

A second procedure requires two receivers to be initially located at two known control points. The units are operated for at least 15 min in order to establish data defining the relative location of the two points. Then one of the GPS receivers is moved to subsequent positions until all points have been occupied. As in the previous procedure, signals from a minimum of four satellites must be acquired.

GPS Computing The data for time and position of a satellite acquired by a GPS station is subsequently postprocessed on a computer. The object is to convert the time and satellite-position data to the earth-surface position of the GPS receiver. At least four satellites are needed for a complete (three-dimensional) definition of coordinate location and elevation of a control point. The computer program typically requires input of the ephemerides-coordinate location of the (at least) four satellites, the propagation velocity of the radio transmission from the satellite, and a satellite-clock offset determined by calibration or by receipt of correction data from the satellite.

General Survey Computing The microcomputer is now an integral part of the processing of survey data. Software vendors have developed many programs that perform virtually every computation required by the professional surveyor. Some programs will also produce the graphic output required for almost every survey: site drawings, plat drawings, profile and transverse sections, and topographic maps.

The Total Station The construction of the total station device is such that it performs electronically all the functions of a transit, optical theodolite, level, and tape. It has built-in EDM capability. Thus the total data-gathering requirements are available in a single instrument: horizontal and vertical angles plus the distance from the instrument's optical center to the EDM reflector. A built-in microprocessor converts the slope distance to the desired horizontal distance, and also to vertical distance for leveling requirements. If the height of the instrument's optical center and the height of the reflector are keyed in, the on-board computer can display that actual elevation difference between ground points with correction for earth curvature and atmospheric refraction. A typical total station is shown in Fig. 16.3.11.

Another feature found in some total stations is data-collection capability. This permits data as read by the instrument (angle, distance) to be electronically output to a data collector for transfer to a computer for later processing. A total station operating in conjunction with a remote processing unit allows a survey to be conducted by a single person. The variety of features found on total station devices is enormous.

The total station changes some of the traditional procedures in surveying practice. An example is the laying out of a route curve as shown in Fig. 16.3.24. The references describe the newer methods.

Operations management is concerned with the production of the goods and services of an organization. In particular, operations management problems focus on determining the way an organization will produce high-quality goods or services in an efficient manner. We define efficiency as producing goods and services in a timely and cost-efficient manner. In the past, the field was limited to the study of manufacturing processes, but in the last several decades the emphasis has included the study of service processes, which now number more organizations than manufacturing in the United States. Many of the same principles of effective operations management that have been found to work in manufacturing organizations will optimize the efficiency and quality of service organizations.

Operations management has generated increased interest among organizations today because of the competitive advantage that accrues to the organization that has a high-quality product or service and manages its efficiency of production in an optimal way. The terminology that is common in business today is due to an emphasis on operations management strategies. Some examples include six sigma, lean manufacturing, supply chain management, and just-in-time inventory methods.

FORECASTING

There are three general types of forecasting models used in organizations today. These are time series models, regression models, and subjective models.

Time series models are models that are based upon the assumptions that the past behavior of the variable to be forecasted, say sales, is the best indicator of the future behavior of sales. Some of the common models that have been used in many firms include moving-average methods and exponential smoothing methods. More complex models due to Box and Jenkins are used when simpler models do not satisfy.

Moving-average methods are based upon simply averaging the past n observations of a stream of data to obtain a forecast for the next period. For example, a three-period moving average of sales would be obtained by averaging the past three periods of sales. This would be the forecast for the next period (or future periods) sales. The formula for a moving average forecast of sales is simply

$$S_{t+1} = \sum_{i=t-N+1} X_i/N$$

where S_t is the forecast in period t, X_i is sales in period i, and N is the number of periods in the moving average.

An obvious weakness of moving-average forecasts is that equal weight is placed on all observations. It seems more plausible to weigh the more recent observations higher in determining a forecast. **Exponential smoothing** is a common method that allows more recent observations to have more weight in the averaging scheme. The model for exponential smoothing is:

$$S_{t+1} = \alpha X_t + (1 - \alpha)S_t$$

where α is the smoothing coefficient.

Note that the model is dependent upon the choice of α. If α is near 1, there is very little smoothing taking place and the forecast follows the rapid changes in the data. Note that if α equals 1, the forecast for the next period is simply the actual observation for the previous period. If α is near zero, the forecast approaches the average of the past data. In practice, common values of α are between 0.1 and 0.3.

Trend and seasonalities are not accounted for in the exponential smoothing model presented above. One can account for trend in a model by using a model called **double exponential** smoothing, which is a simple extension of the model presented above. **Seasonalities** are common in many industries. Consider the demand for the sale of turkeys. One would expect there would be peaks around the Thanksgiving and Christmas holidays in the United States. The usual exponential smoothing or double exponential smoothing models would yield forecasts that lag the actual demand. One simple and effective method for handling these seasonalities is to first **deseasonalize** the data by calculating the seasonal component for the data. An example of this would be to calculate the percentage of sales occurring in each month by averaging the last 3 years of monthly data (assuming there is a monthly seasonality) and then dividing the data by this monthly index. One can then develop a forecast on the deseasonalized data and, when the forecast is obtained, multiply the forecast by the seasonal index for the month in which a forecast is desired.

More complicated methods for forecasting time series are due to George Box and Gwilym Jenkins and are based upon a set of models called ARIMA, or mixed autoregressive and moving-average models. These are more general and powerful models of the class mentioned above and have been shown to be extremely effective in forecasting in practice. Consult their book for a detailed explanation of this class of models.

A second class of forecasting models is based upon using explanatory variables in a **regression** model to forecast sales. The regression model may be represented by the function F, where

$$Y = F(X_1, X_2, \ldots, X_k) + \varepsilon$$

The variables labeled X_j, $j = 1, 2, \ldots, k$ are the explanatory variables, and the variable Y is called the dependent variable. The term ε represents the error. For example, we may hypothesize that sales (Y) can be explained by price (X_1) and average delivery time (X_2). We can build the model by entering data from the past where we have recorded average delivery time in a month, the price in a month, and sales in a month.

Human judgment is the basis for a third class of models. These are commonly used in practice and, at times, yield accurate forecasts. Perhaps the most common types of judgmental forecasts are those based upon management or sales force opinions obtained from discussions with customers. Surveys of customers are also used to build these types of forecasts.

INVENTORY MANAGEMENT

Inventory decisions have a major impact on the profitability of an organization. Organizations that carry large inventories incur large holding costs, which impact the bottom line. On the other hand, maintaining low inventories may prevent an organization from meeting the variability in demand. Additionally, low inventories may not allow flexibility in scheduling, may not allow the organization to take account of economic order quantities, or may not allow for variation that occurs in vendor-supplied inputs. Thus, the inventory decision is very important in organizations. Essentially, the inventory decision can be broken down into two major components. These are (*a*) determining when items should be ordered and (*b*) determining how much to order.

The standard criterion on which to base inventory decision is cost. Four costs are generally considered. These are holding or carrying costs, ordering costs, setup costs, and shortage costs. **Holding costs** include as a major component the cost of the capital tied up in the inventory and additional costs include the cost of storage, insurance, deterioration, obsolescence, etc. **Ordering costs** refer to the costs incurred when a purchase order is placed or when a production order is given. **Setup costs** include the clerical costs in changing production. **Shortage costs** are difficult to measure since they include a component for lost sales, lost customers, or penalties for late delivery.

When analyzing inventory decisions, analysts place inventory in two categories: independent demand inventory and dependent demand inventory. Independent demand items are items whose demand does not depend on the demand for another item. Dependent demand items are ones for which the demand depends on the demand for another item. For example, the demand for bicycles in an organization may be an independent demand item. Wheels for the bicycle, on the other hand, are dependent demand items, since their demand depends on the demand for bicycles. That is, if the demand estimate for bicycles is 500 units, the demand for wheels is 1,000 units.

The most common inventory model is labeled the **economic order quantity (EOQ)** model. It is used when one is interested in determining the optimal order quantity where the criterion is cost minimization and where the inventory demand item is independent. The assumptions of the EOQ model are that demand is satisfied on time, price is fixed (there are no price breaks), stock is depleted linearly, and there are no stockouts. Under these assumptions one can show that the EOQ is

$$\text{EOQ} = (2 R c_p / c_h)^{1/2}$$

where c_p is the ordering costs, R is the yearly demand, and c_h is the holding costs. In addition, it can be shown that the reorder point is when the inventory reaches a level of P, where

$$P = L \times R/52$$

where L is the lead time in weeks. Other similar models are developed for the situations where price breaks are available or where backorders are allowable.

An equivalent model to the EOQ is available for the situation where the analyst wishes to determine the **economic production quantity** or lot size **(EPQ)**. Here, one can find the EPQ as

$$\text{EPQ} = \{2c_p R/[c_h(1 - r/p)]\}^{1/2}$$

where r = daily usage and p = production rate per day.

When demand is not constant, organizations must provide a level of safety stock if they wish to maintain a certain service level. Safety stock, then, is the excess inventory carried over expected demand. In the standard EOQ model, which is also called the *fixed order quantity* model, the EOQ is calculated in the same way if the demand is constant or varies. But if the demand varies, the **reorder point** differs. If the demand varies, the reorder point must be calculated by using some knowledge of the distribution of demand. For example, if demand is normally distributed with standard deviation, the reorder point becomes

$$P = d L + z$$

where d is the average daily demand, L is the lead time in days, and z is the number of standard deviations associated with a particular service level probability.

Another way to address this problem is to use a fixed time period model. Here, order quantities vary from time period to time period but the reorder point remains the same. An advantage of this model is that one does not have to constantly account for the inventory; all one must keep track of is the time period. A disadvantage of this model is that it requires the maintenance of a higher level of inventory. Most textbooks present the models and discuss the implications of the fixed time period model.

There are other simpler systems that enjoy popularity in applications because they do not rely on any assumptions such as a normal distribution of demand or constant usage. Some common systems include the ABC system of classifying inventory and one- and two-bin systems.

The **ABC** system for inventory management essentially classifies inventory into one of three levels: A, B, and C. The classification is based upon the dollar value of inventory, which is determined by multiplying annual usage times the cost. Then, the A items are defined as the ones with the top 75 to 80 percent of dollar value. B items are the items with the next 15 percent of value and C items are those with the next 5 to 10 percent of value. Once the items are classified, management uses this information to determine where to apply the greatest control.

The **one-bin system** is very simple to manage but has a disadvantage in its cost that may be far from minimal compared to more complex systems. To use the one-bin system the analyst simply replenishes inventory up to a maximum level on a regular basis, say weekly for A items. The **two-bin system** is one in which there are two bins of the same inventory. Inventory is used from the first bin until it is used up; subsequently an order is placed for replenishment and inventory is used from the second bin. The second bin should contain enough inventory to cover needs during the order lead time. The amount in the second bin thus should equal P, where P is the order point defined above.

The methods discussed above constitute some of the more valuable methods of inventory management available to managers but, at times, various industries employ other methods that are more usable because of the difficulty in managing a large number of items. For example, shoes are distributed according to batches organized by sizes. Department stores use a method called "open to buy," which refers to the budgeted value of inventory minus the amount that was currently spent for various departments. That is, instead of managing individual inventory items, the manager focuses on managing the cost of inventory for a department as a whole.

As mentioned earlier, the demand for inventory can be independent or dependent. When demand for an inventory item is dependent upon the demand for another item, such as the case for bicycle wheels examined before, the methods of managing inventory differ from the case where demand is independent. A common technique for managing dependent demand inventories is the method of **materials requirements planning (MRP)**, which is an accounting information system technique used for keeping track of inventory needs for these items. MRP has been popular for about 30 years, and computer programs and systems to perform the cumbersome calculations associated with MRP are readily available.

MRP is based upon knowledge of the bill of materials for an item, the master production schedule, and a record of the inventories currently in stock. The bill of materials is simply a list of the components of a particular product. For our bicycle example, the bill of materials would contain two wheels, two tires, a set of handlebars, a set of rear brakes, front brakes, and various other items. The master production schedule provides information on when to produce these bicycles and what quantity to produce. The MRP then uses these inputs along with lead times to provide the production manager with planned order releases along with various other kinds of information, depending upon the needs of the manager. In our simple example, suppose our forecasted demand is such that we need to produce 3,000 bicycles in March and in June; this would be the master production schedule. Suppose we have 3,000 wheels in inventory and the lead time for wheels is 1 month. The MRP would calculate that the organization needs 6,000 wheels in March and in June, but since the organization has 3,000 on hand it would show the necessary order releases are for 3,000 wheels on February 1 and for 6,000 wheels on May 1.

Of course, in practice MRP is much more complicated than the simple example presented here, for a number of reasons. For example, some firms produce many products and some of these have common parts, or dependent items. Order releases must account for these factors. Also, firms might want to take advantage of price breaks for larger lots or by ordering less often to minimize ordering costs. In MRP, this problem is called **lot sizing.** A variety of techniques for lot sizing are available and range from the simplest, called *lot-for-lot ordering*, to complex ones such as dynamic programming techniques—for example, the Wagner Whitin model. The lot-for-lot model, for example, indicates that orders are to be placed when they are needed for each period; here, holding costs are minimized.

Related to MRP is an approach to broaden the scope of MRP to the firm as a whole. That is, all of the factors going into production are considered together on a larger scale than just the production system. This includes the overall planning of the business. Marketing and finance functions, for example, might take part in the determination of the master production schedule, forecasting, the financing requirements of the process, etc. This approach is called **MRP II** and has been popular for about 20 years.

An approach to managing production systems that includes the management of its inventory is called a **just-in-time** approach. This approach was initially used at Toyota in Japan and is very much related to the teachings of W. Edwards Deming in that it requires that the production system be in a state of statistical control, that suppliers be kept to a minimum, that scrap and rework are to be avoided as a policy rather than as a cost consideration, that preventive maintenance be performed, that continuous improvement is in place, and that workers are team based. Because the system is in control and there is a minimum of scrap or rework, an innovative method of managing the inventory is possible. This method is to manage inventory, whether purchased from a vendor or work-in-process inventory, so that large stocks of inventory are not necessary to be held, thereby minimizing holding costs. Other common elements of just-in-time systems are that setups are quick, and therefore not costly, and that lot sizes are small. Additionally, just-in-time systems move work in a pull versus push way. Push systems work with less regard for the forecast or the demands of higher upstream stations. Pull systems, on the other hand, work in a just-in-time method such that the upstream demand is pulled from downstream. As a simple example, a firm might produce according to expected demand only rather than by efficient lot sizes.

A drawback encountered in just-in-time systems is that, since the supplier is penalized for late delivery, it often prepares and stores finished product which is then shipped to arrive at the customer just in time. The carrying cost for this storage, which the customer thinks has been avoided, is passed on to the customer in the form of an increased price.

One way in which to manage the information in a pull system is with a **kanban sheet,** which is simply a record of what work is taking place. For example, a kanban sheet might be attached to a lot of parts. When upstream demand requires that this lot is needed for production, the kanban sheet is placed in an area where the need for replenishment is indicated.

JIT systems are conceptually very attractive and have been used to advantage by a number of companies, especially those in Japan.

SCHEDULING

Scheduling the accomplishment of tasks within the operations of a manufacturing or service environment is dependent upon a number of factors. First, there are differences between services and manufacturing in that the concept of an inventory of service has little meaning. Second, within manufacturing there are different types of production systems used for different types of products. More specifically these can be broken down into systems in which the same product is made many times (flow shop), a system in which several products are made by the same manufacturer on the same production system, a system in which similar products are made to order (job shop), and finally a system in which a single product is made (project). Some examples of these are respectively automobile production, a private press, a machine shop producing milled products, and construction of a skyscraper.

In a service environment, operations scheduling is a matter of providing the service when it is demanded by the customer. Analytical approaches involve developing forecasts of when customers arrive and the probability distributions of these arrivals and using these to build service capacity so that desired service levels are achieved. These service levels are usually expressed in terms of the probability or percentage of the time customers are serviced within a time limit. For example, the credit card company MBNA answers more than 90 percent of its phone calls from customers within two rings.

Some organizations such as doctors' offices schedule by appointment. The demand is then known and the service supply can be provided to meet that customer demand. Airlines use reservations to accomplish much of the same objective. Of course the determination of feasible schedules involves forecasting as well.

Complex service operations such as hospitals have compound scheduling problems encompassing the issues mentioned above in addition to the consideration that multiple service providers of various types are needed. For example, scheduling surgery involves scheduling surgeons, nurses, anesthesiologists, operating rooms, etc.

Scheduling for the situation when a product is produced in a series of workstations, or a flowshop, is called assembly line balancing. The product spends a period of time in each workstation; this time is referred to as the *cycle time*. The objective of assembly line balancing is to allocate all of the tasks needed to complete a product into workstations. Criteria for evaluation of assembly line balances include the cycle time required, the number of workstations required, and the amount of slack in the assembly line, which is the sum of the idle time in the workstations.

To perform assembly line balancing for producing a particular product, one needs to establish the precedence relationships between the tasks and determine the task times for each of the tasks. In the situation where cycle time is specified, one can calculate the theoretical minimum number of workstations; it is the next highest integer obtained from the ratio S/C, where S is the sum of the task times and C is the cycle time. In assembly line balancing, one then assigns tasks to workstations such that precedence relationships are not violated and, in addition, the sum of the task times for each station is less than the cycle time.

When one assigns tasks to workstations, one finds that there usually will be alternative assignments. Researchers have investigated the performance of a number of heuristics to use in these situations. Some of the more common are to assign tasks to workstations such that the longest tasks are assigned first without, of course, violating precedence relationships, and to assign tasks according to positional weights, where positional weight is the sum of the task times and the times of all of the tasks that follow.

A graph showing the precedence relationships for an 8-task assembly line is shown in Fig. 17.1.1. The times for the various tasks are:

Task	1	2	3	4	5	6	7	8	Total
Time	2	4	3	4	5	4	6	4	32

Thus, if the cycle time is 7, the theoretical minimum number of workstations is $32/7 = 4.55 = 5$.

If we allocate tasks to stations such that the longer tasks are assigned first, we have the following balance:

Station	1	2	3	4	5	6
Tasks	1,2	5	3,6	4	7	8
Time	6	5	7	4	6	4
Slack	1	2	0	3	1	2

In practice the problem is usually more complex because task times are stochastic variables and actual results may differ from the expected. Additionally, some tasks may require special training, which may change the way in which tasks are assigned to workstations. Many other

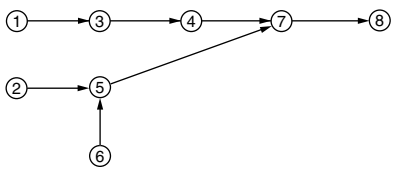

Fig. 17.1.1 Network showing precedence relationships for an 8-task assembly line. Code numbers within nodes signify events. Connecting lines with directional arrows indicate operations that are dependent on prerequisite operations.

situations occur that make the procedures described above a starting point in the assembly line balancing decision.

When a firm produces a number of products using similar equipment and locations, the scheduling problem becomes more complex because the production manager needs to make decisions on the size of the lot produced and the sequencing of the lots. In some cases the economic lot size can be determined by using methods discussed in the section on inventory management; methods are also available for multiple products. Sequencing becomes an issue of satisfying the needs of the customers, whether they be internal or external, and minimizing the cost of holding inventory.

A common tool used for evaluating various types of schedules is called the **Gantt chart.** This is a simple chart that provides a visual record of the order of processing tasks over time (Fig. 17.1.2). Here, M_1 and M_2 represent two machines in a job shop. The numbers within the blocks show the processing order, or schedule, to complete three jobs, each of which requires processing time on each of the two machines. Note that all the jobs can be done first on machine 1 or on machine 2 but not on both simultaneously.

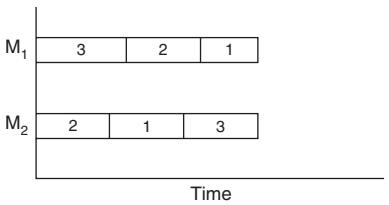

Fig. 17.1.2 Sample Gantt chart.

In job shop scheduling the object is to determine the sequence in which machines will process jobs. The evaluation criteria are varied. Some common criteria include **makespan,** which is the total time to process all jobs; **mean flowtime,** which is the average time a job is in the shop; and **average lateness** per job, which is the average time a job takes longer than the promised time.

If arrivals are static and there is one machine to process jobs, an optimal schedule in terms of minimizing mean flow time is to schedule jobs by processing time, with the shortest jobs being processed first. Note that makespan for this situation is the same for all processing orders.

When there are two machines and n jobs to process on these machines and the order is the same for each job, a method called Johnson's rule can be used to minimize makespan. A variant, Jackson's rule, can be used if jobs can be performed on machine 1 only, machine 2 only, first machine 1 then machine 2, or first machine 2 then machine 1. This rule minimizes the makespan of the sequence.

With three machines and n jobs, Johnson's rule can be used by employing a trick in the solution procedure. If there are m machines and n jobs, Campbell's heuristic can be used to minimize makespan. This is not an optimal procedure since there is not an efficient method available to find an exact solution.

If, on the other hand, jobs arrive intermittently throughout a time period, which is the usual case in a job shop, one must rely on schedules based on priority dispatch rules. In these cases, jobs with the smallest priority are scheduled first. One common rule is the shortest processing time rule. This rule can be dominant in terms of minimizing lateness, makespan, and flowtime. First come, first serve is another common priority dispatch rule. Some others include: random priority, least work remaining, total work fewest operations remaining, due date, slack, and critical ratio, which is the ratio of the time remaining before delivery divided by the remaining processing time. One can evaluate the effectiveness of all of these rules for a particular situation by constructing Gantt charts of each of the resulting schedules and comparing these on the basis of makespan, mean flow time, and average lateness. Implementation involves choosing that one that best fits the needs of the organization. Subsequently, one should monitor the results of the solution over time to see, if, in fact, it is providing the best solution in terms of optimizing the solution criteria.

Scheduling projects is somewhat different from scheduling for assembly lines for a single or multiple product or for job shops. Projects are different in that the firm is producing a single unit (or small number) of the product. Some examples include implementing an MRP or MRP II system in an organization, building a skyscraper, or doing a consulting project for an organization. For many projects the Gantt chart is a useful tool in that it lists tasks to be accomplished, the time it should take to accomplish them, and the sequence and procedure of the tasks.

Researchers have made improvements to this method with the use of PERT and CPM charts to help them schedule and better manage projects. **PERT** is an acronym for program evaluation and review technique and **CPM** is an acronym for critical path method. These methods were initially different in that PERT used probabilistic times for tasks and CPM used deterministic times, but after the more than 50 years in which these methods have been applied there is little to distinguish the two methods.

PERT and CPM rely on a network diagram, which is a graph which contains a number of nodes and arrows. Usually the arrows designate the tasks to be performed and the nodes represent the beginning and end of these tasks. See Fig. 17.1.1. The value of the network diagram is that it clearly displays all of the tasks that must be completed to complete the project, the precedence relationships between these tasks, and, in some graphs, the time to complete each task. Of special interest among the various paths from the beginning to the ending node is the critical path. The **critical path** is the path that is the longest in terms of the time it takes to go from the beginning to the ending node. It is of interest because any delay in accomplishing tasks on the critical path will result in a delay of the completion of the project. To shorten the length of the project, tasks on the critical path will have to be shortened.

One advantage of PERT and CPM are that the graphical display clearly indicates tasks and precedences. Once the critical path has been determined managers can closely monitor tasks on the critical path and, further, monitor tasks not on the critical path that have **slack,** which is the difference between the time it takes to complete a task and the time allowable to complete the task. Another advantage of the use of these techniques is that they help the manager to organize all information and data required to complete the project.

AGGREGATE PLANNING

Aggregate planning is the task of determining how much to produce of a product, what workforce level to use, and what inventory to carry for a period of time. One use of the aggregate plan is as an input into the master production schedule. It is dependent, of course, on the forecast for the product for each of the periods for which the plan is to be made and the amount on inventory on hand along with the costs of the various components.

Factors that can be used to match production to demand include the ability to hire employees and lay off employees; the ability to vary the number of shifts, the length of shifts and the amount of overtime; the ability to subcontract; and the ability to vary the amount of inventory held or backordered.

Aggregate plans are usually evaluated on the basis of objective factors such as cost and meeting demand on time, as well as subjective factors such as lost sales potential. Costs to be considered in most approaches include the basic cost of producing the product (fixed and variable costs); costs associated with hiring, layoffs, and overtime; costs of inventory (holding and backorder costs); and the cost of subcontracting.

There are a number of approaches used to develop aggregate plans in industry, and these range from simple trial-and-error evaluations of plans on a spreadsheet to sophisticated mathematical programming or artificial intelligence models to develop plans that are optimal in terms of particular criteria.

The most simple planning method, trial and error using a spreadsheet, consists of trying various plans and seeing what they yield in

terms of meeting production schedules and, in addition, what costs are incurred in the various categories mentioned above. One of the important reasons for using this type of planning method is that a number of subjective considerations can be incorporated into the solution. These include constraints such as, say, maintaining a stable workforce, eliminating shortages or backorders, eliminating subcontracting, etc. Some of these may be hard to model when one is using sophisticated modeling methods but are relatively easy to incorporate into a trial and error method.

Sophisticated methods of aggregate planning include methods such as mathematical programming, of which linear programming is a subset (covered later in this section), and expert systems approaches to the problem. Mathematical programming methods involve deciding upon what criterion to optimize and what constraints are to be placed upon the system. The objective function may be one where the costs of producing the product (which include costs of hiring, layoffs, subcontracting, inventory holding and shortage costs, etc.) are minimized. Constraints are then written that ensure that, say, the amount of inventory available for a particular period is such that demand is satisfied in that period. Note that the inventory can be obtained from inventory on hand, from production in a variety of ways, and from subcontracting. Linear constraints such as these become part of the mathematical model. The mathematical program built in the way above then is optimized using a computer program and the outputs of this program are the optimal plan and the costs of this plan.

One of the advantages of the mathematical programming approach is that cost is minimized. A disadvantage is that some constraints are not easily modeled in some cases. For example, subcontractors may offer price breaks for certain quantities of products or inventory produced. In practice, most firms use the trial-and-error approach.

QUALITY MANAGEMENT

In the past, much of the emphasis on quality management was placed on inspection. An organization produced a product and inspected samples of that product, usually at the end of production. Technology consisted of implementing inspection sampling schemes.

In the early 1980s, many organizations began to modify their methods to adhere to the teachings of proponents such as W. Edwards Deming. Deming emphasized strategic changes in the management of quality. He argued that quality was not a cost to be minimized but rather a constraint that had to be met in order for a firm to remain in business. Some of his more revolutionary contributions were that rework should be eliminated, that high quality is associated with high efficiency, and that an organization should always try to get better. Deming labeled this **continuous improvement.** Deming had a list of 14 points that he called the basis of transformation of American industry. These are (Deming, 1993, p. 23):

1. Create constancy of purpose toward improvement of product and service, with the aim to become competitive and to stay in business, and to provide jobs.
2. Adopt the new philosophy. We are in a new economic age. Western management must awaken to the challenge, must learn its responsibilities, and take on leadership for change.
3. Cease dependence on inspection to achieve quality. Eliminate the need for inspection on a mass basis by building quality into the product in the first place.
4. End the practice of awarding business on the basis of price tag. Instead, minimize total cost. Move toward a single supplier for any one item, on a long-term relationship of loyalty and trust.
5. Improve constantly and forever the system of production and service, to improve quality and productivity, and thus constantly decrease costs.
6. Institute training on the job.
7. Institute leadership. The aim of supervision should be to help people and machines and gadgets to do a better job. Supervision of management is in need of overhaul, as is supervision of production workers.
8. Drive out fear, so that everyone may work effectively for the company.
9. Break down barriers between departments. People in research, design, sales, and production must work as a team, to foresee problems of production and in use that may be encountered with the product or service.
10. Eliminate slogans, exhortations, and targets for the workforce asking for zero defects and new levels of productivity. Such exhortations only create adversarial relationships, as the bulk of the causes of low quality and low productivity belong to the system and thus lie beyond the power of the workforce.
11. a. Eliminate work standards (quotas) on the factory floor. Substitute leadership.
    b. Eliminate management by objective. Eliminate management by numbers and numerical goals. Substitute leadership.
12. a. Remove barriers that rob the hourly worker of the right to pride of workmanship. The responsibility of supervisors must be changed from sheer numbers to quality.
    b. Remove barriers that rob people in management and in engineering of their right to pride of workmanship. This means, *inter alia*, abolishment of the annual or merit rating and of management by objective.
13. Institute a vigorous program of education and self-improvement.
14. Put everybody in the company to work to accomplish the transformation. The transformation is everybody's job.

One of the essential requirements of the Deming idea is that if a problem in the production of a product occurs, it should be fixed before any more of the product is produced. This concept, of course, can be applied to any organization, as all organizations produce either a product or a service. In service organizations, if the service that is provided is poor, one risks losing the customer forever. Moreover, some marketing researchers claim that a dissatisfied customer tells several other customers about the bad experience and this may magnify the cost of a poor service encounter.

STATISTICAL PROCESS CONTROL

The primary set of tools in managing the production of a good or service so that quality is optimized is called **statistical process control** or **SPC**. SPC has as its purpose the identification of the quality of a process, the identification of the factors that influence the quality of a process, the elimination of factors that cause excess variability in the process, the monitoring of a process so that problems are quickly detected and eliminated, and the continuous improvement of a process. Most of the tools in SPC are graphical; these have the added advantage of ease of use, understanding, and communication. Perhaps the most important of these tools is the **control chart,** which is a graph of a quality measurement over time. This quality measurement has been calculated from a sample taken from the process because sampling is more efficient than 100 percent inspection in most cases, when one considers cost. The control chart is used to determine the current performance of a process, to determine the capability of a process, and to monitor a process.

The concept behind the control chart is that it is a tool for separating the variation of the process quality into two parts. Deming calls these two parts **special causes of variability** and **common causes of variability**. Some other common usage is assignable causes (special) and chance or natural (common) variability. Special-cause variability is due to problems with machines, operators, or raw materials and is usually large compared to common-cause variability, which is the variability in the process due to all of the other factors of production. When a process has had all of the special causes of variability removed, it is said to be stable or in a state of statistical control. Further reduction in the remaining common-cause variability is called process improvement but should not be attempted until the process is stable.

Other common tools for SPC include graphs such as histograms, scatterplots, stem and leaf diagrams, Pareto charts, and boxplots. Most textbooks in statistical quality control give in-depth coverage of these

topics. Section 17.3, Engineering Statistics and Quality Control, covers some of the tools mentioned here as well as others in more detail.

There are several steps in SPC. The first step is to define quality. In the past product quality was measured by specifications determined by engineers. A more contemporary view of the measurement of quality is to use customer input into the design of the product or service and subsequently to use these specifications of the dimensions of quality as targets.

The second step in SPC is to measure the current quality of a process; this step is called process performance evaluation. One accurate method of measuring quality is to take random samples from the process over time. In SPC, though, one is interested in eliminating special causes of variability after one does a process performance evaluation so the most common form of sampling is by rational subgroups. These are samples chosen so that any differences due to machines, operators, or raw materials will be apparent in the data. While not as accurate in terms of providing an estimate of quality as a random sample, rational subgrouping provides a very accurate measure of quality and, more important, allows an analyst to have some insight into what special causes of variability are present. For example, a process performance evaluation might show that quality depends upon the supplier of raw material, as in a case where the product quality obtained from shifts in which a particular supplier's inputs are used is much worse than the quality when other suppliers' raw materials are used. The value of rational subgrouping is that these types of differences are apparent if the rational subgroups are cleverly chosen.

The process of removing special causes of variability is called *process capability analysis*. In the example above, the analyst might work with the particular supplier to find and eliminate the causes of poor-quality input.

After a process has undergone a process capability analysis and special causes of variability are removed, the process should be monitored. Monitoring involves taking samples from the process at particular times and calculating a statistic that measures quality. Some common statistics are the sample mean, the sample range, the sample proportion defective, and the sample number of defects per unit. These statistics are plotted on a control chart; for these statistics the control charts are respectively the X bar chart, the R chart, the p chart and the c chart. A control chart is used to visually determine if a special cause of poor quality has occurred; if it has, ideally the process is shut down and the special cause removed.

The last step in the SPC is process improvement, which ideally happens continuously. Thus, it has the name *continuous improvement*. In this step, the analyst tries to continuously reduce the common-cause variability through observational studies with rational subgrouping or experimental designs.

In practice there have been many general attempts to push the idea of quality in the workplace. Some advocates such as Deming, Juran, and Crosby came up with platforms for convincing managers that their methods would ensure successful quality efforts within an organization. Other general schemes to manage quality have appeared over the past several decades and include total quality management, ISO certification, the Malcom Baldridge national quality award, and reengineering. Perhaps the most successful is the current platform called six sigma which originated at Motorola under the leadership of Bob Galvin and at GE under Jack Welch.

Six sigma is a method that fully uses the methods discussed above in SPC. It gets its name from the fact that six sigma means there are not more than 3.4 defects per million, an admirable goal. Some of the major ideas behind six sigma include teaching everyone involved the standard statistical tools of SPC such as those discussed above, teaching a structured process such as SPC as a general problem-solving tool, making decisions analytically by using data rather than intuition or experience, and striving for a continuous need to reduce variation in a process. One of the advantages of six sigma is that its use is suggested in all areas of an organization, not just manufacturing.

Six sigma has generated admirable results because it stands on a strong theoretical foundation and is plausible. It is also not beyond the scope of anyone in its complexity. And, empirically, it has had a major financial impact on many firms.

LINEAR PROGRAMMING

At the heart of management's responsibility is the best or optimum use of limited resources including money, personnel, materials, facilities, and time. Linear programming, a mathematical technique, permits determination of the best use which can be made of available resources. It provides a systematic and efficient procedure which can be used as a guide in decision making.

As an example, imagine the simple problem of a small machine shop that manufactures two models, standard and deluxe. Each standard model requires 2 h of grinding and 4 h of polishing. Each deluxe model requires 5 h of grinding and 2 h of polishing. The manufacturer has three grinders and two polishers; therefore, in a 40-h week there are 120 h of grinding capacity and 80 h of polishing capacity. There is a profit of $3 on each standard model and $4 on each deluxe model and a ready market for both models. The management must decide on: (1) the allocation of the available production capacity to standard and deluxe models and (2) the number of units of each model in order to maximize profit.

To solve this linear programming problem, the symbol X is assigned to the number of standard models and Y to the number of deluxe models. The profit from making X standard models and Y deluxe models is $3X + 4Y$ dollars. The term *profit* refers to the **profit contribution,** also referred to as **contribution margin** or **marginal income.** The profit contribution per unit is the selling price per unit less the unit variable cost. Total contribution is the per-unit contribution multiplied by the number of units.

The restrictions on machine capacity are expressed in this manner: To manufacture one standard unit requires 2 h of grinding time, so that making X standard models uses $2X$ h. Similarly, the production of Y deluxe models uses $5Y$ h of grinding time. With 120 h of grinding time available, the grinding capacity is written as follows: $2X + 5Y \leq 120$ h of grinding capacity per week. The limitation on polishing capacity is expressed as follows: $4X + 2Y \leq 80$ h per week. In summary, the basic information is:

	Grinding time	Polishing time	Profit contribution
Standard model	2 h	4 h	$3
Deluxe model	5 h	2 h	4
Plant capacity	120 h	80 h	

Two basic linear programming techniques, the graphic method and the simplex method, are described and illustrated using the above capacity-allocation-profit-contribution maximization data.

Graphic Method

Operations	Hours available	Hours required per model		Maximum number of models	
		Standard	Deluxe	Standard	Deluxe
Grinding	120	2	5	$\frac{120}{2} = 60$	$\frac{120}{5} = 24$
Polishing	80	4	2	$\frac{80}{4} = 20$	$\frac{80}{2} = 40$

The lowest number in each of the two columns at the extreme right measures the impact of the hours limitations. The company can produce 20 standard models with a profit contribution of \$60 (20 × \$3) or 24 deluxe models at a profit contribution of \$96 (24 × \$4). Is there a better solution?

To determine production levels in order to maximize the profit contribution of $\$3X + \$4Y$ when:

$$\begin{aligned} 2X + 5Y &\le 120 \text{ h} && \text{grinding constraint} \\ 4X + 2Y &\le 80 \text{ h} && \text{polishing constrain} \end{aligned}$$

a graph (Fig. 17.1.3) is drawn with the constraints shown. The two-dimensional graphic technique is limited to problems having only two variables—in this example, standard and deluxe models. However, more than two constraints can be considered, although this case uses only two, grinding and polishing.

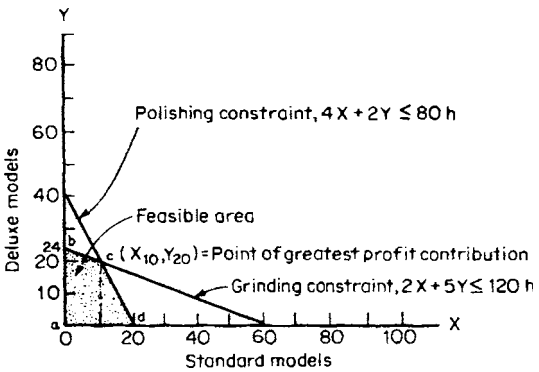

Fig. 17.1.3 Graph depicting feasible solution.

The **constraints** define the solution space when they are sketched on the graph. The solution space, representing the area of feasible solutions, is bounded by the corner points *a, b, c,* and *d* on the graph. Any combination of standard and deluxe units that falls within the solution space is a feasible solution. However, the *best* feasible solution, according to mathematical laws, is in this case found at one of the corner points. Consequently, all corner-point variables must be tried to find the combination which maximizes the profit contribution: $\$3X + \$4Y$.

Trying values at each of the corner points:

$$\begin{aligned} a &= (X = 0, Y = 0); \$3(0) + \$4(0) = \$ 0 \text{ profit} \\ b &= (X = 0, Y = 24); \$3(0) + \$4(24) = \$ 96 \text{ profit} \\ c &= (X = 10, Y = 20); \$3(10) + \$4(20) = \$110 \text{ profit} \\ d &= (X = 20, Y = 0); \$3(20) + \$4(0) = \$ 60 \text{ profit} \end{aligned}$$

Therefore, in order to maximize profit the plant should schedule 10 standard models and 20 deluxe models.

Simplex Method The simplex method is considered one of the basic techniques from which many linear programming techniques are directly or indirectly derived. The method uses an iterative, stepwise process which approaches an optimum solution in order to reach an objective function of maximization (for profit) or minimization (for cost). The pertinent data are recorded in a tabular form known as the **simplex tableau.** The components of the tableau are as follows (see Table 17.1.1):

The **objective row** of the matrix consists of the coefficients of the objective function, which is the profit contribution per unit of each of the products.

The **variable row** has the names of the variables of the problem including slack variables. **Slack variables** S_1 and S_2 are introduced in order to transform the set of inequalities into a set of equations. The use of slack variables involves simply the addition of an arbitrary variable to one side of the inequality, transforming it into an equality. This arbitrary variable is called **slack variable,** since it takes up the slack in the inequality. The simplex method requires the use of equations, in contrast to the inequalities used by the graphic method.

The **problem rows** contain the coefficients of the equations which represent constraints upon the satisfaction of the objective function. Each constraint equation adds an additional problem row.

The **objective column** receives different entries at each iteration, representing the profit per unit of the variables. In this first tableau (the only one illustrated due to space limitations) zeros are listed because they are the coefficients of the slack variables of the objective function. This column indicates that at the very beginning every S_n has a net worth of zero profit.

The **variable column** receives different notations at each iteration by replacement. These notations are the variables used to find the profit contribution of the particular iteration. In this first matrix a situation of no (zero) production is considered. For this reason, zeros are marked in the objective column and the slacks are recorded in the variable column. As the iterations proceed, by replacements, appropriate values and notations will be entered in these two columns, objective and variable.

The **quantity column** shows the constant values of the constraint equations.

Based on the data used in the graphic method and with a knowledge of the basic components of the simplex tableau, the first matrix can now be set up.

Letting X and Y be respectively the number of items of the standard model and the deluxe model that are to be manufactured, the system of inequalities or the set of constraint equations is

$$\begin{aligned} 2X + 5Y &\le 120 \\ 4X + 2Y &\le 80 \end{aligned}$$

in which both X and Y must be positive values or zero ($X \ge 0$; $Y \ge 0$) for this problem.

The objective function is $3X + 4Y = P$; these two steps were the same for the graphic method.

The set of inequalities used by the graphic method must next be transformed into a set of equations by the use of slack variables. The inequalities rewritten as equalities are

$$\begin{aligned} 2X + 5Y + S_1 &= 120 \\ 4X + 2Y + S_2 &= 80 \end{aligned}$$

and the objective function becomes

$$3X + 4Y + 0S_1 + 0S_2 = P \qquad \text{to be maximized}$$

The first tableau with the first solution would then appear as shown in Table 17.1.1.

The tableau carries also the first solution which is shown in the **index row.** The index row carries values computed by the following steps:

1. Multiply the values of the quantity column and those columns to the right of the quantity column by the corresponding value, by rows, of the objective column.
2. Add the results of the products by column of the matrix.
3. Subtract the values in the objective row from the results in step 2.

For this operation the objective row is assumed to have a zero value in the quantity column. By convention the profit contribution entered in the cell lying in the quantity column and in the index row is zero, a condition valid only for the first tableau; in the subsequent matrices it will be a positive value.

Index row:

Steps 1 and 2:	Step 3:
$120(0) + 80(0) = 0$	$0 - 0 = 0$
$2(0) + 4(0) = 0$	$0 - 3 = -3$
$5(0) + 2(0) = 0$	$0 - 4 = -4$
$1(0) + 0(0) = 0$	$0 - 0 = 0$
$0(0) + 1(0) = 0$	$0 - 0 = 0$

Table 17.1.1 First Simplex Tableau and First Solution

		0	3	4	0	0	Objective row
	Mix	Quantity	X	Y	S_1	S_2	Variable row
0	S_1	120	2	5	1	0	Problem rows
0	S_2	80	4	2	0	1	
		0	–3	–4	0	0	Index row
Objective column	Variable column	Quantity column					

In this first tableau the slack variables were introduced into the product mix, variable column, to find *a feasible* solution to the problem. It can be proven mathematically that beginning with slack variables assures a feasible solution. One possible solution might have S_1 take a value of 120 and S_2 a value of 80. This approach satisfies the constraint equation but is undesirable since the resulting profit is zero.

It is a rule of the simplex method that the optimum solution has not been reached if the index row carries any negative values at the completion of an iteration in a maximization problem. Consequently, this first tableau does not carry the optimum solution since negative values appear in its index row. A second tableau or matrix must now be prepared, step by step, according to the rules of the simplex method.

Duality of Linear Programming Problems and the Problem of Shadow Prices Every linear programming problem has associated with it another linear programming problem called its **dual.** This duality relationship states that for every maximization (or minimization) problem in linear programming, there is a unique, similar problem of minimization (or maximization) involving the same data which describe the original problem. The possibility of solving any linear programming problem by starting from two different points of view offers considerable advantage. The two paired problems are defined as the dual problems because both are formed by the same set of data, although differently arranged in their mathematical presentation. Either can be considered to be the **primal;** consequently the other becomes its dual.

Shadow prices are the values assigned to one unit of capacity and represent economic values per unit of scarce resources involved in the restrictions of a linear programming problem. To maximize or minimize the total value of the total output it is necessary to assign a quantity of unit values to each input. These quantities, as cost coefficients in the dual, take the name of "shadow prices," "accounting prices," "fictitious prices," or "imputed prices" (values). They indicate the amount by which total profits would be increased if the producing division could increase its productive capacity by a unit. The shadow prices, expressed by monetary units (dollars) per unit of each element, represent the least cost of any extra unit of the element under consideration, in other words, a kind of marginal cost. The real use of shadow prices (or values) is for management's evaluation of the manufacturing process.

QUEUING THEORY

Queuing theory or **waiting-line** theory problems involve the matching of servers, who provide, to randomly arriving customers, services which take random amounts of time. Typical questions addressed by queuing theory studies are: how long does the average customer wait before being waited on and how many servers are needed to assure that only a given fraction of customers waits longer than a given amount of time.

In the typical problem applicable to queuing theory solution, people (or customers or parts) arrive at a server (or machine) and wait in line (in a queue) until service is rendered. There may be one or more servers. On completion of the service, the person leaves the system. The rate at which people arrive to be serviced is often considered to be a random variable with a Poisson distribution having a parameter λ. The average rate at which services can be provided is also generally a Poisson distribution with a parameter μ. The symbol k is often used to indicate the number of servers.

MONTE CARLO

Monte Carlo simulation can be a helpful method in gaining insight to problems where the system under study is too complex to describe or the model which has been developed to represent the system does not lend itself to an analytical solution by other mathematical techniques. Briefly, the method involves building a mathematical model of the system to be studied which calculates results based on the input variables, or **parameters.** In general the variables are of two kinds: decision parameters, which represent variables which the analyst can choose, and stochastic, or random, variables, which may take on a range of values and which the analyst cannot control.

The random variables are selected from specially prepared probability tables which give the probability that the variable will have a particular value. All the random variables must be independent. That means that the probability distribution of each variable is **independent** of the values chosen for the others. If there is any correlation between the random variables, that correlation will have to be built into the system model.

For example, in a model of a business situation where market share is to be calculated, a decision-type variable representing selling price can be selected by the analyst. A variable for the price of the competitive product can be randomly selected. Another random variable for the rate of change of market share can also be randomly selected. The purpose of the model is to use these variables to calculate a market share suitable to those market conditions. The algebra of the model will take the effects of all the variables into account. Since the rate-of-change variable can take many values which cannot be accurately predicted, as can the competitive price variable, many runs will be made with different randomly selected values for the random variables. Consequently a range of probable answers will be obtained. This is usually in the form of a **histogram.** A histogram is a graph, or table, showing values of the output and the probability that those values will occur. The results, when translated into words, are expressed in the typical Monte Carlo form of: if such a price is chosen, the following probability distribution of market shares is to be expected.

17.2 COST ACCOUNTING

by Scott Jones

REFERENCES: Horngren and Foster, "Cost Accounting—A Managerial Emphasis," Prentice-Hall. Anthony and Govindarajan, "Management Control Systems," Irwin. Cooper and Kaplan, "The Design of Cost Management Systems—Text, Cases, and Readings," Prentice-Hall.

ROLE AND PURPOSE OF COST ACCOUNTING

Cost measurements and reporting procedures are integral components of management information systems, providing financial measurements of economic value and reports useful to many and varied objectives. In a functional organization, where lines of authority are drawn between engineering, production, marketing, finance, and so on, cost accounting information is primarily used by managers for control in guiding departmental units toward the attainment of specific organizational goals. In team-oriented organizations, authority is distributed to multifunctional teams empowered as a group to make decisions. The focus of cost accounting in this organizational structure is not so much on control, but on supporting decisions through the collection of relevant information for decision making. Cost accounting also provides insight for the attainment of competitive advantage by providing an information set and analytical framework useful for the analysis of product or process design, or service delivery alternatives.

The basic purpose of cost measurements and reporting procedures can be organized into a few fundamental areas. These are: (1) identifying and measuring the economic value to be placed on goods and services for reporting periodic results to external information users (creditors, stockholders, and regulators); (2) providing control frameworks for the implementation of specific organizational objectives; (3) supporting operational and strategic decision making aimed at achieving and sustaining competitive advantage.

MEASURING AND REPORTING COSTS TO STOCKHOLDERS

Accounting in general and cost accounting in particular are most visible to the general public in the role of **external reporting.** In this role, cost accounting is geared toward measuring and reporting periodic results, typically annual, to users outside of the company such as stockholders, creditors, and regulators. The annual report presents to these users management forecasts for the coming period and results of past years operations as reflected in **general-purpose financial statements.** (See also Sec. 17.1, "Operations Management.") Performance is usually captured through the presentation of three reports: the income statement, the balance sheet, and the statement of cash flows (see Fig. 17.2.1). These statements are audited by independent certified public accountants who attest that the results reported present a fair picture of the financial position of the company and that prescribed rules have been followed in preparing the reports. The accounting principles and procedures that guide the preparation of those reports are governed by **generally accepted accounting principles** (GAAP).

The underlying principles that guide GAAP financial statements encourage comparability among companies and across time. Therefore, these rules are usually too constraining for reports destined for internal use. External reports such as the balance sheet and income statement are prepared on the **accrual basis.** Under this basis, revenues are recognized (reported to stockholders) when earned, likewise costs are expensed against (matched with) revenue when incurred. This is to be contrasted with the **cash basis,** which recognizes revenues and expenses when cash is collected or paid. For example, if a drill press is purchased for use in the factory, a cash outflow occurs when the item is paid for. The cash basis would recognize the purchase price of the drill press as an expense when the payment is made. On the other hand, the accrual basis of accounting would capitalize the price paid, and this amount would be the cost (or basis) of the asset called *drill press.* In accrual accounting, an asset is something having future economic benefit, and therefore the cost of this asset must be distributed among the periods of time when it is used to generate revenue. The cost of the drill press would be expensed periodically by deducting a small amount of that cost from revenue as the drill press is used over its economic life, which may be several years. This periodic charge is called *depreciation.* To capture the effects that revenue-generating activities have on cash, GAAP financial statements also include the statement of cash flows. The statement of cash flows is not prepared on an accrual basis; rather, it reflects the amount of cash flowing into a company during a period, as well as the cash outflow. The first section of that statement, "Cash flows from operating activities," is essentially an income statement prepared on the cash basis.

Another application of cost accounting measurements for external users involves the preparation of reports such as income tax returns for governmental agencies. Federal, state, and local tax authorities prescribe specific accounting procedures to be applied in determining taxable income. These rules are conceptually similar to general-purpose financial reporting but differ mainly in technical aspects of the computations, which are modified to support whatever public finance goals may exist for a particular period. Whereas GAAP financial statements allow for the analysis of credit and investment opportunities, Internal Revenue Service regulations are designed to raise revenue, stimulate the economy, or both. Regulations may be primarily aimed at reducing the federal deficit and hence assign rather long "useful lives" to depreciable assets; at other times in history useful lives were shortened to stimulate investment and economic growth. For GAAP, management usually estimates the useful life of an asset for purposes of depreciation. For IRS purposes, the amount of depreciation is based on the **class life** of the asset, and the depreciation system elected by the taxpayer. Class life is based on whether the asset is specialized or general purpose, and in what industry the asset is employed.

CLASSIFICATIONS OF COSTS

The purposes of cost accounting require classifications of costs so that they are recognized (1) by the nature of the item (a natural classification), (2) in their relation to the product, (3) with respect to the accounting period to which they apply, (4) in their tendency to vary with volume or activity, (5) in their relation to departments, (6) for control and analysis, and (7) for planning and decision making.

Direct material and direct labor may be listed among the items which have a **variable** nature. Factory overhead, however, must be carefully examined with regard to items of a variable and a fixed nature. It is impossible to budget and control factory-overhead items successfully without regard to their tendency to be fixed or variable; the division is a necessary prerequisite to successful budgeting and intelligent cost planning and analysis.

In general, **variable expenses** show the following characteristics: (1) variability of total amount in direct proportion to volume, (2) comparatively constant cost per unit or product in the face of changing volume, (3) easy and reasonably accurate assignments to operating departments, and (4) incurrence controllable by the responsible department head.

The characteristics of **fixed expenses** are (1) fixed amount within a relative output range, (2) decrease of fixed cost per unit with increased output, (3) assignment to departments often made by managerial

decisions or cost-allocation methods, and (4) control for incurrence resting with top management rather than departmental supervisors. Whether an expense is classified as fixed or variable may well be the result of managerial decisions.

Some **factory overhead** items are semivariable in nature; i.e., they vary with production but not in direct proportion to the volume. For practical purposes, it is desirable to resolve each semivariable expense item into its variable and fixed components.

A factory is generally organized along departmental lines for production purposes. This factory departmentalization is the basis for the important classification and subsequent accumulation of costs by departments to achieve (1) cost control and (2) accurate costing. The departments of a company generally fall into two categories: (1) producing, or productive, departments, and (2) nonproducing, or service, departments. A producing department is one in which manual and machine operations are performed directly upon any part of the product manufactured. A service department is one that is not directly engaged in production but renders a particular type of service for the benefit of other departments. The expense incurred in the operation of service departments represents a part of the total factory overhead that must be absorbed in the cost of the product.

For **product costing,** the factory may be divided into departments, and departments may also be subdivided into cost centers. As a product passes through a cost center or department, it is charged with a share of the indirect expenses on the basis of a departmental factory-overhead rate. For cost-control purposes, budgets are established for departments and cost centers. Actual expenses are compared with budget allowances in order to determine the efficiency of a department and to measure the manager's success in controlling expenses.

Factory overhead, which is charged to a product or a job on the basis of a predetermined overhead rate, is considered indirect with regard to the product or the job to which the expense is charged. Service-department expenses are prorated to other service departments and/or to the producing departments. The proration is accomplished by using some rational basis such as area occupied or number of workers. The prorated costs are termed **indirect departmental charges.** When all service-department expenses have been prorated to the producing departments, each producing department's total factory overhead will consist of its own direct departmental expense and the indirect (or prorated, or apportioned) charges. This total cost is charged to the product or the job on the basis of the predetermined factory-overhead rate.

A company's cost system provides the data required for establishing **standard costs** and for the preparation and operation of a **budget.**

The **budget** program enlists all members of management in the task of creating a workable and acceptable plan of action, welds the plan into a homogeneous unit, communicates to the managerial levels differences between planned activity and actual performance, and points out unfavorable conditions which need corrective action. The budget not only will help promote coordination of people, clarification of policy, and crystallization of plans, but with successful use will create greater internal harmony and unanimity of purpose among managers and workers.

The established **standard-cost** values for material, labor, and factory overhead form the foundation for the budget. Since standard costs are an invaluable aid in the process of setting prices, it is essential to set these standard costs at realistic levels. The measurement of deviations from established standards or norms is accomplished through the use of variance accounts.

Costs as a basis for planning are estimated costs which may be incurred if any one of several alternative courses of action is adopted. Different types of costs involve varying kinds of consideration in managerial planning and decision making.

METHODS OF ACCUMULATING COSTS IN RECORDS OF ACCOUNT

The balance sheet lists the components of inventory as raw materials, work in process, and finished goods. These accounts reflect the cost of unsold production at various stages of completion. The costs in work in process and finished goods are accumulated or tabulated in the record of accounts according to one of two methods:

1. The Job-Order Cost Method When orders are placed in the factory for specific jobs or lots of product, which can be identified through all manufacturing processes, a job cost system is appropriate. This method has certain characteristics. A manufacturing order often corresponds to a customer's order, though sometimes a manufacturing order may be for stock. The customer's order may be obtained on the basis of a bid price computed from an estimated cost for the job. The goods in each order are kept physically separate from those of other jobs. The costs of a manufacturing order are entered on a job cost sheet which shows the total cost of the job upon completion of the order. This cost is compared with the estimated cost and with the price which the customer agreed to pay.

2. The Process Cost Method When production proceeds in a continuous flow, when units of product are not separately identifiable, and when there are no specific jobs or lots of product, a process cost system is appropriate, for it has certain characteristics: work is ordered through the plant for a specific time period until the raw materials on hand have all been processed or until a specified quantity has been produced; goods are sold from the stock of finished goods on hand since a customer's order is not separately processed in the factory; the cost-of-production sheet is a record of the costs incurred in operating the process—or a series of processes—for a period of time. It shows the quantity produced in pounds, tons, gallons, or other units, and the cost per unit is obtained by dividing the total costs of the period by the total units produced. Performance is indicated by comparing the quantity produced and the cost per unit of the current period with similar figures of other periods or with standard cost figures.

ELEMENTS OF COSTS

The main items of costs shown on the income statement are factory costs which include direct materials, direct labor and factory overhead; and selling and administrative expenses. A breakdown of costs is shown in Figure 17.2.2.

Materials The cost of materials purchased is recorded from purchase invoices. When the materials are used in the factory, an assumption must be made as to **cost flow,** that is, whether to charge them to operations at average prices, at costs based on the first-in, first-out method of costing, or at costs based on the last-in, first-out method of costing. Each method will lead to a different cost figure, depending on how prices change. Each situation must be studied individually to determine which practice will give a maximum of accuracy in cost figures with a minimum of accounting and clerical effort. Once the choice has been made, records must be set up to charge materials to operations based on requisitions. Indirect material is necessary to the completion of the product, but its consumption with regard to the final product is either so small or so complex that it would be futile to treat it as a direct-material item.

Labor Labor also consists of two categories: direct and indirect. Direct labor, also called **productive labor,** is expended immediately on the materials comprising the finished product. Indirect labor, in contrast to direct labor, cannot be traced specifically to the construction

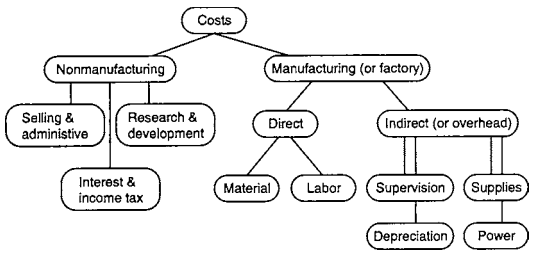

Figure 17.2.2 Summary diagram of cost relationships.

or composition of the finished product. The term includes the labor of supervisors, shop clerks, general helpers, cleaners, and those employees engaged in maintenance work.

Factory Overhead Indirect materials or factory supplies and indirect labor constitute an important segment of factory overhead. In addition, costs of fuel, power, small tools, depreciation, taxes on real estate, patent amortization, rent, inspection, supervision, social security taxes, health and accident insurance, workers' compensation insurance, and many others fall into this large category. These expenses must be collected and allocated to all jobs or units produced. Many expenses are definitely applicable to a specific department and are easily assigned thereto. Other expenses relate to the entire plant and must be prorated to departments on some suitable basis. For instance, heat might be prorated to departments on the basis of volume of space occupied. The expenses of the service departments are prorated to the producing departments on some basis such as service rendered in the case of a maintenance department or per dollar of payroll processed in the case of a cost department.

The charging of factory overhead to jobs or products is accomplished by means of an overhead or burden rate. This rate is essentially a ratio computed to show the relationship of the total burden of a department to some other easily measurable total figure for the department. For example, the total burden cost of a department may be divided by its direct-labor cost to give a percentage-of-direct-labor rate. This percentage applied to the direct-labor cost of a job or a product gives the amount of overhead chargeable thereto. Other common types of burden rates are the labor-hour rate (departmental expenses ÷ total direct-labor hours) and the machine-hour rate (departmental expenses ÷ total machine hours available). Labor rates are most commonly used. When, however, machines perform the greater amount of the work, machine-hour rates give better results. It must be clearly understood that these rates are computed in advance of production, generally at the beginning of the year. They are used throughout the fiscal period unless seasonal fluctuations or unusual changes in expense amounts necessitate the creation of a new rate. The determination of the overhead rate is closely tied up with overhead budgets.

Departmental Classification As mentioned above, the establishment of departmental lines is important not only for costing purposes but also for budgetary control purposes. Departmental lines are set up in order to (1) segregate basically different processes of production, (2) secure the smoothest possible flow of production, and (3) establish lines of responsibility for control over production and costs. When the costing methods are designed to fit in with the departmentalization of factory and office, costs can be accumulated within a department with production being on either the job-order or process cost method.

ACTIVITY-BASED COSTING

The method of assigning overhead to products based on labor hours or machine hours is referred to as **volume-based** overhead absorption because the amount assigned will vary strictly with the volume of either labor or machine time consumed. In applications where production costs may not be strictly driven by volume of labor hours, **activity-based** or **transaction** costing is appropriate. This situation typically occurs when there are many options or alternatives available to the customer. Typically, these products are produced in low volumes and have a high degree of complexity. An example would be the option of a premium radio in an automobile. Though the actual purchase cost of that radio would not be overlooked in pricing the automobile, the indirect costs would be overlooked in a volume-based system because the indirect costs associated with the premium radio, such as holding an additional item of inventory, documenting and producing separate receiving orders, added clerical and assembly coordination effort, increased engineering complexity, and so on would be grouped under the general category of overhead. On the other hand, in an activity-based system, indirect costs would be assigned to a unique cost pool, such as shown in Fig. 17.2.3 and 17.2.4, which compare the procedures of volume and activity-based costing. The striking difference is that the overhead cost pool used in volume systems is not present. In activity-based systems, many more cost pools are used and are closely related to some **causal aspect** of the process such as machine setup, receiving orders, or material movement. The costs are assigned to products based on the relative amounts of each cost driver consumed by that product. Therefore, low-volume options such as the premium radio receive a larger share of indirect costs relative to the actual volume of labor used to insert the component. The amount of each cost pool attributed to a product can then be spread over the number of units produced and a more accurate assignment of costs obtained.

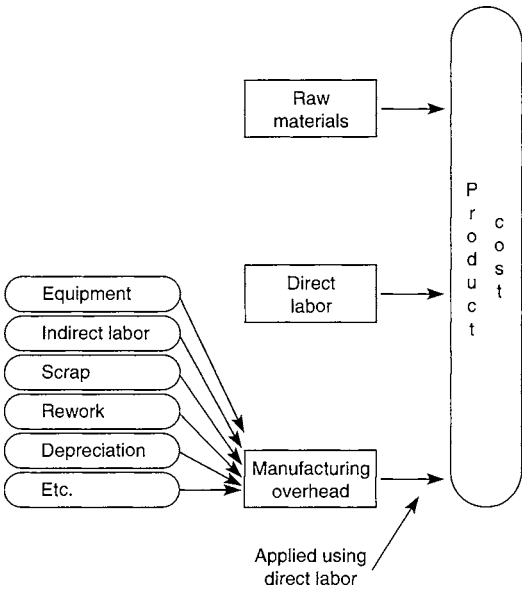

Fig. 17.2.3 Volume-based costing.

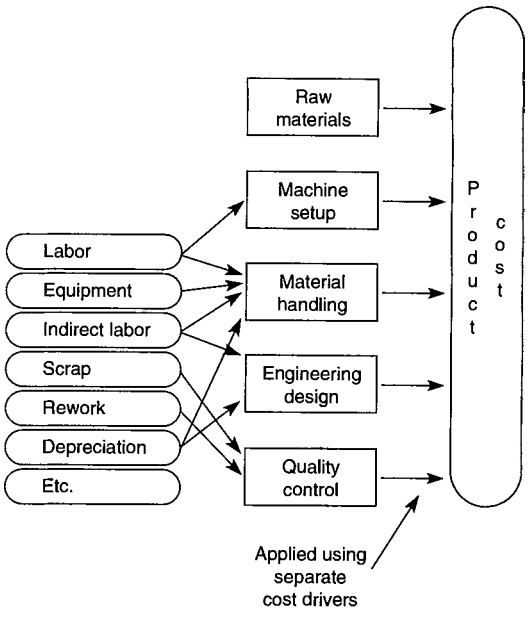

Fig. 17.2.4 Activity-based costing.

MANAGEMENT AND THE CONTROL FUNCTION

To be successful, management must integrate its own knowledge, skills, and practices with the know-how and experience of those who are entrusted with the task of carrying out company objectives. Management,

together with its employees and workers, can achieve its objectives through performance of the three managerial functions: (1) planning and setting objectives, (2) organizing, and (3) controlling.

Planning is a basic function of the management process. Without planning there is no need to organize or control. However, planning must precede doing, and the budget is the most important planning tool of an enterprise.

Organizing is essentially the establishment of the framework within which the required activities are to be performed, together with a list of who should perform them. Creation of an organization requires the establishment of organizational or functional units generally known as departments, divisions, sections, floors, branches, etc.

Controlling is the process or procedure by which management ensures operative performance which corresponds with plans. The control process is pictured diagrammatically in Fig. 17.2.5. Recognition of accounting as an important tool in the controlling phase is evidenced through the role of performance reports in pointing out areas and jobs or tasks which require corrective action. These reports should make possible "management by exception."

The effectiveness of the control of costs depends upon proper communication through control and action reports from the accountant to the various levels of operating management. An organization chart is essential to the development of a cost system and cost reports which parallel the responsibilities of individuals for implementing management plans. The coordinated development of a company's organization with the cost and budgetary system will lead to "responsibility accounting." Responsibility accounting plays a key role in determining the type of cost system used.

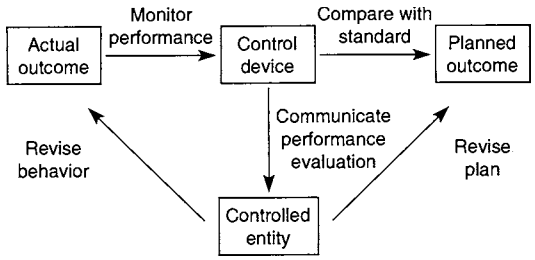

Fig. 17.2.5 The control process.

TYPES OF COST SYSTEMS

The construction of a cost system requires a thorough understanding of (1) the organizational structure of the company, (2) the manufacturing procedure, and (3) the type of information which management requires of the cost system.

1. The organization chart gives a graphic picture of the ranking authority of superintendents, department heads, and managers who are responsible for (*a*) providing the detailed information needed by the accounting division in order to install a successful system; (*b*) incurring expenditures in personnel, materials, and other cost elements, which the cost accountant must segregate and report to those in charge. The cost system with its operating accounts must correspond to organizational divisions of authority so that the individual supervisor, department head, or executive can be held "accountable" for the costs incurred in the department.

2. The manufacturing procedure and shop methods lead to a consideration of the type of pay (piece rate, incentive, day rate, etc.); the method of collecting hours worked; the control of inventories; the problem of costing tools, dies, jigs, and machinery; and many other problems connected with the factory.

3. The organizational setup on the one hand and the manufacturing procedure on the other form the background for the design of a cost system that is based on (*a*) recognition of the various cost elements, (*b*) departmentalization of factory and office, and (*c*) the chart of accounts.

Any cost system should be perfected so that it will (1) aid in the control and management of the company; (2) measure the efficiency of personnel, materials, and machines; (3) help in eliminating waste; (4) provide comparison within individual industries; (5) provide a means of valuing inventories; and (6) aid in establishing selling prices. In an organization departmentalized or segmented along product lines, it is often arbitrary to allocate certain indirect costs especially when common facilities or personnel are shared. This is because there is no objective basis to compute a division of common costs. Control methods for evaluating performance often rely on the **segment margin** statement.

Example of a Segment Margin Statement

	Product A	Product B	Total
Sales	$9,000	$11,000	$20,000
Direct material & labor	(4,000)	(5,000)	(9,000)
Contribution margin	5,000	6,000	11,000
Product specific overhead	(1,000)	(2,500)	(3,500)
Segment margin	4,000	3,500	7,500
Common costs			(2,000)
Operating income			$5,500

The cost system's value is greatly enhanced when it is interlocked with a **budgetary control system.** When budget figures are based upon standard costs, the greatest benefit will be derived from such a combination.

Basically, two types of cost systems exist: (1) the **actual** (or **historical**) and (2) the **standard** (or **predetermined**). The actual cost system accumulates and summarizes costs as they occur and determines a final product cost after all manufacturing operations have been completed. The job is charged with actual quantities and costs of materials used and labor expended; the overhead or burden is allocated on the basis of some predetermined overhead rate. This predetermined overhead rate shows that even the so-called **actual system** does not entirely live up to its name. Under a standard cost system all costs are predetermined in advance of production. Both the actual (historical) and the standard cost system may be used in connection with either (1) the job-order cost method or (2) the process cost method.

BUDGETS AND STANDARD COSTS

A budget provides management with the information necessary to attain the following major objectives of budgetary control: (1) an organized procedure for planning; (2) a means for coordinating the activities of the various divisions of a business; (3) a basis for cost control. The planning phase provides the means for formalizing and coordinating the plans of the many individuals whose decisions influence the conduct of a business. Sales, production, and expense budgets must be established. Their establishment leads necessarily to the second phase of coordination. Production must be planned in relation to expected sales, materials and labor must be acquired or hired in line with expected production requirements, facilities must be expanded only as foreseeable future needs justify, and finances must be planned in relation to volume of sales and production. The third phase of cost control is predicated on the idea that actual costs will be compared with budgeted costs, thus relating what actually happened with what should have happened. To accomplish this purpose, a good measure of what costs should be under any given set of conditions must be provided. The most important condition affecting costs is volume or rate of activity. By predetermining, through the use of the flexible budget, the expenses allowed for any given rate of activity and comparing it with the actual expense, a better measurement of the performance of an individual department is achieved and the control of costs is more readily accomplished.

In the construction of overhead budgets the volume or activity of the entire organization as well as of the individual department is of considerable importance in their relationship to existing capacity. Capacity must be looked upon as that fixed amount of plant, machinery, and personnel to which management has committed itself and with which it expects to conduct the business. Volume or activity is the variable factor in business related to capacity by the fact that volume attempts to make the best use of the existing capacity. To find a profitable solution to this relationship is one of the most difficult problems faced by business management and the accountant who tries to help with appropriate cost data. Volume, particularly of a department, is often expressed in terms of direct-labor hours. With different rates of capacity, a different cost per hour of labor will be computed. This relationship can be demonstrated in the following manner:

Percentage of productive capacity	60%	80%	100%
Direct-labor hours	600	800	1,000
Factory overhead			
Fixed overhead	$1,200	$1,200	$1,200
Variable overhead	600	800	1,000
Total	$1,800	$2,000	$2,200
Overhead rate per direct-labor hour	$3.00	$2.50	$2.20

The existence of fixed overhead causes a higher rate at lower capacity utilization. It is desirable to select that overhead rate which permits a full recovery of production costs by the end of the business cycle. The above tabulation reveals another important axiom with respect to fixed and variable overhead. Fixed overhead remains constant in total but varies in respect to cost per unit or hour. Variable overhead varies in total but remains fixed in relationship to the unit or hour.

Standard Costs The budget, as a statement of expected costs, acts as a guidepost which keeps business on a charted course. Standards, however, do not tell what the costs are expected to be but rather what they will be if certain performances are attained. In a well-managed business, costs never exceed the budget. They should constantly approach predetermined standards. The uses of standard costs are of prime importance for (1) controlling and reducing costs, (2) promoting and measuring efficiencies, (3) simplifying the costing procedures, (4) evaluating inventories, (5) calculating and setting selling prices. The success of a standard cost system depends upon the reliability and accuracy of the standards. To be effective, standards should be established for a definite period of time so that control can be exercised and variances from standards computed. Standards are set for materials, labor, and factory overhead. When actual costs differ from standard costs with respect to material and labor, two causes can generally be detected. (1) The price may be higher or lower or the rate paid a worker may be different; the difference is called a material price or a labor rate variance. (2) The quantity of the material used may be more or less than the standard quantity or the hours used by the worker may be more or less. The difference is called material-quantity variance or labor-efficiency variance, respectively. For factory overhead, the computation is somewhat more elaborate. Actual expenses are compared not only with standard expenses but also with budget figures. Various methods are in vogue, resulting in different kinds of overhead variances. Most accountants compute a controllable and a volume variance. The controllable variance deals chiefly with variable expenses and measures the efficiency of the manager's ability to hold costs within the budget allowance. The volume variance portrays fixed overhead with respect to the use or nonuse of existing capacity. It measures the success of management in its ability to fill capacity with sales or production volume. These two variances can be analyzed further into an expenditure and efficiency variance for the controllable variances and into an effectiveness and capacity variance for the volume variance. Such detailed analyses might bring forth additional information which would help management in making decisions. Of absolute importance for any cost system is the fact that the information must reach management promptly, with regularity, and in a report that is analytical, permitting quick comparison with targets and goals. Only in this manner can management, which includes all echelons from the foreman to the president, exercise control over costs and therewith over profits.

TRANSFER PRICING

A **transfer price** refers to the selling price of a good or service when both the buyer and seller are within the same organization. For example, one division of a company may produce a component, such as an engine, and transfer this component to an assembly division. For purposes of control, these organizational units may be treated as **profit centers** (responsible for earning a specified profit or return on investment). Accordingly, the transfer price is a revenue for the seller and a cost to the buyer. Because organizational control is at issue whenever interdivisional transfers are made, companies must often specify a policy to dictate the basis for determining a transfer price. Transfer prices should be based on market prices when available. Most taxing authorities require intercompany transfers to be made at market price as well. To solve situations of suboptimal resource usage (e.g., idle capacity) it is often possible to construct transfer prices based on manufacturing cost plus some allowance for profit. If the producing division is a **cost center** (responsible for controlling costs to achieve a certain budgeted level), in order to promote efficiency transfers are usually made on the basis of **standard cost.**

SUPPORTING DECISION MAKING

The analytical phase of cost accounting has become more important and influential in the last few years. Management must make many decisions, some of a short-range, others of a long-range nature. To base judgment upon good, reliable data and analyses is a major task for controllers and their staffs. Cost analysis comprises such matters as analysis of distribution costs, gross-profit analysis, break-even analysis, profit-volume analysis, differential-cost analysis, direct costing, capital-expenditure analysis, return on capital employed, and price analysis. A detailed discussion of each phase mentioned lies beyond the scope of this section, but a short description is appropriate.

Distribution-cost analysis deals with allocation of selling expenses to territories, customers, channels of distribution, products, and sales representatives. Once so allocated it might be possible to determine the most profitable and the least profitable commodity, product, territory, or customer. Segment margin statements are useful for this analysis. Standards have been introduced recently in these analyses. The Robinson-Patman Act, an amendment to Section 2 of the Clayton Act, gave additional impetus to the analytical phase of distribution costs. This act prohibits pricing the same product at different amounts when the amounts do not reflect actual cost differences (such as distribution or warranty).

Gross-profit analysis attempts to determine the causes for an increase or decrease in the gross profit. Any change in the gross profit is due to one or a combination of the following: (1) changes in the selling price of the products; (2) changes in the volume sold; (3) changes in the types of products sold, called the sales-mix; (4) changes in the cost elements. Cost elements are analyzed through budgetary control methods. Sales figures must be scrutinized to unearth the changes from the contemplated course and therewith from the final profit.

Break-even analysis, generally presented in the form of a break-even chart, constitutes one of the briefest and most easily understood devices for data presentation for policy-making decisions. The name "break-even" implies that point at which the company neither makes a profit nor suffers a loss from the operations of the business. A break-even chart can be defined as a portrayal in graphic form of the relation of production and sales to profit or, more briefly, a graphic variable income statement. The computation of the break-even point can be made by the following formula.

$$\text{Break-even sales volume} = \frac{\text{total fixed expenses}}{1 - \dfrac{\text{total variable expenses}}{\text{total sales volume}}}$$

EXAMPLE. Assume fixed expenses, $13,800,000; variable expenses, $27,000,000; total sales volume, $50,000,000. Computation: Break-even sales volume = $13,800,000/[1 − ($27,000,000/$50,000,000)] = $30,000,000.

Results can be obtained in chart form (Fig. 17.2.6).

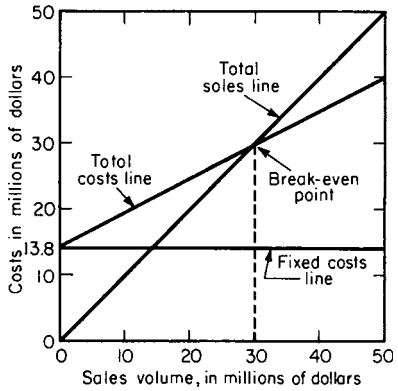

Fig. 17.2.6 Illustrative break-even chart.

Cost-volume-profit analysis deals with the effect that a change of volume, cost, price, and product-mix will have on profits. Managements of many enterprises attempt to stimulate the public to purchase their products by conducting intensive promotion campaigns in radio, press, mail, and television. The customer, however, makes the final decision. What management wants to know is which product or model will yield the most profitable margin; which is the least profitable; what effect a reduction in sales price will have on final profit; what effect a shift in volume or product-mix will have on product costs and profits; what the new break-even point will be under such changing conditions; what the effect of expected increases in wages or other operating costs on profit will be; what the effect will be on costs, profit, and sales volume should there be an expansion of the plant. Cost-volume-profit analysis can also be presented graphically in a so-called *volume-profit-analysis graph.* Using the same data as in the break-even chart, a volume-profit analysis graph takes the form shown in Fig. 17.2.7.

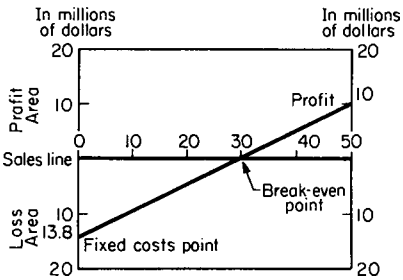

Fig. 17.2.7 Illustrative cost-volume-profit analysis graph.

Differential-cost analysis treats differences, as the title suggests. These differences, also called alternative courses, arise when management wants to know whether or not to take business at a special price, to risk a decline in price of total sales, to sacrifice volume for price, to shut down part of the plant, or to enlarge plant capacity. While accountants generally use the term **"differential,"** economists speak of **"marginal"** and engineers of **"incremental"** costs in connection with such a study. As in any of the previously discussed analyses, the classification of costs into their fixed and variable components is absolutely essential. However, while in break-even analysis the emphasis rests upon the fixed expenses, differential-cost studies stress the variable costs. The differential-cost statement presents only the differences in the following manner:

	Present business	Additional business	Total
Sales	$100,000	$10,000	$110,000
Variable costs	60,000	6,000	66,000
Marginal income	40,000	4,000	44,000
Fixed expenses	30,000	none	30,000
Profit	$ 10,000	$ 4,000	$ 14,000

This statement shows that additional business is charged with the variable expenses only because present business is absorbing all fixed expenses.

Direct costing is a costing method which charges the products with only those costs that vary directly with volume. Variable or direct costs such as direct materials, direct labor, and variable manufacturing expenses are examples of costs chargeable to the product. Costs that are a function of time rather than of production are excluded from the cost of the product. The only costs assignable to inventories are variable costs, and because they should vary in proportion to increases or decreases in production, the unit cost assigned to inventories should be uniform.

CAPITAL-EXPENDITURE DECISIONS

The preparation of a capital-expenditure budget must be preceded by an analytical and decision-making process by management. This area of managerial decisions not only is important to the success of the company but also is crucial in case of errors. Financial requirements, present and anticipated costs, profits, tax considerations, and legal, personnel, and market problems must be studied and reviewed before making the final decision.

Five evaluation techniques are generally accepted as representative tools for decision making: (1) **payback-** or **payout-period method;** (2) **average-return-on-investment method;** (3) **present-value method;** (4) **discounted-cash-flow method;** and (5) **economic value added (EVA).** None of these methods serves every purpose or every firm. The methods should, however, aid management in exercising judgment and making decisions. Of significance in the evaluation of a capital expenditure is the time value of money which is employed in the present value and the discounted-cash-flow methods. The **present value** means that a dollar received a year hence is not the equivalent of a dollar received today, because the use of money has a value. For this reason, the estimated results of an investment proposal can be stated as a cash equivalent at the present time, i.e., its present value. Present-value tables have been devised to facilitate application of present-value theory.

In the present-value method the discount rate is known or at least predetermined. In the **discounted-cash-flow** (DCF) method the rate is to be calculated and is defined as the rate of discount at which the sum of positive present values equals the sum of negative present values. The DCF method permits management to amortize corporate profits by selecting proposals with the highest rates of return as long as the rates are higher than the company's own **cost of capital** plus management's allowance for risk and uncertainty. Cost of capital represents the expected return for a given level of risk that investors demand for investing their money in a given firm or venture. However, when related to capital-expenditure planning, the cost of capital refers to a specific cost of capital from a particular financing effort to provide funds for a specific project or numerous projects. Such use of the concept connotes the marginal cost of capital point of view and implies linkage of the financing and investment decisions. It is, therefore, not surprising that the cost of capital differs, depending upon the sources. A company could obtain funds from (1) bonds, (2) preferred and common stock, (3) use of retained earnings, and (4) loans from banks. If a company obtains funds by some combination of these sources to achieve or maintain a particular capital structure, then the cost of capital (money) is the weighted average cost of each money source.

Return-on-Capital Concept This aids management in making decisions with respect to proposed capital expenditures. This concept can also be used for (1) measuring operating performance, (2) profit planning and decision making, and (3) product pricing. The return on capital may be expressed as the product of two factors: the percentage of profit to sales and the rate of capital turnover. In the form of an equation, the method appears as

$$\frac{\text{Profit}}{\text{Sales}} = \text{profit margin} \quad \left.\begin{matrix}\downarrow\\ \times \rightarrow =\\ \uparrow\end{matrix}\right. \quad \text{return on capital investment}$$

$$\frac{\text{Sales}}{\text{Capital}} = \text{Investment turnover}$$

Whether for top executive, plant or product manager, plant engineer, sales representative, or accountant, the concept of return on capital employed tends to mesh the interest of the entire organization. An understanding and appreciation of the return-on-capital concept by all employees help in building an organization interested in achieving fair profits and an adequate rate of return.

COST MANAGEMENT

Often, programs of **continuous improvement** require that costs be computed according to the activity-based method. That method facilitates identifying and setting priorities for the elimination of non-value-adding activities. **Non-value-added** activities decrease cycle time efficiency, where cycle time efficiency is the sum of all value-added activity times divided by total cycle time. The engineer may redesign the product using common parts or through process redesign so as to eliminate those activities or cost pools that add to product cost without adding to value. Some examples of these activities are material movement, run setup, and queue time.

Efforts to manage product costs by eliminating non-value-adding activities are frequently the result of a need to attain a specific target cost. Traditionally selling price was determined by adding a required markup to total cost. Global competition has forced producers to accept a market price determined by competitive forces:

$$\text{Target cost} = \text{market selling price} - \text{required return on investment}$$

Accordingly, the company that stays in business is the one that can accept this price and still earn a return on investment. **Target costing** is a concerted effort to design, produce, and deliver the product at a cost that will assure long-term survival.

Engineers may also focus on process throughput as a means of cost management. The **theory of constraints** proposes that profit is maximized when process throughput is maximized. The underlying assumption is that costs are fixed in the short run and cost per unit is lowest when fixed costs are distributed over the largest possible volume. This goal is accomplished by reducing cycle time through the elimination of process bottlenecks.

17.3 ENGINEERING STATISTICS AND QUALITY CONTROL

ENGINEERING STATISTICS AND QUALITY CONTROL

Statistical models and statistical methods play an important role in modern engineering. Phenomena such as turbulence, vibration, and the strength of fiber bundles have statistical models for some of their underlying theories. Engineers now have available to them batteries of computer programs to assist in the analysis of masses of complex data. Many textbooks are needed to cover fully all these models and methods; many are areas of specialization in themselves. On the other hand, every engineer has a need for easy-to-use, self-contained statistical methods to assist in the analysis of data and the planning of tests and experiments. The sections to follow give methods that can be used in many everyday situations, yet they require a minimum of background to use and need little, if any, calculation to obtain good results.

STATISTICS AND VARIABILITY

One of the primary problems in the interpretation of engineering and scientific data is coping with **variability.** Variability is inherent in every physical process; no two individuals in any population are the same. For example, it makes no real sense to speak of the tensile strength of a synthetic fiber manufactured under certain conditions; some of the fibers will be stronger than others. Many factors, including variations of raw materials, operation of equipment, and test conditions themselves, may account for differences. Some factors may be carefully controlled, but variability will be observed in any data taken from the process. Even tightly designed and controlled laboratory experiments will exhibit variability.

Variability or variation is one of the basic concepts of statistics. Statistical methods are aimed at giving objective, quantitative, and reproducible ways of assessing the effects of variability. In particular, they aim to provide measures of the uncertainty in conclusions drawn from observational data that are inherently variable.

A second important concept is that of a **random sample.** To make valid inferences or conclusions from a set of observational data, the data should be able to be considered a random sample. What does this mean? In an operational sense it means that everything we are interested in seeing should have an equal chance of being represented in the observations we obtain. Some examples of what not to do may help. If machine setup is an important contributor to differences, then all observations should not be taken from one setup. If instrumental variation can be important, then measurements on the same item should not be taken successively—time to "forget" the last reading should pass. A random sample of n items in a warehouse is not the first n that you can find. It is the n that is selected by a procedure guaranteed to give each item of interest an equal chance of selection. One should be guided by generalizations of the fact that the apples on top of a basket may not be representative of all apples in the basket.

CHARACTERIZING OBSERVATIONAL DATA: THE AVERAGE AND STANDARD DEVIATION

The two statistics most commonly used to characterize observational data are the **average** and the **standard deviation.** Denote by $x_1, x_2, \ldots, x_n$

the n individual observations in a random sample from some process. Then the average and standard deviation are defined as follows:
Average:

$$\bar{x} = \sum_{i=1}^{n} x_i/n$$

Standard deviation:

$$s = \left[\sum_{i=1}^{n} (x_i - \bar{x})^2/(n-1)\right]^{1/2}$$

Clearly, the average gives one number around which the n observations tend to cluster. The standard deviation gives a measure of how the n observations vary or spread about this average. The square of the standard deviation is called the **variance.** If we consider a unit mass at each point x_i, then the variance is equivalent to a moment of inertia about an axis through $\bar{x}$. It is readily seen that for a fixed value of $\bar{x}$, greater spreads from the average will produce larger values of the standard deviation s. The average and the standard deviation can be used jointly to summarize where the observations are concentrated. Tchebysheff's theorem states: A fraction of at least $1 - (1/k^2)$ of the observations lie within k standard deviations of the average. The theorem guarantees lower bounds on the percentage of observations within k (also known as z in some textbooks) standard deviations of the average.

Interval	Lower bound on % of measurements
$\bar{x} - 2s$ to $\bar{x} + 2s$	75%
$\bar{x} - 3s$ to $\bar{x} + 3s$	89%
$\bar{x} - 4s$ to $\bar{x} + 4s$	94%
$\bar{x} - 5s$ to $\bar{x} + 5s$	96%
$\bar{x} - 6s$ to $\bar{x} + 6s$	97%

Since the average and the standard deviation are computed from a sample, they are themselves subject to fluctuation. However, if μ, is the long-term average of the process and σ is the long-term standard deviation, then:

$$\text{Average } (\bar{x}) = \mu, \text{ process average}$$
$$\text{Average } (s) = \sigma, \text{ process standard deviation}$$

Furthermore, the intervals $\mu \pm k\sigma$ contain the same percentage of all values, as do the intervals $\bar{x} \pm ks$ for the sample; that is, at least 89 percent of all the long-term values will be contained in the interval $\mu - 3\sigma$ to $\mu + 3\sigma$, etc.

Range Estimate of the Standard Deviation

For $n \leq 20$ it is more convenient to compute the range r to estimate the standard deviation σ. The range is $x_{(n)} - x_{(1)}$, where $x_{(n)}$ is the largest value in a random sample of size n and $x_{(1)}$ is the smallest value. For example, if $n = 10$ and the observations are 310, 309, 312, 316, 314, 303, 306, 308, 302, 305, the range is $r = 316 - 302 = 14$. An estimate of the standard deviation σ is obtained by multiplying r by the factor f_n in Table 17.3.1. The average value of $r \cdot f_n$ is σ. Thus, in the example above, an estimate of σ and a value that can be used for s is $0.3249r = 0.3249(14) = 4.5486$.

Table 17.3.1 Average of Range $f_n = s$

Sample size	f_n	Sample size	f_n
2	0.8862	11	0.3152
3	0.5908	12	0.3069
4	0.4857	13	0.2998
5	0.4299	14	0.2935
6	0.3946	15	0.2880
7	0.3698	16	0.2831
8	0.3512	17	0.2787
9	0.3367	18	0.2747
10	0.3249	19	0.2711
		20	0.2677

PROCESS VARIABILITY—HOW MUCH DATA?

Since the output of all processes is variable, one can make reasonable decisions about the output only if one can obtain a measure of how much variability or spread one can expect to see under normal conditions. Variability cannot be measured accurately with a small amount of data. Methods for assessing how much data are needed are given for two general situations.

Specified Tolerances

A convenient statement about the variability or spread of a process can be based on the smallest and largest values in a random sample of the output. There are no practical limitations on its use. Suppose that we have a random sample of n values from our process. Denote the values by $X_1, X_2, \ldots, X_n$. After obtaining the values we find the smallest, $X_{(1)}$, and the largest, $X_{(n)}$. Now we want to assess what percent of all future values that this process might generate will be covered by $X_{(1)}$ and $X_{(n)}$. In statistics, $X_{(1)}$ and $X_{(n)}$ are called **tolerance limits.** If the process generates bolts and X is the diameter, then the engineering concept of tolerance and the statistical concept of tolerance are seen to be quite similar.

Let p be the percentage of all the process values that on a long-term basis will be between $X_{(1)}$ and $X_{(n)}$. Let P be a lower bound for this percentage p. Now consider the probability statement: Probability $(p \geq P) = C$. The quantity C we call **confidence.** Since it is a probability its value is between 0 and 1. As C approaches 1 our confidence in the percentage P increases. The interpretation of P and C can be explained in terms of Table 17.3.2.

Suppose that we take a random sample of size $n = 269$ values from our process output; the smallest value is 10 and the largest is 54. In Table 17.3.2 we see that 269 is the entry for $P = 99$ and $C = 0.75$. This tells us that at least $P = 99$ percent of all future values that this process will generate will be between 10 and 54, the smallest and largest values seen in the sample of 269. The confidence $C = 0.75 = {}^3/_4$ tells us that the chances are 3 out of 4 that our statement is correct. As we increase the sample size n, we increase the chances that our statement is correct. For example, if our sample size had been $n = 473$, then $C = 0.95$ and the chances are 95 in 100 that we are correct in making the statement that at least 99 percent of all process values will be between the 10 and 54 seen in the sample. Similarly, if the sample size had been 740, then the chances of being correct increase to 995 in 1000. If sample size n is decreased sufficiently, the confidence $C = 0.50 = {}^1/_2$ indicates that the chances are one in two of being right, *and* one in two of being *wrong.* Therefore, it is important to select n so as to keep C as large as possible. The cost of acquiring the data will determine the upper limit for n.

Further information on tolerance limits can be found in Wilks (1962) and Duncan (1986).

Wear-Out and Life Tests

A special case of coverage occurs if our interest is in a wear-out phenomenon or a life test. For example, suppose we put a number of incandescent light bulbs on test; our interest is in the length of time to failure. Clearly we do not want to wait until all specimens fail to draw a conclusion; it

Table 17.3.2

	Confidence, C			
P, %	0.995	0.99	0.95	0.75
99.9	7427	6636	4742	2692
99.5	1483	1325	947	538
99	740	661	473	269
98	368	330	235	134
97	245	219	156	89
96	183	163	117	67
95	146	130	93	53
90	71	64	46	26
80	34	31	22	13
75	27	24	18	10

NOTE: Sample size r required to have a confidence C that at least P percent of all future values will be included between the smallest and largest values in a random sample.

Table 17.3.3

	Confidence, C			
Q, %	0.995	0.99	0.95	0.75
0.1	5296	4603	2995	1386
1	528	459	299	138
2	263	228	149	69
3	174	152	99	46
4	130	113	74	34
5	104	90	59	28
10	51	44	29	14
15	33	29	19	9
20	24	21	14	7
25	19	17	11	5

NOTE: Sample size r required to have a confidence C that fewer than Q percent of future units will fail in a time shorter than the shortest life in the sample. For a more extensive table of values, see Owen (1962).

might take an inordinate length of time for the last one to fail. From a practical point of view we would probably be interested in those that fail first anyway. If the sample size is properly chosen, there will be important information as soon as we obtain the first failure.

In a random sample of size n let the failure times be $T_1 \geq T_2 \geq \ldots \geq T_n$. The value T_1 is thus the smallest value in a random sample of size n. Now let q be the percentage of future units that can be expected to fail in a time less than T_1, the smallest value in the sample. As before we can make a probability statement about q. Let Q be an upper bound to q. Then we can compute: Probability $(q \leq Q) = C$.

For example, suppose that we put a random sample of 299 items on test and the first one fails in time $T_1 = 151$ h. From Table 17.3.3 we see that 299 is an entry for $Q = 1$ and $C = 0.95$. Thus we can conclude that not more than 1 percent of future units should fail in a time less than 151 h. The confidence in the statement is 95 chances in 100 of being correct. Again referring to Table 17.3.3, we see that if $T_1 = 151$ were based on a sample of 528, then the confidence would be increased to 995 chances in 1000. Most importantly, Table 17.3.3 tells us that we need to test a very large sample if we want to have high confidence that only a small percentage of future units will fail in a time less than the smallest observed. The theory behind Table 17.3.3 can be found in Wilks (1962). For a more extensive table of values see Owen (1962). If $Q' = Q/100$, use

$$r = [\log (1 - C)]/[\log (1 - Q')]$$

CORRELATION AND ASSOCIATION

One of the most common problems in the analysis of engineering data is to determine if a correlation or an association exists between two variables X and Y, where the data occur in pairs (X_i, Y_i). The "corner test of association" developed by Olmstead and Tukey (1947) is a quick and simple test to assist in making this determination.

Corner Test

Conditions for Use Each pair (X_i, Y_i) should have been obtained independently; there are no other practical assumptions for its use. Of course, the user should consider the physical process generating the data when interpreting any correlation or association that is determined to exist.

Procedure

1. Make a scatter plot on graph paper of the data pairs (X_i, Y_i), with the usual convention that X is the horizontal scale and Y the vertical.
2. Determine the median X_m of the X_i values. Determine the median Y_m of the Y_i values.

The median splits the data into two parts so that there is an equal number of values above and below the median. Let N denote the total number of points. If N is odd, then N can be written as $2k + 1$ and the median is the $(k + 1)$st value as the values are ordered from the smallest to the largest. If N is even, then N can be written as $2k$. Then the median is taken to be midway between the kth and $(k + 1)$st values.

3. Draw a vertical line through X_m.
4. Draw a horizontal line through Y_m.
5. The lines in (3) and (4) divide the graph into four quadrants. Label the upper right and lower left as plus. Label the upper left and lower right as minus.
6. Begin at the right side of the plot. Count the values, in order of decreasing X, until forced to cross the horizontal median Y_m. Give the count a plus sign if the values are in a plus quadrant, a minus sign if they are in a minus quadrant.
7. Repeat the procedure in (6), moving down from above until you have to cross the vertical median, moving from left to right until you have to cross the horizontal median, and moving up from below until you have to cross the vertical median.
8. Compute the algebraic sum of the four counts obtained in (6) and (7). Denote the sum by T.

Test If $|T| \geq 11$, then there is evidence of correlation between X and Y; $|T|$ is the value of T ignoring the sign.

Table 17.3.4

i	X	Y	i	X	Y
1	10.45	4.1	18	9.65	3.8
2	13.81	2.7	19	7.44	5.4
3	12.22	1.6	20	10.70	7.6
4	9.05	4.3	21	13.38	6.0
5	17.86	2.6	22	13.00	10.4
6	14.54	0.1	23	13.90	10.7
7	19.99	3.7	24	11.94	9.4
8	8.73	3.5	25	14.11	10.7
9	4.66	5.3	26	0.93	12.9
10	13.88	3.9	27	3.18	12.5
11	5.10	4.4	28	13.13	6.5
12	3.98	4.1	29	13.45	11.7
13	8.12	6.3	30	12.70	9.6
14	12.26	6.6	31	15.95	8.5
15	10.30	6.5	32	7.30	16.6
16	5.40	11.9	33	7.78	8.8
17	10.39	5.8			

NOTE: Data are on paper samples. X is proportional to reciprocal of light transmission. Y is proportional to tensile strength.

EXAMPLE. Table 17.3.4 gives 33 pairs of values obtained from samples of a paper product. The X coordinate is proportional to the reciprocal of light transmitted by the sample. The Y coordinate is proportional to tensile strength.

1. The 33 pairs of values are plotted in Fig. 17.3.1.

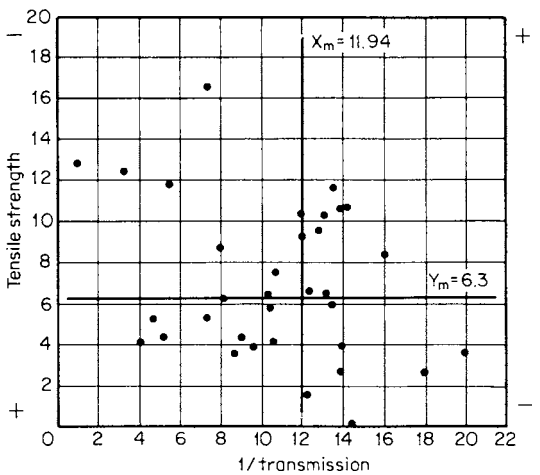

Fig. 17.3.1 Plot of example data used in conjunction with the Corner Test.

2. The median of X values is $X_m = 11.94$. The median of Y values is $Y_m = 6.3$.
3 to 5. The medians are shown in Fig. 17.3.1, and the quadrants are labeled.
6 to 7. The counts are as follows:

Right to left:	−2	(points at 19.99 and 17.86 on X)
Top to bottom:	−4	(points at 16.6, 12.9, 12.5, 11.7 on Y)
Left to right:	−2	(points at 0.93 and 3.18 on X)
Bottom to top:	−4	(points at 0.1, 1.6, 2.6, 2.7 on Y)

8. The algebraic sum of the counts is -12. Hence $T = -12$. And since $|T| \geq 11$, one can conclude that there is evidence of correlation or association between the variables X and Y.

COMPARISON OF METHODS OR PROCESSES

A common problem in engineering investigations is that of using experimental or observational data to assess the performance of two processes, two treatment methods, or the like. Often one process or treatment is a standard or the one in current use. The other is an alternative that is a candidate to replace the standard. Sometimes it is cheaper, and one hopes to see no performance difference. Sometimes it is supposed to offer superior performance, and one hopes to see a measurable difference in the variable of interest. In either case we know that the variable of interest will have a distribution of values; and if the two processes are to be measurably different the distribution of values should not overlap too much. For an objective assessment we need to have some way to calibrate the overlap. A quick and easy-to-use test for this purpose is the **outside count test** developed by Tukey (1959).

Two Methods—Outside Count Test

Conditions for Use Given two groups of measurements taken under conditions 1 and 2 (treatments, methods, etc.), we identify the direction of difference by insisting that the two groups have minimum overlap. Use 1 to denote the group with the smaller number of measurements and let N_1 be the number of measurements for that group. Let N_2 be the number of measurements for the other group. The number of observations for each group should be about the same.

The conditions to be satisfied are:

$$4 \leq N_1 \leq N_2 \leq 30$$
$$N_2 \leq (4N_1/3) + 3$$

Procedure

1. Count the number of values in the one group *exceeding* all values in the other.
2. Count the number of values in the other group *falling below* all those in the other.
3. Sum the two counts in (1) and (2). (It is required that neither count be zero. One group must have the largest value and the other the smallest.)

Test If the sum of the two counts in (3) is 7 or larger, there is sufficient evidence to conclude that the two methods are measurably different.

EXAMPLE. The following data represent the results of a trial of two methods for increasing the wear resistance of a grinding wheel. The data are proportional to wear:

Method 1: 13.06**, 9.52, 9.98, 8.83, 12.78, 9.00, 11.56, 8.10*, 12.21.
Method 2: 8.44, 9.64, 9.94, 7.30, 8.74, 6.30*, 10.78**, 7.24, 9.30, 6.66.

The smallest value for each method is marked with an asterisk; the largest value is marked with two asterisks.

Count 1: The largest value is 13.06 for method 1. The values 13.06, 12.78, 12.21, and 11.56 for method 1 exceed the largest value for method 2, viz., 10.78. Hence the count is 4.

Count 2: The smallest value for method 1 is 8.10. For method 2 the values 7.30, 6.30, 7.24, and 6.66 are less than 8.10. Hence the count is 4.

Count 3: The total count is $4 + 4 = 8 > 7$.

The data support the conclusion that method 2 produces measurably less wear than method 1.

Several Methods

The problem outlined in the preceding section can be generalized so that one can make a comparison of several processes, treatments, methods, or the like. Again, if there are differences among the methods, the values that we see should not overlap too much. We give you two easy-to-use tests. The first is for the situation where there is an equal amount of data for each method. For the second, the amount of data may differ. Each method will be demonstrated using the data in Table 17.3.5.

Table 17.3.5

	Supplier			
Sample no.	1	2	3	4
1	45.37	30.05	41.30	46.21
2	21.68	36.04	31.09	36.01
3	43.91	18.04	24.31	46.28
4	47.76*	32.91	15.64	21.80
5	23.81	41.67	54.85*	28.57
6	19.90	37.40	32.96	48.45
7	44.68	46.67*	45.48	33.49
8	11.81	27.93	45.14	53.07*
9	35.42	45.20	45.49	35.65
10	39.85	29.54	52.82	14.95

NOTE: The data are proportional to the time to failure of a standard cutting tool. Asterisks denote largest value in each group.

Several Methods—Overlap Test

Conditions for Use Independent data should be obtained for each of the k methods. *The number of values n should be the same* for each method.

Procedure

1. For each of the k methods, determine the *largest* value. Label it with an asterisk.
2. Scan the largest values. Label the group with the *largest largest* value as BIG. Label the group with the *smallest* largest value as SMALL, and its largest value as S.
3. In the group labeled BIG *count* the number of values that are larger than S, the largest value in SMALL. Denote this count by C.
4. Enter Table 17.3.6 for n values of k groups. If C exceeds the tabled value, then the data support a conclusion that the methods are different. Otherwise, they do not.

EXAMPLE. 1. In Table 17.3.5 the largest value for each of the four groups is marked with an asterisk.
2. Group 3 is BIG. Group 2 is SMALL; the largest value in Group 2 is $S = 46.67$.
3. The number of values in Group 3 larger than 46.67 is 2 (52.82, 54.85).
4. Enter Table 17.3.6 with $n = 10$ and $k = 4$. The entry is 5 which is greater than 2. Hence, the data do not support a conclusion that the time to failure for the cutting tools of the four suppliers is measurably different.

Several Methods—Rank Test

Conditions for Use Independent data should be obtained for each of the methods. The amount of data for each method may be different.

Procedure

1. Let n_i be the number of values in Group i.
2. Let $N = \sum_1^k n_i$ be the total number of values.
3. Rank each value from 1 to N beginning with the smallest. (If there are ties among t values, divide the successive ranks equally among them.)
4. Compute r_i, the sum of the ranks for the ith group. [*Note:* For a check $\sum_1^k r_i = N(N + 1)/2$.]

Table 17.3.6 95% Point for *k*-Sample Problems

	k							
n	3	4	5	6	7	8	9	10
5	4	4	4	4	4	4	4	4
6	4	4	4	5	5	5	5	5
7	4	5	5	5	5	5	5	5
8	4	5	5	5	5	5	5	5
9	5	5	5	5	5	5	6	6
10	5	5	5	5	6	6	6	6
12	5	5	5	6	6	6	6	6
14	5	5	6	6	6	6	6	6
16	5	5	6	6	6	6	6	6
18	5	6	6	6	6	6	6	7
20	5	6	6	6	6	6	7	7
25	5	6	6	6	6	7	7	7
30	5	6	6	6	7	7	7	7
40	5	6	6	7	7	7	7	7
>40	6	6	7	7	7	7	8	8

NOTE: k is the number of groups; n is the number of values per group. For other n, k, and percentage points see Conover (1968).

Test

1. Compute

$$T = [12/N(N+1)]\left[\sum_{1}^{k}(r_i^2/n_i)\right] - 3(N+1)$$

2. Go to Table 17.3.7; find the entry under $k-1$.

If T exceeds the entry, then the data support the conclusion that the groups are different. Otherwise, they do not.

Table 17.3.7 Chi-Square Distribution

k	*w*	*k*	*w*
1	3.841	16	26.30
2	5.991	17	27.59
3	7.815	18	28.87
4	9.488	19	30.14
5	11.07	20	31.41
6	12.59	22	33.92
7	14.07	24	36.42
8	15.51	26	38.89
9	16.92	28	41.34
10	18.31	30	43.77
11	19.68	40	55.76
12	21.03	50	67.50
13	22.36	60	79.08
14	23.68	70	90.53
15	25.00	80	101.9

NOTE: Entries are $P(W > w) = p = 0.05$. For other values of k and p, see Pearson and Hartley (1962).

EXAMPLE. We again use the data shown in Table 17.3.5. In Table 17.3.8 the numerical values representing times to failure have been replaced by their ranks. To facilitate such ranking it is convenient to order the values in each group from smallest to largest. Then all values are ranked from smallest to largest. In Table 17.3.8 the values have been reordered this way. The ranks are in parentheses.

1. The number of values in each group is 10. Hence $n_i = 10$ for each value of i.
2. The total number of values $N = 40$.

3 and 4. The sum of the ranks r_i is shown for each group. [Note that $\Sigma r_i = 820 = (40)(41)/2$.]

$$\begin{aligned} T &= [12/N(N+1)][\Sigma(r_i^2/10)] - 3(N+1) \\ &= [12/(40)(41)][170182/10] - 3(41) \\ &= 124.523 - 123. = 1.523 \end{aligned}$$

Now go to Table 17.3.7 and obtain the entry under $k = 4 - 1 = 3$. The entry is 7.815, which is larger than 1.523. Hence, the data do not support a conclusion that the time to failure for the cutting tools for the four suppliers is measurably different.

Table 17.3.8

Supplier*			
1	2	3	4
11.81 (1)	18.04 (4)	15.64 (3)	14.95 (2)
19.90 (5)	27.93 (10)	24.31 (9)	21.80 (7)
21.68 (6)	29.54 (12)	21.09 (14)	28.57 (11)
23.81 (8)	30.05 (13)	32.96 (16)	33.49 (17)
35.42 (18)	32.91 (15)	41.30 (24)	35.65 (19)
39.85 (23)	36.04 (21)	45.14 (28)	36.01 (20)
43.91 (26)	37.40 (22)	45.48 (31)	46.21 (33)
44.68 (27)	41.67 (25)	45.49 (32)	46.28 (34)
45.37 (30)	45.20 (29)	52.82 (38)	48.45 (37)
47.76 (36)	46.67 (35)	54.85 (40)	53.07 (39)
180	186	235	219 r_i
32400	34596	55225	47961 r_i^2

* These are the data of Table 17.3.5 with the values for each supplier listed from smallest to largest. The values in parentheses are the ranks of the time to failure values from smallest to largest.

GO/NO-GO DATA

Quite often the data that we encounter will be **attribute** or **go/no-go data;** that is, we will not have quantitative measurements but only a characterization as to whether an item does or does not have some attribute. For example, if a manufactured part has a specification that it should not be shorter than 2 in, we might construct a template; and if a part is to meet the specification, it should not fit into the template. After inspecting a series of units with the template our data would consist of a tabulation of "gos" and "no-gos"—those that did not meet the specification and those that did.

If the items that are checked for an attribute are obtained by random sampling, the resulting data will follow what is known as the **binomial distribution.** Its standard form is as follows:

p is the long-term fraction of failures
$q = 1 - p$ is the long-term fraction of successes
n is the size of the random sample.

Then the probability that our sample gives x failures and $n - x$ successes is

$$f(x;n,p) = \binom{n}{x} p^x q^{n-x}; x = 0,1,2,\ldots,n$$

where

$$\binom{n}{x} = n!/x!(n-x)!$$

From $f(x; n, p)$, for a given n and p, we can calculate the probability of x failures in a sample size n. Similarly, by summing terms for different values of x, we can calculate the probability of having more than w failures or fewer than r failures, etc. Here we are not going to try to be so precise; rather we are going to try to show the general picture of the relationship between x, p, and n by the use of examples and the graph in Fig. 17.3.2.

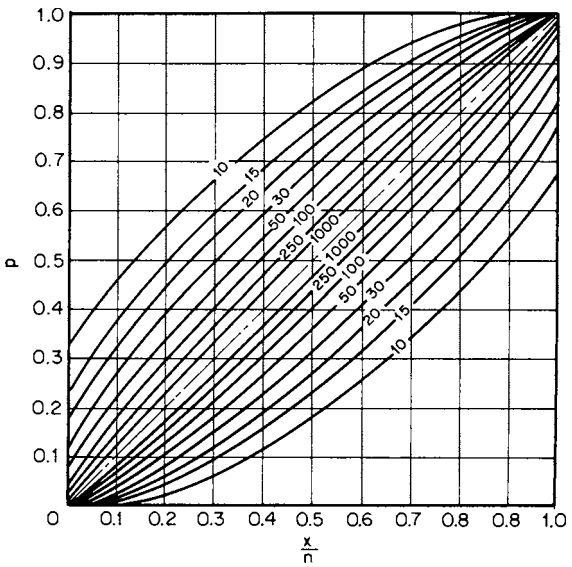

Fig. 17.3.2 Binomial distribution, 95 percent confidence bands. *(Reproduced with the permission of the Biometrika Trust from C. J. Clopper and E. S. Pearson, "The Use of Confidence or Fiducial Limits Illustrated in the Case of the Binomial,"* Biometrika, 26 (1934), p. 410.)

Estimating the Failure Rate

In a manufacturing process a general index of quality is the fraction of items which fail to pass a certain test. Suppose that we take a random sample of size $n = 100$ from the process and observe $x_0 = 10$ failures. Clearly we have met the conditions for a binomial distribution and an estimate of p, the long-term failure rate is $\hat{p} = x_0/n = 10/100 = 0.1$. However, we would also like to know the accuracy of the estimate. In other words, if we operate the process for a long time under these conditions and obtain a large sample, what might be the value of p? One simple way to assess the estimate of $\hat{p}$ is to find values p_1 and p_2 ($p_1 < p_2$) such that the following probabilities are satisfied for a fixed value of α:

$$\Pr[x \geq x_0 | p_1] = \alpha/2$$
$$\Pr[x \leq x_0 | p_2] = \alpha/2$$

These values are the solutions for p of the two equations.

$$\sum_{x=x_0}^{n} \binom{n}{x} p_1^x (1 - p_1)^{n-x} = \alpha/2$$
$$\sum_{x=0}^{x_0} \binom{n}{x} p_2^x (1 - p_2)^{n-x} = \alpha/2$$

General solutions for these equations for $\alpha = 0.05$ are shown in Fig. 17.3.2. If we go to Fig. 17.3.2 with $x/n = 0.1$ and read where the lines for $n = 100$ intersect the ordinate or p scale, we see that $p_1 = 0.07$ and $p_2 = 0.18$. We can then state that we have reasonable confidence (the probability is 0.95) that the long-term failure rate for the process is between 0.07 and 0.18.

Estimating the Sample Size

It should be evident that Fig. 17.3.2 can also be used to determine how large a sample is needed to estimate a proportion or a percentage with a specific accuracy or tolerance. Suppose that the proportion of interest is assumed to be around $p = 0.20$. Now enter Fig. 17.3.2 with $x/n = 0.20$. From the figure we see that if we take a sample of size 50, our estimate will have a range of about ± 0.10 (actually -0.10, $+0.13$). On the other hand, if the sample size is 250, the estimate will have a range of about ± 0.06.

Often one wants to compare the performance of two processes. As above, suppose that the rate p for our process is 0.20. We have a modification that we want to test; however, to be economical the modification has to bring the rate p down to 0.15 or less. If the modification is going to be assessed on the p's for the standard and the modification, then we do not want the uncertainty in their estimates to overlap and the uncertainty should be less than half of 0.05 where 0.05 = (0.20 − 0.15). Figure 17.3.2 shows that we would have to use a sample size of at least 1000. This demonstrates that attribute sampling is effective only when the items and their characterization are not expensive. Otherwise, it is best to go to measurements where smaller sample sizes can be used to assess differences.

A more detailed exposition of the binomial distribution and its uses can be found in Brownlee (1970).

Statistical Software Packages

There are numerous statistical software packages available that may be used to determine sample sizes, design experiments, fit curves to data, test for goodness of fit, and perform basic statistical calculations. The packages include both standardized and customized menus, features for importing and exporting data to and from external files, and well-presented analysis summaries and reports. For example, a widely used statistical package called JMP was developed and is periodically upgraded by the SAS Institute, Inc.

CONTROL CHARTS

When an industrial process is under control it is in a state of "statistical equilibrium." By equilibrium we mean that we can characterize its output by a fixed average μ and a fixed standard deviation σ. The variation in output is what one would expect to see from that μ and σ, as bounded by the values given in Tchebysheff's theorem, let us say. However, if control is lost, we tend to get a greater spread in values. In effect, the average μ, or the standard deviation σ is changing because of some cause. The causes of lack of control are manifold—it can be a change in raw materials, tool wear, instrumentaton failure, operator error, etc. The important thing is that one wants to be able to detect when this lack of control occurs and take the appropriate steps to make corrections.

One of the most frequently used statistical tools for analyzing the state of an industrial process is the control chart. The two most commonly used charts are those for the **average** and the **range.** The control chart procedure consists of these steps:

1. Choose a characteristic X which will be used to describe the product coming from the process.

2. At time t_i, take a small number of observations n on the process. The number n should be small enough so that it is reasonable to assume that conditions will not change during the course of obtaining the observstions.

3. For each set of n observations, compute the average $\bar{x}_i$ and the range r_i as defined in the section "Characterizing Observational Data."

There are two different control situations of interest.

4a. *Control standards given.* Suppose that from past operation of the process or from the need to meet certain specifications, a goal average μ^* and a goal standard deviation σ^* are specified. Then we set up two charts as follows:

Average chart:	Upper limit line:	$\mu^* + A\sigma^*$
	Central line:	μ^*
	Lower limit line:	$\mu^* - A\sigma^*$
Range chart:	Upper limit line:	$D_2\sigma^*$
	Central line:	$d\sigma^*$
	Lower limit line:	$D_1\sigma^*$

Table 17.3.9 Factors for Control-Chart Limits

Sample size n	For averages		For ranges				
	A	A_2	d	D_1	D_2	D_3	D_4
2	2.12	1.88	1.128	0	3.69	0	3.27
3	1.73	1.02	1.693	0	4.36	0	2.57
4	1.50	0.73	2.059	0	4.70	0	2.28
5	1.34	0.58	2.326	0	4.92	0	2.11
6	1.22	0.48	2.534	0	5.08	0	2.00
7	1.13	0.42	2.704	0.21	5.20	0.08	1.92
8	1.06	0.37	2.847	0.39	5.31	0.14	1.86
9	1.00	0.34	2.970	0.55	5.39	0.18	1.82
10	0.95	0.31	3.078	0.69	5.47	0.22	1.78

The values of A, d, D_1, and D_2 depend upon n and can be found in Table 17.3.9.

Plot the values of $\bar{x}_i$ and r_i obtained in (3) on the two charts as shown in Fig. 17.3.3. Whenever a value falls outside the limit lines, there is an indication of lack of control, and one is justified in seeking the causes for a change.

4b. *Control, no standards given.* Often one has no prior information about the process μ and σ, and one wants to determine if the process behaves as though it is in statistical equilibrium, and if not, take actions to get it there. In this case one has to determine the central lines for the charts from process data. To do this one first accumulates the data for 25 to 50 time periods as indicated in (2). Then two charts are set up as follows: Let K be the 25 to 50 time periods observed. Compute an overall average $\bar{X} = \Sigma_{i=1}^{k} \bar{x}_i/K$ and the average range $\bar{R} = \Sigma_{i=1}^{k} r_i/K$. Set up charts with limits defined from:

Average chart:	Upper limit line:	$\bar{X} + A_2\bar{R}$
	Central line:	$\bar{X}$
	Lower limit line:	$\bar{X} - A_2\bar{R}$
Range chart:	Upper limit line:	$D_4\bar{R}$
	Central line:	$\bar{R}$
	Lower limit line:	$D_3\bar{R}$

The values of A_2, D_3, and D_4 depend upon n and can be found in Table 17.3.9. The individual $\bar{x}_i$ and r_i are plotted on the charts, and again a value outside the limits is an indication of lack of control and is justification for seeking the cause for a change.

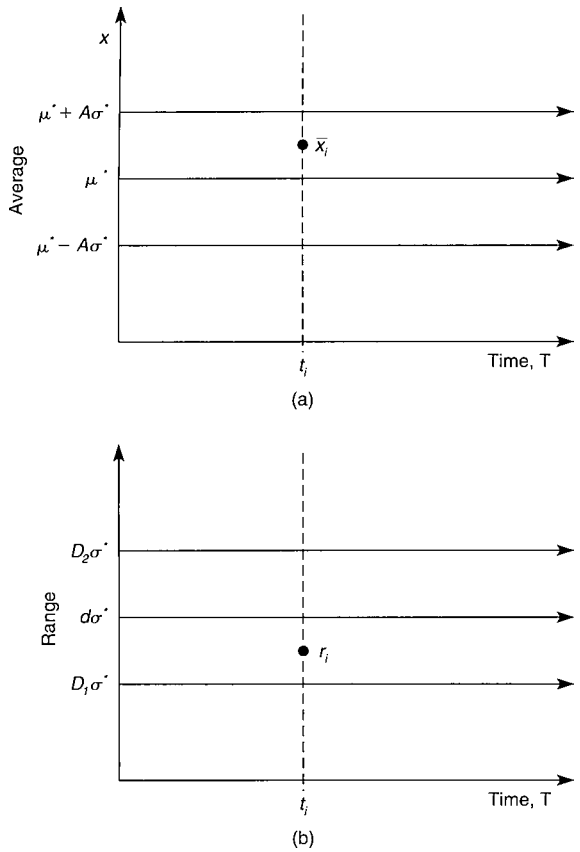

Fig. 17.3.3 Control chart. (*a*) Average chart; (*b*) range chart.

Process Capability Indices

If the process is in statistical control, an estimate for the process standard deviation can be obtained by using

$$\hat{\sigma} = \bar{R}/d$$

In turn, $\hat{\sigma}$ is used to calculate the **process capability indices** C_p and C_{pk}. These two indices compare the actual spread of the data with the desired range (usually as specified by a customer). C_p is used when the actual process average is equal to the goal average. C_{pk} is used when the actual process average is not equal to the goal average. The desired range is called the **specification tolerance** (ST) and is equal to the upper specification limit minus the lower specification limit, namely, $2A\sigma^*$.

C_p is given by the following equation:

$$C_p = \text{ST}/6\hat{\sigma} = 2A\sigma^*/6\hat{\sigma}$$

If $C_p \geq 1$, the process is considered to be capable, which means that most or all of the data stayed within the desired range. If $C_p < 1$, the process is considered to be not capable and requires adjustment. Ideally, one should control the process variability so that $C_p \geq 2$.

The other index, C_{pk}, is given by

$$C_{pk} = C_p(1 - k)$$

where $$k = 2(\mu^* - \bar{X})/\text{ST} = (\mu^* - \bar{X})/\text{A}\sigma^*$$

and $$\bar{X} = \Sigma\, \bar{x}_i/K$$

The $(1 - k)$ factor modifies C_p so as to allow the actual average $\bar{X}$ to be different from the goal average μ^*. Ideally, one should control the process so that $C_{pk} \geq 1.5$. In process capability analysis, the indices should be calculated on a frequent basis, but the trends should be examined only monthly or quarterly in order to be meaningful.

Charts for Go/No-Go Data

The control chart concept can also be used for attribute or go/no-go data. The procedures are, in general, the same as outlined for averages and ranges. Briefly, they are as follows:

1. Select a sample of size n from the process; for best results n should be in the range of 50 to 100.
2. Let x_i denote the number of defective units in the sample of size n at time t_i; then $\hat{p}_i = x_i/n$ is an estimate of the process fraction defective.
3. Set control limits for a standard fraction defective p^* at

$$p^* \pm 3[p^*(1 - p^*)/n]^{1/2}$$

If no standard is given, then take $K = 25$ to 50 samples of size n to get a good estimate of the fraction-defective p. Define $\bar{p} = \Sigma_{i=1}^{K} \hat{p}_i/K$. In this case set control limits at

$$\bar{p} \pm 3[\bar{p}(1 - \bar{p})/n]^{1/2}$$

4. Interpret a $\hat{p}_i$ outside the limits as an indication of a change worthy of investigation.

Further information on control charts can be found in Duncan (1986).

17.4 METHODS ENGINEERING

by Vincent M. Altamuro

REFERENCES: ASME Standard Industrial Engineering Terminology. Barnes, "Motion and Time Study," Wiley. Krick, "Methods Engineering," Wiley. Maynard, Stegemerten, and Schwab, "Methods-Time-Measurement," McGraw-Hill.

SCOPE OF METHODS ENGINEERING

Methods engineering is concerned with the selection, development, and documentation of the methods by which work is to be done. It includes the analysis of input and output conditions, assisting in the choice of the processes to be used, operations and work flow analyses, workplace design, assisting in tool and equipment selection and specifications, ergonomic and human factors considerations, workplace layout, motion analysis and standardization, and the establishment of work time standards. A primary concern of methods engineering is the integration of humans and equipment in the work processes and facilities.

PROCESS ANALYSIS

Process analysis is that step in the conversion of raw materials to a finished product at which decisions are made regarding what methods, machines, tools, inspections and routings are best. In many cases, the product's specifications can be altered slightly, without diminishing its function or quality level, so as to allow processing by a preferred method. For this reason, it is desirable to have the product's designer and the process engineer work together before specifications are finalized.

WORKPLACE DESIGN

Material usually flows through a facility, stopping briefly at stations where additional work is done on it to bring it closer to a finished product. These workstations, or workplaces, must be designed to permit performance of the required operations, to contain all the tooling and equipment needed to fit the capabilities and limitations of the people working at them, to be safe and to interface smoothly with neighboring workplaces.

Human engineering and ergonomic factors must be considered so that all work, tools, and machine activation devices are not only within the comfortable reach of the operator but are designed for safe and efficient operation. A workplace chart (Fig. 17.4.1) which analyzes the required actions of both hands is an aid in workplace design.

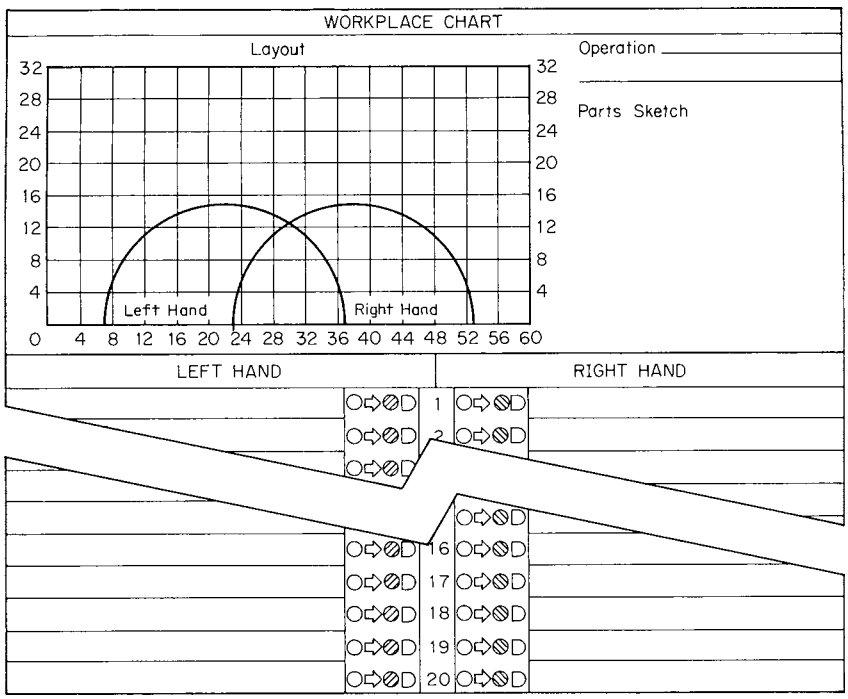

Fig. 17.4.1 Workplace layout chart.

METHODS DESIGN

Methods design is the analysis of the various ways a task can be done so as to establish the one best way. It includes *motion analysis*—the study of the actions the operator can use and the advantages and/or disadvantages of each variation—and *standardization of procedure*—the selection and recording of the selected and authorized work methods.

While "time and motion study" is the more commonly used term, it is more correct to use "motion and time study," as the motion study to establish the standard procedure must be done prior to the establishment of a standard time to perform that work.

According to ASME Standard Industrial Engineering Terminology, motion study is defined as

> . . . the analysis of the manual and the eye movements occurring in an operation or work cycle for the purpose of eliminating wasted movements and establishing a better sequence and coordination of movements.

In the same publication, time study is defined as

> . . . the procedure by which the actual elapsed time for performing an operation or subdivisions or elements thereof is determined by the use of a suitable timing device and recorded. The procedure usually but not always includes the adjustment of the actual time as the result of performance rating to derive the time which should be required to perform the task by a workman working at a standard pace and following a standard method under standard conditions.

Attempts have been made to separate the two functions and to assign each to a specialist. Although motion study deals with method and time study deals with time, the two are nearly inseparable in practical application work. The method determines the time required, and the time determines which of two or more methods is the best. It has, therefore, been found best to have both functions handled by the same individual.

ELEMENTS OF MOTION AND TIME STUDY

Figure 17.4.2 presents graphically the steps which should be taken to make a good motion and time study and shows their relation to each other and the order in which they must be performed.

METHOD DEVELOPMENT

The first steps are concerned with the development of the method. Starting with the drawing of the product, the operations which must be performed are determined and tools and equipment are specified. In large companies, this is usually done by a specialist called a process engineer. In smaller companies, processing is commonly done by the time study specialist.

Next, the detailed method by which each operation should be performed is developed. The procedures used for this are known as operation analysis and motion study.

OPERATION ANALYSIS

Operation analysis is the procedure employed to study all major factors which affect a given operation. It is used for the purpose of uncovering possibilities of improving the method. The study is made by reviewing the operation with an open mind and asking either of oneself or others questions which are likely to lead to methods-improving ideas. If this is done systematically, so that the possibility of overlooking factors which should be considered is minimized, worthwhile improvements are almost certain to result.

The 10 major factors explored during operation analysis, together with typical questions which should be asked about each factor, are as follows:

1. Purpose of operation
   - *a.* Is the result accomplished by the operation necessary?
   - *b.* Can the purpose of the operation be accomplished better in any other way?

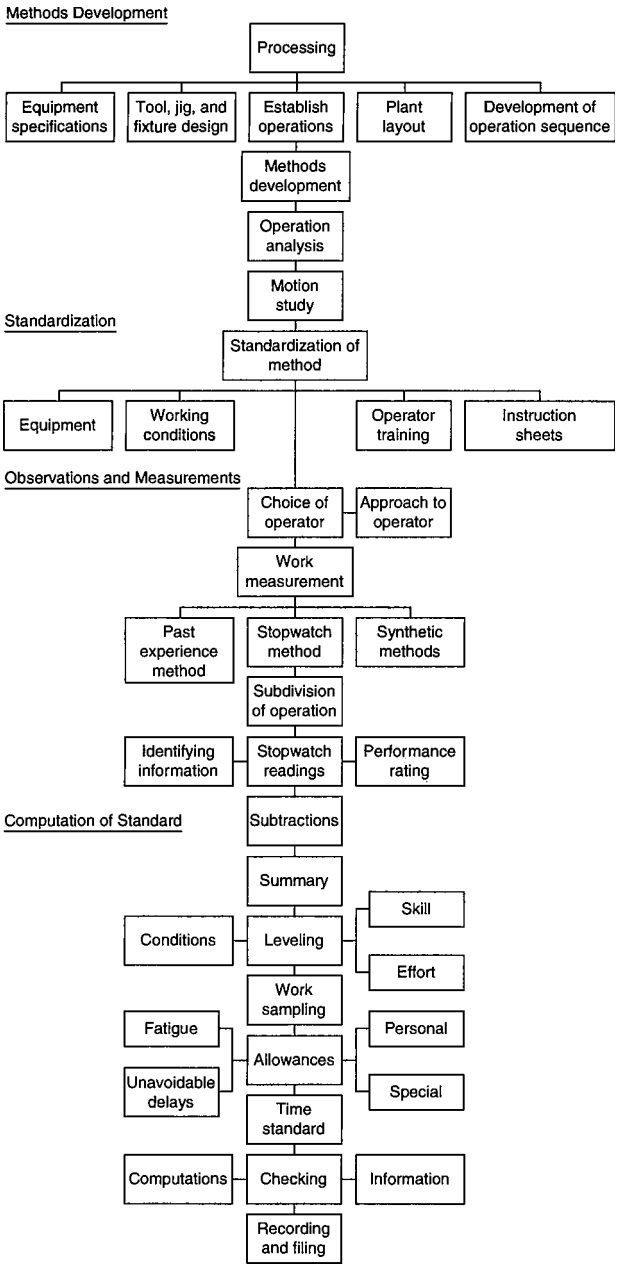

Fig. 17.4.2 Graphic analysis of the elements of motion and time study.

2. Design of part
   - *a.* Can motions be eliminated by design changes which will not affect the functioning and other desirable characteristics of the product?
   - *b.* Is the design satisfactory for automated assembly?
3. Complete survey of all operations performed on part
   - *a.* Can the operation being analyzed be eliminated by changing the procedure or the sequence of operations?
   - *b.* Can it be combined with another operation?
4. Inspection requirements
   - *a.* Are tolerance, allowance, finish, and other requirements necessary?

   b. Will changing the requirements of a previous operation make this operation easier to perform?
5. Material
   a. Is the material furnished in a suitable condition for use?
   b. Is material utilized to best advantage during processing?
6. Material handling
   a. Where should incoming and outgoing material be located with respect to the work station?
   b. Can a progressive assembly line be set up?
7. Workplace layout, setup, and tool equipment
   a. Does the workplace layout conform to the principles of motion economy?
   b. Can the work be held in the machine by other means to better advantage?
8. Common possibilities for job improvement
   a. Can "drop delivery" be used?
   b. Can foot-operated mechanisms be used to free the hand for other work?
9. Working conditions
   a. Has safety received due consideration?
   b. Are new workers properly introduced to their surroundings, and are sufficient instructions given them?
10. Method
   a. Is the repetitiveness of the job sufficient to justify more detailed motion study?
   b. Should full automation be considered?

When the method has been developed, conditions are standardized, and the operators are trained to follow the approved method.

At this time, not before, the job is ready for time study. Suitable operators are selected, the purposes of the study are carefully explained to them, and the time study observations are made. During the study, time study specialists rate the performance being given by operators either by judging the skill and effort they are exhibiting or by assessing the speed with which motions are made as compared with what they consider to be a normal working pace. The final step is to compute the standard.

PRINCIPLES OF MOTION STUDY

Operation analysis is a primary analysis which eliminates inefficiencies. Motion study is a secondary analysis which refines the method still further. Motion study may and often does suggest further improvements in the factors considered during operation analyses, such as tools, material handling, design, and workplace layouts. In addition, it studies the human factors as well as the mechanical and sets up operations in conformance with the limitations, both physical and psychological, of those who must perform them.

The technique of motion study rests on the concept originally advanced by Frank B. and Lillian M. Gilbreth that all work is performed by using a relatively few basic operations in varying combinations and sequences. These Gilbreth Basic Elements have also been called "therbligs" and "basic divisions of accomplishment."

The basic elements together with their symbols (for definitions see ASME Industrial Engineering Terminology), grouped in accordance with their effect on accomplishment, are as follows:

Group 1 Accomplishes	
Reach	R
Move	M
Grasp	G
Position	P
Disengage	D
Release	RL
Examine	E
Do	DO

Group 2 Retards accomplishment	
Change direction	CD
Preposition	PP
Search	S
Select	SE
Plan	PL
Balancing delay	BD

Group 3 Does not accomplish	
Hold	H
Avoidable delay	AD
Unavoidable delay	UD
Rest to overcome fatigue	F

Group 1 is the useful group of basic elements or the ones that accomplish work. They do not necessarily accomplish it in the most effective way, however, and a study of these elements will often uncover possibilities for improvement.

Group 2 contains the basic elements that tend to retard accomplishment when present. In most cases, they do this by slowing down the group 1 basic elements. They should be eliminated wherever possible.

Group 3 is the nonaccomplishment group. The greatest improvements in method usually come from the elimination of the group 3 basic elements from the cycle. This is done by rearranging the motion sequence, by providing mechanical holding fixtures, and by improving the workplace layout.

An operation may be analyzed into its basic elements either by observation or by making a micromotion study of a motion picture of the operation.

Methods improvement may be made on any operation by eliminating insofar as possible the group 2 and group 3 basic elements and by arranging the workplace so that the group 1 basic elements are performed in the shortest reasonable time. In doing this, certain laws of motion economy are followed. The following, derived from the laws originally stated by the Gilbreths, are the most important.

1. When both hands begin and complete their motions simultaneously and are not idle during rest periods, maximum performance is approached.
2. When motions of the arms are made simultaneously in opposite directions over symmetrical paths, rhythm and automaticity develop most naturally.
3. The motion sequence which employs the fewest basic elements is the best for performing a given task.
4. When motions are confined to the lowest practical classification, maximum performance and minimum fatigue are approached. Motion classifications are: Class 1, finger motions; Class 2, finger and wrist motions; Class 3, finger, wrist, and forearm motions; Class 4, finger, wrist, forearm, and upper-arm motions; Class 5, finger, wrist, forearm, upper-arm, and body motions.

STANDARDIZING THE JOB

When an acceptable method has been devised, equipment, materials, and conditions must be standardized so that the method can always be followed. Information and records describing the standard method must be carefully made and preserved, for experience has shown that, unless this is done, minor variations creep in which may in time cause a major problem. In the case of repetitive work, a job is not standardized until each piece is delivered to operators in the same condition, and it is possible for them to perform their work on each piece by completing a set cycle of motions, doing a definite amount of work with the same equipment under uniform working conditions.

The operator or operators must then be taught to follow the approved method. Operator training is always important if reasonable production is to be obtained, but it is an absolute necessity where methods have been devised by motion study. It is quite apparent that the operators cannot be

expected to discover for themselves the method which the time-study specialist developed as the result of hours of concentrated study. They must, therefore, be carefully trained if they are to be expected to reach standard production. In addition, an accurate time study cannot be made until the operator is following the approved method with reasonable proficiency.

WORK MEASUREMENT

Work measurement is the calculation of the amount of time it should take to do a standardized job. It utilizes the concept of a standard time. The standard time to perform a task is the agreed-upon and reproducible calculated time that a hypothetical typical person working at a normal rate of speed should take to do the job using the specified method with the proper tools and materials. It is the normal time determined to be required to complete one prescribed cycle of an operation, including noncyclic tasks, allowances, and unavoidable delays.

Time Study Methods There are several bases upon which time standards may be calculated. They include:

1. *Application of past experience.* The time required to do the operation in the past, either recorded or remembered, may be used as the present standard or as a basis for estimating a standard for a similar operation or the same operation being done under changed conditions.

2. *Direct observation and measurement.* The operation may be observed and its time recorded as it is actually performed and adjustments may be made to allow for the estimated pace rate of the operator and for special allowances. A stop watch or other recording instrument may be used or work sampling may be employed, which makes statistical inferences based upon random observations.

3. *Synthetic techniques.* A time standard for an actual or proposed operation may be constructed from the sum of the times to perform its several components. The times of the components are extracted from standard charts, tables, graphs, and formulas in manuals or in computer databases and totaled to arrive at the overall time for the entire operation. Standard data or predetermined motion times may be used. Methods-time measurement (MTM), basic-motion times (BMT), work factor (WF), and others are some of the systems available.

TIME STUDY OBSERVATIONS

The time study specialist can study any operator he or she wishes so long as that operator is using the accepted method. By applying what is known as the leveling procedure, the time study specialist should arrive at the same final time standard regardless of whether studying the fastest or the slowest worker.

The manner in which the operator is approached at the beginning of the study is important. This is particularly true if the operator is not accustomed to being studied. Time study specialists should be courteous and unassuming and should show a recognition of and a respect for the problems of the operator. They should be frank in their dealings with the operator and should be willing at any time to explain what they are doing and how they do it.

The first step in making time study observations is to subdivide the operation into a number of smaller operations which will be studied and timed separately. These subdivisions are known as elements, or elemental operations. Each element is exactly described in a few well-chosen words, which are recorded on the top of the time study form. Figure 17.4.3 shows how this is done. The beginning and ending points

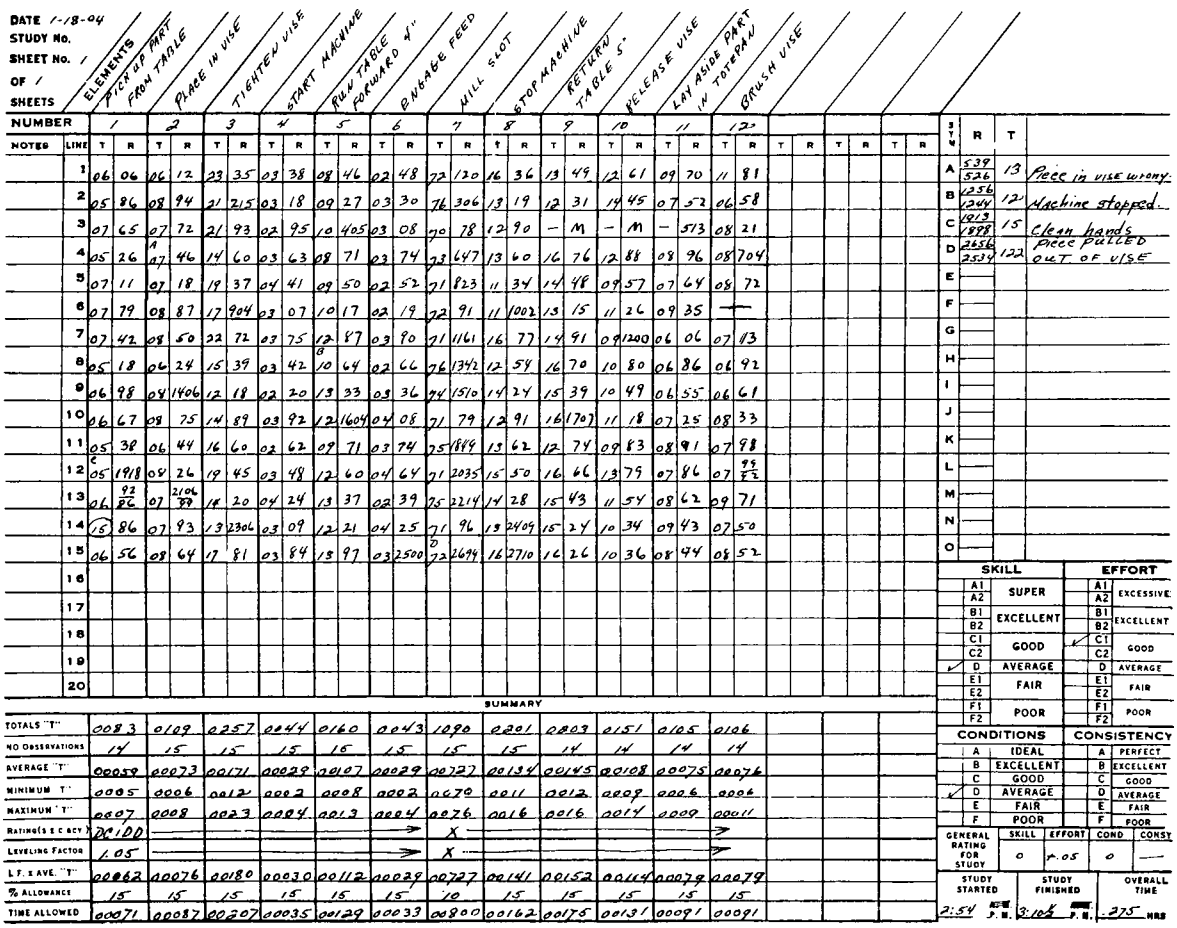

Fig. 17.4.3 Face of a time study form.

of these elements must be clearly recognizable so that the chances of overlapping watch readings will be minimized.

The timing is done with the aid of a stopwatch, or less frequently, with a special type of "time study machine." There are several types of stopwatches as well as several methods of recording watch readings in common use. The study illustrated by Fig. 17.4.3 was made using a decimal-hour stopwatch that reads directly in ten-thousandths of an hour. The readings were recorded using what is known as the continuous method of recording. In this method, the watch runs continuously from the beginning of the study to the end. Thus every moment of time is accounted for, something that may be important if the correctness of the study is ever questioned. The watch is read at the end of each elemental operation, and the reading is recorded in the "R" column under the proper element description. The elapsed time for each element is later secured by subtracting successive readings. This observation procedure gives results as accurate as any other and more accurate than some.

Occasionally variations from the regular sequence of elemental operations occur. The time study specialist must be prepared to handle such situations when they happen. These variations may be divided into four general classes as follows: (1) elements performed out of order, (2) elements missed by the time study specialist, (3) elements omitted by the operator, (4) foreign elements.

The time study illustrated by Fig. 17.4.3 contains examples of each of these kinds of irregularity. Elements 12 and 1 on lines 12 and 13 were performed out of order. On line 3, the time study specialist missed obtaining the watch readings for elements 9 and 10. On line 6, element 12 was omitted by the operator. Foreign elements A, B, C, and D occurred during regular elements 2, 5, 1, and 7, respectively. A study of these examples will show how the time study specialist handles variations from the regular sequence of elements which occur during the making of a time study.

A time study to be of value for future use must tell the whole story of a job in such a way that it will be understood by anyone familiar with the time study procedure. This will not be possible unless all identifying and other pertinent information is recorded at the time the study is made. Records should be made to show complete identification of the operator; the part or assembly; the machines, tools, and equipment used; the operation; the department in which the operation was performed; and the conditions existing at the time the study was made. Sketches are generally a desirable part of this description. Figure 17.4.4 shows the information which would be recorded on the reverse side of the time study form illustrated by Fig. 17.4.3.

PERFORMANCE RATING

The objective of a time study is to determine the time which a worker giving average performance will require to do the job under average or normal conditions. It is important to understand that when the time study specialist speaks of average performance, he or she is not referring to the mathematical average of all human beings, or even the average of all persons engaged in a given occupation. Average performance is established by definition and not statistically. It represents the time study specialist's conception of the normal, steady, but unhurried performance which may reasonably be expected from anyone qualified for the work. If sufficient inducement is offered by incentives or otherwise, this performance may be considerably surpassed.

If all operators available for study worked at the average performance level, the task of establishing a standard would be easy. It would

STUDY No. 1 DATE 1-18-64
OPERATION: Mill Slot
DEPARTMENT: 10
OPERATOR: MAN WOMAN NAME Gross No. 33
EQUIPMENT: #3 Le Blond Horizontal Milling Machine
MACHINE TOOL No. 3589
SPECIAL TOOLS, JIGS, FIXTURES, ETC.: 6" dia. spl. side cutter
CONDITIONS: Some castings have rough spots on sides which make them hard to hold in vise. Material supply, light, temperature, and ventilation ave.

be necessary merely to average the elapsed elemental times determined from time study and add an allowance for fatigue and personal and unavoidable delays. It is seldom, however, that a performance is observed which is rated throughout as average. Therefore, to establish a standard which represents the time which would be taken had an average performance been observed, it is necessary to use some method of adjusting the recorded elemental times when other than average performance is timed.

One of the well-known methods of doing this is the **leveling procedure.** When properly applied it gives excellent results. It must be correctly understood, of course, and the time study specialist who uses it must be thoroughly trained to apply it correctly.

The procedure recognizes that when the correct method is being followed, skill, effort, and working conditions will affect the level at which the operator works. These factors are judged during the making of the time study. Skill is defined as *proficiency at following a given method.* This is not subject to variation at will by the operator but develops with practice over a period of time. Effort is defined as *the will to work.* It is controllable by the operator within the limits imposed by skill. Conditions are those conditions which affect the operator and not those which affect the method.

Definitions have been established for different degrees of skill, effort, and conditions. Numerical factors have been established by extensive research for each degree of skill, effort, and conditions. These are shown by Fig. 17.4.5. The algebraic sum of these numerical values added to 1.0 gives the leveling factor by which all actual elemental times are multiplied to bring them to the average or normal level. The leveling factor represents in effect the amount in percent which actual performance times are above and below the average performance level.

ALLOWANCES FOR FATIGUE AND PERSONAL AND UNAVOIDABLE DELAYS

The leveled elemental time values are net elapsed times adjusted to the average performance level. They do not provide for delays and other legitimate allowances. Something, therefore, must be added to take care of such things as fatigue, and special conditions of the work.

Fatigue allowances vary according to the nature of the work. Flat percentages are determined for each general class of work, such as bench work, machine-tool operation, hard physical labor, and so on. Personal allowances are the same for most classes of work. Unavoidable delay allowances vary with the nature of the work and the conditions under which it is performed. Peculiar conditions surrounding specific jobs sometimes require additional special allowances.

It is apparent, therefore, that the proper allowance factor to use can only be determined by a study of the class of work to which it is to be applied. Allowances are determined either by a series of all-day time studies or by a statistical method known as work sampling, or both. When an allowance factor has once been established, it is then applied to all time studies made on that class of work thereafter.

DEVELOPING THE TIME STANDARD

When time study observations have been completed, a series of calculations are made to develop the time standard. Elapsed times are determined by subtracting successive watch readings. Each subtraction is recorded between the two watch readings that determine its value. Elapsed time is noted in ink to ensure a permanent record and to distinguish it from the watch readings which are usually recorded in pencil. A study of Fig. 17.4.3 will show how subtractions are entered on the time study form and later summarized.

The several elapsed times for each element are next carefully compared and examined for abnormal values. If any are found, they are circled so that they can be distinguished and excluded from the summary.

The remaining elapsed times for each element are added and are averaged by dividing by the number of elapsed time readings. The results are average elapsed times which represent the time taken by the operator during that particular study. These times must be adjusted by multiplying them by a leveling factor to bring them to the average performance level. This factor is determined by the rating of skill, effort, and conditions made during the period of observation.

Each average elapsed time is multiplied by the leveling factor, except when the element is not controlled by the operator. An element that is outside the control of the operator, such as element 7 in Fig. 17.4.3 which is a cut with power feed, should not be leveled, because it is unaffected by the ability of the operator. As long as the proper feed and speed are used, the time for performing this element will be the same whether the worker is an expert or a learner.

If workers were able to work continuously, the leveled time would be the correct value to allow for doing the operation studied, but constant application to the job is neither possible nor desirable. In the course of a day, there are certain to be occasional interruptions and delays, for which due allowance must be made in establishing the final standard. Therefore, each elemental time is increased by an allowance which covers time that will be consumed by personal and unavoidable delays, fatigue, and any special factors that may affect the job.

The numbers and descriptions of the elemental operations together with their allowed time are transcribed on the back of the time study form as shown by Fig. 17.4.4. The number of times an elemental operations occurs on each piece or cycle of the operation is taken into account, and the total time allowed for each element is determined and recorded. The final standard for the operation is the sum of the amounts recorded in the "time-allowed" column. When all computations have been checked and all supporting records have been properly identified and filed, the task of developing the time standard is complete.

TIME FORMULAS AND STANDARD DATA

On repetitive work, time study is a satisfactory tool of work measurement. A single time study may be sufficient to establish a standard which will cover the work of one or more operators for a long period of time.

As quantities become smaller, however, the cost of establishing standards by individual time study increases until at length it becomes prohibitive. In the extreme case, where products are manufactured in quantities of one, it would require at least one time study specialist for each operator if standards were established by detailed time study, and the standards would not be available until after the jobs had been completed.

In order to simplify the task of setting standards on a given class of work and in order to improve the consistency of the standards, standard data are frequently used by time study specialists. A compilation of standard data

in its simplest form is merely a list of all the different elements that have occurred during all the time studies made on a given class of work, with representative time values for each element. Every element that differs even slightly from any other element has its own time value.

When a job comes into the shop on which no standard has previously been established, time study specialists analyze the job either mentally or by direct observation and determine the elements required to perform it. They then select time values from the standard data for each element. Their sum gives the standard for the job.

This method, although a decided improvement from a time, cost, and consistency standpoint over individual time study, is capable of further refinement and improvement. On a given class of work, certain elements will be performed—for example, "pick up part"—on every piece produced, while others—such as "secure in steady rest"—will be performed only when a piece has certain characteristics. In some cases, the performance of a certain element will always require the performance of another element, e.g., "start machine" will always require the subsequent performance of the element "stop machine." Then again, the time for performing certain elements—for example, "engage feed"—will be the same regardless of the characteristics of the part being worked upon, while the time for performing certain other elements—like "lay part aside"—will be affected by the size and shape of the part.

Thus it is possible to make certain combinations and groupings which will simplify the task of applying standard data. Time study specialists construct various charts, and tables which they still call standard data, or, in the ultimate refinement, develop time formulas. A time formula is a convenient arrangement of standard data which simplifies their accurate application. Much of the analysis which is necessary when applying standard data is done once and for all at the time the formula is derived. The job characteristics which make the performance of certain elements or groups of elements necessary are determined, and the formula is expressed in terms of these characteristics.

Figure 17.4.3 illustrates a detailed time study made to establish a standard on a simple milling machine operation. The same standard can be derived much more quickly from the following time formula:

$$\text{Curve } A + \text{Table } T = \text{each piece time}$$

Curve *A* combines the times for the variable elements "pick up part from table," "place in vise," and "lay aside part in totepan" with the times for the constant elements "tighten vise," "start machine," "run table forward 4 in," "engage feed," "stop machine," "release vise," and "brush vise." Table *T* combines the times for "mill slot" and "return table." The standard time for milling a slot in a brass clamp of any size is computed by determining the variable characteristics of the job from the drawing—in this case, the volume of the clamp and the perimeter of the cut—and adding together the time read from curve *A* and the time read from Table *T*.

The amount of time which the use of time formulas will save the time study specialist is readily apparent. It takes a certain amount of time and no little know-how to develop a time formula, but once it is available, the job of establishing accurate standards becomes a simple, fairly routine task. The time required to make and work up a time study will be from 1 to 100 or more hours, depending upon the length of the operation cycle studied. The time required to establish a standard from a time formula will, in the majority of cases, range from 1 to 15 min, depending upon the complexity of the formula and the amount of time required to determine the characteristics of the job. Where all the necessary information may be obtained from the drawing of the part, the standard may generally be computed in less than 5 min.

USES OF TIME STANDARDS

Some of the more common uses of time standards are in connection with

1. Wage incentive plans
2. Plant layout
3. Plant capacity studies
4. Production planning and control
5. Standard costs
6. Budgetary control
7. Cost reduction activities
8. Product design
9. Tool design
10. Top-management controls
11. Equipment selection
12. Bidding for new business
13. Machine loading
14. Effective labor utilization
15. Material-handling studies

Time standards can be established not only for direct labor operations but also for indirect work, such as maintenance and repair, inspection, office and clerical operations, engineering, and management. They can also be set for machinery and equipment, including robots.

17.5 COST OF ELECTRIC POWER

by Andrew M. Donaldson and Robert F. Gambon

REFERENCES: Department of Energy (DOE), "Electric Plant Cost and Power Production Expenses," 1991. Electric Power Research Institute, "Technical Assessment Guide," 1993. Oak Ridge National Laboratory, "CONCEPT-V, A Computer Code for Conceptual Cost Estimates of Steam Electric Power Plants." "Handy-Whitman Index of Public Utility Construction Costs," Whitman, Requardt and Associates. Grant and Ireson, "Principles of Engineering Economy," Ronald Press.

In simplest terms, the cost of electric power is the cost of the initial energy source plus the cost of converting that energy into electricity (generation), plus the cost of delivering that electricity to the consumer (transmission and distribution).

That initial energy source is the potential and kinetic energy of hydroelectric power; the chemical energy of fossil, biomass, and waste power; or the atomic energy of nuclear power. In addition, there are other energy sources for the conversion to electricity. These other sources include energy derived from solar radiation, wind, and ocean waves, but these sources are limited, inefficient, and currently not cost-effective without subsidy. These alternative generation approaches are not addressed herein.

The cost of the initial energy and its conversion to electricity constitute generation and is the major factor in electric power cost and is the primary concern of this section. The largest contributor to electricity cost of fossil fuel plants is delivered fuel followed by plant capital cost amortization, and operations personnel and maintenance expenses. The higher the fuel cost and the lower the plant efficiency, the greater the effect of fuel cost on the final electric price. For natural gas, which is generally the most expensive fossil fuel, a combination of lower plant capital cost and/or higher plant efficiency is necessary for cost competitiveness. Electricity production with natural gas in a 33 percent efficient Rankine cycle steam boiler and turbine makes little sense today because the same fuel can be used in a large-frame combustion turbine combined-cycle plant and approaches 60 percent efficiency. The traditionally lower delivered cost of coal allows it to be used economically in the Rankine cycle. However, for many recent years, low gas prices and restrictive environmental regulations combined with the high efficiency and lower construction cost of combustion turbine combined-cycle

plants have almost stopped coal plant construction. Only larger electricity producers conscious of the need for fuel diversity in their generation base have even considered coal in the last 5 to 10 years.

Environmental regulations have severely restricted coal use, but improving emission control equipment and increasing natural gas prices are likely to result in a resurgence of coal plants in the early twenty-first century.

For hydroelectric, geothermal, nuclear, and waste fuel plants, the highest cost contributor to electricity price is paying for the capital investment that is the power plant, followed by operations and maintenance.

Of course, economics have been overshadowed by public opinion and politics when it comes to nuclear and large hydroelectric plants, which have not been constructed in the United States in 20 years.

Generation costs consist of production expenses (fuel plus operating and maintenance expenses) and fixed charges on investment (cost of investment capital, depreciation or amortization, taxes, and insurance).

Interconnected power supply systems must price power to include transmission costs, distribution costs, and commercial expenses. Power price savings are realized by scheduling the installation and operation of a range of plant types to optimize overall generation costs. Generally, efficient plants burning lowest-cost fuels or operating on river water flows that are available the year round are assigned to continuous baseload operation at or near full capacity. Plants bearing low unit-kilowatt investment costs and lower efficiencies typically are installed to provide peaking capacity. Operation of these units during short daily periods of peak load limits their energy output and thus minimizes characteristic cost penalties associated with their poorer station efficiency or their requirement for higher-priced fuels. These higher unit cost per kilowatt but higher energy density **peaking plants** supply peak energy needs but are idle most of the time. This approach is preferable to building high capital cost but more efficient central stations that would sit idle most of the time until load growth catches up to capacity.

Power generating stations also participate in regional **transmission grid** systems supplementing capacity and reserve needs of neighboring systems, and by the daily and seasonal exchange of off-peak, low-incremental-cost energy. Historically, there have been significant regional differences in the price of power. These differences have reflected such factors as availability of hydroelectric energy, the cost of fossil fuels, labor costs, ownnership type and investment composition, local tax structure, and the opportunities pooling and coordination provide to exploit the economies of scale. This exchange of capacity and reserves to serve neighboring grid and spread the benefits of economies of scale, combined with regional power cost differences, led to the advent of state-by-state deregulation of the power industry, and proliferation of "nonutility" generators.

The early industrial areas of this country in the northern Midwest and New England areas were increasingly served by aging and decreasingly efficient power plants, often burning oil or requiring long-distance coal deliveries. These fuels have shown volatility on the world market and escalating delivery costs. The flight of heavy power-demanding industry from these areas allowed residential and light industrial growth to be picked up by the aging plants without new, more efficient capacity being added. The population density increased but the same old plants were kept in operation, often past their original life expectancy.

Since the early 1980s regulators and well-intentioned environmentalists have opposed nearly every new power plant. Existing plants, with their higher cost of replacement, were under no replacement pressure, since installing new, efficient, cost-effective power plants was delayed because of this environment. Regulators that refused requests from utilities for price increases, which would have allowed eventual new construction, further exacerbated the situation, preserving inefficiency.

Regional retail power price differences like 12 cents per kilowatt in areas of New York versus 6 cents per kilowatt in Georgia contributed to industry and job flight away from areas with high-priced electricity. As a result, business continues to look for lower electric rates, while politicians search for opportunities to keep jobs and voters in the area. Out of this dilemma, the idea of deregulation, in search of lower-cost electric supplies, was born. Opening some markets produced temporary downward pressure on prices even in regulated areas but also produced chaos and threatened the reliability of the national electric system that powers the U.S. economy.

The deregulation promises of lower prices were often temporary, as were the companies offering the lower prices. The California deregulation situation, with tremendous electricity price swings and state-assisted bankruptcy of one of California's largest utilities, and the Enron scandal exposed in 2001, have severely reduced the number of nonutility generators and the likelihood of deregulation. However, some states, such as Pennsylvania, have had some success in the deregulation of electricity. The electrical supply, distribution, reliability, and price chaos of the early twentieth century electrical system, which led to utility regulation, was just repeated for entry into the twenty-first century.

This section, while aware of the short-term volatility resulting from regulation, deregulation, and politics will concentrate on the long-term aspects affecting the cost of power.

Cost or price is a basic characteristic of power supply. Along with relative abundance, reliability, and high quality of service, low prices have encouraged the widespread use of electric energy that has come to be associated with our national way of life. Industrial use of electric energy is particularly heavy in the electroprocess and metallurgical industries. The price of electricity has a significant effect on the end-product cost in these industries. In many manufacturing and process industries, quality of service in terms of voltage regulation, frequency control, and reliability is a major concern. Uninterrupted supply is of crucial importance in many process industries where a power failure causes material waste or damage to equipment, in addition to loss of production revenue. Because of the flexibility and convenience of electric power, future increases in industrial, residential, and commercial consumption are anticipated despite deregulation, fuel price increases, environmental considerations, and energy conservation efforts.

Various types of power-generating units are owned and operated by industry and private sector investors to provide power (and thermal energy) to industrial facilities and often sell excess power to the local utility at the avoided cost of incremental power for the utility. Inside-the-fence cogenerators at paper mills and other industrial facilities that are electrical and thermal consumers but provide only a fraction of their electric generation to the grid are not considered in this section. However, the calculations and information in this section can assist in deciding the advisability of purchasing versus generating electric power. Larger cogenerating facilities built under the "qualifying facility" (QF) sections of the **Public Utilities Regulatory Policies Act (PURPA)** that have electricity production for wholesale to the grid or local utility as their main objective are included in this section. With the PURPA regulations no longer restricting the development of **nonutility generators (NUGs),** a significant portion of new generation in the 1990s was provided by NUGs. Of course, many "nonutility generators" had regulated utility parents.

CONSTRUCTED PLANT COSTS

A **central station** serving a transmission system is designed to meet not only the existing and prospective loads of the system in which it is to function but also the pooling and integration obligations to adjacent systems. Service requirements which establish station size, type, location, and design characteristics ultimately affect cost of delivered power. Selection of plant type and the overall philosophy followed in design must accommodate a combination of objectives which may include high operating efficiency, minimum investment, high reliability and availability, maximum reserve capability margins, rapid load change capability, quick-start capability, or service adaptability as spinning reserve.

For a given plant, the design must account for siting factors such as environmental impacts, subsoil conditions, local meteorology and air quality, quality and quantity of available water supply, access for construction, transmission intertie, fuel delivery and storage, and maintainability. In addition, plant siting and design will be significantly affected by legal restrictions on effluents which may have adverse impacts on the environment. In the case of **nuclear plants,** siting must also consider the proximity of population centers and the size of exclusion areas. Reactor plant design must bear the investments required to control radioactive

releases and to provide safeguard systems which protect against accidents. No new nuclear power plants are contemplated to begin the licensing process in the United States until 2010 or beyond. **Fossil-fueled power plants** may be sited adjacent to fuel supplies or in proximity to load centers, thereby increasing transmission costs on the one hand or fuel delivery charges on the other. Depending primarily on climate, plants may be enclosed, semienclosed, or of the outdoor type. Spare auxiliary components can be installed to improve reliability. Increased investments in sophisticated heat cycles and controls, for improved equipment performance, can achieve higher plant efficiencies. **Combustion-turbine, simple and combined-cycle plant** outputs are restricted by both increased elevation and high ambient air temperatures. Hydroelectric sites are frequently very distant from load centers and thus require added costs for extensive transmission facilities. Also, **hydroelectric facilities** may provide for flood control, navigation, or recreation as by-products of power production. In such instances, total cost should be properly allocated to the various product elements of the multipurpose project.

An **industrial power plant** provided to meet the requirements of an isolated load entails design considerations and exhibits cost characteristics which differ from those of a central station power plant assigned an integrated role within a connected generating system. Industrial power plants often produce both thermal and electric power. Industrial facilities must often accommodate both base- and peak-load requirements. They may be designed to provide for on-site reserve capacity or spinning reserve capacity. Frequency control and voltage regulation must be viewed as a special problem because of the limited capability of a single plant to meet load changes.

Table 17.5.1 provides typical installed cost data for central station generating plants. The figures represent costs of facilities in place, excluding interest during construction. The cost of land, waste-disposal facilities, and fuel is not included. Costs apply to plants completed in 2003. Interest during construction can be estimated by multiplying the simple interest rate per year by the construction period in years and dividing by 2 to reflect the carrying costs on the average commitment of capital toward equipment and labor during construction. Escalation effects for plants to be completed beyond this date may be extrapolated in accordance with anticipated cost trends for labor, material, and equipment. Historical cost trends, by region, as experienced in the power industry, which can be helpful in forecasting future costs, may be determined by use of the figures in Table 17.5.2. Escalation can significantly affect plant costs on future projects, especially in view of the 10- to 12-year engineering and construction periods historically experienced for nuclear facilities and the corresponding 5 to 6 years required for fossil-fueled power plants. In addition to rising equipment, construction labor, and material costs, major factors influencing the upward trend in plant costs include increased investment in environmental control systems, an emphasis on improved quality assurance and plant reliability, and a concern for safety, particularly in the nuclear field.

Table 17.5.1 Typical Investments Costs* (2003 Price Level)

Plant description			
Type	Net capacity, MW	Fuel	Total investment cost in $/net kW
Combustion turbine			
Simple cycle	200	Gas	250–400
Combined cycle	500	Gas	400–600
Conventional steam plant			
Fossil	500	Coal	1,200–1,500
	500	Oil	1,100–1,300
	500	Gas	900–1,000

* Capital investments exclude costs for the following: initial fuel supply, cost of decommissioning for nuclear plants, main transformers, switchyard, transmission facilities, waste disposal, land and land rights, and interest during construction.

Conventional Steam-Electric Plants Conventional fossil plant investment costs given in Table 17.5.1 are for 500-MW nominal units which are deemed to be representative of future central station fossil units. Costs will vary from those in the table due to equipment arrangement, pollution control systems, foundations, and cooling-water-system designs dictated by plant site conditions. The variety of cycle arrangements and steam conditions selected also affects plant capital cost. Plant designers try to economically balance investment and operating costs for each plant. Present-day parameters, in the face of current economics, call for a drum boiler, regenerative reheat cycles at initial steam pressures of 2,400 psig with superheat and reheat temperatures of 1,000°F (539°C). Similar temperature levels are employed for 3,500-psig initial steam pressure supercritical-reheat and double-reheat cycles which require higher investment outlays in exchange for efficiency or heat rate improvements of between 5 and 10 percent. Increased investment costs are also caused by more generous boiler-furnace sizing, and larger fuel and ash-handling, precipitator, and scrubber facilities required for burning poor quality coals. Investment increments are also required to provide partial enclosure of the turbine building and furnace structure and to fully enclose the boiler by providing extended housing to weatherprotect duct work and breeching.

Nuclear Plants The construction of nuclear power plant capacity in the United States has been suspended for over 20 years. A new generation of smaller light-water reactor nuclear power plants is currently in the conceptual design stage. Costs associated with these units, including siting, licensing, and fuel cycle, remain unclear, as they are precommercial.

In general, light-water reactor nuclear plants require considerably higher investments than do fossil-fueled plants, reflecting the need for leakproof reactor pressure containment structures, radiation shielding, and a host of reactor plant safety-related devices and redundant equipment. Also, light-water reactor plants operate at lower initial steam conditions than do fossil-fueled plants and, because of their poorer turbine

cycle efficiency, require larger steam flows and increased equipment sizes at added investment.

Combustion Turbine/Combined-Cycle Plants Simple and combined-cycle plants are offered by a number of vendors in the 100- to 1000-MW size range. These plants consist of multiple installations of combustion gas turbines arranged to exhaust to waste-heat steam generators which may be equipped for supplementary firing of fuel. Steam produced is supplied to a conventional steam turbine cycle. Advantages of combustion turbine–based plants are lower unit investment costs, efficient thermal performance, increased flexibility (which allows independent operation of the gas-turbine portion of the plant), shorter installation schedules, reduced cooling-water requirements, and the reduction in sulfur oxide and particulate emissions characteristic of gaseous fuels. The disadvantages of combustion turbines are the high costs of fuel and combustion turbine maintenance.

Hydroelectric Plants Hydroelectric generation offers unique advantages. Fuel, a heavy contributor to thermal plant operating costs, is eliminated. Also, hydro facilities last longer than do other plant types; thus they carry lower depreciation rates. They have lower maintenance and operating expenses, eliminate air and thermal discharges, and because of their relatively simple design, exhibit attractive availability and forced-outage rates. Quick-start capability and rapid response to load change ideally suit hydro turbines to spinning reserve and frequency-control assignments.

The constructed cost of a hydroelectric station is strongly site dependent. Overall costs fluctuate significantly with variations in dam costs, intake and discharge system requirements, pondage required to firm up capacity, and with the cost of relocating facilities within the areas inundated by the impoundments. For a given investment in structures, available head and flow quantity may vary considerably, resulting in a wide range of outputs and unit investment costs. Installed plant costs are competitive with other facilities. Cost prediction for future hydroelectric construction is difficult, particularly in view of the decreasing availability of economical sites and restrictions imposed by concern for the ecological and social consequences of disrupting the natural flow patterns of rivers and streams. As with nuclear, no new large hydroelectric plants have been constructed in over 20 years. A number of dams and associated power plants have been demolished or otherwise taken out of service to save fish or restore waterways to some past condition. Any new capacity in this area has come from upgrading existing hydroturbines for greater output and efficiency.

Pumped-Storage Plants Pumped-storage plants involve a special application of hydroelectric generation, allowing the use of off-peak energy supplied at incremental charges by low-operating-cost thermal stations to elevate and store water for the daily generation of energy during peak-load hours. Pumped hydro projects must justify the inefficiencies of storage pumping and hydroelectric reconversion of off-peak thermal plant energy by investment cost savings over competing peaking plants. Installation of a pumped hydro station calls for a suitable high head site which minimizes required water storage and upper and lower reservoir areas and an available makeup source to supply the evaporative losses of the closed hydraulic loop. Despite the added complications of installing both pumping and generating units, or of utilizing reversible motor-generator pump-turbines, costs for pumped hydro stations generally fall below those for conventional hydroelectric stations. Differences in gross head, impoundment, and siting make plant cost comparisons difficult.

Geothermal Plants Geothermal generation utilizes the earth's heat by extracting it from steam or hot water found within the earth's crust. Prevalent in geological formations underlying the western United States and the Gulf of Mexico, geothermal energy is predominantly unexploited, but it is receiving increased attention in view of escalating demands on limited worldwide fossil-fuel supplies. Because natural geothermal heat supplants fuel, the atmospheric release of combustion products is eliminated. Nevertheless, noxious gases and chemical residues, usually contained in geothermal steam and hot water, must be treated when geothemral resources are tapped. There is a current lack of significant cost data covering geothermal plants. Because boiler and associated fuel-handling facilities are eliminated, investment in these generating plants is considerably less than the cost of comparable fossil-fueled units. However, overall investment chargeable to geothermal facilities includes significant exploration and drilling costs which are site dependent and cannot be accurately predicted without extensive geophysical investigation.

Environmental Considerations Environmental protection has become a dominant factor in the siting and design of new power generating stations. Both stack emissions to the atmosphere and thermal discharges to natural water courses must be significantly reduced in order to meet increasingly stringent environmental criteria. In many cases older plants are being required to reduce emission levels to achieve legislated ambient air-quality standards and to control thermal discharges by the use of closed cooling systems to prevent aquatic thermal pollution.

Control of **air pollution** in fossil-fueled power plants includes the reduction of particulates, sulfur oxides, and nitrogen oxides in flue gas emissions. Particulate collection can be achieved by electrostatic precipitators, baghouse filters, or as part of stack gas scrubbing. Stack gas scrubbing is required for all new coal-fired power plants, regardless of sulfur content of the fuel. Fossil-fueled power plants are believed to be a major contributor to acid rain.

Scrubbers reduce sulfur oxide emissions by contacting flue gas with a sorbate composed of metal (usually sodium, magnesium, or calcium) hydroxides in solution which act as bases to produce sulfate and sulfite precipitates when they contact sulfur oxides in the flue gas. Wet scrabbers contact flue gas with a sorbate in solution. Dry scrubbers evaporate sorbate solution into the gas stream.

Fossil-fueled power plants are required to burn low-sulfur fuels. Restrictions on the use of oil in new power plants and its high cost have virtually eliminated new central station steam power plants designed to utilize oil.

Control of nitrogen oxides NO_x is attained primarily through modifications to flame propagation and the combustion processes.

NO_x control for combustion turbines is typically staged combustion. New burner designs and the use of water or steam injection into the combustion zone have effectively reduced emissions to acceptable rates. For steam boilers, changes to the burners and combustion zone were deemed insufficient and introduction of ammonia or urea spray has been incorporated with or without a catalyst [selective catalytic reduction (SCR) and selective noncatalytic reduction (SNCR), respectively]. The two systems, SCR and SNCR, operate at different temperatures. The SCR system includes ammonia injection across the flue gas in an area of the gas path at approximately 700°F. The flue gas then passes through a vanadium pentoxide (V_2O_5) catalyst. This combination removes NO_x with a removal efficiency of approximately 90 percent. SNCR operates at approximately 1600 to 2100°F but does not require a catalyst. Its removal efficiency is approximately 70 percent.

In order to avoid plant discharges of waste heat to the aquatic environment, evaporative-type closed-cooling cycles are employed in lieu of once-through cooling system designs. Closed-loop cooling systems in current use employ evaporative **cooling towers** or **cooling ponds.**

More advanced closed-cooling-loop designs use dry and wet-dry cooling towers. These represent alternates to conventional evaporative systems where makeup water is in short supply or where visible vapor plumes or ice formed by vapor discharge present hazards. The penalties for dry-tower cooling are significantly higher than those for conventional evaporative designs. Large, more costly water-to-air heat-transfer surfaces are required, and characteristically higher condensing temperatures result in higher turbine backpressure, restricting plant capability and reducing efficiency.

Evaporative cooling systems (wet towers) have a significant advantage over hybrid (wet and dry sections) and all-dry cooling systems in initial installed and operating costs. A dry cooling tower system can be $200 to $400 per kW more expensive. For a large facility the operating penalty can be $1,000 per kW or more because of the additional fan power requirements. Hybrid systems, which are a combination of an evaporative section and a dry heat exchanger section, are often used in

areas where water usage is a concern or fogging issues are present. The wet/dry hybrid arrangement utilizes the required amount of wet and dry surface to meet the site constraints. In the Northeast, many smaller facilities (under 100 MW) have used the wet/dry arrangement to minimize fogging or icing of nearby highways. In the western half of the United States, wet/dry towers have been used to conserve the precious and sometimes scarce water resources. Another consideration for the addition of any dry surface beyond the typical evaporative cooling system is the effect on efficiency. Use of a dry cooling system can easily increase the condensing temperature for the Rankine cycle by 20 to 30°F. The efficiency and output penalty of the increase in heat rejection temperature can approach 5 to 10 percent, which can reduce overall efficiency by several percent or more.

FIXED CHARGES

Costs that are established by the amount of capital investment in plant and which are fixed regardless of production level are termed **fixed charges.** Annual fixed charges are ordinarily expressed as a percentage of investment and include interest or the cost of money, funds applied to amortize investment or to allow for replacement of depreciated plant, and charges covering property taxes and insurance. Additionally, fixed charges may include an interim replacement allowance to cover the replacement cost of plant equipment not expected to last the full life of the plant.

For investor-owned utilities, the **cost of money** employed for plant expansion depends upon financial market conditions in general and upon the attitude of investors with regard to a particular utility enterprise or specific project. Funds for investor-owned utility expansion are derived from both the risk capital (equity) and debt capital (bond) markets. Prevailing return rates for investments in utility plant facilities are influenced by the rate-setting practices of public utility regulatory agencies and by supply-and-demand factors in the investment market.

Public utility facilities owned by state and municipal government organizations are generally financed by long-term revenue bonds, most of which qualify for tax-free-income status. Interest rates currently fall between 4 and 6 percent and reflect the tax relief on interest income enjoyed by the bondholders.

Generating facilities are often financed by industrial concerns whose primary business is the production of a manufactured product. In these instances, the annual cost of money invested in power facilities will be established by considering alternate investment of the required funds in manufacturing plant. Inasmuch as returns on equity capital invested in manufacturing industries are usually on the order of 10 to 20 percent, the rate of return for industrial power plants will tend to be set at these higher levels.

Nonutility Generators (NUGs) generally form a project-specific limited liability corporation, or LLC, and borrow through nonrecourse financing at or above market rates. They put up a minimum of capital. In the early days of NUGs, the project would get equity contributions from the equipment vendors and contractors to cover the equity required by the banks as "down payment." The plant and its revenue stream would collateralize the balance. Later revenue from earlier operating plants and real equity was required to satisfy the loan. As we enter the twenty-first century, project financing has seen numerous project defaults and the decline of many independent NUGs and utility-spawned NUGs. Equity requirements for new projects have increased dramatically, as well as the expected interest rates. Lenders expect multiple layers of guarantee from all participants. The short-lived electricity trading market has shrunk and the expectation of huge short-term profits that could justify and secure merchant generating has disappeared. New NUG generation will require guaranteed fuel costs, a reasonable expectation of electric sales through renewable sales contracts, and/or an electric price tied profitably to fuel and operating costs.

Table 17.5.3 Representative Useful Life of Alternate Utility Facilities

Facility	Representative useful service life, years
Steam-electric generating plant	30
Hydroelectric plant	50
Combustion turbine-combined cycle	30
Nuclear plant	30
Transmission and distribution plant	40

Corporate federal taxes are levied on equity capital income. Thus, corporate earnings on equity investment must exceed the return paid the investor by an amount sufficient to cover the tax increment.

The amortization of debt capital or the provision for **depreciation** over the physical life of utility plant facilities may be effected by several methods. Straight-line depreciation requiring uniform charges in each year over a predetermined period of useful service is commonly applied because of its simplicity. The percentage method of depreciation assumes a constant percentage decrease in the value of capital investment from its value the previous year, thereby resulting in annual depreciation charges which progressively diminish. The sinking-fund method of economic analysis assumes equal annual payments which, when invested at a given interest rate, will accumulate the capital value of facilities less their salvage value, over a predetermined useful service life. Table 17.5.3 illustrates the representative useful life for alternate utility facilities.

Use may be made of interest tables which show, for any rate of interest and any number of years, the equal annual payment (sinking-fund) rate which will amortize an investment and additionally will yield an annual return on investment equal to the interest rate.

$$\text{Equal annual payment} = \frac{i(1+i)^n}{(1+i)^n - 1}$$

where n = number of years of life, and i = interest rate or rate of return.

Property taxes and property insurance premiums are normally established as a function of plant investment and thus are properly included as fixed charges. Property taxes vary with the location of installed facilities and with the rates levied by the various governmental authorities having jurisdiction. In general, public power authorities will be free of taxes, although public enterprises often render payments to government in lieu of taxes. Annual property tax rates for private enterprise will amount to perhaps 2 to 4 percent of investment, while property insurance may account for annual costs of between 0.3 and 0.5 percent.

A representative makeup of fixed charges on investment in a conventional steam-electric station having a useful service life of 30 years is shown in various classes of ownership in Table 17.5.4.

Table 17.5.4 Typical of Fixed-Charge Rate for Conventional Fossil-Fueled Steam-Electric Plant with 30-Year Economic Life

	Investor-owned utility, %	Government-owned utility, %	Industrial-commercial ownership, %
Rate of return or interest	6.4	5.0	8.0
Amortization or depreciation	1.2	1.5	0.9
Federal income tax	1.5	0.0	4.3
Local taxes (or payment in lieu of taxes)	2.0	2.0	2.0
Insurance	0.3	0.3	0.3
Total	11.4	8.8	15.5

Table 17.5.5 Operating Expense for Fuel for Representative Heat Rates and Fuel Prices

	Nominal size, MW	Typical heat rate, Btu/kWh	Fuel price, ¢/MBtu	Fuel cost, mills/kWh
Conventional coal fired	500	9,800	200	19.6
Advanced light-water reactor	600	10,700	60	6.4
Combustion turbine/combined cycle	500	7,000	400	28
Combustion turbine/simple cycle	200	8,000	400	32

NOTE: Operating fuel cost, mills/kWh = (Btu/kWh) × (¢/Btu) × 10^{-5}

OPERATING EXPENSES

Fossil Fuels Currently, fossil fuels contribute approximately three-fourths of the primary energy consumed by the United States in the production of electric energy. Generating station demands for fossil fuels are continuing to increase as the electric utility and industrial power markets grow. Price comparisons of fossil fuel are generally made on the basis of delivered cost per million Btu. This cost includes mine-mouth or well-head price, plus the cost of delivery by pipeline or carrier. Price comparisons must recognize that solid and, to a lesser extent, liquid fuels require plant investments and operating expenditures for fuel receipt, storage, handling and processing facilities, and for ash collection and removal. High transportation cost contributions on a Btu basis will be incurred by high-moisture and ash-content coals with low heating values. It is, therefore, advantageous to fire lignite and subbituminous coals at mine-mouth generating plants.

Coal represents our most abundant indigenous energy resource, with enough economically recoverable supplies at current use rates to last well into the twenty-first century. About half of the recoverable coal reserves have a sulfur content above 1 percent and are considered high-sulfur coal. Low-sulfur coals are found chiefly in the low-load areas of the mountainous West, and delivered cost at the major markets east of the Mississippi include high transportation charges. Increasingly, coal production is bearing the cost of more rigid enforcement of stringent mine safety regulations, coal washing environmental compliance, and the charges associated with strip-mine land restoration. Delivered price depends upon transportation economies as may be affected by barging, unit train haulage, or pumping in slurry pipelines. Delivered price levels for coal fuel vary with plant location. Plants conveniently located with respect to eastern coal reserves report delivered-coal prices in the general range of $1.25 to $2.50 per million Btu, depending upon sulfur and ash content. Low-sulfur western subbituminous coals have delivered prices of between $1.00 to $2.00 per million Btu.

The domestic supply of **petroleum** is now outstripped by nationwide demand. The United States has become dependent on overseas sources to meet growing energy demands. The consequences of this trend are a continued unfavorable balance of payments and dependence on foreign oil supplies from politically unstable areas in the Middle East and North Africa. Residual and distillate oil prices have risen because of short supply and pressure by the major oil producers on worldwide market price levels. Blends of low-sulfur oils delivered during 2004 to generating plants along the eastern seaboard range from $3.50 per million Btu to as high as $4.50 per million Btu for the 0.3 percent sulfur fuel required for firing in some metropolitan areas. During this same period distillate oil commanded a nationwide price ranging from approximately $5.00 to $7.00 per million Btu.

Consumption of **natural gas** as a power fuel is increasing because it is clean burning, convenient to handle, and generally requires smaller and cheaper furnaces. Historically, its limited supply made it best-suited for consumption by residential and commercial users and meeting industrial process needs. Present-day power plant use of natural gas is on the rise. The proliferation of larger, more efficient combustion turbines like the 150+ MW "F series" machines designed for combined-cycle application has increased the consumption of natural gas for power generation. During the 1990s almost all new generation was natural gas-fired combustion turbine combined-cycle.

Fuel prices for 2004 ranged from $4.00 to $6.00 per million Btu. Price levels of natural gas, severely regulated in the past by government controls imposed at the well, have been falling sharply in response to current supply-and-demand factors and gas deregulation.

Nuclear Fuel Reactor plant fuel costs present a special case. Actually, the initial core loading which will support operation of a nuclear plant over its early years of life requires a single purchase prior to commissioning of the plant. For comparison with fossil-fuel prices, therefore, nuclear-fuel cycle costs, including first-core investment, periodic charges for reload fuel, and spent-fuel shipment and processing costs, are ordinarily extrapolated at assigned load factors over the life of the plant and are converted to an economic equivalent expressed in dollars per million Btu of released fission heat. Nuclear-fuel costs are not only influenced by ore prices and by fuel fabrication and processing costs, they are also sensitive to investment and uranium-enrichment costs. Future costs are subject to inflationary pressures and cost-saving technology changes such as extended burn-up cycles. Charges up to $1 per million Btu are representative of the levelized fuel prices for nuclear plants.

Operating Costs of Fuel Fuel price contributions to energy-generation costs will reflect start-up and will depend upon plant efficiencies which, at low loads, show considerable departure from the best-point performance achieved at or near full unit loadings. These factors significantly affect the operating expenses of load-following utility system units as well as plants assigned fluctuating demands in manufacturing or industrial service. As an example, calculated performance for a nominal 500-MW, 2,400-psig coal-fired regenerative reheat steam unit shows a best-point heat rate of 9,800 Btu/net kWh at rated output. Load reduction yields heat rates of 10,500 and 12,400 Btu/kWh at loadings of 250 MW and 125 MW, respectively. Typical operating-expense ranges for given fuel prices and estimated full-load heat rates may be determined directly where continuous operation at or near unit rating is assumed (Table 17.5.5).

Operating Labor and Maintenance In addition to fuel costs, operating expenses include labor costs for plant operation and maintenance, plus charges for operating supplies and maintenance materials, general administrative expenses, and other costs incidental to normal plant operation. Operating labor and maintenance costs vary considerably with unit size, operating regimen, plant-design conditions, type of facility, and the local labor market. Representative figures appear in Table 17.5.6.

Table 17.5.6 Representative Operating and Maintenance Costs (2004 Price Level)

Type of plant	Nominal size, MW	Fuel	Operating and maintenance costs, mills/kWh
Conventional fossil	500	Coal	5–9
Advanced lightwater reactor	600	Nuclear	5–12
Combustion turbine/ combined cycle	500	Gas	6–11
Combustion turbine/ simple cycle	200	Gas	7–12
Conventional hydro	300	—	6–9

NOTE: Unit kilowatt-hour costs include labor, maintenance materials, operating supplies, and incidental expenses. Costs shown assume base-load operation.

Environmental Controls Systems and equipment required for air and water pollution abatement generally carry increased fuel and maintenance labor and materials costs. Reductions in plant output resulting from the higher condensing pressures associated with cooling-tower operation or the added auxiliary power for stack gas clean-up systems lower plant efficiency and increase fuel consumption.

OVERALL GENERATION COSTS

The total cost of power generation may now be estimated by reference to the preceding material assuming type of ownership, capital structure, plant type, fuel, and loading regimen. Table 17.5.7 comprises an illustrative tabulation of the factors determining the overall generation cost of an investor-owned generating facility.

It should be noted that capacity factor, or the ratio of average-actual to peak-capable load carried by a given generating facility, will have a significant effect on generation expenses. In addition to the effects of part-load operation on fuel costs as previously discussed, capacity factor will determine the plant generation which will support fixed charges. High-capacity-factor operation will spread fixed charges over a large number of kilowatt-hours of output, thereby reducing unit generation costs. During its initial life, a thermal plant is usually operated at high-capacity factor. As inevitable obsolescence brings newer and more efficient equipment into service, a unit's baseload position on the utility system load duration curve is relinquished, and capacity factor tends to drop. This decline in capacity factor must be acknowledged in estimating output and generation costs over the life of a given facility.

Most modern electric utilities incorporate computerized systems designed to economically dispatch power generated at each production plant feeding the load. Individual generating-unit loads are assigned in a manner that can be demonstrated to result in minimum overall cost; i.e., at each system power level, load is shared between units so that all operate at the same incremental production cost. Telemetered data reflecting system load and generation is transmitted to central dispatch computers by multiplexing via power line carrier, microwave, or telephone lines. The communication schemes include channels for transmitting load adjustment commands developed by the computer to on-line generating units. Loading instructions account for the unit production efficiencies and transmission losses associated with each dispatch assignment.

TRANSMISSION COSTS

Because of a growing scarcity of urban sites, increasing emphasis on environmental protection, and public attitudes, it has become more and more difficult to site major power stations near centers of load. As a consequence, added cost of transmission along with attendant resistive power losses add significantly to the overall cost of service. Because of the distances involved, these costs are generally greatest for nuclear facilities, mine-mouth stations, and hydroelectric plants where remoteness or remote resources strongly govern siting. Transmission plant investment also reflects a trend toward interconnection of neighboring utilities. Designed to improve service reliability by the pooling of reserves and to effect savings by capacity and energy interchanges, such interties must carry substantial ratings so that emergency power transfers can be accommodated without exceeding system stability limits. Costs for major overhead transmission ties (1,000 MVA and up) are estimated to range between $400,000 and $900,000 per circuit mile depending on terrain and voltage level. Investments are also sensitive to factors of climate and proximity to urban areas that can increase right-of-way costs significantly. Where underground transmission is elected, installed investment costs can be as much as 10 times the cost of overhead lines.

Transmission and distribution systems have seen a large-scale change in ownership in deregulated areas of the country as regional grids were sold, divested, or handed to new owner/operators. These grid systems that had been maintained by high-cash-flow integrated utilities were now the responsibility of lower-cash-flow entities receiving only a small percentage of the retail price of electricity. Extensive blackouts, like the August 2003 blackout that darkened Ohio to New York City and parts of Canada, can result from insufficient transmission line investment, publicly restricted transmission line additions, and capacity increases, as was demonstrated in this situation.

The choice of **transmission voltage** level and whether ac or dc is used for bulk power transfer depends on the amount of power transmitted, the transmission distance involved, and at each voltage level, the cost of line and substation equipment. Voltages generally employed are 230, 345, 500, and 765 kV ac and 5000 + kV dc. Where long distances on the order of 400 mi (650 km) or more are encountered, dc transmission becomes economically attractive. For shorter lines, however, savings in fewer conductors and lighter transmission towers are nullified by the high cost of dc-ac conversion equipment at both line terminals.

Table 17.5.7 Total Cost of Generating Power
(Plant type: 500-MW conventional fossil; plant net heat rate: 9,800 Btu/kWh)

	Generating costs, mills/kWh
Coal fuel @ $2.00/mBtu	19.6
Operating and maintenance	7.0
Fixed charges @ 11.4% per annum	24.0
Total operating costs	50.6

NOTES: Fixed charges are based on assumed initial plant investment of 1,580/kW and 7,500 h/year of operation. Values shown are typical and could vary significantly for individual plants.

POWER PRICES

The price of power delivered must account for the production costs at each generating station in addition to transmission and distribution costs. As previously noted, these costs depend upon labor rates, fuel prices, and material charges. They reflect investment levels in generating plant and the fixed-charge rates established by funding patterns, type of ownership, and expected equipment service life. Overall system production costs are affected by the investment requirements of specific mixes of generating equipment types, and by the manner in which load is shared by units, i.e., how production is allocated between highly efficient base-load stations and the less-efficient peaking equipment which normally runs for only a few hours each day. Also, important cost reductions are achieved in hydro systems by controlling natural and stored water flows to allow optimized sizing and scheduling of hydroelectric output, thereby reducing needs for thermal peaking capacity and decreasing the generation requirements of high fuel cost fossil plants.

Power prices cover the investment charges, maintenance costs, and capacity and energy losses chargeable to the transmission and distribution plant. They also include the administrative costs incurred to maintain corporate enterprise and the commercial expense of metering and billing. The advertising and public relations cost of competition or the cost of preparing for competition in a deregulated market must be considered.

Generally, power prices must provide a return to cover the average cost of power production throughout a given system. For smaller utility systems and commercial and industrial companies, each plant must provide an adequate return based solely on the individual plant's costs rather than an average as discussed above. Rate schedules and supply contracts, however, are drawn to reflect the reduced cost of off-peak energy produced by available generating units during periods of low system load. Additionally, prices for high load factor service often recognize the cost reductions effected by spreading fixed charges over increased units of energy output. Large blocks of capacity and energy supplied for industrial use are often priced by establishing an annual charge for capacity which equals the fixed charges on investment in committed generation and transmission plant, plus charges for energy representing the sum of the variable kilowatt-hour production costs for fuel, maintenance, and operation.

Historically, utilities have applied rate schedules which promote consumption by applying progressively lower rates to blocks of increased energy usage. Rationale for such pricing is the savings that load growth can

Table 17.5.8 Average Cost, in Cents per Kilowatt-Hour, for Consumers by Sector, Census Division, and State, 2002

realize through economies of scale, as well as the improved utilization of existing utility plant. However, regulatory pressure, reflecting a policy of minimizing the cost to the consumer, impact on the environment, and the critical need to conserve high-cost imported fuel, has favored a marginal cost-pricing system more nearly reflecting the actual cost of production and transmission of a particular user's supply of power. Rate setting under this conservationist approach calls for flat, rather than reduced, rates as usage increases and for high unit energy charges during peak-load periods.

Cogeneration facilities designed for the **dual-purpose production of power and process steam** permit investment savings, principally in steam-generation plants, which result in combined production charges falling below the total cost of separate, single-purpose production of power and of steam. Such savings can permit proportionate decreases in the prices ordinarily charged for separate single-purpose production of each of the products, or they may be assigned in total to reduce the price of one or the other by-product. This latter option is often exercised in the case of dual-purpose water product plants arranged for seawater flash evaporation using power-turbine extraction as a process steam source. Where severe shortages of fresh water exist, social considerations favor the total assignment of dual-purpose savings to the water product. Thus, minimal prices for desalted product water are achieved, while dual-purpose power is marketed at prices competing with single-purpose power generation costs. Similarly, assignment of the total savings of dual-purpose power and process steam production to the power product may justify on-site industrial plant power generation in preference to outside purchases of higher-priced utility system power supplies.

Since the 1980s, some facilities qualifying under the PURPA regulations have provided very low-priced steam to a host industrial plant as a means to satisfy the PURPA regulations and sell electricity to the local utility, whether the utility wanted the facility or not. Changes to the pricing structures payable by the local utilities to the "qualifying facility" and the eventual end of the PURPA statute eliminated the "free steam" approach from cogeneration.

Where hydro facilities supply power in combination with irrigation, flood control, navigation, or recreational benefits, power costs are largely sensitive to the allocation of investment charges against each of the multipurpose project functions. Should generation be treated as a by-product, power prices can be reduced drastically to reflect equipment operating expenses and the limited fixed charges covering investment in only the generating plant itself.

Cheap fuel, advances in design, the economies of scale, and the economic application of alternate generating unit types produced downward trends in the price of electric service in the 1960s. In the 1970s these trends were reversed by inflationary effects on plant costs, high interest rates, and the increased fuel prices. A dwindling number of favorable plant sites, licensing delays, and the added costs of environmental impact controls combined to cause further upward pressure on power prices in the 1980s. However, falling interest rates and fuel prices began to slow the rate of increase in the cost of electric power. These stabilizing influences have continued into the 1990s, tempered by stricter environmental regulation costs. Increases in electric rates are expected into the foreseeable future.

The twenty-first century has started with good and bad deregulation cases, corporate financial problems (such as Enron), and increased terrorist attacks on the U.S. infrastructure. All of these factors, coupled with a significant rise in the price of natural gas in the first several years of the new millennium, have resulted in continual escalation of the price of electricity. Table 17.5.8 shows the electricity prices by sector for each region and state in the United States for the year 2002.

17.6 HUMAN FACTORS AND ERGONOMICS

SCOPE

The mission of human factors engineering/ergonomics (HFE/E) is to improve the performance, reliability, efficiency, and the risk management of systems in which humans work in concert with machines, man/machine/systems (MMS). This discipline developed many of its techniques during and after World War II. The life-or-death stakes and the advances in military technology made even minor improvements in the performance and reliability of manned military systems highly desirable and major improvements essential. The design of MMS interact with experimental psychology, physiology, and physical anthropology and with aeronautical, electrical, industrial, mechanical, systems, computer, and cognitive engineering.

MMS cover a wide range of enterprises, from piloting a jet aircraft to microsurgery. Achieving the goals of HFE/E in MMS requires a knowledge of humans as sensors, manipulators, responders, information processors, and decision makers. The expected performance of the "man" in MMS is affected by: training and motivation, variability of behavior among humans, personal stress, work load, age, fatigue, substance abuse, and by environmental conditions: vibration, noise, temperature, gravity, and distractions from the task. Some of the references for this section are sources for details and data on the impact of these many human-related variables. Other references provide engineering theory and practice for the design of MMS. What follows is an introduction to HFE/E findings that are likely to be helpful to mechanical engineers.

VISION

The visual pathway in psychomotor tasks, written or iconic messages, and searching for targets is primary in most MMS. Other senses, in declining order of importance to MMS design, are: hearing, which is superior to vision for alerting or warning signals; kinesthesis and vestibular senses, which facilitate positional awareness; and touch and pain.

High-resolution vision requires that the image of the object seen be projected by the eye's lens upon an approximately 2° central sector of the retina, known as the *fovea*, composed entirely of photoreceptors called

cones. Cones generate color vision and respond to light intensity from the limit of brightness tolerance to that of candlelight reflected from a newspaper. As it scans its field of view, the eye continually moves in pulses of approximately 50 ms, pausing to fixate its fovea on objects in this field. Each fixation pause is about 250 to 300 ms, but can be as long as 1 minute when the viewer is uncertain about the image on his fovea.

The density of cones on the retina falls steeply beyond its area of concentration on the fovea and reaches a flat minimum at an eccentricity of about 20°. Beyond the fovea a second set of retinal photoreceptors, rods, appears among the cones. Rods provide vision from low brightness levels to the darkest conditions for which vision is still possible. Rods reach their maximum sensitivity to low light levels after about 30 min in the dark. In a twilight level of brightness comparable to snow under a full moon, rods and cones operate together. The number of rods on the retina increases in density until reaching a maximum at an eccentricity of about 20°. Although much greater than that of cones, rod density gradually declines as it approaches the limiting eccentricity of 80°. This peripheral vision supports orientation and motion detection.

Visual perception is the brain's interpretation of visual images. The perception of the size and distance of an object begins when the eyes' lenses, controlled by the ciliary muscles, accommodate so as to focus upon the object. Estimates of an object's apparent distance are influenced by: this muscle action, the visual cues leading to the object, and the anticipated size of the object. These cues may be inadequate or they may be inconsistent with one another, and as a consequence a perception of distance that differs from reality may emerge. The vision of an automobile driver may be momentarily focused on the dashboard displays at a distance of 0.5 m. Refocusing on an object appearing unexpectedly in the road ahead may take as long as 0.4 s. The object may be unfamiliar and helpful visual cues obscured by darkness or fog. The probability of an accident is increased by this briefly held misperception of object size or distance.

Some of the characteristics of vision can support a two-parameter model for the probability of success over time in searching with the naked eye for a target alone in a visual field. This simplified model must be elaborated when the proposed application differs greatly from the experimental conditions under which it was validated. This is a common condition when most HFE/E models or data are used.

Assuming the search is random and p_{sg} is the probability of finding the target during a single glimpse or one fixation, then the probability of finding the target after k glimpses is:

$$P_k = 1 - (1 - p_{sg})^k \tag{17.6.1}$$

Each glimpse plus movement time is T seconds, therefore the elapsed search time is $t = kT$; the probability of finding the target by this time is:

$$P(t) = 1 - e^{-mt} \qquad t_{mean} = 1/m \qquad m \approx p_{sg}/T \tag{17.6.2}$$

This model was confirmed for $0.006 \leq p_{sg} \leq 0.80$, different size sectors of the sky, different target sizes, and different target contrasts. In unpracticed random searches for a command in a menu on a monitor, the single-glimpse probability of detection, $p_{sg,}$ was 0.08. After practice, p_{sg} increased to 0.60. Were the search systematic with no overlap of fixation areas the probability of detection, P_{sys}, for search for a limited time t would be:

$$P_{sys}(t) = p_{sg}\, t/T, \tag{17.6.3}$$

where $P_{sys} \leq 1$.

This model for the probability of finding targets becomes more elaborate when the target must be found from among camouflaged decoys as well as from among decoys differing from it by contrast, shape, area, color, and velocity as well as by area of search, numbers and spatial density of decoys and of targets, and the use of auditory aids.

PSYCHOMOTOR PERFORMANCE

A program of skilled psychomotor behavior can be constructed in several ways: by incrementally aggregating a sequence of discrete reaction times and movements, by continuous closed-loop control known as manual control or tracking, by complex open-loop activities, and by various combinations.

Manual reaction time (RT), like the eyes' fixation time, increases with uncertainty. This increase in RT can be quantified when a subject must select the correct manual response out of n possible responses to a corresponding visual signal out of n probable signals. For situations in which the independent or the sequential probability, p_i, for the occurrence of each of these n signals can be estimated, uncertainty can be expressed as information theory entropy, H:

$$H = \sum_i^n p_i \log_2 (1/p_i + 1) \tag{17.6.4}$$

For the range $0 \leq H \leq 3$, there is an empirical equation, known as the Hick-Hyman law for RT, for these manual responses:

$$\mathrm{RT} = a + bH \tag{17.6.5}$$

The constants $a \approx 200$ ms and $b \approx 150$ ms are influenced by practice and by the compatibility between the geometry of the physical presentation of the stimulus and that of the mechanism for responding.

For rapid discrete or repetitive actions, usually by the hands, movement time (MT) is proportional to the difficulty of the task as defined by Fitts' law. Equation (17.6.6) defines the index of difficulty, I_D, in terms of target width W and movement amplitude A. MTs from a wide range of rapid movements, as in operating a key pad or sorting items into bins, can be described. In applications, d is about 100 ms and c, which depends on the movement geometry, is approximately 200 ms. Estimates of MT enable comparisons to be made among different operating procedures.

$$I_D = \log_2 (2A/W) \tag{17.6.6}$$

$$\mathrm{MT} = c + d\, I_D \tag{17.6.7}$$

To be useful, measurements of RT and MT must come from a stable plateau of skilled performance that can be determined by units of error or of time to complete the given task. For many psychomotor tasks, skilled learning follows a power function

$$T_n = T_1 n^{-\beta} \tag{17.6.8}$$

where T_1 is the time to perform the task on the first trial. T_n the time to perform the task on the nth trial, and n is the number of trials. In the development of psychomotor skill, $0.2 \leq \beta \leq 0.6$.

SKILL AND ERRORS

The highest skill level in tracking is attained after extensive training when an operator fully familiar with the dynamics of the machine, the manipulator under her control, and the appropriate responses to the input signals can extract what coherence is present in these signals, develop pathways that reorganize the perceptual system, adapt her behavior to create a repertory of special responses, and select from this repertory the appropriate response for the best MMS performance. The procedure resulting in this performance is known as successive organization of perception (SOP). SOP results in a virtual display that provides the operator with the information that would have been present in the actual display had it been augmented. In closed-loop control situations, the precognitive mode response can be anticipatory and compensate for inherent human control lags. In an open-loop mode, the response may be programmed as in executing the sequential actions in preparing to stop a car on approaching a red light or otherwise responding to behavioral cues.

As psychomotor skills develop with training, errors diminish, and a plateau of stable, skilled performance is reached. Transient errors occur and are shed as training progresses. Posttraining errors are departures from the expected performance of a motivated, skilled operator. These errors may place the MMS in danger. Their number increases under the following pressures on human performance: divided attention, multitasking, and physiologically impairment such as fatigue, hypoxia, and alcohol or drug use. Errors can be divided into two classes: (1) mistakes, errors in the thought processes behind an action or decision,

and (2) slips, errors in the detection or interpretation of sensory signals and unintended responses. The thinking processes which lead to mistakes have been reconstructed; for example, inappropriate expectations can result in misinterpreting a situation acting accordingly and making a malign error. The basic sources for such reconstructions are accident reports, anecdotes, interviews with participants, and introspection on the part of the analyst. If the mistake is made under time pressure, it is difficult for the operator to reexamine the situation, sort out his misconceptions, and examine his options in a deliberate manner. Mistakes can be decreased by training methods, personnel selection, and operating procedures that emphasize the examination of options and impose redundancy for critical actions to lessen the chance that operators will persevere in erroneous behavior.

By applying HFE/E findings in the selection and positioning of information displays, controls, monitors, and keyboards, and by accommodating the physical dimensions of the operator, the designer can make slips such as misreading a display or reaching for the wrong switch less likely. In the unlikely event that an error does occur, emergency corrective procedures and warnings must be part of the MMS design. Warnings can address different sensory modalities with audio signals, speech, annunciators, lights, and vibration, either separately or in various combinations determined by the task being performed and the environment of the person or persons to be warned.

The probabilities of slips occurring can be estimated from the existing databases in HFE/E and from manned and unmanned simulator studies. These estimates, together with the failure probabilities for the inanimate components of the MMS, can be incorporated into flowcharts for the MMS to determine those locations where further risk management procedures are necessary.

MANUAL CONTROL

The body of knowledge in manual control developed from the USAF's mid-twentieth-century interest in mathematically modeling the dynamic response of pilots in order to provide aeronautical engineers with data for designing aircraft of high performance, stability, and positive evaluations from their pilots. Classical control theory provided the structure for this model. The core was a quasi-linear transfer function or describing function for the pilot's dynamics represented as $Y_p(j\omega)$,$Y_p(s)$, or Y_p, depending on the projected analysis. The quasi-linear human controller's response to an input comprises two parts: describing function components that correspond to the response of the equivalent linear elements driven by that input, and a "remnant" component that represents the difference between the response of the actual system and a system composed of equivalent linear elements. Test pilots operating fixed- and moving-base flight simulators as well as actual aircraft provided the empirical data for $Y_p(j\omega)$. Aircraft dynamics, the controlled element, $Y_c(j\omega)$, confine the dynamic response of motivated pilots to a limited range so that intersubject variability is suppressed. Consequently, adequate measurements for $Y_p(j\omega)$ can be obtained from a small number of skilled, motivated test subjects.

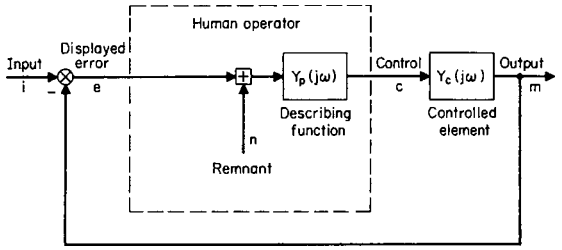

Fig. 17.6.1 Simplified block diagram for manual control.

The compensatory mode, Fig. 17.6.1, the most common and extensively studied mode of closed loop control, is present in vehicle control and many other configurations. In this mode, the human tracks a moving visual signal so as to keep its position as close to a reference marker as she can. This signal is the MMS's error $e(t)$, which is the difference between $i(t)$, the input to the MMS, and $m(t)$, the MMS output. Detecting cyclical and coherent structures in $e(t)$ and from these developing estimates of $m(t)$ and $i(t)$ are the first step in the SOP progression of evolving virtual displays. Maintaining system stability and minimizing the closed-loop system's error are basic design goals for closed-loop systems. If the open-loop gain $|Y_p(j\omega)Y_c(j\omega)|$ in the compensatory mode is too high, instability can occur in the closed-loop task. An expert pilot may unwittingly regress from a higher level in the SOP procedure to the compensatory mode. In this mode the pilot may inadvertently generate excessive open-loop gain and destabilize an otherwise stable system. Potentially destructive pilot-induced oscillations of the aircraft about its flight path are the result.

Compensatory pursuit and precognitive modes of the SOP procedures are presented in Figure 17.6.2. In the pursuit mode the operator

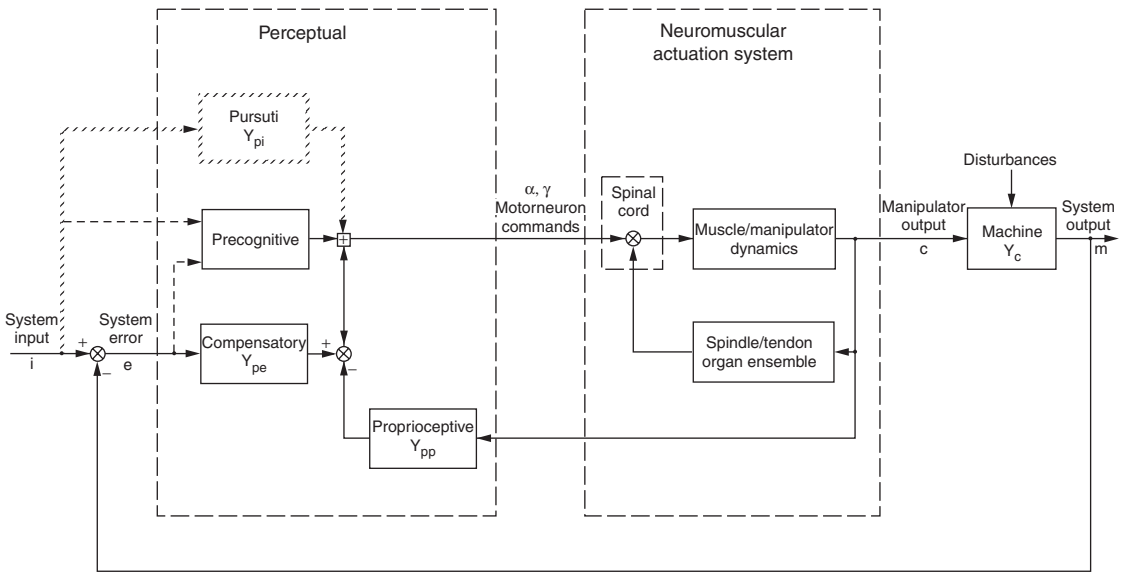

Fig. 17.6.2 Compensatory, pursuit, and precognitive pathways.

attempts to follow $i(t)$ with a cursor driven by the MMS dynamics. The perceptual pathways composing SOP for the human controller can be separated into sensory mechanisms that generate internal signals and to a central processor that integrates them, extracts coherence, and determines the human operator's dynamic responses. The describing functions and remnant depend explicitly on: the task variables, MMS inputs and disturbances, controlled element dynamics, and the operator-centered variables. The effects of these variables have been integrated into a set of rules for applying and adjusting human-operator describing functions for compensatory closed-loop control. The following conditions must apply before using these rules:

1. The forcing functions that act as inputs to the MMS are unpredictable, have bandwidth ω_i below 6.2 rad/s, and continuous waveforms.
2. The controlled element is a low-order system or can be so approximated and has no highly resonant modes over the input bandwidth.
3. The display and controls are reasonably well scaled and smooth so as to minimize the effects of thresholds, detents, and friction.
4. The other task demands are sufficiently light to permit the operator to devote the majority of his or her attention to minimizing the displayed error.

McRUER'S RULE

Under the foregoing conditions, which are commonly met in most operational control tasks, theory, experiments, and practice have shown that the operator compensates for the dynamics of the controlled element so that the open-loop characteristics of the MMS act like an integrator in series with an effective time delay in the frequency range most critical to system stability and performance. The frequency within this range where the open-loop gain of the MMS is unity is the crossover frequency ω_c. By compensating in this way, the operator creates a desirable, stable control system in accordance with good engineering design. This behavior by the human controller is known as **McRuer's rule,** and it is expressed by the crossover model**:**

$$Y_p(j\omega)Y_c(j\omega) \approx \frac{\omega_c e^{-j\omega\tau}}{j\omega}. \qquad (17.6.9)$$

Many of the basic qualities of feedback systems relate to ω_c, which is a close measure of the bandwidth of the closed-loop system. In the range of input bandwidth frequencies from very low up to and approaching ω_c, the output $m(t)$ of the closed loop system follows the system input $i(t)$, and the system error $e(t)$, is reduced. At increasingly higher input bandwidths beyond ω_c these properties are lost as $e(t)$ increases and $i(t)$ and $m(t)$ are no longer similar. For desirable closed-loop performance, ω_c must exceed the largest frequency in the input or in disturbances to the system that have appreciable power.

The effective time delay τ is the sum of perceptual and neuromuscular lags as affected by the demands of the tracking task.

As the controlled-element dynamics demand more lead from the operator to conform to the crossover model, the concomitant increased anticipation required of the operator imposes a cost. This is reflected in increases in τ, and affects the operator's evaluation of the MMS. Table 17.6.1 lists crossover model parameters.

As an illustration consider automobile heading control. At low to moderate speeds, this can be approximated by the controlled element $Y_c(j\omega) = K_c/j\omega$. Since the heading rate is proportional to the position of the steering wheel, the driver need only generate proportional control, i. e., zero lead. The effective time delay will then be 0.18 s and the maximum effective closed-loop system bandwidth will be the maximum crossover frequency or 4.7/rad/s.

Attitude control of a spacecraft with damper off can be approximated in the region of human control by $Y_c(j\omega) = K_c/(j\omega)^2$. Maintaining stability demands more of the operator than did automobile heading control, for the operator must generate a low-frequency lead. The cost incurred by control is an increase in the effective time delay τ to 0.32 s. A significant consequence is the reduction of the maximum system crossover frequency, and thus the maximum effective closed loop system bandwidth, to 3.3 rad/s.

For a single-loop control system of maximum crossover frequency ω_c, the attainable relative mean square error coherent with an input bandwidth, ω_i and variance, σ_i can be estimated:

$$\overline{e^2}_i/\sigma_i^2 \approx \frac{(\omega_i/\omega_c)^2}{3} \qquad (17.6.10)$$

Thus for similar MMS input characteristics, the estimated attainable mean square error for attitude control of a spacecraft is twice the estimated attainable mean square error for the less demanding heading control of an automobile.

MODELING THE HUMAN IN THE MMS

The crossover model is a first approximation in the process of elaborating models for human operators of increasingly more complex control systems in which there may be competing demands for the operator's attention. The process has been described in a reductionist fashion by analyzing the input-output behavior of the human into subsystem components. The sensory mechanism subsystems in Fig. 17.6.2 include optics, the retina, oculomotor muscles, eye dynamics, and the dynamics of linear acceleration and angular velocities acting on the vestibular and kinesthetic sensors. The central elements act to integrate and to equalize the outputs of these subsystems so as to generate commands to the neuromuscular actuation system, which is divisible into dynamic subsystems. These components are adjusted according to **McRuer's rule** so that the crossover model obtains and then is integrated to describe the operator's behavior in a structural-isomorphic model. In contrast, the algorithmic or optimal control model (OCM) proceeds in a holistic fashion and mimics the human's total response by the application of optimal control computational methods to those human properties subject to adaptation and hence optimization. The OCM proceeds by minimizing a quadratic performance index with an optimum linear predictor operating on estimated delayed state vectors to emulate the human's control actions. The computational procedure results in very high-order transfer functions for the human. PC-compatible programs, for example, Program CC Version 5, have been written for both the classical model and the OCM. Since **McRuer's rule** is the best understood, most widely applicable empirically tested description of human dynamics, the crossover model serves as the standard for comparing the classical model with the OCM model. This has been done for $Y_c = K_c/s$ and the comparison is good for frequencies less than 15 rad/s.

Manual control models present one perspective of the virtual human. Other perspectives are reach, strength, movements, and eye point of regard. Digital models exist which allow 3-D virtual humans to be placed in 3-D CAD-generated virtual environments. In the design of automobile, aircraft, spacecraft, or submarine interiors as well as factory work stations and large construction machinery, engineers are able to examine a human's activity in virtual environments and to sort through design options. One such digital human model, Jack/Jill, manufactured by EDS, has 69 segments, 68 interconnected joints, a 17-segment spine, 16-segment hands, coupled shoulder/clavicle joints, and 135 degrees of freedom to mimic the motions and positions of a wide range of humans.

Table 17.6.1 Crossover Model Parameters, ω_i = 2.5 rad/s

Controlled-element dynamics	K_c	$K_c/(j\omega)$	$K_c/(j\omega)^2$
Operator lead unit to establish control	−1 (integral)	0 (proportional)	+1 (low frequency lead)
Effective time delay τ, seconds	0.14	0.18	0.32
Maximum crossover frequency ω_c, rad/s	5.7	4.7	3.3

Joint limits as derived from NASA studies and sizes and shapes based on SAE measurements and ANSUR 88 data round out the engineer's ability to select digital manikins for specific problems and representative of 5th, 50th, or 95th percentile human actors. The virtual human operator can thus be used to simulate a population of potential users and determine the diversity permitted by a particular design.

Risk management of slips could be addressed by Jack/Jill simulating a control room operator confronted with an arrangement of manual controls such as knobs or levers. By selecting 5th and 95th percentile operators and adding statistical variability to their head position, eye point of regard, and reach, the probabilities for slip errors occurring for configurations of manual controls under different time pressures could be estimated.

17.7 AUTOMATIC MANUFACTURING

by Vincent M. Altamuro

The production of many products involves both **fabrication** and **assembly** activities. Fabrication is the making of the component piece parts that are later assembled into the final product. Fabrication methods include casting, molding, forging, forming, stamping, and machining. Assembly may be manual or automatic. Automatic manufacturing can range from **semiautomatic** to **fully automatic,** depending on the number of human operations required. Automatic manufacturing installations may also be called **fixed** and **flexible** according to how easily they can be altered to make product variations. These several available modes allow the creation of a mode that draws on all of them—the **autofacturing** mode, that combination of the manual and the specific types of automatic operations which best achieves the quality, operational, and economic objectives sought.

The selection of assembly mode must be consistent with the design of the product, the personnel skills, the equipment available, and other factors. Manual assembly is suitable for low volume output and relatively short production runs with high product-to-product variations. Fixed automatic assembly is suitable for high-speed, high-volume production of uniform products. Also called *hard, dedicated,* or *conventional* automation, it can produce low-unit-cost items of uniformly high quality once its machinery is perfected and until a product variation is wanted. If a product's assembly cost is the sum of its *setup cost* (the cost of getting everything ready to make it) and its *run cost* (the cost of making it), then manual assembly has a relatively low setup cost but a high run cost, while fixed automatic assembly has the reverse. Flexible automatic assembly is suitable for midrange-volume production with variations in product specifications. Also called *soft* or *programmable* automation, it uses robots and other computer-based equipment that are more easily movable and adjustable so as to reduce setup costs and still enjoy low run costs. It fits between fully manual and fully fixed automatic assembly, as shown in Fig. 17.7.1.

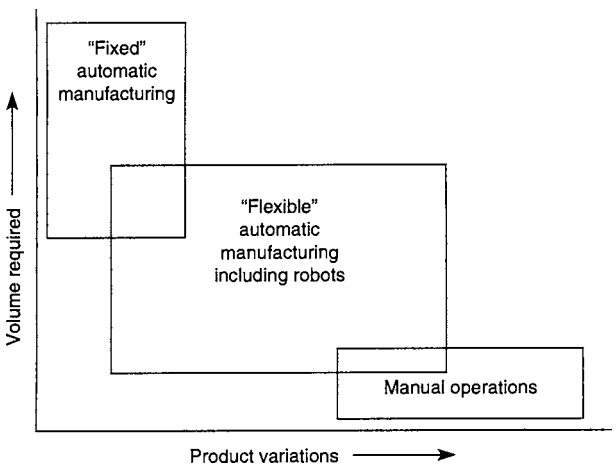

Fig. 17.7.1 The most appropriate assembly mode, as a function of output volume and variations.

Autofacturing is a production system that is comprised primarily of automated equipment which is configured as several integrated subsystems, using one common database and computer controls to make, test, and transport specifically designed products at high and uniform quality levels meeting flexible specifications with a minimum of human effort. There are many levels of autofacturing from individual cells, or *islands,* all the way up to a complete and integrated system. Most situations are somewhere in between, but progressing toward a total system.

Autofacturing is a subset of the overall field of automation. It refers to automated manufacturing activities as distinguished from the many other things called automation, such as data processing, office automation, electronic funds transfers, automated banking, central station telephone operations, airline ticket reservations, and the like.

An autofacturing system is composed of several integrated subsystems. Also, along with other systems such as marketing and distribution systems, general accounting and cost accounting systems, management information systems (MISs), and others, it is a subsystem of the corporation's overall operating system. All subsystems should be interconnected, complementary, in balance, and integrated into one total system. Some of the prerequisites and subsystems of an autofacturing system are listed and described below.

DESIGN FOR ASSEMBLY

After management decisions have been made regarding policy, practices, and long-range objectives, decisions must be made about the best combination of a multitude of characteristics of the product. These include the goals to be achieved by it: its salability, functionality, safety, targeted life, repairability, recyclability, ease of use, size, shape, color, and many other considerations, some reinforcing others and some in conflict with others. Designing the product for ease and economy of fabrication, assembly, test, handling, shipping, and installation are some important considerations. Then, the basis of all of the above determinations, decisions can be made regarding the best levels and mix of autofacturing. That includes deciding which portions of the product should be made by people, hard automation, or programmable devices, since the size, shape, and features of its several parts may be different and better suited for one mode over the others.

Human assemblers, for example, have the advantage of three-dimensional vision, color sensitivity, two hands, eye-hand coordination, the facility to jiggle parts together, the ability to back off when things do not go together as they should and look for the reason rather than force them, the ability to pick out patterns which are varied or complex, etc. However, they cannot work in dangerous environments, apply large or exact forces, perform with precision consistently cycle after cycle, or handle very large, very small, or very fragile items, etc.

Hard automation requires the input of a steady, voluminous stream of very uniform parts, all positioned and oriented precisely so that the high-speed machines can operate without jamming or stopping. Machines and instrumentation are better than humans in monitoring and responding rapidly and consistently to many stimuli simultaneously—some beyond the range of human capabilities. They also can be made to

do several things at once for long periods of time with little variance or deterioration of performance.

Soft, or programmable, automation permits variations in inputs, as it can sense and adjust for deviations and continue to operate. It is usually faster than manual work but slower than dedicated machines, and its output can permit variations from the standard product so as to achieve marketing and inventory advantages that often more than offset its added cost per unit of output.

In autofacturing, each assembly operation is analyzed to determine whether it is best done manually, with fixed, or with flexible automation. An autofacturing system, then, results in a mixed mode of operation, each with that portion of the product designed to be assembled in the most efficient way available. In it, the actions of conventional machines, automated equipment, human operators, and robots are all interrelated and in balance.

There are over 100 guidelines on how to configure a product and its component piece parts so that they can be assembled as easily and economically as possible. The most important of these rules are as follows:

1. *Minimize and simplify.* Reduce the number of piece parts as much as possible. Determine the essential functions of each part. Transfer functions to other parts. Combine parts. Eliminate as many parts as economically feasible. Simplify before automating.

2. *Modularize.* Design the product such that parts are grouped into modules or sections of the end product. Create modules, like building blocks, so that they can be selected and joined in various ways to make different products. This will aid in assembly, test, repair, and replacement of more manageable subassemblies. It will also make it possible to follow rule 3 below.

3. *Create families of products.* Products should be designed so as to have as much commonality with other products as possible in their modules and piece parts. Products related in a series of escalating capabilities or features can all be built with the same platform (base, power supply, etc.), case, panels, circuit boards, and other common and interchangeable parts. Product distinctions, such as extra features, should be the last components assembled so that the work in process is common for as long as possible. Parts that make a product distinctive should be grouped into the same module. Even seemingly different products can be designed to have the same power supply, switches, gears, and other internal components and modules.

4. *Design parts to have as many different uses as possible,* depending on how they are installed and which portion of them is used. Determine whether the extra cost of the added complexity is more than offset by the benefits.

5. *Use the best overall method to make each part.* That is, consider not only its fabrication costs, but the relative costs of handling, subsequent operations, assembly, inspection, scrap, etc.

6. *Design in layers.* Where possible, design the product so that it is made up of layers of components, such that making it requires the adding of one layer on top of another, built up from the base to the cover or outer case. See Fig. 17.7.2.

7. *Assemble in short, straight vertical strokes.* If rule 6, above, is observed, then this should be possible. Avoid the need for lateral, curved, or complex motion paths in assembling components. Minimize the number of directions of assembly. Minimize the amount of lifting, rotating, and other handling of the components, subassemblies, or product. See Fig. 17.7.2.

8. *Present parts appropriately.* Bring parts to the machines, robots, and human operators in the position and orientation best suited to use without the need for rehandling or repositioning. Hold them in trays, on reels, in connected strips, etc. rather than disoriented in a tote box or bin. Parts stamped from strips or molded should be left on their webs as long as possible, for they are orderly. Parts to be fed to assembly stations by vibratory bowl feeders should be designed so as to feed through easily and not jam, snag, tangle, nest, shingle, bridge, or interlock.

9. *Design for symmetry and orientation.* To the degree possible, design parts to be symmetrical so that no matter what position they are in, it is proper for assembly. If perfect symmetry is not possible, strive to have the parts go together in as many ways as possible. Where that is not possible, accentuate the asymmetry and give the parts an orientation feature, so that a person or robot can easily sense it and orient the part correctly. See Fig. 17.7.2.

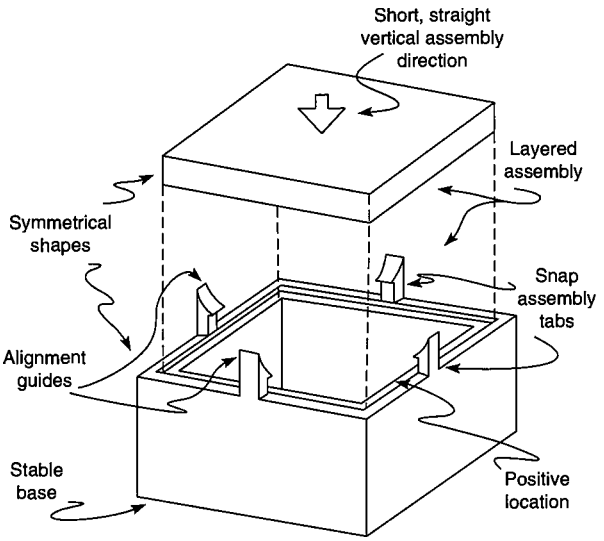

Fig. 17.7.2 Selected design for assembly guidelines.

10. *Make errors impossible.* Design the product and its parts so that the components physically cannot be assembled wrong. If a part has internal or hard-to-sense features, add a feature that can be sensed, even if it has no operational function. Do not have the dimensions of a part be too similar if the part's proper orientation and assembly depend on discerning a small difference.

11. *Give each part a positive location.* Through the use of shoulders, recesses, guides, tabs, and the like, create an exact place where each component is to go. See Fig. 17.7.2.

12. *Minimize fasteners.* Eliminate or reduce to the lowest essential number the product's discrete fasteners. Nuts, bolts, screws, and the like are difficult and expensive to handle and assemble. They should be used only where future disassembly, adjustments, or other needs make them necessary. Very short screws, bolts, and rivets are more difficult to position than are their longer counterparts, as the weight of their heads often makes them fall out of the holes. It is more difficult to place the blade of a driver in screws and bolts with round heads and slotted tops than in those whose tops are flat with closed patterns for the driver's matching blade tips.

13. *Snap in.* Where possible have the parts snap together instead of being held with discrete fasteners. Plastic tabs can be added to a part while it is being molded at negligible extra cost. The operations of placing the part in position for assembly and of assembling it become a single action when it is snapped into place. See Fig. 17.7.2.

14. *Reduce variations.* Where fasteners must be used, have as few variations as possible. Seven or eight different screw sizes can often be reduced to two or three. The added cost of overdesign where a slightly larger size than needed is used is more than made up in purchasing, handling, inventory, record keeping, and tooling savings.

15. *Chamfer.* Assembly can be speeded up and less expensive tooling can be used if holes are chamfered and pins are slightly pointed and rounded. See Fig. 17.7.3.

16. *Avoid problem parts.* Flimsy, amorphous, and long flexible parts such as wire, fabric, insulation, and the like are difficult to handle and should be avoided or provided for in the process. Some coil springs tangle because of their helix and wire diameter or if they are open at their ends.

17. *Help the robot.* Give different parts a common feature so that the same gripper can be used to handle them all. Changing grippers takes

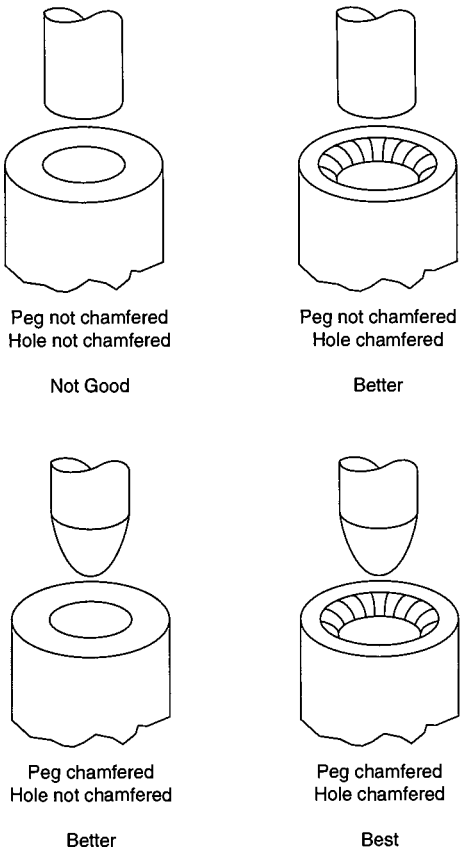

Fig. 17.7.3 The use of chamfers to accommodate slight misalignments.

time. Extra or complex grippers add to expense. Allow space around components so that the gripper can get in to assemble the part. Design the grippers to fit the contours of the parts or to wrap around them rather than merely hold them with pressure and friction. This will minimize slippage and movement.

AUTOFACTURING SUBSYSTEMS

Material Holding, Feeding, and Metering In the progression from raw materials and purchased parts to the finished product, the first autofacturing system subsystems are those whose functions are to hold, feed, and meter the correct amount of input to the operating stations at the correct time. In designating the holding system, the material must be described in detail. Then the required holding status must be defined. Is it to be held in bulk form or as discrete items? Is each item unique or the same as all the others? Must each item be segregated from the others or may they all be commingled at this stage? Then, the best-suited holding devices must be specified, e.g., bins, hoppers, reservoirs, reels, spools, bobbins, trays, racks. Subsequent to holding, the material or parts are to be fed into the next stage of the process. Again, a series of determinations must be made. Are parts to be fed individually or en masse, in metered amounts or at any rate, separated or connected, oriented or unaligned, selectively or randomly, pretested or untested, interruptible or nonstop? Then the most suitable feeding and metering devices must be specified, e.g., dispensers, pumps, applicators, vibratory feeders, escapements. See also Sec. 10.1.

Operations The operating stations of the system include those machines, tools, and devices that convert the raw materials to parts or finished products, or bring parts together and assemble them into finished products. It is at these stations that the casting, molding, bending, machining, soldering, welding, riveting, bolting, snapping together, painting, and the like are done. The operators of the machines may be humans or robots or the machines may be designed to operate automatically or under the direction of a computer.

Transferring When more than one operation is required, means of transferring the work in process from one machine or station to the next must be provided. In many companies, the time that material is on a machine and being processed is much less than the time it is being unfixtured from the machine, moved to the next machine and fixtured in it, with several delays, storages, and handlings in between. Work can also be transferred while on a machine, but to other tooling or test stations of it. Some such machines are the in-line (or straight line) pallet (or platen) and plain (or nonpallet) transfer machines and the dial (or turret) rotary table machines. These may move continuously or intermittently (indexing). They may be of the trunnion, center column, or shuttle-table type and may be purchased as standard or special custom designs. Robots and other mechanisms are often used to transfer work from station to station within a machine and between machines. See Secs. 10.5 and 10.6. It is important that the inputs and outputs of the individual stations and machines be in balance, in order to avoid idle equipment and work-in-process buildups.

Sensing There will be many points within an autofacturing system at which the sensing of conditions will be required. Sensing is a function which usually must be done prior to measurement, inspection/test, counting, sorting, computing, actuating/moving, feedback/control, and correction. Sensors can be used to measure position, presence or proximity, characteristics, or conditions of the parts, product, machines, tooling/fixture, equipment, people, and environment. Contact-type sensors include mechanical, electromechanical, electrical, chemical, and air jet. Noncontact-type sensors include permanent magnet, electromagnet, capacitance, inductance, reluctance (magnet and variable), sonic/ultrasonic, photoelectric/optoelectronic, laser, radio frequency, eddy current, thermal and relative expansion, Hall effect, air (pressure and fluidic), and inertial/accelerometer.

In deciding whether to use a sensor, where, and what type, the questions to ask are

1. What *should* happen?
2. What *could* happen?
3. What measurable phenomena, conditions, data, features, properties, changes, etc. will be present to distinguish item 2 from item 1?
4. When is the earliest that item 3 can be detected?
5. Where? How?
6. What is the best sensor or combination of sensors to do this?
7. What should be done with the information sensed?

Measurement, Inspection, and Test In autofacturing, it is essential that the product be inspected while on the machines and while it is being made. The objective is to make only good products. To do this, critical parameters are sensed and measured in real time. If they begin to drift beyond preset statistical limits, error signals are fed back and adjustments in the machine are made automatically to bring the variables back in control before any bad products are made. It is important, therefore, that the product be designed so that there is access to inspection and test points during processing. It also means that the machines should include sensors and inspection stations amid the processing stations.

Equipment Monitoring and Performance Maintenance In addition to the product, all of the machines and equipment must be monitored constantly to assure continued peak performance and to avoid breakdowns. Again, a multitude of sensors, clocks, and counters is a must for the measurement, feedback, correction, and control of the status of the system. For tooling, where wear is certain, automatic tool changers that pull the used tool out and replace it with a new one can be used. An operator or maintenance person then removes the used tool from the device and loads it with another new one so the tool changer is ready again. In some cases, duplicate modular workstations are kept on hand so that a malfunctioning one can be replaced rapidly.

Sorting, Counting, and Marking After the product is made, its characteristics can be sensed and measured and it can be sorted according to

whatever decision rules are set. Deflection devices—such as conveyor belt gates, air jets, and the like—can be used to divert each class of product to its own receptacle. They can then be counted (with the data going to the computer) and marked or labeled, as desired.

Wrapping and Packaging The wrapping and packaging of the product is just as much an integrated part of the overall system as is assembly, and should be just as automated. Even the packing cartons should be designed to facilitate automated operations. Instead of conventional flaps that tend to close and block the robot's path in trying to put products in, boxes should have straight sides and a lid so that both the products and the lid can be handled in straight, vertical motions.

Automated Material Handling and Automated Warehousing An aim of autofacturing is to have the raw material and purchased parts flow from the receiving department to the shipping department as smoothly and with as few stops, temporary storages, and handlings as possible as they are gradually converted to finished products. To do this, automated material handling and warehousing equipment must be installed whose capacities are in balance with the outputs of the production machines. The equipment available ranges from forklift trucks and automatic guided vehicles (AGV) to robots and automatic storage and retrieval systems (AS/RS). See Sec. 10.7 and the other sections cited above for descriptions of such equipment.

Order Picking, Packing, and Shipping The automation of the factory does not end with the production and storage of the products. As orders are received, the correct number of the correct items must be picked, packed, and shipped from inventory. A perfect autofacturing system would be one wherein the production and demand for items is so balanced that products are shipped directly from the final production and inspection station. In all cases, the receipt of orders should be entered into the same computer system that schedules production so that the match between what is being sold and what is being made is as close as possible.

Operator/Machine Interfaces Even the most automatic machines occasionally require the attention of a human attendant or maintenance person. The fields of study that examine the human/machine interfaces and the degrees of effort and responses of people at work are called *human engineering, human factors engineering, biomechanics, ergonomics,* and *cybernetics.* While each concentrates on a particular aspect of the subject, they are all concerned with matching the needs and capabilities of humans to the designs of the machines (and total environment) with which they interface. Humans control machines via buttons, knobs, handles, switches, keyboards, voice recognition devices, and the like, and these must all be designed, colored, located, etc. to minimize human effort and errors and to maximize effectiveness. Machines output information to humans via lights, sounds, dials, gages, video screens, and the like. These, too, must be designed to maximize response and minimize errors. At all times, the human/machine interface must be designed with safety in mind. See Sec. 17.6.

Communication, Computation, and Control The system's robots and other equipment have a multitude of microprocessors embedded in them. That, and the fact that they also have many sophisticated sensors and heuristic programs justifies calling them "smart" machines. They, in turn, are controlled by more powerful microcomputers that report to minicomputers, thence to a powerful central host computer. The host computer does not control each detail of the system; it merely integrates and balances a distributed and hierarchical communication, computation, and control capability that uses the same database and is linked by a local-area network (LAN).

Auxiliary Systems There are several ancillary systems that can be employed to enhance automated manufacturing and the autofacturing system. Some of these are group technology (GT), concurrent engineering or simultaneous engineering, and computer-aided design and computer-aided manufacturing (CAD/CAM) in the product design and prototyping stages; just-in-time (JIT) delivery, material requirements planning (MRP), and manufacturing resources planning (MRP II) in the production planning and inventory control stages; computer-aided testing (CAT) and total quality control (TQC) in the production, inspection, and testing stages; computer-integrated manufacturing (CIM) in the communication, computation, and control stages; and management information systems (MISs) in the reporting and analysis stages.

MICRON AND NANO AUTOFACTURING

As some products get smaller for operational, energy, space, and economic reasons, they can reach the point of size reduction to where human workers cannot see them, let alone manipulate them for fabrication, assembly, and test. In such cases, microelectromechanical systems (MEMS) and nanotechnology methods and processes, rather than human methods, must be used, and an autofacturing mode is essential. These very small, very thin, very elemental parts, components, sensors, activators, devices, and products are becoming prevalent in computers, electronic circuits, communications, medicine, warfare, automotive, appliances, robots, toys, games, and other products. Micron technology deals with things in the size of a millionth of a metre (0.00004 inches). Nanotechnology deals with things in the size of a billionth of a metre (0.00000004 inches).

MEMS processes are similar to those used to fabricate integrated circuit "chips" or microprocessors, such as photolithography, thin film deposition, and etching. But where only one side of a wafer is typically processed to create integrated circuits, MEMS fabrication typically processes both sides of a wafer and sometimes a stack of them to create 3-D items. The MEMS processes are still in development, but they may be divided into four technologies: (1) bulk, a subtractive process in which material is selectively removed until the desired configuration is achieved; (2) surface, an additive process in which layers of various materials are added to a substrate; (3) hybrid, a combination process in which bulk techniques are used on surface processed substrates; and (4) high-aspect ratio, which uses deep ultraviolet lithography and x-ray techniques to create micron-sized items out of polymers, metals, and ceramic materials. Some MEMS products in existence combine sensing capabilities with information processing to detect, interpret, activate, and control systems. They are being used in automobile air bags, robots, aircraft guidance systems, missiles, and elsewhere.

In nanotechnology, the goal is to produce items much much smaller than those micron sized, striving for the range of 10 to 100 nanometres. The dot at the end of this sentence can hold approximately 350 million nanometre-sized objects. The measurement of objects in the nanometre range is not new; what is new is nanomanipulation—the creating of objects in that range. To create new, better, and useful materials and devices of this size requires mastering the science and art of observing, moving, manipulating, rearranging, and positioning individual atoms and molecules of matter. To obtain the item sought, it is built atom by atom, molecule by molecule, and causing them to arrange themselves in the structure desired. To accomplish this not only is a full autofacturing mode essential, but special apparatus such as scanning probe microscopes (SPM), scanning tunnel microscopes (STM), atomic-force microscopes (AFM), in addition to photolithography and soft lithography having smaller feature sizes, and others.

There are two approaches being pursued: nanofabrication, also called nanoengineering, which is the building of the item with man-made tools; and self-assembly, which is causing the atoms and molecules to move together and adhere in the desired way and shape, based upon their size, shape composition, and physical properties—much like nature causes soil, water, air and the energy of the sun to combine to form trees and vegetation. Some areas where nano items may find application are in pharmaceuticals, chemicals, energy, agriculture, food, bar codes, communication, electronics, avionics, transportation, motors, military, materials, and a wide range of everyday products. One problem with creating such small objects is that atoms do not always act according the laws of classical physics; at the nano level quantum mechanics phenomena may occur.

18.1 ENVIRONMENTAL CONTROL

by Pascal M. Rapier and Andrew C. Klein

REFERENCES: "McGraw-Hill Encyclopedia of Environmental Science." Beckmann, "Health Hazards of Not Going Nuclear," Golem Press, Boulder, CO. Edinger et al., "Heat Exchange and Transport in the Environment," P.B. 240757 NTIS, USDA, Nov. 1974. Corbitt, "Standard Handbook of Environmental Engineering," McGraw-Hill. Current updated revisions of pertinent local and federal regulations.

PRINCIPLE OF ENVIRONMENTAL CONTROL

Nature has provided two almost inexhaustible sumps for maintaining a steady state environment on earth. The first of these is the 2.7 K background temperature of absolute space, which nature uses for heat rejection to close its heat balances. The second is the oceans, which serve to close the material balances of its cyclic processes by accepting the combined runoffs of the continents. The greatest engineering progress comes when people control their environmental activities so as to take maximum advantage at minimum cost of these sumps and of nature's cyclic processes. This is the **basic principle** upon which the science of **environmental control** is founded. With it, any environmental problem can be modeled on a conveniently small scale and then solved precisely by LeChatelier's controlled equilibria principle for any large-scale operation. When the principle is applied to obtain optimum yield of a desired end product or result, it will help predict the necessary input compositions, pressure, temperature, and concentration. This same principle is applied in other diverse fields of study such as genetics.

NATIONAL POLICY

The National Environmental Policy Act of 1969, Public Law 91-190 (NEPA), concerns air, water, and land quality and conservation of natural resources. Section 2 of NEPA declares a national policy which will encourage productive and enjoyable harmony between people and their environment and which will enrich their understanding of ecological systems and natural resources.

Section 101(b) (2) provides for the "widest range of beneficial uses of the environment without degradation, risk to health or safety, or other undesirable consequences."

Section 101(b) (5) provides for achieving "a balance between population and resource use which will permit high standards of living" (e.g., cost/benefit balancing).

Section 101(b) (6) provides for enhancing the quality of renewable resources and the maximum attainable recycling of depletable resources (e.g., developing breeder reactors to extend nuclear fuel reserves).

Section 102(c) requires that all agencies of the federal government shall file environmental impact statements. These detail in a published document for each case: (*a*) its adverse environmental effects, (*b*) its alternatives, (*c*) its enhancement of long-term environmental productivity, and (*c*) its irreversible and irretrievable commitments of natural resources.

Legislation most responsive to the NEPA objectives so far is the Magnetic Fusion Energy Act of 1980. Aiming for a working magnetic fusion system by the year 2000, this act set as a goal a controlled nuclear fusion economy by the middle to late twenty-first century. (See Considine, "Energy Technology Handbook," McGraw-Hill.)

AN OVERVIEW OF ECOLOGY

(See also Sec. 9.1.)

Ecology is the study of the **biosphere,** a hypothetical system comprising the surface of the earth and all the subsystems necessary to maintain a steady-state life-support system. The **thermal cycle** is open, isenthalpic, and irreversible. Solar energy is utilized, becomes degraded, and is finally rejected into outer space by means of long-wave radiation through the optical window of the earth's atmosphere. Major quasi-cyclic processes in the biosphere, necessary for life support, are the **hydrological cycle,** the **carbon cycle,** the **nitrogen cycle,** the **potassium cycle,** the **phosphorous cycle,** and the **sulfur cycle.** These are almost closed cycles, which are occasionally interrupted and renewed by techtonic geological upheavals.

In these cycles, vegetation and animal wastes decay, thereby furnishing nutrients to land, air, and water. New green plants grow, animals eat them, and the recycling continues. Ecologically, the bacteria which decompose all these wastes are called *destroyers,* the green plants which employ photosynthesis are called *producers,* and animals which eat the plants are called *consumers.* A hypothetically bounded small portion of the biosphere is called an **ecosystem**. All ecosystems are **open,** as their essential cycles extend into the biosphere.

An ecologically idealized community would be one in which the ecosystem, including the surrounding agricultural area, would operate steady-state, almost closed cycle. Tucson, Arizona, approaches this state, its crops being irrigated by tertiary sewage treatment so that water and all the plant nutrients, are recycled. Minerals entering the ecosystem through the Santa Cruz River and imported fuels are almost counterbalanced by exports of crops from the area and by irrigation runoff into the normally dry Gila River bed. These activities conform to nature's naturally occurring cycles, and maintain the fertility of the soil.

In larger, heavily overpopulated communities, however, people's activities are counter to nature's, and so humanity suffers. The earth is denuded of local vegetation, and crops are imported. All the nitrogen, potassium, sulfur, and phosphorus contained in the agricultural commodities and fuels, instead of being recycled to the farmlands, are burned or handled by the waste disposal systems of the communities and dumped into rivers and harbors, thereby reaching the oceans and being lost to the continents, despite the recycling and soil fixation methods intended by nature to prevent such losses. Severe pollution problems result, mainly from nonpoint sources and storm run-offs which are not amenable to control, no matter how much money is spent. But the major damage done is depletion of wetlands, forests, and farmlands and buildup of atmospheric CO_2 from fossil-fuel use. It is irreversible and irretrievable and will continue until our society finally faces the fact that the changes required to help stem these events must be made on a local as well as planetwide level.

Environmental control seeks to subdue and to utilize nature's ecological cycles in order to serve people's needs, thereby conserving natural energy and mineral resources, and to replenish desirable local flora and fauna populations by agriculture and cultivation to provide adequate food, clothing, and shelter. Environmental control seeks to extend depletable fuel supplies with clean, abundant forms of gravitational, solar, and nuclear energy (fission and fusion). Also, replenishable substitutes for other depletable resources are sought, as well as recovery and recycling means for scarce and irretrievable substances. Environmental control seeks to conserve land and water quality by diversion into adequately controlled drainage canals of concentrated runoffs, e.g., from irrigation, municipalities, industries and mining, so that these nonrecyclable, unsalvageable mixtures are ultimately discharged into the oceans, where they blend inconsequentially with the vastly larger amounts of runoff from the continents, occurring naturally as part of the hydrological cycle. The public standard of living is highest when all these things are done voluntarily by a responsible, cost-conscious citizenry.

The following subsections describe typical, cost-effective, and productive practices among the free nations. These should be considered to the extent permitted by local regulations.

COST/BENEFIT BALANCING AND ISO 9000 REGISTRATION

REFERENCES: Summary of UWAG-EEI Comments on EPA's Proposed Regulations under 304, 306, and 316(a) of Public Law 92-500, the Federal Water Pollution Control Act Amendments of 1972, June 1974. Effluent Limitations Guidelines for Steam Electric Power Generating Point Source Category 40 CFR, Chapter I, Subchapter N, Part 423. Craig, "The No Nonsense Guide to Achieving ISO 9000 Registration," ASME.

Cost/Benefit Calculations

In order to assess the feasibility [under Section 304b (1B) of the FWPCA Amendments of 1972] of any environmental control technology or augment, both the public cost and benefit of its operation must be considered. For demonstrating feasibility, this dimensionless cost/benefit ratio has the limits

$$0 \le C/B \le 1$$

The upper limit of unity means that \$1 spent in the incremental public operational costs of the augment will yield \$1 of return in public benefits. If an augment is required for which the cost/benefit ratio is greater than unity, it is unfeasible. (It is more feasible to accept the pollution.) If an augment is required for which the cost/benefit ratio is negative, the public benefit is negative and constitutes a public detriment. The more that is spent on such an augment, the worse the environmental degradation becomes.

NOTE: Financial items cited in the examples below are for illustrative purposes only, and will vary with location and time.

EXAMPLE. Once-through vs. recirculating cooling systems: A 1,000-MW(e) steam/electric generating plant is operating with once-through cooling on a river. The heat rate is 10,300 Btu/kWh (0.33 thermal efficiency), with about one-half of the heat, or 5,150 Btu/kWh, being discharged into the river. The public benefit of this thermal enrichment is a stable and abundant fish population, which is estimated to offset all public detriments except occasional fish kills caused by emergency shut-downs. These average each year not more than 8-h duration and \$45,000 public detriment.

Proper environmental management to provide emergency heating of the water during unexpected outages will avoid the fish kills with an estimated 90 percent confidence factor. A cooling tower retrofit will reduce the thermal discharge by 90 percent but will substitute some undesirable atmospheric, noise, and stream pollution conditions. Neglect these problems, but otherwise compare the feasibility of an open-recirculation cooling tower retrofit with that of proper environmental management.

First alternative: Environmental management of existing plant. The annual public detriment for the fish kills is \$0.045/kW(e) of installed capacity. For avoiding these by emergency heating of the river water, let the estimated operating cost to the consumer be \$1 per million Btu. The annual environmental management cost for an 8-h outage per year becomes:

$$8 \text{ h} \times \$.00515/\text{kWh} = \$0.0412/\text{kW(e)}$$

The cost/benefit ratio becomes \$0.412/\$.045 or 0.916, so that 91.6¢ spent will yield \$1 return in public benefits. This is a wise investment. For the existing plant the possibility of a fish kill is reduced to one-tenth its original value, and the remaining annual public detriment becomes \$0.0045 per kW(e) of installed capacity.

Second alternative: Retrofit of an open recirculating cooling tower. The viability of a cooling tower retrofit must be assessed on the basis of this reduced public detriment for the existing plant. The estimated annual operating cost to the public for a cooling tower augment, based on public operational overhead, a 1970 overall plant investment, and a 3 percent incremental capacity loss, due to the retrofit, is \$20/kW(e) of installed capacity. Dividing this by the \$0.0045 expected public benefit yield a cost/benefit ratio of 4,444. This means that \$4,444 must be spent (and the cost passed on to consumer) for every dollar of public benefit. As this is clearly not in the public interest, it is unfeasible. It is cheaper to replenish the fish supply. Moreover, the 3 percent capacity loss of power generation due to the augment results in a 3 percent wastage of fuel and a 3 percent increase in the total thermal discharge to the environment. Energy, in contrast to the fish population, is a nonreplenishable natural resource. It must be conserved, and it must be considered when assessing the public detriment. Valued at 3 percent of the heat rate, \$1 per million Btu and 0.9 load factor, this waste of natural resources will cost \$2.435 per kW(e) annually.

Loss of cooling water by evaporation in the cooling tower is also a public detriment that can be conservatively valued at 25¢ per 1,000 gal. At 5,150 Btu/kWh thermal discharge rate and 0.9 evaporative load factor, this depletion of a natural resource will cost:

$$0.9 \times 5{,}150 \times \$0.25 \times 24 \times 365 \div 8.33 \times 10^6 = \$1.219/\text{kW(e)}$$

Subtracting these two detriments, amounting to \$3.654, from the annual public benefit of \$0.0045 for conserving the fish population yields a negative public benefit due to the augment of −\$3.65. The overall cost/benefit of this installation therefore becomes

$$\$20/(-\$3.65) = -5.48$$

The negative sign indicates that money spent to improve the environment by this means simply makes matters worse. The expected public benefit is not possible, and therefore the technology is not economically achievable.

Achieving and Practicing ISO 9000 Registration

Both capital and operating costs of a new or reorganized operation or venture can be minimized through the mechanism of ISO 9000 registration. In this way parts, machinery, construction, management, and operating and servicing techniques are standardized locally, and ultimately internationally. The favorable economics that ensue are of immeasurable consequence in a competitive marketplace and contribute to the optimum utilization of labor, facilities, and raw materials. A large portion of the benefits which accrue are related to personnel involved in the business entity.

Direct Water Cooling

For large-scale power generation, natural surface cooling in open water bodies is most cost-effective. The intake and outfall should be so oriented as to minimize possibility of heat recirculation and short-circuiting, which can usually be done by locating the outfall sufficiently down current of the intake.

Surface discharge of the condenser water as a hot, buoyant plume requires the least area of water surface for heat dissipation, yields the largest value for the overall surface heat transfer coefficient K, and hence minimizes both the cost and environmental impact of the facility.

The surface heat-transfer coefficient K combines the heat loss contributions due to longwave radiation, evaporation, and convection into a function which can be reliably estimated by two independent equations (J. E. Edinger, 1974):

$$K = H_s(T_s - T_{dp})^{-1} \tag{18.1.1}$$

$$K = \frac{T_s - 183.16}{20} + (0.47 + B)f(W) \tag{18.1.2}$$

where K = overall surface heat-transfer coefficient, W/(m^2 · K); H_s = gross 24-h average sunshine factor, W/m^2; T_s = water surface temperature, ambient, K; T_{dp} = dew point temperature, K; W = wind speed, m/s; $f(W)$ = wind speed function, $9.2 + 0.46W^2$ (Brady, 1969), W/(m^2 · mm Hg); B = slope of vapor pressure curve at $T_m = \frac{1}{2}(T_s - T_{dp})$, mm Hg/K.

The derivative of the 1967 ASME steam table saturation line B is given accurately over the temperature range 0 to 50°C by the Rapier log-hyperbolic curve fit

$$B = \frac{5{,}301.734}{T_m^2} \exp\left(20.94673 - \frac{5{,}301.734}{T_m}\right)$$

The overall heat transfer coefficient K can be most accurately obtained from Eq. (18.1.1), since all the variables can be directly measured; then the wind speed function $f(W)$ can be determined for the particular site by substitution of K into Eq. (18.1.2). On the other hand, if T_s is not known, both T_s and K can be approximated by iteration between the two equations, after adopting a reasonable wind speed function, such as the Brady parabola, given above.

Once the value of K has been determined and the temperature rise through the condensers has been decided upon, the initial temperature difference or excess above ambient lake surface temperature at the discharge point, and the final temperature difference or excess above ambient at the plant intake, can be readily calculated, since the effective area A_e in square metres from the discharge point up to the

intake determines the log-mean temperature difference, as given by the equation

$$\text{LMTD, °C} = \frac{\text{thermal discharge rate, W}}{KA_e}$$

At locations where limited quantities of water are available, some heat recirculation occurs and, particularly during summer months, can cause temperatures in excess of 32°C at the inlet of the plant. When considering such a location, tradeoffs should be made to determine whether it is more economical to accept a higher temperature at the inlet or to install auxiliary cooling means such as towers or spray ponds.

EXAMPLE. During July, a proposed inland lake site has a gross sunshine factor of 387.3, a dew point of 13.9°C, and a wind speed of 4.07 m/s. Iteration yields 26.1°C for the water surface temperature and 31.8 W/(m^2 · K) for the heat-transfer coefficient. If thermally loading the lake will cause a temperature excess of more than 8° at the intake, tradeoffs should be considered here.

CONTROL OF THERMAL DISCHARGES

(See also Sec. 9.5.)

REFERENCES: Water Resources and Waste Heat, *Power Eng.,* pp. 26–33, June 1973.

The total solar flux reaching the earth is 182 trillion kW; 32.4 trillion kW is utilized in the hydrological cycle, whereby freshwater distilled from the oceans is utilized on the continents by the plant and animal kingdoms and finally drains back into the ocean to complete the cycle. The entire thermal demand estimated for the United States in 1980 was 5 billion kW, very small compared with the solar flux in the earth's biosphere. The temperature of the earth's biosphere is stabilized by reradiating the solar flux as long wave radiation back into absolute space through the "optical window" (7- to 13-μm wavelength) of the earth's atmosphere. For example, if once-through cooling for 25,000 MW(e) power generation were added to Lake Michigan, the average surface temperature rise would be limited to ¼°F by longwave radiation from the surface of the lake.

The Joint Committee on Atomic Energy, 93d Congress (1973), anticipated that by 1980 the total heat dissipated into the environment by the generation and use of energy in the United States will be equivalent to 43.2 million bbl of oil per day. The combined heat loss caused by electric and industrial power generation will be 11.5 million bbl per day, or 26.6 percent, which includes all the point sources. Distributed and diffuse sources, such as automotive, residential, commercial, and industrial heating and cooling systems, which constitute the balance, account for 73.4 percent of the heat dissipation, and create "heat islands" around every major metropolis. About half the heat loss from power generation is presently discharged into bodies of water via nonconsumptive once-through cooling systems and does not contribute to the "heat island." The use of consumptive evaporative cooling for this would add to the atmospheric discharges in the "heat island" and raise the ambient temperatures. By 1978, increased urbanization in the Los Angeles Basin will raise the ambient temperature an estimated 5°F. The surface temperatures of water bodies in the Basin would be raised over 5°F, which exceeds guideline limitations for thermal discharges. By the year 2000, if evaporative cooling towers are required for all the incremental power generating capacity, the New York-Philadelphia "heat island" will suffer a mean ambient temperature increase of about 15°F, and the cooling towers will consume twice the flow of the entire Colorado River Basin, 31,000 ft^3/s, or 3,000 times their 1970 consumption of water. Not included is the "greenhouse" effect of excess CO_2 in the atmosphere from the burning of fossil fuels. An estimated trillion tons of CO_2 will have accumulated, and trapped solar radiation will have raised the earth's mean temperature 3.6°F (2 K). (See Plass, Carbon Dioxide and Climate, *Sci. Amer.,* 41–47, July 1959, pp. 41–47. Also pp. 173–175, Sept. 1983.)

For the year 2000, the percentages of total heat discharged to the environment from various human activities have been estimated as shown in Table 18.1.1.

Table 18.1.1 Heat Discharged into Environment; Year 2000 (Estimate)

Thermal discharge source	Coolant	Total heat, %
Residential and commercial	Atraospheric and water	31.75
Industrial	Atmospheric and water	27.00
Transportation (all forms)	Atmospheric	22.20
Electric power generation	Atmospheric and water	14.30
Electric power consumption	Atmosphere	4.75
Total heat into environment		100.00

The data and projections cited above are dated, and certainly the current situation is different from all projections, but only in degree. The data in Table 18.1.1 are useful in that they address a global problem. Increased use of nuclear fuel to power central-station electric generating plants reduces the heat discharged into the atmosphere from exhaust stacks, but there is almost the same amount of rejected heat dissipated to condenser cooling water or to the atmosphere in cooling towers. Likewise, there is much controversy among the polity in the matter of the greenhouse effect, ozone holes, mandated use of electric-driven vehicles, and so on. The solutions offered to ameliorate those problems are not universally acceptable, but recognition of the existence of problems in this regard is not usually contested. In certain quarters the solution prated is for so-called renewable sources of energy which are "benign" (i.e., solar energy), but the technology is not refined yet to make the extraction of solar energy competitive. Much intellectual effort and well-intentioned persuasion must be brought to bear on this and associated type problems as the population grows and the consumption of fossil fuels continues apace.

The largest thermal discharge, 31.75 percent, is primarily attributable to residential and commercial heating and ventilating systems, with air conditioning units making the most undesirable contributions to the environmental "heat island" effect. Cogenerative district heating, better thermal insulation, and reduction of electrical loads (such as by replacing electrical heating units with steam or gas-fired units and atmospheric air conditioners with once-through, water-cooled units) could substantially reduce the undesirable side effects.

The second largest thermal discharge is from industry. Because of keen marketplace competition, thermal processes have been selected to provide the most favorable cost/benefit ratio for the consumer. Regulatory control here, except to prevent malpractices, can do more public harm than good. Industrial/nuclear power complexes, where practicable, will produce the maximum public benefit.

Transportation is the third largest contributor to the "heat island" effect and the one with the worst side effects. Thermal discharge to city streets could be reduced to one-third its present value and petroleum stocks conserved if all-electric transportation could be substituted economically for the internal combustion engine. This would be particularly advantageous in the summertime.

The smallest contributor to the "heat island" effect is electric power generation, which accounts for 7.15 percent of the total atmospheric discharge, with another 7.15 percent thermal discharge to water. Irrigation canals, navigation canals, and artificial waterway complexes designed to include treated municipal effluents could, if implemented in the future, provide sufficient water for a significant number of thermal power generating units, save energy, and reduce the atmospheric discharge near cities by as much as 7.15 percent.

In short, the environmental impact of heat discharged by human activities can be minimized and fuel conserved by cascading processes to get the highest practicable thermodynamic efficiencies and the lowest practicable heat-sink temperatures. Greater efforts must be brought to bear in the matter of curtailment of CO_2 emissions from all sources, inasmuch as they are recognized to have a deleterious effect in polluting the global environment as well as bringing about higher ambient temperatures. Reforestation and/or the maintenance of green spaces and the increased utilization of nonfossil fuels are looked upon with favor in these regards.

Use of Cooling Towers

(See Sec. 9.5.)

REFERENCES: Nomographs for Thermal Pollution Control Systems, EPA 660/2-73-004, Sept. 1973.

In locales where water supplies are inadequate to provide nonconsumptive once-through cooling, evaporative open-recirculating cooling towers become necessary. These consume water at about 2 percent of the recirculation rate, but reduce circulation into rivers or streams by over 95 percent even when employing low concentrating cycles. Nomographs are available from EPA which provide cost comparisons of the cooling systems sampled by Table 18.1.2. Selection of the most feasible cooling system depends on specific site conditions. Economics dictate once-through cooling where possible, wet cooling towers or ponds where water supplies are limited, and dry cooling towers where water is unavailable. All of these will contribute significantly to the "heat island" effect unless specifically designed to provide buoyant plumes that will puncture inversion layers.

Table 18.1.2 Cooling System Augments

Cooling systems	Relative capital cost	Power consumption
Natural draft wet towers	3.2	Low
Mechanical draft wet towers	1	High
Spray ponds	2.3	High
Cooling ponds	1.4	Low
Natural/mechanical draft dry towers	7.3/6.7	Medium/high

Wet cooling towers substitute water pollution for thermal pollution by concentrating blowdown, require chemical treatment, and release heavy-metal corrosion products into the blowdown stream. Their operation requires an optimized water chemistry which balances the acid treatment and cycles of concentration to provide nonaggressive water with a slightly positive Langlier index, and to retard the buildup of scale. The Langlier (saturation) index is the difference between the actual measured pH and the calculated pH_s at saturation with $CaCO_3$. A zero Langlier index balances pH, alkalinity, and calcium hardness, and establishes the threshold for alkaline scale formation. (For further information on this and other water treatments, see Betz, "Handbook of Industrial Water Conditioning," Betz Laboratories.) For environmental reasons, pretreatments based upon zinc, chromate, and phosphate inhibitors should generally be avoided, while posttreatments to remove pollutants and corrosion products from the blowdown may have to be employed. With all constraints considered, the most economical design results from a series of tradeoffs. Dry cooling towers are justified only where water shortages preclude the use of evaporative coolers, as their cost, inefficiency, and environmental impact from abnormal heating of the air are otherwise excessive.

Cooling towers may be required by environmental regulations, and "zero discharge" of blowdown may also be required, with high concentrating cycles and "perpetual storage" of the resultant salty wastes. The salty plume will cause additional difficulties. Blowdown volume can be reduced by concentrating to 10 percent solids using vapor compression. The power requirement for this is 90 kWh/kgal evaporated. Further concentration requires open kettles. (For further information, see Kolflat, Cooling Tower Practices, *Power Eng.,* pp. 32–39, Jan. 1974, and Boles and Levin, Treating Cooling Tower Blowdown, *Power,* pp. 68–76, Aug. 1974.)

WASTEWATER CONTROL

REFERENCES: The Clean Water Act of 1972, as amended through 1981, PL 97-117. Sittig, "Resource Recovery and Recycling Handbook of Industrial Wastes," Noyes Data Corp., Park Ridge, NJ. Lund, "Industrial Pollution Control Handbook," McGraw-Hill. "Pollution Control Technology," Research and Education Association, New York. Current updated revisions of pertinent local and federal regulations.

Industrial Categorization by the 1972 FWPCA Amendments (Clean Water Act)

The Federal Water Pollution Control Act (FWPCA) Amendments of 1972, Public Law 92-500, preempt all existing federal regulations by authorizing guidelines for "effluent discharges," rather than by controlling "receiving water quality."

Title III, Section 306(b)(1)(A) categorizes sources. "Source" means any building, structure, facility, or installation from which there is or may be the discharge of pollutants for which effluent limitations guidelines and revisions will be developed. These are published periodically in the Federal Register, under the 40 CFR part numbers shown by Table 18.1.3. The limitations were to be achieved by July 1, 1977, for "best practicable control technology currently available" (BPCTCA) and by July 1, 1983, for "best available technology economically achievable" (BATEA).

Both BPCTCA and BATEA guidelines must meet feasibility and achievability criteria under cost/benefit testing and will be modified periodically to reflect current needs and technology.

Pretreatment guidelines have been established by EPA under Section 307(b) to control industries with effluent discharges into municipal systems. Industrial wastes not so regulated become part of the municipal wastewater flow and thus a municipal responsibility.

Permit and Application for Industrial Discharges

The Permit Program for Industrial Discharges under the provisions of the "Refuse Act of 1899" was previously administered by the Army Corps of Engineers. The Clean Water Act of 1972 incorporated this program and transferred control from the Army Corps of Engineers to the EPA.

A Permit Program Application plus an environmental report [see NEPA-102(c) for criteria] is filed by the discharger with the state, which then refers it to the Regional EPA permit section for review. The state draws a permit that includes limitations, compliance schedules, and state monitoring requirements, making the permit forms available to the public 30 days prior to issuing the permit. Hearings on the permit may cause much delay. After this procedure is completed, the permit may be issued for a maximum of 5 years.

Environmental Considerations for Construction Projects

Introduction The environmental considerations which follow should be taken into account by industry when preparing an environmental report for construction projects, and before an effluent discharge

Table 18.1.3 Industries Categorized under 40 CFR, Chapter I, Subchapter N

Industrial groups	Part nos.	Stds. of performance
1. Food and grain processing	405–409	In general, BPCTCA 1977 guidelines limit pH* between 6 and 9, BOD,* TSS,* and COD,* to the ppm range, toxic substances, e.g., Ba, Pb, Hg, Ag, As, Cr^{+6}, F, to nontoxic concentration. BATEA 1983 guidelines limit these further on nonprocess streams, and seek "zero discharge" of process streams.
2. Textiles	410	
3. Feed lots; meat products	412; 432	
4. Chemical; petroleum metallurgy	410–424	
5. Power generation	423	
6. Leather, glass, and rubber products	425–427	
7. Wood products, paper, and pulp	428–431	
8. Oil, gas, coal, minerals and biochemicals	434–440	
9. Tars, asphalt, paint inks, and gums	443–458	
10. Pesticides, chems. and explosives	455–457	
11. Photographic, hospts.	459–460	

* BOD (biochemical oxygen demand); TSS (total suspended solids); COD (chemical oxygen demand); pH (log of the reciprocal hydrogen ion concentration).

permit can be granted. Cost/benefit factors for applicable environmental control technologies and regulations limiting effluent discharges should be obtained and included in the record of public hearings and should lead to rational decision-making based on a total short- and long-term project cost to the public consumer in relation to the worth of anticipated public benefits. (*Note:* Cost/benefit ratios for meeting effluent discharge regulations can be obtained from the comments submitted to EPA by the categories of industries listed by Table 18.1.3. Public costs generally range from 100 to 1,000 times greater than social or environmental benefits. The engineer will also find these reports a valuable source of design information for environmental projects.)

It should be recognized that the considerations identified should be individually tailored to respond to the unique guidelines for effluent discharge encountered on a particular project and in a particular state.

General Construction Projects

1. What site selection criteria will be used? Will they include cost/benefit balancing of all environmental worth factors such as the conservation of land and fuel reserves, air and water quality, noise, impacts on residents of the area, fish, wildlife, and vegetation? Will alternative sites and alternative orientations of the plant on the selected site be considered?
2. What disposition will be made of solid and liquid residues (ashes and chemical and industrial wastes)? Does the disposal method include adequate cassetting or neutralization to minimize the danger of soil or water pollution? What steps are planned to contain and reclaim ash dumps and chemical and oil spills to avoid pollution of surface and groundwater by runoff? What provision has been made for the disposal of waste-concentrated brines? If waste disposal into water bodies is planned, what will be the dollar value of its detriment to aquatic life? To what degree will tidal action and currents dilute plant effluents? What disposition will be made of potentially harmful and toxic corrosion products occurring in the plant effluent? Can they be injected into underground aquifers? What provision will be made for controlling the release of waste material into water bodies? If additional units are constructed, what will be the total load of waste materials? What downstream environmental effects can be anticipated with respect to humans, crops, forests, and wildlife? With what cost-effectiveness can any harmful effects be minimized by dilution and toxic materials be discharged below toxic concentrations to merge into the normal background of compositions?
3. What public benefits and detriments will thermal effluents have on the receiving waters? What temperature increase can be anticipated? Is there sufficient water motion in the receiving bodies to dissipate heat effectively? Has the use of cooling towers been explored? What is the probable cost of their public detriment, incurred by the cooling towers' consumptive use of water and energy, by producing fog and undesirable weather conditions through the dissipation of waste heat, and by producing blowdown which may require treatment?
4. What impact will the impoundment for a water supply have in terms of the destruction of agricultural, forest lands, and habitats for fish and wildlife? What measures are planned to mitigate the loss of natural habitats for fish and wildlife? To what degree will archaeological and scenic values be affected? How will the reservoir and downstream flow affect water quality parameters, i.e., temperature, dissolved oxygen, nutrients, nitrogen concentration, hydrogen sulfide, and color?
5. How vulnerable is the facility to surface subsidence, earthquakes, hunicanes, war, insurrection, and other catastrophes? What is the probable annual cost (e.g., liability insurance cost) of the environmental degradation which could be expected from such catastrophes? What preventive and remedial safeguards for downstream inhabitants will be incorporated in plant design and construction? What provisions are made for training plant operators in environmental protection?
6. Have the environmental consequences of transportation, pipeline, and power transmission been considered in site selection? What steps are planned to avoid soil erosion and the silting of streams as pipelines, transmission facilities, and access roads are constructed?
7. What provision has been made for recycling and for industrial by-product development associated with the facility? (See also Sec. 6.10.) What impact will that activity have on the environment?

Process Selection, Recycling, and Ultimate Disposal of Residual Wastes

(See also Sec. 6.10.)

In the design of an industrial installation, segregation of process and nonprocess streams, together with good housekeeping practices and diversion of storm waters will generally result in minimum volumes of water requiring special treatments before being discharged. Wastewater treatment processes involved are: chemical and physical treatments for removal of undesirable waste products; suspended and dissolved solids from process waste streams; removal of corrosion products and carbonaceous wastes (biological treatment) from nonprocess streams; oil-water separations; suspended-solids removal from storm runoffs; good housekeeping and protected stockpiling to prevent contamination of runoffs; and blending of treated effluents and impoundment to meet local end-of-pipe regulations (see Table 18.1.4).

Recycling of consumer and commercial wastes back to their sources (e.g., crankcase oil, glycol, fat, photographic and plating wastes, paper, rags, rubber, metals, and irrigational and fertilizer values of municipal wastes), following the good housekeeping practices of industry, is a very cost-effective method for reducing municipal stream pollution. However, within most industries recycling of salvageable material is almost always practiced to the point of optimum return, so that proposed benefits from further recycling in an effort to obtain "zero discharge" are usually minimal. Recycling, or "closed-cycle" water reuse schemes consume water and produce blow-down streams of concentrated pollutants in contrast to "open-cycle" schemes, whereby solids have traditionally been discharged at normal and below toxic levels, within the assimilative capacity of the receiving bodies of water. The latter, and not the former, conserves water and enhances the naturally occurring ecological cycles—provided, of course, that abnormal toxic substances are not discharged, but are removed by a posttreatment for ultimate disposal.

Descriptions, flow sheets, and costs for a variety of industrial water use and recovery schemes are found in "Water Reuse, Industry's Opportunity" (1973), published by the AIChE.

Table 18.1.4 Removal Process Guide for Selected Contaminants

Treatment processes	pH, acidic, alkaline	Suspended and precipitated solids	Bacteria, odor, organic, color	Nutrients (N, P)	Herbicides, pesticides, CN^-	TDS	Oils, solvents	Heavy metals Cr^{6+}
Chemical*	C	B	A	A	A	A, B	B	A, B
Clarification† and settling		G, D, I	D, E, H	H, D		D	F, H, D	D, I
Selected‡ biological			J, K	J, K	K		J	
Desalting§			O, M	L, N		L	O, M	L, N
Sludge¶ dewatering		P	P				P	P

* A, selected chemical treatment; B, coagulation; C, neutralization.
† D, selected clarification; E, aeration, oxidation; F, flotation, decantation; G, filtration; H, lagooning; I, sedimentation.
‡ J, secondary (e.g., aerobic, anaerobic); K, tertiary (e.g., carbon adsorption; extended aeration); anaerobic dentrification.
§ L, selected desalting and brine blowdown; M, membranes; N, ion exchange; O, distillation.
¶ P, dewatering (e.g., gravity, centrifugal, vacuum filtration; drying).

Water reuse by consumptive processes always results in a stream of concentrated residual wastes for which an ultimate disposal site must be found. Thus, for brine from saline-water conversion processes, there are four major avenues: (1) ocean discharge; (2) underground discharge into saline aquifers; (3) dry lake beds, liner protected; and (4) solidification and use for landfill. Reference to current regulatory and trade publications should be made to determine which of these is permitted for a given situation.

ATMOSPHERIC POLLUTION

REFERENCES: Laws: Current Legislation, *Chem. Eng.,* June 21, 1971. Victor Sussman, New Priorities in Air Pollution Control, *Jour. Air Poll. Control Assoc.,* **21,** no. 4, April 1971, p. 201. Corbitt, "Standard Handbook of Environmental Engineering," McGraw-Hill. Current updated revisions of pertinent local and federal regulations.

Abstract of Federal Air Pollution Control Legislation

Clean Air Amendments, 1965 Authorized federal control of new motor vehicle emissions. Extended federal control to cover international pollution originating in the United States.

Clean Air Act of November 21, 1967 Under Public Law 90-148 the states are held responsible for establishing local air quality standards consistent with federal criteria.

Clean Air Act Amendments of 1977 Under Public Law 95-95, the EPA can require offending sources to be shut down immediately. Unsatisfactory state enforcement programs can be taken over and run by the EPA. New plants and new additions to old ones must have the best available pollution control technology, and meet emission standards, including zero levels for hazardous substances. A 90 percent reduction from baseline in automotive emissions is required.

The deadline set forth in the act requiring cities to comply with federal standards by 1987 was not possible to meet universally, although some cities did meet the criteria for SO_2 and ozone.

Clean Air Act of 1990 This was the first new air pollution legislation since the 1977 amendments. Briefly, its major requirements are to reduce SO_2 emission by 50 percent and to set emission standards for a number of chemicals which had not been addressed in previous legislation, as amended. The gradual phaseout of use of CFCs is set forth, with complete elimination set for 1996. Airborne pollution respects no national boundaries; accordingly, there has been much cooperation among sovereign nations to solve, among others, the serious problem of acid rain resulting from some forms of pollution.

Some Existing Federal Standards The EPA publishes in the Federal Register national ambient air quality standards covering six pollutants (see Table 18.1.5).

Effect of Energy Crisis on Legislation The energy crisis of the 1970s led Congress in 1974 to consider legislation to postpone the NEPA and to modify the Clean Air Act in order to provide relief from the shortage of petroleum and natural gas. Currently, there are abundant supplies of all types of fossil fuels available in the global market, and at competitive prices. There was no actual postponement of then-extant legislation, but concerted efforts to abate CO_2 pollution resulting from a fossil-fuel-based economy continue. (See discussion above under "Control of Thermal Discharges.") Electric power generation increases worldwide. Most of it is represented by fossil fuel plants as dictated by local resources available and the state of those local economies. Few unexploited very large water power sites exist, and of those, only a handful are economically viable in the current market. Nuclear-powered plants are being emplaced in many parts of the world, although no new plants have been ordered in the United States for almost 20 years. In some quarters it appears inevitable that the conflicting requirements of pollution abatement, reduction of CO_2 in the atmosphere, and reluctance to exploit nuclear power will ultimately result in the reemergence of nuclear power. The timing is not clear, and it will be a function, among other things, of the successful and timely resolution of the problems attendant disposal of high-level radioactive wastes, depletion of fossil fuel reserves, and possible development of advanced-type nuclear reactors which may prove economically and environmentally viable sometime in the twenty-first century.

It would be prudent to conserve irreplaceable natural resources by utilizing them in the most productive energy, materials, and ecological cycles. Often, alternative methods are at cross purposes with those objectives and result in inadvertent squandering of those resources.

Table 18.1.5 Ambient Air Quality Standards

Pollutant	Primary	Secondary, if not same as primary

Total of above categories, kg	139,100	19,210	4.5	21,200	18,120	4,850

* Add 17 percent for cigarette smoking (1984 estimate).

NOTES: Each column shows estimates of the pollutants released to the atmosphere if the entire population used the noted fuel or method of incineration.

SO_x—oxides of sulfur—SO_2 and SO_3.

NO_x—oxides of nitrogen.

Aldehydes measured as formaldehyde.

Organic acids measured as acetic acid.

Total includes only above categories and does not imply total contamination in the ambient atmosphere.

SOURCES: Eliassen, Domestic and Municipal Sources of Air Pollution, *Proc. National Conference on Air Pollution,* 1958.

Domestic and Municipal Sources of Air Pollution

(See Tables 18.1.7 and 18.1.8.)

All **pollutants** are usually classified as gases, vapors, and **particulate matter** (see Table 18.1.6 and Fig. 18.1.1). Particulate matter includes: **Dusts**—a loose term applied to solid particles predominantly larger than colloidal and capable of temporary gas suspension. Dusts do not tend to flocculate except under electrostatic forces; they do not diffuse but settle under the influence of gravity. Dusts result from such operations as crushing, grinding, drilling, screening, and blasting. **Fumes**—the solid particles generated by condensation from the gaseous state, generally after volatilization from melted substances, and often accompanied by a chemical reaction such as oxidation. For example, zinc vapor will evaporate from the surface of heated liquid metal and will then condense upon contact with ambient air to form small, fluffy particles of zinc oxide. Fumes are usually less than 1 μm, although they may coalesce or flocculate to form larger particles. **Smokes**—gas-borne particles (usually less than 0.5 μm) resulting from incomplete combustion of materials such as wood, tobacco, coal, and oil. **Mists** and **plumes**—loose terms applied to dispersions of liquid particles (0.1 to 2.5 μm), the dispersion being of low concentration and the particles **large.**

Low-Emission Automotive Propulsion Systems

(See Secs. 9.6 and 11.1.)

The automobile is a major source of air pollution and a significant contributor to photochemical smog (caused by the products of photoreactions in the atmosphere—organic peroxides, peracids, hydroxy peracids, peroxyacyl nitrate, and other compounds). For every 1,000 gal of gasoline consumed by an automobile engine, there are discharged the following air pollutants, in pounds: carbon monoxide, 3,000; hydrocarbons, 200 to 400; nitrogen oxides, 50 to 150; aldehydes, 5; sulphur compounds, 5 to 10; organic acids, 2; ammonia, 2; solids, 0.3.

Conventional Gasoline Engines A major thrust aimed at the reduction of air pollution from automotive exhausts resulted in enactment of legislation to increase the fuel economy obtained by passenger cars. Commonly known as the **corporate average fuel economy (CAFE)** program, the legislation sought to increase average fuel economy from 18 mi/gal (1978) to 27.5 mi/gal (1985). Current average fuel economy for passenger cars is slightly above 28 mi/gal (1995).

In the quest to reduce pollutants entrained in automotive exhaust gases, it was also recognized that the alarmingly high levels of lead in the local atmosphere, especially in large urban areas and their surrounds, had to be eliminated. This led to a dual approach: introduction of nonleaded gasoline (with the concommitant phaseout of leaded fuel) and incorporation of catalytic converters as original equipment by passenger car manufacturers. The two matters went hand in hand, for it was known that a practical catalytic converter would be rendered ineffective if it were contaminated by lead (or phosphorus). At this time, all passenger cars (with a few exceptions, e.g., some off-road vehicles on farms) are equipped with catalytic converters. The converter functions to reduce the levels of emission of carbon monoxide (CO), hydrocarbons (HC), and oxides of nitrogen (NO_x). Chemical reactions take place when the exhaust gases pass through the converter, resulting in conversion of the offending

Table 18.1.8 Sources of Air and Typical Loss Rates

Class	Aerosols	Gases and vapors	Typical loss rates
Combustion processes	Dust, fume	NO_2, SO_2, CO, organics, acids	0.05–1.5% by weight of fuel
Stationary engines	Fume	NO_2, CO, acids, organics	4–7% by weight of fuel (hydrocarbons)
Petroleum operations	Dust, mist	SO_2, H_2S, NH_3, CO, hydrocarbons, mercaptans	0.25–1.5% by weight of material processed
Chemical processes	Dust, mist, fume, spray	Process-dependent (SO_2, CO, NH_3, acids, organics, solvents, odors, sulfides)	0.5–2% by weight of material processed
Pyro- and electro-metallurgical processes	Dust, fume	SO_2, CO, fluorides, organics	0.5–2% by weight of material processed
Mineral processing	Dust, fume	Process-dependent (SO_2, CO, fluorides, organics)	1–3% by weight of material processed
Food and feed operations	Dust, mist	Odorous materials	0.25–1% by weight of material processed

pollutants to CO_2, water vapor, and nitrogen. The catalytic converter will function properly only if free of contaminants (lead and phosphorus, cited above) and if maintained properly to prevent operation at extremely high temperatures. Continued improvements in design and construction have proved effective in reducing pollutants ascribable to automotive exhaust gases, and have done so at no appreciable loss in fuel economy.

Fuel Injection Gasoline Engines A typical fuel injection engine of about 1,700-cm^3 displacement and burning 91 octane fuel, when compared with a conventional two-carburetor engine of the same displacement and using the same gasoline, will demonstrate an improved gasoline economy and substantially lower emissions because of improved combustion.

Stratified-Charge Gasoline Engines In the stratified-charge engine, a rich mixture is ignited in a precombustion chamber by a spark plug and is then fed into the main combustion chamber, where it ignites a much leaner mixture of gas and air. By this means, relatively low peak combustion temperatures, a slow rate of combustion, and an overabundance of free air are obtained. The respective results are low emissions of NO_x, hydrocarbons, and CO, without misfiring.

Methanol, Ethanol, and Propane Engines These are basically modified gasoline engines. Pure methanol and ethanol burn almost pollution-free, even without a converter. They have heating values slightly over one-half those for gasoline, but their combustion efficiency is higher. Methanol and ethanol can be synthesized from coal gas; ethanol is also produced from vegetable matter (primarily grains). Combined fuel consisting of gasoline and ethanol (gasahol) has been introduced in some parts of the country, but has yet to become a definitive widespread fuel, primarily because of the current abundance of petroleum feedstocks. (See Considine, "Energy Technology Handbook," McGraw-Hill.)

Two-Stroke Diesel Engines (See Sec. 9.6.) With its high compression ratio (up to 21) and complete combustion, the two-stroke diesel engine is an excellent performer. Emissions are quite low and it is highly efficient. Its apparent disadvantages, such as high weight, high initial cost, noise, slow acceleration, and difficult cold-weather starting, have been worked on and overcome, so that the passenger car diesel engine is now available from several manufacturers.

Philips (Stirling Cycle) Engines (See Secs. 4.1 and 9.1.) These are external combustion engines, using helium or freon as a working fluid. Consequently, they require no pollution control devices, since combustion occurs in a highly efficient burner system. In the Stirling cycle, the engine, too, is highly efficient and has a low specific fuel consumption. With its heat exchangers, the system is somewhat bulky and requires expensive construction techniques. Nevertheless, the engine holds considerable promise because it can utilize almost any kind of fuel.

Gas Turbines Much effort has been invested to develop gas turbine driven vehicles. Numerous problems and high cost have all but ruled these highly efficient devices out of consideration.

Hydrogen Fuel Cells (See Sec. 9.1.) In 1974 a compact fuel system was developed that reacts gasoline with other liquids to produce hydrogen. In addition, a packaged industrial power plant was developed which re-forms fossil fuel into hydrogen and, using fuel cells, delivers 26 MW of net power at a 9,000 Btu/kWh heat rate. Thus, it is now within the range of practicality to power electrically driven automobiles with compact, lightweight fuel cell generating systems that operate at high overall thermal efficiency, and are pollution-free. Considerable developmental effort will have to be made, however, to design the automobile. This system, if successfully developed, could outperform the huge, heavy, and underpowered electric storage battery systems currently proposed for electric vehicles.

Classification of Solid Pollutants

The **micrometre** (10^{-6} m), abbreviated μm, is customarily used to measure fine particles. Particles over 10 μm (10^{-5} m) are classified by Gibbs as **dusts;** between 0.1 and 10 μm, **clouds;** between 0.001 and 0.1 μm, **smokes;** below 0.001 μm, molecular dimensions. The law governing the **terminal velocity of the settling of particles** under the influence of gravity varies with the size of the particle. In the turbulent region (above 2,000 μm)

$$V_t = Ks^{1/2}p^{1/2}D^{1/2} = k_1\sqrt{SD}$$

In the intermediate region (between 1,000 and 100 μm), the law is $V_n = K's^{2/3}\rho^{-1/3}\eta^{-1/3}D = k_2s^{2/3}D$. In the streamline region (2 to 50 μm), Stokes' law holds: $V_s = K''sD^2\eta^{-1} = k_3sD^2$. From 0.1 to 1.0 μm, Cunningham's correction must be applied to Stokes' law:

$$V_c = V_s(1 + 1.72\lambda/D) = V_s(1 + 0.172/D)$$

Below 0.1 μm, the movement due to molecular shock (brownian motion) exceeds that due to velocity. In these equations, V is the terminal velocity, ft/min; D, particle diameter, μm; p, gas pressure, atm; s, specific gravity; ρ, gas density, g/cm^3; η, gas viscosity, P; λ, mean free path of the gas molecules, μm. The equations for falling in standard air are given below, where values of the constants give velocities in m/s. For irregular shapes, $k_1 = 0.142$, $k_2 = 0.00259$, and $k_3 = 1.98\ (10)^{-5}$. For spheres, $k_1 = 0.243$, $k_2 = 4.11\ (10)^{-3}$, and $k_3 = 3.0\ (10)^{-5}$.

The **Tyler standard screen scale** is related to particle size as below:

Meshes per in	10	20	35	48	64	100	150	200	325
Micrometre scale	1,650	830	420	300	220	150	110	74	44

Diameters of the more common gas molecules range from about 0.0003 to 0.00045 μm; their mean free path is from 0.06 to 0.2 μm at atmospheric pressure.

The size ranges of **particles** in typical **aerosols** and **industrial dusts** are, in micrometres: raindrops, 500 to 5,000; mist, 40 to 500; fog, 1 to 40; tobacco smoke, 0.01 to 0.15; oil smoke, 0.03 to 1.0; pigments, 1 to 7; fly ash, 3 to 70; carbon black, 0.04 to 0.2; pulverized coal, 10 to 400; foundry dusts, 1 to 200; cement, 10 to 150; metallurgical fumes, 0.1 to 100; sprayed zinc dust (condensed), 2 to 15; normal impurities in quiet outdoor air, less than 1; dust particles causing silicosis, below 10; pollens, 20 to 60; plant spores, 10 to 30; and bacteria, 1 to 15.

Normal **city air** carries around 0.0006 g of suspended matter per cubic foot (1.37 mg/m^3), which is a practical limit for most industrial gas cleaning; the amount of dust in normal air in manufacturing plants frequently is as high as 0.002 gr/ft^3 (4.58 mg/m^3). The amount of dust in **blast-furnace gas** after passing the first dust catcher is of the order of 10 gr/ft^3 (22.9 g/m^3), the same as raw hot producer gas. All dust content figures are based on air volumes at 60°F and 1 atm (15.6°C and 101,000 N/m^2).

Cleaning Apparatus

The removal of suspended matter is accomplished by the following methods. Each particle case must be studied to find the most desirable method. Economic considerations require that cleaning should not be any more thorough than necessary.

Gravity Separation This method is applicable only to the larger-sized suspended particles (100 μm and over). A long horizontal chamber is built, in which the gases are slowed down to a velocity which will allow the particles to settle to the bottom of the chamber. Even gas flow should be maintained throughout the chamber. Hoppers or a drag scraper are used to collect the settled-out material. The settling rate can be calculated by Stokes' equation above, and the size of the settling chamber for a given particle size determined.

Inertia Separation An effort is made in inertia separators to magnify the settling tendency of solid or liquid particles in gases by increasing the velocity of the gas and by providing for rapid changes in direction which, by inertia, cause the particles to leave the gas stream. Baffle chambers are used for this purpose with a zigzag movement of the gas.

Of all inertia separators, the **cyclone** type constitutes the most widely used industrial dust collector. The gas is passed tangentially into a vertical cylinder with a conical bottom. The gas follows a spiral path, with most of the separation taking place in the smaller sections of the cyclone. Cyclones can be used when particles of over 5 μm diam are involved. **Multiclones** have a large number of parallel, small cyclone units. The gas pressure drop is about 4 times the entrance velocity head (1 to 4 in w.g.). The dust content of the cleaned gas is seldom less than 1 gr/ft^3 (2.29 g/m^3).

In the **Rotoclone** apparatus, the impeller is a concave disk with curved blades along which the dust slips and is discharged over the edge of the disk into a ring-shaped dust chamber. The main air stream leaves in a wide scroll on the side of this chamber. The apparatus is usually preceded by a cyclone for removal of coarse dust. By spraying water in the entering air, the precipitation efficiency of dust removal can be materially raised. Particles of minimum size 8 μm are claimed to be removed by the dry apparatus, 1 μm by the wet apparatus. The power for dust separation cannot readily be separated from that for compressing the gases. The power requirement is 3 bhp per 1,000 ft^3/min for an outlet

pressure of 10 in w.g.; in the water-sprayed machine, the required power is at least 25 percent more.

Static spray scrubbers are usually of the tower type, the gas passing upward countercurrently to the descending liquid. Sets of sprays are placed in the top zone, with various materials used in layers to channel and mix the gas and water. Hurdles, cylindrical tiles, and random-packed ceramic tiles or metal spirals are common packing materials. With a gas flow-rate of about 350 ft^3/min per ft^2 of cross-sectional area and a water rate of 25 gal/Mft^3 of gas, a cleanliness of 0.1 to 0.3 gr/ft^3 can be obtained with blast furnace, coke oven, and producer gas. The pressure drop through a tower scrubber is in the range of 4 to 10 in w.g. The scrubber process is used as the primary cleaning and cooling stages before the cleaning of gases.

Dynamic Spray Scrubbers Contact between water droplets and suspended matter in gas is improved by mechanical agitation of gas and water.

An example of dynamic spray scrubbers is the **Pease-Anthony venturi.** In this system, the gas is forced through a venturi throat in which the gas is mixed with high-pressure water sprays. A tank after the venturi is needed to cool and eliminate the moisture. Cleanliness in the range of 0.1 to 0.3 gr/ft^3 has been reported.

Filtration is comparatively little used for cleaning fuel gases; it is in extensive use in cleaning air and waste gases. Materials used for gas filtration are ordinarily thickly woven cotton or wool cloth for temperatures up to 250°F; for higher temperatures, metal cloth or woven glass cloth is advisable. The gases filtered should be well above their dew point, as condensation on the filter cloth plugs the pores. If necessary, saturated gas should be reheated. The cloth is frequently made into "bags," tubes of 6 to 12 in in diameter and up to 40 ft long, suspended from a steel framework (baghouse). The gas inlet is at the lower end through a header to which the bags are connected in parallel; the outlet is through a housing surrounding all the bags. At frequent intervals, the operation of all or part of each unit is interrupted while the bags are pulsed, shaken, or reverse-air-cleaned to dislodge the accumulated dust, which drops back into the gas-inlet header and is removed by a conveyor screw. The dust content can be reduced to 0.01 gr/ft^3 or less at reasonable cost. The apparatus also is used for the recovery of valuable solids from gases.

Electrical Precipitation This principle, although involving highly technical physioelectrical phenomena, is generally familiar to all. If suspended particles are placed in a high-voltage electric field, they receive an electric charge and move toward one or the other of the electrodes between which the electric field is established. If one electrode is a pipe or flat plate and the other electrode is a wire axially suspended in the center of the pipe or between two plates, the field is strongest around the wire and weakest near the surface of the pipe or plate. The charged dust particles move from the strong part of the field toward the weak part of the field.

Two types of precipitators are manufactured. **The vertical-round type** is usually built in a cylindrical tank having a header sheet near the inside top. In this header sheet are nested pipes which act as the collecting electrodes. The high-voltage ionizing electrodes are twisted square steel rods, about ¼ in in size, supported from above the header sheet and hung axially in the collecting electrode pipes. Water is introduced above the header sheet and flows over weir rings at the tops of the pipes to form a water film on the inside of the pipes. **The horizontal-plate type** has vertical parallel plates as collecting electrodes. The discharge electrodes are a series of wires suspended equidistantly between the plates, and can be operated as either a "wet" or "dry" unit. When used as a wet precipitator, weir boxes are built on the top of each plate to produce a wetting of both sides of the plate, washing the collected particles down the plate. As a dry precipitator, a rapping device operated on a time cycle shakes the plates, causing the collected particles to fall into a hopper under the plates. Dry collection requires injection of a conductive gas such as SO_3 to work efficiently. (See Marchello, "Control of Air Pollution Sources," Marcel Dekker, p. 182.)

The electrical apparatus provided with a precipitator to produce a dc potential of 30,000 to 90,000 V can be mechanical, vacuum tube, or solid state. Power packs are self-contained cabinet-type units, built in sizes from 2½ to 50 kVA. Rectifiers are mounted in a substation building close to the precipitator or can be mounted in weatherproof enclosures on the roof of the precipitator. Controls can be at a distance because the wiring is of low potential.

The efficiency of dust removal by precipitators is expressed as $\log (1 - E) = t \log K$, where E = the efficiency as fraction removal; t = the time the gas is in the electric field, s; and K = an apparatus constant varying from 0.05 to 0.80 ("Cottrell Electrical Precipitators," Western Precipitator Corp.; see also Schmidt and Anderson, *Elec. Eng.,* 1938). The above function implies that small variations of t cause considerable variations of $(1 - E)$, the fraction of dust left in the gas. This indicates a sensitivity of the precipitators to overload. (See Table 18.1.12 for common applications).

Precipitators working on coke oven gas for tar removal, under favorable temperature and moisture conditions, show outlet figures of 0.005 gr of dry tar per ft^3 of gas with inlet of 0.25 gr/ft^3. The outlet tar content increases rapidly upon overloading the apparatus.

Precipitators for blast furnace gas reduce the dust to about 0.01 gr/ft^3. Electric precipitators are used for removal of suspended matter from gases and air from boiler gases, metallurgical fumes, cement and lime dusts, etc. Precipitators can be built for dust in practically all particle sizes, as well as mist. They cannot collect material in the gaseous or vapor state. Precipitators are not applicable where explosive gas or dust is involved in the presence of air or oxygen in explosive proportions because of the hazard of ignition by an electric spark.

Blast-Furnace Gas Cleaning Modern equipment for this service represents a field in which gas cleaning has been developed to a high degree of efficiency. The method described here is used on most modern blast-furnace gas-cleaning plants.

The **dust catcher** is a large cylindrical steel tank, brick-lined, about 30 to 40 ft in diameter. The dust catcher is fundamentally a settling chamber. Dust is dropped out of the gas by reducing the velocity of the flow. Gas enters at 400°F approx and with 10 to 20 gr of dust per cubic foot. A good dust catcher will clean the gas to 3 gr of dust per cubic foot.

The **primary washer** is a cylindrical steel shell 16 to 21 ft in diameter, with a conical bottom section. Four to five banks of ceramic, round, or cross-partition tile are arranged in the tower. At the top, sprays cover the top bank of tile with an even distribution of water at the rate of 7 to 9 gal/(ft^2 · min). Size of the tower is determined with a gas rate of 350 ft^3/min per ft^2 of cross-sectional area. The gas enters the washer at an angle of 45° downward, passes up through the tile and out a main at the top of the washer. The water passes down through the tile banks and collects the dust removed from the gas. The water collects in the bottom section and overflows through a pipe arranged with a gas seal. The water then is sent to a thickener for removal of the iron-ore dust. The gas enters the washer at 400°F approx and is cooled to 100°F approx. The dust content of the gas is reduced to about 0.15 to 0.30 gr/ft^3, which is satisfactory for entrance into a precipitator or Theisen disintegrator.

Electrostatic precipitators reduce the dust content of the gas to the cleanliness required by its final use. The following are common requirements for blast furnace gas in grains per cubic foot at standard conditions (1 atm, 70°F): hot blast stoves, 0.01; boilers, 0.01; soaking pits, 0.10; coke ovens, 0.005.

Effect of Sulfur Gases and Particulates on Vegetation

J., Possible Benefits from Sulfur in the Atmosphere. *Combustion,* **44,** no. 4, 1972, pp. 16, 17; Grennard and Ross, Progress Report on Sulfur Dioxide, *Combustion,* **45,** no. 7, 1974, pp. 4–9; Wagner, TVA's Proposed Clean Air Strategy, *Public Utilities Fortnightly,* pp. 34–37, June 6, 1974. Current updated revisions of pertinent local and federal regulations.

Damage from Sulfur Fumigation Vegetation is damaged by abnormal concentrations (above 0.3 ppm) of sulfur gases at ground level. Users of sulfur-bearing fuels may become involved with damage claims where ground-level concentrations are of consequent increasing importance. The contaminants causing damage to vegetation are sulfur trioxide (SO_3), sulfates, sulfur dioxide (SO_2), and particulate materials.

Particulate materials on leaf surfaces have no harmful effect other than to exclude sunlight, and to that extent, retard growth.

Sulfur trioxide is hygroscopic and occurs at ground level as sulfuric acid mist. Plant damage has been observed in the field. Sulfur trioxide is deleterious to plants, animals, and humans.

Impure sulfur dioxide (SO_2) has the greatest effect on plants. Concentrations greater than 0.3 ppm will damage the leaves of sensitive vegetation if maintained for over 5 h. Animals and humans are more resistant than plants. Concentrations above 0.5 to 2.0 ppm are recognizable by smell and taste. The concentration and the duration of the fumigation determine the degree of injury. (See Table 18.1.9). Environmental conditions of temperature, humidity, soil moisture, soil fertility, nutrient supply, light intensity, age of plants, and moist-leaf conditions have a marked influence on the effect of sulfur dioxide on vegetation.

Table 18.1.9 Suspectibility of Vegetation to Injury by Sulfur Dioxide (from Field Observation)

Maximum susceptibility	Moderate susceptibility	Resistant
	Weeds	
Plantain	Bracken fern	Goldenrod
Ragweed	Wild carrot	Small-leaved milkweed
Smartweed	Wild grape	Knotweed
Dewberry	Sweet clover	Milkweed
Greenbriar		
Dandelion		
Galinsoga		
Pigweed (redroot)		
	Wildflowers	
Greenbriar	Blackberry	Goldenrod
Galinsoga	Witch hazel	Small-leaved milkweed
Dandelion	Huckleberry	Elderberry
	Blueberry	Mountain laurel
	Bracken fern	Yarrow
	Viburnum	Knotweed
	Wild carrot	Joe-Pye weed
	Sweet clover	Milkweed
	Farm crops	
Alfalfa	Alsike clover	Potato

Hemlock	Scotch pine	Blue spruce
Hawthorn	Norway spruce	Black locust
Black birch	Sumac	Black oak
Yellow birch	Ash	Red oak
	Wild cherry	White oak
	Domestic apple	Sugar maple
	Willow	Swamp red maple
		Norway maple

Benefits from Sulfur in the Atmosphere In normal atmospheric concentrations below 0.3 ppm, as occurs in metropolitan areas 95 percent of the time, sulfur dioxide is an essential plant nutrient. Vegetation utilizes it for growth by absorption from the atmosphere through leaves, and from rain-saturated earth through the roots. Fossil fuels, by virtue of their origin as former vegetation, contain from 0.4 to over 4 percent sulfur (Table 18.1.10). To maintain the natural ecological sulfur cycle for sustaining plant growth, this organic sulfur should be recycled back into the soil. As sulfur in stack gases is brought down by rainfall largely over a radius of about 15 mi from steam-electric plants in rural areas, averaging about 5 lb/(acre · yr) (0.55 g/m^2), anywhere from 20 to 50 percent of the annual sulfur requirement for crops can be furnished by stack emissions, while the balance must be supplied by fertilizers. Agriculture requires annually 10 to 40 lb/acre (1.11 to 4.44 g/m^2) of sulfur, which, in the absence of stack emissions, must be furnished by direct sulfur application for optimum yields of crops.

The sulfur dioxide problem, therefore, is mainly one of preventing excessive ground-level concentrations, whereby a normal plant nutrient can become a menace. Two methods of control are possible when burning fossil fuels: sulfur oxide removal by wet scrubbing, or dispersion by tall stacks with subsequent precipitation by normal rainfall.

Sulfur Oxide Removal Processes Stack-gas scrubbing processes remove sulfur from the flue gas but also increase the buildup of atmospheric CO_2. In 1973 the seven most promising stack-gas scrabbing processes selected for further study by the Sulfur Oxide Control Technology Assessment Panel were

1. Catalytic oxidation of SO_2 to SO_3, to recover sulfuric acid as a saleable by-product
2. Wet lime/limestone scrubbing, which produces calcium sulfite sludge for disposal
3. Alkali scrubbing without regeneration, which produces 18 percent sodium sulfite brine for disposal
4. Alkali scrubbing with lime regeneration, which produces calcium sulfite sludge for disposal
5. Alkali scrubbing with thermal regeneration, which recovers SO_2 gas by-product, and a sodium sulfite/sulfate brine for disposal
6. Magnesium oxide scrabbing, with off-site sulfuric acid manufacture and regeneration of magnesium oxide by others
7. Alkali scrubbing, plus electrodialytic regeneration to recover SO_2 gas and a purge stream of impure brine

A comparison of these systems is given by Table 18.1.11. The sulfur dioxide emissions limitations (SDEL) case, with its low-cost and negligible environmental impact, is technically justifiable with a cost/benefit ratio of 0.19. The other designs are bulky, costly, noisy, and experimental. They consume energy, water, fuel, and chemicals, and require direct sulfur application to surrounding agricultural areas, plus waste sludge disposal. These adverse environmental impacts usually result in negative total public benefits, unjustifiable except under unusually favorable circumstances.

By far the most difficult and costly environmental hazard produced by sulfur removal is the volume of high chemical-oxygen-demand (COD) liquid and solid wastes produced. This contaminated thixotropic sludge is environmentally unacceptable for landfill or for any other conceivable use. Reduction to elemental sulfur for permanent underground storage by an inverse Frasch process would reduce the volume of wastes, but the cost is exorbitant. Moreover, even if sulfur is removed, the buildup of acid gases (mainly CO_2) in the global atmosphere will continue unabated, along with increasing acid rains, as the CO_2 content of the air increases. Substitution of nuclear fuels for fossil fuels will correct the situation.

Sulfur Dioxide Emission Limitation (SDEL) Programs

To avoid the water pollution difficulties and the wet sludge disposal difficulties introduced by wet scrabbing, Tennessee Valley Authority and others have developed various SDEL programs.

SDEL methods employ combinations of five or more sensing, dispersing, and limitation approaches simultaneously.

Table 18.1.10 Emission of Sulfur-Bearing Gases and Solids from a 1,000,000-kW (1,000-MW) Fossil Fuel Fired Power Station

Fuel:	Mid-western bit coal	Eastern bit coal	Central Ill. bit coal	High-sulfur fuel oil	Low-sulfur fuel oil
Firing method:	Pulv.-coal round burners	Pulv.-coal round burners	Cyclone burners	Round burners	Round burners
Sulfur content of fuel, %	4.14	1.15	4.65	2.41	0.40
Ash content of fuel, %	18.16	7.59	15.00	0.10	0.10
Sulfur-bearing gases leaving boiler:					
Sulfur dioxide, lb/h	69,000	15,100	97,500	23,200	3,620
Sulfur trioxide, lb/h	3,450	755	4,875	1,160	180
Total sulfur-bearing gases, lb/h	72,450	15,855	102,375	24,360	3,800
Solids in flue gas leaving boiler:					
Sulfur compounds, lb/h	4,600	920	920	2,520	420
Carbon, lb/h	8,280	2,760	1,190	4,200	4,200
Fly ash, lb/h	118,680	38,640	20,250	420	420
Total solids, lb/h	131,560	42,320	22,360	7,140	5,040
Collection efficiency,* %	99+‡	99+‡	99+‡	†	†
Solids in flue gas leaving stack, lb/h	360	360	15	†	†

* Based on clear stack.
† See text. Firebox temperatures are kept below 1,900°F to control NO_2 emissions.
‡ Total efficiency whether combination mechanical and electrostatic units or electrostatic alone, with SO_3 injection.
NOTE: 1 lb/h = $7.55(10)^{-3}$ kg/s.

Table 18.1.11 Comparison of SO_2 Control Systems

Process	Requirements	Throwaway or recovery	Additional cost of power generation, %	SO_2 control efficiency, %	Additional plant capacity investment, %
Sulfur dioxide emission limitation	Fuel-switching and tall stacks		1–2.35	99+	1–2.8
Low-sulfur fuel (coal or oil)			28–85	Varies	—
Dry fluidized-bed combustors	Limestone (200% of stoichiometric)	Throwaway $CaSO_3/CaSO_4$	25–38	50–90	25–90
Wet lime/limestone scrubbing	Lime (100–120% stoich.); limestone (120–150% stoich.)	Throwaway $CaSO_3/CaSO_4$	19–37	60–85	17–30
MgO scrubbing	MgO carbon and fuel (for regeneration and drying)	Recover conc. H_2SO_4	25–50	90	20–35
Catalytic oxidation (add-on)	V_2O_5 catalyst heat	Recover dilute H_2SO_4	25–45	85–90	25–40
Na_2SO_3 scrubbing	Sodium makeup heat	Recover conc. H_2SO_4 or sulfur	25–50	90	25–40
Double alkali	Sodium makeup plus lime (100–130% stoich.)	Throwaway $CaSO_3/CaSO_4$	17–35	90	15–30

BASIS: 80 percent plant load factor. Yearly fixed charges are 18 percent of capital investment. Cost ranges are for 200- to 1,000-MW plant sizes. Costs of sludge disposal ponds not included.
SOURCES: Burns and Roe data, TVA's Clean Air Strategy. *Public Utilities Fortnightly,* 34: June 6, 1974.

1. Very tall stacks (1,000 ft) for dispersing SO_2 gases high in the atmosphere, thereby minimizing unacceptable ground-level concentrations and occurrences. (See the Holland equation for stack height, below.)
2. Atmospheric (AFBC) and pressurized (PFBC) fluidized bed combustor units utilizing pulverized coal with limestone or dolomite added to the bed to absorb sulfur dioxide. The bed is cooled internally by steam coils. Ninety percent sulfur removal along with low NO_x is possible. Stack gases are cleaned mechanically and electrostatically. (See Energy Technology Conference VIII, Government Institutes, Rockville, MD, pp. 893–919.)
3. Computers, which quickly correlate meteorological and plant operational data, so as to anticipate and prevent unacceptable ground-level concentrations.
4. Sensors and monitors, which sense and record automatically the local ambient SO_2 concentrations, and pH's, thereby ensuring the effectiveness of the control operations. (Limestone application is made directly to lakes in the area to raise pH.)
5. Emission limitations, accomplished by fuel switching between high-and low-sulfur fuels during normal power plant operations, and by local power generation curtailment during emergency situations, when even switching to low-sulfur fuels might not provide acceptable ground-level concentrations.
6. Daily local plant weather observations and meteorological measurements by means of light aircraft and balloons. These approaches allow high sulfur fuels to be burned most of the time, thereby conserving scarce low sulfur fuels for domestic and other ground level uses not employing SDEL methods.

As opposed to wet scrubbers for SO_2 control, SDEL methods are estimated to require less than one-tenth the total investment cost and one-thirteenth the annual operating cost, exclusive of wet sludge disposal costs.

Atmospheric Dispersion of Pollutants from Stacks

Stacks can provide effective atmospheric dispersion of gaseous and particulate pollutants with acceptable ground-level concentrations. Theoretical and empirical formulas are available to estimate the dispersion of air borne pollutants continuously emitted from stacks. Effective stack height of a plume is given by $H = h_s + h_r$. (See notation below.)

Notation

Symbol	Definition	System of consistent units
b	Atmospheric-dispersal parameter	Dimensionless
d	Stack-exit diameter	m
H	Effective stack height	m
h_r	Rise of plume	m
h_s	Stack height	m
p	Atmospheric-dispersal parameter	Dimensionless
Q	Emission rate of pollutant	m^3/s
Q_h	Heat emission rate	cal/s
q	Atmospheric-dispersal parameter	Dimensionless
u	Mean wind speed	m/s
v	Stack-exit velocity	m/s
X_g	Ground-level concentration of pollutant at a distance x from base of stack	ppm by vol
X_{mg}	Maximum ground-level concentration of pollutant at a distance x_m from base of stack	ppm by vol
x	Downwind distance from emission source in direction of mean wind	m
x_m	Distance from base of stack to maximum ground-level concentration	m
σ_A	Basic diffusion parameter related to azimuth plume angle in radians	m^{1-q}
σ_E	Basic diffusion parameter related to elevation plume angle in radians	m^{1-p}

The Holland formula, recommended for calculating h_r, is $h_r = (1.5vd + 4.09 \times 10^{-5} Q_h)/u$. A ratio of stack height h_s to building height of 2½ to 1 or more is commonly used to avoid entrapment of the plume in the vortex of adjacent buildings and the associated high values of groundlevel concentration X_g. Stack-exit velocity v should be 14 to 28 m/s (45 to 90 ft/s) to minimize plume entrapment in stack vortices. The lower the ratio of stack inside to outside diameter at its top, the higher the necessary v.

The **Cramer equation,** recommended for calculating X_g, is $X_g = 10^6 Q/(\pi u x^b \sigma_A \sigma_E) \exp [H^2/(2\sigma_E^2 x^{2p})]$. The equation is for sampling intervals of approximately 20 min, with X_g varying approximately inversely as the one-fifth power of the interval.

Simplified approximate formulas for X_{mg} and x_m are

$$X_{mg} = 2Q10^6\sigma_E/(\pi e^{uH^{1.9}}\sigma_A) \qquad \text{and} \qquad x_m = H/(1.35\sigma_E)$$

Atmospheric dispersal characteristics and hence the values of X_g, X_{mg}, and x_m are influenced by thermal stratification and atmospheric turbulence. A superadiabatic (adiabatic) (subadiabatic) lapse rate, i.e., a

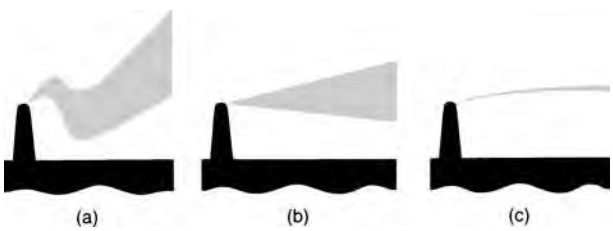

Fig. 18.1.2 Height and plume behavior for (*a*) unstable, (*b*) neutral, and (*c*) stable conditions.

drop in temperature with altitude greater than (equal to) (less than) 5.4°F per 1,000 ft (9.84 K/km) results in an unstable (neutral) (stable) atmosphere with much (moderate) (very little) vertical mixing. (See Fig. 18.1.2.)

The recommended parameters for use in the Cramer equations under the above conditions of thermal stratification are:

Thermal stratification	σ_A, rad	σ_E, rad	b	p	q
Unstable	0.39	0.13	2	1.1	0.9
Neutral	0.21	0.07	1.85	1.0	0.85
Stable	0.12	0.04	1.6	0.8	0.8

The above formulas deal only with steady-state conditions. There are transient meteorological conditions which can result in significant ground-level concentrations of pollutants and which cannot readily be analyzed by computations. These conditions include the breakup of a temperature inversion and the slow, steady buildup of pollutants during stagnations accompanied by deep ground fogs in a valley. For large power plants, high stacks (400 ft and more) (122 m), high stack-exit velocities [45 to 90 ft/s (13.7 to 27.4 m/s)], and adequate exit temperatures [250 to 300°F (394 to 422 K)] are usually effective in avoiding such fumigations.

Stack Emissions

Emission of sulfur-bearing gases and solids from a 1,000-MW fossilfuel fired power station is shown in Table 18.1.10. (See also Tables 18.1.12 and 18.1.13 for more data.) Reducing the remaining solids in stack emissions from bituminous coal fired (excluding stoker firing) power boilers to 0.02 gr/standard ft^3 (45.8 mg/m^3) and less results in a clear stack discharge. This requires collection efficiencies of 99+ percent, attainable with commercial equipment. These high collection-efficiency requirements demonstrate the need for optical instruments which will readily determine stack-emission quality. The **Ringelman chart** is frequently used to evaluate stack emission, but it is a crude and inaccurate method. A good indicator is a stack emission invisible to the naked human eye. With oil firing, present practice is to control stack emissions by furnace design, combustion control, use of additives, and multiple cyclone-type collectors located in the low- or high-temperature zones of the flue-gas system. For future plants of 1,000 MW and larger, use of high-temperature electrostatic precipitators located ahead of the air preheater may be considered.

Air Pollution Control in Various Industries

(See Tables 18.1.12 and 18.1.13.)

Industrial sources of air pollution and typical loss rates are given in Table 18.1.8.

Nonferrous metal smelting (e.g., copper, zinc, lead) and thermal operations (e.g., blast furnace, sintering, converters) are sources of air pollution and of potentially recoverable metallic materials. A large variety of collection equipment has been tried. Experience has proved that precipitators, cloth filters, and gas washers are best.

Paper industry sources of air pollution are (1) recovery furnace gases and (2) lime kiln exhaust gases. Noxious gases require scrubbing. **Recovery-furnace gases** in the sulfate and soda processes of manufacture emit solids [2 to 6 gr/standard ft^3 (4.6 to 13.7 g/m^3)] which are mainly sodium salts. The small particle size is particularly bothersome because of the large, obscuring plume in the stack tail. Chemically, the solids are destructive to painted and finished surfaces (e.g., automobiles, structures). Valuable constituents are recovered for return to the cycle. Electrostatic precipitators with 95 to 99 percent efficiency are favored for collection and return of solids. Corrosion-resistant materials (glazed tile, special cements) must be used to reduce maintenance. **Lime kilns** are used to calcine calcium carbonate and recover it as CaO for use in the process. The consequent air pollutant is recovered by gas washers and mechanical collectors.

Cement industry sources of air pollutants are (1) clinker kilns and (2) bagging and other mechanical operations. The **kilns** are the major source of air pollution, with large, unattractive exhaust plumes depositing cement-making solids on the landscape and on painted surfaces. Damage is reduced by the use of electrostatic precipitators with the wet process and cyclones plus cloth filters with the dry process. **Bagging and other mechanical losses** are reduced by use of cloth filters following cyclone separators.

Table 18.1.12 Common Applications of Industrial Precipitators

Industry	Application	Gas-flow range, ft^3/min*	Temp. range, °F	Percent weight of dust (below 10)	Usual efficiencies, %	Dust conc. range in ppm† by wt in air	Temp. range, K
Electric power	Fly ash from pulverized-coalfired boilers	50,000–750,000	270–600	25–75	95–99 +	760–9,500	405–589
Portland cement	Dust from kilns	50,000–1,000,000	300–750	35–75	85–99 +	950–29,000	422–672
	Dust from dryers	30,000–100,000	125–350	10–60	95–99	1,905–29,000	325–450
	Mill ventilation	2,000–10,000	50–125	35–75	95–99	9,500–98,000	283–325
Steel	Cleaning blast-furnace gas for fuel	20,000–100,000	90–110	100	95–99	38–950	306–317
	Collecting tars from coke-oven gases	50,000–200,000	80–120	100	95–99	190–1,905	300–322
	Collecting fume from open-hearth and electric furnaces	30,000–400,000	300–700	95	90–99	95–5,700	422–644
Nonferrous metals	Fume from kilns, roasters, sintering machines, aluminum potlines, etc.	5,000–1,000,000	150–1100	10–100	90–98	5,700–95,000	339–867
Pulp and paper	Soda-fume recovery in kraft pulp mills	50,000–200,000	275–350	99	90–95	950–7,600	408–450
Chemical	Acid mist	2,500–20,000	100–200	100	95–99	38–1,905	311–367

	Separate dust from vaporized phosphorus	2,500–7,500	500–600	30–85	99 +	19–1,905	533–589
Petroleum	Powdered catalyst recovery	50,000–150,000	350–550	50–75	90–99.9	190–4,800	450–561
Rock products	Roofing, magnesite, dolomite, etc.	5,000–200,000	100–700	30–45	90–98	950–4,800	311–644
Gas	Tar from gas	2,000–50,000	50–150	100	90–98	19–3,800	283–339
Carbon black	Collecting and agglomerating carbon black	20,000–150,000	300–700	100	10–35	57–9,500	422–644
Gypsum	Dust from kettles, conveyors, etc.	5,000–20,000	250–350	95	90–98	2,850–9,500	394–450

* $ft^3/min = 4.72(10)^{-4}\ m^3/s$.
† 1 ppm = 0.525 gr/1,000 ft^3 = 2 mg/m^3, in air.
SOURCE: Holden and Ackley, "Air Pollution Handbook," McGraw-Hill.

Carbon-black production utilizes electrostatic precipitators, cloth filters, and scrubbers to collect the black from the gas stream and to control air pollution.

Iron and steel industry sources of air pollution are cupolas, oxygen-furnaces, electric-furnaces, and sintering operations. The dispersoids in these operations are mostly oxides of iron in particle sizes below 10 μm and with loadings ranging to 15 gr/standard ft^3 (34.3 g/m^3). Dust emittance is acceptably controlled generally by use of precipitators and scrubbers for open-hearth and basic oxygen processes, use of cloth filters and scrubbers for electric furnaces, and use of precipitators, scrubbers, and filters for sintering.

Petroleum-refining sources of air pollution are mainly gaseous in nature. Mercaptans are removed by scrubbing. Solid dispersoids from the fluid-cracking processes are removed by electrostatic precipitators and/or cyclone-type collectors.

Miscellaneous Dusts Four industrial dusts have been classified as causing severe respiratory ailments: asbestos, causing asbestosis; crystalline silica, causing silicosis; cotton and cottonseed dust, a powerful allergen causing bronchial asthma and byssonosis; and lead, causing plumbism.

In mining operations and foundries, cyclonic collectors, followed by baghouses, have been found most effective. Likewise, in textiles and in cottonseed-oil pressing, baghouses following the lint-collecting cyclones can remove almost 100 percent of the hazardous pollutant.

Large central incineration plants can produce odors, noxious gases, and particulates (see Sec. 7.4). Odors and noxious gases can be minimized by carefully controlled combustion, using modern traveling-grate continuous systems. Furnace temperatures between 1,600 and 1,900°F (1,150 to 1,300 K) are recommended. Particulates can be minimized by well-managed covered conveying of dust-bearing refuse, incinerator residues and fly ash, and the use of electrostatic precipitators and wet scrubbers to comply with increasingly stringent air quality standards. (See Table 18.1.13 .) Gaseous emissions of SO_x, CO, and NO_x do not cause problems with continuous incineration, as their concentrations are small, but HCl and HF from plastics are hazardous. Stack height should be sufficient to minimize ground effects of any residual pollution. Municipal refuse can also be fired into waste heat utility boilers, a fuel conservation measure which will be increasingly important in electric power cogeneration.

RADIOACTIVE WASTE MANAGEMENT

REFERENCES: Cochran and Tsoulfanidis, "The Nuclear Fuel Cycle: Analysis and Management," American Nuclear Society. "Radiological Health Handbook." Nuclear Waste Policy Act of 1982 and its 1987 amendments. Low Level Radioactive Waste Policy Act of 1980 and its 1985 amendments, 10 CFR 50 Appendix 1, and 10 CFR 20. Current updated revisions of pertinent local and federal regulations.

General Considerations

Under existing legislation and authorization the Nuclear Regulatory Commission (NRC) has the primary responsibility for developing and regulating waste management methods and practices, sites of operation, and enforcement of all applicable standards, including those developed adjunctively with EPA. Radioactive wastes are generally divided into five general categories by the Nuclear Waste Policy Act: (1) **high-level waste (HLW);** (2) **transuranic (TRU) waste;** (3) **low-level waste (LLW);** (4) **uranium mill tailings;** and (5) **naturally occurring and accelerator-produced radioactive material (NARM).** HLW is "the highly radioactive material resulting from the reprocessing of spent nuclear fuel, including liquid waste produced directly in reprocessing, and any solid material derived from such liquid waste that contains fission products in sufficient concentrations, and other highly radioactive material that the NRC, consistent with existing law, determines by rule requires permanent isolation." TRU wastes are wastes that contain alpha-particle-emitting radioisotopes with atomic numbers greater than 92 and half-lives longer than 5 years. LLW is defined as material which is "not HLW, spent nuclear fuel, TRU or by-product material, and material which the NRC, consistent

with existing law, classifies as LLW." LLW is generated by the nuclear power industry, hospitals, and other medical facilities, universities, and research laboratories. Examples of LLW include contaminated clothing, tools, syringes, cotton wipes, paper, rags, and other trash. Uranium mill tailings also are treated as radioactive wastes and are not transported from their generation point. NARM is not regulated by the NRC, but is regulated by the individual states. Usually, most NARM qualifies as LLW and most often is treated as such.

HLW and TRU wastes are covered under the **Nuclear Waste Policy Act (NWPA),** which spells out the step-by-step procedures for all tasks related to their disposal. The NWPA details the process to be followed in the selection of repositories for the disposal of HLW, TRU waste, and spent nuclear fuel; the development of interim storage and monitored retrievable storage for HLW and spent fuel; and the responsibilities and obligations of the Department of Energy and the nuclear utilities.

LLW is governed by the **Low Level Radioactive Waste Policy Act (LLRWPA).** The LLRWPA dictates that every state is responsible for the disposal of all LLW generated within its borders, and assumes that the LLW can be stored safely on a regional basis. To carry out the disposal of LLW, many states have entered into "compacts" with other states to site and operate regional disposal facilities. Other states have chosen to develop their own disposal sites. The LLW generated by nuclear power plants usually consists of three types: gases, liquids, and solids.

Gases From the buildings which contain the fuel-handling system, auxiliary equipment, and waste systems, ventilating air, filtered if necessary, is released through a vent which is monitored for radioactive gases, iodine, and airborne particulates. Automatic controls will shut down the ventilating system, thereby stopping any release of airborne radioactivity as the monitor set points dictate.

Ventilating air for the containment vessel, which holds the reactor, primary pumps, and steam generators, is drawn when it is necessary for inspections or for other reasons to purge the vessel. **Purge air** is filtered through high-efficiency particulate air (HEPA) and through charcoal filters before release. In case monitor set points are exceeded, purging is automatically curtailed.

The third source of gases is the nitrogen cover gas of the volume control system in the PWR, and the steam jet ejector system in the BWR. Krypton, xenon, and iodine are produced within the reactor and mix with the cover gas. To release them, the principle employed is to "delay and decay" by compressing them into decay tanks of about 45 days' storage capacity in the PWR case, and into decay pipes of 20- to 60-min storage capacity in the BWR case. All releases are carefully monitored to be within established limits.

Liquids Liquid radwaste streams from boiling water reactors may be classified into two major systems. In one of these, relatively high-radioactivity, low-conductivity water is reclaimed by filtration and deionization, and is stored for recycling into plant makeup systems. In the other, relatively low-radioactivity, high-conductivity water from floor and laboratory drains, laundry drains, makeup demineralizer regeneration, and equipment decontamination is treated by various means, such as filtration, waste concentration, and deionization, is monitored and recycled for in-plant use. Pressurized water reactors can be characterized by three major liquid streams. The first of these consists of borated, relatively high-radioactivity demineralized water from the primary cooling loop. During the feed-and-bleed operating mode, borated water is removed and replaced with freshwater, which slowly reduces the amount of chemical shim (boric acid) present. A boric acid evaporator makes it possible to recover boric acid and to recycle a large portion of the distillate. The second major stream consists of floor and equipment drains from the containment vessel and the auxiliary building and from the radiochemistry laboratory, which go to a large **waste holdup tank.** These are subsequently transferred to an evaporator, and the distillate therefrom is deionized, passed through a radiation monitor, and then recycled. With both types of reactor, the heavy ends, crud, and dirt concentrate in the evaporator feed tank. This waste is pumped to the radwaste **drumming station,** where it is solidified with Portland cement or chemical grout. The third of the major streams is soapy water from laundry and showers. Because of foaming difficulties, this stream is not always processed through an evaporator, but instead is filtered or put through a reverse osmosis unit, monitored for radioactivity, and if satisfactory, released.

Solids Solid wastes for BWRs and PWRs are handled similarly. Evaporator and filter sludges are pumped to the radwaste drumming station and solidified with Portland cement or chemical grout in 55-gal (or larger) drums. Spent ion-exchange resins that are not regenerated are sent to an accumulation tank for decay and are then flushed into a shipping cask and dewatered for removal to a burial ground. They may also be solidified. Balable wastes are drummed but, if highly radioactive, are set in concrete. Large, heavy, junk equipment items can sometimes be stored on-site more economically than cutting them up and packaging them for off-site shipment.

Reference to current federal regulations and trade publications must be made to keep abreast of the latest developments.

SOLID AND HAZARDOUS WASTE MANAGEMENT

REFERENCES: "Pollution Control Technology, Solid Waste Disposal," Research & Educational Assn., New York. Sittig, "Handbook of Toxic and Hazardous Chemicals"; also Sittig, "Resource Recovery and Recycling Handbook of Industrial Wastes," Noyes Data Corp., Park Ridge, NJ. Exner, "Detoxication of Hazardous Waste," Ann Arbor Science Publishers. The Resource Conservation and Recovery Act of 1976 (RCRA) (as amended in 1980), PL 96–482 and CERCLA, PL 96-510 (SW-171). Metry, "The Handbook of Hazardous Waste Management," Technomic Publishing, Westport, CT. Peirce and Vesilind, "Hazardous Waste Management," Ann Arbor Science Publishers, Ann Arbor, MI. Current EPA regulations. Current updated revisions of pertinent local and federal regulations.

Solid waste includes solids discarded permanently, or temporarily, and materials suspended in air or water. Also forming part of this group are wet solids with insufficient liquid content to be free-flowing. Total solid wastes (excluding sewage) produced currently in the United States amount to about 250 million tons/year, or about 1 ton/(person · year), and include all industrial, domestic, commercial, and agricultural wastes. Between 4 and 5 percent of that total constitutes **hazardous wastes** subject to special handling and/or disposal. It is projected that the total solid waste stream will increase to 300 to 350 million tons by early in the twenty-first century. The increasing accumulation of dry waste which results from the high standard of living of modern society will deplete existing economically exploited natural resources and further aggravate the already costly waste disposal problem. Product and energy recovery, therefore, constitutes the preferable direction to follow rather than elaborate means of disposal. There is, however, a growth factor for solid residuals which is caused by environmental control legislation: unpredictable amounts of waste generated by air and water pollution control. Environmental regulations in effect simply transfer the pollution from those media to the solid state, and vice versa.

Federal Environmental Legislation See RCRA and CERCLA following.

Solid Waste Disposal

Solid waste handling involves two main steps: collection and disposal. **Solid waste conditioning** involves recovering those materials of value already present while conditioning the rest for conversion, recycling, or ultimate disposal. **Solid waste segregation** prior to collection into refuse, combustible wastes, noncombustible wastes, and hazardous waste is always a beneficial preconditioning step.

The principal solid disposal methods used are **incineration, landfill, and ocean disposal.** Many mining and processing operations leave a process residue on the premises since disposal cost elsewhere is prohibitive. Examples are red mud from refining bauxite and sulfite sludge from SO_2 stack gas scrubbing processes.

Landfilling requires spreading and compacting the waste and covering it with soil. This system is applicable both to biodegradable and nondegradable types of wastes. Leaching contamination of ground water must be prevented by installing liners. Careful attention must be given to possible subsidence and gas formation in landfilling. Topsoil disposal is limited to biodegradable organic materials.

Ocean dumping takes advantage of the ocean bottom trench configuration and the dispersing effects of ocean currents. Until recently, ocean dumping was the ultimate form of ocean disposal, but the practice has effectively ceased. The cost/benefit of ocean disposal was very favorable compared to alternate methods, but is now highly regulated and, with rare exceptions, the practice is proscribed and illegal. Ecological considerations effectively rule out this form of waste disposal for the foreseeable future.

Incineration is a volume reduction process rather than solid waste disposal, resulting in a residue which still must ultimately be disposed of. Heating values of solid wastes range from 5,000 to 15,000 Btu/lb for ordinary trash and industrial wastes. The growth of incineration is affected by higher fuel costs, construction costs, and added expense for air pollution and hazardous waste control.

Another means of solid waste reduction is **composting,** not widely used because of the limited market for its products, but ultimately may become more widely spread to maintain a rural-urban ecological balance.

Product Recovery

The average solid waste (per 100 lb) produced daily in the United States is roughly 6 lb industrial (from process), 5 lb municipal, and 89 lb mine tailings, smelter slags, dredging spoil, and agricultural wastes. Materials salvaged from solid waste recycled back to their sources not only reduce disposal costs but also conserve farmland values and natural resources. Recovery of metal, paper, glass, plastics, and hazardous substances is an outstanding example of materials recycling.

Materials separation from solid waste may be performed by physical or chemical means. The most common types of equipment used are material separators (varies with application: magnetic, thermal, flotation, size reduction—shredders, crushers, grinders, and pulverizers), materials flow (conveyors, lifters), mixers, and blenders. (See Sec. 10.)

Basic chemical conversion processes for industrial waste are hydrogenation, oxidation, acetylation, cross-linking cellulosic materials. For more detail, see Engdahl, "Solid Waste Processing—A State of the Art Report on Unit Operations and Processes," Public Health Service Publication No. 1856, Supt. of Documents, Washington, DC.

Table 18.1.14 Cost/Benefit Evaluation of Recycled Sewage Sludge as Fertilizer (Denver)*

	Total cost delivery and application, $/dry ton	Current worth of nutrients, $/dry ton	Disposal cost savings, $/dry ton	Total benefit (worth and savings), $/dry ton	Cost/ benefit
Air-dried (trucked)	$ 4.00	$ 8.37	$11.34	$19.71	0.20
Liquid (5% solids) (trucked)	14.00	12.20	11.34	23.54	0.595
Liquid (5% solids) (pipelined)	9.00	12.20	11.34	23.54	0.382

* 1975 data.

Biochemical processing of wastes from the food and chemical industries is common practice. An example is recovery of B-complex vitamins and animal feed from solid brewery wastes.

Pyrolysis of organic wastes can economically utilize them as supplementary fuels depending upon waste types and waste energy conversion processes. New efforts are being made in that direction to process municipal refuse as well as industrial and hazardous wastes.

Dry sludge production from municipal sewage has been achieved with the development of activated sludge processes using high purity oxygen. These processes reduce the volume of activated sludge by two-thirds and improve its dewatering characteristics.

Table 18.1.14 itemizes the 1975 cost factors at Denver from which cost benefit ratios have been developed. (See Cost/Benefit Balancing.) The cost benefit for air-dried sludge is particularly favorable, inasmuch as for every 20¢ invested, the public consumer receives $1.00 in benefits (1990 data).

RCRA AND CERCLA

The Resource Conservation and Recovery Act of 1976 (RCRA), as amended in 1980, regulates current and future waste disposal practices, including both municipal and hazardous waste, while the **Comprehensive Environmental Response Compensation and Liability Act (CERCLA),** or "Superfund," cleans up old, hazardous waste sites. Also, see 39 CFR 158, parts 240 and 241. "Thermal Processing and Land Disposal of Solid Waste."

Hazardous Waste Management RCRA defines *hazardous waste* as a solid waste, or combination of solid wastes, which because of its quantity, concentration, or physical, chemical, or infectious characteristics may

> cause, or significantly contribute to an increase in mortality or an increase in serious irreversible, or incapacitating reversible, illness; or pose a substantial present or potential hazard to human health or the environment when improperly treated, stored, transported, or disposed of, or otherwise managed.

The act requires EPA to promulgate regulations establishing criteria and standards for all aspects of hazardous waste management. The regulations developed by the EPA designate a large number of substances as hazardous and also provide specific characteristics to determine whether a particular waste is hazardous. The characteristics include ignitability, corrosivity, reactivity, and EP toxicity.

The EPA also promulgated regulations establishing standards for hazardous waste treatment, storage, and disposal facilities. Provisions include groundwater protection, development and implementation of contingency plans, closure and postclosure activities, and specific facility performance standards. The standards cover facilities such as tanks, surface impoundments, land treatment, landfills, incineration, underground injection, and physical, chemical, and biological treatment. Other regulations cover "cradle-to-grave" control of the collection, source separation, storage, transportation, processing, treatment, recovery, and disposal of such wastes. Generators of these wastes bear the ultimate legal responsibility and are required to keep specific records for the disposition of their hazardous wastes by means of a manifest system.

18.2 OCCUPATIONAL SAFETY AND HEALTH

by Pascal M. Rapier and Andrew C. Klein

REFERENCES: "General Industry Guide for Applying Safety and Health Standards," 29 CFR 1910 OSHA, U.S. Dept. of Labor, 1973, and Amendments. 29 CRF 1910.1–1910.309, *Fed. Reg.,* **37:**202, Oct. 18, 1972, and Amendments. Current updated revisions of pertinent local and federal regulations.

WORKER'S COMPENSATION LAWS

Worker's compensation laws in this country were introduced in 1911 and have now been enacted in all the states. The principle involved is that the worker injured or disabled in industry should be enabled, through proper medical treatment, to return to wage-earning capacity as promptly as possible and, while incapacitated, should receive compensation in lieu of wages, regardless of fault. The expense of medical treatment and compensation should properly be borne by industry and become a part of the cost of its products. The laws generally provide that workers injured in industry shall be furnished the necessary medical treatment, and, in addition, compensation based on a percentage of their average weekly wages, payable periodically. Dependents of employees killed in industry are likewise compensated.

Many states have supplemented their worker's compensation laws by providing comparable benefits in cases of incapacity or death due to occupational disease. Some states make these provisions applicable only in case of specified occupational diseases; others make them of general application to cases of any disease directly attributable to the employment. At the present time, all states and the District of Columbia provide for compensation benefits in occupational-disease cases either by enlarging the scope of the worker's compensation law, by separate legislative enactment, or by judicial construction.

The enactment of worker's compensation laws has been followed in many jurisdictions by more stringent provisions relating to factory inspections for the prevention of accidents in industry and of occupational disease.

The enactment of worker's compensation and occupational-disease laws has increased materially the cost of insurance to industry. The

increased cost and the certainty with which it is applied have put a premium on accident-prevention work. This cost can be materially reduced by the installation of safety devices. Experience has shown that approximately 80 percent of all industrial accidents are preventable.

SAFETY

REFERENCES: "General Industry Guide for Applying Safety and Health Standards," 29 CFR 1910 OSHA, U.S. Dept. of Labor, 1973. 29 CRF 1910.1–1910.309, *Fed. Reg.,* **37:**202, Oct. 18, 1972. "Accident Prevention Manual for Industrial Operations." National Safety Council. "Manual of Accident Prevention in Construction," Associated General Contractors of America, Inc. American Conference of Governmental Industrial Hygienists, "Industrial Ventilation—A Manual of Recommended Practice." Blake, "Industrial Safety." Prentice-Hall. DeReamer, "Modern Safety Practices," Wiley. Heinrich, "Industrial Accident Prevention," McGraw-Hill. Patty (ed.), "Industrial Hygiene and Toxicology," Interscience. Simonds and Grimaldi, "Safety Management," Irwin. Stubbs (ed.), "Handbook of Heavy Construction," McGraw-Hill. Labor laws applicable in the jurisdiction where the working enterprise is located.

The person(s) responsible for overseeing the safety of all operating personnel must be cognizant of the latest laws and regulations pertaining to worker safety, which are changed and/or updated from time to time.

The logical time to install safety devices is when new machines are being built, while general construction work is being done, or when alterations or repairs are being made; results can be accomplished with a minimum of expense and delay at the time plans and specifications are being prepared.

Checking for Safety To ensure that the question of safety will not be overlooked, it is well to have all plans, specifications, and drawings checked for safety, making special provision for this in each set of specifications and in the title plate of each drawing.

Buildings

(See 29 CFR 1910, Subparts D, E, and F, as amended.)

Plant Arrangement A fundamental factor in effective accident prevention is the provision of ample ground space in the plant site to reduce crowding of buildings, congestion of plant traffic, unusual fire hazards, unsafe yard conditions, etc. One-story buildings have definite advantages in regard to fire hazards, building collapse, and natural lighting.

Where a plant is located near a main line of a railroad, consideration for safe access by employees and vehicular traffic should be given serious attention. Safe passageways from one building to another are also important. Blind corners, doorways opening onto yard railway tracks, etc., should be avoided as much as possible, and, where such conditions must necessarily exist, safety railings, gates, signs, or gongs should be installed to warn pedestrians of danger.

Because of their inherent **hazards of fire and explosion,** the storage, handling, and utilization of *flammable liquids* should be carefully controlled. The National Fire Codes, promulgated by the NFPA, are considered authoritative in establishing minimum safeguards necessary to control these hazards. It is necessary in any event to conform to the requirements of any applicable state and local code.

Buildings in which **dusty operations** are carried on should be designed to present a minimum area of projections, ledges, and resting places for dust accumulations.

Floors, Stairways, Aisles, etc. Probably the most important factor to be considered in connection with floors, stairways, etc., concerns **slipperiness.** Floors and stairs should be free from projecting nails, bolt-heads, etc., as noiseless as possible, wear well, and be strong enough to carry safely any static or moving load. The weight of modern industrial machinery and material handling equipment should be carefully considered in checking floor-load calculations. Floors and stairways should be kept clear of unnecessary obstructions over which workers may trip.

Spilling of oil, water, acid, etc., should be prevented to eliminate slipping hazards. Splash guards, drip collectors, etc., can be designed in many instances to reduce slippage. Excessive spillage of dusty materials onto the floor is sometimes taken care of by installing floor gratings beneath which pits or conveyor systems are located to collect the falling material.

Ample aisle space is very important, especially in foundries where workers carry ladles of molten metal and where there is considerable shop traffic involving power-driven trucks, etc. Aisles should be clearly marked off to assist in keeping them clear. One-way traffic is often advantageous.

Stairways should be provided with **handrails** on both sides, and an intermediate middle handrail should be installed on stairways over 88 in in width. Nonslip treads on stairs are desirable. Stairways should be adequately lighted (see Sec. 12.5).

Exits and Fire Escapes (See Life Safety Code NFPA.) As far as practicable, all doors should open outward or with the natural direction of egress; they must not block passageways from other floors or parts of the building.

For factories, not less than two means of exit should be provided on every floor, including basements, of all buildings or sections; these exits should be separated in such a manner that they are not likely to be cut off by a single local fire. The location of stairways around or adjacent to passenger elevators is undesirable unless there is separation by fire walls.

Outside fire escapes are inferior to stairways as means of egress. Where they are used, they should be located on blank walls or arranged so that persons on them will be protected from flames issuing from windows or openings underneath by use of wired glass in standard metal frames, fire doors, etc. Outside fire escapes, to provide maximum protection for persons using them during fire, should be enclosed in noncombustible towers which will protect against weather, smoke, or fire, with access through or over some intermediate balcony or structure to the building proper.

Lighting (See Sec. 12.5.) Adequate lighting has a definite bearing on the prevention of accidents. Workrooms should be well lighted to reduce eye strain and the possibility of permanent eye impairment and also to remove any danger of employees falling over obstructions or being caught in machinery in darkened areas.

Ventilation (See Sec. 12.4.) A lack of adequate ventilation in a workroom tends to bring on fatigue and reduces the alertness of workers, thus making them more susceptible to accidents. Where injurious dusts or noxious vapors are encountered, it is necessary to provide for their removal by the installation of adequate local exhaust systems (see Sec. 12.4 and ACGIH "Industrial Ventilation" and ASA Standard, "Fundamentals Governing the Design and Operation of Local Exhaust Systems").

Identification of Piping (See Sec. 8.7.) It is desirable that a plan of identifying the contents of various pipelines be adopted so that in case of an emergency it will be possible to determine quickly the service of all pipelines involved.

Mechanical Guarding in Machine Design

(29 CFR 1910, Subpart 0, as Amended.)

The most logical time at which to consider the safeguarding of a machine is during its design. In this stage, features of safe operation can be incorporated so that there will be a minimum of specific guarding required on the finished machine. The following points are fundamental considerations concerning accident prevention which should be taken into account in machine design.

Care should be taken in arranging clearances of moving parts to avoid shearing or crushing points in which hands or other parts of operator's body might be caught or injured.

Arrangements should be made so that adjustments, inspections, and hand lubrications can be done safely.

Machines should be so designed that operators are not required to stand in an uncomfortable position, reach over moving parts, or exert themselves in awkward positions.

Machines should be designed so that there will be little danger of the operator tripping over parts of the frame or striking against projecting parts during normal operation movements.

Careful attention should be given to strength of all parts whose failure might result in injury to operator.

All guards, covers, or enclosures should be designed strong enough to prevent the possibility of their giving way and permitting an accident in case the operator should fall or be thrown against them.

Point-of-Operation Guarding The point of operation on a machine is taken to be that zone where the work of the machine is actually performed and where the operator, by manipulating the material being processed, is exposed to a hazard from moving parts of the machine. Guards for point-of-operation protection are placed on the machines as additional equipment. The first requirement for a successful guard of this type is that it shall be convenient and not interfere with the operator's movement or affect the output of the machine. The following statements describe several basic principles which may be utilized in point-of-operation guarding.

Where possible, the **danger point** should be completely **covered** by a barrier or enclosure before the hazardous operation of the machine begins. This may be accomplished for example on a treadle-controlled machine by having the treadle operate the guard which, when in proper location, will then activate the machine.

Operator's hands may be kept out of dangerous positions by installing **starting devices** so located that, to operate the machines, both hands of the operator must be out of the danger zone.

Feeding devices may be used so that material to be processed is placed in a feeding mechanism at a point where there is no exposure to moving parts. Special holders or feeding tongs can also be used to place work in hazardous positions.

Electronic controls, which operate by the interruption of a light beam or other energy source to protect the danger zone, may be used to start and stop machines.

Electrical interlocks on guarding devices may be utilized in operating circuits so that unless a guard is in proper position the circuit is open and no current will flow until the machine is safely protected by the guard being brought into proper position.

Automation has minimized the hazards associated with the manual handling of stock and has eliminated the need for repetitive exposure at the point of operation, but the urgency of making repairs or adjustments introduces the need for special precautions covering maintenance work, such as locking out the power source.

Electric Equipment

(See 29 CFR 1910, Subpart S, as amended.)

In considering electrical equipment for industrial establishments, it should be borne in mind that the **hazard** to human life **increases with increase in voltage.** Thus, economy in transmission wiring and copper parts, which is achieved through the use of high voltage motors, may be offset by increased danger of accident. For small motors, lights, and general service inside industrial plants, installations of 110 or 220 V are recommended.

All **switches, fuse boxes, terminals, starting rheostats, motors,** etc., located within 8 ft of a floor or working platform, should be enclosed or guarded in such a manner as will prevent accidental contact with live parts, irrespective of voltage. **Switches** should be arranged so that they can be locked in the open position, to guard against a switch being activated accidentally while workers are at work on the lines or equipment that the switch controls. **Equipment for operation at 550 V and higher** should be isolated from other operating equipment, in separate rooms or enclosures, with provision to lock these enclosures. **All metallic cases, frames, and supports** of such equipment should be permanently grounded; foundation bolts should not be depended upon for this purpose, but substantial ground conductors should be used. It is preferable to have these ground wires accessible for inspection. **All low voltage secondary circuits** of 300 V or less (such as light, motor, and meter circuits) should be permanently grounded whenever a neutral point is available for the purpose. Secondary circuits of 250 V or less should be permanently grounded even though a neutral point is not available. Whenever grounding has to be omitted, the frame or casing of the apparatus should be permanently grounded, and all live parts of the secondary circuit should be shielded to prevent accidental contact therewith. It is also desirable to have floors or platforms adjacent to switchboards built of nonconducting material, or suitably insulated. In the absence of such construction, rubber mats may be used.

Portable electric lamps, tools, and machines are subjected to severe operating conditions. Many electric shock fatalities have occurred on electric portables, even with 110-V lighting circuits. Cable used to service portable equipment should be high-grade insulated cord designed for the service, not ordinary twisted lamp cord. Its mechanical attachment to both the portable and the attachment plug or source of power should be designed to prevent sharp bending or chafing that would break down the insulation. All portable lamps should have nonmetallic sockets (such as rubber, plastic, or porcelain). The heavier portable tools and machines cannot practically have their metallic parts insulated from contact by the operator, and protection from shock due to accidental charge thereon must be provided by means of a special grounding wire. Such protective grounding should be in the form of an additional wire in the cable that feeds the portable device. One end should be permanently connected to the machine frame and the other connected to ground through an additional pole in both the attachment plug and the receptacle to which the device is to be attached.

Occupational-Disease Prevention

(See 29 CFR 1910, Subpart G, as amended.)

In any industrial operation where a toxic material is being processed in such a manner that those persons engaged in or working near the operation are exposed to appreciable quantities of dusts, fumes, vapor, or gas, it is important that adequate control measures be adopted. The following statements cover the major considerations involved in the application of effective control to industrial occupational disease.

Contaminants (See 29 CFR 1910, 93.) The physical and chemical characteristics of a contaminant should be known. In the case of dusts or fumes, the chemical nature, particle size, solubility, etc., should be determined. For gases or vapors, the composition, vapor pressure, flash point, etc., are important factors. In all atmospheric contamination, the quantity of material in the worker's breathing zone must be known before the degree of hazard can be evaluated. The chemical characteristics are important in the selection of materials to be used in the construction of any control equipment where corrosion, etc., might be factors.

A careful investigation should be made to determine accurately the sources from which the contaminant is being produced or from which it is being dispersed. The most common types of dust-producing operations are crashing, screening, grinding, polishing, etc. Dispersion of dust is encountered in practically all dry handling operations of fine materials. Vapors and fumes are produced by chemical processes and reactions and are most commonly found in connection with the use of solvents.

A number of testing instruments and procedures have been developed for determining quantitatively the concentrations or amounts of various toxic material in the atmosphere of a work room (see ACGIH, "Air Sampling Instruments" and reports of U.S. Public Health Service and U.S. Bureau of Mines; see also AIHA Hygienic Guide Series and ACGIH, "Annual Threshold Limits"). In general, the seriousness of any exposure involving a health hazard is directly proportional to the dosage (concentration and length of time of the exposure). Engineering control should be directed to the reduction of these two factors.

Local Ventilation at the Source of Contaminant Removal by means of exhaust hoods, enclosures, etc., so located as to prevent the escape into occupied areas of any appreciable amount of contaminant at its source is the most effective method of control. For details of hood design, piping, collectors, fan characteristics, and for general principles of exhaust design system, see Sec. 12.4. and ANSI Standard, "Fundamentals Governing the Design and Operation of Local Exhaust Systems"; AFS, "Engineering Manual for Control of In-plant Environment in Foundries."

Natural ventilation has a limited application in industrial occupational disease control. It is important with a natural ventilation system to maintain close supervision of adjustment as required by changes in temperature, wind directions, etc. Regular tests of air content should be made to check on the degree of dilution being obtained. This method of control is not recommended for exposures where severe hazards exist owing to extreme toxicity or high concentrations.

Isolation Under some circumstances, the isolation of a hazardous operation, physically, or in point of time, is required. For example, a

hazardous operation may be carried on in a separated room in which all contamination can be confined or it may be carried on outside regular working hours when no one except the persons engaged in the operation will be present. By isolating an operation, the number of persons exposed to any accompanying hazard may be reduced to a minimum.

Process Revision The possibility of substituting a less toxic material should be borne in mind; e.g., high-boiling-point distillates for benzol in rubber cements, thinners, etc.; dolomite lime for quartz in foundry parting compounds. It may be possible to reduce the concentrations of objectionable contaminants and the time of exposure by changing handling operations, by substituting mechanical feeds or conveyors for manual operations, or by installing automatic machinery or controls so as to dispense with the presence of an attendant. An automatic temperature or pressure control device, in connection with a chemical process, may reduce materially the time of an operator's exposure as well as prevent the production of excess or undesirable fumes or gases. An enclosed conveyor system handling dry material and automatically weighing it may be utilized to eliminate a severe exposure that would result from hand shoveling.

Physical Hazards In addition to exposures to toxic gases, vapors, dusts, fumes, etc., there are several physical conditions such as abnormal pressures, temperatures, and humidities as well as radiation (including ultraviolet; infrared; X-ray; α, β, and γ rays from radioactive substances; and radiation from handling radioactive isotopes), all of which may, in case of excessive exposure, prove detrimental to the health of exposed persons. Evaluation depends on physical methods of measurement. Protective measures include shielding from radiation and control of exposure time rather than ventilation, as in the case of atmospheric contaminations.

Ambient Noise Control (See also Sec. 12.6.) Outer property noise propagation is regulated by EPA, under provisions of the Noise Control Act of 1972; Section 6 applies to new-product noise emission standards; Section 17 is concerned with noise emission regulations for railroads and Section 18 for motor carriers. EPA is directed to publish noise emission guidelines in the *Federal Register*. The regulation for aircraft-airports are promulgated by the Federal Aviation Administration (FAA) consistent with Section 611 of the Federal Aviation Act of 1958 and guidelines proposed by EPA.

Occupational Noise Exposure Mandatory protection of employees against noise is required by 29 CFR 1910.95 as follows:

(a) Protection against the effects of noise exposure shall be provided when the sound levels exceed those shown in Table 18.2.1 when measured on the A scale of a standard sound-level meter at slow response. When noise levels are determined by octave band analysis, the equivalent A-weighted sound level may be determined from Fig. 18.2.1. Octave band sound-pressure levels may be converted to the equivalent A-weighted sound level by plotting them on this graph and noting the A-weighted sound level corresponding to the point of highest penetration into the sound-level contours. This equivalent A-weighted sound level, which may differ from the actual A-weighted sound level of the noise, is used to determine exposure limits from Table 18.2.1.

Table 18.2.1 Permissible Noise Exposure*

Duration, h/day	Sound level, slow response, dBA
8	90
6	92
4	95
3	97
2	100
1½	102
1	105
½	110
¼ or less	115

* 29 CFR 1910.95.

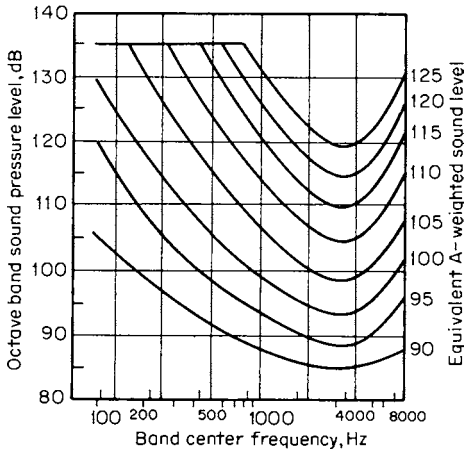

Fig. 18.2.1 Equivalent sound-level contours.

(*b*) (1) When employees are subjected to sound levels exceeding those listed in Table 18.2.1, feasible administrative or engineering controls shall be utilized. If such controls fail to reduce sound levels within the levels of Table 18.2.1, personal protective equipment shall be provided and used to reduce sound levels within the levels of the table. (2) If the variations in noise level involve maxima at intervals of 1 s or less, it is to be considered continuous. (3) In all cases where the sound levels exceed the values shown herein, a continuing, effective hearing conservation program shall be administered.

When the daily noise exposure is composed of two or more periods of noise exposure of different levels, their combined effect should be considered, rather than the individual effect of each. If the sum of the fractions $C_1/T_1 + C_2/T_2 + \cdots + C_n/T_n$ exceeds unity, then the mixed exposure should be considered to exceed the limit value. C_n indicates the total time of exposure at a specified noise level, and T_n indicates the total time of exposure permitted at that level. Exposure to impulsive or impact noise should not exceed 140-dB peak sound-pressure level.

Personal Respiratory Protection (See 29 CFR 1910, 134, as amended.) Where it is not practicable to control air contamination in the breathing zone of workers by adequate exhaust ventilation, etc., and it is necessary for personnel to be exposed to harmful amounts of dust, smoke, fumes, or gases or to work in an atmosphere with a deficiency of oxygen, personal respiratory equipment must be provided. Such equipment is not, in general, suited for prolonged daily use because of inherent discomfort and inconvenience to the wearer. For emergency or temporary situations or until effective control of contamination can be developed and applied, personal respiratory protection should be given very careful consideration where harmful exposures are encountered (see "The Respirator Manual," prepared jointly by the American Industrial Hygiene Association and the American Conference of Governmental Industrial Hygienists). The U.S. Bureau of Mines (Schedules 19 and 21) has developed certain standards for approval of respiratory protection devices. The equipment may be (1) **supplied-air respirators** (hose type), devices that supply clean, respirable air to the wearer through a hose line extending from a source outside the contaminated zone; (2) **supplied-oxygen respirators** (self-contained type of oxygenbreathing apparatus), devices that supply oxygen to the wearer from a source of supply that he or she carries as part of the respirator; or (3) **filter-type respirators,** which may be chemical filter respirators that remove the harmful constituents from air passing through them by chemical reactions, absorption, and adsorption, including ordinary gas masks and chemical respirators; or which may be mechanical-filter respirators that remove the harmful constituents from air by mechanical filtration, including dust, mist, or fume respirators.

Safety Codes and Published Material: OSHA The American National Standards Institute (ANSI) publishes a series of ANSI Standards. State and local ordinances must be complied with as required.

The National Safety Council publishes a series of Industrial Data Sheets and Safe Practice Pamphlets covering the safeguarding of industrial operations, in addition to literature, posters, films, and other safety educational material. The annual publication "Accident Facts" reports current trends in accident experience on an overall basis.

United States government agencies, such as the Bureau of Mines, the Bureau of Labor Statistics, the National Bureau of Standards, and the Division of Labor Standards publish statistical information concerning industrial-accident occurrence and accident prevention. The National Fire Protection Association (NFPA) promulgates fire codes and publishes information of all types relating to fire protection.

The Williams Steiger Act of 1970 created the **Federal Occupational Safety and Health Administration** (OSHA), which has now codified and published blanket standards for national enforcement in all public safety and health areas. Updated revisions will continue to appear in the Federal Register under Title 29 CFR 1910 and 1518, and these standards make all preexisting standards obsolete.

Radiation Health Physics (Nuclear Regulatory Commission, Code of Federal Regulations 10 CFR 20; International Commission of Radiological Protection, Pub. 30, "Radiological Health Handbook") **Radiation,** which accompanies all nuclear reactions, can be advantageous or disadvantageous, depending generally on the manner in which contact is made and on the amount of energy involved. In its application to humans, the common terminology includes **radiation absorbed dose (rad)** and **dose equivalent,** measured in SI units as **gray (Gy)** and **sieverts (Sv),** respectively. In an older, though still common, usage, the respective units are designated **rad** and **rem.** Absorbed dose, measured in grays (or rads), is a measure of the energy absorbed from radiation per unit mass of irradiated material. Absorbed dose is applicable to all types of ionizing radiation and irradiating material. The amount of biological damage to human tissue, however, depends on the type of radiation and its energy. Thus, absorbed dose measurements must be modified in order to relate the amount of energy absorbed to the biological effect. Dose equivalent, as measured in sieverts (or rems), accounts for these effects through the use of **radiation weighting factors** (formerly known as **quality factors)** Q. For radiation protection purposes, the **dose equivalent** is defined as the product of the absorbed dose and the radiation weighting factor. The currently accepted weighting factors are 1, for photons and electrons of all energies; 5, for protons with energies greater than 2 meV; 20, for alpha particles, fission fragments, and heavy nuclei; from 5 to 20, for neutrons, depending on the neutron energy.

Exposure to radiation may be divided into two general types: (1) external exposure, which is that resulting from radiation sources external to the body; and (2) internal exposure, which is that resulting from radionuclides within the body. Radiation-protection standards are established for both types of exposure. Limits for external exposure are given in units of sieverts per unit of time. Basic limits currently are based on a control point of 1 year. Local operational rules may specify control limits for shorter exposure times (day, week, month), such limits being based on the basic limits. Radiation-protection standards for controlling internal exposures are based on the same basic limits as those for external exposures. Controls, however, are affected by the use of **annual levels of intake (ALIs)** and **derived air concentration (DAC)** values established for all radionuclides. Many factors (physical, chemical, biological, and physiological) are involved in determining the ALI and DAC of a radionuclide. As such, the ALIs and DACs of the radionuclides have a very wide range of values. All **ALIs** and **DACs** are normally expressed in terms of **bequerels** and **bequerels per cubic metre,** respectively. Generally, ALI and DAC values are based on a 40-h workweek for persons exposed to radiation.

Monitoring is the periodic or continuous determination of the presence and extent of ionizing radiation and radioactive contamination. It provides information for radiation protection and normally is assigned to a health physics group, which establishes schedules, executes or supervises the operation, and evaluates their results. It is divided into these special types: personnel, area, source, surface, air, and water.

Regulations governing exposure to radiation are promulgated in the form of Nuclear Regulation Commission regulations found in 10 CFR 20. The current **occupational dose limit** is 0.050 Sv (or 5.0 rem) total effective dose equivalent per year. The total effective dose equivalent includes both external and internal doses. Additional radiation protection limits exist for radiation exposures to individual organs of the body, the lens of eye, and the extremities. Reference to the current full statement of 10 CFR 20 is mandatory for a complete understanding of the regulations.

18.3 FIRE PROTECTION

by Pascal M. Rapier and Andrew C. Klein

REFERENCES: "Fire Protection Handbook," "National Fire Codes," "Fire Inspection Manual," National Fire Protection Assn. "Handbook of Industrial Loss Prevention," McGraw-Hill. "Uniform Building Code 1976," International Conference of Building Officials, Building Offic. and Code Admin. International (BOCA). Fire Insurance Assn. (FIA), Factory Mutual (FM), Code of Federal Regulations: 29 CFR 1518, July 1976, and 29 CFR 1910, July 1976, Jan. 28, 1977, as amended. Current updated revisions of pertinent local and federal regulations.

IMPORTANCE OF FIRE PROTECTION

(29 CFR 1910, Subpart L)

The profitable use or availability for use of facilities is the aim of all business, whether industrial, mercantile, professional, scientific, or educational. Destruction of or damage to the facilities cripples the attainment of that purpose.

Monetary compensation for destroyed property and for resulting lost profits is obtained by the purchase of insurance. Reputation, goodwill, and other intangible factors may be irreparably damaged. Loss of life is not recoverable. Loss by fire is largely an avoidable, nonproductive tax resulting from carelessness, ignorance, apathy, or incompetence. The annual fire loss in the United States (refer to NFPA) has increased steadily since 1964 at about 8 to 12 percent per year, reflecting the population and economic growth and inflation. In recent years, the number of losses has exceeded 2 million. Building fires have made up in excess of 80 percent of the **amount** of loss but only about 40 percent of the **number.**

Fire-Loss Prevention Neither insurance organizations nor legally established regulatory bodies assume the responsibility of industry for conserving its own resources and operating its facilities safely, although they may detect deficiencies or a lack of compliance with regulations and may serve in a consulting capacity. Fire loss prevention is an indispensable element in industry and business. It exists only with top management direction and the support of labor.

The designation **fire protection** usually encompasses the entire field of **prevention of loss by fire,** including both the causes for the occurrence of fires and methods for minimizing their consequences. Included along with fire are other destructive agencies such as explosion, lightning, electric current, wind, earthquake, nuclear excursions, and radioactive contamination. OSHA and building codes mandate minimum standards

of protection to prevent injury and loss of life. Higher standards to protect investment are a worthwhile management option.

Fire brigades (29 CFR 1910.164) are essential to the development and maintenance of an effective fire protection program at every job site. By prompt, immediate response and notification of the local fire department, every effort should be made to bring the fire quickly under control during the early minutes of an outbreak. The immediate availability of the correct fire protection and suppression equipment is essential.

Fire protection engineering involves the application of sound engineering principles to the reduction of loss by fire and related hazards. The Society of Fire Protection Engineers has established a well-defined scope for fire-protection engineering practice, both in building design and in safe operating practices.

Limitation of Loss With large businesses it is difficult to limit single destructive occurrences to an amount that will not be catastrophic to the owner or to others having a financial interest. Principles and methods for preventing large losses by fire are well known to fire protection engineers.

Sources of Fire Protection Information Much specific, detailed, and technical information is given in the standards, codes, and rules of the NFPA, Factory Mutual Engineering Division, Factory Insurance Assoc., American Insurance Association, ANSI, Underwriters Laboratories Inc., and may also be found in the procedures of many insurance companies and inspection bureaus.

The NFPA "Handbook of Fire Protection" and the Factory Mutual "Handbook of Industrial Loss Prevention" are especially comprehensive references. The most complete and readily available source of standards is the "National Fire Codes," prepared and published by the NFPA, currently in ten volumes as follows: 1—Flammable Liquids; 2—Gases; 3—Combustible Solids, Dusts, and Explosives; 4—Building Construction and Facilities; 5—Electrical; 6—Sprinklers, Fire Pumps and Water Tanks; 7—Alarms and Special Extinguishing Systems; 8—Portable and Manual Fire-control Equipment; 9—Occupancy Standards and Process Hazards; 10—Transportation. Many of the standards have been adopted by insurance inspection and advisory groups, such as the American Insurance Association, and by Federal, state, and municipal regulatory bodies and have been incorporated into building codes and other regulations. The Occupational Safety and Health Administration (OSHA) U.S. Dept. of Labor, is promulgating blanket national standards for fire protection, which appear in the Federal Register under Title 29, Code of Federal Regulations for the working place, and Part 1518 during construction. Where applicable, these supersede and make obsolete all existing standards.

CONSTRUCTION

Building construction and the protection of buildings and their contents against fire are frequently governed by local building codes and ordinances and by insurance standards. When new construction or changes are planned, the property owner should have the advice of a competent fire protection engineer and should consult local authorities and insurance carriers to avoid delay and the possibility of expensive changes later.

Some construction features which have increasing importance in fire-loss prevention are (1) the trend toward large fire areas which present high values to possible loss and make manual fire fighting difficult; (2) blank wall, air-conditioned, and artificially lighted buildings which interfere with ready access; and (3) mechanization of materials handling, resulting in conveyor systems that interconnect areas, and in larger storage areas with high-piled stock which make fires difficult to extinguish. These cause increased cost of fire protection and emphasize the need for automatic fire control methods, sources of dependable water supplies, and special extinguishing systems. A measure that should be adopted where practical is the use of outdoor, totally enclosed process equipment, with shelters provided only for control rooms, laboratories, and some maintenance functions.

Types of Construction **Fire-resistive** refers to types that withstand considerable fire without serious damage, such as reinforced concrete or protected steel. **Noncombustible** refers to any construction that contains no elements of burnable material built which may be structurally damaged by fire, such as unprotected metal. **Combustible** means structures entirely of combustible materials or having combustible elements of such character and distribution that a fire can spread and contribute fuel so that severe damage results. Combustible types of construction are frequently subdivided into (1) "heavy timber," also called "plank on timber," "mill" or "slow burning" that has masonry walls with floors and roof of plank on heavy timbers; (2) "ordinary construction" that has masonry walls with floors and roof made of boards on joists and is sometimes called "quick burning"; (3) "wood frame" that has all of its elements of wood, except that the exterior may be surfaced with a noncombustible sheathing.

Many types of construction have composite elements that may include combustible materials. Insulation, acoustic materials, and surface treatments may aid the start and contribute to the rapid spread of fire. A roof of interlocking metal sheets, with asphalt on its upper surface as part of a vapor barrier or as an adhesive for insulation or weather surfacing, can, if initially heated by a local interior exposing fire, furnish gaseous fuel through the joints to produce a spreading damaging fire. Owing to the difficulty and cost of protection, enclosed spaces at roofs, ceilings, in walls, and below floors should be avoided. Important steel structural members and steel supports for heavy equipment that may be exposed to severe fire should have heat-insulating protection. Economic tradeoffs, based on the probability of exposure, should be made.

Fire Performance of Building Materials The kind and amount of fire protection needed are governed by the fire performance of materials used in construction and by the combustibility of building contents. Completely noncombustible construction avoids the need for sprinkler protection, provided that contents are also certain to be noncombustible. Knowledge of the fire performance of materials, based upon tests made by qualified laboratories, is essential before they are adopted (see Sec. 6.8). Fire performance is in two categories, fire resistance and fire hazard.

Fire resistance measures the susceptibility of materials to damage by exposure to fire and is usually measured as the time period of exposure, without significant damage, to a standard fire-exposure as specified by standard fire tests, such as "ASTM E-119 Fire Tests of Building Construction and Materials," and expressed as a **fire-resistance classification** in hours as ½ h, 2 h, 6 h, etc.

Fire-hazard indicators are also in two generally recognized categories used by the Underwriters Laboratories. The **listing** of specific appliances and materials indicates that the products comply with the Laboratories' test requirements, with particular reference to fire-preventive and fire protective capabilities when the manufacturer's instructions and limitations of use have been followed. The **fire-hazard classification** of materials and products is related mainly to burning characteristics. It has a numerical basis determined by (1) flame spread, (2) fuel contributed, (3) smoke-developed. A fire hazard classification of 0 indicates a material with a fire performance equivalent to that of cement board composition. A value of 100 corresponds to the behavior of red oak lumber. Building codes and other regulations generally prescribe limiting values for fire hazard classifications.

Protection against Exposure Fires Protection of buildings or other structures against fires in nearby property must sometimes be provided. A practical barrier against a conflagration is the presence of fire-resistive buildings along the exposed side. Usually the most severe exposure is localized, and protection against it may be provided by a blank brick or concrete wall, by wired-glass metal-frame windows, or by open sprinklers alone or in combination. The relative value of various safeguards against exposure fires has been estimated to be roughly blank brick or concrete walls, 100; tin-clad shutters, 60; wired-glass windows, metal frames, glass block (4 in minimum thickness), 40; wired-glass windows, wooden frames, 20; plain glass windows, 5; additional value of open sprinklers with any of the foregoing, except blank fire walls, 30; open windows, 0.

Horizontal Cutoffs Provide effective fire walls between important buildings, and subdivide large building areas in order to limit the probable maximum damage from a single fire.

Vertical Cutoffs Enclose stairs, elevator wells, vertical conveyors, chutes, and other floor openings with adequate fire-resistive walls, having

fire doors or their equivalent at openings to prevent the rapid spread of fire and heat upward from floor to floor.

Isolation of Hazards Cut off hazardous occupancies by fire-resistive partitions or fire walls or, if the degree of hazard warrants, isolate them in separate buildings. Make provision for adequate ventilation and for explosion vents where needed.

Floor Leakage Provide drained, watertight floors over large values susceptible to water damage.

Storehouses and Vaults Provide suitable storehouses for large quantities of combustible raw stock, tools, and patterns, and for valuable finished goods. Provide reliable vaults for the storage of business records and valuable drawings.

SAFEGUARDS DURING BUILDING CONSTRUCTION

(20 CFR 1518, Subpart F.)

A building under construction is more vulnerable to fire than the same building completed and in use with normal fire protection. As construction progresses, concentrations of readily combustible materials appear at new locations from day to day. So do many potential ignition sources—temporary heaters, welders' torches, roofers' tar kettles, and workers' discarded matches or cigarettes. If fire starts, wall and floor openings create draft and help flames to spread rapidly. Many serious construction fires have taken place. Most can be prevented. Guard against cutting and welding hazards by proper supervision of operations. Plan in advance for effective notification of, and coordinated firefighting operations with, any available public fire department. (See 29 CFR 1518.24.)

Start installation of the fire-protective equipment—including water supplies, yard mains, and hydrants—as soon as construction of the building starts. Make layouts for sprinklers as soon as building drawings are completed, and let contracts without delay. It is sometimes possible to arrange for limited temporary protection by providing connections for hose from the piping system which furnishes water for construction uses. Have hose and nozzles available as soon as the yard piping, hydrants, and water supplies are ready. Distribute ample hand extinguishing equipment throughout the premises, including contractor's temporary buildings.

Temporary Heating Arrange any needed heat safely. Use coke as fuel for salamanders, rather than wood trash or rubbish. Oil-fired heaters, if well-designed and properly located, are safer. Unit heaters are still better and are recommended if an adequate steam supply is available. Locate salamanders or oil heaters away from woodwork or tarpaulins. Keep the floor clean and free from combustible material. Flame-proofed, water-repellent tarpaulins are available, and their use is advised. The tarpaulin salamander wooden-form combination has caused many serious fires, particularly in reinforced concrete construction work during freezing weather. Scaffolding constructed of metal, or of fire-retardant-treated wood, largely avoids a serious fire hazard. Locate construction sheds a safe distance from a building under erection, never inside.

Temporary Storage Keep combustible storage out of buildings under construction, as far as possible and at least 10 ft (3.05 m) from structures when stored outside. Under no conditions erect canvas tents or wooden shelters inside. A safe location and good fire protection are important for valuable equipment or machinery, delivered before the building is ready for its installation.

AUTOMATIC SPRINKLERS

(29 CFR 1910.195.)

Advantages of Automatic Sprinklers Automatic sprinklers are the most dependable and effective means of fire protection. The advantages are (1) automatic sprinklers go into operation soon after a fire starts, and before it has gained dangerous proportions; (2) the automatic sprinklers that open are over, and in the vicinity of, the fire; (3) fires at all locations, including out-of-the-way places, are controlled as effectively as fires easily seen and reached; (4) sprinklers operate where fire fighters could not enter or would be driven out by heat or smoke; (5) sprinklers are always ready; (6) only sprinklers that are needed to control a fire operate, so that water is used to better advantage than from hose streams.

Where Sprinklers Are Needed Automatic sprinklers are needed for complete protection where there is an appreciable amount of combustible material in either building construction or in building contents, e.g., (1) throughout buildings having floors or roofs of sufficient combustibility to contribute to a spreading fire, whether or not the contents are combustible; (2) in wholly noncombustible buildings where contents are combustible, including the storage or use of flammable liquids; (3) in concealed spaces, such as attics and under low roofs, if they contain any combustibles, including heat insulation and exposed electric wiring; (4) in vacant spaces beneath a combustible first floor of a building, unless the floor is completely tight, the space sealed against entry, and no possible sources of ignition are present; (5) in dryers, large ducts, closets, and small offices, unless there is no fuel for a fire in either the construction or the contents; (6) under wide storage shelves or work tables over 4 ft in width having any combustible stock, and under canopies over platforms where combustible materials may be present.

Sprinklers over Electric Equipment If the construction is fire-resistive or adequately fireproofed, sprinklers can generally be omitted in electric generator rooms and over switchboards. If voltages exceed 600, it is generally better to replace combustible roofs or ceilings with non-combustible construction or to protect all exposed woodwork with metal lath and cement plaster, rather than to install sprinklers. Metal shields or hoods may be used to protect generators, switchboards, or other important electrical equipment from possible water damage.

Automatic-Sprinkler Equipment The responsibility for the design of automatic sprinkler systems should be given only to experienced and responsible parties. Approval of preliminary layouts and working plans are usually required by municipal or insurance inspection bureaus before installation is started. Sprinkler installation is a well-established trade by itself. Standards for the Installation of Sprinkler Systems are given in complete detail in a publication under that name by the National Fire Protection Assoc.

Dry Pipe Systems The ordinary wet pipe sprinkler system cannot be used where subject to temperatures below freezing. A dry pipe system must be substituted. In the dry pipe system the sprinkler piping contains air under pressure instead of water. When a sprinkler is opened by fire, the air pressure falls and water is admitted automatically by the operation of a dry pipe valve.

Special Sprinkler Systems The deluge system is a special type of sprinkler equipment frequently used in hazardous occupancies, such as airplane hangers and storage areas for flammable liquids or materials, where a flash fire could spread before the regular automatic sprinklers became operative, and where the prompt discharge of a large amount of water over a considerable area is needed. The deluge system has sprinkler heads with the fusible element removed. Water is controlled by a quick-opening valve (deluge valve) operated by heat sensitive elements distributed over the area protected. Piping and heads are arranged as in a standard sprinkler system, with larger pipe sizes.

Precision systems are actuated by heat-sensitive devices, smoke detectors, or ionization detectors, which trip a controlling valve and admit water to the otherwise dry sprinkler piping before the regular closed automatic sprinkler heads operate. The system has the advantage of giving an alarm before sprinklers operate. Accidental opening of automatic sprinklers or mechanical breakage of piping does not result in the discharge of water.

Deluge and other systems actuated by heat-sensitive or other special devices introduce additional mechanical equipment and lose the simplicity of the standard automatic sprinkler system. Some additional skilled maintenance is required. Various arrangements for mechanically supervising the condition of such equipment can be provided.

Nonfreeze sprinkler systems are small and are sometimes used in relatively unimportant locations where it is impracticable to provide heat.

They consist of special piping connections to wet-pipe systems, with a nonfreezing solution in the exposed piping. Antifreeze solutions (glycols) are acceptable for this purpose. They should be limited to systems with less than 20 heads. It is better to provide heat, to connect to existing dry pipe systems, or to provide small dry pipe valves. Nonfreeze systems are preferable to shutting off the sprinklers and draining the piping during the winter. No portion of an automatic sprinkler system connected to a public water supply should be filled with a nonfreeze liquid without determining that the arrangement will comply with water department health regulations.

Outside sprinklers are used for protection against fire from outside sources. Windows in outside walls present the most frequent problem. Outside sprinklers may be operated either manually or automatically. The effectiveness of these systems depends on the water supply valve opening in time. They can sometimes be adapted to automatic control by a thermostatically operated deluge valve.

Types of Automatic Sprinkler Heads Approved automatic-sprinkler heads are well standardized as to the rate of water discharge, pattern of discharge, and temperature operating characteristics. The essential elements of an automatic sprinkler are a nozzle, a closing device that is released at a definite temperature, and a deflector that produces the desired distribution pattern. Temperature ratings appropriate for the location must be selected. The ratings for normal atmospheric temperatures, not substantially above 100°F, are 135 to 165°F. Ratings for other ceiling temperature ranges are as follows:

Max ceiling temp		Sprinkler rating	
°F	K	°F	K
101–150	311–338	175–212	352–373
151–225	339–380	250–286	394–414
226–300	381–442	325–360	436–455

Heads of higher rating are obtainable for ambient temperatures up to 500°F. Corrosion-resistant heads, usually wax or plastic coated, are obtainable for use in corrosive atmospheres.

Sprinkler Flow Alarms The flow of water from a sprinkler system may be made to sound an alarm which gives warning of both a fire and accidental leakage from the system. This alarm may be either a hydraulic gong or an electric bell, or both. If the property has no constant attendance, or if added security is desired, central-station supervisory service is available in many industrial centers. This service transmits water flow alarms to public fire departments and can perform numerous other supervisory functions. Preaction alarms give advance notice of hazard.

Location and Spacing of Automatic Sprinklers As the purpose of an automatic sprinkler system is to protect both building and contents, the water distribution pattern and the quantity of water applied must be held within close limits. Sprinklers customarily are installed so that the discharge from one head is allowed for each 60 to 130 ft^2 of floor area. The distance between adjacent heads should not exceed 15 ft. Spacing averages 80 to 120 ft^2 per head with 8 to 12 ft between heads.

Recent developments in sprinkler system design for the more severe hazards produced by high piled combustible goods or flammable liquids are leading to standards including a **discharge density** in terms of gallons per minute per square foot of floor area. In this consideration building contents, rather than building construction, are the determining factor. Densities called for commonly have been in a range of 0.15 to 0.3 gal/min per ft^2 of floor area. High-piled storage of combustible materials, such as rolled paper, imposes a severe hazard which may call for a water density of 0.6 gal/min per ft^2, or more. NFPA standards (1973) call for intermediate levels of sprinkler heads in high rack storage areas. Open and deluge sprinklers require hydraulically designed systems based on friction loss instead of standard pipe schedules (see NFPA No. 13, No. 13a, and No. 231c).

The number of heads, to be supplied through pipes of standard sizes, with ordinary hazards and reasonably uniform water discharge, is as follows:

Size of pipe, in	Max. no. of sprinklers	Size of pipe, in	Max. no. of sprinklers
1	2	3½	65
1¼	3	4	100
1½	5	5	160
2	10	6	275
2½	20	8	400
3	40		

Not more than eight sprinklers should be on one branch line on either side of a cross main. For deluge systems, with which all heads are open and must be supplied simultaneously, and for especially hazardous occupancies where a large proportion of the automatic heads are expected to operate, larger pipe sizes are required as follows:

Size of pipe, in	Max. no. of sprinklers	Size of pipe, in	Max. no. of sprinklers
1	1	3	27
1¼	2	3½	40
1½	5	4	55
2	8	5	90
2½	15	6	150

WATER SUPPLIES FOR FIRE PROTECTION

(See Sec. 3.3 for hydraulics, Sec. 8.7 for piping, Sec. 9.6 for engines, Secs. 14.1 and 14.2 for pumps.)

Insurance companies or their inspection and engineering bureaus should be consulted concerning water supply requirements for fire service. In addition to providing water for automatic sprinklers, the supply should be adequate for hydrants and hose streams. Common water supplies are public water systems, gravity tanks or private reservoirs, and fire pumps taking suction from aboveground suction tanks, rivers, or ponds. Two or more independent supplies are usually needed for larger properties. Strong, dependable public water systems alone are adequate only for small plants, of good construction, having safe occupancies, and not dangerously exposed.

The "primary" water supply automatically maintains pressure on the property fire system at all times. The "secondary" supply supplements it as needed. The **primary supply** should not be less than 500 gal/min available at a pressure that will be effective for automatic sprinklers at the highest plant elevation. A **secondary water supply** serves several purposes. The most important usually is to provide more water, frequently at higher pressure than is available from the constant primary supply. A secondary supply is also of value in maintaining protection at any time the primary supply may be interrupted due to public supply deficiencies or to the necessity of taking tanks or reservoirs out of service for repairs and maintenance.

High water demands for special hazard protection, especially where large areas must have deluge system protection, can seldom be met by connections to public water systems. Fire pumps and suction reservoirs can give the added volume of water at desirably high pressure for the expected duration of the total demand, which is made up of the anticipated sprinkler demand and an allowance for the number of hose streams likely to be used. Large airplane hangars, large building areas containing flammable liquids, or very extensive properties that could have a general fire, approaching conflagration proportions, can have an estimated total demand of 5,000 gal/min or even more.

Gravity Water Tanks The smallest gravity tank on a tower considered advisable for fire protection is 25,000 gal, which may be suitable for the protection of small properties. Water from tanks of such limited size should be reserved for automatic sprinklers only. Tanks of 50,000- to 100,000-gal capacity may provide either the primary or secondary

supplies for large properties of moderate hazard. Tanks combining fire service and domestic or industrial supplies in a single structure are allowable, provided that the amount needed for the fire supply cannot be withdrawn into the industrial use system.

Gravity tanks should be at such elevation that the bottom of the tank will be at least 35 ft above the highest sprinkler to be supplied. The bottom of large tanks, intended to provide water for hose streams as well as sprinklers, should be at least 75 ft, and preferably 100 ft, above ground level.

Pressure Tanks Hydropneumatic steel tanks can be used for primary water supplies for demands of short duration, such as needed to bring automatic fire pumps into full operation. Under some conditions they can be used to facilitate the automatic control of the automatic fire pumps by providing a rapid drop in the control pressure. High cost and limited capacity deter the general use of pressure tanks.

Private Fire Pumps Well-located fire pumps with ample suction supplies and capable of maintaining high pressure over a long period provide a very satisfactory secondary supply. Centrifugal fire pumps of approved design are in common use. Practically all new installations use centrifugal pumps driven by electric motors, gasoline or diesel engines, or steam turbines. The electric motor driven centrifugal pump is most desirable because of simplicity of control and operation. Gasoline engine drives are used to a limited extent where other reliable sources of power are not available, or as auxiliary units in connection with other pumps.

Adequate suction and reliable power supply are essential for fire pumps. The suction supply should be sufficient to operate the pump at rated capacity for at least 1½ h at the smaller plants, and an inexhaustible suction supply is desirable for good protection of the largest industrial properties.

An automatically controlled, electrically driven centrifugal fire pump is sometimes used as a booster pump when the public water is of good volume but too low in pressure for direct use in sprinkler systems.

Fire pumps are used in capacities of 500, 750, 1,000, 1,500, and occasionally 2,000 or 2,500 gal/min. The 750 and 1,000 gal/min sizes are most common.

Fire Department Connections For properties where the public water supply is at comparatively low pressure but adequate in quantity, fire department connections to the plant fire-service piping can serve as a valuable auxiliary for pumpers to deliver water into the fire system at high pressures. In city properties, particularly, fire department connections are usually a part of the sprinkler system.

UNDERGROUND WATER PIPING FOR FIRE SERVICE

Complete specifications or standards covering all of the main features of underground piping for fire service are given in NFPA National Fire Codes, vol. 6, "Sprinklers, Fire Pumps, and Water Tanks," and the Factory Mutual "Handbook of Industrial Loss Prevention." The "Handbook of Cast-Iron Pipe," published by the Cast-Iron Research Association, contains much useful information.

Underground Mains Buried underground piping should be located so that hydrants and control valves are at a safe distance from possible falling building walls. A complete loop system around buildings or groups of buildings, with multiple supplies preferably connected at opposite sides and with prudently located division valves, affords the best hydraulic characteristics for heavy flows and for freedom from impairments. Pipe trenches should allow careful laying and uniform support for the pipe. Foreign materials should be kept out of the pipe. Pipe should be anchored at bends, dead ends, and branch connections. The system should be hydraulically tested for 2 h at a minimum pressure of 200 lb/in^2 or at least 50 lb/in^2 in excess of the maximum static pressure if it is to be more than 150 lb/in^2. Leakage at joints must be less than specified amounts. Underground piping should be thoroughly flushed before it is connected to indoor piping. Pipe should be buried well below the deepest frost penetration as shown by weather charts. In the coldest areas a cover of at least 5 ft is necessary. In the southern states 2½ ft may be adequate, except that under roadways a greater cover may be needed for protection against traffic loads. Clearance to prevent breakage by settlement is needed at foundation walls.

Soil Corrosion Rapid external corrosion of cast iron pipe may be expected if the mains pass under coal piles, through cinder fill, or where pickling liquors, acids, alkalies, or salts penetrate the soil. Cast iron pipe covered with heavy coating of asphalt, or other pipe suitably covered should be used to offset soil corrosion in such locations. Backfill should be of clear sand or gravel. (See Secs. 6.8 and 6.9.)

Type of Pipe Pipe for underground use is usually cast iron or steel. Ordinarily the working water pressure rating does not need to exceed 150 lb/in^2. Representative specifications for pipe suitable for fire service are: "Specifications for Cast-Iron Pit-Cast Pipe" (ANSI A21.2 or AWWA C102), "Specifications for Cast-Iron Pipe Centrifugally Cast in Sand-Lined Molds" (ANSI 21.8 or AWWA C108); asbestos-cement pipe should conform to "Tentative Standard Specifications for Asbestos-Cement Water Pipe" (AWWA C400) or "Commodity Federal Specification SS-P-55/A."

OUTSIDE HYDRANTS AND HOSE

Location of Hydrants Where space permits, outdoor hydrants and hose provide a supplemental to automatic sprinklers and afford means for fighting fires in combustible yard storage, in railroad cars and vehicles, and small combustible unsprinkled sheds. Recommended space between hydrants varies from 150 to 300 ft, depending upon the type of buildings and the character of outdoor combustibles. Hose for outdoor use, 2½ in in size, is made of woven cotton or modern synthetic fiber and rubber-lined.

STANDPIPES AND INSIDE HOSE

(29 CFR 1910.158.)

Standpipe systems furnish the best means of obtaining effective fire streams in the upper stories of buildings. They are designed for small hose streams used by the occupants and for large hose streams to be used by public or plant fire departments. Outlets may be designed to supply both. In buildings of unusual height, standpipes are sometimes supplied by a series of fire pumps and tanks at different elevations.

Small hose is of particular value in areas with hazardous occupancies, such as opener, picker, spinning, and woodworking rooms. Hose should be 1½-in cotton, rubber-lined, or unlined linen, with ⅜- or ½-in nozzles. Spray-type nozzles are usually best for the hazards mentioned. The water supply should preferably be taken from a connection independent of the sprinkler piping so that hose streams will be available when the sprinklers are shut off after a fire or during sprinkler repairs or changes. Small hose, for fire service only, in locations of ordinary hazards, may be connected to wet pipe sprinkler systems, but in no case should hose connections be made to sprinkler lines smaller than 2½-in diam. (See Sec. 8.7.)

SPECIAL FORMS OF FIRE PROTECTION

Special types of protection are adapted to the control of unusual hazards, such as flammable liquids. Equipment should be secured from makers specializing in the form of protection required, but such use does not supplant general building protection by automatic sprinklers.

Water Spray A dense strong spray of water from suitably designed nozzles is effective for controlling fires in flammable liquids of moderate hazard, for unusually flammable solid materials, and for surface fires of ordinary combustible materials. Such a system may be most appropriate for the protection of transformers and other oil-filled electric equipment and for systems handling fuel or lubricating oil under pressure. The entire zone to be protected must be within reach of the strong spray. Water pressures of 50 lb/in^2 prevail with properly designed equipment. (See Sec. 3.3.)

Foam Foams for fire control provide a blanketing action to exclude air and in some cases to give useful insulating effect. Foams

are commonly designated as "chemical foam" and "air foam," depending upon their service or method of production. For flammable-liquid fires, foam is available for manual or automatic applications with a selection of characteristics appropriate for a wide variety of conditions. The amount of foam varies from ½ ft^3 to several cubic feet per square foot of surface protected. Rate of application and means of distribution largely determine its effectiveness. A sprinkler system, designated as "Foam-water," provides an initial discharge of very fluid foam backed up by a sprinkler discharge of water. Special **alcohol type** foam is needed for application to alcohols, alcohol-type liquids, and organic solvents, all of which seriously break down the commonly used foams. **High expansion** foams are available. They are easily produced in a **high expansion foam generator** by blowing air through a screen wet with a continuous spray of water having a bubble producing additive. The foam is very light and fluid and can be applied to fill completely and quickly a room or other enclosed area of considerable size. One gallon of high-expansion foam-producing liquid can form as much as 1,000 gal of foam. Ordinary foam producing liquids yield only about 10 gal of foam per gal of liquid.

Carbon Dioxide (29 CFR 1910.161) For (1) flammable liquids; (2) electric equipment, such as large enclosed electric generators; and (3) hazards where a space-filling effect by an inert atmosphere is needed, or where a nonwetting extinguishing agent is desired. Carbon dioxide for fire extinguishing is available in small cylinders for manual use, in banks of large cylinders, or in refrigerated storage tanks for piped extinguishing systems.

Dry chemical (29 CFR 1910.160) extinguishers and extinguishing systems are mainly used for flammable liquids and electrical fires. They are effective also on surface fires in combustible fibers. Multipurpose dry chemical extinguishers have special ingredients which make them suitable for fires in ordinary combustibles.

PORTABLE HAND EXTINGUISHERS

(29 CFR 1910.157)

Hand-operated extinguishers and small hose are effective when employees are on hand to attack fires immediately after discovery. They are frequently used to put out the final vestiges of fires brought under control by automatic sprinklers. Grouped by hazards, the hand extinguishers are selected from four classifications, as shown by Table 18.3.1.

Table 18.3.1 Portable Extinguishers by Hazard Classification

Extinguisher type	Class A general purpose	Class B flammable liquids	Class C electrical fires	Class D combustible metal
Foam	x			
Loaded stream	x	x		
Dry chemical		x	x	
CO_2 (plastic horn)		x	x	
Vaporizing liquid		x	x	
Dry powder				x

18.4 PATENTS, TRADEMARKS, AND COPYRIGHTS

by Raymond E. Farrell and Bernadette M. Bennett

PATENTS

REFERENCES: Chisum, "Patents," Matthew Bender, Patent Act of 1952, 35 U.S.C. Rules of Practice of U.S. Patent and Trademark Office, 37 CFR §1, et seq. U.S. Patent and Trademark Office website (www.uspto.gov).

United States

(All statutory references are to the Patent Act of 1952, 35 U.S.C., et seq.)

Types of Patents Granted in the United States United States patents are classified as utility, design, and plant patents with the first category comprising the vast majority of patents granted in the United States. A design patent can be obtained for any "new, original and ornamental design for an article of manufacture" (35 U.S.C. §171). The emphasis in design patents is on the ornamental, rather than functional, aspects of the article of manufacture. A plant patent may be obtained by "whoever invents or discovers and asexually reproduces any distinct and new variety of plant" (35 U.S.C. §161), and gives that person the right to exclude others from asexually reproducing the plant or selling or using the plant so produced (35 U.S.C. §163).

The Patent Grant In return for a full disclosure of an invention to the public in the patent document, the United States will grant to a patentee, his or her heirs or assigns, the **right to exclude** others from making, using, offering to sell, or selling the patented invention, including products made by a patented process, within the United States; or importing into the United States any patented invention, including products made by a patented process, during the term of the patent (35 U.S.C. §154). Patent rights may be assigned or licensed to other persons or entities. Multiple licenses can be granted under a single patent, giving each licensee nonexclusive rights under the patent. Geographic and use limitations are also possible in a license as a means of maximizing the patent owner's benefit from her or his patent. The right to exclude conferred by a patent may be exercised by the patent owner in the form of an infringement action in the federal court system which has exclusive jurisdiction over lawsuits relating to patents. Remedies that may be awarded to the patent owner in the event of a successful infringement action include injunction against further infringement, damages which may be increased up to 3 times the amount found in the case of willful infringement, and in exceptional cases attorneys' fees (35 U.S.C. §§281–289). A provisional right of a reasonable royalty is also available for infringement of the claims of a published patent application for the period beginning with the publication date of the application and ending with the patent issue date. This remedy is available if the published claims are substantially identical to the claims which ultimately issued in the patent (35 U.S.C. §154).

The exclusionary right granted by a patent *does not* grant to the patentee any express right to make, use, offer to sell, or sell the patented invention. The patentee's ability to perform any of these acts is the same as that of any one else; i.e., the performance of such acts is subject to the claims of any other enforceable U.S. patents which may cover any of the acts. Thus, it is possible for a patentee to be infringing another patent which is broader in scope. This could occur, e.g., in the situation where patent A was previously issued to another inventor and is a broader patent than patent B which was issued because it is a patentable improvement over the prior art including the disclosure of patent A. Therefore, prior to making, using, offering to sell, or selling the invention, it is highly recommended that a patent owner conduct a separate evaluation of his or her ability to commercially practice, the invention without infringing the rights of other patents.

Patent Term The term for design patents is 14 years from the issue date of the patent (35 U.S.C. §173). The term for utility and plant patents depends upon its filing date and is subject to the payment of maintenance fees and any express disclaimers which may have been made for a portion of the patent term. The term for patents based on applications filed before June 8, 1995, is the greater of the 20-year term

or 17 years from the patent issue date. Patents based on applications filed on or after June 8, 1995, have a term which begins on the date the patent issues and ends 20 years from the filing date of the application or from the filing date of the earliest application that the patent claims the benefit of. The 20-year term does not begin from the filing date of a prior filed U.S. provisional application or a national application of a foreign country either of which the patent may claim priority to.

Separate patent term adjustments or extensions may be available under certain circumstances for utility and plant patents. For applications filed between June 8, 1995, and May 28, 2000, patent term extensions are available for a maximum of 5 years for delays in the granting of a patent due to interference proceedings (35 U.S.C. §135) or secrecy orders (35 U.S.C. §181) in the case of *original* utility and plant patents, i.e., those which do not claim the benefit of the filing date of an earlier application, or successful appeals of any utility or plant patent to the U.S. Patent and Trademark Office (PTO) or the courts. The term for *original* utility and plant patents based on applications filed on or after May 29, 2000, may be adjusted for certain patent term guarantees afforded by the patent statute at 35 U.S.C. §154. In particular, the term of a utility or plant patent may be adjusted for certain delays on the part of the PTO during prosecution of the application; the failure of the PTO to issue a patent within 3 years from the actual filing date in the United States; delays to an original patent application due to interference proceedings (35 U.S.C. §135), secrecy orders (35 U.S.C. §181), and successful appeals to the PTO or courts. For a limited number of patents with very special types of claims delineated in the patent statute, the term of the patent may be extended or restored (35 U.S.C. §§155–156). After a patent expires, which may occur at the end of its term including any adjustments and extensions or upon the failure to pay required maintenance fees, the subject matter of the patent enters the public domain.

Determining What Is Patentable The basic statutory requirements for patentability are utility of the invention (35 U.S.C. §101), novelty (35 U.S.C. §102), and nonobviousness (35 U.S.C. §103). To meet the utility requirement, an inventor need only disclose in his or her patent an invention which is new, useful, and nonobvious in the field of applied technology as opposed to theoretical or abstract ideas.

The novelty and nonobviousness requirements of the patent laws are assessed in light of the prior art which generally comprises all written materials antedating the inventor's application for a patent and/or his or her actual date of invention (see section on interferences below for more detail on what constitutes date of invention). Also included in prior art are prior public uses and sales by others of the same or similar processes or products as that of the inventor. A prior public disclosure or offer to sell by the inventor made more than 1 year before the inventor's patent application also constitutes prior art which can prevent the grant of a patent [35 U.S.C. §102(b)]. Thus, it is crucial that patent applications be promptly filed (within a year) after any effort at commercial exploitation of an invention by or on behalf of the inventor. If, however, the inventor wishes to secure foreign patent protection, it is imperative that a U.S. or an international application under the Patent Cooperation Treaty be filed before the inventor makes any such public disclosure or offers to sell the invention. This is so because foreign countries require absolute novelty and do not provide any grace period in which to file a patent application. In assessing an invention against the novelty requirement of 35 U.S.C. §102, the courts have held that if the invention is different—without regard to how different—from each item of prior art, it meets that requirement. In other words, if no single piece of prior art discloses the invention, it is considered novel under 35 U.S.C. §102.

Since few inventions—at least not those for which patent protection is sought—are identical to any single item of prior art, the patentability of most patents must be assessed under 35 U.S.C. §103, i.e., whether "the differences between the subject matter sought to be patented and the prior art are such that the subject matter as a whole would have been obvious at the time the invention was made to a person having ordinary skill in the art to which said subject matter pertains." Such assessment requires a factual determination at the time of the invention of: the prior art, differences between the prior art and the invention, the level of skill in the art to which the invention pertains, and a further assessment whether those differences would have been obvious in light of the level of skill of the practitioners in the art. To assist in this determination, the Supreme Court has indicated that courts should look to important background facts such as long-felt need for the invention, failure of others to achieve the invention, and ultimately, any commercial success of the invention [*Graham v. John Deere Company of Kansas City,* 383 U.S. 1, 86 S.Ct. 684 (1966)].

Documentation of an Invention Recordation of developments is essential in ongoing research. A notebook is commonly used to record, explain, and date research work. The notebook entries should be signed by the researcher and witnessed by one or more persons who have direct knowledge of, and understand, what was being done during the making of the invention.

During patent proceedings, proof of the date of invention may become critical. The date of invention may become important to antedate a prior art reference or to determine priority of invention as between two inventors in a PTO interference proceeding. In both instances, the priority of invention usually must be established by contemporaneous, witnessed documentation of the work underlying the invention as contained in the researcher's notebook. Hence, a notebook is invaluable to prove the invention date.

In light of globalization, inventive activity is not limited to the borders of the United States. The patent statute at 35 U.S.C. §104 provides that evidence of inventive activity in the territory of a World Trade Organization (WTO) member country, Canada, or Mexico be treated the same as inventive activity in the United States. Thus, companies or individuals engaging in research in foreign countries may rely on that activity to prove a date of invention.

Preparing the Patent Application A recommended first step in preparing an application is to evaluate the prior art and its relation to the invention for which patent protection is to be sought, utilizing the obviousness guidelines of the Supreme Court noted above. The most comprehensive source of prior art patents is located at the PTO in Alexandria, Va., where millions of patents and publications are searchable in the public search room by using computer search tools which facilitate searching the PTO's patent databases including published applications, issued patents, as well as certain foreign applications and patents. Other proprietary search services exist whereby patent searching can be conducted via the Internet without having to physically go to the PTO. Compilations of U.S. patents can also be found in specific libraries designated as Patent and Trademark Depository Libraries (PTDLs) located across the country. Copies of U.S. patents can be viewed and downloaded via the Internet at www.uspto.gov. Search results should be evaluated by a competent patent attorney or agent who can advise whether the invention is patentable over the prior art uncovered and who can also focus on the differences between the invention and prior art when preparing a patent application covering he invention.

If the invention, after careful evaluation, is considered to be patentable, the next step is identification of the proper inventors. In the United States, patent applications are filed in the name of the individual(s) who contributed to all or part of the invention rather than the legal owner of the invention or application, e.g., the inventor's employer. Where two or more persons contributed to all or part of the invention (a joint invention), the respective efforts of these persons must have been made in collaboration with each other and the invention must be the product of their aggregate efforts.

The patent application comprises four essential parts: the specification or detailed description of the invention; claims, particularly pointing out the features which the inventor considers to be his or her invention; a drawing illustrating the invention, where applicable; and an oath or declaration of the inventor(s) stating a belief that he or she believes himself or herself to be the original and first inventor of the invention claimed in the application (35 U.S.C. §§111–115).

In addition to the standard patent application, applicants may elect to file a provisional application. A provisional application only requires the filing of a specification complying with 35 U.S.C. §112, paragraph 1, and drawings where necessary for the understanding of the invention.

The application must be made in the name of the inventors, include the appropriate filing fee and a suitable cover sheet. A provisional application does not require any claims, nor does it require an oath or declaration. A provisional application is not examined by the PTO, cannot claim priority of an earlier application, and cannot issue as a patent. In addition, provisional applications will automatically become abandoned 12 months after filing and can become abandoned prior to the expiration of that 12-month-period for failure to respond to a PTO requirement or to pay a required fee. A provisional application may be revived, but its pendency cannot extend beyond 12 months from its filing date. The provisional application is a form of domestic priority system which provides a quick and inexpensive method to establish an early effective filing date which establishes a constructive reduction to practice for any invention described in the application. However, this priority is only effective provided a suitable nonprovisional application is filed prior to the expiration of the provisional application.

Proceedings in the U.S. Patent and Trademark Office After the application is filed with the appropriate fee, an examiner in the PTO reviews the application to ensure compliance with all statutory requirements as to the form of the application and to independently assess the patentability of the claims in the application in light of the prior art. If the examiner concludes the invention claimed in the application is not patentable over prior art, all such claims will be rejected. The applicant then has the opportunity to rebut the rejection by arguing the novelty of the invention over the prior art and/or amending the claimed invention. If the examiner maintains the rejection of the claims, an administrative appeal to the Patent Office Board of Appeals and Interferences is available to challenge such rejection, and a further appeal to the federal courts is available from an adverse decision of the Board of Appeals (35 U.S.C. §§134, 141, 145). If the claims of the application are found to be patentably distinct from the prior art, a patent will be granted upon payment of an issue fee.

To maintain a patent, the owner must also make periodic maintenance payments to the PTO before the fourth, eighth, and twelfth anniversaries of the patent grant. These maintenance payments increase as the patent ages. Since all the above-mentioned fees change annually, the fees should be determined in advance to avoid the consequences of fee underpayment.

Reissue and Reexamination of Patent If through inadvertence, accident, or mistake, the original patent was defective or claimed too much or too little, the error may be repaired by a reissue proceeding provided the subject matter needed to correct the mistake appeared in the original patent (35 U.S.C. §251). The term of a reissued patent expires the day the original patent would have expired.

Also, if the patentability of a patent is put in question, either the patent owner or a third party may ask the PTO to reexamine and reevaluate the patent vis-à-vis the prior art. The PTO then proceeds to examine the patent much the same as it would with an original application.

Foreign Countries

International Convention for the Protection of Industrial Property The important provision of the convention is that any person who has duly applied for a patent in one of the contracting states shall have a right of priority for 12 months in making application in the other states.

Patent Cooperation Treaty (PCT) and European Patent Convention (EPC) To simplify the process of obtaining foreign patents, it is now possible to file a single application, e.g., in the United States, and have that application mature into a patent in each country worldwide which is a member of the Patent Cooperation Treaty. Similarly, if the focus of intended patent protection is in Europe, a single application in the European Patent Office located in Berlin, Munich, or the Hague can be issued as a patent in most of the countries on the European continent under the European Patent Convention.

Use of either the PCT or EPC provisions will generally be cost-effective versus separate filings in individual countries, since, for example, translation costs are usually minimized or eliminated. However, as in all such complex matters, knowledgeable patent professional counsel should be consulted.

TRADEMARKS

REFERENCES: Callman, "Unfair Competition, Trademarks and Monopolies," Callaghan and Co., Chicago. McCarthy, "Trademarks and Unfair Competition," Lawyers Cooperative, Bancroft-Whitney. Gilson, "Trademark Protection and Practice," Matthew Bender.

United States

[Section references (§) refer to Lanham Act of 1946, and 15 U.S.C., both section numbers being given.]

What Is a Trademark? The term *trademark* includes any word, name, symbol, or device or any combination thereof adopted and used by manufacturers or merchants to identify their goods and distinguish them from those manufactured or sold by others (§45, §1127). A *service mark* is defined as a mark used in the sale or advertising of services to identify the services of one person and distinguish them from the services of others (§45, §1127).

How Rights in a Mark Are Obtained Unlike a patent, but somewhat like a copyright, ownership of a mark is obtained by use. If use occurs only within a state, a mark may be registered in that state. Forms for registering marks under state law are obtainable from the Secretary of State of each state. If use occurs only in interstate or foreign commerce, a mark may be registered in the U.S. Patent and Trademark Office (PTO) by filing an application in the form prescribed (37 CFR Pt. IV). After federal registration the symbol ® may be used with the mark. Prior to federal registration, the symbols **TM** for a trademark or **SM** for a service mark may be used to give notice of a claim of common law or state law rights.

A person who has a bona fide, good-faith intention to use a trademark in commerce, but is not actually using the mark, may apply for federal registration by filing an Intent To Use application in the PTO. Thus, a person who is not actually using a mark may still obtain federal registration provided that person commences using the mark in interstate commerce within a specified period after allowance of the Intent To Use application.

Tests for Registrability and Infringement A mark may be registrable on the Principal Register of the PTO only if, when applied to the goods or used in connection with the services, it is not likely to cause confusion or mistake or to deceive. The same test is used to determine whether a mark infringes on an earlier mark. Marks that are descriptive, misdescriptive, geographical, or primarily merely a surname may not be registrable on the Principal Register, if at all, until after 5 years of substantially exclusive and continuous use in interstate commerce (§2[f], §1052[f]). Marks not registrable on the Principal Register may be registrable on the Supplemental Register if they are capable of becoming distinctive as to the applicant's goods or services (§23, §1091).

Term of Registration Federal registrations remain in force for 10 years unless canceled. However, unless an affidavit is filed during the sixth year after registration showing that the mark is still in use, the Commissioner of Patents and Trademarks will cancel the registration of the mark (§8, §1058). In addition, federal registrations only remain in force for marks which are actually in use. Nonuse of a registered mark can result in finding that the mark has been abandoned by its owner. The law currently provides that nonuse of a mark for 2 years or longer is prima facie evidence that the mark has been abandoned. Within the sixth year after registration on the Principal Register, a registered mark may become more secure from legal challenge, i.e., "incontestable" upon the filing of the required affidavit (§15[3], §1065[b]). During the last 6 months of the registration term, an application for renewal may be filed (§9, §1059). Unlike with patents, an unlimited number of renewals are available for trademark registrations, with the proviso that the mark is in use. The terms of state registrations vary.

Preliminary Search Before adopting a mark, it is advisable to have a search made in the PTO to determine whether the mark under consideration would conflict with any pending application, registrations, or others' use of the mark in connection with any similar goods or services.

Cost of Registering a Mark Government fees and time for payment are fixed by law (§31, §1113) but attorneys' fees vary.

Effect of Federal Registration Federal registration of a mark affords nationwide protection, and once the certificate has been issued, no person

can acquire any additional rights superior to those obtained by the federal registrant. Federal registration of a mark establishes federal jurisdiction in an infringement action, can be the basis for treble damages, and is admissible as evidence of trademark rights. Registration on the Principal Register constitutes constructive notice, constitutes prima facie or conclusive evidence of the exclusive right to use the mark in interstate commerce, may become incontestable, and may be recorded with the U.S. Customs Department to bar importation of goods bearing an infringing trademark.

Assignment of a Mark A mark can be assigned only in conjunction with the goodwill of the business or that portion thereof with which the mark is associated. Assignments of registered marks or of applications for registration should be recorded in the United States Patent and Trademark Office within 3 months after the date of assignment (§10, §1060).

Foreign Countries

The Madrid Protocol Similar to the PCT and EPC processes to obtain foreign coverage of a patent, the Madrid Protocol enables an applicant to file a single trademark application and potentially gain registration worldwide. At present, the Madrid Protocol has 77 countries that are members (also referred to as Contracting Parties). The multistage process begins with the filing of a single international trademark application, e.g., with the PTO, with the possibility that the application will mature into a registered trademark in the member countries selected by the applicant.

If trademark registration is desired in multiple countries, use of the Madrid Protocol will generally be cost-effective compared to separate filings in each individual country. Due to the complexity of international trademark filing, foreign protection of a mark should be undertaken after consultation with an attorney.

COPYRIGHTS

REFERENCES: Nimmer, "Nimmer on Copyright," Matthew Bender. Copyright Act of 1976, 17 U.S.C. §101 et seq. Copyright Office Regulations, 37 CFR, Chapter 2.

United States

[Section references (§) refer to Copyright Act of 1976, 17 U.S.C.]

Subject Matter of Copyright Neither publication nor registration at the Copyright Office is required to secure a copyright. The copyright is automatically established when the work is created. Copyright protection subsists in works of authorship in literary works; musical works including any accompanying words; dramatic works including any accompanying music; pantomimes and choreographic works; pictorial, graphic, and sculptural works; motion pictures and other audiovisual works; sound recordings, and architectural works but not in any idea, procedure, process, system, method of operation, concept, principle, or discovery [§102]. However, copyright protection may be obtained for computer programs, including both the source code and object code. Original designs of useful articles are also subject matter for copyright (§ 1301). Additionally, the law provides explicit protection for vessel hulls. An owner of an original vessel hull design is granted certain exclusive rights provides that the application for registration of the design is made within 2 years of the design being made public. Only designs for actual vessel hulls that are publicly exhibited, publicly distributed, or offered for sale or sold to the public on or after October 28, 1998, are eligible for protection. Issuance of a design patent for the same vessel design terminates protection of the design under Chapter 13 of the copyright law.

Registration Copyright registration is effected by submitting an application to the Register of Copyrights along with the fee (currently $30). Deposit requirements exist for applicants to submit copies of the works. These requirements vary for different types of works to be registered. Forms for the registering the various types of works as well as informative circulars are available from the Library of Congress via the Internet at www.copyright.gov. Although a copyright may be registered any time during its term, in order to preserve the maximum available statutory remedies for infringement, the copyright should be registered within 3 months of first publication of the work, or in the case of unpublished works it should be registered as soon as the work is in its fixed form (§412).

Form of Copyright Notice Use of copyright notice is no longer required in the United States. However, the notice should still be used because it informs the public that the work is protected by copyright, identifies the copyright owner, and shows the year of first publication. Should there be an infringement of the work, if a proper notice of copyright is used on the published copy or copies and the infringer had access to the copy, then a defense based on innocent infringement in mitigation of actual or statutory damages will be given no weight except as provided in §504(c)(2) of the copyright law.

If a notice is placed on the copies, it shall consist of three elements: (1) the symbol © (c in a circle), or the word *Copyright*, or the abbreviation *Copr.*; (2) the year of first publication of the work; and (3) the name of the copyright owner (§401). For phonorecords, instead of the © symbol, the notice shall include the symbol Ⓟ(P in a circle) as well as the other two elements (§402).

Who May Obtain Copyright Only the author or those deriving their rights through the author can rightfully claim copyright protection. Where a copyrighted work is prepared by an employee within the scope of his or her employment (a "work made for hire"), the employer and not the employee is considered to be the author. The name of the author (creator of the work) is normally used in the copyright notice even though an assignee may file the application for registration.

Duration of Copyright Copyright in a work created on or after January 1, 1978, subsists from its creation and, with certain exceptions, endures for a term consisting of the life of the author and 70 years after the author's death (§302). Where the work was not a work for hire and is a joint work prepared by two or more authors, the term lasts for 70 years after the last surviving author's death. For works made for hire, and anonymous and pseudonymous works where the author's identity is not revealed in Copyright Office records, the duration of copyright will be the shorter of 95 years from publication or 120 years from creation. Copyright in a work created before January 1, 1978, but not theretofore in the public domain or copyrighted, subsists from January 1, 1978, and endures for the term provided by §302. In no case, however, shall the copyright term in such a work expire before December 31, 2002; and, if the work is published on or before December 31, 2002, the term of copyright shall not expire before December 31, 2047 (§303). Any copyright, the first term of which is subsisting on January 1, 1978, shall endure for 28 years from the date it was originally secured, with certain exceptions (§304). All terms of copyright provided by §302–304 run to the end of the calendar year in which they would otherwise expire (§305).

Infringement of Copyright A violation of any of the exclusive rights (§1) by a person not licensed could lead to liability (§101) for infringement. Actions for infringement of copyright are brought in the U.S. district courts.

Foreign Countries

The Berne Convention Under this convention a U.S. citizen may obtain a copyright in most countries of the world simply by publishing within the United States.

REFRIGERATION MACHINES AND PROCESSES

(For general theory of refrigeration, see Sec. 4; for air-conditioning uses, see Sec. 12.4; for cryogenics, see Sec. 19.2.)

Refrigeration is a term used to describe thermal systems which maintain a process space or material at a temperature less than available from ambient conditions. Heat is transferred from the materials to be cooled into a lower-temperature substance referred to as the **refrigerant.** The refrigerant is cooled by physical processes which pump heat into the ambient environment. These apply several physical phenomena such as phase changes, sensible heating, thermoelectric effects, work extraction by mechanical devices, and endothermic chemical reactions. Stored energy in the form of ice, sublimating solid carbon dioxide, and cold liquids are included with processes described by the word **refrigeration.**

Many refrigeration systems use a continuous cycle. This requires that the refrigerant be recovered for recycling after it has absorbed heat from the product or space to be cooled. The most commonly used system has a recirculating fluid that boils at a low temperature to remove heat. The vapor is compressed to a pressure such that the condensing temperature is elevated. The vapor is cooled and condensed by a heat exchanger which rejects the heat into the environment. The condensed liquid is passed through a restricting valve or orifice. The liquid changes into a mixture of liquid and vapor that is colder than the refrigerated space. This expansion at constant enthalpy is known as the *Joule-Thompson effect*. An expansive turbine can remove heat from a high-pressure vapor by extracting energy in the form of mechanical work. When the exhaust conditions are proper, the material will be a mixture of gas and condensate. This fluid can be used as a refrigerant or stored in liquid form as product. The remaining vapor can be recycled as needed to continue the process.

The equipment used in refrigeration processes is referred to as follows: high-pressure vapor heat exchangers are called *condensers,* low-pressure heat exchangers are called *evaporators,* throttling devices are called *expansion valves* or *capillaries,* and pressure-raising devices are called *compressors*.

With continuous recirculation of the cycle fluid, the low-temperature heat pickup must be pumped, via energy input, to a higher level so as to discharge it to atmospheric temperature. In this sense the system acts as an **energy-transport** device or **heat pump** or, from another viewpoint, as a temperature transformer. This philosophy of energy transport may equally well be applied to more remote systems, such as thermoelectric. It is, of course, a manifestation of the principles of the Second Law, and the effectiveness of the system's operation may be evaluated numerically.

Efficiency ratings of refrigeration equipment are expressed several ways. Some of the more common terms include **coefficient of performance** (COP) and **energy efficiency ratio** (EER). **COP** is defined as refrigerant effect divided by net work input, where the refrigerant effect is the absolute value of the heat transferred from the lower temperature source, and the net work input is the absolute value of heat transferred to the higher temperature sink minus the refrigerant effect. COP can alternatively be defined as the ratio calculated by dividing the total heating capacity in Btu per hour provided by the refrigeration system, including circulating fan heat, but excluding supplementary resistance, by the total electric input in watts × 3.412. This definition applies primarily to heat pumps. **EER** is a ratio calculated by dividing the cooling capacity in Btu per hour by the power input in watts at any set of rating conditions, expressed in Btu/W · h.

Because load on equipment used for comfort applications varies, additional criteria to rate efficiency at part load have been introduced. ARI Standard 550/590-1998 has **integrated part load value** (IPLV) and **nonstandard part load value** (NPLV). The IPLV uses a standard rating point with specific values for evaporator and condenser temperatures, water flows, and fouling factors at specific load percentages. The NPLV allows selection of these values to be more representative of the actual operating conditions. Other terms used primarily for residential and commercial air-conditioning units and heat pumps include **seasonal energy efficiency ratio** (SEER) and **heating season performance factor** (HSPF). These also adjust ratings for the variations encountered over a normal heating or cooling season.

The various association and society standards have specific conditions at which equipment is rated. In efficiency comparisons, familiarity with the specific rating method is important. The factors used in the calculation of manufacturer's published data may not be representative of the specific application. Part load conditions must be considered in any evaluation when the unit will not normally be fully loaded. If the load is constant and is known, comparisons should be made at that point. Other important factors include whether the stated efficiency is just the compressor efficiency, or if it includes motor, seal, bearing, and drive losses. It is also recommended that rated operating conditions be adjusted to actual conditions when known. For example, the actual condensing temperatures may be significantly higher or lower than rated conditions depending on the geographic region.

Units of Refrigeration In the United States, refrigeration capacity is defined in terms of the standard ton. A **standard ton of refrigeration** corresponds to a heat absorption at a rate of 288,000 Btu/day or 200 Btu/min (3.5168 kW). The heat absorption per day is approximately the heat of fusion of 1 ton (907.19 kg) of ice at 32°F (0°C). The **standard rating** of a refrigerating machine, using a condensable vapor, is the number of standard tons of refrigeration it can produce under the following conditions: (1) liquid only enters the expansion valve and vapor only enters the compressor or the absorber of an absorption system; (2) the liquid entering the expansion valve is subcooled 9°F (5°C) and the vapor entering the compressor or absorber is superheated 9°F (5°C), these temperatures to be measured within 10 ft (3.05 m) of the compressor cylinder or absorber; (3) the pressure at the compressor or absorber inlet corresponds to a saturation temperature of 5°F (−15°C); and (4) the pressure at the compressor or absorber outlet corresponds to a saturation temperature of 86°F (30°C).

The **British unit of refrigeration** corresponds to a heat-absorption rate of 237.6 Btu/min (4.175 kW) with inlet and outlet pressures corresponding to saturation temperatures of 23°F (−5°C) and 59°F (15°C), respectively. In locations outside the United States it is common practice to use kilowatts to specify refrigeration capacity. One kilowatt of refrigeration capacity is roughly equivalent to 0.2844 tons. Occasionally a unit of refrigeration capacity called the **frigorie** is used. A frigorie is approximately equivalent to 50 Btu/min (0.8786 kW), or one-quarter of a standard ton of refrigeration.

PROPERTIES OF REFRIGERANTS

(For detailed properties, see Sec. 4.)

Refrigerants are the transport fluids which convey the heat energy from the low-temperature level to the high-temperature level, where it can, in terms of heat transfer, give up its heat. In the broad sense, gases involved in liquefaction processes or in gas-compression cycles go through low-temperature phases and hence may be termed "refrigerants," in a way similar to the more conventional vapor-compression fluids.

Refrigerants are **designated by number**. The identifying number may be preceded by the letter R, the word "Refrigerant," or the manufacturer's

trademark or trade name. The trade marks or trade names shall not be used to identify refrigerants on equipment or in specifications. ANSI/ASHRAE Standard 34-2001, "Designation and Safety Classification of Refrigerants," and addenda cover the designation methodology and safety classifications for toxicity and flammability.

The **safety classification** is designated by a two-character alphanumeric system. The first character indicates toxicity, and is either an A or B, with lower toxicity indicated by an A. The second character indicates flammability, and is a 1, 2, or 3, with the lowest flammability indicated by a 1.

There are two terms widely used to describe the relative effect refrigerants and other chemicals have on the environment. The **ozone depletion potential** (ODP) is the ozone-destroying effect of a substance compared to a similar mass of Refrigerant 11. The **global warming potential** (GWP) is the relative measure of the warming caused by a substance versus a similar mass of carbon dioxide. Substances that increase global warming are referred to as "greenhouse gases."

Much of the damage to the atmospheric ozone layer is believed to be the result of decomposition of chlorofluorocarbon (CFC) and hydrochlorofluorocarbon (HCFC) chemicals. An international agreement known as the Montreal Protocol took effect in 1989. This agreement and subsequent amendments to it resulted in scheduled phaseouts of CFC and HCFC refrigerants. The schedule is dependent on the specific refrigerant and the country, with CFCs and developed nations having the most aggressive phaseouts.

International legislation has primarily addressed ozone depletion; however, global warming is an important and an emerging issue. There have been international meetings initiated by the United Nations Environmental Programme (UNEP) resulting in the Kyoto Protocol. Framework to reduce global warming has been developed, and legislation is being proposed. As with ODP, both CFC and HCFC refrigerants are affected. In addition, the replacement hydrofluorocarbon (HFC) refrigerants are under increased scrutiny, especially in Europe. Global warming is a significantly more complex issue since there are many sources of greenhouse gas emissions. A common debate is whether HFC equipment has a lower overall global warming impact due to its higher efficiency and reduced power consumption than refrigerants with lower GWP but higher power consumption. A listing of the ODP, GWP, and 8-hour toxicity limits (AEL or TLV) for various refrigerants is given in Table 19.1.1.

As a result of the legislation requiring phaseout of CFC and HCFC refrigerants, new refrigerants, primarily HFCs, have been commercialized to replace them. There has also been a renewed interest in nonhalocarbon refrigerants such as ammonia and carbon dioxide. A listing of **replacement refrigerants** for existing CFC and HCFC compounds is given in Table 19.1.2.

Table 19.1.1 Environmental Properties of Refrigerants

Refrigerant	ODP	GWP	Toxicity, ppm (v/v)	AEL,* TLV†	Flash point, lower/upper, vol. %
R-11	1	4600	1000	TLV	None
R-12	1	10600	1000	TLV	None
R-22	0.055	1700	1000	TLV	None
R-114	1	9800	1000	TLV	None
R-123	0.02	95	50	AEL	None
R-124	0.22	599	1000	AEL	None
R-125	0	2800	1000	AEL	None
R-134a	0	1300	1000	AEL	None
R-401A	0.037	1120	1000	AEL	None
R-401B	0.04	1220	1000	AEL	None
R-402A	0.021	2330	1000	AEL	None
R-402B	0.033	2080	1000	AEL	None
R-404A	0	3260	1000	AEL	None
R-407C	0	1530	1000	AEL	None
R-410A	0	1730	1000	AEL	None
R-502	0.334	4520	1000	TLV	None
R-508B	0	10350	1000	AEL	None

*AEL is the recommended time-weighted average concentration of an airborne chemical to which nearly all workers may be exposed during an 8-h and/or 12-h day, 40-h week without adverse effect. Determined by E. I. du Pont de Nemours and Company for compounds that do not have a TLV.

†TLV, established for industrial chemicals by the American Conference of Governmental Industrial Hygienists, is the recommended time-weighted average concentration of an airborne chemical to which nearly all workers may be exposed during an 8-h day, 40-h week without adverse effect.

Table 19.1.2 Replacement Refrigerant Compounds

Current refrigerant	Replacement refrigerant	Type	Application*
R-11 (CFC)	R-123 (HCFC)†	HCFC	Chillers [+25°F (−3.9°C)]
R-12 (CFC)	R-134a†	HFC	Medium temp [−5°F (−20.6°C)]
	R-401B	HCFC	
R-13 (CFC)	R-508B	PFC	Low temp [−80°F (−62.2°C)]
R-22 (HCFC)†	R-407C	HFC	Retrofit and new equipment
	R-410A	HFC	New Equipment
R-500 (CFC)	R-401B	HCFC	
R-503 (CFC)	R-508B	PFC	

*Lower optimum use temperature.

†See Figs. 19.1.1 to 19.1.3 for the thermodynamic properties of R-22, R-123, and R-134a.

SOURCE: Data from E. I. du Pont de Nemours and Company, Bulletin 300151B.

The term "replacement refrigerant" does not mean the replacement can simply be substituted for the existing refrigerant in the existing equipment. In many cases "replacement" refers to the application, such as temperature range, capacity range, or compressor type. Where existing equipment can be converted, the new refrigerant may not be miscible with the petroleum-based lubricant used with the CFC refrigerant. Synthetic oils such as polyol ester and polyalkylene glycol must be used with the new refrigerants. Seals, bushings, gaskets, and motor insulation (hermetic machines) may also need replacement. Centrifugal machines may require compressor wheel or speed changes to meet the head requirements of the replacement refrigerant. Controls may need to be replaced or reset. The resulting efficiency and capacity will likely be different from that of the original machine.

The owner must decide whether field conversion is justified. The following should be considered: the cost of conversion versus the cost of a new machine, the anticipated capacity and efficiency of the converted equipment versus that of a new machine, and the condition and remaining life of the converted equipment.

The refrigerant charge in a system must be handled in an environmentally acceptable manner to accomplish repairs requiring refrigerant removal. Venting of refrigerant is prohibited. Sections 608 and 609 of the Clean Air Act mandate the recovery of CFC, HCFC, HFC, and PFC refrigerants. The rules on recovery, recycling, repair of leaks, reporting, record keeping, and technician certification are strict, with the imposition of severe penalties for violation. For further information concerning regulations related to refrigerants, visit the EPA's website at http://www.epa.gov.

The **normal boiling point** is an important attribute of refrigerants for vapor compression systems. The desirable characteristic is a positive gage pressure throughout the refrigerating system. This will eliminate contamination of the refrigerant and resulting heat-transfer inefficiencies due to air inleakage. Table 19.1.3 shows some common fluids in order of boiling point: included are halocarbon compounds that offer reduced ozone depletion potential, hydrocarbons, sulfur compounds, and inorganic compounds.

The desirable thermal properties of a refrigerant are (1) convenient evaporation and condensation pressures, (2) high critical and low freezing temperatures, (3) high latent heat of evaporation and high vapor specific heat, (4) low viscosity and high film heat conductivity. Desirable practical properties include (1) low cost, (2) chemical and physical inertness under operating conditions, (3) noncorrosiveness toward ordinary construction materials, and (4) low explosive hazard both alone and mixed with air. The refrigerant should be nonpoisonous and nonirritating and should not cause deterioration in the lubricant used. Leakage should be detectable by simple tests, easily performed.

The **specific volume of refrigerant** to be handled determines the size of positive displacement compressors, but with centrifugal compressors a large volume is not objectionable and may be an advantage for small units.

A comparison of various refrigerants based on *ideal performance* is given in Table 19.1.4. The results are for the **standard temperature range**

* Values may be slightly in error.

of 5 to 86°F (−15 to 30°C) and also for certain other ranges. For these calculations, zero piston clearance and expansion through a throttle valve were assumed. The use of an expansion cylinder instead of a valve would have yielded work (available for supplying some of the work of compression), but this is always a negligible quantity, except when the compression pressure approaches the critical pressure, as for carbon dioxide. Theoretical *coefficients of performance* may be obtained by dividing 4.72 by the theoretical horsepower given in the table.

Ammonia (R-717) is used extensively in commercial, industrial, and moderately low-temperature installations. It is toxic, and recent laws regulate the operation, maintenance, and design of ammonia systems that contain 10,000 lb of refrigerant or more. (See Document 29 CFR 1910.119 of the Federal Register for further information.) Ammonia is provided commercially in several purity grades. It is recommended that refrigerant-grade anhydrous ammonia of 99.95 percent purity be used. Moisture contamination from impure ammonia will accumulate in evaporator coils and inhibit performance. Ammonia is corrosive to copper and copper-bearing alloys. It is not miscible to any large extent with lubricating oils. Exposure to it in a confined space at concentrations below 400 ppm is rarely fatal. Ammonia is immediately fatal at 0.5 to 0.6 percent by volume. The presence of ammonia can be detected by burning a sulfur candle in the vicinity of a leak. A white cloud will form if ammonia vapors are present. Hydrochloric acid solutions and wetted litmus papers will also react with ammonia to give visible evidence of the presence of vapors. See Tables 19.1.5 and 19.1.6 for thermodynamic properties of R-717.

Carbon dioxide (R-744) was used for a long time as a "safety refrigerant." It is not toxic, and exposure to it is not dangerous unless concentrations are high. Like many other refrigerants, it is heavier than air, and caution must be exercised in confined spaces, as it may displace oxygen and result in asphyxiation. With cooling water at 70°F (21°C), the condensing pressure of CO_2 is high, and since its critical temperature is 87.8°F (31°C), condensation will not occur at water temperatures above this. Specific power consumption is high on CO_2 machines.

Sulfur dioxide (R-764) has rapidly gone out of use. It is extremely corrosive unless absolutely anhydrous. It is extremely irritating in small concentrations and toxic in high concentrations.

Methyl chloride (R-40) (CH_3Cl), an anesthetic in amounts of 5 to 10 percent by volume, has been used in air-cooled units of moderate or small sizes. It is miscible with mineral oils; small amounts of moisture in a methyl chloride system will cause trouble by freezing in expansion valves.

For industrial work, butane (C_4H_{10}), propane (C_3H_8), and, at low temperatures, ethane (C_2H_6) are used. **Dieline** (dichloroethylene, $C_2H_2Cl_2$) and **Carrene** (dichloromethane, CH_2Cl_2) have been used to some extent, usually in centrifugal compressors.

In order to create refrigerants with thermodynamic properties similar to those being phased out, some refrigerants are blends of two or more other refrigerants. Blends have 400 and 500 series designations. For example, R-407C is a blend of three HFC refrigerants, R-32, R-125, and R-134a. It is designed to be used in new equipment and as a service replacement for existing R-22 machines. The thermodynamic properties are shown in Fig. 19.1.4.

Use caution when using blended refrigerants in centrifugal compressors. The compressor impeller may act to separate the components of the blend by molecular weight. For safety purposes, blends are classified on the basis of worst-case fractionation.

Building codes often require monitoring of refrigerant levels in equipment spaces. In addition to a monitor, an alarm system and exhaust facilities should be installed to prevent exposure above the acceptable exposure limit (AEL). ANSI/ASHRAE 15-2004, "Safety Standard for Refrigeration Systems," and addenda have recommendations covering equipment room safety.

Leak Detection Detection and repair of refrigerant leaks is an essential part of responsible refrigeration equipment operation. Worker safety, environmental impact, and refrigerant cost are the primary reasons for a detection and repair program. Section 608 of the Clean Air Act as amended July 24, 2003, has rules governing the keeping of service records documenting the date and type of service and the quantity of refrigerant added. This currently applies to equipment that contains 50 or more pounds of refrigerant.

Area monitors are useful for determining that a leak has occurred. Handheld detectors are useful for determining a specific leak location. For many years, refrigerant leaks were detected with a halide torch. Copper gauze was kept hot by the essentially colorless flame of burning methyl alcohol. An intense green color was imparted to the flame by the presence of even minute amounts of chlorine. The alternative refrigerants have no chlorine or a lower amount of chlorine. Some refrigerants are flammable. New types of detection equipment are required.

Nonselective, halogen-specific, and compound-specific detectors are available. Each type has limitations, and selection must be based on the specific application. For example, the nonspecific-type detector is poorly suited for area monitoring because of its high detection limit and potential for false alarms, but is a reliable, low-cost choice for pinpointing leaks. The halogen-specific detectors can be applied for either leak pinpointing or area monitoring. They are best applied where only one refrigerant is in use. The compound-specific detectors are relatively expensive, but are very selective. They are best applied in environments where several refrigerants or other chemical compounds may be present.

The pressure-temperature relations for the saturated vapors of many of the commercially important refrigerants are given in Fig. 19.1.5. If the temperature at which the refrigeration is desired and the temperature at which heat can be discarded (condenser temperature) are known, the chart is convenient for determining for any chosen refrigerant the pressures which must be maintained. For instance, if the use of methyl chloride is contemplated in an air-cooled cabinet food freezer located in a room where the air temperature may rise to 90°F (32°C), the compressor discharge must be at least 100 psia (690 kPa absolute), and if the cabinet cooling coil is to be held at −30°F (−34°C), compressor suction will be 9 psia (62 kPa absolute).

The large volumes required for HCFC-123 and dieline can be handled satisfactorily by centrifugal compressors. When the evaporating pressure is below atmospheric—as in the case of HCFC-123, dieline, ammonia in food freezers, sulfur dioxide, water vapor, and butane—air leaks are likely to occur. The air tends to accumulate in the condenser and the heat-transfer performance is degraded.

Refrigerating systems which operate with a positive pressure in the equipment will leak refrigerant into the atmosphere. Many HFC- and HCFC-type refrigerants are practically odorless. Dangerous concentrations can build up in unventilated enclosed rooms such as freezers should a significant leak occur. Leak detection devices are available commercially to provide warnings of equipment leakage before harmful

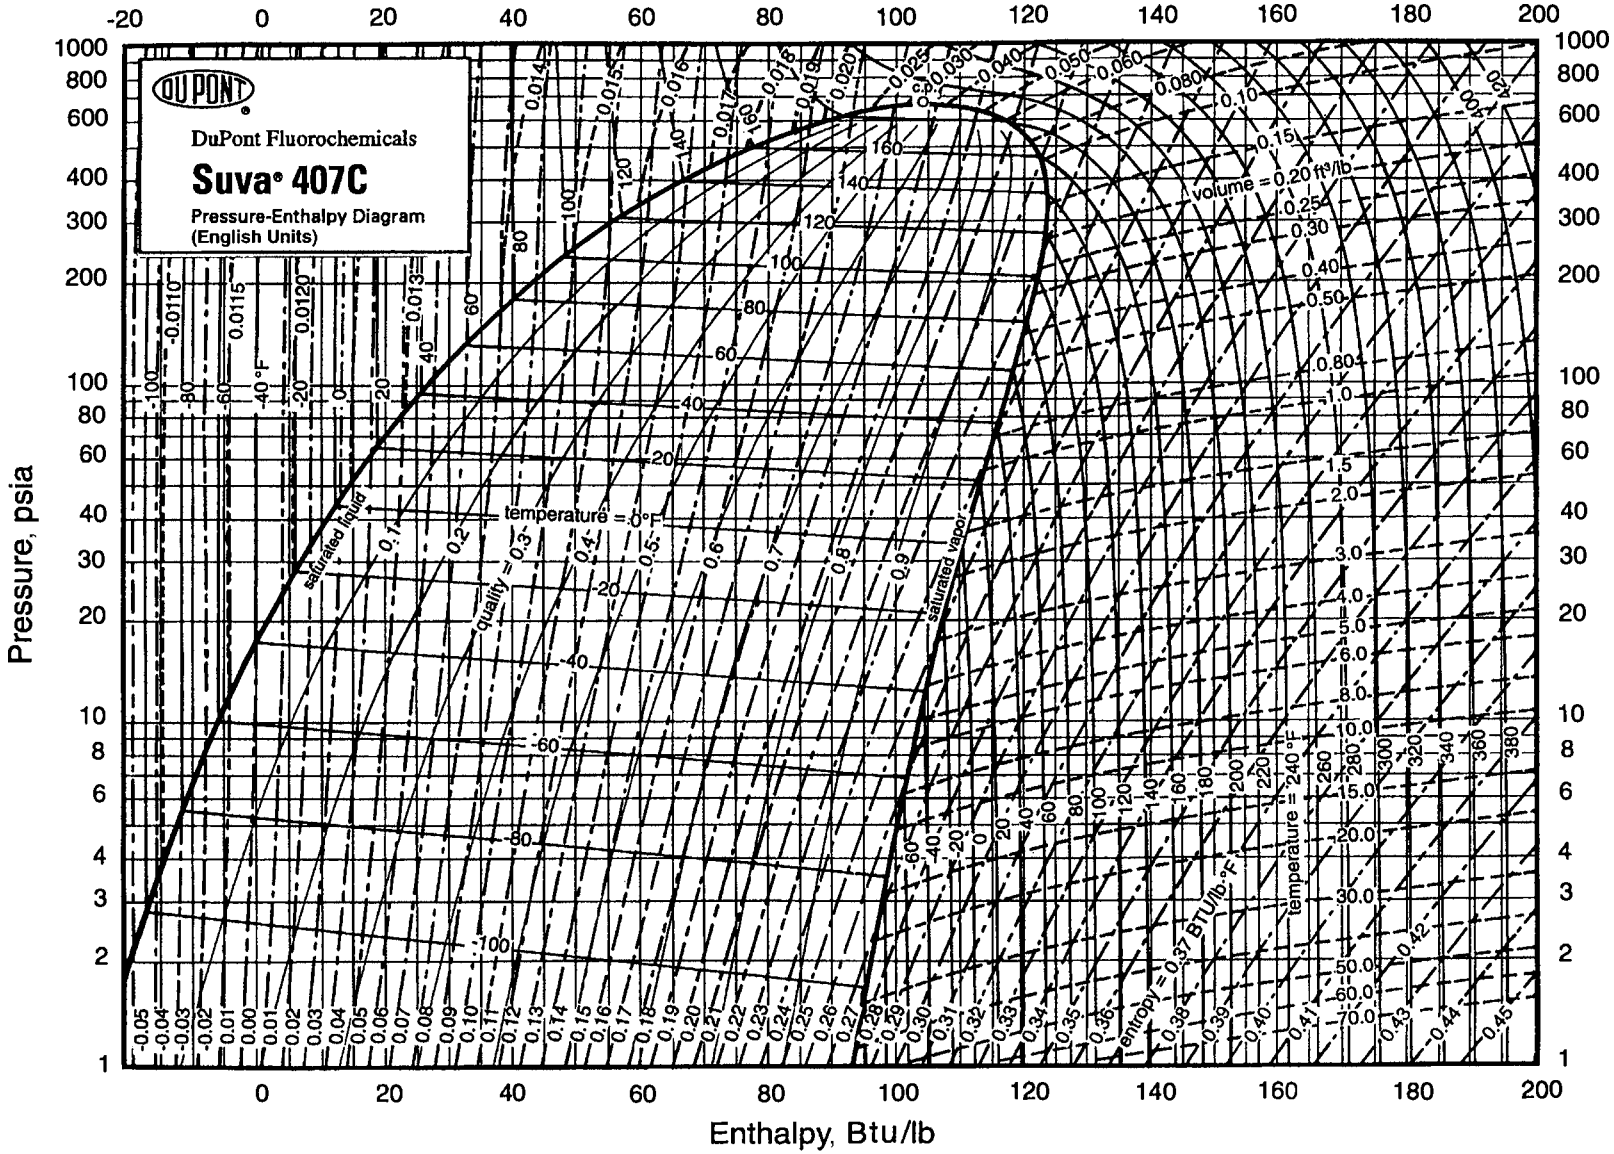

Fig. 19.1.4 Thermodynamic properties of SUVA® 407C (R-407C). (*Reprinted with permission of E. I. du Pont de Nemours and Company.*)

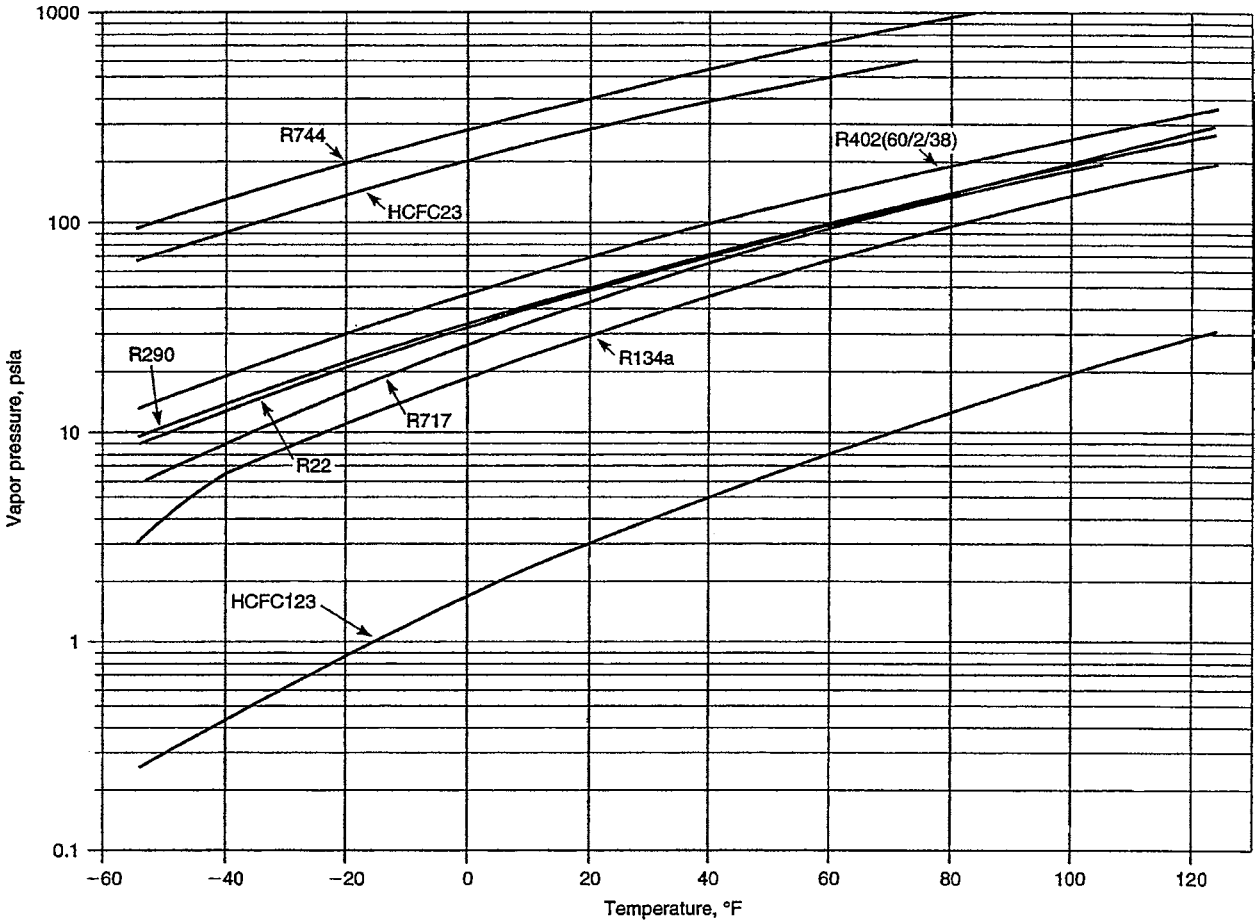

Fig. 19.1.5 Pressure-temperature relations for saturated liquids of refrigerants.

concentrations are present in occupied spaces. Addition of certain fluorescent compounds into the refrigerant in an operating system will allow identification of equipment leaks. The additives are placed into the refrigeration lubricant when the system is serviced or charged. The compound travels through the system with the refrigerant and oil mixture. At the point of leakage, the fluorescent compound escapes from the system, and is left as a deposit on the outside surface of equipment. When illuminated by ultraviolet light, the deposit at the leak point becomes visible.

OVERALL CYCLES

Figure 19.1.6 represents the simple closed-circuit **vapor-compression** system. The upper heat exchanger is a vapor condenser (with some superheat), and after the throttling expansion valve, the lower one is the evaporator in which the refrigerant liquid at reduced pressure and temperature evaporates with the inward refrigeration heat flow. The refrigerant vapor is elevated by the compressor to a higher pressure and condensing temperature so that it will liquefy in its transfer of heat to the atmospheric level. Figures 19.1.7 and 19.1.8 illustrate the cycle.

Figure 19.1.9 is the counterpart of Fig. 19.1.6 and represents the closed sensible-heat **gas-compression** cycle, with an expander (either displacement or turbine-type) parallel to a gas compression which may provide a compressor-work "assist" in addition to its exhaust stream of cold gas. This is the refrigeration version of the Brayton cycle (see Sec. 4),

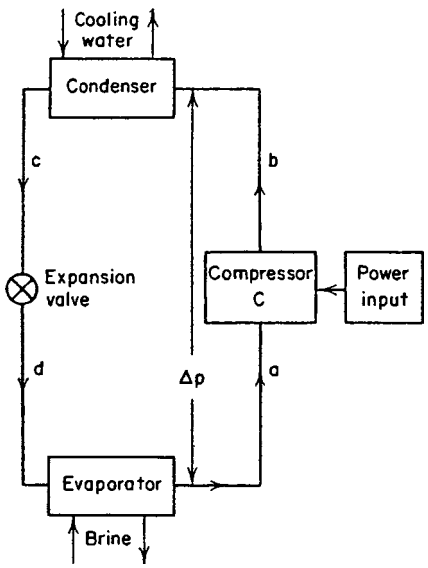

Fig. 19.1.6 Simple closed-circuit vapor-compression system.

the upper exchanger serving to cool the hot compressed gas, and the lower exchanger handling the sensible-heat refrigeration effect. In place of the expander, an expansion valve could be used; this is particularly effective on very low-temperature open-cycle operations, such as with gas liquefaction processes incorporating secondary "cold-regenerating" heat exchangers.

An extended temperature-entropy diagram (Fig. 19.1.10) illustrates paths for gas-compression sensible-heat cycles as follows: (1) 1-2-3-4 isentropic expander; (2) 1-2-3-4′ polytropic expander; (3) 1-2-5-6 throttling (isenthalpic); and (4) 1-2-7-8 throttling (low temperature).

COMPONENTS OF COMPRESSION SYSTEMS

A refrigeration system is an energy-transport complex of assorted components. It may be a conventional system in which the same fluid, the refrigerant, recirculates continuously in a closed circuit, or it may entail a partially open system with discharge of some of the processed fluid either as a liquefied gas or as a solidified gas, with replacement makeup, e.g., by air liquefaction and solid carbon dioxide production. Components include vapor and gas compressors; liquid pumps; heat-transfer equipment (gas coolers, intercoolers, aftercoolers, exchangers, economizers); vapor condensers and the counterpart evaporators; liquid coolers and receivers; expanders; control valves and pressure-drop throttling devices (capillaries, refrigerant-mixture separating chambers, stream-mixing chambers); and connecting piping and insulation.

Codes and **standards** have been published by various associations and societies. These cover design, selection, designation, testing, sound ratings, safety, efficiency, and other areas relating to mechanical refrigeration. Publication of a comprehensive list is impractical because of frequent revisions. Several of the organizations include Air Conditioning Contractors of America (ACCA), American National Standards Institute (ANSI), Air-Conditioning and Refrigeration Institute (ARI), American Society of Heating, Refrigerating and Air-Conditioning Engineers, Inc. (ASHRAE), The American Society of Mechanical Engineers (ASME), Canadian Standards Association (CSA), International Institute of Ammonia Refrigeration (IIAR), and Underwriters Laboratories Inc. (UL). A list of current codes and standards can be obtained by contacting the particular organization.

Several of the more general refrigeration equipment standards include: ANSI/ASHRAE 15 "Safety Standard for Refrigeration Systems"; ANSI/ASHRAE 34 "Designation and Safety Classification of Refrigerants"; and CAN/CSA-C22.2 "General Standard on Refrigeration Equipment.

There are numerous additional standards relating to specific types of refrigeration equipment (air conditioners, heat pumps, chillers) or specific components (compressors, water- or air-cooled condensers, lubricating oil). Because refrigeration equipment requires auxiliaries (electric motors, steam turbines, piping, insulation) and is part of a larger system such as food processing or heating, ventilating, and air conditioning

(HVAC), other standards not relating directly to refrigeration may apply. Any installation must also comply with building and fire code requirements.

Compression may be single stage (Fig. 19.1.6) or multiple stage. Displacement compressors include reciprocating piston, screw, rotary vane, scroll, and trochoidal compressors. The volumetric capacity of the compressors is always less than the swept volume of pistons or the volume displaced in cyclic rotation by the other forms of displacement devices such as screws, nutating scrolls, or rotating vanes. The true measure of compressor capacity is the volumetric efficiency. It is influenced by cylinder, screw mesh, or cavity clearance volume; pressure ratio; nature of the gas; pressure drops and passage volume in the valves or vanes; suction heating; and the equivalent compression exponent *n*. The numerical value of *n* expresses the effect of heat transfer to or from the gas during compression of the gas. Normally it lies between $n = 1.0$ and $n = k$ (adiabatic), such as for the ideal (isentropic). Figure 19.1.11 indicates the comparative volumetric efficiency of a pair of reciprocating and screw compressors. **Reciprocating compressors** are disadvantaged by high discharge temperatures and excessive clearance volume losses associated with compression ratios greater than 12 to 1 in a single compression stage. Compound compression staging is a practical solution if reciprocating machinery is applied across cycle compression ratios greater than 10 to 1. **Screw** compressors with oil injection systems can operate reliably as a single stage with compression ratios greater than 20 to 1. **Rotary vane** compressors are fixed-volume-ratio machines and can be used across compression ratios of 18 to 1, vane material and lubricating oil permitting; however, in the larger-size machines, a 7 to 1 compression ratio is commonly used in order to maintain efficiency. **Scroll** compressors have been used in commercial practice for systems that have capacities less than 10 tons (35 kW). **Trochoidal** compressors are often called "Wankel" compressors because, in one form, the rotor is similar to the Wankel internal combustion engine rotor.

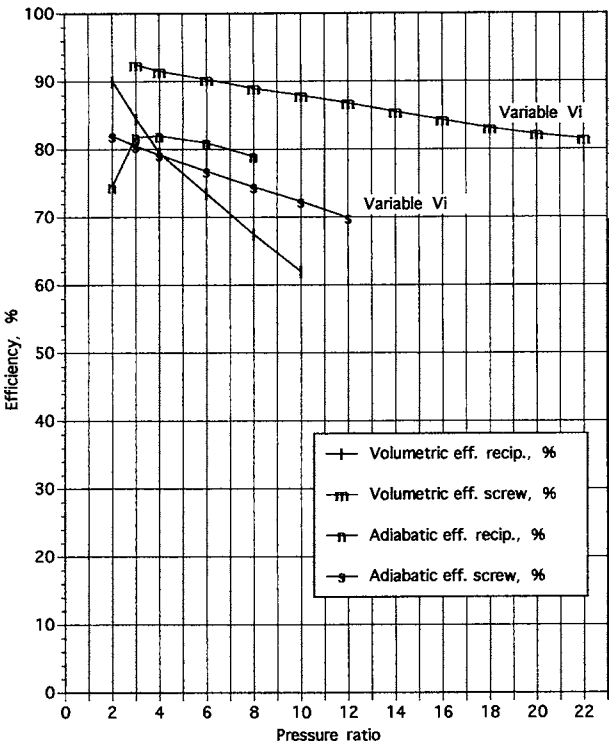

Fig. 19.1.11 Screw and reciprocating compressor volumetric and adiabatic efficiency versus pressure ratio. *(Courtesy of J. W. Pillis, "Development of a Variable Volume Ratio Screw Compressor," Frick Company, 1983.)*

Reciprocating-piston compressors may be horizontal or vertical. The pistons can be designed to be either single acting or double acting with compression occurring on either stroke of the piston. Commercial designs have evolved into multiple cylinder machines arranged in a V block similar to an automotive engine. Average piston speed may be as great as 800 ft/min (4 m/s). Design characteristics of the suction and discharge valves installed on the cylinder determine the energy efficiency, and maintenance frequency. Valves most frequently used are the free-floating reed, clamped reed, and ring valve. Gas velocity through the valves is limited to 12,000 ft/min (61 m/s) with R-717 and 9,000 ft/min (46 m/s) with HCFC-22. For additional information on reciprocating compressors in refrigeration service, refer to the ASHRAE Handbook, ASHRAE Handbook, 2004 Systems and Equipment, pp. 34.4 to 34.9.

Screw compressors are available in several designs, both single screw and twin screw, with oil-free and oil-injected designs in both types. Twin-screw oil-injected compressors are slightly more energy efficient at moderate compression ratios. Many of the commercially available screw compressors are fixed-volume-ratio machines. (See also Sec. 14.) If the compression ratio varies, the operational efficiency of the compressor also varies significantly. The energy reductions that are available by operating with cooler condensing pressures during spring, fall, and winter may not be fully achievable. Capacity control can be accomplished with a movable slide valve that varies the internal volume, valved suction ports, variable-speed drives, and hot-gas bypass. The slide valve is the most common method. Figure 19.1.11 illustrates the adiabatic efficiency of a twin-screw compressor with a movable slide stop control and a reciprocating compressor. Flash intercoolers (Fig. 19.1.13), also called *economizers,* can be provided to improve energy efficiency on the larger-capacity machines.

Air-cooled compressors are used where discharge temperatures are low; water cooling is used where discharge temperatures are high, as with ammonia, and on larger industrial units. **Oil separators** return to the compressor the lubricating oil carried over by the refrigerant vapors. **Rotary compressors** of the vane, eccentric, gear, and screw types are in use.

Kinetic compressors include high-speed centrifugal and axial flow machines, usually multistaged, and jet-entrainment devices. Centrifugal machines are especially adapted to high-volume flow (>500 ft^3/min) (0.24 m^3/s). (See also Sec. 14.)

The entire machine-compression operation may be replaced by a secondary absorber-pump-generator system, in which the complex is known as an absorption refrigeration system.

Dual (or **multiple effect) compression** may be used when refrigeration at two temperatures is desired. The compressor takes vapor from a lower temperature expansion coil during the first part of its intake stroke, and from a higher temperature expansion coil at or near the end of the stroke. The mixture is then compressed and condensed.

In **wet compression,** cooling is obtained during compression by spraying liquid refrigerant into the compressor cylinder. The desuperheating of the compressed vapors results in better heat transfer in condensers and more nearly isothermal compression; the disadvantages are reduced compressor capacity and the problem of control of the amount of injection.

Table 19.1.7 shows some ideal performance values for a single-state ammonia system under different conditions.

Condensers are usually shell-and-tube type, with the refrigerant passing outside the tubes. Older industrial installations still use **double-pipe condensers.** In double-pipe condensers, gas flows between the two pipes while water passes through the inner. The outside pipe diameter may be 2 in (5 cm); the inner, 1¼ in (3.2 cm). In some instances, the pipes are exposed to the atmosphere either with or without water drip. In an **evaporative condenser** the refrigerant vapor is condensed as it passes through tubes over which water is sprayed; the water is then evaporated by air flowing over the wet tubes. In this way, cooling-water requirements are reduced to from 5 to 15 percent of the water requirements of a nonevaporative condenser with no water reuse. The evaporative condenser combines in a single unit a refrigerant condenser and the atmospheric cooling tower or spray pond which is required if the

cooling water is to be reused. Air-cooled finned-tube condensers with forced ventilation are widely used on small units, and shell-and-coil or double-tube water-cooled condensers on medium units.

Evaporators may have plain or finned surfaces. Fin density is available from 1 to 14 fins per inch. Fin density of 2 to 4 fins per inch is specified for air-cooling service below 28°F (− 2.2°C), because air can flow through the coil while thin layers of frost are forming. Four types of defrosting methods are used: hot gas from the compressor, electrical air heaters, hot water, and room air circulation. Flooded evaporators are operated practically full of refrigerant. The level is controlled by a float valve. Wet-expansion evaporators are operated with a level approaching flooded operation. Dry-expansion (once-through) units operate with an indefinite amount of liquid in the evaporator. Usually a thermal bulb measures the outlet pipe temperature and adjusts a thermostatic expansion valve to maintain 15°F (8.3°C) superheat in the outlet vapor. Flooded or wet operation gives high heat-transfer rates. Pumped recirculation of refrigerant is used to promote heat transfer in finned coil evaporators, and also on some shell and tube evaporators (liquid chillers) by completely wetting the surfaces with a rapidly moving layer of refrigerant. The most commonly used liquid feed ratio is 3 to 1. However, a feed ratio as high as 6 to 1 may be required to accommodate distribution imbalances in the piping system. Combined liquid and vapor **return piping** should be sloped at 0.25 in/ft (2.08 percent) to prevent formation of waves in the liquid-phase layer that can react with the flowing vapors to cause liquid hammer that, in turn, can severely damage piping components. **Receivers** and **recirculating pumps** must be carefully matched to the operating system to prevent pump cavitation, liquid droplet carryover, and gross liquid overlow due to surges of liquid that may occur as a result of equipment operations such as defrosting processes. Specifically, the tank drop leg liquid velocity should be limited to 100 ft/min (0.51 m/s) and the vapor velocity over the liquid level in the tank should also be limited to 100 ft/min (0.51 m/s).

For a low-cost unit operating in limited space under conditions of motion, dry operation is preferred.

Controls are required on the liquid level of the refrigerant and on the temperature of the refrigerated space. The liquid control regulates the flow of refrigerant into the evaporator and also serves as the pressure barrier between the high operating pressure of the condenser and the lower operating pressure of the evaporator. It may take the form of a **capillary tube** between the condenser (high side) and the evaporator (low side), in which case it is nonadjustable. Plugging due to dirt is a common difficulty. Capillary-tube liquid control is largely confined to relatively small units assembled and charged at the factory and particularly for hermetically sealed systems. The **constant-pressure expansion valve,** maintaining a constant evaporator pressure, and the **thermal expansion valve,** maintaining a constant superheat leaving the evaporator, are standard liquid controls for most commercial applications. A **low-side float** liquid control, used with a flooded evaporator operating at evaporator (low) pressure, consists of a float-operated valve to admit liquid refrigerant to the evaporator in accordance with demand so that a constant liquid level is held in it. A **high-side float** liquid control is often used with a single flooded evaporator; the float operating the valve between the evaporator and the condenser is in a float chamber containing liquid refrigerant at the condenser (high-side) pressure. As the liquid level in the float chamber falls, the valve closes, thus preventing hot gaseous refrigerant from passing from the high to the low side as is possible when using a capillary or a low-side float.

Several types of noncondensable-gas removal devices have been developed to remove tramp air from refrigerating systems. The exhaust of the purge system contains a portion of the refrigerant. This refrigerant loss is detrimental to the environment, and the replacement of lost refrigerant is costly. Three types of refrigerant purge systems have been developed. One uses a scavenging condenser, cooled by system refrigerant, followed by a carbon absorption device to remove the last vestiges of refrigerant from the purge vapors. Other types, such as oil-absorption systems and reverse-osmosis systems, are developed but not offered commercially. The efficiency of purge systems is specified by the weight ratio of refrigerant lost to the air that is exhausted.

Vapor-Compression Circuits

Compound Low-Temperature Systems Multistaging is advantageous as it reduces operating temperatures by intercooling and power requirements if the fluid superheats considerably on adiabatic compression, as with ammonia; with F-12 refrigerant, propane, and butane, the superheat is negligible (see Figs. 19.1.12 to 19.1.15).

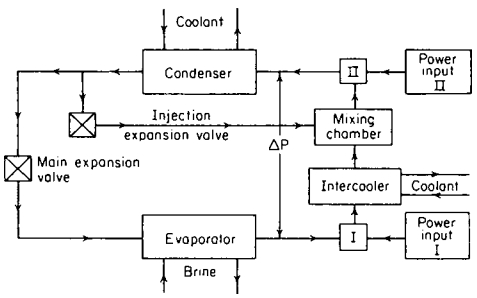

Fig. 19.1.12 Two-stage system with conventional intercooler plus refrigerant injection.

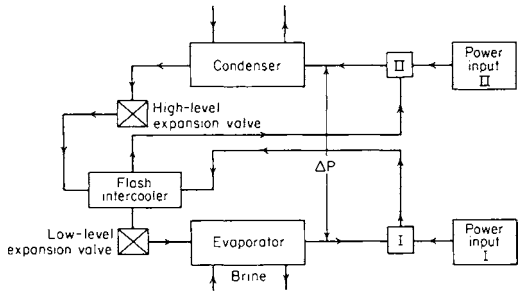

Fig. 19.1.13 Two-stage system with flash intercooler.

Gas Intercooler Plus Liquid Injection Since gas temperature in the intercooler is limited by cooling water temperature, further favorable reduction of gas temperature, prior to entrance to the second stage, may be accomplished by direct injection, via an expansion valve, of refrigerant liquid (Fig. 19.1.12).

Flash Intercooler With a flash intercooler separator located midway between successive expansion valves, the gas leaving the low-stage (I) compressor passes through the flash intercooler, gets cooled by direct contact with the liquid, and, augmented by the flash vapor and at reduced temperature, enters the second stage (II) (Fig. 19.1.13).

For positive-displacement compressors, selection of flash intercooler temperature is determined by the following relation:

$$P_{\text{intermediate}} = (P_{\text{I suction}} \times P_{\text{II discharge}})^{1/2}$$

where P = pressure in absolute units, lb/in^2 abs (Pa). This equation is valid for centrifugal machines with modification. The common practice is to limit single-impeller-stage adiabatic head to approximately 10,000 ft (3,000m) for low-molecular-weight gas and 6,000 ft (1,800 m) for the heavier HCFC and HFC refrigerants. Economical rotor design may require an interstage pressure that does not match the ideal flash intercooler pressure. Where choice is required, select a pressure slightly greater than the ideal pressure given by the above equation.

Low-Temperature Booster Plus Single Stage For the addition of a second lower-temperature evaporator to an existing single-stage system, a booster for the low-temperature vapor may be employed, its output feeding into the single-stage suction. The booster is a centrifugal or rotary compressor, suitable for handling the large vapor volumes encountered at low temperatures (and pressures); the reciprocating compressor is more advantageous at high pressures (Fig. 19.1.14).

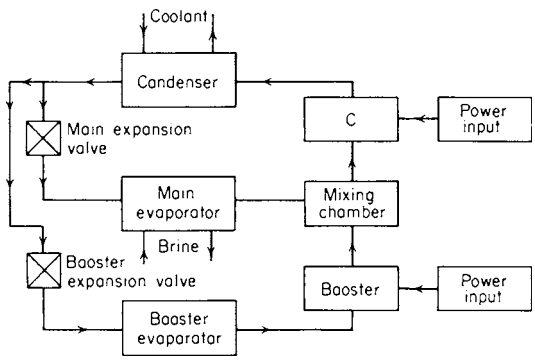

Fig. 19.1.14 Two-stage system incorporating low-temperature booster circuit.

Cascade Systems with Segregated Circuits Here two separate circuits are employed with the low-stage vapor condensed in the second-stage evaporator. Two different refrigerants may be appropriately chosen, a lower-boiling-point refrigerant serving for the first stage. Thus, for low temperatures (< -50°C or -50°F), CO_2 may be employed in the lower stage with NH_3 in the second stage condensing the CO_2. Or the same refrigerant may be used in both stages, limiting the migration of the lubricant to the low-temperature realm (Fig. 19.1.15).

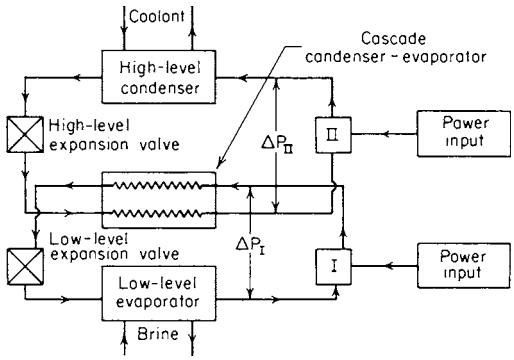

Fig. 19.1.15 Two-stage system in cascade form.

Water-vapor refrigeration is necessarily limited to near-atmospheric temperature levels; it involves large suction volumes at high vacuum and utilizes a nontoxic refrigerant; this type of refrigeration was frequently used in the early days of space air conditioning. It utilizes (1) centrifugal compressors or (2) steam-jet compressors, entraining low-density water vapor from the evaporator. The centrifugal water-vapor compressor, usually multistage, must operate at high speeds (7,000 to 10,000 r/min). Operation at high vacuum in the evaporator requires an air pump at the condenser to eliminate leakage effects.

Steam-jet refrigeration systems are used where cooling to temperatures above 0°C is desired. Applications include industrial air conditioning and cooling of city gas to condense out tar and other objectionable impurities, of gas absorbers to increase efficiency of absorption, of reaction units where heat removal and temperature control are important during chemical transformations, and of wort and mash in the brewing and other fermentation industries particularly in the summer months. Jet refrigeration has been used for cooling passenger trains and is coming into popularity for marine installations, e.g., cooling of banana boats and large passenger vessels. The system is a compression-type refrigerator: it uses water as a refrigerant, a part of which is evaporated to produce cooling of the remainder, steam-jet ejectors to compress the water vapor resulting from evaporation, and a condenser, either the surface type, where refrigerant water is to be reused, or the barometric type, where refrigerant water can be discarded. The advantages of the system are: low installation cost; the absence of moving parts except for small liquid pumps; and safety, since no noxious or toxic refrigerants are used.

For considerable differences in temperatures between condensing-water temperature and refrigerating temperatures (10°C or more), cooling of the refrigerant water by evaporation in two stages operating at different pressures (and temperatures) will usually give better operating economy, but at somewhat higher installation cost.

Figure 19.1.16 shows the variation of refrigerating capacity with variation of the chilled-water temperature, capacity increasing as chilled-water temperature rises.

Household compression machines are designed for continuous automatic operation and for conservation of the charges of refrigerant and oil. These units are almost universally motor-driven air-cooled compressors, the principal exception being the Electrolux-Servel absorption unit. The compressor may be hermetically sealed, with the compressor and motor enclosed in the same casing, or may use a shaft seal, embodying some form of sylphon bellows, with an outside coil spring at the place where the crankshaft passes out of the casing.

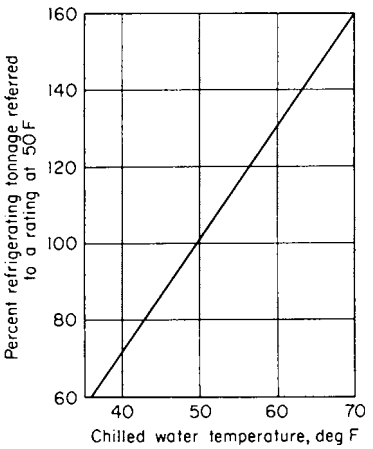

Fig. 19.1.16 Variation of refrigerating capacity with the jet-chilled water temperature in steam refrigeration.

The compressor may be reciprocating, but rotary types are being increasingly used either with a floating piston ring driven by an eccentric or with sliding blades. Lubrication is by internal forced-feed circulation in most cases. The condenser may be of the radiator, coil, or plate type, cooled by natural draft, by a fan on the main motor, or by a separate motor. Refrigerant feed control to the evaporator may be by (1) float feed (flooded system), (2) pressure-actuated diaphragm valve, or most commonly (3) fixed orifice. The fixed orifice may be either a plate orifice or a capillary tube. The evaporator is usually made of aluminum. Controls are generally pressure-operated thermostatic switches. The power consumption of an average home refrigerator (18 ft^3) (0.5 m^2) is 133 kWh per month. A typical home deep freezer consumes approximately 152 kWh per month.

ABSORPTION SYSTEMS

Absorption refrigeration machines are essentially vapor-compression plants (Fig. 19.1.6) in which the mechanical compressor has been replaced by a thermally activated arrangement (Fig. 19.1.17). The basic element are the **absorber, pump, heat exchanger, throttle valve,** and **generator.**

In an absorption cycle, a secondary fluid, the **absorbent,** is used to absorb the primary fluid, the **refrigerant,** after the refrigerant has left the evaporator. The vaporized refrigerant is converted back to liquid phase in the absorber. Heat released in the absorption process must be rejected to cooling water. The solution of absorbent and refrigerant is then pumped to the generator. A heat exchanger may be used for heat recovery and a corresponding increase in efficiency. In the generator, heat is added, and the more volatile refrigerant is separated from the absorbent through distillation. The refrigerant continues to the condenser, expansion valve, and evaporator, while the absorbent returns to the absorber.

Although there are many refrigerant-absorbent combinations, the most common systems are **ammonia-water** and **water-lithium bromide.** A common variation of the absorption system is the **Electrolux-Servel** process (Platen-Munters Patent). It has had wide application in gas-fired household refrigeration machines and air-conditioning systems. The use of hydrogen in a hermetically sealed system eliminates the use of pumps and other moving parts.

Absorption machines represent only a small percentage of refrigeration systems in operation. This is because they are generally bulky and difficult to operate efficiently. There has been renewed interest in absorption machines with the advent of high energy costs. This is because an absorption machine is an excellent way to utilize waste heat. Examples of potential applications are varied. One example may be on an exothermic process, or where extensive use of steam turbine with limited turndown results in vented steam especially during warm weather when air conditioning is required. A site where peak electrical demand is set by air-conditioning load and ratcheted demand charges are high may justify absorption refrigeration if adequate steam-generation facilities are already present.

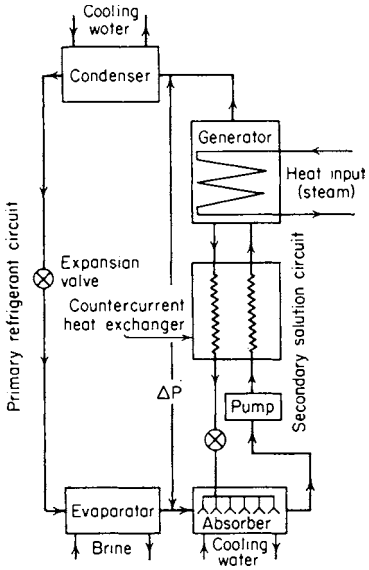

Fig. 19.1.17 Elemental absorption system circuit.

A typical absorption machine requires about 20 lb (9 kg) of steam for 1 ton (3.5 kW) of refrigeration effect at 45°F (7°C).

A more detailed explanation of absorption systems is found in ASHRAE Handbook, 2005 Fundamentals, pp. 1.13 to 1.20.

AIR MACHINES

Compressed-air machines in which air is compressed, cooled, and then adiabatically expanded in an engine while doing work are obsolete for usual industrial refrigeration because of bulk and inefficiency. Their coefficient of performance is less than unity as compared with 4 or 5 for vapor machines. Operation may be closed cycle, in which the air is reused, or open cycle, in which the air is discarded after expansion. Compression ratios of about 3 seem best. In the **dense-air** closed system, the pressure at the compressor intake averages 75 lb/in^2 gage (560 kPa) and up to 250 lb/in^2 gage (1,700 kPa) at the outlet. The use of superatmospheric pressure throughout the cycle decreases the size, and the reuse of dried air eliminates the ice formation on engine valves which occurs with open-system operation. Air cycles are used for liquefaction of the so-called permanent gases and to an increasing extent for comfort cooling in high-speed planes where the small lightweight equipment and the safety of the cooling medium are important. High-speed (90,000 to 100,000 r/min) gas turbines are used to extract work from 5 to 100 lb/in^2 gage compressed air.

THERMOELECTRIC COOLING

Thermoelectric cooling utilizes the **Peltier effect** whereby a temperature differential will occur between two junctions of a closed loop of dissimilar metallic conductors when an electric current is imposed. It is variously called *Peltier effect cooling, thermoelectric refrigeration,* and *electronic cooling.* It is the inverse of the thermocouple operating principle whereby a temperature differential across the junctions of two dissimilar metals produces an electric current.

The capacity of a thermoelectric couple is small. System capacity can be increased by increasing the number of elements used. The temperature produced can be lowered by cascading the systems. Capacities approaching 25 tons (87.9 kW) cooling effect have been achieved, and temperatures as low as −266°F (−166°C) have been attained.

Aside from limited practical capacities, the major disadvantage of a thermoelectric cooling system is its poor coefficient of performance. The absence of moving parts, silent operation, ability to function in zero gravity, and lack of pressurized vessels, has given thermoelectric cooling wide space-program application. Other applications include use on submarines, electronic equipment cooling, and small units such as drinking water coolers or units for use in recreational vehicles.

The elements of a thermoelectric cooler are quite simple and are equivalent to those of a thermoelectric generator (see Sec. 9). For development of various output capacities, the number of basic elements is proportionately increased; they all act in parallel, and their outputs add together. **Semiconductor** materials, such as bismuth-telluride-selenide and bismuth-antimony-telluride alloys, are employed.

With an input to the circuit of low-voltage direct current and with heat continuously abstracted at one junction at room temperature, the other junction will become cold. Essentially each of the two junctions becomes an "activity cell," in which at the lower refrigeration temperature level, heat is converted into electrical effect, and at the higher atmospheric temperature, the electrical effect is converted into heat. This establishes the basis of "heat-pump" operation: the lower-temperature heat requirement must be supplied, essentially as in the evaporator of a vapor-compression system, by heat withdrawal via heat transfer, from all connected surroundings. The energy-transport circuit thus parallels the machine-activated circuit of Fig. 19.1.6. The amount of heat for a single-component circuit depends on the circulating electric current, on the properties and dimensions of the two conductors (*p* and *n* types), and on the resultant temperature difference between the high side room temperature and the low side input heat that is divided into two groups, useless and useful. The **useless heat** is the heat conduction between the high and low temperature through the thermoelements plus the current-generated resistance-loss heat within the elements that flows to the colder junction. The **useful heat** is the refrigeration effect in a regular evaporator. All the heat must in turn be discharged via the Peltier effect at the higher room temperature, as in the condenser of a vapor-compression system. Ultimate performance of the circuit depends on the voltage-generating nature of the two dissimilar conductors and on their electrical resistance, thermal conductivity, and physical dimensions. The different properties are mathematically combined into a **figure of merit, Z.**

METHODS OF APPLYING REFRIGERATION

In **direct expansion systems** the evaporator is placed in the space which is to be cooled; in **indirect systems** a secondary fluid (**brine**) is cooled by contact with the evaporator surface, and the cooled brine goes to the space which is to be refrigerated. Brine systems require 40 to 60 percent more surface than do direct expansion; they have an equalizing effect due to the large heat capacity of cold brine, they are safer (particularly if the refrigerating effect must be carried considerable distance or widely distributed), and they permit closer temperature regulation than is possible with direct expansion. If two temperatures are to be held, the lower may be direct expansion, the higher by brine cooling. Development of better controls and newer piping methods has made direct expansion more attractive than previously.

Brines used for industrial refrigeration are usually aqueous solutions of calcium chloride, ethylene glycol, propylene glycol, or undiluted methylene chloride, and silicone-based alkylated fluids. Calcium chloride should not contain over 0.2 percent magnesia, calculated as magnesium chloride. Calcium chloride brines are recommended down to −45°F (−43°C). Brines should be chemically neutral: acidic brines attack ferrous materials, alkaline brines attack zinc, ammonia in brine (resulting from leaks in the ammonia system) is especially harmful to most nonferrous metals. Corrosion by brine is increased by the presence of oxygen, air, or carbon dioxide and by galvanic action between dissimilar metals. Corrosion inhibitors are widely used, a satisfactory one being about 1,600 g of sodium chromate or dichromate per 1 m^3 of calcium chloride brine or 3,200 g per 1 m^3 of sodium chloride brine.

The properties of sodium and calcium chloride brines are given in Tables 19.1.8 to 19.1.10.

The density of brine is measured by a **salinometer** (or **salometer**), which is a simple hydrometer the indications on which are 4 times greater than on the corresponding Baumé scale (see Sec. 1).

It is undesirable to use a **strength of solution** of salt greater than is necessitated by its freezing temperature, as the specific heat (Table 19.1.9) decreases as the concentration of the brine increases, and consequently the stronger the brine, the less heat a given amount of it is able to convey between certain definite temperatures and the more power is required to pump the brine. Moreover, brine which is too strong may cause clogging of pipes, etc., by depositing salt. On the other hand, if the solution is too weak it may not be able to withstand the temperature existing in the expansion coil, so that a layer of thin ice will form around the latter and interfere with the absorption of heat from the brine. The surface of the expansion coils in the brine tank should be inspected from time to time to see if any ice has formed on them. In larger plants, it is customary to use a solution with a freezing point not less than 10°F (5.5°C) below the lowest temperature which will be obtained in the operation of the plant. In smaller isolated plants and where careful supervision is not ensured, it is customary to make the solution as strong as possible without being unstable, usually 1.240 to 1.250 sp gr.

Ethylene glycol brine is used in various strengths from 15 to 50 percent by weight for refrigeration temperatures down to −1°F (−18°C). It is toxic, and therefore its usage is not recommended in food or beverage processing equipment where a leak can contaminate the product. A corrosion inhibitor is recommended to protect carbon steel equipment and piping. Specific heat ranges from 0.975 to 0.76 Btu/ lb · °F (4,080 to 3,180 J/kg · K) in typical systems. Specific gravity varies from 1.08 to 1.05.

Propylene glycol brine in 15 to 35 percent weight strength is considered nontoxic and is often used in brewing and other food and beverage applications. The brine is more viscous (10 centipoise at −6.7°C for 30 percent weight solution) than ethylene glycol. Specific heat varies from 0.9 to 0.975 Btu/lb · °F. Specific gravity ranges from 1.05 to 1.01. Propylene glycol has often replaced ethylene glycol due to the latter's toxicity.

Methylene chloride brine is often used in systems requiring −20 to −125°F (−30 to −87°C) low temperatures. It has low flammability. Hydrolysis and water contamination must be prevented to avoid equipment corrosion. Specific heat varies from 0.269 to 0.273 Btu/lb · °F (1,126 to 1,142 J/kg · K). Specific gravity ranges from 1.4 to 1.5.

Proprietary chemical blends, such as Dowtherm J and Syltherm, are used where the fluid properties are advantageous. Dowtherm J, a mixture of isomers of an alkylated aromatic compound, is usable between the temperatures of 358°F (181°C) and −120°F (−84°C). The usual range of service is between 0°F (−18°C) and −70°F (−21°C). Physical properties vary from 0.412 to 0.390 Btu/lb · °F (0.412 to 0.390 cal/g · °C) for specific heat; 0.894 to 0.926 for specific gravity (ref. 68°F water); 0.079 to 0.084 Btu · ft/h · ft^2 · °F (0.136 to 0.145 W/m · K) for thermal conductivity; and 1.72 to 4.61 cP in the range of usage.

Sodium chloride brine usage is being reduced due to its corrosivity and its relatively high freezing point.

Table 19.1.11 gives a comparison of the performance of the four major brines in a typical shell and tube chiller. This chart does not indicate effects of specific heat, ingredient cost, pumping power requirements, or system investment cost in the selection of brines.

Brine coolers may be of three types: shell-and-tube, shell-and-coil, and double pipe. The shell-and-tube type is the most widely used, the brine flowing through the tubes which are surrounded by the evaporating refrigerant. Tubes may be arranged for multipass operation. The effective heat-transfer surface varies from 8 to 15 ft^2 per ton (0.21 to 0.4 m^2/kW), varying with temperature and brine velocity. A submerged coil in an open brine tank is used for ice making by the can process.

Table 19.1.8 Properties of Calcium Chloride Solutions
(For variation of specific gravity, with temperature, see Table 19.1.9.)

The **double-pipe cooler** is usually of 2-in (50-mm) inner or brine-flow pipe and 3-in (75-mm) outer pipe. The commercial rating is 15 to 20 ft (5 to 6 m) length of coil per ton of refrigeration.

The **shell-and-tube cooler** is used with closed heads and is erected both vertically and horizontally; brine flows through the tubes and ammonia is in the shell. It is made in sizes from 1 to 350 tons with ratings of 8 to 15 ft^2 effective surface per ton, varying with the temperature and brine velocities; tubes 1 to 2½ in (25 to 63 mm) arranged multipass. This type of cooler has largely displaced all other types in recent installations (Table 19.1.12).

REFRIGERANT PIPING

(See also Sec. 8.)

It is important to the proper operation of a refrigeration system that the piping or mains interconnecting the compressors, condensers, evaporators, and receivers be properly sized. This piping must be considered in three categories, viz., liquid lines, suction lines, and discharge lines. Essentially pipeline sizing is governed by pressure drop, first cost, operating cost, noise, and oil entrainment. Excessive pressure drops penalize compressor efficiencies and may affect control-valve operation adversely. Liquid-line velocities for most refrigerants are in the order of 60 to 400 ft/min (3.3 to 22 m/s), suction lines from 700 to 4,600 ft/min (38 to 250 m/s), and discharge lines from 1,000 to 5,000 ft/min (55 to 275 m/s). Pressure drops vary approximately as the square of the velocity (or tonnage) and directly as the length of the piping. For liquid lines, when evaporator is located above condenser, the following pressure drops in pounds per square inch per foot (kilopascals per metre) of static lift should be allowed: ammonia, 0.26 (5.9); R 12, 0.57 (12.9); R 22, 0.51 (11.5); R 11, 0.64 (14.5). See also Secs. 3 and 4.)

Ammonia Mains For the average installation, Table 19.1.13 shows the maximum tons of refrigeration normally allowed for various sizes of standard pipe, based on 100 ft (30 m) equivalent length of piping (measured length plus allowance for valves and fittings). The gas pressure drops per 100 ft (30 m) equivalent length upon which Table 19.1.13 is based are as follows: suction lines at 5 lb/in^2 (gage) (34.5 kPa) = 0.25 lb/in^2 (1.7 kPa); suction lines at 20 lb/in^2 (gage) (138 kPa) = 0.50 lb/in^2 (3.4 kPa); suction lines at 45 lb/in^2 (gage) (310 kPa) = 1 lb/in^2 (6.9 kPa); and discharge lines = 1 lb/in^2 (6.9 kPa).

Standard-weight (schedule 40) steel pipe is used for ammonia mains, except for liquid lines 1½ (38 mm) and smaller where extra-strong (schedule 80) pipe is used. Joints may be either screwed, flanged, or welded, but welding is preferred.

R 12 Mains Maximum tons refrigerant for various pressure drops per 100 ft equivalent length of R 12 mains are given in Table 19.1.14. For average conditions, allowable pressure drops in R 12 suction lines are 0.5 to 1.0 lb/in^2 (3.4 to 6.9 kPa) below 0°F (−18°C) evaporator temperature; 1.0 to 1.5 lb/in^2 (6.9 to 10.3 kPa) from 0 to 25°F (−18 to −4°C); and 2.0 to 2.5 lb/in^2 (13.8 to 17.2 kPa) from 25 to 50°F (−4 to 10°C). Discharge-line pressure drops upon which Table 19.1.14 is based are approximately 1 lb/in^2 (6.89 kPa) per 100 ft (30 m) equivalent length. Pressure drops of 1 to 4 lb/in^2 (6.9 to 27.6 kPa) are permissible. Liquid-line pressure drops of 3 to 5 lb/in^2 (20.7 to 34.5 kPa) per 100 ft (30 m) equivalent length are normal, with 10 lb/in^2 (69 kPa) usually considered maximum. To facilitate oil return in vertical suction lines with the evaporator located below the compressor, the velocity in the vertical section should be 1,000 ft/min (38 m/s) or more. Suction-line capacities in Table 19.1.14 may be increased 9 percent for 50°F (10°C) evaporator temperature and will decrease approximately 7 percent for each 10°F (5.6°C) below 40°F (4.4°C).

R 22 piping will, in general, be smaller for the same tonnage than R 12 piping. Suction lines will handle about one-third more tonnage for the same pressure drop. Liquid and discharge lines can be the same as for the equivalent tonnage of R 12 or slightly smaller.

Piping may be standard-weight steel pipe, but copper tubing is used in most cases. Medium-weight type L copper tubing is normally used for land installations, and the heavier type K copper tubing is used for marine work. Joints in the copper tubing may be flared compression fittings for tubing ¾ in (18 mm) OD and smaller. However, hard solder (silver-base alloy melting above 1000°F) (540°C) is preferred for most tubing connections. Copper tubing is almost always used for liquid lines. Steel pipe may be used for the larger suction and discharge lines but should be sandblasted on the inside and carefully cleaned before installation.

Piping flexibility is an important consideration, especially in low-temperature systems [0°F(−18°C) or colder] and where large-diameter or long runs of piping are utilized. The coefficient of thermal expansion is about 9×10^{-6}/°F (16×10^{-6}/°C) for carbon steel pipe. This means a 20-ft (6-m) length will shrink about 0.15 in (3.8 mm) when cooled from 70 to 0°F (21 to −18°C). If the piping configuration were such to exert a moment on a compressor flange, premature equipment failure could result. Long runs of cold brine lines should be analyzed for proper anchoring, guiding, and support to prevent system failure.

Flexibility is provided by a combination of changes in direction and use of properly positioned anchors, spring hangers, and guides. Refer to Sec. 5 for additional information on piping flexibility.

Mains of Other Refrigerants For sizing piping for other refrigerants, reference may be made to the ASHRAE Handbook, 2006, Refrigeration, Chapters 2 and 3.

COLD STORAGE

The first consideration in cold-storage room design is the temperature to be maintained in the refrigerated space. The temperature can generally be divided into three ranges: above 32°F (0°C), 32°F (0°C) and below, and 0°F (−18°C) and below. Methods of construction and degree of insulation are dependent on the maintained temperature. Other more specialized design considerations are humidity control, ventilation requirements, controlled atmosphere (control of O_2, N_2, or CO_2), fire protection, and material-handling facilities (see Table 19.1.15).

Cold-storage rooms can either be site fabricated or prefabricated. The increasing availability of preinsulated panels with low *U* factors has led to increasing use of prefabricated rooms. Many of these are available as complete packages with the refrigeration system included.

Vapor Barrier Although good insulation is important, a well-designed and installed vapor barrier is the key to maintaining satisfactory insulation performance and life. A poor vapor barrier allows moisture to condense in the insulation, greatly reducing its insulating value. A well-designed system is of little value if poorly installed. Poor workmanship, in fact, accounts for most vapor barrier inadequacies.

Common vapor barrier materials include metal foils, polyethylene, asphalted felts and kraft paper, hot-melt asphalt, and special vapor barrier paints. Vapor barriers must be installed on the warm side of the wall.

Table 19.1.15 Cold-Storage Usage and Transmission Factors

	Room volume, ft³									
	20	50	100	500	1,000	2,000	5,000	10,000	50,000	100,000

Theoretical *U* factor†	0.086		0.066		0.055		0.046		0.035	
Practical *U* factor‡	0.111		0.083		0.066		0.055		0.046	
Piping *U* factor§	2.5		2.2		2.0		1.8		1.6	

* Btu per cu ft per 24 h per °F temp diff between outside and inside. Usage load includes 10°F or less of product cooling, and infiltration losses, etc., but does not include any freezing of product or fan motor loads when unit coolers are used. Values are for normal conditions and should not be used for unusual product loads.

† Theoretical *U* factor is based on corkboard ($k = 0.30$) with plaster on both sides, Btu per ft² per h per °F temp diff.

‡ Practical *U* factor allows for inefficiency of joints and structural supports in insulation.

§ Piping *U* factor is Btu/ft² outside pipe surface per h per °F temp diff between cooling medium and air (gravity circulation). Allowance has been made for frosting at the lower temperatures.

Insulation In recent years newer insulating materials have largely supplanted the use of plaster and corkboard in cold-storage room construction. Insulation has generally been used in three forms for this application: board form, panelized, and poured, sprayed, or foamed in place.

Board form insulation includes corkboard, rigid polystyrene, polyisocyanurate, and polyurethane, foamed, and fibrous glass.

Panelized insulation has gained acceptance, particularly in prefabricated installations. The outer metal skin can serve as a vapor barrier, and the panels are factory insulated with polystyrene, polyisocyanurate, polyurethane, or fibrous glass. U values as low as 0.035 have been attained in 4-in (100-mm) thick panels.

Poured, sprayed, or foamed in place insulation has its greatest applications on existing installations. It is primarily a urethane material. The application requires special equipment, and precautionary measures must be taken.

Cold Storage Temperatures A great deal of research and experience are required to obtain authoritative information on optimum temperatures and humidities for various products in cold storage. Table 19.1.16 is representative of good practice. The safe storage period depends upon the product and the storage temperature, and operational techniques vary greatly. Modern cold-storage warehouses of the larger concerns are cooled by brine which is furnished at two different temperatures only. The higher temperature for the mild-temperature warehouses is 10 to 12°F (−12 to −11°C), and the low-temperature brine for the freezers is −10 to −12°F (−23 to −24°C). All temperatures above that of the brine are obtained by regulating the amount of brine circulated in any particular set of coils. In the low-temperature warehouses, the piping is arranged for two classes of service: (1) **sharp freezers,** where the goods which are to be frozen are kept in a blast of air whose temperature is −30°F (−34°C) while their temperature is brought down quickly to the holding temperature (say in from 6 to 10 h) after which they are stored in (2) **holding rooms** where the desired temperature is maintained.

The system of cooling which is now being installed in the highest type of warehouses consists of a coil room containing the necessary brine-type or wetted, direct-expansion-type coils, through which the air from the different rooms is circulated by a pressure blower. The inlet and outlet of each room are so arranged that the cooled circulating air will cover the entire room in its transit; this is usually accomplished by having the cold-air inlet in the center of the room and two cold air outlets—one at each end of the room. The piping ratio for the coil rooms in this system, assuming a high-grade insulation with 2 to 4 Btu transmission per ft^2 per 24 h per °F temp diff, should be 1 ft^2 of external pipe surface to 15 ft^3 of space to be cooled [with brine at −10 to −12°F (−23 to −24°C)] for warehouses carrying temperatures of zero and below, and 1 ft^2 of pipe surface to 24 ft^3 of space to be cooled [with brine at 10 to 12°F (−12 to −11°C)] in warehouses carrying mild temperatures of from 30 to 40° F (−1 to 4°C). Another system is used in which the blower and coils are supplemented by coils in the rooms. With this arrangement, it is possible to reduce temperatures quickly and hold them with the coils.

The average coil transmission in cold-storage rooms without forced circulation of the air is about 2 Btu per ft^2 of outside metal surface per h per °F temp diff with horizontal piping and 2.5 Btu with vertical piping. When forced air circulation is used, the transmission rate will increase to 20 Btu or more. In **brine circulation,** the brine, at same compressor back pressure, has a higher temperature than the ammonia, and consequently 1½ times as much pipe or more is used in brine circulation as is direct expansion for a given back pressure.

Piping of Rooms The **size of pipe** usually employed for piping rooms varies from 1 to 2 in (25 to 50 mm) with either brine circulation or direct expansion.

The extra cost of liberal piping allowance will often be offset by the consequent improvement in the efficiency of operation of the compressor. An expansion valve should be provided for every 500-ft (150 m) length of 1-in (25 mm) pipe, every 650 ft (200 m) of 1¼-in (30 mm) pipe, and every 1,000 ft (300 mm) of 2-in (50 mm) pipe when direct expansion is used.

Values of **overall coefficients of heat transfer** in Btu/h · ft^2 · °F for refrigerating practice are given in Tables 19.1.15 and 19.1.17. (See Sec. 4.)

Brine circulation is generally preferred to direct expansion so as to avoid danger from escaping ammonia or other refrigerant in case the pipes should leak. An advantage of the brine system is that there is always a considerable mass of refrigerated brine which can be drawn on in case the machinery should have to be stopped for any reason. In small plants, the general machinery may be stopped at night and only the brine pump be kept going to distribute the surplus refrigeration which has been accumulated in the brine during the day. Brine piping must consist of two lines, a flow and a return, usually of the same size. Brine storage is seldom used in large plants because of its bulk, its first cost, and the practical inability to store much refrigeration.

The **brine coils** in each cooled space are in parallel across the supply and return pipes. It has been common practice to allow 100 to 120 running ft (30 to 36 m) of **pipe** per circuit for low temperatures, and 400 to 440 (120 to 135 m) for high temperatures. The **tons refrigeration produced by brine** at various temperature differences and rates of pumping may be calculated approximately as follows: tons refrigeration = gal/min × °F range/28.

Air Conditioning of Low-Temperature Storage Rooms Bacterial growth and chemical decomposition are retarded by lowering the

Table 19.1.17 Overall Coefficients of Heat Transfer
(Btu/ft^2 · h · °F)

Can ice-making piping

* *U* factor increases to 3.3 at 15°F temp diff with ammonia recirculation systems.
NOTE: Forced circulation of the air increases the coefficient to 1½ to 2½ times the values for still air. One inch of frost decreases the value 25 percent.

temperature of perishable goods. Too low a temperature will freeze the goods and may result in spoilage. A holding temperature above the freezing point of the article is best for storage conditions. The maintenance of a proper relative **humidity** in a storage space holding unwrapped goods is as important as the maintenance of the proper temperature. High humidity favors the growth of mold and bacteria. Low humidities rob the product of moisture resulting in losses in value through impaired appearance and lost weight. **Air motion** is of importance in maintaining uniform conditions throughout the storage space. Too high air velocities cause excessive drying, and stagnant air through high humidities will cause mold. An optimum air motion falling between stagnation on one side and excessive drying on the other must be selected.

Low-temperature conditioning for storage purposes is preferably accomplished by the use of **cold-diffuser methods.** The cold diffuser connected to or located in the storage space consists of a fan and cooling means. The cooling means may be either a brine or cold-water spray or a surface-type cooler using brine, or a volatile refrigerant such as ammonia, Freon, etc. Unitary equipment, performing the functions of the cold diffuser, is commercially available. For the requirements for various perishable products, see ASHRAE Handbooks, 1993 Fundamentals and 1995 Applications, 1994 Refrigeration, and Table 19.1.16.

Quick freezing is freezing in 2 h or less; as employed for foods the temperatures may be as low as −20 to −50°F (−29 to −46°C). The methods of freezing include direct immersion in cold brine or a brine spray with the commodity held in a metal container. Another procedure is the use of a freezing tunnel approximately 50 ft (15 m) long, equipped with a stainless-steel conveyor belt. The commodities to be frozen pass through this tunnel in 15 to 30 min. The speed of the belt is variable, and the heat transfer is accomplished by high-velocity air circulation at a number of points in the tunnel, the circulation being transverse to the belt. The circulating air is cooled by brine sprays or wetted, direct-expansion coils which maintain the required temperature and the high humidity necessary to prevent shrinkage. In another process, packages of the material to be quick-frozen are clamped between steel platens containing evaporating refrigerant. Successful results are obtained with temperatures as high as 0°F (−18°C). Storage may be at −5 to −10°F (−20 to −23°C) and transportation at 10°F (−12°C) or lower.

Cold-storage lockers for individual family use are used in large numbers, particularly in suburban and rural areas. Lockers are rented usually on a yearly basis. A locker plant may have several hundred rental steel lockers, 6-ft^3 (0.17-m^3) capacity each, placed in rooms at about 0°F (−18°C); a room for cutting and wrapping the meat; and a sharp freezer room held at about −20°F (−29°C). Two compressors are frequently specified or a single compressor using automatic control valves on the separate rooms. Ammonia and R 12, operating under direct expansion, are commonly used.

ICE MAKING

Ice refrigeration is economical for some applications. The use of natural ice is fast disappearing. Manufactured ice is made by several methods. In the can system, galvanized cans containing up to 400 lb (180 kg) of water are immersed in brine for 25 to 40 h for freezing. Air dissolved in the water separates as bubbles causing opacity unless the water is agitated during the early stages of cooling, and any dissolved impurities come out of solution to form a central off-color core in the ice block unless the core is removed and replaced with fresh water just before freezing. The time and investment required for making ice in cans are often uneconomical. In the **Flakice** method (Crosby Field, *Trans. ASME,* May 1951, pp. 347–357) refrigerant is sprayed against the inner wall of a flexible, slowly rotating cylinder which is partially immersed in a tank of water. As the cylinder rotates, a thin layer of ice forms on the outside and then is broken off as further rotation causes the cylinder surface to flex under the action of an internal cam. For a patent history of small ice machines of this type, refer to Crosby Field, *Refrig. Eng.,* **58,** Dec., 1950, p. 1163. In the **PakIce** process (Taylor, *Refrig. Eng.,* **22,** 1931, p. 307) liquid ammonia is evaporated in an annular space formed by two concentric cylinders, the inner being corrugated. Water sprayed on the inner corrugated surface quickly freezes in a thin layer about .25 mm thick and is continually removed by mechanical scrapers. In an **extrusion method** (Watt, *Trans. ASME,* 1949) a slightly tapered circular or rectangular vertical cylinder with large end up is open at the top, but closed by a ram at the bottom. This cylinder has a jacket in which refrigerant is evaporated directly against the cylinder walls. Water enters the cylinder and freezes to a tapered block at the start of the operation. As soon as this occurs, the ram lifts (about 6 mm), shearing the ice block from the cold cylinder walls. Water admitted to this space quickly freezes, the ram again operates and the block of ice is again lifted, and shearing occurs again between the freshly formed ice and the cylinder walls, but not at the fresh ice and old ice interface. In this way, a continuous cylinder of ice is formed by the series of nested ice shells. The installation and upkeep costs are small and so is the space required per ton of the ice produced; a pilot-plant 1-ton (907 kg) unit requires 3 ft^2 (0.3 m^2) of floor space.

Batch ice makers can manufacture up to 75 tons (68 tonnes) of ice per day. These machines use constant-diameter ice-forming tubes to produce ice in shell and toroidal forms. The ice forms on a bank of vertical tubes in either of two configurations: inside the tubes for pellets or outside of the tubes for shell ice. A water distribution system is provided

at the top. An ice conveyor and mechanical size-reducing device is mounted below the tubes. The refrigerant is circulated through the annulus of concentric tubes when ice pellets are made, and inside of single tubes when shell ice is made. The refrigerant supply can be designed for flooded operation; however, equipment capacity is reduced. The cycle starts as water passes through the distributors and flows over the surface of the tubes as a film. The refrigerant freezes the water to form a thickening layer of ice as time passes. Unfrozen water drains out of the tube into a sump. Then the water is recirculated, by a pump, up to the distribution system at the top of the tube bank. A purge of water is taken from the sump to remove accumulated salts and other impurities. When harvest is initiated, the refrigerant system is drained, and hot gas from the condenser is introduced into the refrigerant side of the tube and the pressure is raised. This causes the ice to partially melt and release from the tube wall. The cylinder or shell of ice falls by gravity into the conveying and size-reducing machinery. The size of an ice pellet can vary from 0.75 in (19 mm) to 1.375 in (35 mm) outside diameter. Ice clarity can be controlled by flushing the ice with water before and during harvest. The machine is controlled by digital logic microprocessors. Energy consumption when using 65°F (18°C) feedwater varies from 1.94 to 2.33 tons (6.8 to 8.2 kW) refrigeration per ton (909 kg) of ice when using R-717 versus HCFC-22 in a recirculation system. Standard model ice makers can be operated with the refrigerant system either in the flooded condition or with circulating pumped refrigerant in the tubes. Similar units lose 18 percent capacity when operating in a flooded state compared to operating with pumped recirculating refrigerant.

Making clear ice using continuous methods is often accomplished by washing the newly frozen ice surface with cold water. This method can increase water requirements by up to 50 percent and energy usage by 15 percent.

The refrigeration tonnage required for making 1 ton (909 kg) of ice varies from 1.84 with 55°F (12.8°C) inlet water temperature to about 2.0 if the water to be frozen enters as high as 75°F (23.9°C).

SKATING RINKS

Rinks for ice skating, hockey, or curling vary in size from about 400 ft^2 (37 m^2) area to 16,000 ft^2 (1,486 m^2) or more. Construction of the ice floor is important. For a low-cost, efficient unit, brine pipes are laid directly in sand, which is kept wet during freezing to increase heat transfer. As freezing progresses, a layer of ice is built up by spraying water on the surface. The expense of maintaining such a floor in a satisfactory level condition may be considerable, and corrosion of the pipes, from the outside in, in contact with the wet sand may be excessive, particularly during shutdown periods. Moreover, it is not possible to use such a floor for other purposes. When a floor for diversified activities is needed, it is usual to provide a lower layer of insulation, primarily to prevent sweating on ceilings under the floor, surmounted by a concrete slab in which the steel pipes carrying the brine are imbedded and on which the ice layer is formed. This construction protects the pipe from external corrosion, affords fast freezing, and makes possible use of the floor in a few hours for purposes where an ice surface is not desired. Floor pipes can be mild steel or polyethylene and are usually 1 or 1¼ in (25 or 32 mm) spaced 3 to 6 in (75 to 150 mm) on centers; care must be exercised to ensure a uniform distribution of brine. Brine flow may be 10 gal/min per ton of refrigeration, corresponding to about 1 gal/min per 10 to 20 ft^2 of piping surface. In a few installations, cold brine is sprayed directly against the under side of a steel floor on which the ice layer is frozen. Close control of ice surface temperature is necessary for good skating, usually $-3°C \pm 0.5$. Refrigeration capacity should be from 0.4 to 0.85 ton per 100 ft^2 (150 to 320 W per m^2) of floor surface, although the load may be much higher for open-air rinks or other unusual conditions.

REFRIGERATION IN THE CHEMICAL INDUSTRIES

The use of refrigeration in petroleum and other industries is widespread. In petroleum processing, refrigeration is used (1) to control vapor pressure of highly volatile constituents (methane, ethane, propane, and butane), such control being necessary during distillation, during processing, and for recovery of gasoline fractions from natural gas; (2) to shift the solubility relationship so that undesired constituents such as asphalt and wax in lubricating oils may be removed by precipitation; (3) to produce selective chemical reaction such as occurs when sulphuric acid is used to remove gum-forming constituents from light fuels or when an alkylate fuel fraction is formed by combining a low molecular weight unsaturated with a similar saturated hydrocarbon. Alkylate is a valuable and important constituent of aviation fuels.

For (1), temperature ranging from −35°F (−38°C) or lower to as high as 60°F (15°C) are required, the refrigerant being ammonia, propane, or butane. For the higher temperatures spray-cooled water or jet refrigerating units (see above) are sometimes satisfactory. For (2), it is possible to use propane as a combined solvent and refrigerant, evaporation of the propane causing the required cooling, temperature level [approximately −40°F (−40°C)] being controlled by the pressure held on the equipment. The propane vapor is recompressed, condensed, and reused as in any compression cycle. As much as ⅓ ton of refrigeration per barrel of lubricating oil dewaxed is needed. For (3), temperatures of up to 60°F (−16 to 15°C) are general, and ammonia is a satisfactory and widely used refrigerant.

The chemical industry uses refrigeration to control condensation polymerization processes in the manufacture of synthetic rubbers and plastics. Syntheses of refrigerants and other chemicals require systems to maintain temperatures which range from 5°C down to −85°C in process equipment. Large centralized refrigeration systems which use ethylene glycol and methylene chloride brine are common. Several modern chemical processes use the eventual product as a refrigerant (for example, the manufacture of ammonia). Cascade systems with segregated circuits are used to produce temperatures below −50°C.

Recently imposed regulations limit volatile organic vapor emissions to the atmosphere from storage tank vents and other process systems. The recovery efficiency required of cleanup systems has led to development of refrigerated liquid absorption processes to scrub vaporous effluents from organic chemical storage tanks. Recently installed systems have required liquid absorbent temperatures of −40°F (−40°C). The capacity of these systems varies from 2 tons (7 kW) to 500 tons (1760 kW). The absorbent liquid is often accumulated from the effluent stream over a period of time.

DEEP REFRIGERATION

Dry ice (solid CO_2) is useful as a refrigerating medium in special cases. The main objection to the general use of dry ice is its cost, but the ease in its handling, its low temperature [−110°F (−79°C) at atmospheric pressure], its noncorrosive and nontoxic properties, its high latent heat, and the absence of liquid drip make it desirable. The heat absorbed per pound of solid CO_2 during sublimation at atmospheric pressure and −110°F (−70°C) is 245 Btu approx. The specific heat of the gas at constant pressure is about 0.2.

Carbon dioxide is obtained commercially either by fermentation or by burning. The gas is compressed, usually in three stages, and cooled to atmospheric temperature, thereby forming a liquid at about 1,000 psia (690 kPa); the liquid is then throttled to below 5.3 atm pressure. During throttling part of the CO_2 solidifies and is compressed to form a dense ice. The fraction that returns to the vapor phase is recompressed.

Production of Solid Carbon Dioxide Figure 19.1.18 shows a simple cycle and Fig. 19.1.19 the elemental pressure-enthalpy diagram for the production of solid carbon dioxide. From the high pressure at atmospheric temperature the liquid is throttled (isenthalpic) to atmospheric pressure, the resultant point being within the sublimation solid-vapor zone below the triple-point realm. In this resultant throttling expansion, part of the CO_2 solidifies; it is then removed in the separator from the residual vapor and is compacted to form a dense CO_2 ice. The fraction representing the vapor phase is augmented by fresh makeup gas to continue the production cycle.

Beyond the manufacture of dry ice, operation at deep refrigerations, such as air liquefaction [at −312°F (−191°C) approx], lead into

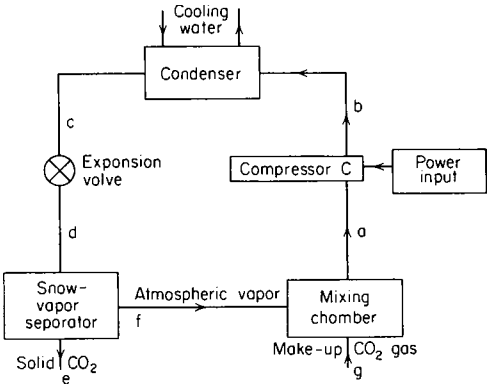

Fig. 19.1.18 Elemental dry-ice production circuit.

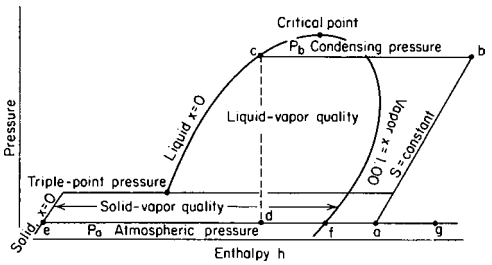

Fig. 19.1.19 Pressure-enthalpy diagram illustrating dry-ice production circuit.

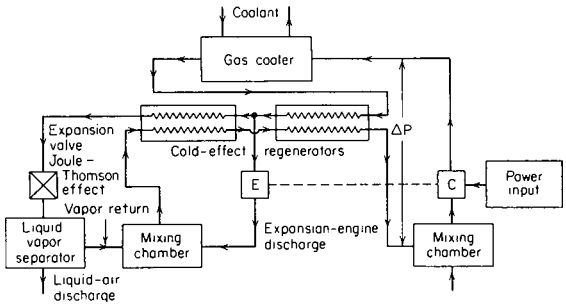

Fig. 19.1.21 Elemental Claude system circuit.

cryogenics (see Sec. 19). Illustrative systems are (1) Linde (throttling) and (2) Claude (expander). In the elemental **Linde system** (Fig. 19.1.20), by virtue of the "cold-effect" regenerator, the process air is reduced in temperature by the return fraction of the air from the separator. The throttling process thus ends in the "wet zone" at atmospheric pressure with generation of low-temperature liquid air that flows from the separator. In the **Claude system** (Fig. 19.1.21), use is made of an expander (whose work output reduces the net work requirement of the compressor) and of an expansion valve with the Joule-Thomson effect.

19.2 CRYOGENICS

Notation

Some symbols in this section differ from the notation of engineering practice but are retained to facilitate use of the prevalent scientific sources of information.

A = area, ft^2 (m^2)
b.c.c. = body centered cubic lattice structure
C = specific heat, Btu/lbm · °R(J/kg · K)
C_p, C_v = specific heats at constant pressure and volume respectively, Btu/lbm · °R(J/kg · K)
f.c.c. = face centered cubic lattic structure
H = enthalpy, Btu/lbm (J/kg)
H = magnetic field, $G(T)$
h.c.p. = hexagonal close-packed lattice structure
κ = thermal conductivity, Btu/h · ft · °R (W/m · K)
σ = electrical conductivity (reciprocal of resistivity) or pair separation for zero potential in Lenard-Jones equation
s = Boltzmann's constant
L = length, ft (m)
LH_2 = liquid hydrogen (H_2)
LHe = liquid helium (He)
LN_2 = liquid nitrogen (N_2)
LNG = liquefied natural gas
LO_2 = liquid oxygen (O_2)
n = number of moles
P = pressure, psia or torr (vacuum) (Pa)

R_e = electrical resistance, Ω
T = temperature, °R (K)
V = volume, ft^3 (m^3)
α = thermal linear-expansion coefficient, °R^{-1} (K^{-1}), or accommodation coefficient
η = viscosity, lbm/ft · h (N · s/m^2)
ρ = density, lbm/ft^3 (kg/m^3)
ΔT = temp difference, °R(K)
* = Denotes property divided by quantum parameter (Table 19.2.5) which is not the critical point value.

Cryogenics is the study, production, and utilization of low temperatures. Cryogenic temperatures have been defined so ambiguously that "upper limits" to the cryogenic range from 216 to 396° R (120 K to 220 K) may be found in the literature. In this section the cryogenic range for a property of a given substance is considered to embrace the scale between absolute zero and the temperature above which the property has the expected or normal behavior. Cryogenics thus embraces the unusual and unexpected variations which appear at low temperatures and make extrapolations of properties from ambient to low temperatures unreliable.

Progressively lower temperatures become increasingly difficult to attain in practice. A cryogenic refrigerator operating on the Carnot cycle (ideal) will require the least amount of input work to effect refrigeration (remove heat) at a lower temperature and reject it at a higher temperature (usually ambient temperature). As the working temperature of a refrigerator is lowered, the work required to transfer a given amount of heat increases as demonstrated by the Carnot limitation, to wit, $W = Q[(T_1 - T_2)/T_2]$, where W is the work required to extract the heat Q at a low temperature T_2 and reject it at a higher temperature T_1 (see Sec. 4). The actual work is always greater than this because of inefficiencies of mechanical equipment, thermal losses associated with finite temperature differences in heat exchangers, and heat leaks from the surroundings to the cold equipment. Cryogenic refrigerators built to date do not approach this limit very closely; typically less than 40 percent of Carnot efficiency for the largest refrigerators and progressively less as the size of the refrigerator becomes smaller.

REFRIGERATION METHODS

(See also Sec. 4 and Sec. 19.1, "Mechanical Refrigeration.")

Cryogenic refrigerators (cryocoolers) may be classified by (1) the functions they perform (e.g., the delivery of liquid cryogens, the separation of mixtures of gases, and the maintenance of spaces at cryogenic temperatures, (2) their refrigerating capacities and (3) the temperatures they reach. Large industrial-sized plants (*a*) deliver LNG (~120 K), LO_2 (~83 K), LN_2 (~77 K), LH_2 (~20 K), and LHe (~4 K), (*b*) separate gaseous mixtures, e.g. the constituents of the atmosphere, H_2 from petroleum refinery gases, H_2 and CO from coke oven and coal-water gas reactors, and He from natural gas, and (c) provide refrigeration to maintain spaces at low temperatures. For the latter, i.e., (c), a unit has been manufactured and installed that delivers 13 kW of refrigeration at less than 3.8 K.

An important area of refrigerator development that is being commercially exploited now is laboratory-sized cryogenic refrigerators for laboratory research and development at LHe temperatures (<5 K). These refrigerators are used for many different purposes, refrigerating for example: high-field superconducting electromagnets, LHe bubble chambers for high-energy (nuclear) particle research, experimental superconducting electric generators and motors and superconducting magnets for levitation of railroad trains. Another area of commercial exploitation that is important for the progress of cryogenic physics research is the development of refrigerators for the continuous production of refrigeration at temperatures below 1 K. These include L^3He evaporation refrigerators and L^3He-L^4He dilution refrigerators that reach temperatures of 0.4 and 0.003 K, respectively.

Of various methods of refrigeration, the most commonly used to produce temperatures as low as 1 K are (1) the evaporation of a volatile liquid (referred to as the **cascade** method when applied in several successive stages using progressively lower-boiling liquids), (2) Joule-Thomson (isenthalpic) expansion of a compressed gas, and (3) an adiabatic (isentropic) expansion of a compressed gas in an engine (reciprocating or turbine) or from a bomb or cylinder through a throttling valve (Simon expansion). Using L^3He, method (1) is capable of reaching temperatures as low as ~0.4 K. Numerous refrigeration cycles have been devised utilizing various combinations of the above three methods. The final stage of refrigeration in plants that deliver liquid cryogens is generally a Joule-Thomson (isenthalpic) expansion. **Expansion engines** (reciprocating and turbine) are commonly used for producing the refrigeration needed to reach the final stage. Turbine expanders are preferred for the large refrigerators because their efficiencies (70 to 85 percent) are higher than for reciprocating expanders. The efficiencies of the heat exchangers for counterflowing "cold" and "warm" gases are an important factor in the overall refrigerator efficiency. In industrial plants heat exchanger efficiencies reach 98 percent. Their design represents a compromise between the attainment of a high heat-transfer coefficient, on the one hand, and a low resistance to the flow on the other.

Figure 19.2.1 typifies a commonly employed modified Brayton cycle which uses an expansion engine for generating the refrigeration. The theoretical figure of merit (the ratio of the work W_c done by the compressor to the heat Q, transferred to the refrigerant at the low temperature) is for this cycle

$$\frac{W_c}{Q} = \frac{RT_1 \ln (P_1/P_5)}{M(H_4 - H_3)}$$

where M is the molecular weight of the gas whose enthalpy per unit mass is H. The other symbols are defined by reference in Fig. 19.2.1.

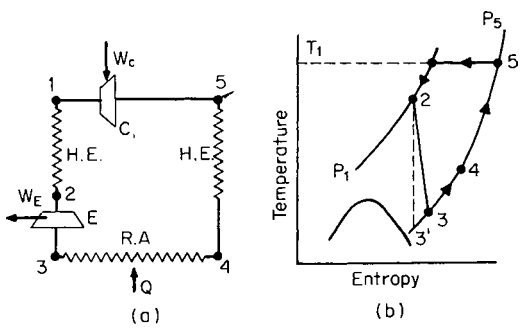

Fig. 19.2.1 (*a*) Schematic of a modified (isothermal compression) Brayton cycle, and (*b*) the process path. W_c is the energy (work) to drive the compressor *C*. Q is the heat absorbed by the refrigerator from the refrigerated area R.A., where the working fluid passes from state 3 to state 4. The heat-exchanger (H.E.) processes are isobaric. The dashed line 2–3′ is the ideal isentropic expansion; 2–3 represents the actual expansion in the expander E.

The **Stirling refrigerating engine** and modifications of it are used in a number of commercial makes of laboratory and miniature-sized refrigerators. The Stirling-cycle refrigerator is well suited to (1) the liquefaction of air on a laboratory scale (~7 L/h), (2) the recondensation of evaporated liquid cryogens, and (3) the refrigeration of closed spaces where the refrigeration load is not very large. These laboratory scale refrigerators supply ~1 kW of refrigeration at ~80 K and ~2 kW at 160 K. They are used with liquid air fractionating columns for the production of LN_2 (~7 L/h) and LO_2 (~5 L/h).

The Stirling-cycle refrigerator consists of a piston for compressing isothermally the working fluid (usually He), and a displacer which can operate in the same cylinder with the piston. The displacer and piston are connected to the same electrically driven shaft but displaced in phase by 90°. The displacer pushes compressed gas isochorically from the warm region where it was compressed, through the regenerator into the cold region where the compressed gas is expanded isothermally doing work on the piston and producing refrigeration. The regenerator consists of a porous mass (packed metal wool of high heat capacity) in which a steep temperature gradient is established between the warm region of compression and the cold region of expansion. The displacer returns the gas after expansion to the region for compression through the

regenerator in which it is warmed to the temperature of the isothermal compression. The refrigerant (He) is recycled. The regenerators in the larger refrigerators are usually placed around the outside of the engine cylinders, but in small capacity, lower temperature refrigerators they are put inside the displacers.

In Stirling refrigerators that reach temperatures of 17 K and produce 1 W of refrigeration at 25 K, the compressed He is expanded in two or three stages at temperatures intermediate between room temperature and the lowest temperature reached. There is only a single piston for compression. The expansion in stages allows part of the heat that leaks into the coldest region of a single stage engine to be absorbed and removed at a higher (intermediate) temperature where the efficiency for transferring heat is greater.

The **Vuilleumier refrigerating engine** is a modification of the Stirling refrigerator. It *resembles* two single Stirling engines placed back to back. One of the engines operates as a heat engine and the other as a refrigerator. The lower temperature at which the heat engine discharges its waste heat, is also the top temperature at which the refrigerator engine discharges its waste heat. Hence, the Vuilleumier refrigerator operates at elevated, intermediate and low temperature levels which may be 800, 300 (ambient), and 90 K, respectively. Each engine has a cylinder, a displacer, and a regenerator, and the two engines are connected to a common crankshaft but displaced by 90°. Very little external power is needed to operate the two displacers which are operated in sinusoidal motion, displaced 90° in phase. The working fluid (He) is recycled.

The **Gifford-McMahon refrigerator** is another modification of the Stirling-cycle refrigerator. It may be single stage for refrigeration at higher temperatures (~80 K), or multistage for lower temperatures. Each stage has a cylinder, a displacer and a regenerator. The displacer pushes gas (usually He) under a very small head of pressure from the top of the cylinder, where the temperature is ambient, through the regenerator, into the bottom of the cylinder which is the cold region of the refrigerator. Compressed He is supplied from an external source—the refrigerator has no piston for compressing gas. Only a small source of external energy is needed for driving the displacer which has very little work to do in overcoming the forces of friction. The valves that control the admission of compressed He to the top of the cylinder, and the expansion of the cold compressed He from the bottom of the cylinder are externally operated by a drive mechanism. The cycling rate is < 2 Hz. The expansion of the cold He is of the adiabatic-Simon-bomb type. Expanded gas is discharged from the refrigerator.

Some applications of cryogenic refrigerators require very high reliability without maintenance. The fewer the working parts, the more likely is the needed reliability to be achieved. The **pulse-tube** and **thermoacoustic refrigerators** are advantageous in this respect in that they have only one moving part, and that part operates at ambient temperature. Pressure oscillations are introduced into a tube with a closed end and fitted with the proper arrangement of heat exchangers. For the optimum frequency of the pulsation, a temperature gradient is established between the heat exchangers, and this gradient can pump heat from a low temperature to a higher one. A number of different designs have resulted, including single-stage and multistage units, and operating frequencies have ranged from about 1 Hz up to acoustic frequencies. This type of refrigerator is capable of reaching low temperatures down to 28 K with a single-stage unit, 26 K with a two-stage unit, and 11.5 K with a three-stage unit, all with ambient temperature heat sinks. Present research is also focused on the use of an acoustically driven pulse-tube refrigerator that would have no moving parts and no close tolerances of the components, thus making it inexpensive and easy to produce.

Magnetic refrigeration, originally proposed in 1925, depends upon the ability of paramagnetic materials at low temperature (or ferromagnetic materials near their Curie temperatures) to warm up (or expel heat at constant temperature) with the application of a magnetic field. Conversely, these materials will cool (or absorb heat at constant temperature) upon removal or reduction of the magnetic field. With the use of a paramagnetic material magnetized at a higher temperature of about 1.5 K, temperatures of about 0.001 K have been reached by a single demagnetization. Magnetic refrigeration is applicable over a wide range of temperatures, and recent research work is leading to continuous application of this process by mechanisms that promise a considerable increase in efficiency over that of more conventional refrigerators.

^{3}He-^{4}He dilution refrigerators for reaching temperatures between 0.01 and 0.3 K and generating continuously as much as 750 ergs/s of refrigeration are commercially available. Refrigeration results from the solution of L^{3}He in L^{4}He, the heat of solution being negative. Figure 19.2.2 is a schematic diagram of a dilution refrigerator. ^{3}He vapor from the "still" at ~1 K (the upper operating temperature of the refrigerator) is collected and returned by a pump to the "mixing" chamber where solution takes place. The ^{3}He arrives at the mixing chamber as L^{3}He near the mixing chamber temperature (the lower operating temperature of the refrigerator) after flowing through a heat exchanger counter to the flow

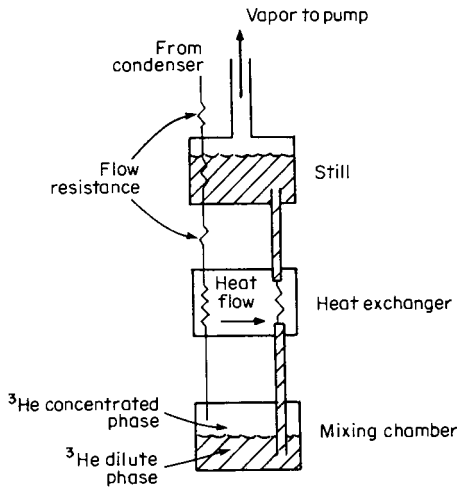

Fig. 19.2.2 Schematic diagram of the mixing chamber and still of a ^{3}He-^{4}He dilution refrigerator.

of cold ^{3}He-^{4}He solution on its way to the "still." In the electrically heated still, ^{3}He is evaporated from the solution. The evaporated ^{3}He is withdrawn by the collecting pump (diffusion) that returns the ^{3}He to the mixing chamber. At 1 K the vapor pressure of L^{4}He is negligible. L^{4}He in the still, freed of ^{3}He, returns to the mixing chamber by super-fluid flow, building up in the mixing chamber an osmotic pressure that drives ^{3}He atoms towards the still against the forces of viscous flow.

In the mixing chamber there is a two-phase separation of ^{3}He and ^{4}He. A layer of nearly pure L^{3}He of lower density rides on a heavier L^{4}He-rich layer containing ~ 6 percent ^{3}He. At temperatures lower than 0.87 K liquid solutions of ^{3}He and ^{4}He separate into two liquid phases, one ^{3}He-rich and the other ^{4}He-rich, in thermodynamic equilibrium. At 0 K, the ^{3}He-rich phase is 100 percent ^{3}He, whereas the ^{4}He-rich phase (in equilibrium with L^{3}He phase) contains ~ 6 percent ^{3}He.

In the mixing chamber, L^{3}He enters the upper ^{3}He-rich phase; solution of ^{3}He in ^{4}He takes place at the interphase boundary. The lower (denser) ^{4}He-rich phase connects with the still.

Starting at 50 mK (a temperature reached in a ^{3}He-^{4}He dilution refrigerator), temperatures in the 2- to 3-mK range are attainable with a **Pomeranchuk refrigerator.** Refrigeration is generated by compression of a mixture of liquid and solid phases of ^{3}He at pressures in excess of 28.9 atm, the minimum P at which these phases can coexist in equilibrium. The entropy of solid ^{3}He exceeds the entropy of L^{3}He, which is contrary to the normal behavior for other substances. This occurs in ^{3}He because of its nuclear magnetic properties. The ^{3}He nucleus is magnetic and at temperatures in the mK range and above, in solid ^{3}He, the nuclear

moments are randomly oriented whereas in L^3He, at temperatures lower than ~ 0.3 K, the nuclear moments are paired or partially paired, antiferromagnetically. An adiabatic increase of P converts liquid to solid with a reduction in T, whereas an isothermal increase of P results in an absorption of heat. ^3He, condensed, is confined in a container with flexible metal walls in the "cold" region of a ^3He-^4He dilution refrigerator. The ^3He container is surrounded with L^4He which serves as the pressure transmitting fluid.

GAS LIQUEFACTION

A conventional method of gas liquefaction utilizes a gas compressor, a countercurrent heat exchanger, and a throttling valve through which the gas expands isenthalpically (Joule-Thomson) and cools if it has already been cooled below its inversion temperature. After expansion, the cold gas returns through the heat exchanger, in which it exchanges heat with the countercurrent compressed gas flowing to the throttling valve. It leaves the heat exchanger near the temperature of the entering compressed gas. The temperature decreases at the throttling valve until the condensing temperature is reached, and then liquefaction occurs at a rate determined by the rate of refrigeration.

The rate of liquefaction x in pounds per hour is $x = \{[H$ (expanded *gas* out) $- H$ (compressed *gas* in)] $w - q\}/[H$ (compressed *gas* in) $- H$ (*liquid* following valve)], where the H's are enthalpies in Btu per pound for the final heat exchanger, w is the flow rate in the same units as x, and q is the heat leak in Btu per hour from outside into the heat exchanger. For an ideal heat exchanger the expanded gas leaves at the temperature of the entering compressed gas. In practice, there is a small difference in temperature which represents a small loss of refrigeration. For ideal gases, H is independent of P for a given T, and hence no liquefaction of an ideal gas results. The H's of air, O_2, N_2, A, CO_2, the hydrocarbons, and the normal refrigerants decrease with increasing pressure at ambient T, except at very high P's, and these gases are liquefiable by this kind of isenthalpic (Joule-Thomson) expansion. The H's of H_2 and He at ambient T, however, increase with increasing P, even at low P's, and hence an auxiliary mechanism is required for the liquefaction of these gases. In one method, the stream of compressed gas is split in the liquefier, and a part goes to an engine in which it is cooled by an isentropic expansion with the performance of work. This part of the flow, thus cooled, is sent to a heat exchanger, where it flows counter to the other fraction of compressed gas, cooling it to a temperature below the inversion temperature (see Sec. 4). This flow of compressed gas, thus precooled, is run through another and final heat exchanger with a throttling valve at its lower end, with the result that the quantity x is liquefied.

Another method of precooling H_2 and He below their inversion temperatures makes use of a boiling liquid cryogen through which the compressed gas flows in a heat exchanger. LN_2 is used for precooling H_2, and LH_2 for He.

APPLICATIONS OF CRYOGENICS

Gases, such as O_2, N_2, natural gas, H_2, and He, are liquefied for transportation because of the gain in density at low pressure. Shipments have been made of LH_2 by trailer trucks in quantities of 13×10^3 gal (50 m^3) for thousands of miles and by railway tank cars holding as much as 28×10^3 gal (100 m^3). LHe is regularly shipped in quantities from 25 gal (0.1 m^3) to 10,000 gal (40 m^3). Liquid cryogens are used as liquid refrigerants. The aerospace, steel, and bottled-gas industries are the principal users of liquefied cryogens. Important applications as coolants can be found in vacuum technology, electronics, biology, medicine, and metal forming.

In recent years, large superconducting magnets have been undergoing development for a variety of applications including fusion reactors, energy storage, electric-power transmission, high-energy physics experiments, and magnetically levitated trains. Magnets of Nb-Ti are available with fields up to 80 kG (8 T) with large magnetic field volumes (1 m^3). Higher field magnets [up to 1500 kG (15 T)] of Nb_3Sn are available with smaller magnetic field volumes (10^{-4} m^3). The Los Alamos National Laboratory installed a 30-MJ superconducting magnetic energy-storage system in the Bonneville Power Administration's Tacoma, Washington, substation to provide stabilization of utility long-line power-transmission systems. The response characteristics of the unit have been demonstrated on the utility's power grid, and the unit has been run successfully for extended periods. Two 100-m long superconducting ac transmission cables have been successfully tested at Brookhaven National Laboratory at 4,100 A and the equivalent of 138 kV three-phase. At the other end of the size spectrum, Josephson junction devices are being considered for applications such as radiation detectors, highly precise and accurate electrical measurements, geophysical instrumentation, medical instrumentation, and computer memory cells.

Cryogenics is also becoming increasingly important in the storage and transport of energy. Large quantities of natural gas are routinely transported as a liquid (LNG). Peak shaving in municipal gas systems is accomplished by storage of LNG. If, due to depletion of fossil fuels, hydrogen becomes an important synthetic portable fuel, cryogenic hydrogen will play an important role as it already does in space applications including the shuttle. Another potential application is aircraft fuel. This may be extended to surface transportation applications.

PROPERTIES OF SOLIDS AT LOW TEMPERATURES

(See also Sec. 4.)

Specific heats of solids in general decrease with decreasing T, becoming zero at 0°R (Fig. 19.2.3). The downward approach to $C_p = 0$ at 0° R is interrupted for some substances (principally compounds) by "bumps" on the curve (excess C_p that rises to a maximum and then decreases). Paramagnetic salts undergoing transitions to either a ferromagnetic or an antiferromagnetic state are examples. This excess specific heat of a paramagnetic salt is connected with the effectiveness of the salt for reaching low temperatures by the method of adiabatic demagnetization. There are also transitions in solids from a more orderly to a less orderly arrangement of atoms and molecules in the lattice that give rise to excess C_p. The transition in solid ortho- and normal H_2 below 20°R (11 K) is an example. In Fig. 19.2.3, C_p's are plotted for various materials.

Heat is transferred in dielectrics by lattice vibrations, or waves. In good electrical conductors, heat is transferred principally by the conduction electrons, and thermal and electrical conductivities are related by the Wiedemann-Franz law; $\kappa/\sigma T = \text{const}$. This means that the ratio

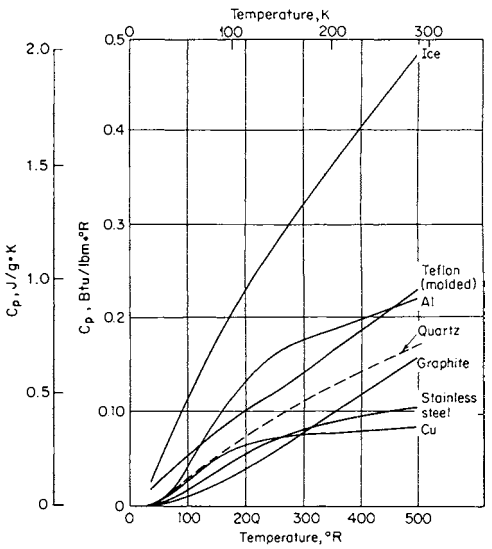

Fig. 19.2.3 Specific heats of solids at low temperatures.

of the thermal and electrical conductivities at a given T is approximately the same for the good conductors. In the poor electrical conductors, alloys for example, both lattice waves and conduction electrons play important parts in the transfer of heat. The κ's of "pure" dielectrics and "pure" metals rise with increasing T from $\kappa = 0$ at 0°R (proportional to T for metals and to T^3 for dielectrics), reach a maximum, normally between 10 and 100°R (5 and 55 K), and then decrease to a value approximately independent of T (Fig. 19.2.5 and ice in Fig. 19.2.4). The κ's of alloys (Fig. 19.2.4) are an order of magnitude smaller than for "pure" metals and *do not* exhibit the maxima characteristic of the "pure" metals at low T. Lattice disorder introduced by alloying, even in small amounts, and working a metal, even a pure metal, reduces κ. Annealing, in general, raises κ.

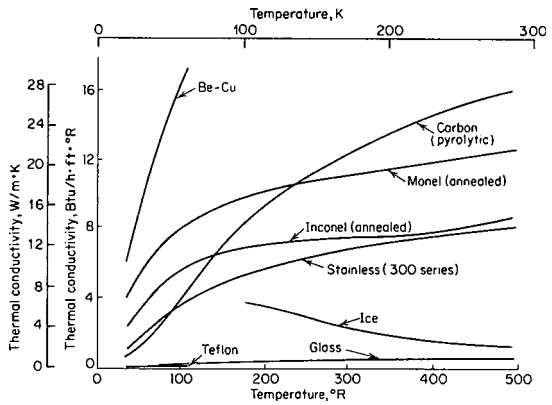

Fig. 19.2.4 Thermal conductivity of solids at low temperatures, part 1.

At 0°R, an absolutely pure and perfect single crystal of metal would have zero electrical resistance, $R_e = 0$. **Electrical resistance** arises from the scattering of the conduction electrons as they move through the lattice of metal ions under the influence of an externally applied electric field. Scattering arises for two reasons: (1) the amplitudes of the thermal vibrations of the lattice which increase with T at a rate proportional to $\sqrt{C}$ of the metal, and (2) the imperfections in the regularity of the lattice

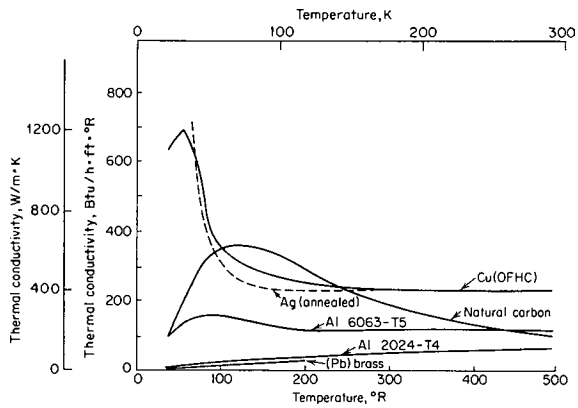

Fig. 19.2.5 Thermal conductivity of solids at low temperatures, part 2.

as caused by impurity atoms (solid-solution alloys included), lattice vacancies, dislocations, and grain boundaries. Resistances for "pure" metals increase with T and are roughly proportional to $C \cdot T$, except at very small T's where they are proportional to T^5 for absolutely pure crystals. The resistance due to impurities and imperfections is very roughly independent of T (Matthiessen's rule). For very pure metals, R_e is approximately constant below 20°R (11 K). Magnetic impurities can give rise to a minimum in resistivity [usually below 36°R (20 K)] called the Kondo effect. Resistivity in $\Omega \cdot$ cm (Fig. 19.2.6) is the R_e of a 1-cm cube.

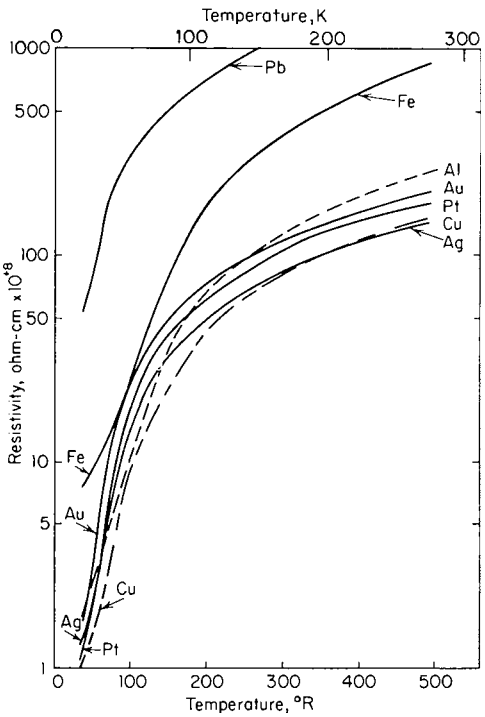

Fig. 19.2.6 Electric resistivity of solids at low temperatures.

Some metals, including elements (none from column 1 of the Mendeleeff table or the ferromagnetic elements), intermetallic compounds, metal alloys, and a number of oxides exhibit the phenomenon of **superconductivity,** characterized by a zero dc electrical resistance from 0°R up to a transition temperature T_c, at which normal resistance (value extrapolated from higher T) appears. In pure, single crystals the transition range ΔT, from $R_e = 0$ to the normal value, may be as small as a few millidegrees. Until the discovery of the so-called high-temperature superconductors (HTSCs), the higher T_c in a practical superconductor was that of the compound Nb_3Ge at 41.9°R (23.3 K). The search for higher T_c materials continues with T_c's that have already been reported as high as 239°R (133 K). Closed circuits consisting entirely of superconductors can support a persistent, resistanceless current without an external source of voltage. A superconducting circuit therefore maintains constant the value of the total magnetic flux that was enclosed by the circuit at the time it entered the superconducting state. Hence, superconducting materials influence the magnetic fields in their environment. For this reason, their use in the construction of equipment and apparatus must sometimes be avoided when expected temperatures could be below their T_c. Lead brasses and some solders, in particular Pb-Sn alloys, become superconductors.

Superconductivity, in materials designated Type 1 superconductor, is characterized by (1) perfect electric conductivity ($R_e = 0$) and (2) the internal magnetic induction $B = 0$ when H (external) is not zero (the Meissner effect). Persistent currents at the surface of the specimen shield the interior from H (external). H parallel to the surface of a specimen is continuous at the surface and falls off exponentially below the surface. The penetration depth of H for perfect (chemically and mechanically) specimens is of the order of 5×10^{-8} m. The penetration depth is larger for alloys, specimens with lattice imperfections, and all superconducting specimens near their superconducting transition temperatures T_c.

The normal-to-superconducting transition temperature T_c is also a function of H (external) as well as of the current being carried by the superconductor. For a Type I superconductor, the effect of H (external) is expressed by $T_c = T_{c0}\,[1 - (H_c/H_0)]^{1/2}$ where T_{c0} is the value of T_c at essentially zero H, and H_0 is the value of H_c at 0 K. For every $H < H_c$, a further decrease in T_c occurs when the superconductor is carrying a current, the maximum current density for maintaining the superconducting state being denoted J_c. Thus the superconducting state exists when $T < T_c$, $H < H_c$, and $J < J_c$, and the normal, or resistive, state exists when either $T > T_c$, $H > H_c$, or $J > J_c$. Because T_c decreases with increases in H and J, the practical application of a superconductor requires that it be maintained at a temperature considerably below its T_c.

Tables 19.2.1 and 19.2.2 are only representative. The number of superconductors including compounds and alloys runs into the hundreds. Of the chemical elements, 38 are known to become superconductors. Some that are not superconductors at normal pressures have high-pressure allotropic modifications that are superconductors, e.g., Bi, Si, and Ge at pressures of ~25, 130, and 120×10^8 Pa, respectively. Many of the superconducting alloys have nonsuperconducting constituents, and there are compounds all of whose constituent elements in their pure state are nonsuperconductors (see Table 19.2.2). It is interesting that good conductors Cu, Ag, and Au do not become superconductors to the lowest temperatures at which they have been tested (~ 0.01 K).

Table 19.2.1 Transition Temperature T_0 and Critical Magnetic Fields H_0 of Some Type I Superconductors

Superconductor	T_0, K	H_0, A/m*
Nb	9.25	1.57×10^5
Pb	7.23	6.4×10^4
V	5.31	8.8×10^4
Hg	4.154	3.3×10^4
Sn	3.722	2.4×10^4
In	3.405	2.2×10^4

Table 19.2.2 Transition Temperatures T_0 and Upper Critical Fields H_{c2} of Some High-Field, Type II Superconductors

Superconductor	T_0, K	H_{c2}, A/m*	T, K, for H_{c2}
$Al_{0.75}Ge_{0.25}Nb_3$	18.5	3.4×10^7	4.2
Nb_3Sn	18.0	1.9×10^7	4.2
$N_{0.93}Nb$	15.9	1.3×10^7	0
GaV_3	14.8	1.9×10^7	0
NbZr	10.8	7.4×10^6	0
$Nb_{0.2}Ti_{0.8}$	7.5	6.4×10^6	4.2
$Ti_{0.6}V_{0.4}$	7.0	8.8×10^6	2

* To convert to oersteds, divide by 79.57.

Type I superconductor is the designation given to those superconductors that exhibit a complete Meissner effect for $0 < H < H_c$; i.e., $B = 0$ until H_c is reached and penetration of the specimen by B becomes complete. The superconducting elemental metals in the pure and mechanically perfect state are Type I superconductors. Superconducting alloys (intermetallic compounds, solid solutions, and mixed phases) and work-hardened (unannealed) metals are Type II superconductors. For Type II superconductors, the Meissner effect is complete only for $0 < H < H_{c1}$ where H_{c1} is smaller than H_c. For $H_{c1} < H < H_{c2}$, the magnetic field penetrates the body of the specimen in the form of current vortices, called *fluxons,* that generate a fixed quantized amount of magnetic flux. Each fluxon is a cylindrical region of circulating current centered on a resistive core of material in which the superconductivity is suppressed. Hence the region defined by $H_{c1} < H < H_{c2}$ is called the *mixed state* of a Type II superconductor. The number of fluxons increases with H from zero at H_{c1} to a density at which complete overlap of the cores occurs along with the restoration of the normal state at H_{c2}. Thus H_{c2} is an upper limit to the superconducting state that increases as T decreases.

The alloys commonly used for high-field superconducting magnets (Nb_3Sn, NbTi, and NbZr, see Table 19.2.2) are Type II superconductors. H_c's for Type I superconductors are small, whereas magnet alloy wires have H_{c2} values that are 100 to 1,000 times higher.

The fluxons in the mixed state of a Type II superconductor transporting a current are acted on by a Lorentz force that is proportional to $\mathbf{i} \times \mathbf{B}$ and acts in a direction perpendicular to **B,** and to **i** (the current intensity). Unless the fluxons are pinned to crystal lattice sites they are propelled across the superconductor under the influence of the Lorentz force. This movement involves the performance of work by the current and results in (1) production of heat within the superconductor and (2) the appearance of electrical resistance to the flow of current and, eventually, the destruction of the superconducting state. Fluxons are pinned by lattice imperfections (chemical and mechanical) and their displacement is resisted until the Lorentz force exceeds a breakaway value, freeing the fluxons to move. Lattice imperfections are introduced in the wires for high-field superconducting magnets to pin fluxons as well as to increase H_{c2}. Currents avoid the normal core of a pinned fluxon and thus retain their resistanceless character.

A current exceeding the critical value destroys the superconducting state. This critical current is determined by the critical Lorentz force (the product of current and magnetic field) at which pinning forces are exceeded. Hence, the critical value of an applied field depends on the current transported by the superconductor and vice versa. In general, the larger the applied field, the smaller is the critical current and vice versa. For superconducting magnets, it is essential that the values of the limiting magnetic field and the limiting current be simultaneously large.

For the Types I and II superconductors discussed above, practical application requires operation in the temperature region of 12 K or lower. Thus the lower limit (ideal refrigeration) for the work to heat removal ratio is seen to be 24 for operation between ambient temperature and 12 K. Raising the operating temperature of a superconducting system to 20, 40, or 77 K (the temperature of liquid nitrogen boiling at normal atmospheric pressure) reduces this ratio to 14, 6.5, and 2.9 respectively. Although the actual refrigerator may take 2.5 or more times this ratio, the saving in input energy that can be effected by raising the operating temperature is obvious. The equipment for producing refrigeration at these higher temperatures is also less complicated and less expensive than that needed for producing refrigeration at the lower temperatures required for the operation of the low-temperature superconductors.

In 1986 a true breakthrough was achieved in producing superconductors able to enter the superconducting state at much higher temperatures. The high-temperature superconductors (HTSCs) are oxide compounds consisting of several elements. They are more like ceramics and have a complicated crystal structure consisting of layers of Cu-O separated by other oxides. All of them exhibit highly anisotropic superconducting properties and their performance is greatly influenced by the oxygen content of the compound. If the crystals are not properly oriented so that there is too great an angle between the crystal axes of adjacent crystals (e.g., greater than about 5°), intergranular supercurrent flow is supressed and the HTSCs will have sections of superconductor connected by rather poorly conducting junctions. This has been referred to as "having weak links." Therefore, it is desirable to prepare the HTSC material in such a way that it is biaxially textured, in order to minimize weak links. Also, the ability of these superconductors to conduct useful quantities of current can be severely limited by an imposed magnetic field at temperatures near the high end of their superconducting range. The magnetic field enters the superconductor in fluxons, or vortices. When these vortices move through the superconductor, electrical resistance is generated and the superconductor behaves much like a normal metal. Therefore it is necessary to "pin" the vortices so they cannot move. As with low-temperature superconductors, vortices are pinned by lattice imperfections, either chemical or mechanical.

At temperatures below 30 K, the extraordinarily high H_{c2} of the HTCSs allows them to carry high current densities at much higher magnetic fields than is possible with the conventional, low-temperature superconductors. At higher temperatures a new phenomenon has been observed, the "melting" of the vortex lattice that limits the ability of crystal imperfections to pin vortices at magnetic fields far below H_{c2}. The HTSCs are fabricated as thin films and multifilimentary wires. The necessity for optimum chemistry of the constituents, proper crystal orientation, and the fact that the ceramic-like nature of the superconductor makes it brittle complicate both the manufacture of the wires in useful lengths and the subsequent fabrication of equipment such as coils for motors and generators. There are two classes of compounds that have received the most attention in these research efforts. One class is referred to as BSCCO because it consists of the oxides of bismuth, strontium, calcium, and copper in varying ratios. The other class is referred to as YBCO because it consists of oxides of yttrium, barium, and copper.

A great deal of research is continuing in the attempt to improve the commercial usefulness of the HTSCs. This research has made enormous strides in finding production methods for practical superconductors and ways to produce them more economically. There are already fabrication methods that enable the production of kilometre lengths of superconductors capable of carrying very high currents (about 10^5 A/cm^2) in self-field at 77 K. These efforts should make possible the large-scale utilization of HTSCs. Table 19.2.3 lists several of the HTSCs, along with the pertinent properties.

Table 19.2.3 Properties and Status of some HTSCs

HTSC*	T_c, K	Comments
$La_{2-x}Ba_xCuO_4$	35	First HTSC discovered
$YBa_2Cu_3O_7$ (YBCO or 1–2–3)	95	First HTSC with T_c above normal boiling point of liquid nitrogen, $H_{c2} > 30$ T at 77 K
$HgBa_2Ca_2Cu_3O_{8+\delta}$	133	Highest T_c to date
$Bi_2Sr_2Ca_2Cu_3O_8$ (2223 BSCCO)	110	$H_{c2} = 30$ T at 77 K, $J_c > 8 \times 10^4$ A/cm^2 at 77 K and $H_{ext} = 0$; industrial pilot-plant-scale production
$Tl_2Ba_2CaCu_2O_8$ (2212 TBCCO)	~115	$J_c = 7 \times 10^6$ A/cm^2 at 75 K and $H_{ext} = 0$

* These HTSCs are representative of classes of superconductors.

The discovery in 2001 of superconductivity in the relatively common intermetallic compound, magnesium diboride (MgB_2), with a transition temperature of about 40 K, opens new possibilities to the application of low-temperature superconductors (LTSCs). MgB_2 is easier than the HTSCs to produce, handle, and fabricate into wires, and MgB_2 reduces the energy requirement for refrigeration by about an order of magnitude compared to that of the previously known LTSCs. MgB_2 can be used for the manufacture of superconducting magnets, and its use should make more feasible the utilization of superconducting electric power transmission lines.

The **coefficient of linear expansion** α is $(1/L)\,(dL/dT)$. Thermal expansion of asymmetric crystals differs along different crystal axes. For an isotropic solid, the volume or cubical-expansion coefficient $(1/V)\,(dV/dT) = 3\alpha$. Expansion coefficients do not vary appreciably in the temperature region near ambient temperatures, but they all approach zero at 0°R, and the approach to zero is tangential to the T axis ($d\alpha/dT = 0$ at 0°R.) Some expansion coefficients are negative at low temperatures, e.g., stainless steel, some Invars, and fused quartz. The expansivities of some crystals are negative in some directions even though their volume coefficients are positive. Cold-working may produce differences in expansivity in different directions. Annealing restores isotropy. Figure 19.2.7 shows the relative change in length, the integral of α from T to 528°R (293 K).

Because the cold interiors of cryogenic equipment must at times be warmed to ambient temperature, provisions have to be made for those changes in dimensions of the interior that results from large changes in T. Even for equipment of ordinary size, these changes can be too large for accommodation within the elastic limits of the materials of construction or of the structure. In such situations, flexibility has to be designed into

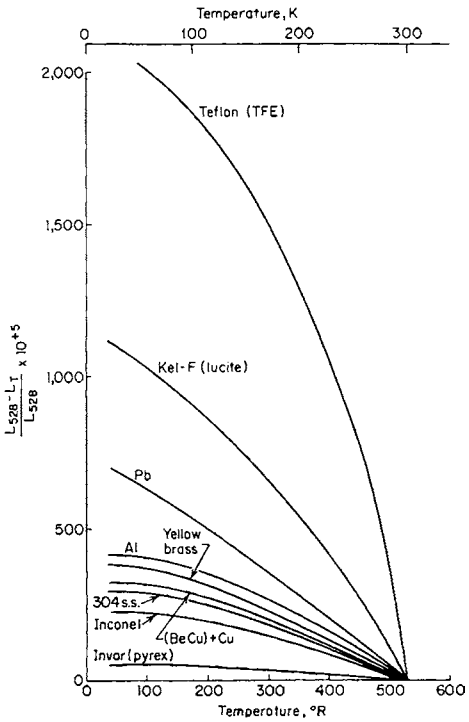

Fig. 19.2.7 Relative change in length from T to 528°R (293 K), equal to $\int_t^{528^\circ R} \alpha\, dt$. Bracketed materials are within ~5 percent of the curve shown.

the structure. For example, bellows and U bends are commonly employed to obtain this flexibility in insulated transfer lines for liquid cryogens.

The **mechanical properties** important for the design and construction of cryogenic equipment are the same as for other temperatures (see also Sec. 5). Frequently, the choice of materials for the construction of cryogenic equipment will depend upon other considerations besides mechanical strength, e.g., lightness (density or weight), thermal conductivity (heat transfer along structural support members), and thermal expansivity (change of dimensions when cycling between ambient and low temperatures). Frequently, mechanical properties at low temperature are significantly different from properties at ambient temperature. This makes room-temperature data unreliable for engineering use at low temperatures.

It is not possible to make generalizations that would not have numerous exceptions about the temperature variations of the mechanical properties. In this discussion, Figs. 19.2.8 to 19.2.10 are only illustrative guides. There is no substitute for test data on a truly representative specimen when designing for the limit of effectiveness of a cryogenic material or structure. Just as the mechanical properties at ambient temperatures are dependent upon the impurities (metallic and nonmetallic), their chemical nature and concentration, the thermal history of the specimen, the amount and kind of working (microstructure and dislocations of the lattice), and the rate of loading and type of stress (uni-, bi-, and triaxial), so also are the changes, quantitative and qualitative, in the mechanical properties when changing the temperature from ambient to low.

Metals, nonmetallic solids (glass), plastics, and elastomers are discussed in order. The metals are classed by their lattice (crystal) symmetry.

The **f.c.c. metals** and their alloys are most commonly used for the construction of cryogenic equipment. Al, Cu, Ni, their alloys, and the austenitic stainless steels of the 18–8 type (300 series) are f.c.c. They do not exhibit an impact (or a notched-tensile) ductile-to-brittle transition at low temperatures. As a general rule, which has some exceptions, the mechanical properties of these metals improve as T is reduced: (1) Young's modulus at 40°R (22 K) is 5 to 20 percent larger than at 530°R (294 K), (2) the yield strength at 40°R (22 K) is considerably greater than the strength at 530°R (294 K). (Cu is an exception; see Fig. 19.2.9), and (3) the fatigue properties at low T are improved. There is a large

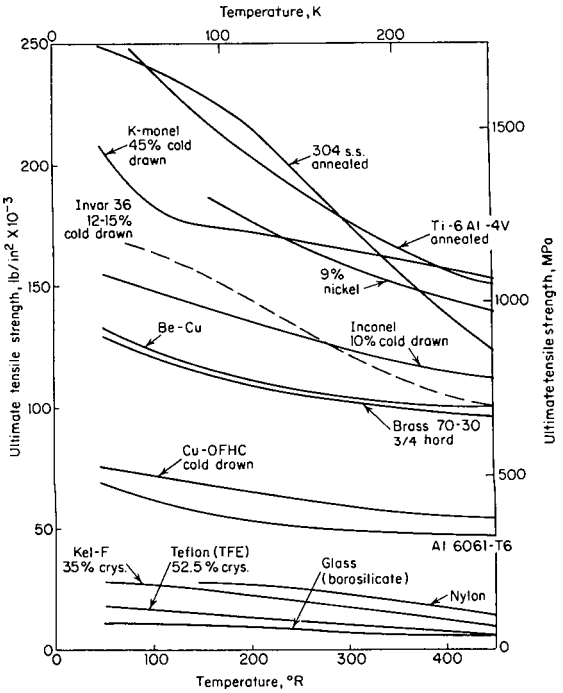

Fig. 19.2.8 Ultimate tensile strength of solids at low temperatures.

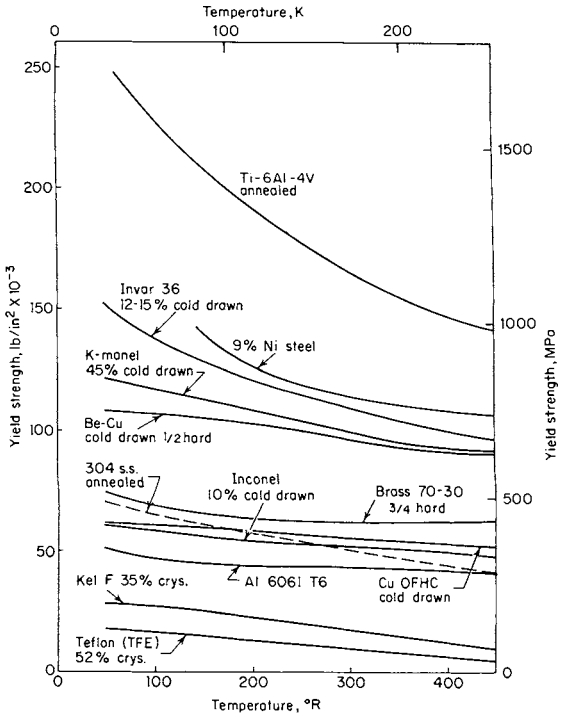

Fig. 19.2.9 Yield strength of solids at low temperatures.

difference between the yield strength and the ultimate tensile strength of these metals and alloys, especially when they have been annealed. Pb (f.c.c.) and In (face centered tetragonal) are used for low-*T* deformable gaskets because of their creep properties. Low-*T* creep data are meager, but the rate of creep decreases with *T*.

Beta brass (f.c.c.) is ductile down to 7°R, though it is like all alloys of Cu in being less ductile than Cu itself. Thin brass is sometimes porous, and this limits its usefulness for high-vacuum enclosures at low temperatures. Free-machining brass normally contains Pb, which even in low concentrations can render the brass superconducting at LHe temperatures. In the superconducting state, it may then affect the magnetic field in its vicinity (see electrical properties, above).

The b.c.c. **metals and alloys** are normally classed as undesirable. These include Fe, the martensitic steels (low carbon and the 400 series of stainless steels), Mo, and Nb. If not brittle at room temperature, they have a ductile-to-brittle transition at low *T*. Working can induce the austenite-to-martensite transition in some steels. AISI 301 austenitic stainless is an example. It remains moderately "tough" at very low *T* and is a valuable material for construction, but cold-drawing, in excess of 70 percent strain, induces a partial transformation of structure and reduces the elongation and notched-strength ratio to nearly zero. This same type of reduction in toughness is observed in the "heat-treatable" stainless steels. Improved tensile properties can be obtained by

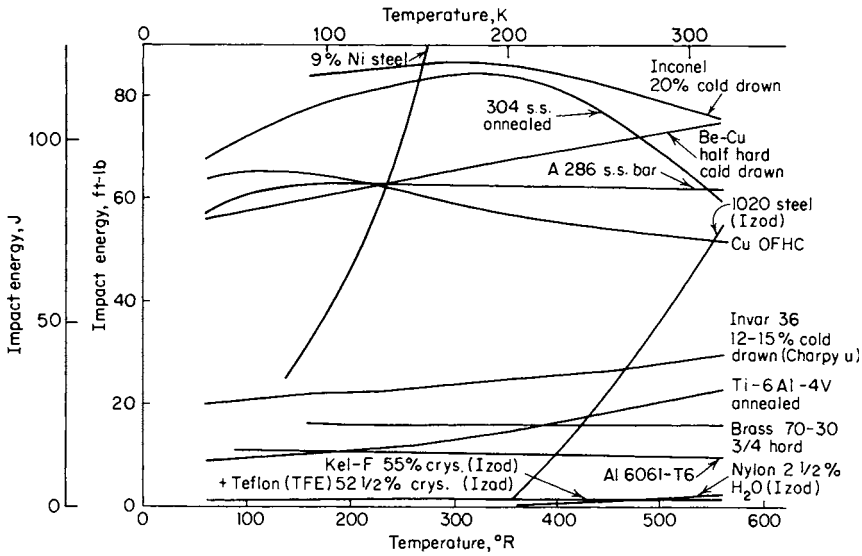

Fig. 19.2.10 Impact energy for solids at low temperatures (Charpy V unless noted). For Kel-F, nylon, and Teflon, the impact energy units are foot-pound per inch of notch width.

cold-working and by heat-treating. These alloys usually have decreased toughness at low temperatures. Alloys of V, Nb and Ta, although not f.c.c., behave well as regards brittleness at low temperatures. These alloys have the advantage of being suitable for use at high *T.* Carbon steels, though brittle, have found special uses at low temperatures, e.g., in the construction of the expansion engines of the Collins He liquefier and cryostat.

The **h.c.p. metals** exhibit properties intermediate between those of the f.c.c. and b.c.c. metals; e.g., Zn undergoes a brittle-to-ductile transition, whereas Zr and pure Ti do not. Ti and some Ti alloys, having a h.c.p. structure, remain moderately ductile at low *T* and are excellent for many applications. They have high strength-to-weight and strength-to-thermal-conductivity ratios. The low-*T* properties of Ti and its alloys are extremely sensitive to even small amounts of O, N, H, and C.

Brittle materials, when in very thin sheets, can have a high degree of flexibility, and this makes them useful for some cryogenic applications. **Flexibility** cannot be used as a criterion for ductility.

Ordinarily, normal welding practices are observed in the construction of cryogenic equipment. These practices, however, are modified in accordance with available knowledge of the performance of the metals at low *T.*

Nonmetal materials for construction are in many cases brittle, or they are susceptible to brittle fracture. The strength of **glass,** measured at a constant rate of loading, increases on going to low *T.* Failure occurs at a lower stress when the glass surface contains cracks and abrasions. The strength of glass can be improved by tempering the surface, i.e., by putting the surface under compression.

The **plastics** increase in strength as *T* is decreased, but this is accompanied by a rapid decrease in elongation in a tensile test and a decrease in impact resistance. Teflon and the glass-reinforced plastics (e.g., glass-reinforced epoxy resin) retain appreciable impact resistance as *T* is lowered. Teflon, which is polytetrafluoroethylene, can be deformed plastically at *T*'s as low as 7°R (3.9 K). The amount is considerably less than at room temperature, but it is enough to make Teflon very useful for some cryogenic applications. The glass-reinforced epoxies, besides having appreciable impact resistance at low *T*'s, also have high strength-to-weight and strength-to-thermal-conductivity ratios.

All the **elastomers** become brittle at low *T.* However, elastomers like natural rubber, nitrile rubber, Viton A, and plastics such as Mylar and nylon that become brittle at low *T* can be used for static seal gaskets when *highly compressed* at room temperature, prior to cooling.

PROPERTIES OF CRYOGENIC FLUIDS (CRYOGENS)

Table 19.2.4 indicates the **temperature ranges** accessible with liquid cryogen baths. There are two inaccessible ranges: (1) between helium and hydrogen [9.36 to 24.9°R (5.2 to 13.8 K)] and (2) between neon and oxygen [80 to 97.9°R (44.4 to 54.4 K)]. The limiting temperatures are set by the critical and triple points. Pumping on a cryogen bath to lower the pressure results in lower temperatures ultimately reaching the triple point; except for helium, further pumping leads to solidification and in practice poor heat-transfer. Raising the bath pressure results in higher boiling temperatures with the limit set by the critical temperature, above which liquid and vapor phases cannot coexist. Cryogen baths are most frequently operated near atmospheric pressure.

The algebraic sign of the Joule-Thomson coefficient determines whether a gas cools or warms upon free expansion. Figure 19.2.11, based on the law of corresponding states, allows rough calculations of inversion temperatures and pressures. Free (Joule-Thomson) expansion inside the "cooling" region results in cooling, i.e., refrigeration; outside this region, heating results. Upper inversion temperatures at 14.7 psia (0.101 MPa) are given in Table 19.2.4.

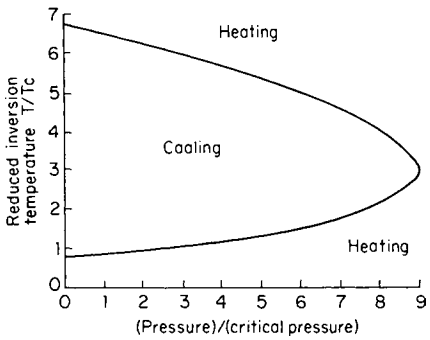

Fig. 19.2.11 Reduced inversion temperature versus reduced pressure.

Volumetric latent heats (Table 19.2.4) decrease with the lower-boiling cryogens and emphasize the importance of the insulation in storing and handling LH_2 and LHe.

Two forms of **hydrogen** and **deuterium** exist: **ortho** and **para.** The ortho and para molecules differ in the relative orientation of the nuclear spins of the two atoms composing the diatomic molecule. In the ortho form of H_2 the nuclear spins of the two atoms in the molecule are parallel (in the same direction), whereas in the para form the spins are antiparallel. The relative orientations for ortho and para D_2 differ from those for H_2. The thermodynamic equilibrium composition of ortho and para varieties is temperature dependent as shown in Fig. 19.2.12.

In liquid hydrogen, the uncatalyzed ortho-para reaction is second order (proportional to the square of the o-H_2 concentration) with a rate

Table 19.2.4 Common Cryogen Properties

§ Melting point, 14.7 lb/in² abs.

constant of 0.0114/h. Thus, in the course of uncatalyzed liquefaction, normal LH_2 (75 percent ortho) is produced. Since the heat of conversion of o-H_2 to p-H_2 at the normal boiling point is 302 Btu/lbm (702 J/g) (greater than the heat of vaporization; see Table 19.2.4), long-term storage of normal LH_2 is impractical. Therefore, in the commercial production of LH_2 a catalyst is used to produce LH_2 with more than 95 percent para which for practical purposes is equivalent to the equilibrium composition (99.8 percent para).

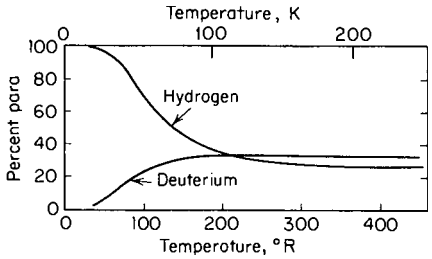

Fig. 19.2.12 Thermodynamic equilibrium composition of ortho and para varieties of H_2 and D_2; percent ortho = 100 − percent para.

For pressures of no more than 150 lb/in^2 (1.03 MPa) and temperatures at least twice the critical temperature, the ideal gas law ($PV = nRT$) enables one to calculate PVT data with sufficient accuracy for many engineering purposes. For cases in which the ideal gas law is not adequate or in which experimental data are not available, the procedures outlined in Sec. 4 may be used. The theoretical prediction of PVT data for liquids is considerably more difficult than for gases. Consequently no universal equation analogous to the perfect gas law exists for extensive ranges of P and T.

Reduced quantum mechanical correlations of saturated liquid densities, viscosities, and thermal conductivities for several cryogens are shown in Figs. 19.2.13 to 19.2.15. Dashed lines represent areas void of experimental data.

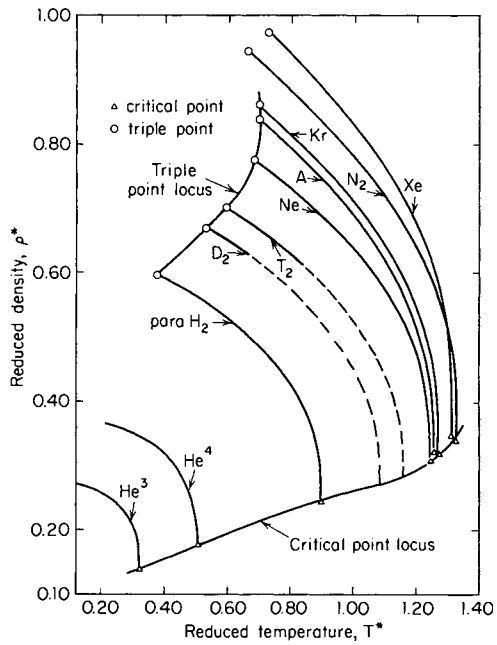

Fig. 19.2.13 Reduced density versus reduced temperature along the saturation curve for cryogenic liquids. Values of T^* are obtained by dividing the desired temperature (°R) by the value of T/T^* given in Table 19.2.5. Reduced density ρ^* must be multiplied by ρ/ρ^* given in Table 19.2.5 to obtain density in lbm/ft^3. Multiply lbm/ft^3 by 16.01 to obtain kg/m^3 and °R by 0.556 to obtain K.

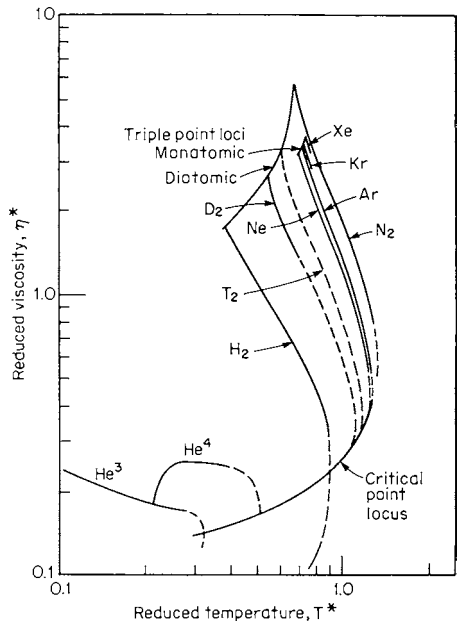

Fig. 19.2.14 Reduced viscosity versus reduced temperature along the saturation curve for cryogenic liquids. Values of T^* are obtained by dividing the desired temperature (°R) by the value of T/T^* given in Table 19.2.5. Reduced viscosity η^* must be multiplied by η/η^* given in Table 19.2.5 to obtain viscosity in lbm/ft · h. Multiply lbm/ft · h by 0.000413 to obtain Pa · s.

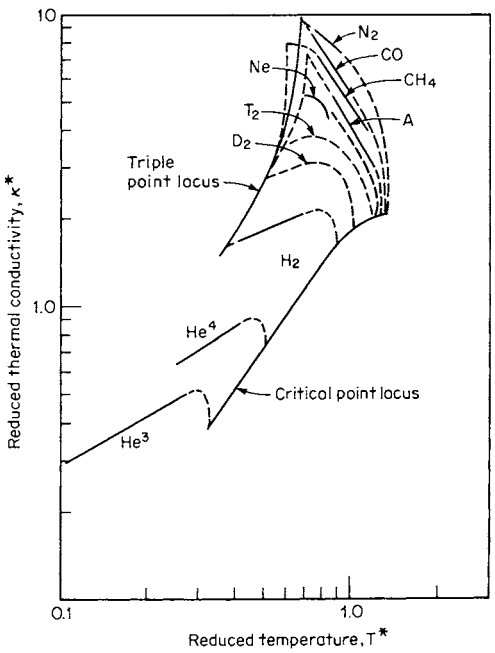

Fig. 19.2.15 Reduced thermal conductivity versus reduced temperature along the saturation curve for cryogenic liquids. Values of T^* are obtained by dividing the desired temperature (°R) by the value of T/T^* given in Table 19.2.5. Reuced thermal conductivity κ^* must be multiplied by κ/κ^* given in Table 19.2.5 to obtain thermal conductivity in Btu/h · ft · °R. Multiply by 1.73 to obtain W/m · K.

Utilization of Figs. 19.2.13 to 19.2.15 requires knowledge of the constants ε and σ for the Lennard-Jones function for the intermolecular potential energy $\varphi(r)$ of a pair of molecules separated by a distance r, so that $\varphi(r) = 4\varepsilon[(\sigma/r)^{12} - (\sigma/r)^6]$. Here ε is the depth of the minimum in the potential energy of a pair of molecules, and σ is the separation of the pair at which $\varphi = 0$. To facilitate use of Figs. 19.2.13 to 19.2.15, all required constants and conversion factors have been combined and are listed in Table 19.2.5.

Table 19.2.5 Multiplication Factors for Use with Figs. 19.2.13 to 19.2.15

Substance	T/T*, °R	ρ/ρ^*, lbm/ft^3	η/η^*, lb/ft-hr	κ/κ^*, Btu/(h · ft · °R)

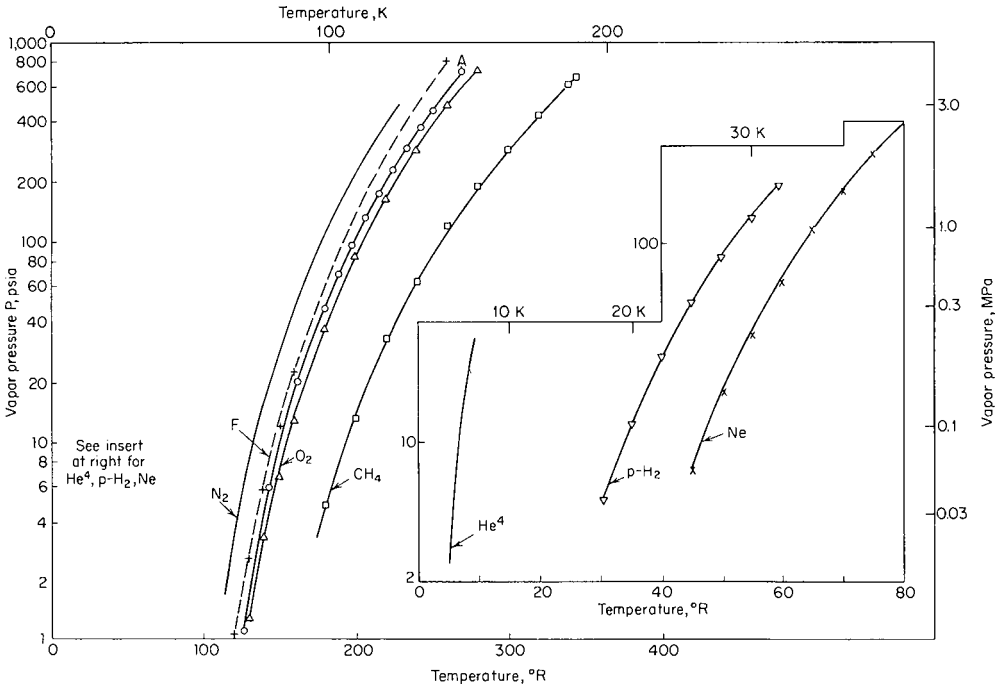

Fig. 19.2.18 Vapor pressures of the common cryogens.

For gases, kinetic theory predicts an increase of **viscosity** with rising temperature as shown in Fig. 19.2.16 ($\eta \sim \sqrt{T}$). Normally, the **thermal conductivities** of liquids decrease with increasing temperature, whereas the thermal conductivities of gases increase. Fig. 19.2.17 presents thermal conductivity for several gases as a function of temperature at 14.7 psia (0.1013 MPa).

Figure 19.2.18 is a graph of **vapor pressures** of the common cryogens.

Figure 19.2.19 presents **specific heats** at constant pressure for several of the cryogenic liquids, while Fig. 19.2.20 presents the specific heats for liquid hydrogen and helium along the saturation curve. Specific heats of gases are given in Fig. 19.2.21.

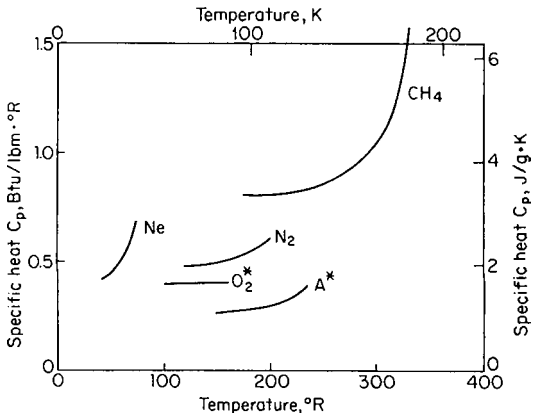

Fig. 19.2.19 Specific heat at constant pressure (C_p) for liquid cryogens at saturation pressure. Asterisk means C_p evaluated along an isobar at 14.7 lb/in^2 abs (0.1013 MPa) instead of saturation pressure.

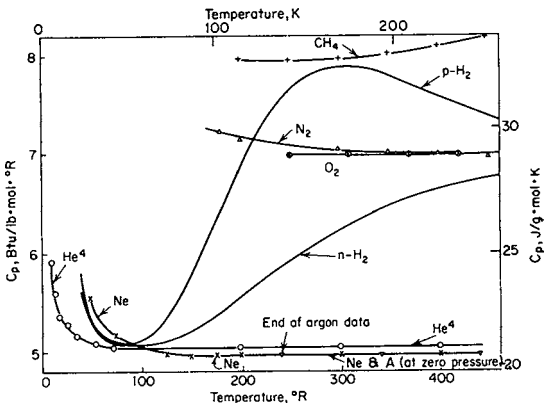

Fig. 19.2.21 Specific heat C_p of cryogen gases at 14.7 lb/in^2 abs (0.1013 MPa) versus temperature.

INSTRUMENTATION

(See also Secs. 15 and 16.)

The usual instrumentation problems of engineering practice are further complicated by low-temperature problems which require special calibration procedures.

Pressures are measured with normally used apparatus, e.g., bourdon gages, transducers, and manometers. If the measuring device is located outside the cryogenic environment and insulated from it by a thermal barrier, no special problems are introduced. Occasionally response time requirements necessitate the placing of the transducer in the cryogen space. Then the problems of temperature compensation and calibration must be considered.

Level measurements currently utilize several methods. The differential-pressure method can in principle be used with all cryogens. With cryogens of low densities and low heats of vaporization (e.g., H_2 and He) pressure oscillation occurs in the liquid leg. In the case of LH_2 these can be eliminated by the proper design of the liquid leg and the introduction of He gas which does not condense.

Direct weighing is also used to determine "levels," although difficulties are encountered owing to the large tare-to-cryogen weight ratios (as large as 10 to 1 for a full container in the case of H_2) and extraneous loadings introduced by permanently connected piping, frost, and wind. Weighing systems have nevertheless been successfully used on 50,000-gal (190 m^3) LH_2 dewars with an accuracy in level changes of 250 gal (1 m^3).

With the **capacitance gage,** the sensing element consists of a concentric tube capacitor which can be calibrated to give liquid-level measurements accurate to a few tenths of a percent. An inexpensive, accurate **point-level sensor** is easily fabricated from a carbon resistor, typically 1/10 W, 1,500 Ω. Its use depends upon the fact that its resistance is a strong function of temperature (Fig. 19.2.22). A small current (50 to 80 mA) is passed through the resistor to heat it. Since heat from the resistor is dissipated more readily in the liquid than in the gas, the temperature of the resistor

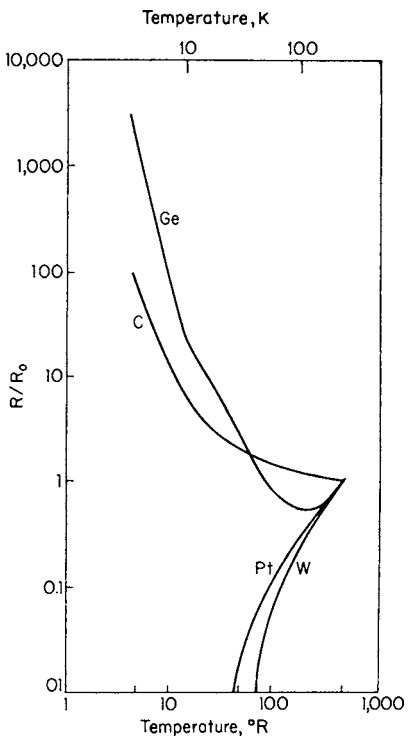

Fig. 19.2.22 Ratio of resistance R to the resistance R_0 at 492°R (273 K) versus temperature for several resistance thermometers. (Values for germanium and carbon are representative only.)

undergoes a step increase when the resistor environment changes from liquid to gas, whereas the resistance decreases stepwise.

Flow measurements utilize orifices, venturis, and turbine-type meters. Various devices for direct mass-flow measurement exist, but none are widely used. "Quality" meters have been built to determine the percentage liquid in two-phase flow. The determination of quality is complicated by nonequilibrium of temperature in the gas phase.

Temperature measurements are usually made with thermocouples, resistance thermometers, and vapor-pressure thermometers.

The **vapor-pressure thermometer** depends upon a vapor-pressure-temperature relationship (see Fig. 19.2.18). In general, a small cavity is filled with a gas which has a condensation temperature in the vicinity of the temperature to be measured. If sufficient gas is present, the pressure will be that of the liquid vapor pressure at the coldest part of the measuring system. Maximum speed of response is obtained if the total quantity of gas is minimized to permit only a thin film of liquid to form. In the case of H_2, a catalyst (e.g., iron hydroxide) to promote ortho-para conversion should be included in the bulb for an accurate measurement since the vapor pressure of H_2 is dependent upon its ortho-para composition (see above).

The pressure at the surface of a liquid cryogen in a dewar may, under conditions of thermal equilibrium, be used to measure the temperature of the cryogen and of apparatus immersed in it. Corrections for the pressure of the hydrostatic head of liquid may be required. If using this method, it should be realized that large vertical temperature gradients can exist in an unstirred liquid cryogen in a vessel with good insulation.

Thermocouples are favored for the measurement of temperatures because of their low cost, ease of application, and rapid response. The thermoelectric powers (temperature sensitivities) of the thermocouples commonly used at higher T's decrease with decreasing temperature, and spurious emfs generated in wires of non-uniform composition are troublesome. The proper use of a reference junction at a known fixed temperature close to the temperature being measured is often advantageous for accuracy. Variability in composition of thermocouple alloys makes individual calibrations necessary for accurate results. Figure 19.2.23 gives typical thermocouple emf-versus-temperature curves for some common thermocouples. A thermocouple consisting of gold with 0.07-at % iron versus chromel has been found useful over the entire temperature range from 2 to 300 K. Its sensitivity increases from 11 μV/K at 4 K to 17 μV/K at 77 K to 22 μV/K at 300 K.

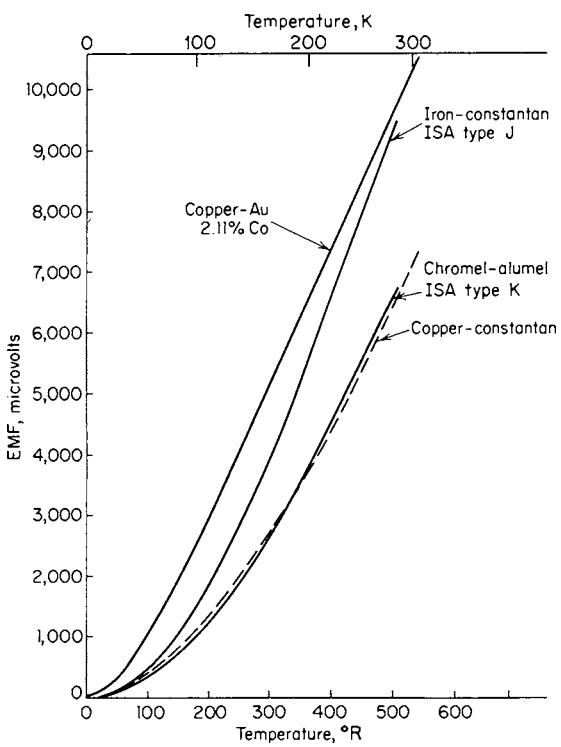

Fig. 19.2.23 EMF versus temperature for several thermocouples.

Radio carbon resistors (*Allen Bradley* for 2 to 100 K and *Speer Carbon* for 0.01 to 4.2 K) are much used as temperature sensors because of their low cost and high sensitivity. However, the permanence and stability of their calibrations are not very good, and germanium (doped) resistance thermometers are preferred (0.01 to 100 K) for their good reproducibility of calibration, although they are considerably more expensive.

The carbon and germanium resistors (thermometers) in magnetic fields H exhibit a magnetoresistance (Hall) effect, proportional to H^2, which complicates the determination of temperatures. Recent developments include: (1) a carbon-glass electrical resistor which has a stable calibration; and (2) the electrical capacitance thermometer (dielectric: $SrTiO_3$, a perovskite in solution in a solid SiO_2 or Al_2O_3 glass) with very small (approaching zero) magnetic effect and a stable calibration. The capacitance thermometer is preferred when magnetic fields are present.

The Rh-0.5-at % Fe, wire-coil thermometers, usable in the range of 0.1 to 300 K, have a high sensitivity especially below 10 K.

INSULATION

(See also Sec. 6.)

The degree of thermal isolation required at low T's is normally greater than at elevated T's because it is more costly to remove heat leaking into a low-temperature system than to replace heat lost at elevated T's, as demonstrated by the Carnot cycle. Other differences between insulating for low and elevated temperatures are:

1. Condensation of moisture in low-temperature insulation is possible. When this occurs, the conductance of the insulation is significantly increased. This problem is avoided by a vapor barrier on the outside of the insulation.

2. Condensation of the atmosphere in the insulation and surface washing by the condensed liquid are possible when the insulating surfaces are below 150°R (83 K). This can result in a large added transfer of heat. It is avoided by using an outer cover or surface impermeable to air, and evacuating the insulating space or replacing the atmosphere in it with a noncondensable gas.

At low temperatures, as at other temperatures, the fundamental modes of heat transfer are conduction and radiation, and it is against these that insulation is used. Convection of heat is practically eliminated by the insulation.

Low-T insulation categories are (1) high vacuum, with or without multiple radiation shields, (2) powders, (3) rigid foams, and (4) low-conductivity solids, such as balsa wood and corkboard.

1. (i) **Heat is transferred across an evacuated space** by radiation and by conduction through the residual gas. The conductivity of a gas is almost independent of its density (pressure) as the pressure is reduced in an evacuated space until the free paths of the molecules are increased to an appreciable fraction of the separation of the containing walls.

The molecular *mean* free path at 1 atm (0.1013 MPa) and 492°R (273 K) in air is 4×10^{-6} in (10^{-7} m); in H_2, 6×10^{-6} in (1.5×10^{-7} m); and in He, 10×10^{-6} in (2.5×10^{-7} m). At pressures lower than about 10^{-3} torr (0.133 Pa), the rate of heat transfer Q by residual gas between parallel surfaces at T_1 and T_2 less than 1 in (0.0254 m) apart is approximately $(Q/A) \approx (\text{const})\ \alpha P(T_2 - T_1)$, where P is pressure *measured* in torr with a gage at *ambient* T and α is an *overall* accommodation coefficient of gas molecules in collision with the walls. Thus, $\alpha = \alpha_1\alpha_2/[\alpha_2 + \alpha_1(1 - \alpha_2)]$, where α_1 and α_2 are accommodation coefficients of gas molecules at the two walls (see Table 19.2.7). Table 19.2.8 gives the values of the *(const)* in the equation for Q/A.

The **rate of radiative heat transfer** between parallel surfaces at T_1 and $T_2 > T_1$, where emissivities are e_1 and e_2, respectively, is $Q = e_1e_2s/[e_2 + (1 - e_2)e_1][T_2^4 - T_1^4)$, where s is the Stefan-Boltzmann constant whose value is 1.712×10^{-9} Btu/ft$^2 \cdot$ h $\cdot$ °R^4

(5.67×10^{-8} W/m²K⁴) (see also Sec. 4). Table 19.2.9 contains emissivities for 540°R (300 K) thermal radiation; these for most engineering purposes may be considered equivalent to minimal values of the *e*'s for very carefully prepared and cleaned surfaces. Organic coatings have high emissivities approaching unity (> 0.9). Mechanically polished surfaces have higher *e*'s than the minimal values. Handling a surface transfers an absorbing (high *e*) coating to it.

(ii) **Refrigerated Radiation Shield** An LN_2 (140°R) (78 K) cooled surface interposed in the insulating vacuum space of an LH_2 or an LHe container reduces the heat transferred by radiation to the LH_2 or LHe by a factor of about 250 when compared with that transferred by a surface of the same emissivity at room temperature without the interposition of the refrigerated shield. Nearly all the heat radiated by the surface at room temperature is absorbed by the LN_2, and this results in evaporation of the relatively inexpensive LN_2.

(iii) **A floating radiation shield** is an opaque layer (e.g., a metal sheet), having surfaces of low emissivity suspended in the vacuum space with a minimum of thermal contacts with surfaces that are warmer or cooler. If the emissivity of the surfaces of the floating shield is the same as the emissivity of the vacuum-space walls, the floating shield decreases the *radiative* heat transfer by a factor of 2. For *m* floating shields arranged in series between the inner cold and outer warm surfaces, the rate of *radiative* heat transfer becomes $\dot{Q}_m$ (*m* floating shields) = $[1/(m + 1)]\dot{Q}_0$ where $\dot{Q}_0$ = heat transfer for $m = 0$.

(iv) **Multilayer (Super) Insulation** The principle of multiple floating radiation shields has been extended to the use of many thin metal layers (up to 75 layers per inch or 3,000 layers per metre) separated by thin thermal insulation. Best results have been obtained with Al foil separated by glass-fiber paper. Other materials have been used successfully, e.g., nylon nets as separators and aluminized Mylar with no spacer material. The *apparent* thermal *conductivity* of Al foil multilayer insulation spaced with glass fiber paper is variable depending on the number of layers of foil, the thickness of the paper, and the thickness and compacting of the insulating layer. For ΔT = (540 − 36)°R or (300 − 20) K, apparent mean conductivities range from 2.0 to 4.0×10^{-5} Btu/h · ft · °R ($3.5 \text{ to } 7 \times 10^{-5}$ J/s · m · K). For ΔT = [540 − 140°R (300 − 78) K], the values are about one-third larger. Using nylon nets, glass fabric or glass fibers for separating the Al foil increases the conductance from three to seven times. The above conductivities are for the direction normal to the foil surfaces. Lateral conductivities are many thousands of times larger. An advantage of aluminized Mylar is its reduced lateral conductivity. Another advantage is its relatively low density (one-third to one-half of other multilayer insulations). If the residual gas pressure in multilayer insulation is less than 10^{-4} torr, the conductance is practically independent of the residual gas pressure. At 10^{-3} torr (0.133 Pa), the conductance is increased by the order of 50 percent.

2. (i) **Powder insulation** consists of finely divided materials. Conductances of evacuated powders may vary by as much as 100 percent with variations of particle size and *apparent* density (packing) of the powder. The most commonly used powders are perlite, expanded SiO_2 (aerogel), calcium-silicate, diatomaceous earth, and carbon black. The conductance of powder insulation is practically independent of gas pressure down to 10 torr (1.333 kPa), at which pressure it begins to decrease rapidly with decreasing pressure as the free path of the gas molecules becomes comparable with the space between powder particles. The most rapid decrease of conductance occurs between 1 and 10^{-1} torr (133 and 13.3 Pa). At 10^{-3} torr (0.133 Pa) the conductance reaches practically the lower limit. Even at 10^{-2} torr (1.33 Pa) the conductance is quite low. For this reason, good mechanical pumps are adequate for the evacuation of powder insulation (fine mesh filters are needed to protect the pump from being damaged by the powder). When evacuated to 10^{-4} torr (1.33×10^{-2} Pa) or less, the apparent mean thermal conductivity for perlite [540°R (300 K) to 140°R (78 K)] ranges from 0.6 to 1.2 mW/m · K. For nonevacuated perlite filled with He or H_2 an apparent mean thermal conductivity of 115 mW/m · K can be used. With N_2 a typical value is 30 mW/m · K.

The principal function of the powder is to impede the transfer of heat by radiation. Powders are used when radiation would constitute an important heat leak. If an insulating vacuum is bounded by highly reflecting walls, such as clean Cu, Ag, or Al, adding powder may result in an increase of heat transfer because of the paths of solid conduction through the powder.

(ii) **Al powder or flakes added to a powder insulation** reduces the radiative transfer through the insulation. Powdered Al is more effective than flaked Al. The conductance of highly evacuated perlite insulation [ΔT = 540 − 140°R (300 − 78 K)] may be reduced 40 percent by the addition of 25 percent of Al powder. A similar addition of Al powder to Santocel and Cab-O-Sil (diatomaceous earth) reduces the conductance by 70 percent. Metal powder additions are most effective with those powders that are partially transparent to infrared radiation of wave lengths longer than 3 μm.

3. **Rigid-Foam insulation** The foams most used in cryogenic applications are the more or less closed-cell foams. Table 19.2.10 gives thermal conductivities of selected samples of insulating foams. The conductivity of a foam is dependent on the conduction through the intracellular gas, on the transfer by thermal radiation, and on solid conduction. Temperatures below the condensing *T* of the encased gas condense it and improve the insulation. Gases encased when polymer foams are blown gradually diffuse out of the cells and are replaced by ambient gases. The conductivities of many Freon and CO_2 blown foams increase in time as much as 30 percent because of the diffusion of air into the foam. Conductivities may increase by a factor of 3 or 4 when cells are permeated with H_2 or He. Glass and silica foams appear to be the only ones having fully closed cells. The **structural rigidity** of foams may be used to eliminate the need for mechanical supports. It is possible to use rigid foams without inner liners and outer casings. Polymer

† ΔT = 540 to 140°R (300 to 78 K).

foams have relatively high **thermal expansions,** even greater than the same polymer without voids. This makes cracking of the insulation a problem when it is bonded to metal. Sliding expansion joints have been used to overcome this. Mylar film bags (0.001 in or 0.025 mm thick) have been used to hold cryogenic liquids inside rigid-foam insulation and plastic films outside to keep the ambient atmosphere from the insulation.

4. **Balsa wood and corkboard** have been used for insulating cryogens that are not very cold, e.g., liquid methane (201°R or 112 K) and higher-boiling cryogens. The conductivities of these insulators (Table 19.2.10) are considerably higher than for the other types of low-*T* insulation discussed above. Their use, therefore, is restricted to special applications, as where their ability to support internal structures mechanically is important.

Conduction of heat along structural supports passing through the insulation merits special attention for an adequate realization of the benefits of superior insulation. Ideal materials of construction would have high mechanical strength and low thermal conductivity. In Table 19.2.11, the yield strengths, in tension, of construction materials are compared with their thermal conductivities. This kind of comparison favors the nonmetallic materials in Table 19.2.11. When large quantities of cryogens are handled in the field, metals are commonly used for structural members because glass and plastics (Teflon excepted) are brittle at low *T*'s.

Minimizing the transfer of heat through the supporting structure offers opportunities for ingenuity and inventiveness in design. The transfer is minimized by lengthening the supporting members. A stack of thin metal disks or washers, utilizing the contact resistance between adjacent disks, will increase thermal resistance without increase in length of support. A stack of 0.0008-in (0.02-mm) stainless steel disks under a compressive stress of 1,000 lb/in² (6.895 MPa), in vacuum, has the same thermal resistance as a solid rod 50 times the length of the stack.

Insulation Selection Because of their smaller heats of vaporization and greater cost of production, the lowest-*T* cryogens (LHe and LH_2) ordinarily merit more effective insulation than the higher-boiling cryogens like LO_2 and LN_2, and these in turn are ordinarily better insulated than other cryogens boiling at still more elevated *T*'s. The choice of insulation ordinarily involves the conditions of use of the equipment, as well as considerations of the tolerable loss of refrigeration and the cost of the insulation and its installation. If equipment is to have intermittent, rather than long, uninterrupted operating periods, the insulation heat capacity and time lag in reaching steady state are important. An insulation with large heat capacity (e.g., powders) will evaporate large quantities of refrigerant and take a long time to reach steady state. Powders are compacted by mechanical shocks and vibrations. Continued mechanical loading will compact both multilayer insulation and powders. Weight and bulkiness of the insulation can be important. The heat transported by the mechanical supports and vents connecting the cold interior with the warm exterior becomes the minimum refrigeration loss, attainable only with perfect insulation of the rest of the system. A large loss of refrigeration through supports and vents ordinarily reduces the attractiveness of costly insulation having the lowest conductance.

SAFETY

Precautions are needed for the safe handling and storage of cryogens because (1) air can contaminate the cryogen, creating a potential explosive, either directly as when air mixes with H_2 or CH_4 or indirectly by transforming an inert cryogen like LN_2 into an oxidant (a potential hazard for combustible insulation), and (2) moisture and air can freeze on cold surfaces, clogging vents and preventing normal operation of valves.

Vent systems should be sized for sufficient exhaust velocities to prevent back-diffusion of air into the cryogen space. Storage at slightly

¶ Room-temperature value.

elevated pressure is preferable to prevent in-leakage of contaminants. Condensation can also be a problem on poorly insulated lines carrying low-boiling cryogens; frost is not a hazard but the oxygen-enriched condensed air is hazardous in the presence of combustibles. The insulation of liquid vent lines is a necessary precaution. Where this is not possible, appropriately placed guttering can prevent the contact of any condensed air with combustible objects.

Any space, either containing a cryogen or being refrigerated by a cryogen, should be protected with proper **safety-relief mechanisms,** i.e., relief valves or rupture disks. Such space includes less obvious ones such as the insulating vacuum space surrounding a cryogenic fluid or a section of line which can trap liquid between two valves. A heat leak to trapped liquid confined without a vent for escape of vapor may develop pressures sufficient to burst the containing vessel. Gas pressures necessary to maintain liquid density at ambient temperature are for helium, 18,000 lb/in^2 (124 MPa); for hydrogen, 28,000 lb/in^2 (193 MPa); and for nitrogen, 43,000 lb/in^2 (296 MPa).

The **selection of structural** materials calls for consideration of the effects of low temperatures on the properties of those materials. A number of otherwise suitable materials become brittle at low temperature (Fig. 19.2.10). Materials must perform satisfactorily over the complete range from cryogenic to room temperature, with hydrogen embrittlement particularly significant. While hydrogen embrittlement is not believed to be a problem at liquid-hydrogen temperatures, it has been shown to occur at room temperature. The 300-series stainless steels, aluminum alloys and BeCu, among other alloys, are more resistant to hydrogen embrittlement.

In calculating allowable stresses, room temperature yield and tensile strengths should be used because (1) pressure testing of containers at ambient temperature is frequently necessary, and (2) in the case of large vessels, large unknown temperature gradients can exist above the liquid level both in the ullage space and in the walls of the vessel. The 300-series stainless steels are normally austenitic (f.c.c.). However, in some 300-series stainless steels austenite is partially transformed by cold-working and possibly by temperature cycling to martensite. As martensite is brittle at low T's, the ductility of these steels is reduced by this kind of treatment. For this reason, it is recommended as an added safety factor that room temperature strength of the 300 series stainless steels be used for the design of structural members.

Careful **stress analysis** is essential and must include stresses due to (1) thermal contraction of equipment, and (2) radial, axial, and circumferential temperature gradients caused by non-uniform cooling rates. The latter are frequently encountered in the cool-down of cryogenic transfer lines.

Cryogenic equipment should be **purged** before being placed in service to remove unwanted condensables and gases that could form explosive mixtures. Commonly used methods are (1) evacuating and back-filling with purge gas and (2) flowing of purge gas through the system.

The cryogen can be a direct **hazard to personnel.** Cryogen "burns" can result from direct contact with either the cryogen or uninsulated equipment containing the cryogen. The large evolution of gases associated with cryogenic spills can result in asphyxiation. Asphyxiation is a hazard in entering a warmed cryogenic vessel. Further safety details are found in the references.

19.3 OPTICS

FUNDAMENTAL THEORIES OF LIGHT

Optics is the science of light, and light is **photons.** The fundamental theory of photons is quantum electrodynamics, and Richard Feynman explains it with great clarity in his book for the layman, "QED: The Strange Theory of Light and Matter."

Photons are the particles that mediate the electromagnetic force, and they have three fundamental properties: energy, polarization, and constant velocity in a vacuum. The **speed of light** in a vacuum, c, is a fundamental physical constant with the defined value of 299,792,458 m/s (often approximated as 3×10^8 m/s). Every photon has an energy, which determines its frequency and wavelength. These are related by $E = hf$ and $\lambda = c/f$, where E is the photon energy, h is Plank's constant, f is the frequency, and λ is the **wavelength.** Polarization is fundamentally related to the quantum spin of the photon. The classical interpretation is that a photon is an electromagnetic wave packet with perpendicular electric and magnetic fields that are also perpendicular to the direction of propagation. The polarization is the direction of the electric field component.

Light is photons with wavelengths shorter than the resolution of the human eye and long enough that their behavior is primarily wavelike (roughly 0.1 to 300 μm). It is a small portion of the electromagnetic spectrum (Fig. 19.3.1). **Visible light** is the small band with wavelengths of 400 to 760 nm. Longer wavelength light is infrared radiation, and shorter wavelength light is ultraviolet radiation. The human eye is most sensitive near 560 nm. The interactions that light can have with matter are reflection, refraction, interference, diffraction, polarization, absorption, and scattering; however, the last three are beyond the scope of this section.

GEOMETRIC OPTICS: REFLECTION AND REFRACTION

Reflection and refraction govern geometric optics. The speed of light in an optical material, c', is always smaller than the speed of light in a vacuum. The **index of refraction,** $n = c/c'$, is an important optical property of any material. The refractive index for most optical materials depends on the wavelength of the light, and it is typically between 1 and 4. This wavelength dependence is called **dispersion.** A beautiful example of the effects of refraction and dispersion is a rainbow.

The reflection and refraction of a light ray from a flat interface between two media is shown in Fig. 19.3.2. The plane of incidence is defined by the incident light ray and the surface normal at the point of incidence. The **law of reflection** states that the reflected ray lies in the plane of incidence, and that the angle of reflection is equal to the angle of incidence, $I = I''$, as measured from the surface normal. The **law of refraction** (also known as **Snell's law**) states that refracted ray lies in the plane of incidence, and the angle of refraction is related to the angle of incidence by $n' \sin I' = n \sin I$. Total internal reflection occurs when $n > n'$, and $(n/n') \sin I > 1$. The incident ray is reflected with no loss and the transmitted ray vanishes. The critical angle, $I_c = \arcsin (n'/n)$, is the minimum angle at which this occurs.

The refraction of a light ray at a spherical interface between two media with radius of curvature r is shown in Fig. 19.3.3. The optical axis passes through the center of curvature. The image distance l' is related to the object distance l by $(n'/l' - n/l) = (n' - n)/R$, when the

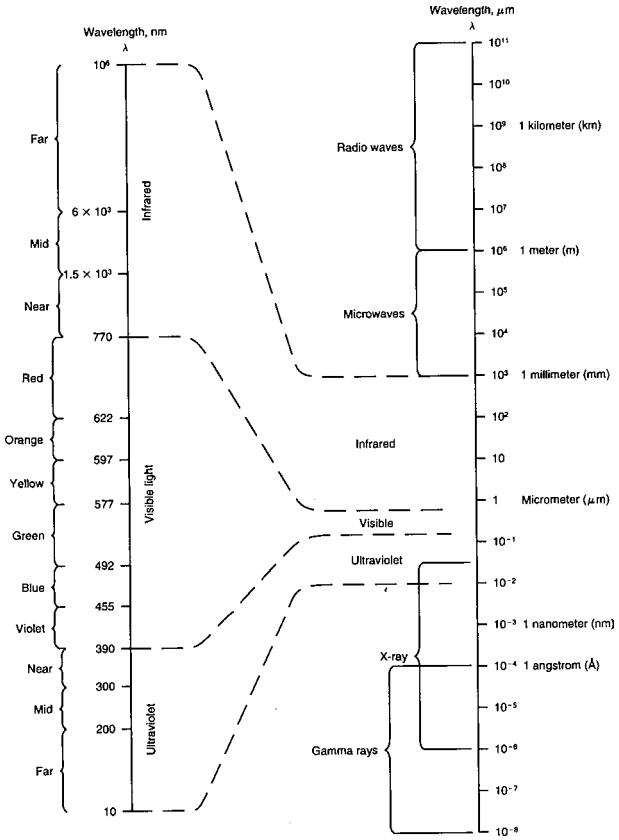

Fig. 19.3.1 Electromagnetic spectrum.

rays are close to the optical axis (the paraxial approximation). The **magnification** m is given by $m = h'/h = nl'/n'l$. If the image is inverted, the magnification is negative. A typical optical assembly contains several lenses, and each lens is two surfaces. The optical properties of the assembly can be found by starting with the object and determining the image for the first surface. The object for all subsequent surfaces is the image of the previous surface.

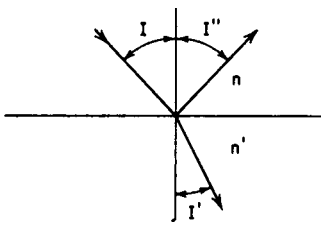

Fig. 19.3.2 Reflection and refraction at a plane surface.

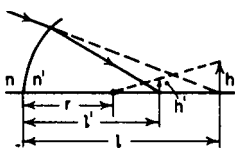

Fig. 19.3.3 Refraction at a spherical surface; all parameters are shown in their positive sense.

A thin lens has a thickness much less than its diameter. The image distance l_I for a thin lens is related to the object distance l_O by $(1/l_O + 1/l_I) = (1/r_1 - 1/r_2)\,(n' - n)/n$, where r_1 and r_2 are the radii of curvature of the surfaces of the lens, and n and n' are the indices of refraction of the medium and the lens, respectively. It is derived by applying the refraction equation from above to the two surfaces of the thin lens. The **focal length** f of a lens is the image distance when the object is at infinity. This leads to the lens maker's equation $1/f = (1/r_1 - 1/r_2)\,(n' - n)/n$ and the gaussian lens equation $1/f = 1/I_O + 1/l_I$. The **optical invariant** (also known as the Lagrange invariant) is an invariant quantity at every surface of an optical system. In its simplest form, the product of the image size and ray angle is a constant. It implies that the field of view and useful aperture are inversely proportional, i.e., a large telescope has a very small field of view, and wide-angle camera has a small aperture.

The relative illumination of the image from the object is proportional to the area of the aperture and inversely proportional to the size of the image. This relationship is characterized by two optical parameters, the ***f* number** and the **numerical aperture** NA. The f number is the ratio of the focal length to the diameter of the clear aperture of a lens system, $f/\# = f/D$, and it typically is used to characterize systems with a large image or object distance. Since the image size is proportional to the square of the focal length, the square of the f number is inversely proportional to the relative intensity. For example, a telescope with a 1-m aperture and a 10-m focal length has an f number of 10, customarily written as $f/10$. Numerical aperture is defined as $\mathrm{NA} = n \sin \phi$, where ϕ is maximum ray angle that passes through the optical system, and it is typically used to characterize systems with small image and object distances. When this angle is small, $f/\# \approx 1/(2\,\mathrm{NA})$.

THE WAVE NATURE OF LIGHT: INTERFERENCE AND DIFFRACTION

Interference is the interaction of waves. The interference is constructive when the waves are in phase and destructive when they are not. Diffraction is the interaction of a wave with an aperture, which often results in the bending of the wave at the edge of the aperture. Both phenomena depend on the wavelength of the wave. A common example of optical interference is the colors observed in a thin film of oil on water. Light reflected from the oil/water boundary interferes with light reflected from the air/oil boundary. The apparent color depends on the thickness of the oil layer and the viewing angle. As these change, different wavelengths interfere constructively and destructively along the path to the eye.

When the light source is monochromatic, the constructive and destructive interference leads to formation of light and dark regions known as **fringes.** If the fringe pattern is caused by the interference of two beams following different paths from the same source, the fringe pattern can be analyzed to determine path length differences with an accuracy smaller than the wavelength of the light (see "Photonics Handbook"). For example, the flatness of an unknown surface can be compared with the flatness of a reference surface. Instruments that make these measurements are known as **interferometers.** The most common types of interferometers are the Fizeau, Michelson, Twyman-Green, and Fabry-Perot.

Diffraction limits the resolution of any optical imaging system. The limit depends on the size of the aperture and the wavelength. The angular resolution of a circular aperture is given by $\phi = 2.44\lambda/D$, where D is the diameter of the aperture. For an aperture with an arbitrary shape, the far-field diffraction limit is approximately $\phi \cong \lambda P/\pi^2 A$, where P and A are the perimeter and area of the aperture, respectively.

A **diffraction grating** is a set of finely spaced narrow apertures with a spacing comparable to the wavelength of the light to be measured. The grating can be imposed on a reflective or transparent surface. The light diffracted by each aperture in the grating interferes with light from nearby apertures. If the surface in Figure 19.3.2 is a reflective diffraction grating, constructive interference occurs when $m\lambda = d(\sin I + \sin I'')$, where d is the spacing and m is an integer which indicates the diffraction order. Physically realizable diffraction orders exist for $|m\lambda/d| < 2$.

SPECIAL TOPICS: LASERS, FIBERS, AND OPTICAL DESIGN

Lasers have become a ubiquitous optical tool. The term *laser* is an acronym for *l*ight *a*mplification by the *s*timulated *e*mission of *r*adiation. Stimulated emission is the underlying physical process that all lasers exploit. The result is an intense, monochromatic optical source that is nearly parallel and spatially coherent. Lasers are used in a broad array of applications, including CD and DVD players, fiber-optic and free-space telecommunications, photolithography, machining, photomedicine, interferometry, and surveying.

An **optical fiber** exploits total internal reflection to transmit light with very little attenuation. A simple bare glass fiber suspended in air will transmit light, but surface contamination and surface defects cause high losses. An optical fiber achieves extremely low attenuation by surrounding a high index core with a low index cladding, which protects the surface of total internal reflection. Single mode optical fibers, used in telecommunications, achieve losses as low as 0.2 dB/km. Large optical fibers are effective light pipes that can illuminate hard-to-reach areas. Coherent bundles of optical fibers are used to transmit images from hard-to-reach areas.

Optical design is the science of precisely manipulating light. Simple optical problems can be solved with the formulas in this section or the references. However, these ideal formulas ignore distortions, aberrations, and tolerances that affect all real optical systems. Sophisticated optical computer-aided design tools use precise ray tracing to accurately predict the performance of an optical design. They include libraries of design templates that can be adapted to meet the requirements of common optical systems and powerful optimizers to maximize the performance of the optical system. The "Photonics Handbook" has more information on optical CAD tools.

20.1 AN INTRODUCTION TO MICROELECTROMECHANICAL SYSTEMS (MEMS)

by Luc G. Fréchette

INTRODUCTION

Trend toward Small Scales

The twentieth century was marked by mankind's accomplishments at ever increasing scales, from civil works such as bridges that span rivers to sophisticated machinery such as airplanes and spacecraft that span our planet and beyond. Although this quest for immensity will remain vibrant, the twenty-first century will likely be marked by achievements at smaller scales. This trend is best demonstrated by the information revolution experienced by our society over the past decades, which was a result of the remarkable development of integrated circuits (ICs), itself enabled by progress in semiconductor manufacturing. The microfabrication approach developed for ICs is based on parallel processing of large arrays of devices on a planar substrate, using photolithography and thin-film processing in a clean room environment. The semiconductor industry leverages this approach to make devices with impressive levels of performance, reliability, and complexity. Today, microprocessors integrating over 100 million transistors per chip can be batch-fabricated in large volumes and at low cost.

Such capabilities are expanding beyond microelectronics to allow the microfabrication of sensors, actuators, and microsystems that implement functions from other physical domains, such as mechanical, thermal, fluidic, magnetic, electrical, optical, chemical, or biological domains. The field of **microelectromechanical systems,** or MEMS, focuses on the miniaturization of such a diverse set of systems through the use of microfabrication technology. It is also referred to as **microsystems technology,** or MST, in Europe and **micromachines** in Asia.

Microsystems and Their Applications

The scale of a device or machine is set by the task it must accomplish as well as the fabrication technology available to implement it. For example, information storage devices, such as hard disk drives and solid-state memory, increase in storage density as technology enables smaller bit size, since bits of information do not have a physical scale associated with them. Similarly, devices pertaining of other physical domains could also be miniaturized to the extent that technology allows, if commercially beneficial. A prime example is **sensors,** i.e., devices that measure a physical quantity, often by converting it to an electrical signal. Most measurement applications would benefit from local, compact, nonintrusive, and inexpensive sensors, suggesting that batch microfabrication may be appropriate. Pressure sensors (Fig. 20.1.1*a*) and accelerometers (Fig. 20.1.7*a*) are common examples. **Actuators** that act on the environment by converting an electrical signal into a mechanical displacement or another physical domain can also potentially be miniaturized, as long as the power transmitted to the environment is small and the action is highly localized. Examples include inkjet printer heads, micromirror arrays for image projection (Fig. 20.1.1*b*), and microvalves for flow control (Fig. 20.1.7*c*). Microfabrication and MEMS technology can also be enabling to implement **microsystems** that would otherwise be impossible or impractical, such as microfluidic labs-on-a-chip that allow interaction with molecules or cells at their length scales (0.1–10 μm).

The annual market for MEMS is estimated at $US 8.2 billion worldwide for 2007,[1] in the following areas: microfluidics (27 percent), inertial sensors (22 percent), optical MEMS (22 percent), pressure sensors (11 percent), RF MEMS (3 percent), and other sensors (10 percent) and actuators (5 percent). These devices are used in the automotive industry, in consumer electronics and computers, for telecommunications, as well as in instrumentation for biochemistry and medicine. The field has experienced an average growth of 16 percent annually since 2000, as a result of novel applications of MEMS and insertion of this disruptive technology into existing markets.

MICROFABRICATION TECHNOLOGY AND MATERIALS

The key enabling technology responsible for the rapid development of microsystems over the past decade is **microfabrication.** Most of today's computer chips are manufactured by the CMOS (complementary

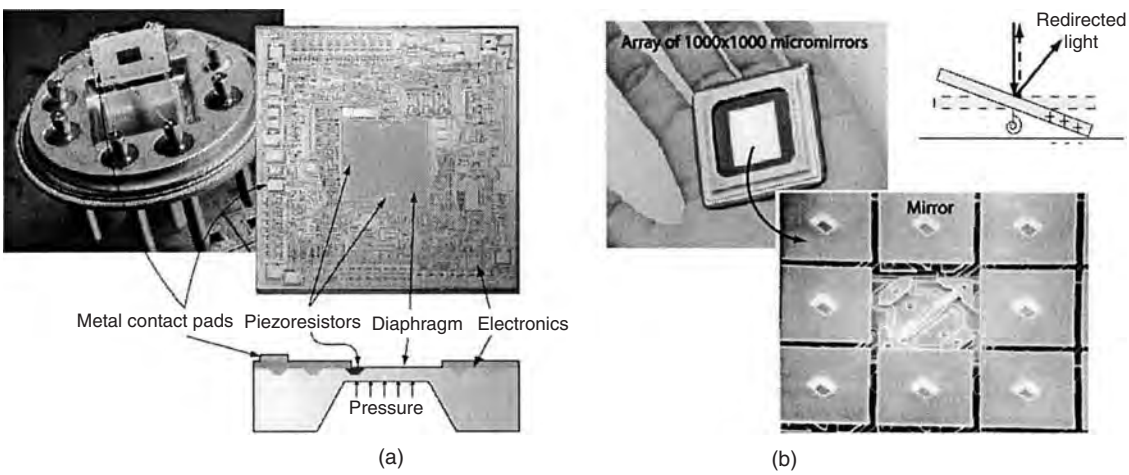

Fig. 20.1.1 Commercial examples of microelectromechanical systems (MEMS). (*a*) Automotive piezoresistive pressure sensor and (*b*) micromirror array for display applications. (*Photo: Texas Instruments.*)

metal-oxide semiconductor) process, which is a sequence of steps that repeatedly deposit and pattern thin films to form an integrated circuit with transistors. Silicon, typically used in microelectronics, has become the dominant material for MEMS because of its material properties (semiconductor, mechanical, thermal) and the extensive processing experience with the silicon material set pioneered by the semiconductor industry. This section describes the underlying microfabrication technologies and materials borrowed from this industry that are the basis for silicon MEMS processing. To gain further insight on microfabrication science and technology, beyond what will be presented here, the reader is referred to classic texts on the subject.[2,3]

Silicon and Its Properties

Most microfabrication processes create devices on the surface or through the thickness of thin, planar, circular substrates, or **wafers.** Single-crystal silicon wafers are the most common starting material, although glass, quartz (single-crystal and fused), and compound semiconductor wafers (GaAs, InP) are also of interest. As provided by the semiconductor industry, single-crystal silicon wafers offer unique properties, such as: (1) stable, defect-free bulk material of high chemical purity; (2) precise substrates with low wafer bow (>25 μm), minimal taper (>15 μm), and mirror polished surfaces (one or both sides); (3) semiconductor properties and the possibility of integrating MEMS with electronics.

Wafers are characterized by the orientation of the **crystal's cubic structure** with respect to the wafer surface. As illustrated in Fig. 20.1.2, principal planes and directions in single-crystal silicon can be identified by **Miller indices.**[2] Specific planes are denoted by (h, k, l), where the indices are components of the direction vector **[h, k, l]** that is normal to the plane. Since the lattice of silicon is cubic, hence symmetric, the three principal directions are identical and interchangeable. Therefore, we commonly refer to families of directions, written <100> to identify the [100], [010], and [001] directions, and equivalently to families of planes, written {100}, for the planes normal to these directions. Wafers are classified by the direction vector that is normal to the wafer surface, so, for example, <100> wafers will have the cubic lattice parallel to the wafer surface. As will be discussed later, the crystalline structure of silicon has been leveraged to create useful structures such as the pressure sensor membrane in Fig. 20.1.1*a* by anisotropic wet etching.

Doping, by introducing impurities in the silicon lattice, controls the substrate's electrical conductivity (which can range from 0.001 to >10,000 $\Omega \cdot$ cm) and also defines the wafer type (Group III atoms such as boron produce **p-type** material, Group V atoms such as phosphorus produce **n-type** material). Mechanically, single-crystal silicon is a strong and light material (ρ = 2.33 kg/m^3, E = 130 to 187 GPa, ν = 0.06 to 0.28, and G = 57 to 79 GPa depending on orientation[2]), but exhibits a brittle behavior with a fracture strength that is process and size dependent (typically 1.2 GPa, but can vary from 0.5 to 7 GPa).[4] Traditional machining of silicon is therefore not common, since it introduces surface cracks that can significantly reduce the fracture strength; etching techniques are therefore used instead. Thermally, silicon is a good conductor (k = 150 W/m $\cdot$ K) and exhibits less thermal expansion and higher specific heat than most metals (CTE = 2.6 $\times$ 10^{-6}/K, c_p = 0.713 kJ/kg $\cdot$ K at 300 K), which tends to reduce thermal stresses. It can sustain relatively high temperatures (brittle-to-ductile transition above 550°C and melting at 1421°C), although the electronic properties of silicon are best conserved below 150°C. These electronic properties are interesting for electromechanical transduction in sensors and will be discussed later.

Thin-Film Processing

A broad range of thin films can be deposited or grown on the surface of a substrate to form mechanical or electrical elements, such as membranes, mechanisms, or circuits. Materials include silicon or silicon-based compounds, metals, and polymers. The most common thin films are summarized in Table 20.1.1 with their characteristics and typical microfabrication approaches. Conductive layers can be formed of metals or doped semiconductors, such as polycrystalline silicon (referred to as **polysilicon**) diffused with boron or phosphorous dopants. Electrical insulation is typically created with silicon dioxide (SiO_2) or silicon nitride (Si_3N_4) films. Materials can be deposited in thin films by various techniques, such as physical vapor deposition, chemical vapor

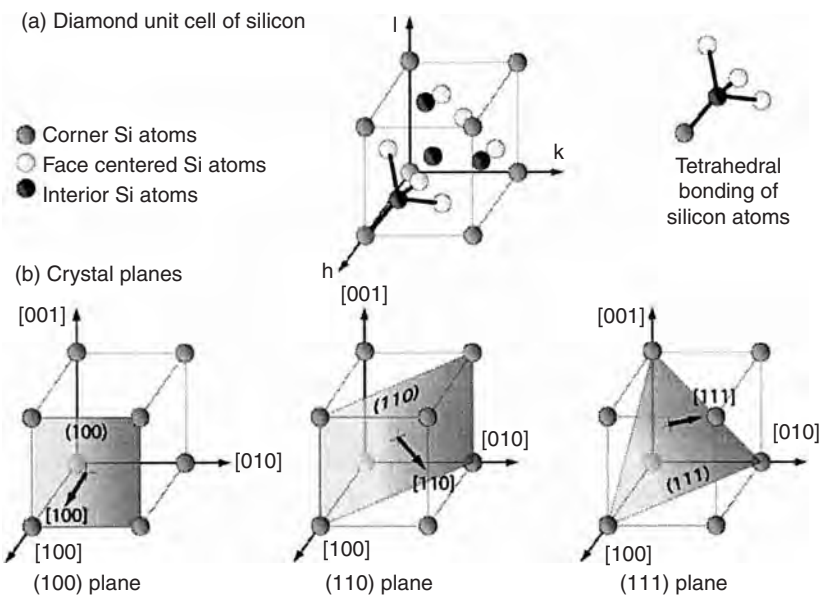

Fig. 20.1.2 Crystal lattice, and Miller indices for silicon. The unit cell (*a*) has the structure of diamond, with each silicon atom covalently bonded to its four adjacent neighbors. The major planes, directions, and corresponding Miller indices are illustrated in (*b*).

Table 20.1.1 Common Substrate and Thin-Film Materials Used for MEMS

Material	Typical application	Fabrication process and characteristics	Material characteristics
Silicon (Si) (substrate)	Most common substrate; compliant or rigid structures; electrical and electronic components	Single-crystal substrate; 300–700 μm thick; many micromachining techniques	Defect-free, high-strength, brittle, thermally conductive semiconductor
Quartz (substrate)	Bulk structural materials for active components	Crystalline or fused silica substrate; 400–700 μm thick; limited micromachining	Piezoelectric properties; visually transparent
Borosilicate glass (Pyrex) (substrate)	Insulating substrate; bulk structures for microfluidics	Amorphous glass substrate; 400–700 μm-thick wafers; anodic bonding to Si; limited micromachining	Thermal expansion matched with Si; visually transparent
Polycrystalline silicon (polySi)	Thin-film structures; piezoresistors; conductors	Polycrystalline; LPCVD; 0.2–2 μm-thick films	Process-dependent properties; semiconductor
Silicon dioxide (SiO_2)	Sacrifical thin film; insulator (thermal and electric)	Amorphous; thermal growth or PECVD; 0.1–10 μm-thick films	Typically high compressive strength; thermal insulator: dielectric
Silicon nitride (Si_3N_4)	Membrane; insulator (electric)	LPCVD or PECVD; 0.1–1 μm-thick films	High tensile strength; dielectric
Metals	Electrical conductors; structural layers	Evaporation or sputtering (Al, Au, Cr, Ti, Pt, W); 20 nm to 2 μm-thick films	Ductile; thermal and electrical conductors
	High-aspect-ratio structures	Electrodeposited (Ni); 1–1000 μm-thick films	
PDMS	Microfluidics; molded microstructures	Flexible polymer; cast; 10–1000 μm-thick films	Low stiffness, dielectric, biocompatible
SU-8	Mold for electroplating; thick structures	Photosensitive epoxy; spin cast; 5–500 μm-thick films	Moderate stiffness, dielectric

deposition, electrochemical deposition, or casting. Since thin-film materials are synthesized as they are deposited or grown, their properties are strongly related to the specific processing conditions. Material properties can be tailored within a certain range, which is useful to match design requirements but requires stringent process control for repeatability. Film thicknesses depend on the process and can vary from a few nanometres (nm) up to tens of micrometres (μm) [1 m = 10^6 μm = 10^9 nm = 10^{10} Å (angstroms)]. As a reference, the human hair is approximately 70 μm in diameter.

In **physical vapor deposition,** a solid piece of the material to be deposited is either vaporized or sputtered in line of sight with the substrate, such that atoms of the material will deposit uniformly on the substrate to form a thin film. Pure metals are easily evaporated, while sputtering can also deposit a wide range of metallic and nonmetallic compounds.

Chemical vapor deposition (CVD) involves a chemical reaction to synthesize a material, such as polycrystalline silicon, as it is deposited over the substrate. This process is often carried out in batches in high-temperature furnaces with a controlled flow of reactants and at low or atmospheric pressure (LPCVD or APCVD, respectively). In a similar environment, the silicon substrate can also be directly oxidized by reacting with a flow of oxygen to form SiO_2 on the surface (the addition of H_2 enhances the oxidation rate, and is referred to as **wet oxidation,** as opposed to **dry oxidation** when only oxygen is used). The chemical reactions for CVD can also be plasma enhanced (PECVD), which allows deposition at lower temperatures, good control of the film properties, and high deposition rates, but requires expensive serial processing.

An alternative approach for metal films, especially thick films (from micrometres to millimetres), is electrochemical deposition, or **electroplating.** The substrate acts as the cathode, where electrons combine with metallic ions in the liquid electrolyte, to cover exposed areas of the wafer with the metal (commonly Ni, but also Cu, Au, NiFe, or NiW).

The substrate can also be covered with solvent-based solutions by directly pouring the solution on the wafer and using gravity or centrifugal forces (**spin casting**) to form a uniform thin film. Spin-on-glass and photosensitive polymers are commonly applied by spin casting and then heated to evaporate the solvents and solidify.

Photolithography

The photolithographic process is used to transfer a pattern onto a planar substrate, using light. As illustrated in Fig. 20.1.3, a thin photosensitive polymer film, or **photoresist,** is first spin-cased on the surface of the wafer. The pattern is then exposed over the film by shining UV light through a photolithographic mask. The mask consists of a glass plate coated with a patterned chrome layer to locally expose the photoresist: the mask blocks the light where chrome is present and allows light to shine through where chrome has been removed. The coated wafer is then developed in a liquid solution, physically dissolving the photoresist in the exposed areas, for *positive* photoresist (for *negative* resist, dark or unexposed areas would be dissolved instead).

This process allows replication of complex, micrometre-scale features over the entire wafer in a single or a few repeated exposures. This parallel fabrication approach is central to the low-cost, high-volume advantage of microfabrication. The feature size is limited to fractions of the wavelength of light used for exposure, but alternative **nanolithography** techniques have been developed to reach tens of nanometres, such as electron beam and nanoimprint lithography.

Etching and Other Patterning Approaches

The pattern created in the photoresist layer is typically transferred to the underlying thin film or into the substrate by etching. The wafer is

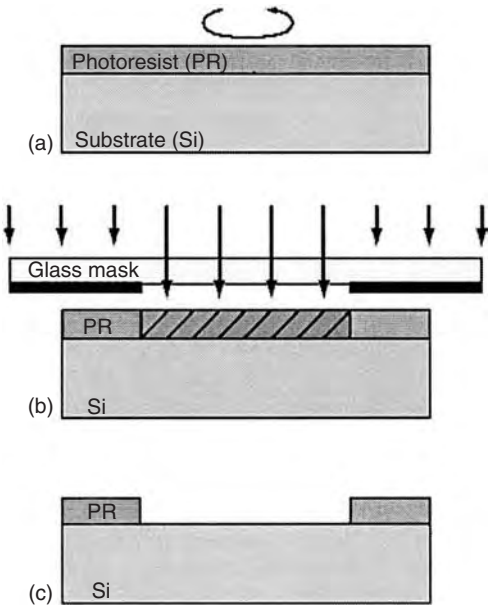

Fig. 20.1.3 Photolithography process: (*a*) spin-coat a layer of photoresist over the wafer and prebake the film; (*b*) expose certain areas to UV light; (*c*) develop photoresist, leaving a physical mask in the nonexposed areas.

immersed in an etchant, which reacts and removes the exposed material, while the photoresist acts as a physical mask that protects the unexposed areas of the wafer. In **wet etching,** a chemical in liquid or vapor phase comes in direct contact with the wafer, preferentially reacting with the exposed material. In **dry etching,** a gas is ionized to create a plasma of free radicals and ions that chemically react with the exposed material or physically ablate the surface through ion bombardment, by driving the ions toward the wafer with an electrical field. This process is referred to as reactive ion etching (RIE) and is most commonly used in microelectronics to form fine patterns in thin films. Given the directionality created by the electrical field applied between the plasma and substrate, anisotropic features with relatively vertical side walls are possible (Fig. 20.1.4*a*). Chemically dominated etching, such as wet etching, is, however, characterized by isotropic removal of material that effectively undercuts the mask and widens the exposed features (Fig. 20.1.4*b*). In addition to etch profiles, etch rate and selectivity are important parameters that characterize an etch process. The etch rate is simply defined as the thickness of material removed per unit time, while selectivity is the ratio of etch rate of the material intentionally removed to that of a secondary material such as the photoresist mask or the underlying substrate.

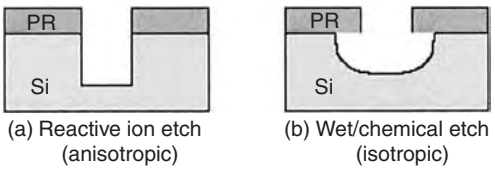

Fig. 20.1.4 Cross section profiles of etched structures: (*a*) reactive-ion-etched features with vertical side walls and (*b*) chemical-etch-dominated process (plasma or wet etching) that results in mask under cut and rounded features.

Reactive ion etching exhibits poor selectivity to photoresist (near 1:1) while chemically dominated etching can show selectivity >100:1. Table 20.1.2 summarizes some of the most common combinations of materials and etchants, along with their properties. After etching, the photoresist is commonly removed in an oxygen plasma (ashing) or in a solution (acid or solvent). The wafer is then ready for subsequent processing.

Lift-off is an alternative patterning approach consists of depositing and patterning the photoresist layer first, then covering the wafer surface with a thin film, commonly a metal. The photoresist is then dissolved to effectively lift-off the metal that covers it while leaving the metal that was deposited in the exposed areas of the mask.

PROCESSING FOR MEMS

The basic microelectronics processing techniques introduced above have been extended to allow the fabrication of movable structures for sensors, actuators, and multiphysical microsystems. The most common approaches are presented next.

Surface Micromachining

One approach consists of depositing and patterning a structural material over a sacrificial thin film. The sacrificial material is then selectively etched to release the structures formed in the top layer. This approach creates thin planar structures that can move with respect to the substrate, normal or parallel to it. Figure 20.1.5 illustrates a surface micromachining process in which alternating layers of polysilicon (to form the structure) and silicon dioxide (as the sacrificial material) are deposited and patterned. Etched openings in the sacrificial layers allow mechanical and electrical connections between the polysilicon layers and attachment to the substrate. A hydrofluoric solution can be used to remove the silicon dioxide and release the structures, since it does not etch silicon significantly. This surface micromachining approach is the basis for successful commercial devices, such as automotive accelerometers,[5] and foundry services, such as polyMUMPs[6] and SUMMIT.[7] Other material combinations can be used, such as aluminum and photoresist[8] or silicon carbide and polysilicon/silicon dioxide.[9]

An alternative approach consists of forming the electromechanical structures into the thin films of a **CMOS wafer,**[10] leveraging the substantial

Table 20.1.2 Common combinations of Materials and Etching Approaches in Micromachining; Many Other Choices Are Available[2]

Material to pattern	Common patterning approaches	Characteristics	Masking materials and selectivity
Si, polySi	RIE (Cl-based)	Slow, directional	PR (5:1)
	DRIE (SF_6)	Fast, vertical profile	PR (70:1); SiO_2 (150:1)
	Wet (KOH, TMAH)	Anisotropic (54.74°)	SiN (>100:1)
SiO_2, glass, quartz	RIE (CF_4)	Directional; isotropic	PR (10:1)
	HF (diluted, BOE)	(quartz: anisotropic)	PR (>20:1)
Si_3N_4	RIE (CF_4)	Directional	PR (10:1); SiO_2 (50:1)
	Phosphoric acid	Isotropic, wet	SiO_2 (10:1); Si (30:1)
Metals	Lift-off (for Au)	Wet, thin film (<1 μm)	—
	RIE (Cl, F, Ar)	Directional, slow	PR (1:1)
	Etchant solutions	Isotropic, wet	PR (>100:1)

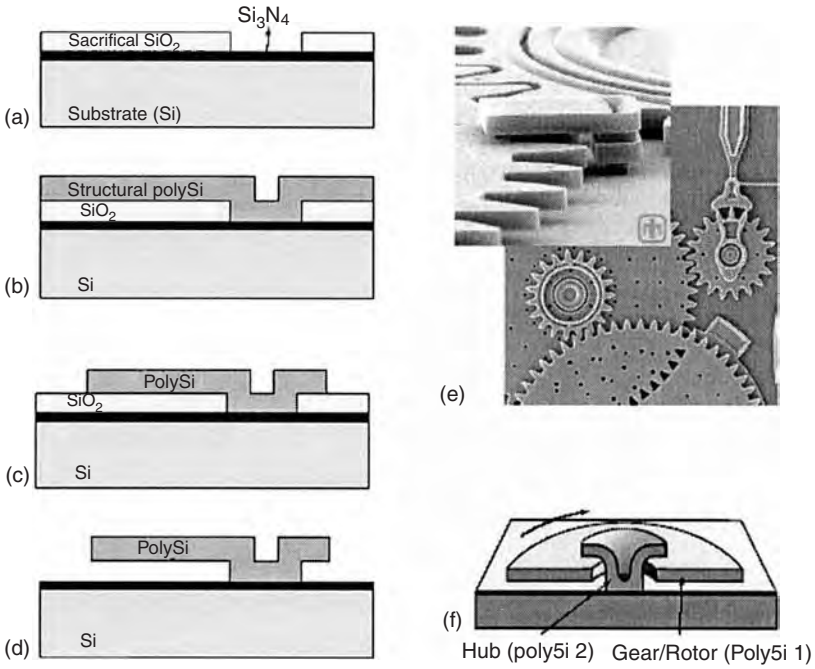

Fig. 20.1.5 Basic principles of surface micromachining: (a) thin silicon nitride (Si_3N_4) and silicon dioxide (SiO_2) films are deposited, and openings are etched in the SiO_2, using lithography and etching; (*b*) a polysilicon film is deposited (LPCVD) and (c) patterned; (d) the polysilicon structures are released by wet etching of the sacrificial SiO_2. Steps (a)–(c) can be repeated to create multilayer structures such as the gear train mechanism (Photo: *Sandia National Lab.*) shown in (*e*). Rotary structures are formed with a hub covering part of the rotor (*f*), separated by SiO_2 before release.

CMOS manufacturing resources and allowing natural integration with electronics. The structures can also extend into the silicon substrate by using bulk micromachining techniques.

Bulk Micromachining

Alternatively, the structures can be formed directly into the substrate, which is referred to as bulk micromachining. Three types of processing methods are available, described by the etchant state: wet, vapor, or plasma (the last two are referred to as dry etching). Although wet etching typically creates isotropic features (rounded etching in all directions), unique formulations can leverage the microstructure of single-crystal silicon to form anisotropic features. Hydroxide-based etchants (such as KOH and TMAH) etch much slower in one direction that the others, exposing the {111} planes of silicon. Depending on the crystallographic orientation of the wafer, {111} planes are either at 54.74° to the wafer surface (<100> silicon wafers) or perpendicular to it (<110> silicon wafers). Furthermore, the etch rate can also depend on dopant type and concentration, such that areas of the wafer that were previously diffused with a dopant can remain after wet etching. These characteristics allow the fabrication of a wide range of geometries, such as pyramidal pits, channels, cantilevers, or membranes as illustrated in Fig. 20.1.6*a*, but with geometric constraints to the crystal planes.

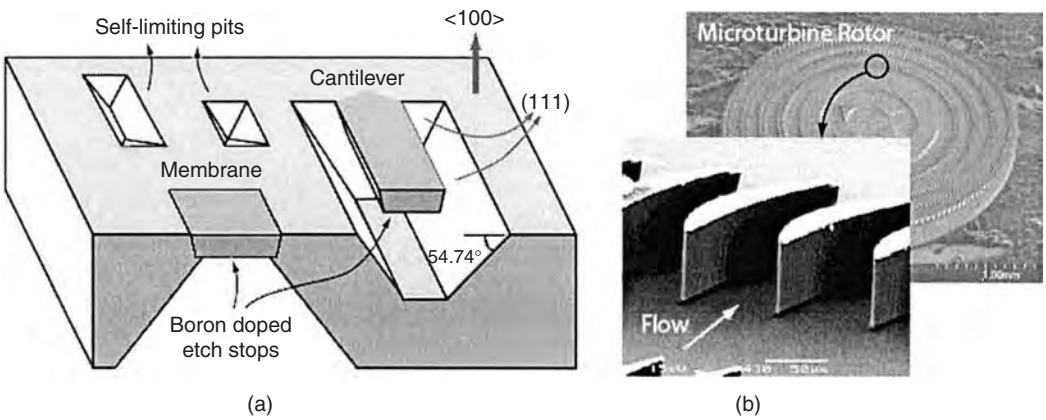

Fig. 20.1.6 Bulk micromachining of Si: (*a*) Anisotropic wet etching of Si. Typical anisotropic features that leverage the crystalline structure of Si. The {111} planes and boron-doped regions etch at significantly lower rates than the rest during wet etching with KOH, EDP, or TMAH; (*b*) deep reactive ion etch (DRIE) structures, showing that unconstrained 2-D shapes are possible, but only with vertical sidewalls.

Commercial pressure sensors are commonly fabricated as single-crystal silicon membranes by anisotropic wet etching, as illustrated in Fig. 20.1.1*a*.

Alternatively, plasma processing can allow **deep reactive ion etching** (DRIE) into silicon substrates of practically any lithographically defined geometry, as illustrated in Fig. 20.1.6*b*. The DRIE process combines isotropic plasma etching with sidewall passivation in order to generate deep trenches with vertical side walls,[11] reaching aspect ratios above 30:1 and fast enough etch rates (>3 μm/min) for through-wafer etching. Compared to wet etching, DRIE allows greater design freedom but requires expensive equipment and serial processing.

Wafer Bonding

In contrast to thin structures created by surface micromachining, thick multilayer devices can be formed by joining patterned or blank substrates together in a process referred to as wafer bonding. Three main bonding techniques are available: anodic bonding (glass to silicon), direct fusion bonding (silicon to silicon), and intermediate layer bonding. The planar substrates are first cleaned and brought into contact in a controlled ambient.

In **anodic bonding,** a potential (500 to 1,000 V) is applied across a contacted pair of sodium-bearing glass and silicon wafers, elevated to a moderate temperature (300 to 450°C). Migration of the sodium ions generates strong attraction forces and a permanent chemical bond is formed between the substrates. This approach is commonly used to create optically accessible flow channels in microfluidic devices and to thermally and mechanically isolate sensors from their package and environment. **Direct fusion bonding** relies on molecular diffusion at the interface of two substrates brought in intimate contact. Silicon wafers can be fusion bonded by aligning, pressing, and heating (800 to 1000°C) them. The bond strength can reach that of the crystalline substrate, but requires clean and polished surfaces (roughness < 1 nm) and precludes materials that would not withstand the high temperature process, such as most metals. Alternatively, an **intermediate layer** can be used to join two substrates, such as eutectic bonds (Au layer), polymers (resists, polyimide), solders, low-melting-temperature glass (frits) or thermocompression bonds. Some intermediate-layer bonds require only low temperatures, but may not allow long-term vacuum cavities due to outgassing (for glasses, polymers, and solders) and yield lower bond strengths.

Wafer bonding is commonly combined with bulk micromachining or thin-film processes to encapsulate sensors in vacuum or controlled environments (wafer-level packaging), form closed cavities for absolute pressure sensors, or create complex microfluidic devices (such as microturbines[12]).

Nonsilicon Materials and Processing

In order to meet the requirements for a growing range of applications such as biomedicine, chemistry, and wireless communications, nontraditional microfabrication materials and processes have been developed. Polymers and metal electroplating are highlighted here.

Polymers The need for low-rigidity materials in MEMS actuators and polymers for **bioMEMS** has led to the development of various thin- and thick-film polymers. For example, vapor-deposited parylene thin films can serve as flexible membranes, joints, and pneumatic actuators.[13] Casting of thick polymer layers, such as polydimethylsiloxane (PDMS), allows rapid fabrication of microchannels for biochemical MEMS. In a process referred to as **soft lithography,**[14] PDMS is cast over a micromachined substrate that acts as a mold. After curing, the cast polymer is pealed from the mold and pressed against a glass substrate or another polymer layer to form microfluidic geometries. Microchannels and other thick structures can also be directly formed in standard photoresists or photosensitive epoxy, such as SU-8.[15]

Electroplating and LIGA In addition to thin film metal processing described earlier, thick metal layers can be formed by electroplating. The most common approach to create thick metal microstructures is **selective electroplating,** in which a seed layer is covered by a patterned thick photoresist or SU-8 mask, such that the metal (e.g., Ni) is plated only in the exposed areas of the mask. The LIGA process (German acronym for lithography, electroplating, and molding) implements this approach by using X-ray lithography to expose very thick photoresist (several millimetres) with vertical sidewalls.[16] This yields very high aspect ratio metal parts (up to 70:1) for MEMS and other micromachines.

ENGINEERING SCIENCE AND PRACTICE FOR MEMS DESIGN

Many of the engineering topics covered throughout this handbook can be applied for the design of microsystems. Engineering practice, however, differs as a result of miniaturization and convergence with the semiconductor world. Here we discuss the design approach for MEMS, the effects of scaling on engineering science, and the most common transduction and operating principles, along with examples of MEMS devices. The reader is referred to the literature[17] for an extended discussion of MEMS design.

MEMS Design Process

Depending on the device complexity and scope of the application, development of MEMS may entail:

1. *Definition of market needs and product specifications.* An assessment must be made to determine if MEMS technology is appropriate for the application, by answering the following questions:
   - Does a MEMS and microfabrication approach bring unique capabilities and performance levels due to: fundamental scaling, unique properties of micromachined materials, potential integration with microelectronics, or large array integration?
   - Is there an economic benefit at the component or system level for using MEMS and microfabrication, such as low unit cost due to batch fabrication, on-chip functionality, or miniaturization?
2. *Choice of operating principle and fabrication process, system-level design, and detailed design.* The conceptual device is defined by using previously demonstrated technology and creative thinking. The principles of operation and the microfabrication approach are intimately related since the implementation is constrained by available fabrication technologies. Analytical and numerical modeling of increasing complexity along with detailed process flow definition completes the device design. Traditional or specialized CAD software can facilitate this effort.[18] Packaging considerations are critical at the design phase to ensure appropriate mechanical, thermal, fluidic, biological, chemical, electrical, magnetic, and/or optical interfaces between the device and the environment.
3. *Process development, fabrication, packaging, and testing.* Lithographic masks are made with the designed patterns and used for device microfabrication. Each fabrication process is developed or improved to achieve the desired microstructures. Iterations with the design phase may be required, ranging from slight mask modifications to adopting alternative process flows. The process accuracy is characterized between fabrication steps. Basic device operation can be tested before dicing the wafer into individual chips. Each device is then packaged and tested. In many commercial MEMS products, the final packaging and qualification steps represent the major production cost, often more than the cost of making the MEMS device itself.

Principles and Implementation of MEMS Sensors and Actuators

Many MEMS devices are sensors that monitor physical, biological, or chemical aspects of their environment to generate a useful signal, often electrical, that is correlated to the measured quantity. An actuator will provide the inverse function by acting on its environment on the basis of an input signal, also usually electrical. Various transduction principles convert a signal, or energy, from one physical domain to another, and can be implemented via microfabrication. They are of two types, based on either a **displacement** or a change in physicochemical **properties.** Most devices serially combine multiple transduction principles on chip to achieve high levels of functionality and sensitivity. The most common approaches are presented here with device examples. The reader is referred to the literature[19] for a comprehensive discussion of transduction mechanisms and their MEMS implementations.

Mechanical Elements: Flexures, Mechanisms, and Other Microstructures

Most MEMS consist of micromechanical components and mechanisms that provide a displacement, in combination with other transduction principles. Some of the most common mechanical elements are depicted in Fig. 20.1.7, and can be classified as flexible structures, mechanisms, or static structures. These include: beams that act as cantilever beams or springs; plates that form membranes, bridges, mirrors, or masses; hub-and-pin joints for rotary gears and motors (see Fig. 20.1.5*e–f*); hinges for large deflections; and microchannels and other internal flow components to guide fluid flow (see Fig. 20.1.6*b*). Continuum elasticity modeling is generally applicable for such components, although the geometries can achieve extreme aspect ratios (up 1000:1) and the material properties can be process-dependent and anisotropic, as discussed previously.

These components can be used in static behavior, or for a desired dynamic response. Micromachined spring-mass systems can be excited at resonance and used as gyroscopes through the Coriolis effect or as chemical sensors by monitoring changes in stiffness or mass. Dynamic behavior, such as resonance and time response, are also affected by fluid film damping.[17] Such sensors are typically packaged under vacuum to reduce this effect, and therefore achieve a large quality factor Q, which is defined as the amplitude at resonance normalized by the displacement at low frequency.

Capacitive Sensing and Electrostatic Actuation

Displacements can be measured or induced with electrostatic charges. Capacitive sensing consists of measuring the change in capacitance between two electrodes (i.e., conductive structures), as for the commercial accelerometer illustrated in Fig. 20.1.7*a* and *b*. Neglecting edge effects, capacitance between parallel plates is simply expressed as $C = \varepsilon A/g$, where a change in capacitance C can result from a change in: overlapping plate area A, due to parallel motion of the plates (electrodes); gap g, due to normal motion of the plates; or even a change in permittivity ε, by insertion of a different material in the gap. When the sensor is combined with on-chip circuits for capacitance measurement, extreme sensitivity can be achieved since parasitic capacitance is reduced, especially when a differential change in capacitance is measured.

Electrostatic actuation is accomplished by applying an electrostatic field between structures attached to flexures or mechanisms that allow relative motion. For simple parallel plates, attraction forces are experienced normal to the plates and parallel to them (when they are offset), as illustrated in Fig. 20.1.8*a*. Since electrostatic forces are proportional to V^2 and vary inversely to the spacing, d or d^2, high voltages and small gaps are desirable. The maximum force is limited by breakdown across the air gap, which occurs above 300 V for micrometre-scale gaps at atmospheric pressure. Comb drive actuators provide in-plane motion (Fig. 20.1.8*b*), while micromirror devices for display applications use electrostatic actuation to tilt a mirror out of plane and redirect light that reflects on an array of individually actuated micromirrors (see Ref. 8 and Fig. 20.1.1*b*).

Piezoresistive Sensing

Stain gages are commonly used in mechanical testing to measure deformations and the related stress in structures. In MEMS, the same principle is used to measure inertial or pressure forces, by transmitting the force to a silicon structure and measuring the induced strain. Crystalline silicon offers the benefit of a large gage factor (GF > 100)

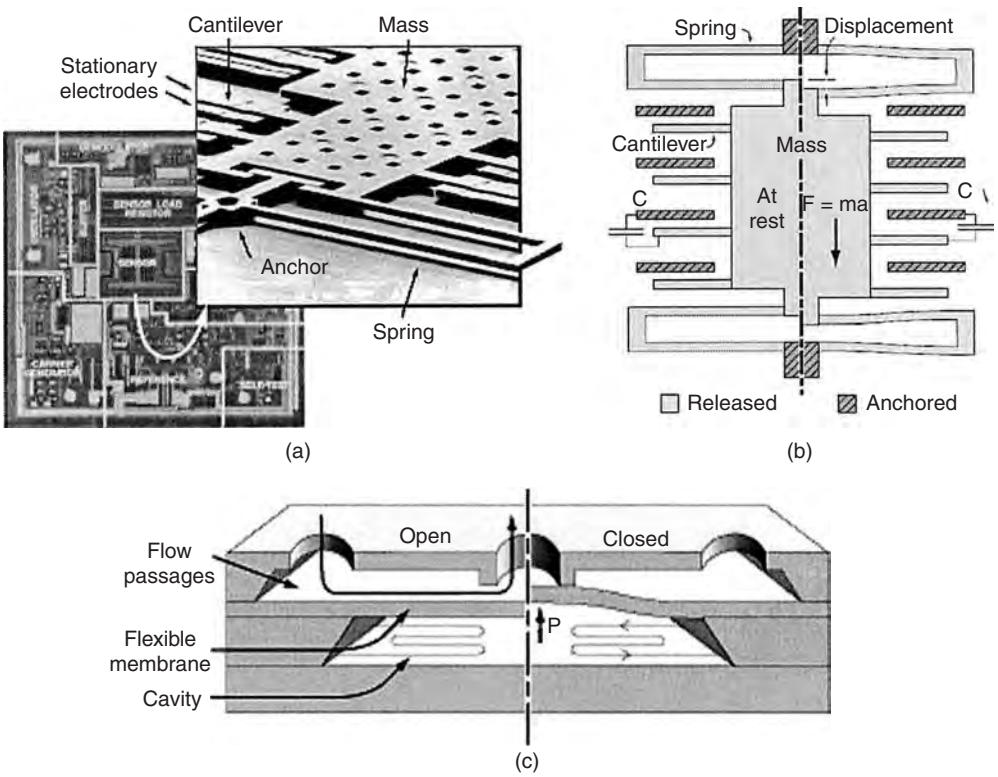

Fig. 20.1.7 Microstructures commonly used in MEMS. (*a*) Capacitive accelerometer. (*Photo: Analog Devices.*) The surface micromachined accelerometer consists of a mass supported on folded beams that act as springs. (*b*) Components and operation. Displacement is measured from the change in capacitance between the stationary and movable electrodes. (*c*) Thermopneumatic valve. Flexible membranes can be used in valves to control the flow through microchannels, as well as in pressure sensors.

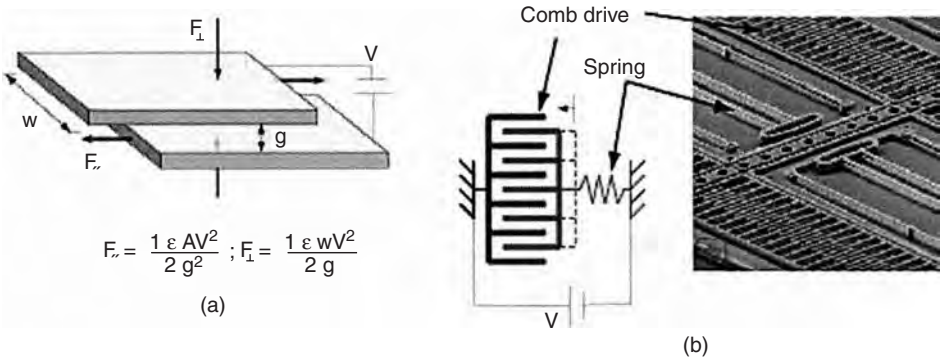

Fig. 20.1.8 (*a*) Electrostatic attraction forces between electrodes with components normal and parallel to the structures. For example, the parallel force is used in (*b*) comb drive actuators to move an electrode structure held by a spring. This configuration is similar to capacitive accelerometers but it is used for actuation instead of sensing. (*Photo: Sandia National Laboratory.*)

compared to metals (GF ≈ 2), where the gage factor is defined as the relative change in resistance per unit strain, $GF = {}^{\Delta R}/_{R}/{}^{\Delta L}/_{L} = \Delta R/\varepsilon R$. Typical implementations for pressure sensors consist of resistances that are diffused on the surface of a bulk micromachined silicon membrane (Fig. 20.1.1*a*). The piezoresistors are connected in a Wheatstone bridge configuration to provide a voltage measurement proportional to the applied pressure difference across the membrane. Piezoresistive accelerometers can operate on a similar principle, by locating a resistor on a silicon beam that supports a proof mass etched from the substrate. Commercial devices can include on-chip temperature compensation, stress isolation with the package, and mechanical stops to prevent excessive stresses.[20]

Piezoelectric Sensing and Actuation

Certain crystalline materials, such as quartz, lead titanate zirconate (PZT), and zinc oxide (ZnO), exhibit an electrical polarization under mechanical strain due to a relative displacement of negative and positive charge centers in the material's microstructure, a phenomenon called **piezoelectricity.**[2] This behavior can be leveraged for force sensing, but also for actuation since an applied electric field will in turn induce mechanical deformation. Traditionally, piezoelectric materials can provide large forces or pressures (>10 MPa) and small displacements (<0.1 μm) at high voltages (>100 V), but piezoelectric thin films applied on flexible beams and membranes in MEMS devices allow larger deflections (up to 10 μm), although at proportionally lower forces. Some commercial ink-jet print heads integrate piezoelectric actuators to generate microdroplets at high frequencies.

Thermal Transduction and Applications

Microsystems can also integrate temperature measurement capabilities, use heat for actuation, or act on their thermal environment. Traditional approaches to measure temperature, such as thermocouples and thermistors, can be implemented via thin-film deposition and patterning to create a solid-state temperature sensor for integration within MEMS devices. For example, resistors can be formed by depositing a thin film of metal or doped polysilicon, characterized by its sheet resistivity $R_{sheet} = \rho/t$, where ρ is the material's electrical resistivity and t is the film thickness. Using photolithography and etching (or through lift-off), the resistor can be patterned into a line of total length l and width w, for a resistance of $R = R_{sheet}\, l/w$ (Fig. 20.1.9*a*). Since the material resistivity is a function of temperature, monitoring electrical resistance provides a measurement of temperature, according to $\Delta R/R_0 = \alpha \Delta T$, where α is the material's **temperature coefficient of resistance** (TCR). Thermocouple junctions have also been microfabricated by depositing and patterning multiple thin metal films. Heat flux can be measured by monitoring the temperature of two overlaid resistors or thermocouple

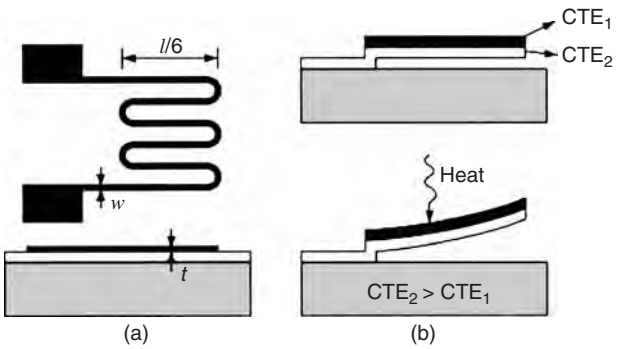

Fig. 20.1.9 Thermal sensing and actuation using thin films. A patterned thin-film resistor (*a*) can act as a temperature sensor by monitoring the change of resistance with temperature, or as a heat source through ohmic heating. A thermal bimorph cantilever (*b*) will curve when heated, so it can act as a thermal sensor or an actuator when electrically heated.

junctions separated by a thermally and electrically insulating film, such as a SiO_2, Si_3N_4, or polyimide.

A resistor can also be used as a heat source, converting electrical energy into heat at a rate of $\dot{Q} = P_{elec} = Vi = Ri^2$. This allows the integration of electrically controlled heaters in MEMS and microfluidic devices. Heat can be a driving mechanism for actuation by raising the local temperature of microstructures or trapped gases to induce thermal expansion, which then results in a membrane or beam deformation. Micropumps, microvalves, and switches can be based on this operating principle, as illustrated in Fig. 20.1.7*c*. Here, an enclosed fluid tends to expand because of resistive heating, increasing the pressure in the cavity and pushing the membrane upward to close the valve. Alternatively, out-of-plane deflections of thin-film cantilevers can be achieved by layering materials with different coefficients of thermal expansion (CTE), referred to as bimorph actuators, as illustrated in Fig. 20.1.9*b*.

To minimize the actuation power and provide accurate temperature measurements, thermal isolation can be achieved through the use of high-aspect-ratio structures and low-thermal-conductivity materials, such as SiO_2 or Si_3N_4 films and glass substrates. Microsystems for cooling are less advanced, but potential approaches include thermoelectrics and microchannel heat exchangers, with single or two-phase flow.

Optical Transduction and Applications

Semiconductor technology was also leveraged to create optoelectronic components such as photodiodes and light-emitting diodes. Silicon-based

MEMS can therefore integrate not only microelectronics but also optical elements for a broader range of transduction principles. When combined with mechanical and/or fluidic elements, optoelectronics can measure the displacement of a shutter that partly covers photodiodes, or detect biological species on-chip with an emitter-detector pair along a microfluidic channel. Light manipulation can also be accomplished by reflecting incident light onto discrete, controllable, movable micromirrors. Commercial devices include actuated micromirror arrays that redirect light onto a display[8] (Fig. 20.1.1*b*) and variable diffraction gratings to separate wavelengths of the light for analytical or telecommunication applications.[21]

Other Transduction Principles and Applications

The range of transduction principles extends beyond the most common ones presented above. It includes principles from material science, such as shape memory alloys; from physics, such as electron tunneling; from chemistry, such as electrochemical spectroscopy; and from biology. Novel approaches are generally spurred by specific needs for sensing, actuation, or miniaturization requirements, but are often limited by the microfabrication technologies and capabilities. The reader is referred to scientific journals for the latest advancements in MEMS science and technology (see references).

PHYSICS AND SCALING

To assess the potential benefits of MEMS technology for a given application or compare various operating principles, it is useful to consider the effects of miniaturization through scaling laws. Two main aspects are to be considered: the length-scale dependence of various physical phenomena and the effect of scale on physical properties and behavior.

Length-Scale Dependence

Most physical phenomena can be classified as **volumetric,** such as gravity or heat capacity, or **surface-dependent,** such as viscous forces and heat transfer. When a physical system is miniaturized, volume scales as $[l^3]$, whereas surface scales as $[l^2]$, where l is a characteristic dimension of the system. The ratio of volume to surface therefore scales as $[l^3/l^2] = [l]$, such that surface phenomena tend to prevail at small scales; this is referred to as the **cube-square law.** This first-order analysis is applied for various physical domains in Table 20.1.3, showing, for example, that electrostatic forces, viscous forces, capillary forces, and heat transfer become prevalent upon miniaturization. In particular at macroscale, electrostatic transduction is not common because of its low energy density compared to magnetic devices. As they are miniaturized, however, electrostatic forces scale as $[l^2]$ or remain constant, assuming constant field strength or constant voltage, respectively. In comparison, magnetic forces are more affected by scaling, and their three-dimensional windings are challenging to microfabricate.

True scaling may not follow these trends exactly, since the capabilities of micromachining allow aspect ratios and material properties that are significantly different from those possible with traditional machining, as discussed next.

Physical Properties and Behavior

Not only can commonly neglected forces and phenomena become important at small scales, but physical behavior can shift dramatically. In traditional engineering, the smallest device features are typically much greater than the atomic or molecular scales of the device's constituents, such that the material behavior can be represented by continuum mechanics. As device scales are reduced, this representation may not hold and discrete molecular interactions become important. In microfluidics, for example, gas flows become rarefied when the mean

Table 20.1.3 Scaling of Forces and Fluxes

Field, forces, fluxes	Basic relation	Scaling proportional to	Note
Fluid mechanics			
Inertial forces	$\frac{1}{2}\rho A U^2$	$[l^2]$	Reynolds number:
Viscous forces	$\tau A = \mu \frac{\partial U}{\partial y} A$	$[l^1]$	$\mathrm{Re} = \frac{\text{inertial}}{\text{viscous}} = \frac{\rho U L}{\mu} \propto [l^1]$
Heat transfer			
Conduction	$q_{\text{cond}} = -k \frac{\partial T}{\partial y} A$	$[l^1]$	Biot number:
Convection	$q_{\text{conv}} = hA\Delta Te \quad (h \propto l^{0.5})$	$[l^{2.5}]$	$Bi = \frac{\text{convection}}{\text{conduction}} \propto [l^{1.5}]$
Energy transport	$\dot{m}\, c_p T = \rho A U\, c_p T$	$[l^2]$	Stanton number:
			$St = \frac{\text{convection}}{\text{transport}} \propto [l^{0.5}]$
Mechanics		$[l^1]$	
Strain energy	$\frac{1}{2}\sigma\varepsilon\, AL = \frac{1}{2}\frac{\sigma}{E}\, AL$	$[l^3]$	
Beam bending	$F = kx \qquad \left(k = \frac{Ewt^3}{L^3}\right)$	$[l^2]$	
Natural frequency	$\omega = \sqrt{k/m}$	$[l^{-1}]$	
Electromagnetism			
Electrostatic forces	$F = \frac{1}{2}\frac{\varepsilon V^2}{d^2} A$	$[l^0]$ $[l^2]$	For constant voltage V For constant field (V/d)
Magnetic forces	$F = \frac{1}{2}\frac{B^2}{\mu_0} A$	$[l^2]$	
Piezoelectric forces	$F = \frac{1}{2}\frac{\varepsilon V}{t} A$	$[l^1]$	
Physicochemistry		$[l^1]$	
Van der Walls	—	$[l^{1/4}]$	
Surface tension	$F = \gamma 2\pi r \cos(\theta_c)$	$[l^1]$	Bond number:
Gravity	$F = mg$	$[l^3]$	$\mathrm{Bo} = \frac{\text{surface}}{\text{gravity}} \propto [l^{-1}]$

free path between molecules, λ, is comparable to channel widths d, as represented by the Knudsen number, $\mathrm{Kn} = \lambda/d$. For $\mathrm{Kn} < 0.01$, flow can be considered a continuum with zero relative velocity along surfaces. In the range $0.01 < \mathrm{Kn} < 0.1$, slip flow may occur at the surfaces, which can be accounted for in continuum modeling through appropriate boundary conditions.[22] For air at atmospheric conditions, this range corresponds to 0.5- to 5-μm gaps, which are relatively common in MEMS. For $\mathrm{Kn} > 0.1$, however, the flow is best represented by statistical molecular interactions. Similar considerations lead to quantum effects for the heat transfer through thin films (less than 0.1 μm) or through nanostructured materials, such as superlattices. Modeling of heat conduction as phonon transport along or through these structures becomes necessary.[23]

Even in the continuum domain, physical phenomena can differ with scale. In microfluidics, flows are typically laminar because of low Reynolds numbers, $\mathrm{Re} = \rho U d/\mu < 1000$–$2000$, where ρ is fluid density, U is a characteristic velocity, and μ is the fluid viscosity. Such flows are well represented by laminar flow theory, such as Poisseuille flow, Couette flow, and more generally, Stokes flow and the Reynolds equation for lubrication theory.[24] The absence of turbulence increases the challenges of mixing in biochemical microsystems, but can also be leveraged to form layered sheets of fluids with well-defined diffusion-based concentration profiles. For liquids, such as water and electrolytes, electrical surface phenomena can become noticeable in microchannels. A charged double layer can form at the surfaces, such that an electrical field applied along the channel will tend to drive the flow along the wall. Because of the small channel diameter, the core flow is entrained by viscous shear to create a plug-flow, uniform velocity profile. This approach requires high electrical fields, which are achievable in microsystems with reasonably high voltages (up to 1000 V) over short channels lengths (millimetres). This approach is commonly used to drive fluids in micro total analysis and lab-on-a-chip devices, and is referred to as **electro-osmosis.**

In electrostatics, the maximum field strength (V/d) at which breakdown occurs is a function of scale. At small gaps ($d < 5$ μm, atmospheric pressure), the voltage limit stops decreasing to reach a minimum near 300 V; it even increases at submicrometre gaps. This results from the lack of molecules in the air gap to create the avalanche of collisions that lead to arcing. This benefits electrostatic actuation by increasing its maximum energy density and forces.

In micromechanics, the crystalline microstructure of silicon components formed by bulk micromachining introduces the need for anisotropic continuum mechanics to accurately predict the stress and strain.[25] Surface micromachined devices or other MEMS devices formed of thin films must be designed with consideration for their residual in-plane stress and stress gradient across the film thickness, which are highly dependent on the processing conditions. Material characterization and process control become critical aspects for the performance and reliability of such devices. In addition, the brittle nature of silicon-based materials excludes plastic deformation and their fracture strength is defined by maximum flaw size in the part. Fortunately, the probability of having a significant flaw in a brittle part increases with its volume and surface area, hence strength and reliability are favored in small scale structures.

BEYOND SENSORS AND ACTUATORS: INTEGRATED MICROSYSTEMS

Although most commercial MEMS can be classified as sensors or actuators, there is an increasing trend toward microsystems that integrate multiple components to perform specific applications. For example:

- Photonic and microoptoelectromechanical systems, or MOEMS, that direct, filter, and characterize light for optical telecommunication applications
- Radio frequency (RF) MEMS that generate and transmit high-frequency signals for wireless communication applications
- BioMEMS and lab-on-a-chip devices that perform high-throughput biological assays and revolutionize medical instrumentation
- Micro total analysis systems (μTAS) for synthesis and characterization of chemical and biochemical products
- Power MEMS to provide miniature power sources, cooling, and propulsion for consumer electronics, people, and small robots.

CONCLUSIONS

MEMS technology can be considered a toolbox to create miniature sensors, actuators, and integrated microsystems. The main tools are the materials and processes used in microfabrication, the engineering science with emphasis on small-scale phenomena, as well as the sensing and actuating principles. The parallel nature of microfabrication processes such as photolithography, thin-film deposition, and etching allows batch fabrication of devices with high accuracy and in large quantities. In-plane device complexity (in terms of number of components in a system) comes for free, allowing large arrays or complex networks to be implemented with micrometre-scale resolution. The devices can naturally integrate electrical and mechanical elements, as well as optical, fluidic, thermal, chemical, or biological functionality on chip.

The microfabrication infrastructure, equipment, process development, and control are, however, expensive, and are best amortized over large production quantities. To this cost must be added the costs of packaging and testing, which can exceed the cost of the chip itself, and the extensive engineering effort to achieve reproducibility and reliability, as required in commercial products. To be commercially successful, MEMS devices must typically offer increased functionality or performance at a lower cost than competing technologies, and in a high-volume market. Lower-volume applications can also be successful when the use of MEMS adds high value to the final product and the market share is protected by intellectual property or unique know-how. Whether commercially successful or not, an ever-increasing range of MEMS devices and technologies is being explored. This will contribute to our MEMS toolbox and enable novel solutions to our greatest challenges, ranging from nano to macro scales and spanning the physical, chemical, and biological worlds.

20.2 INTRODUCTION TO NANOTECHNOLOGY

by Alexander Couzis

Nanotechnology focuses on the fabrication of devices with atomic- or molecular-scale precision. Molecular nanotechnology is defined as the three-dimensional positional control of molecular structure to create materials and devices to molecular precision. Devices with minimum feature sizes less than 100 nanometres (nm) are considered to be products of nanotechnology. A nanometre (nm) is one billionth of a metre (10^{-9} m), that is, about 1/80,000 of the diameter of a human hair, or 10 times the diameter of a hydrogen atom. The nanometre is the unit of length that is generally most appropriate for describing the size of single molecules. The nanoscale marks the interface between the classical and quantum-mechanical worlds. Nanoscience is an interdisciplinary field that encompasses physics, biology, engineering, chemistry, and computer science, among others, and the prefix nano appears with increasing frequency in scientific journals and the news. Thus, as we increase our ability to fabricate computer chips with smaller features and improve our ability to cure disease at the molecular level, nanotechnology is at the ready. Scientists and engineers believe that the fabrication of nanomachines, nanoelectronics, and other nanodevices will help solve numerous problems faced by mankind today related to energy, health, and materials development. Nanotechnology, currently in its early stages, has already provided us with the ability to organize matter on the atomic scale, and there are already numerous products available as a direct result of our rapidly increasing ability to fabricate and characterize feature sizes less than 100 nm. Transparent nanoparticulate titania-based ultraviolet-absorbing coatings,[1–3] particle-based methods for delivery of highly potent anticancer drugs,[4] mirrors that don't fog, biomimetic* coatings with a water contact angle near 180°,[5,6] and gene and protein chips[7,8] are some of the first manifestations of nanotechnology. Breakthroughs in computer science and medicine will be where the real potential of nanotechnology will first be achieved; some breakthroughs are not that for off.

A BRIEF HISTORY OF NANOTECHNOLOGY

The amount of space available to us for information storage (or other uses) is enormous. Richard P. Feynman,[9] in a 1959 lecture titled "There's Plenty of Room at the Bottom," stated that there is nothing besides our clumsy size that keeps us from using this space. At the time of that lecture, it was not possible to manipulate single atoms or molecules because they were far too small for the existing tools, yet Feynman correctly predicted that the time would come when atomically precise manipulation of matter would become possible.

*Systems that mimic biological equivalents.

Feynman also described such atomic scale fabrication as a **bottom-up** approach, as opposed to the **top-down** approach that we are accustomed to. The current top-down method for manufacturing involves the construction of parts through methods such as cutting, carving, and molding. Using these methods, we have been able to fabricate a remarkable variety of machinery and electronics devices. However, the sizes at which we can make these devices is severely limited by our ability to cut, carve, and mold. The current set of top-down tools that allow us to achieve nanoscale-sized devices include chemical vapor deposition, reactive ion etching, optical or deep ultraviolet (UV) or X-ray lithography, electron-beam (e-beam) lithography, ion implantation, etc. All these tools are well developed and have been used for a number of years in the microelectronics industry for the fabrication of central processing units (CPUs), memory, and photonic devices.[10]

Bottom-up manufacturing, on the other hand, would provide components made of single molecules, which are held together by covalent forces that are far stronger than the forces that hold together macroscale components. Furthermore, the amount of information that could be stored in devices built from the bottom up would be enormous. The key obstacle in these approaches is the degree of our ability to exercise positional control over molecules and atoms. At the macroscopic scale, the idea that we can hold parts in our hands and assemble them by properly positioning them with respect to each other goes back to prehistory. At the molecular scale, the idea of holding and positioning molecules is new. One method that provides positional control is referred to as directed self-assembly. In a self-assembly-based process, the intermolecular interactions and the experimental conditions are manipulated precisely so that the parts themselves can spontaneously assemble into the desired structure. This is a well-established and powerful method of synthesizing complex molecular structures. A basic principle in self-assembly is selective affinity: if two molecular parts have complementary shapes and charge patterns—one part has a hollow where the other has a bump, and one part has a positive charge where the other has a negative charge—then they will tend to stick together in one singular way. By stirring these parts, aided by Brownian motion especially if the parts are in solution, the parts will eventually, purely by chance, be brought together in just the right way and combine into a bigger part. This bigger part can combine in the same way with other parts, letting us gradually build a complex whole from molecular pieces by stirring them together. Even though self-assembly is a path to the formation of nanostructures, by itself it would not be able to make the very wide range of products promised by nanotechnology. During self-assembly the molecular components move around and collide into each other in all kinds of ways, and if they aggregate in an undesirable manner, unwanted random structures will result. Many molecular components exhibit this problem, so self-assembly won't work for them.

We can avoid these issues if we can hold and position the parts; this leads to the concept of directed self-assembly. When two sticky parts do come into contact with each other, they'll do so in the right orientation because they are held in the right orientation. In short, positional control at the molecular scale should let us make things that would otherwise be difficult or impossible. Thus, in a competing approach, we develop positioning tools. One such tool is the scanning probe microscope (SPM).[11–13] In SPMs, a very sharp tip is brought down to the surface of the sample being scanned. By monitoring the interaction of the tip with the surface, we can tell that the tip is approaching the surface and so can "feel" the outlines of the surface in front of us. Many different types of physical interactions with the surface are used to detect its presence (see earlier references). Some scanning probe microscopes literally push on the surface and note how hard the surface pushes back. Others connect the surface and probe to a voltage source, and measure the current flow when the probe gets close to the surface. A host of other probe-surface interactions can be measured, and are used to make different types of SPMs. In all of them, the basic idea is the same: when the sharp tip of the probe approaches the surface, a signal is generated, a signal that allows us to map out the surface being probed. The SPM can not only map a surface, but also in many cases the probe-surface interaction can change the surface. This has already been used experimentally to spell out molecular words, and opportunities to modify the surface in a controlled way are being investigated both experimentally and theoretically.[14–16]

Since that initial preview of nanotechnology, several methods have been developed which prove that Feynman was correct. The most notable methods are scanning probe microscopy[1,14,17–22] and the corresponding advancements in supramolecular chemistry.[3,23,24] Scanning probe microscopy gives us the ability to position single atoms and/or molecules in the desired place exactly as Feynman had predicted. Feynman was critical of traditional chemistry's tedious procedures and the random nature of its reactions; recent advances have shown improved potential for use in nanotechnology.

SEMICONDUCTOR FABRICATION[25]

Computer chips (and the silicon-based transistors within them) are rapidly shrinking according to a predictable formula (by a factor of 4 every 3 years—Moore's law). According to the Semiconductor Industry Association's extrapolation of formulas such as this one **(SIA roadmap),** it is expected that the sizes of circuits within chips will reach the size of only a few atoms in about 20 years.

Since almost all of our modern computers are built from silicon **semiconductor** transistors patterned and carved by light **(photolithography),** the shrinking of circuits predicted by the SIA may not be economical in the future, despite the enormous investment made to constantly shrink and improve semiconductor electronics. Smaller circuits require less energy, operate more quickly and, of course, take up less space. Thus, Moore's law has held since computers first became commercially available. However, simple shrinking of components cannot continue much longer.

As a transistor such as the metal-oxide-semiconductor field-effect transistor (MOSFET; one of the primary components used in integrated circuits) is made smaller, both its properties and manufacturing cost change with **scale.** Currently, ultraviolet light is used to create the silicon circuits with a lateral resolution around 200 nm (the wavelength of ultraviolet light). As the circuits shrink below 100 nm, new fabrication methods must be created, but at increasing cost. Furthermore, once the circuit size reaches only a few nanometres, quantum effects such as tunneling must be reckoned with; this drastically affects the computer's ability to function normally. New methods for computer chip fabrication are constantly being sought by microchip manufactures.

ALTERNATIVE ARCHITECTURES FOR NANOCOMPUTING[26]

In addition to single electron transistors, two promising alternatives to traditional computers are molecular computing and quantum computing. These two methods are intimately related, yet deal with information on two different levels. Progress made in these areas during recent years has shown both to be feasible replacements for semiconductor chips.

Quantum computing seeks to write, process, and read information on the quantum level. It is at the nanoscale that quantum mechanical effects (such as wave-particle duality) become apparent. Numerous scientists are seeking ways to store information within the **quantum mechanical** realm. This is not a simple task. Since the laws of quantum mechanics involve unintuitive principles such as superposition and entanglement, a quantum computer would be able to violate some rules that limit our current computers. For instance, taking advantage of superposition allows a quantum bit of information, termed a **qubit,** to be used in several computations at the same time. Taking advantage of entanglement would allow information to be processed over **long distances** without the conventional requirement for wires.

Molecular computation is another method, complementary to quantum computing, that seeks to write, process, and read information within single molecules. One molecule that has proved most promising for molecular computation is deoxyribonucleic acid (DNA). DNA is a long polymer made of four different nucleotides that can be represented by the letters A, T, C, and G. The order or sequence of these nucleotides within DNA provides the information for making protein, the main components of the molecular-scale machinery used by living organisms to carry out life-sustaining functions.

Mathematicians have devised numerous ways to use DNA and the various proteins that come with it to carry out numerical computations that are notoriously difficult for silicon computers, namely **NP-complete** problems. The advantage that molecular computing using DNA has over conventional computing is that it is massively parallel. This means that each DNA molecule can function as a single processor, which greatly improves the speed of computation for complex problems.

MEDICAL APPLICATIONS

Molecular-scale manipulation of matter is receiving abundant attention in medicine. Since all living organisms are composed of molecules, molecular biology has become the primary focus of biotechnology. Countless diseases have been cured by our ability to synthesize small molecules, commonly know as "drugs," that interact with the protein molecules that make up the molecular machinery that keeps us alive. Our understanding of how proteins **interact** with DNA, phospholipids, and other biological molecules allows such progress.

Living systems exist because of the vast amount of highly ordered **molecular machinery** from which they are built. The central principle of molecular biology states that information required to build a living cell or organism is stored in DNA (which was described above for its use in molecular computation). This information is transferred from the DNA to the proteins by **transcription** and **translation.** These processes are all executed by various biomolecular components, mostly protein and nucleic acids.

Molecular biology and the study of these interactions have led to the discovery of numerous pharmaceuticals that have been enormously effective to combat disease. Understanding of molecular mechanisms including substrate recognition, energy expenditure, electron transport, membrane activity, and much more have greatly improved our medical technology.

This is related to nanotechnology for several reasons. First of all, it illustrates the capabilities of molecular-scale machinery. The goal of nanotechnology is molecular and atomic precision; thus nanotechnology has much to learn from nature. Copying, borrowing, and learning from nature is one of the primary techniques used by nanotechnology and has been termed **biomimetics.**[15,27–35] Secondly, our ability to design synthetic, semisynthetic, and natural molecular machinery gives us an enormous potential for curing disease and preserving life. See Refs. 36 and 37. The human body is composed of molecules, hence the availability of molecular nanotechnology will permit dramatic progress in human medical services. More than just an extension of "molecular medicine," nanomedicine will employ molecular machine systems to

address medical problems, and will use molecular knowledge to maintain and improve human health at the molecular scale. Nanomedicine will have extraordinary and far-reaching implications for the medical profession, for the definition of disease, for the diagnosis and treatment of medical conditions including aging, and ultimately for the improvement and extension of natural human biological structure and function.

MOLECULAR SIMULATION[38,39]

A branch of computer science that is allowing rapid progress to be made in nanotechnology is the computer simulation of molecular-scale events. Molecular simulation is able to provide and predict data about molecular systems that would normally require enormous effort to obtain physically. By organizing virtual atoms in a molecular simulation environment, one can effectively model nanoscale systems.

Current limitations of molecular simulation techniques are the molecular simulation algorithm and computation time for complex systems. Force-field algorithms are currently quite efficient and are often used today. However, such models neglect electronic properties of the system. In order to calculate electron density, quantum mechanical models are required. However, as the number of atoms and electrons is increased, the computational complexity of the model quickly reaches the limits of our most modern supercomputers. Thus, as the computational abilities of our computers are improved (often with help from nanoscience), increasingly complex systems will be within the reach of molecular simulation.

CARBON NANOTUBES

Carbon nanotubes are one of nanotechnology's most mentioned building blocks. With one hundred times the tensile strength of steel, thermal conductivity better than all but the purest diamond, and electrical conductivity similar to copper, but with the ability to carry much higher currents, they seem to be a wonder material.

Carbon nanotubes come in a variety of flavors: long, short, single-walled, multiwalled, open, closed, with different types of spiral structure, etc. Each type has specific production costs and applications. Some have been produced in large quantities for years while others are only now being produced commercially with decent purity and in quantities greater than a few grams.

Carbon nanotubes were "discovered" in 1991 by Sumio Iijima of NEC and are effectively long, thin cylinders of graphite. Graphite is made up of layers of carbon atoms arranged in a hexagonal lattice, like chicken wire (see Fig. 20.2.1). Though the chicken wire structure itself is very strong, the layers themselves are not chemically bonded to each other but held together by weak Van der Waals forces.

Taking one of these sheets of chicken wire and rolling it up into a cylinder and joining the loose wire ends will result in a carbon nanotube. In addition to their remarkable tensile strength (usually quoted as 100 times that of steel at one-sixth the weight), carbon nanotubes have shown other surprising properties. They can conduct heat as efficiently as most diamond (only diamond grown by deposition from a vapor is better), conduct electricity as efficiently as copper, yet can also be semiconducting. They can produce streams of electrons very efficiently (field emission), which can be used to create light in displays for televisions or computers, or even in domestic lighting, and they can enhance the fluorescence of materials they are close to. Their electrical properties can be made to change in the presence of certain substances or as a result of mechanical stress. Nanotubes within nanotubes can act like miniature springs, and they can even be stuffed with other materials. Nanotubes and their variants hold promise for storing fuels such as hydrogen or methanol for use in fuel cells, and they make good supports for catalysts.

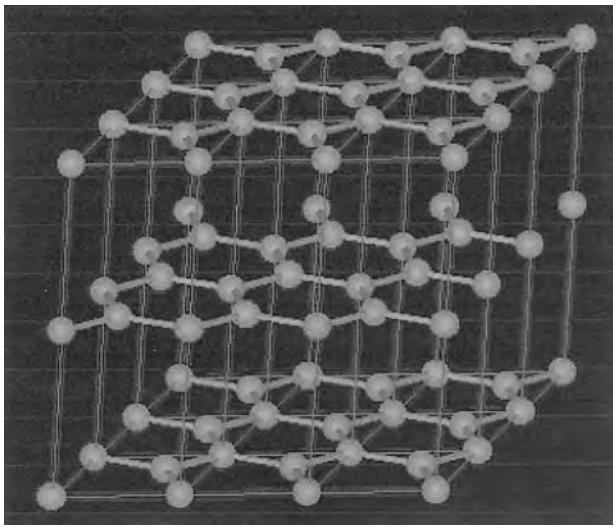

Fig. 20.2.1 Layer structure of graphite.

One of the major classifications of carbon nanotubes is into single-walled varieties (SWNTs), which have a single cylindrical wall, and multiwalled varieties (MWNTs), which have cylinders within cylinders (see Fig. 20.2.2).

The lengths of both types vary greatly, depending on the way they are made, and are generally microscopic rather than nanoscopic, i.e., greater than 100 nanometres. The aspect ratio (length divided by diameter) is typically greater than 100 and can be up to 10,000. Recent developments continue apace.

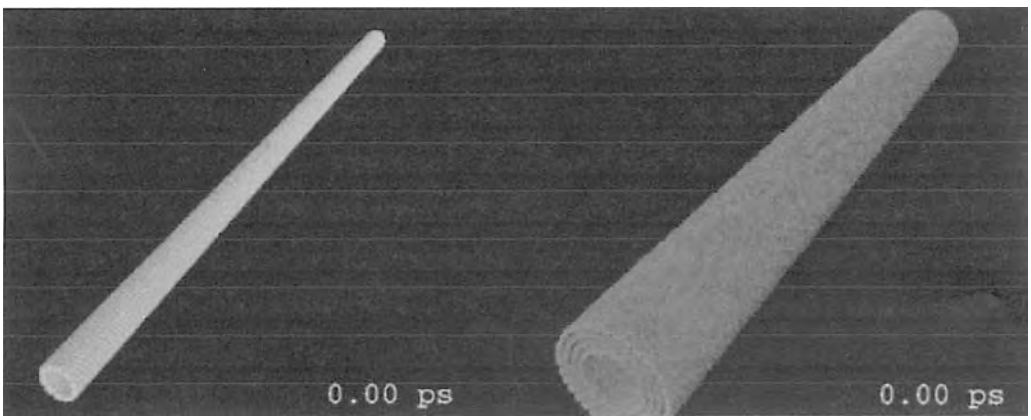

Fig. 20.2.2 Computational image of single- and multiwalled nanotubes.

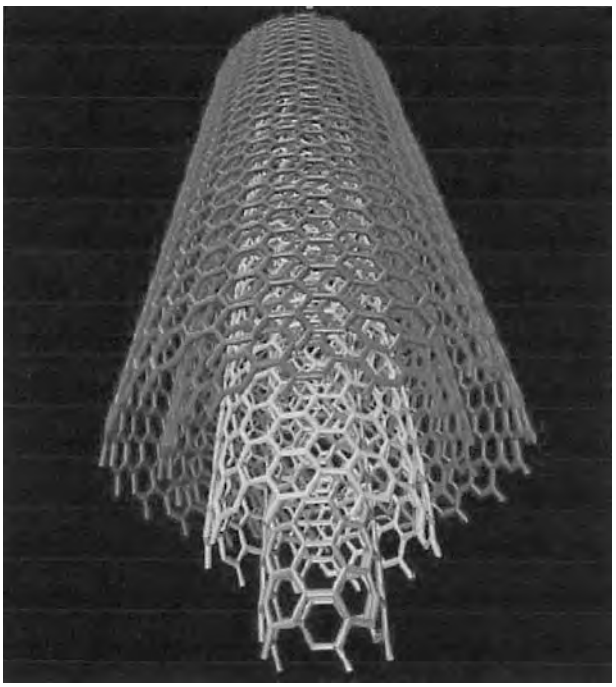

Fig. 20.2.3 Representation of a multiwalled carbon nanotube.

Single-Walled Carbon Nanotubes (SWNTs)

These are the stars of the nanotube world, and are much harder to make than the multiwalled variety. The oft-quoted amazing properties generally refer to SWNTs. As previously described, they are basically tubes of graphite and are normally capped at the ends (see Fig. 20.2.2), although the caps can be removed. The caps are made by mixing in some pentagons with the hexagons and are the reason that nanotubes are considered close cousins to buckminsterfullerene, a roughly spherical molecule made of 60 carbon atoms that looks like a soccer ball and is named after the architect Buckminster Fuller. (The word *fullerene* is used to refer to the variety of such molecular cages, some with more carbon atoms than buckminsterfullerene, and some with fewer.)

The theoretical minimum diameter of a carbon nanotube is around 0.4 nm, which is about as wide as two silicon atoms side by side; nanotubes of this size have been made. Average diameters tend to be around 1.2 nm, depending on the process used to create them. SWNTs are more pliable than their multiwalled counterparts and can be twisted, flattened, and bent into small circles or around sharp bends without breaking.

Discussions of the electrical behavior of carbon nanotubes usually relate to experiments on the single-walled variety. They can be conducting, like metal (such nanotubes are often referred to as metallic nanotubes), or semiconducting. The latter property has given rise to dreams of using nanotubes to make extremely dense electronic circuitry, and the year 2005 saw major advances in creating basic electronic structures from nanotubes in the lab, from transistors up to simple logic elements. The gap between these experiments and commercial nanotube electronics is extremely wide.

Multiwalled Carbon Nanotubes (MWNTs)

Multiwalled carbon nanotubes are basically concentric SWNTs—cylindrical graphitic tubes. In these more complex structures, the different SWNTs that form the MWNT may have quite different structures (length and chirality). MWNTs are typically 100 times longer than they are wide and have outer diameters mostly in the tens of nanometres.

Although it is easier to produce significant quantities of MWNTs than SWNTs, their structures are less well understood than single-wall nanotubes because of their greater complexity and variety. Multitudes of exotic shapes and arrangements, often with imaginative names such as bamboo trunks, sea urchins, necklaces, and coils, have also been observed under different processing conditions. The variety of forms may be interesting but also has a negative side—MWNTs always (so far) have more defects than SWNTs, and these diminish their desirable properties.

Many of the nanotube applications now being considered or put into practice involve multiwalled nanotubes, because they are easier to produce in large quantities at a reasonable price and have been available in decent amounts for much longer than SWNTs. In fact, one of the current major manufacturers of MWNTs, Hyperion Catalysis, does not even sell the nanotubes directly, but only premixed with polymers for composite applications. The tubes typically have 8 to 15 walls and are around 10 nm wide and 10 μm long.

Focus on Structure

A few key studies have explored the structure of carbon nanotubes by using high-resolution microscopy techniques. These experiments have confirmed that nanotubes are cylindrical structures based on the hexagonal lattice of carbon atoms that forms crystalline graphite. Three types of nanotubes are possible, called armchair, zigzag, and chiral nanotubes, depending on how the two-dimensional graphene sheet is "rolled up."

The different types are most easily explained in terms of the unit cell of a carbon nanotube—in other words, the smallest group of atoms that defines its structure (see Fig. 20.2.4*a*). The so-called chiral vector of the nanotube, C_h, is defined by $C_h = n\bar{a}_1 + m\bar{a}_2$, where $\bar{a}_1$ and $\bar{a}_2$ are unit vectors in the two-dimensional hexagonal lattice and n and m are integers. Another important parameter is the chiral angle, which is the angle between C_h and $\bar{a}_1$.

When the graphene sheet is rolled up to form the cylindrical part of the nanotube, the ends of the chiral vector meet each other. The chiral vector thus forms the circumference of the nanotube's circular cross section, and different values of n and m lead to different nanotube structures (see Fig. 20.2.5). Armchair nanotubes are formed when $n = m$ and the chiral angle is 30°. Zigzag nanotubes are formed when either n or m are zero and the chiral angle θ, as shown in Fig. 20.2.4*a*, is 0°. All other nanotubes, with chiral angles intermediate between 0° and 30°, are known as chiral nanotubes.

The properties of nanotubes are determined by their diameter and chiral angle, both of which depend on n and m. The diameter d_t is simply the length of the chiral vector divided by ¼, and we find that $d_t = (\sqrt{3}/\pi)a_{c-c}(m^2 + mn + n^2)^{1/2}$, where a_{c-c} is the distance between neighboring carbon atoms in the flat sheet. In turn, the chiral angle is given by $\tan^{-1}\left[\sqrt{3}n/(2m + n)\right]$.

Measurements of the nanotube diameter and the chiral angle have been made with scanning tunneling microscopy and transmission electron microscopy. However, it remains a major challenge to determine d_t and θ at the same time as measuring a physical property such as resistivity. This is partly because the nanotubes are so small, and partly because the carbon atoms are in constant thermal motion. Also, the nanotubes can be damaged by the electron beam in the microscope.

How to Make Nanotubes

When a Rice University group found a relatively efficient way to produce bundles of ordered SWNTs in 1996, they opened new opportunities for quantitative experimental studies on carbon nanotubes. These ordered nanotubes are prepared by the laser vaporization of a carbon target in a furnace at 1,200°C. A cobalt-nickel catalyst helps the growth of the nanotubes, presumably because it prevents the ends from being "capped" during synthesis, and about 70 to 90 percent of the carbon target can be converted to SWNTs. By using two laser pulses 50 ns apart, growth conditions can be maintained over a larger volume and for a longer time. This scheme provides more uniform vaporization and better

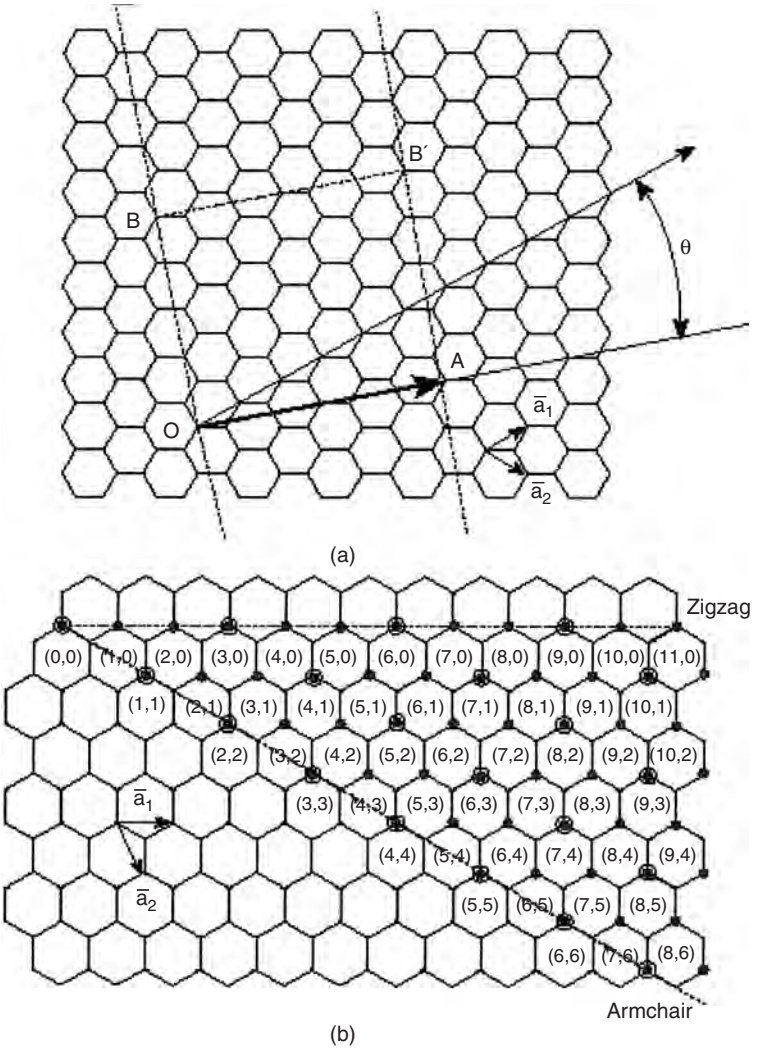

Fig. 20.2.4 Basics of structure.

control of the growth conditions. Flowing argon gas sweeps the nanotubes from the furnace to a water-cooled copper collector just outside of the furnace.

At the University of Montpellier (France) Catherine Journet, Patrick Bernier, and colleagues later developed a carbon-arc method to grow similar arrays of SWNT. In this case, ordered nanotubes were also produced from ionized carbon plasma, and joule heating from the discharge generated the plasma. Several other groups are now making bundles of SWNTs, using variants of these two methods. However, the Rice group has had the largest impact on the field, largely because it was the first to develop an efficient synthesis method and has formed a lot of international collaborations to measure the properties of SWNTs.

In a scanning electron microscope, the nanotube material produced by either of these methods looks like a mat of carbon ropes. The ropes are between 10 and 20 nm across and up to 100 μm long. When examined in a transmission electron microscope, each rope is found to consist of a bundle of SWNTs aligned along a single direction. X-ray diffraction, which views many ropes at once, also shows that the diameters of the SWNTs have a narrow distribution with a strong peak.

For the synthesis conditions used by the Rice and Montpellier groups, the diameter distribution peaked at 1.38 ± 0.02 nm, very close to the diameter of an ideal (10, 10) nanotube. X-ray diffraction measurements by John Fischer and coworkers at the University of Pennsylvania showed that bundles of SWNTs form a two-dimensional triangular lattice. The lattice constant is 1.7 nm and the tubes are separated by 0.315 nm at closest approach, which agrees with prior theoretical modeling by Jean-Christophe Charlier and others at the University of Louvain-la-Neuve (Belgium).

Chemical vapor deposition (CVD) can be used to make either SWNTs or MWNTs, and produces them by heating a precursor gas and flowing it over a metallic or oxide surface with a prepared catalyst (typically a nickel, iron, molybdenum, or cobalt catalyst).

In several gas-phase processes, such as a high-pressure carbon monoxide process, both SWNTs and MWNTs can be produced by using a reaction that takes place on a catalyst flowing in a stream, rather than bonded to a surface.

While MWNTs do not need a catalyst for growth, SWNTs can be grown only with a catalyst. However, the detailed mechanisms responsible for growth are not yet well understood. Experiments show that the width and peak of the diameter distribution depend on the composition of the catalyst, the growth temperature, and various other growth conditions. Great efforts are now being made to produce narrower

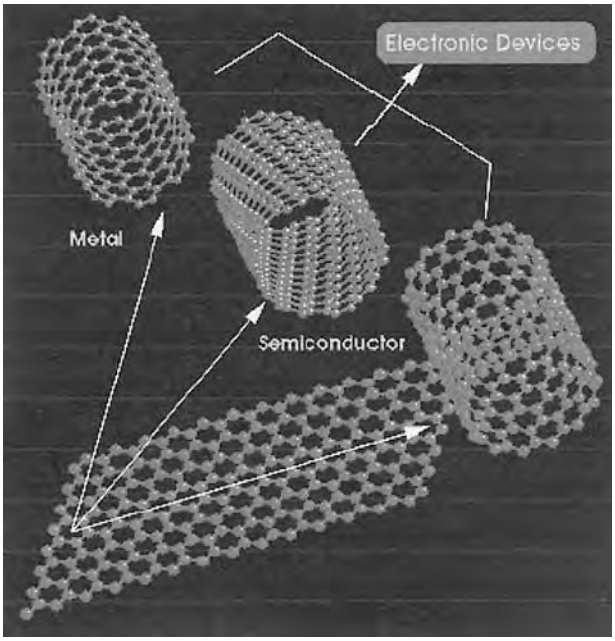

Fig. 20.2.5 Schematic representation of rolling graphite to create a carbon nanotube.

diameter distributions with different mean diameters, and to gain better control of the growth process. From an applications point of view, the emphasis will be on methods that produce high yields of nanotubes at low cost, and some sort of continuous process will probably be needed to grow carbon nanotubes on a commercial scale.

Elastic Nanotube Properties Determining the elastic properties of SWNTs has been one of the most disputed areas of nanotube study in recent years. On the whole, SWNTs are stiffer than steel and are resistant to damage from physical forces. Pressing on the tip of the nanotube will cause it to bend without damage. When the force is removed, the tip of the nanotube will recover to its original state. Quantizing these effects, however, is rather difficult and an exact numerical value cannot be agreed on.

The Young's modulus (elastic modulus) of SWNTs lies close to 1 TPa. The maximum tensile strength is close to 30 GPa.

The results of various studies over the years have shown a large variation in the value reported. In 1996, researchers at NEC in Princeton and the University of Illinois measured the average modulus to be 1.8 TPa. This was measured by first allowing a tube to stand freely and then taking a microscopic image of its tip. The modulus is calculated from the amount of blur seen in the photograph at different temperatures. In 1997, G. Gao, T. Cagin, and W. Goddard III reported three variations on the Young's modulus to five decimal places that were dependent on the chiral vector. They concluded that a (10, 10) armchair tube had a modulus of 640.30 GPa, a (17, 0) zigzag tube had a modulus of 648.43 GPa, and a (12, 6) tube had a value of 673.94 GPa. These values were calculated from the second derivatives of potential.

Further studies were conducted. In 1998, Treacy reported an elastic modulus of 1.25 TPa using the same basic method used 2 years earlier. This compared well with the modulus of MWNTs (1.28 TPa), found by Wong in 1997. Using an atomic force microscope (AFM), they pushed the unanchored end of a free-standing nanotube out of its equilibrium position and recorded the force that the nanotube exerted back onto the tip. In 1999, E. Hernández and Angel Rubio showed, using tight-binding calculations, the Young's modulus was dependent on the size and chirality of the SWNT, ranging from 1.22 TPa for the (10, 0) and (6, 6) tubes to 1.26 TPa for the large (20, 0) SWNTs. However, using first-principle calculations, they calculated a value of 1.09 TPa for a generic tube.

The previous evidence would lead one to assume that the diameter and shape of the nanotube was the determining factor for its elastic modulus. However, when working with different MWNTs, Forró noted that the modulus measurements of MWNTs in 1999 (using AFM) did not strongly depend on the diameter, as had been recently suggested. Instead, they argued that the modulus of MWNTs correlates to the amount of disorder in the nanotube walls. However, the evidence showed that the value for SWNTs does in fact depend on diameter; an individual tube had a modulus of about 1 TPa while bundles (or ropes) of 15 to 20 nm in diameter had a modulus of about 100 GPa.

It has been suggested that the controversy into the value of the modulus is due to the interpretation of the thickness of the walls of the nanotube. If the tube were considered to be a solid cylinder, then it would have a lower Young's modulus. If the tube is considered to be hollow, the modulus gets higher, and the thinner the walls of the nanotube are treated, the higher the modulus will become.

Nanotube Applications

The materials markets are already seeing applications for composites based on multi-walled carbon nanotubes and nanofibers. In many ways this is an old market; carbon fibers have been around commercially for a couple of decades. The benefits of the new materials are the same as those of carbon fibers, but better, given that the main properties considered are strength and conductivity. Carbon fibers are quite large, typically about a tenth of a millimetre in diameter, and blacken the material to which they are added. MWNTs can offer the same improvements in strength to a polymer composite without the blackening and often with a smaller amount of added material (a filler). The greater aspect ratio (length compared to diameter) of the newer materials can make plastics conducting with a smaller filler load, one significant application being electrostatic painting of composites in products such as car parts. Additionally, the surface of the composite is smoother, which benefits more refined structures such as platens for computer disk drives.

When thinking about structural applications such as these, it should be remembered that, in general, as the fibers get smaller, the number of defects decreases, in a progression toward the perfection of the single-walled nanotube. The inverse progression is seen in terms of ease of manufacturing—the more perfect, and thus more structurally valuable, the material, the harder it is to produce in quantity at a good price. This relationship is not written in stone—there is no reason that near-perfect SWNTs should not be producible cheaply and in large quantities. When this happens, and it might not be too far off, the improvements seen in the strength-to-weight ratios of composite materials could soar, impacting a wide variety of industries from sports equipment to furniture, from the construction industry to kitchenware, and from automobiles to airplanes and spacecraft (the aerospace industry is probably the one that stands to reap the greatest rewards). In fact, a carbon nanotube composite has recently been reported that is 6 times stronger than conventional carbon fiber composites.

Just because the perfect nanotube is 100 times stronger than steel at a sixth of the weight doesn't mean one is going to be able to achieve those properties in a bulk material containing them. The chicken wire arrangement that makes up the layers in graphite does adhere well to other materials, which is why graphite is used in lubricants and pencils. The same holds true of nanotubes—they are quite insular in nature, preferring not to interact with other materials. To capitalize on their strength in a composite, they need to latch on to the surrounding polymer, which they are not inclined to do (blending a filler in a polymer is difficult even without these issues—it took a decade to perfect this for the new nanoclay polymers now hitting the markets).

One way of making a nanotube interact with something else, such as a surrounding polymer, is to modify it chemically. This is called **functionalization** and is being explored not just for composite applications but also for a variety of others, such as biosensors. For structural applications, the problem is that functionalization can reduce the valuable qualities of the nanotubes that one is trying to capitalize on.

Of course, in theory there is no need to mix the nanotubes with another material. To make superstrong cables, for example, the best solution would be to use bundles of sufficiently long nanotubes with no other material added. For this reason, one of the dreams of nanotube production is to be able to spin them, like thread, to indefinite lengths. Such a technology would have applications from textiles (the U.S. military is in fact investigating the use of nanotubes for bulletproof vests) to the "space elevator." The space elevator concept, which sounds like something straight out of science fiction, involves anchoring one end of a huge cable to the earth and another to an object in space. The taut cable so produced could then support an elevator that would take passengers and cargo into orbit for a fraction of the cost of the rockets used today. Sounds too far out? In fact, it has been established by NASA as feasible in principle, given a material as strong as SWNTs.

The materials market is a big one, and there are others, which we'll come to, but smaller ones exist too. Nanotubes are already being shipped on the tip of atomic-force microscope probes to enhance atomic-resolution imaging. Nanotube-based chemicals and biosensors should be on the market soon (they face stiff competition from other areas of nanotechnology). The thermal conductivity of nanotubes shows promise in applications from cooling integrated circuits to aerospace materials. Electron beam lithography, which is a method of producing nanoscale patterns in materials, may become considerably cheaper thanks to the field-emission properties of carbon nanotubes. Recent developments show promise of the first significant change in X-ray technology in a century. Entering more speculative territory, nanotubes may one day be used as nanoscale needles that can inject substances into, or sample substances from, individual cells, or they could be used as appendages for miniature machines (the tubes in multiwalled nanotubes slide over each other like graphite, but have preferred locations that they tend to spring back to).

Big markets, apart from materials, in which nanotubes may make an impact, include flat panel displays (near-term commercialization is promised here), lighting, fuel cells, and electronics. This last is one of the most talked-about areas but one of the farthest from commercialization, with one exception, this being the promise of huge computer memories (more than 1,000 times greater in capacity than what you probably have in your machine now) that could, in theory, put a lot of the $40 billion magnetic disk industry out of business. Companies like to make grand claims, however, and in this area there is not just the technological hurdle to face but the even more daunting economic one, a challenge made harder by a host of competing technologies.

Despite an inevitable element of hype, the versatility of nanotubes does suggest that they might one day rank as one of the most important materials ever discovered. In years to come they could find their way into myriad materials and devices around us and quite probably make some of the leaders in this game quite rich.

20.3 FERROELECTRICS/PIEZOELECTRICS AND SHAPE MEMORY ALLOYS

by Jacqueline J. Li

FERROELECTRICS/PIEZOELECTRICS

Ferroelectrics are materials exhibiting a spontaneous dielectric polarization and **hysteresis effects** in the relation between dielectric displacement and electric field. This ferroelectric behavior is observed only below a transition temperature T_c—the so-called Curie temperature. Above the Curie temperature, the materials are no longer ferroelectric and show normal dielectric behavior.

Ferroelectric phenomena were first observed in 1920 by Valasek in Rochelle salt [304-59-6], $KNaC_4H_4O_6{\cdot}4H_2O$. In his description, Valasek called attention to the analogy with ferromagnetic phenomena. *Ferro* is a prefix associated with iron-containing materials. But the hysteresis nature in the relation between dielectric displacement and electric field is remarkably similar to the induction-magnetic field relation for ferromagnetic materials. Ferromagnetic materials generally contain iron. Ferroelectrics are named after the similar hysteresis loop and rarely contain iron as a significant constituent.

Table 20.3.1 (Table I-1 in "Ferroelectric Crystals," Franco Jona and G. Shirane, Dover, 1993) provides a partial list of ferroelectric crystals arranged approximately in chronological order of their discovery.

Most ferroelectric materials are ceramics; some polymers also exhibit ferroelectric behaviors. At present, the number of known pure compounds with ferroelectric properties is about 200; they are classified into about 40 families. Examples of typical ferroelectrics are: potassium dihydrogen phosphate, KH_2PO_4 (commonly abbreviated as KDP), and a number of isomorphous phosphates and arsenates; barium titanate, $BaTiO_3$, and other isomorphous double oxides; Rochelle salt (sodium potassium tartrate tetrahydrate, $NaKC_4H_4O_6{\cdot}4H_2O$); and some other isomorphous crystals. The most widely used ferroelectrics now are lead zirconate titanate solid solutions, $Pb(Zr\text{-}Ti)O_3$ (commonly known as PZT). Before we introduce the general properties and structures of ferroelectric materials, we focus on barium titanate, which is one of the simplest ferroelectric materials.

Barium Titanate

In order to better understand the ferroelectric properties, let's concentrate on barium titanate ($BaTiO_3$), which is the most extensively investigated ferroelectric material and whose structure is far simpler than that of any other ferroelectrics. Its crystal structure is of perovskite type.

Table 20.3.1 Partial List of Ferroelectric Crystals

Name and chemical formula	Curie temperature, °C	Spontaneous polarization, 10^{-6} C/cm^2	Year in which reported
Rochelle salt $NaKC_4H_4O_6 \cdot 4H_2O$	+ 23	0.25	1921
Lithium ammonium tartrate $Li(NH_4)C_4H_4O_6 \cdot H_2O$	−170	0.20	1951
Potassium dihydrogen phosphate KH_2PO_4	−150	4.0	1935
Potassium dideuterium phosphate KD_2PO_4	− 60	5.5	1942
Potassium dihydrogen arsenate KH_2AsO_4	−177	5.0	1938
Barium titanate $BaTiO_3$	+120	26.0	1945
Lead titanate $PbTiO_3$	+490	>50	1950
Potassium niobate $KNbO_3$	+415	30	1951
Potassium tantalate $KTaO_3$	−260	?	1951
Cadmium (pyro) niobate $Cd_2Nb_2O_7$	− 85	~10	1952
Lead (meta) niobate $PbNb_2O_6$	+570	?	1953
Guanidinium aluminium sulfate hexahydrate $C(NH_2)_3Al(SO_4)_2 \cdot 6H_2O$	None	0.35	1955
Methylammonium aluminum alum $CH_3\ NH_3Al(SO_4)_2 \cdot 12H_2O$	− 96	1.0	1956
Ammonium sulfate $(NH_4)_2SO_4$	− 50	0.25	1956
Trilglycine sulfate $(NH_2CH_2COOH)_2 \cdot H_2SO_4$	+ 49	2.8	1956
Colemanite $CaB_3O_4(OH)_3 \cdot H_2O$	− 7	0.65	1956
Dicalcium strontium propionate $Ca_2Sr(CH_3CH_2COO)_6$	+ 8	0.3	1957
Lithium acid selenite $LiH_3(SeO_3)_2$	None	10.0	1959
Sodium nitrite $NaNO_2$	+160	7.0	1958

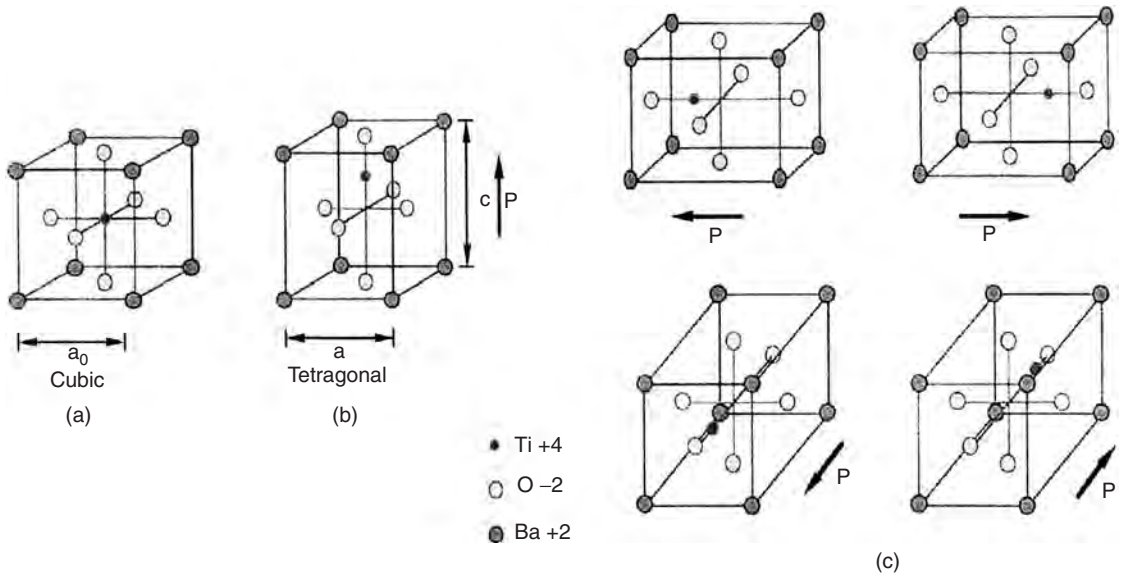

Fig. 20.3.1 (*a*) Cubic structure of a $BaTiO_3$ unit cell above the Curie point of 120°C. (*b*) Tetragonal structure below 120°C. (*c*) 90° reorientation under a compressive stress or a perpendicular electric field.

This structure is common to a large family of compounds with the general formula ABO_3, whose representative in nature is the mineral $CaTiO_3$, called perovskite. Figure 20.3.1*a* shows a unit cell of the cubic perovskite-type lattice of $BaTiO_3$. The Curie temperature of $BaTiO_3$ is at 120°C. Above 120°C, $BaTiO_3$ remains in the centrosymmetric cubic structure and nonpolar phase (nonpiezoelectric, or paraelectric). Upon cooling just below 120°C, $BaTiO_3$ undergoes a phase transformation to a tetragonal modification as shown in Fig. 20.3.1*b*. In this process, the positively charged titanium ion moves from its original central position to a position aligned along the polar axis (or *c* axis), and together with the negatively charged oxygen ions, forms a dipole moment. The total dipole moments in the material with a unit volume define the spontaneous polarization *P*. Between 5°C and 120°C, the crystal has a stable tetragonal structure and the lattice parameters are $a = 0.3992$ nm and $c = 0.4032$ nm. Such a poled crystal can undergo a 180° domain switch under a reversed electric field, or a 90° switch under a compressive stress or under an electric field perpendicular to its original polar direction, as shown in Fig. 20.3.1*c*.

Hysteresis Loop

The ferroelectric material can have zero overall **polarization** under zero applied electric field, due to a random orientation of microscopic-scale domains, regions in which the *c* axes of adjacent unit cells have a common direction. If we first apply a small electric field, we will have only linear relationship between polarization *P* and the electric field *E* because the field is not large enough to switch any of the domains and the crystal will behave like a normal paraelectric. Figure 20.3.2 shows schematic plot of *P* versus *E*. When the applied electric field increases, the dipole orientations are favored to the direction parallel to the applied field direction. In this case, domains with such orientations "grow" at the expense of other, less favorably oriented, ones. When the applied electric field increases more, more domains will switch over in the favored applied field direction and the polarization will increase rapidly, until it reaches a state in which all the domains are aligned in the applied electric field direction. This is a state of saturation and the crystal consists now of a single domain.

If now we decrease the applied field to zero, the polarization will generally not return to zero and some of the domains will remain aligned in the applied field direction. The polarization at this point is called remanant polarization P_r. The extrapolation of the linear portion of the top curve back to the polarization axis represents the value of the spontaneous polarization P_s.

In order to observe the overall polarization of a ferroelectric material, an electric field in the opposite direction needs to be applied. The value of the electric field required to reduce the polarization *P* to zero is called the *coercive field* E_c. Further increase of the field in the opposite direction will, of course, cause complete alignment of the dipoles in this direction, and the cycle can be completed by reversing the field direction once again.

From Fig 20.3.2, the hysteresis loop of the polarization *P* versus the applied field *E* is obtained, which is the most important characteristic of a ferroelectric material. The essential feature of a ferroelectric is not that it has a spontaneous polarization, but rather that this spontaneous polarization can be reversed by means of an electric field.

Electromechanical Coupling Behavior

Because of the nature of polarization and the reorientation or domain switch of a ferroelectric under a specific electric and/or mechanical loading, a coupling behavior between electric and mechanical can be observed. When a ferroelectric material is subjected to an electric field, it can be deformed up to 0.2 percent of strain. Figure 20.3.3 shows the relation between the axial strain and the electric field of a PLZT, which gives a typical butterfly-shaped strain versus electric field curve. On the other hand, under the applied compressive stress loading, a ferroelectric produces a measurable voltage change.

Piezoelectricity

Although ferroelectricity is an intriguing phenomenon, it does not have the practical importance that ferromagnetic materials display (in areas such as magnetic storage of information). The most common applications of ferroelectrics stem from a closely related phenomenon, piezoelectricity. The prefix *piezo* comes from the Greek word for pressure. Piezoelectricity is the ability of certain crystalline materials to develop an electric charge proportional to a mechanical stress. The piezoelectric phenomenon was first discovered by J. Curie and P. Curie in 1880. The direct piezoelectric effect is that electric polarization is produced by mechanical stress. Closely related to it is the converse effect, in which

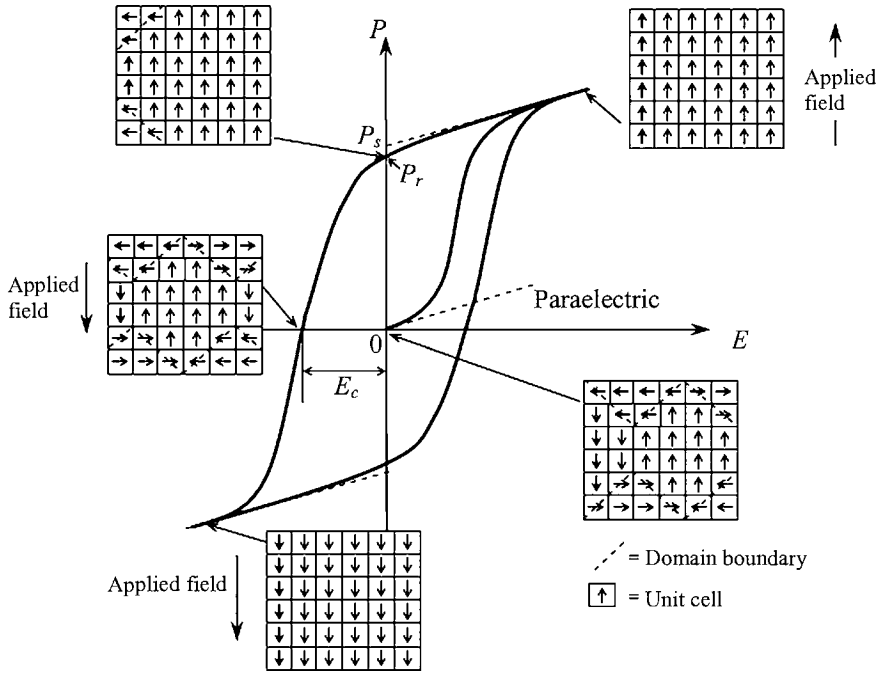

Fig. 20.3.2 Schematic diagram of ferroelectric hysteresis loop.

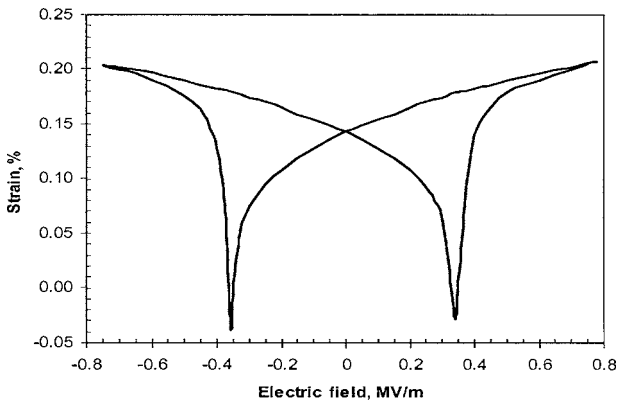

Fig. 20.3.3 The butterfly-shaped strain versus electric field relations of a PLZT.

a crystal becomes strained when an electric field is applied. We can write the two effects that occur in piezoelectrics as

Direct piezoelectric effect: $E = g\sigma$ (20.3.1)

Converse piezoelectric effect: $e = dE$ (20.3.2)

where E is the electric field (V/m), σ is the applied stress (Pa), e is the strain, and g and d are **piezoelectric constants**. The g constant is related to the d constant by the permittivity:

$$g = d/\varepsilon' = d/K\varepsilon_0$$

where ε' is permittivity and K is the relative dielectric constant, which equals to the ratio between the charge stored on an electroded slab of material brought to a given voltage and the charge stored on a set of identical electrodes separated by vacuum ($K = \varepsilon'/\varepsilon_0$). Some piezoelectric materials and their typical values for d are listed in Table 20.3.2.

All ferroelectric materials exhibit piezoelectric behavior in limited elastic range. But not all pyroelectrics that possess a spontaneous polarization are ferroelectric in the sense of possessing a reorientable electric moment. While ferroelectric materials exhibit nonlinear coupling behavior between electrical and mechanical systems and hysteresis loops as discussed above, piezoelectrics have only a linear electrical-mechanical coupling effect. The principal reason that ferroelectrics were discovered so much later was because the formation of domains of differently oriented polarization within virgin single crystals led to a lack of any net polarization and very small pyroelectric and piezoelectric response.

Piezoelectric Polymers

So far we have seen plenty of examples of ceramics showing piezoelectricity. It is known that some natural organic substances, e.g., rubber, wood, and hair, are piezoelectric. Bone also shows a piezoelectricity of the same order as wood. The symmetry of rubber and wood is the same as that for piezoelectric ceramics. In 1969, Kawai discovered that the piezoelectricity in polyvinylidene fluoride (PVDF or PVF_2) is several times larger than that of quartz. A thin PVDF film was extended and poled at 100°C under a high field, such as 300 kV/cm. Some improvements were made in the poling procedure and a high d constant, about 30 pC/N, was obtained.

PVDF is a polymer that has crystallinity of 40 to 50 percent. The PVDF crystal is **dimorphic,** with two phases (α and β phases).The β phase is polar and piezoelectric. To improve the piezoelectricity, some copolymers have been developed. The copolymer VDF/TrFE consists mostly of the piezoelectric β phase of PVDF with high crystallinity, about 90 percent. The magnitude of polarization in TrEF is only half of that in VDF, but the excellent crystallinity improves the piezoelectric coupling in VDF polymers.

Because of the flexibility of the piezoelectric polymer, it usually is supplied in the form of a thin film. This feature makes it suitable for applications in headphones and speakers. Furthermore, the thin-film transducer is applicable to a high-frequency ultrasonic generator. The performance of these materials greatly depends on the thermal and poling conditions. Typical characteristics of piezoelectric polymers are given in Table 20.3.3 (Table 9.4 in Ikeda's book).

Table 20.3.2 The Piezoelectric Constant *d* for Selected Materials

Material	Piezoelectric constant $d \times 10^{-12}$, C/Pa · m² = m/V
Piezoelectric crystals	
Quartz (SiO_2)	2.3
Rochelle salt ($NaKC_4H_4O_6 \cdot 4H_2O$)	11
EDT ($C_6H_{12}N_2O_6$)	10–20
DKT ($N_2C_4H_4O_6 \cdot H_2O$)	10–20
Amonium dihydrogen phosphate—ADP ($NH_4H_2PO_4$)	23
$BaTiO_3$	85.6
Lithium niobate ($LiNbO_3$)	6
Lithium tantalite ($LiTaO_3$)	8
Piezoelectric semiconductors	
BeO	0.24
ZnO	12.4
CdS	10.3
CdSe	7.8
AIN	5
Piezoelectric ceramics	
PZTs ($PbZr\ O_3$ and $PbTiO_3$)	250–365
PLZT	1188
$BaTiO_3$	191
$PbNb_2O_6$	80

Application of Piezoelectrics

Because of the electric and mechanical coupling behavior in piezoelectric materials, they can be used as transducers between electrical and mechanical energy. They also are active materials (or "smart" materials), which have the ability to perform both sensing and responding functions. This ability traditionally is associated only with living systems, as opposed to inanimate matter. The distinguishing feature of smart materials is, then, their ability to imitate this fundamental aspect of life. In practice, piezoelectric transducers are limited to devices involving only very small mechanical displacements and small amounts of electric charge per cycle. They are also the ideal candidates as transducers, actuators, or sensors in microelectromechanical systems (MEMS). A list of representative applications of piezoelectric materials is given below.

1. **Phonograph cartridges.** Phonograph pickups have used more piezoelectric ceramic elements than all other applications combined. In the period from 1935 to 1950, the phonograph pickup field was dominated by the first ferroelectric single crystal, Rochelle salt. A schematic sketch of phonograph pickup elements in the conventional configuration of a cemented sandwich of flat plates of ceramic on a brass vane is shown in Fig. 20.3.4. The forces available from the phonograph record groove are only 1 to 5 g. Typical output voltage for the ceramic is from 0.1 to 0.5 V. Modified lead titanate zirconates (PZTs) have largely replaced barium titanate, as they give approximately twice as much output.

2. **Ultrasonic transducers.** A common application of piezoelectric materials is in ultrasonic transducers. Figure 20.3.5 shows a typical cross section of an ultrasonic transducer. In this cutaway view, the piezoelectric crystal or element is encased in a convenient housing. The constraint of the backing material causes the reverse piezoelectric effect to generate a pressure when the faceplate is pressed against a solid material to be inspected. When the transducer is operated in this way (as an ultrasonic transmitter), an ac electrical signal produces an ultrasonic

Table 20.3.3 Characteristics of Piezoelectric Polymers

	Polymer PVDF	Copolymer P(VDF−TrFE)*	Copolymer P(VDF-TeFE)†	Copolymer P(VDCN−VAc)‡	Composite PZT/PVDF

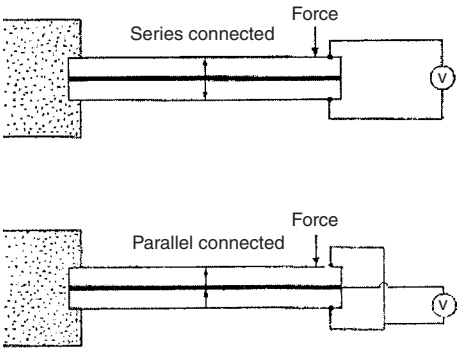

Fig. 20.3.4 Ceramic phonograph pickup, series- and parallel-connected. (*From Jaffe, Cook, and Jaffe, Fig. 12.1.*)

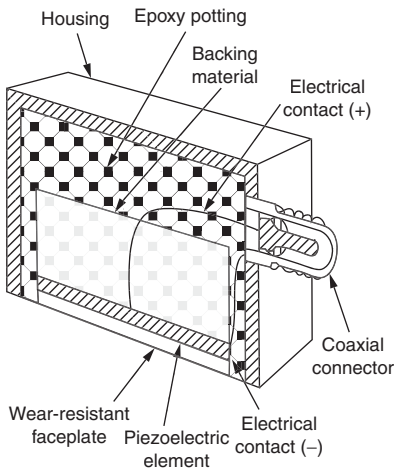

Fig. 20.3.5 A cross section view of an ultrasonic transducer. (*From Metals Handbook, 8th ed. Vol. 11, American Society for Metals, Metals Park, Ohio,* 1976.)

signal of the same frequency (usually in megahertz). When the transducer is operated as an ultrasonic receiver, the direct piezoelectric effect is employed. In that case, the high-frequency elastic wave striking the faceplate generates a measurable voltage oscillation of the same frequency.

3. **Instrument transducers.** PZT ceramics have become the dominant material for piezoelectric accelerometers. In addition to their use in generating ultrasonic waves of frequencies in the order of 1 to 5 MHz to detect flaws and other inhomogeneities in solids or in joints between solid bodies, miniature ceramic transducers have been inserted into blood vessels to record periodic pressure changes connected with the heart beat. Special-purpose transducers such as blast gages and noise-sensing elements to detect boiling of cooling water in nuclear reactors have been served well by piezoelectrics. Much ingenuity has been expended on other schemes that utilize piezoelectrics for measurement of forces that can be related to input variables of aerospace, medical, and industrial instrumentation.

4. **Air transducers.** Air transducers have been widely used in microphones, especially in the hearing-aid field. But with the advent of the transistor, the market became dominated by electrodynamic microphones of low impedance. Progress in techniques for manufacturing thin ceramic bending elements has resulted in recouping some of the microphone market for piezoelectricity. Piezoelectrics also work well as tuned ultrasonic microphones in remote control of television sets.

5. **Actuators.** One example of piezoelectric materials as smart materials is the piezoelectric actuator used in an impact dot-matrix printer. A schematic illustration of such a ceramic actuator is shown in Fig. 20.3.6. In this case, of course, the signal is coming in the form of a computer text or image to be printed. Each character formed in a typical printer is a 24×24 dot matrix. A printing ribbon is impacted by the multiwire array. The printing element is composed of a multilayer piezoelectric device involving 100 thin ceramic sheets. Each sheet is 100 μm thick. The hinged lever provides a displacement magnification of 30 times, resulting in a net motion at the ink ribbon of 0.5 mm with an energy transfer efficiency of >50 percent. The advantages of the piezoelectric design application compared with conventional electromagnetic types are order-of-magnitude higher printing speed, order-of-magnitude lower energy consumption, and reduced printing noise. The reason for the last advantage is that the low level of heat generation by the piezoelectric allows greater sound shielding.

There are many other applications of piezoelectrics such as delay line transducers, wave filters, high-voltage sources, and sensors. Good sources of information on piezoelectric devices and their applications

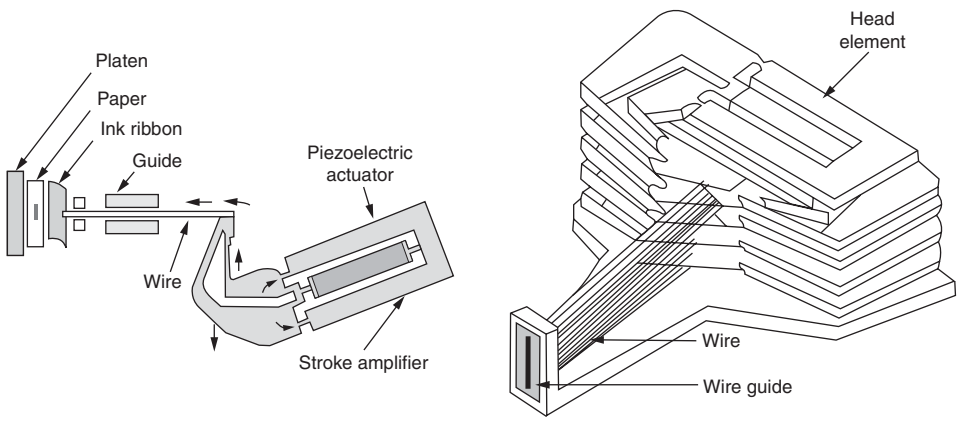

Fig. 20.3.6 A schematic illustration of a piezoelectric actuator in an impact dot-matrix printer. (*a*) Overall structure of the printer head. (*b*) Close-up of the multilayer piezoelectric printer-head element. (*From K. Uchino, MRS Bulletin,* **18;** *42, 1993.*)

can be found in Katz's book (1959) which emphasizes circuit applications, Mason's book (1958), and some other materials science handbooks.

Glossary

Converse piezoelectric effect: A crystal becomes strained when an electric field is applied.

Curie temperature: The temperature at which such a transition from the polar into the nonpolar state occurs.

Direct piezoelectric effect: Electric polarization is produced by mechanical stress.

Domains: Regions with uniform alignment of the electric dipoles or uniform polarization.

Ferroelectric crystal: Pyroelectric crystal with reversible polarization.

Hysteresis loop: The loop traced out by the polarization as the electric field is cycled. A similar loop occurs in magnetic materials.

Paraelectric: A symmetric unit cell material; only a small polarization is possible, as the applied electric field causes a small induced dipole.

Piezoelectricity: A linear interaction between electrical and mechanical systems.

Polarization: Alignment of dipoles so that a charge can be permanently stored.

Pyroelectric: A crystal having a spontaneous polarization.

Pyroelectricity: An interaction between electrical and thermal systems.

Spontaneous polarization: Measured in terms of dipole moment per unit volume, or with reference to the charges induced on the surfaces perpendicular to the polarization, in terms of charge per unit area.

SHAPE MEMORY ALLOYS

Shape memory alloys (SMAs) are metals that, after being strained, at a certain temperature revert back to their original shape. A change in their crystal structure above their transformation temperature causes them to return to their original shape. They exhibit two very unique properties: pseudo-elasticity and the shape memory effect.

The shape memory effect was first discovered by the Swedish physicist Arne Olander in 1932, who used an alloy of gold and cadmium, but not until the 1960s were any serious research advances made in the field of shape memory alloys. In early 1960s, researchers at the U.S. Naval Ordnance Laboratory discovered the shape memory effect in nickel titanium alloy and named it Nitinol (an acronym for nickel titanium naval ordnance laboratory). Still, not until the early 1970s did several commercially available products appear that implemented shape memory alloys. The most effective and widely used SM alloys include NiTi (nickel-titanium), CuZnAl, and CuAlNi.

Most shape memory alloys also exhibit **pseudo-elastic behavior,** which is a generic name for both rubberlike behavior and superelasticity.

Both the shape memory effect and pseudo-elasticity are mainly due to the solid-state phase transformation of the material. There are two stable phases in shape memory alloys—martensite at low temperature and austenite at high temperature.

Martensite (after the German scientist Martens) was originally used to designate the hard microconstituent formed in quenched steels. Now it is used in a wider context to apply to products of all **martensitic transformations.** Such transformations take place in crystalline solids by coordinated displacements of atoms or molecules over distances smaller than interatomic distances in the parent phase. For this reason the transformations are described as being **diffusionless.** More descriptions of martensite can be found in other sections.

Austenite was the name originally given to the face-centered-cubic (FCC) crystal structure of iron. It is now used in a wider context for other metals, alloys with cubic structures.

In general, a shape memory alloy starts martensitic transformation at a temperature M_s during cooling; the transformation is complete when a lower temperature M_f is reached, where the material is said to be in the martensitic state. Above a certain temperature A_s, the material starts to transform back to austenite, and the transformation is completed at a higher temperature, A_f. A schematic illustration of two phases of nitinol, which is a typical shape memory alloy that contains a nearly equal mixture of nickel (55 wt.%) and titanium, is shown in Fig. 20.3.7. If no forces applied during heating or cooling, the microstructure of the alloy will change without macroscopically noticeable shape change.

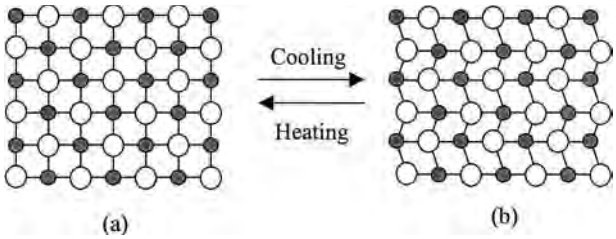

Fig. 20.3.7 Schematic sketch of NiTi microstructure. (*a*) Austenite; (*b*) martensite (twined).

In the martensitic condition, an alloy can be easily deformed into a new shape by nonconventional atomistic mechanisms. The alloy will remain in the new deformed shape as long as the temperature is kept constant. Heating will cause the material to transform back to the austenitic phase and restore its original shape. This restoring effect is called **shape memory effect** (Fig. 20.3.8).

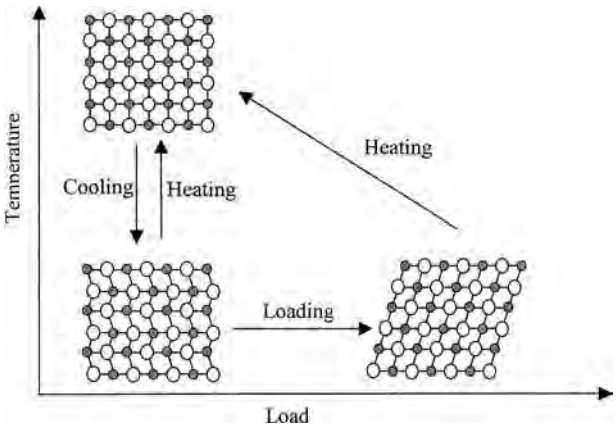

Fig. 20.3.8 Schematic microstructure diagram of the shape memory effect.

In most cases, the memory effect is one-way, which means that, upon cooling, a shape memory alloy does not undergo any shape change, even though the structure changes back to martensite. When the martensite is strained up to several percent, however, that strain is retained until the material is heated again, at which time shape recovery occurs. Upon recooling, the material does not spontaneously change shape, but must be deliberately strained if shape recovery is again desired.

It is possible in some of the shape memory alloys to cause two-way shape memory. That is, shape change occurs upon both heating and cooling. The amount of this shape change is always significantly less than obtained with the one-way shape memory effect, and very little stress can be exerted by the alloy as it tries to assume its low-temperature shape. The heating shape change can still exert very high forces, as with the one-way memory.

Shape memory alloys also exhibit pseudo-elastic behavior. Unlike the shape memory effect, pseudo-elasticity occurs without a change of temperature. In the austenite condition, a SMA undergoes a phase transformation from austenite to deformed martensite (or stress-induced martensite) when a stress loading is applied. Once the stress is released, the material returns to the austenite state, which means its shape is restored. This is called **superelasticity.** A typical stress-strain curve is shown

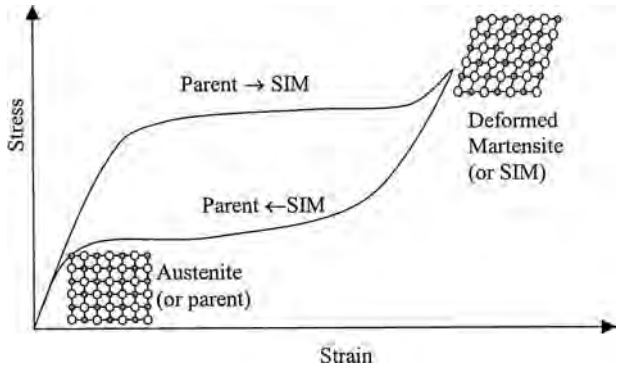

Fig. 20.3.9 Schematic stress-strain curve of a NiTi alloy loaded above M_s temperature and then unloaded. Stress-induced martensite (SIM) is formed during loading, which disappears upon unloading.

in Fig. 20.3.9, while the load-temperature diagram in Fig. 20.3.10 shows the transformation process during a loading and unloading cycle.

Rubberlike behavior was first observed in 1932 by Olander, who studied an Au-Cd alloy. This phenomenon has also been found in several other SMA alloy systems, such as Cu-Al-Ni, Cu-Au-Zn, and Cu-Zn.

Considering the Au-Cd alloy, it is interesting to note that the rubberlike behavior is found only after the martensite is aged at room temperature for at least a few hours. Freshly transformed specimens exhibit the shape memory effect, and bent rods will not spring back to their original shape without aging.

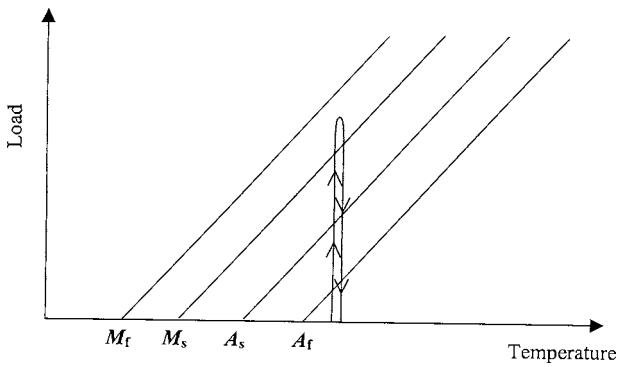

Fig. 20.3.10 Load diagram of the superelastic effect above A_f temperature.

Ruberlike behavior also constitutes a mechanical type of shape memory, as does the process of superelasticity, and, in fact, these two phenomena cannot be distinguished on the basis of stress-strain curves alone. But rubberlike behavior is characteristic of a fully martensitic structure, whereas supperelastic behavior is associated with formation of martensite from the parent phase under stress. These two types of behavior collectively fall in the category of **pseudo-elasticity.**

The most commercially available SMAs are the NiTi alloys and the copper-base alloys. Properties of the two systems (see Table 20.3.4) are quite different. The NiTi alloys have greater shape memory strain (up to 10 percent versus 4 to 5 percent for the copper-base alloys), tend to be much more thermally stable, have excellent corrosion resistance, and have much higher ductility. On the other hand, the copper-base alloys are much less expensive, can be melted and extruded in air with ease, and have a wider range of potential transformation temperatures. The two alloy systems thus have advantages and disadvantages that must be considered in a particular application.

Applications of Shape Memory Alloys

Some examples of applications using shape memory effect are listed below.

Fig. 20.3.11 Coffeepot.

- **Coffeepots:** A nickel-titanium spring in coffeepots marketed in Japan (Fig. 20.3.11) is trained to open a valve and release hot water at the proper temperature to brew a perfect pot of coffee.
- **Linear motor for remote control:** Locks, valves, screens, and other devices can be remotely controlled by a **shape memory linear motor.** A self-limiting electric heating element (PTC) is fixed onto a **shape memory bending element.** Applied heat causes shape recovery of the bending element that is transformed into linear motion of the actuator. As the electric current drops, the temperature falls and the actuator returns to its starting position. Energy consumption is low, and heating elements to operate at any desired voltage are easily available. The main advantage of this application is the direct linear movement, without the need to convert a rotary movement into a linear one. Another advantage is its noiseless operation.
- **Hubble space telescope:** In April 1990 the Hubble space telescope was launched into space aboard the shuttle *Discovery*. The telescope

Table 20.3.4 Some Selected Properties of Shape Memory Alloys

Alloy		Composition, wt.%	Transformation temperature A_f, °C	Modulus of elasticity, GPa	Recovery strain, %
Nitinol*	SE508 tubing	Ni: 55.8 Ti: balance O (max): 0.05 C (max): 0.02	<15	41–75	10
	SE508 wiring	Same as tubing	5–18	41–75	10
	SM495 wire	Ni: 54.5 Ti: balance O (max): 0.05 C (max): 0.02	60	28–41	10
Ni-Ti		Ni: 49–51 (at.%)	−200 to 110	28–83	8.5
Cu-Al-Ni		Al: 14–14.5 Ni: 3–4.5	<200	80–85	4
Cu-Zn-Al		Zn: 38.5–41.5 Al: A few wt.%	<120	70–72	4

was put into orbit around the earth for observing planets and stars and with the aim to obtain pictures 50 times sharper compared to observations from the earth. Several systems of the Hubble space telescope were driven by solar energy. The solar panels that were folded during the launching were unfolded and positioned after the Hubble space telescope was brought into position. The mechanism, designed by Dornier, is reliable and space- and energy-efficient. It used a specially bent Ni-Ti shape memory element to keep the solar panels in the locked position during launch. At a temperature of 115°F, the shape memory element remembered its original straight form and unlocked the panels.

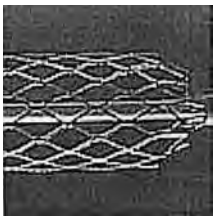

Fig. 20.3.12 Stent.

• **Vascular stents:** A vascular stent is a device that is implanted in a blood vessel (vein or artery) to provide structural reinforcement of the vessel wall (Fig. 20.3.12). The introduction of SMA to stent manufacture allows greater recovery strains for use in wider vessels, or stronger recovery force in narrower vessels.

• **Antiscald devices:** Basically these are an extension that fits between a shower head and water pipe, containing a Ti-based SMA element that expands if water becomes too hot, choking off the flow. A very cheap, easy, and effective alternative to more expensive technologies.

• **Connecting rings:** Rings and cylinders made of SMA that is austenite at ambient temperature can provide significant constraining force around the inner circumference, ensuring a strong join that can be released by cooling the coupling. For instance, NiTi rings on electrical connectors (Fig. 20.3.13) provide a secure joint at ambient temperatures. Yet, they can easily be released by chilling.

Fig. 20.3.13 Electric connector.

Some examples of applications in which pseudo-elasticity is used are:

• **Eyeglass frames:** Nitinol is extensively used in the manufacture of eyeglass frames. It is used in the superelastic state or in the combined shape memory and superelastic states. The frames hold prescription lenses in the proper position so that the wearer gets the maximum benefit from them.

• **Endodontic wire—high-fatigue superelastic wire:** Nickel-titanium alloy has entered the world of endodontics. The flexibility of nickel titanium makes it an ideal material for use in the manufacture of endodontic instruments. Endodontic files using NiTi alloys, both hand and rotary types, have the potential to greatly improve a clinician's ability to negotiate curved root canal systems. Current research is under progress to better define the limitations and strengths of NiTi, and to determine the file designs and techniques to take best advantage of this unique material.

• **Orthodontic arches—low-deformation-resistance superelastic wire:** Superelastic shape memory wires have found wide use as orthodontic wires. The difference between these shape memory wires and a normal wire is a large elastic deformation combined with a low plateau stress obtainable in the shape memory wire. The advantages for the patient are two-fold: fewer visits to the orthodontist, because of the larger elastic stroke, and more comfort, because of lower stress levels.

Glossary

***A_s*:** The temperature at which austenite starts to form.

***A_f*:** The temperature at which a material is completely transformed into austenite.

***M_s*:** The temperature at which the martensitic transformation starts upon cooling.

***M_f*:** The temperature at which the martensitic transformation is completed, where the material is said to be in the martensitic state.

Austenite: The name originally given to the FCC crystal structure of iron. It is a stronger phase with a cubic structure in shape memory alloys at high temperature.

Martensite: The name originally used to designate the hard microconstituent formed in quenched steels. Now it is a phase that forms as the result of a diffusionless solid-state transformation. It is a more deformable phase in shape memory alloys at lower temperature.

Pseudo-elasticity: A generic name for both rubberlike flexibility and superelasticity.

Rubberlike behavior: Some SME alloys show rubberlike flexibility. When bars are bent, they spontaneously unbend upon release of the stress. In order to obtain this behavior, the martensite, after its initial formation, usually must be aged for a period of time; unaged martensites show typical SME behavior. The rubberlike behavior, unlike superelasticity, is a characteristic of the martensite phase—not the parent phase.

Shape memory effect (SME): The ability of certain materials to develop microstructures that, after being deformed, can return to the material to its initial shape when heated. Upon cooling, the specimen does not return to its deformed shape.

Superelasticity (SE): The result of stress-induced phase transformation from austenite directly into deformed martensite under external loading. When the deforming stress is released, the material will transform back to its stable austenitic state and shape. The martensite disappears (reverses) when the stress is released, giving rise to a superelastic stress-strain loop with some stress hysteresis.

20.4 INTRODUCTION TO THE FINITE-ELEMENT METHOD

by Farid Amirouche

INTRODUCTION

The finite-element method (FEM) is essentially a technique used to obtain a solution to complex problems by discretizing a given physical or mathematical problem into smaller fundamental parts called *elements*. Then an analysis of the element is conducted using the required principles or law of mechanics. Finally, the solution to the problem as a whole is obtained through an assembly procedure of the individual solutions of the elements. These finite-element techniques have been used in many fields of engineering and science as numerical tools for solution of problems, using digital computers. For example, FEM can be used in computational fluid dynamics (CFD) where the most fundamental consideration is how one treats a continuous fluid in a discretized fashion on a computer. One method is to discretize the spatial domain into small cells to form a volume mesh or grid, and then apply a suitable algorithm to solve the equations of motion. In addition, such a mesh can be either irregular (for instance, consisting of triangles in 2-D, or pyramidal solids in 3-D) or regular; the distinguishing characteristic of the former is that each cell must be stored separately in memory. Lastly, if the problem is highly dynamic and occupies a wide range of scales, the grid itself can be dynamically modified in time, as in adaptive mesh refinement methods.

In numerical analysis, the **finite-element method** (FEM) is used for solving partial differential equations (PDE) approximately. Solutions are approximated by either eliminating the differential equation completely (steady-state problems) or rendering the PDE into an equivalent ordinary differential equation, which is then solved by using standard techniques such as finite differences. The use of the finite-element method in engineering for the analysis of physical systems is commonly known as finite-element analysis. Finite-element methods have also been developed to approximately solve integral equations such as the heat transport equation.

Finite-element analysis (FEA) or the finite-element method (FEM) is a numerical technique for solution of **boundary-value problems**. It was first developed for use in problems related to trusses and structural analysis in general. The system is represented by a similar model consisting of multiple linked discrete elements. From equations of equilibrium, as will be seen in this section, in conjunction with the appropriate boundary conditions applicable to each element and the system as a whole, a set of simultaneous equations is constructed. The system of equations is then solved for the unknown values by using the techniques of linear algebra. Although it is an approximate method, the accuracy of the FEA method can be improved by refining the mesh in the model by using more elements and nodes.

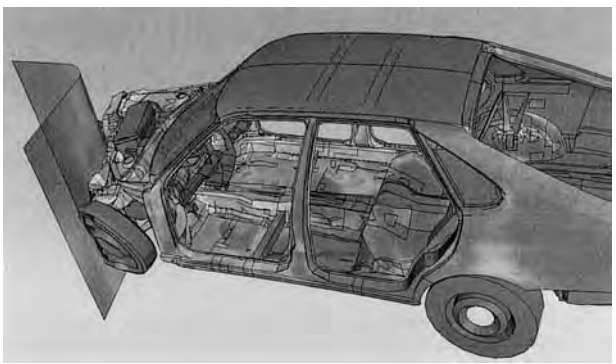

Fig. 20.4.1 Car crash simulation.

Fig. 20.4.2 Car crash simulation results.

A common use of FEA is for the determination of stresses and displacements in mechanical objects and systems. However, it is also routinely used in the analysis of many other types of problems. Figures 20.4.1 and 20.4.2 show the finite-element analysis used for studying car **crash simulation**.

The last decade has witnessed an unprecedented increase in the speed and power of personal computers. Because of this revolution in personal computing power, PC-based FEM programs are becoming very popular and can now perform designs in minutes that not long ago would have required hours or even days of processing time. As computer technology continues to advance, even more sophisticated programs will become available to the designer/engineer at an affordable cost.

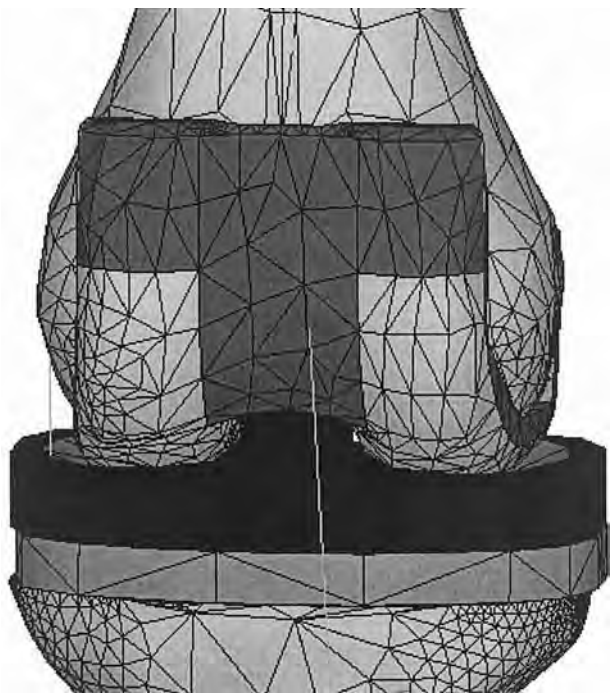

Fig. 20.4.3 FEM of total knee joint.

Three-dimensional FEM can handle greater detail and more complex characterizations of construction materials. Three-dimensional FEM can incorporate nonlinear and nonelastic material models not available in linear elastic analysis (LEA). In finite-element modeling, the structure is divided into a large number of smaller parts, or "elements." Elements may be of different sizes, and may be assigned different properties, depending on their location within the structure. By breaking down the structure into elements, the structural problem is transformed into a finite set of equations that can be solved on a computer. Because a structure can be broken down into finite elements, or "discretized," in any number of ways, it is essential that any design standard incorporating finite elements include rules for systematic three-dimensional meshing.

Finite-element modeling is also a tool used extensively in biomechanics for estimating the mechanical behavior of complex adaptive materials such as trabecular bone. Figure 20.4.3 shows the finite-element model of a knee with a tibial insert. The intrinsic complexities captured by FEM include the volume fraction, connectivity, and anisotropy of bone. In the analysis of total knee arthroplasty (TKA), balancing of the soft tissue can be helped by developing FEM models that can simulate the behavior of the knee during flexion extension and contact pressure in particular at the condyles. The objective of such a study is to optimize the design of the stabilizing post and to understand the mechanism of rollback.

BASIC CONCEPTS IN THE FINITE-ELEMENT METHOD

There are three phases in either using an FE code or simply developing the procedures for solving problems by FEM. Each phase is described below:

1. **Preprocessing phase**
   a. Create and discretize the solution domain into finite elements.
   b. Assume a shape function to represent the physical behavior of an element; that is, an approximate continuous function is assumed to represent the solution of an element.
   c. Develop relationships between input and output equations for an element.
   d. Assemble the elements to present the entire problem. Construct the **global stiffness matrix.**
   e. Apply boundary conditions, initial conditions, and loading conditions.
2. **Solution phase.** Solve a set of linear or nonlinear algebraic equations simultaneously to obtain nodal results, such as displacement values at different nodes or temperature values at different nodes.
3. **Postprocessor phase.** Obtain other important information such as stresses, energy, and any information needed to understand the problem solution.

In the **preprocessing** phase the FEM takes the object to be analyzed and performs a discretization of the body into a limited number of elements. There is usually a selection of the elements used that is best suitable for the problem solution. On the basis of the equation for a single element, the entire problem is formulated by an assembly of these element equations. Before a solution is adapted the boundary conditions, initial conditions, and loading conditions are introduced. At this stage the **solution phase** is adapted in solving a set of linear or nonlinear equations simultaneously. The solution yields values such as displacements or temperatures at the nodes. The final phase of the FEM is the **postprocessor,** where one chooses the type of output to be displayed. The latter might require additional steps in analysis to extract the information needed.

Consider an element of a continuum as shown in Fig. 20.4.4; let the element be represented by a small cube. The nodal points are defined as the end points of the edges of the cube, which are eight in this case.

All the elements are connected through the nodal points. Any deformation of the body caused by external loads or temperatures induces certain displacements at the nodes. In general, the displacements are the

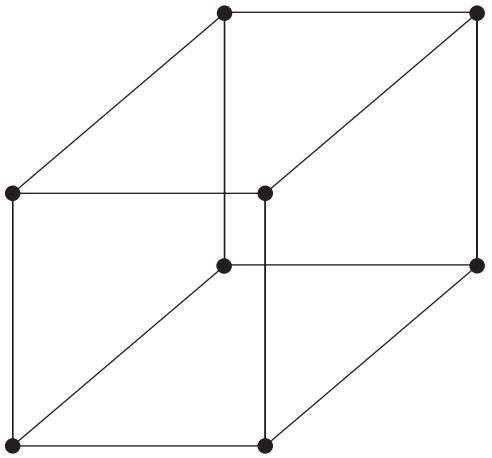

Fig. 20.4.4 Cubic continuum element.

unknowns and are related to the external loads or temperatures through a mathematical relationship of the form

$$f^e = k^e u^e + f^e_{\text{add}} \tag{20.4.1}$$

where k^e (e being the element) is the local element stiffness, f^e is the external forces applied at each element, u^e represents the nodal displacements for the element, and f^e_{add} represents the additional forces. These additional forces could be a result of surface traction or of the material being initially under stress. For the moment, we will assume them to be zero. Hence, Equation (20.4.1) reduces to

$$f^e = k^e u^e \tag{20.4.2}$$

It is important at times to express this equation by using the relationship between stresses and strains:

$$\sigma^e = s^e \varepsilon^e \tag{20.4.3}$$

where σ^e is the element stress matrix and s^e is the constitutive relationship connecting the strain ε^e and *stress* σ^e. From Eq. (20.4.2), we can see that if f^e and k^e are known, u^e can be evaluated. Similarly, if u^e and k^e are known, we can compute f^e.

The finite-element method's most basic function is to automatically generate the **local stiffness matrix** knowing the element type and the properties of the material of the element. Several types of elements that are available in the finite-element library are given in Fig. 20.4.5. The well-known general-purpose FEM packages provide an element library that helps the user in the solution of particular problems. These codes and others can select any of these elements with the proper number of nodes. Thus, it is important at this stage to understand the basic mathematics involved in finite-element formulations.

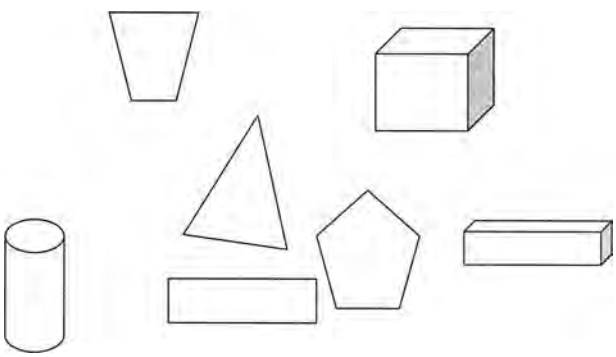

Fig. 20.4.5 Types of elements in the finite-element library.

POTENTIAL ENERGY FORMULATION

The finite-element method is based on the minimization of the total potential energy formulation. When a closed-form solution is not possible, approximation methods such as finite element are the most commonly used in solid mechanics. To illustrate how the finite-element method is formulated. We will consider an elastic body such as the one shown in Fig. 20.4.6, where the body is subjected to a loading force that causes it to deform.

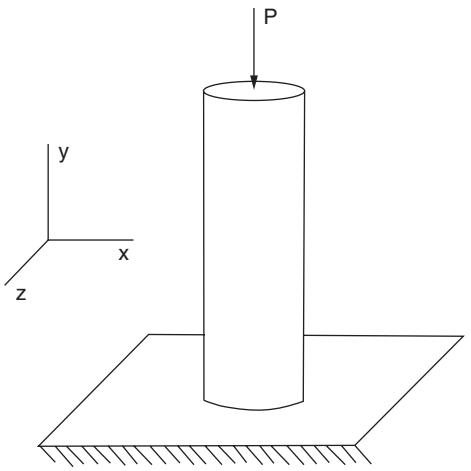

Fig. 20.4.6

From Hooke's law we write

$$P = \frac{AE}{L}\delta \tag{20.4.4}$$

Let δ be the displacement in the y direction, A be the cross-section area, E be Young's modulus, L be the length, and k be the stiffness. Hence $F = ky$, where $F = P$.

The work performed by the compressive force P is stored in the material in a form of strain energy. The finite-element method discretizes bodies into elements, hence if we can compute the strain energy associated with each element, we can then evaluate the total strain energy associated with all external forces applied to the body

Consider the element shown in Fig. 20.4.6. Let the element deformation be denoted as dy. The strain energy is given by the work of F over the deformed length y. The stored energy is

$$dE = \int_0^{y_1} F\,dy = \int_0^{y_1} ky_1\,dy_1 = \frac{1}{2}ky_1^2 \tag{20.4.5}$$

The normal stress and strain are directly related to the stored energy if we make the following substitutions

$$\frac{F}{A} = \sigma_y \Rightarrow F = \sigma_y\,dx\,dz \tag{20.4.6}$$

where σ_y is the stress in the y direction and ε is the strain. Hence

$$d\Lambda = \frac{1}{2}\sigma\varepsilon dV \tag{20.4.7}$$

when the volume of the element is

$$dV = dx\,dy\,dz \tag{20.4.8}$$

We can then write the strain energy for an element as

$$N^e = \int dE = \int \frac{\sigma\varepsilon}{2}\,dV \tag{20.4.9}$$

$$\sigma_{(e)} = E\varepsilon \tag{20.4.10}$$

$$\Lambda_s = \int_v \frac{E\varepsilon^2}{2}dV \tag{20.4.11}$$

The total energy, which consists of the strain energy due to the deformation of the body and the work performed by the external forces, can be expressed as function of the potential energy

$$\Pi = \sum_{e=1}^{n}\Lambda^{(e)} - \sum_{i=1}^{P}F_iu_i \tag{20.4.12}$$

where U denotes displacement along the force F_1 or potential energy Π.

It follows that a stable system requires that the potential energy be minimum at equilibrium

$$\frac{\partial\Pi}{\partial u_i} = \frac{\partial}{\partial u}\left[\sum\Lambda^{(e)} - \sum F_iu_i\right] = 0 \tag{20.4.13}$$

We know that

$$\varepsilon = (u_{i+1} - u_i)/l,$$

Then

$$\frac{\partial\Lambda^e}{\partial u_i} = \frac{A_{\text{avg}}E}{l}(u_i - u_{i+1}) \tag{20.4.14}$$

$$\frac{\partial\Lambda^e}{\partial u_{i+1}} = \frac{A_{\text{avg}}E}{l}(u_{i+1} - u_i) \tag{20.4.15}$$

The above equations can be expressed in a matrix form as

$$\begin{Bmatrix} \frac{\partial\Lambda^{(e)}}{\partial u_i} \\ \frac{\partial\Lambda^{(e)}}{\partial u_{i+1}} \end{Bmatrix} = k_{\text{eq}}\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}\begin{Bmatrix} u_i \\ u_{i+1} \end{Bmatrix} \tag{20.4.16}$$

where $k_{\text{eq}} = (A_{\text{avg}}E)/l$.

Similarly we get

$$\frac{\partial}{\partial u_i}(F_iu_i) = F_i \tag{20.4.17}$$

$$\frac{\partial}{\partial u_{i+1}}(F_{i+1}u_{i+1}) = F_{i+1} \tag{20.4.18}$$

Combining Eqs. (20.4.16), (20.4.17), and (20.4.18), we obtain the elemental force/displacement relation

$$F^{(e)} = k^{(e)}u^{(e)} \tag{20.4.19}$$

where $k^{(e)}$ is the element stiffness matrix, $u^{(e)}$ is the element displacement array associated with nodes i and $i + 1$, and $F^{(e)}$ denotes the forces acting at the nodes.

In summary, we see that the minimization of the concept of potential energy leads to an equation similar to the discrete method adopted early in this section. Other popular methods in finite-element analysis are presented for the reader to show how these methods lead to results similar to those of the minimization of potential energy approach.

CLOSED-FORM SOLUTION

It would be ideal if closed-form solutions of most of the engineering problems existed. This of course is not feasible, and the science of engineering is to obtain a solution that is as close as possible to the exact solution, relying on approximation techniques such as FEM and other numerical techniques. For the sake of validating our approximation resulting from discretizing the problem at hand, let's solve the above problem by means of direct integration, hence getting its closed-form solution.

From the equilibrium conditions, and using Newton's first law for a beam with varying cross-sectional area (see Fig. 20.4.7), we write

$$P - \sigma_{\text{avg}}(A(y)) = 0 \tag{20.4.20}$$

where the stress is related to the strain as

$$\sigma = E\varepsilon \tag{20.4.21}$$

Then we express Eq. (20.4.20) further as

$$P - E\varepsilon A(y) = 0 \tag{20.4.22}$$

Recall that the strain is defined by

$$\varepsilon = \frac{du}{dy} \tag{20.4.23}$$

which makes Eq. (20.4.22) take the following form:

$$P - EA(y)\frac{du}{dy} = 0 \tag{20.4.24}$$

resulting in

$$du = \frac{P\,dy}{EA(y)} \tag{20.4.25}$$

The total deformation is obtained by integrating over the total length:

$$\int_0^u du = \int_0^L \frac{P\,dy}{EA(y)} \tag{20.4.26}$$

Note that the cross-sectional area for Fig. 20.4.7 is

$$A(y) = \left(\frac{r_2 - r_1}{L}\right)y + r_1 \tag{20.4.27}$$

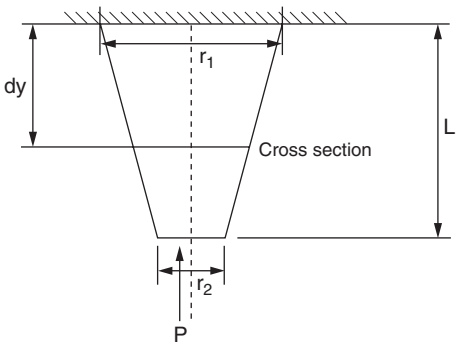

Fig. 20.4.7 Free-body diagram showing constraints and loads.

Then

$$u(y) = \int_0^L \frac{P\,dy}{E\left[\left(\frac{r_2 - r_1}{2}\right)y + r_1\right]} \tag{20.4.28}$$

or

$$u(y) = \frac{P}{E}\int_0^L \frac{dy}{ay + r_1} \tag{20.4.29}$$

where

$$a = \frac{r_2 - r_1}{L} = \text{constant} \tag{20.4.30}$$

Let $z = ay + r_1 \quad \Rightarrow dz = a\,dy$. Then

$$u(y) = \frac{P}{Ea}\int_{r_2}^{aL+r_1} \frac{dz}{z} = \frac{P}{Ea}[\ln(z)] \tag{20.4.31}$$

$$= \frac{P}{Ea}[\ln(ay + r_1)]^2 \tag{20.4.32}$$

And the final solution is found to be

$$u(y) = \frac{P}{Ea}[\ln(aL + r_1) - \ln(r_1)] \tag{20.4.33}$$

The above solution can be used to find displacement at various points along the length.

WEIGHTED RESIDUAL METHOD (WRM)

The WRM assumes an approximate solution to the governing differential equations. The solution criterion is one where the boundary conditions and initial conditions of the problem are satisfied. It is evident that the approximate solution leads to some marginal errors. If we require that the errors vanish over a given interval or at some given point, then we will force the approximate solution to converge to an accurate solution.

Consider the differential equation discussed in previous example, where

$$\begin{cases} A(y)E\dfrac{du}{dy} - P = 0 \\ \text{with} \qquad u(0) = 0 \end{cases} \tag{20.4.34}$$

Let us choose a displacement field u to approximate the solution, which is

$$u(y) = c_0 + c_1 y + c_2 y^2 \tag{20.4.35}$$

where c_0, c_1, and c_2 are unknown coefficients.

If we substitute $u(y)$ and $A(y)$ into the differential equation, we get

$$\left[\left(\frac{r_2 - r_1}{L}\right)y + r_1\right]E(c_1 + 2c_2 y) - P = R \tag{20.4.36}$$

The equation above has two constants, c_1 and c_2. If we require that R vanishes at two points, we will get two equations, which can be used to solve for c_1 and c_2:

$$R\big|_{y=\frac{L}{2}} = 0$$

$$R\big|_{y=L} = 0$$

Solving for c_0, c_1, c_2 we get

$$u(y) = c_1 + c_2 y^2$$

The solution can be compared to the exact solution derived previously.

GALERKIN METHOD

The **Galerkin method** requires the integer of the error function over some selected interval to be forced to zero and the error be orthogonal to some weighting functions ϕ, according to the integral

$$\int \phi_i R\,dy = 0 \tag{20.4.37}$$

where $i = 1, 2, \ldots, n$

The ϕ are selected as part of the approximate solution. This is done simply by assigning the ϕ function to the terms to multiply the coefficients.

Since we assume $u(y) = c_1 y + c_2 y^2$, then $\phi_1 = y$ and $\phi_2 = y^2$. Substituting these two into equation (20.4.37), we get

$$\int_0^L y\left[(10 + y)(c_1 + 2c_2 y) - \frac{180}{E}\right]dy = 0 \tag{20.4.38}$$

$$\int_0^L y^2\left[(10 + y)(c_1 + 2c_2 y) - \frac{180}{E}\right]dy = 0 \tag{20.4.39}$$

Integrating the above two equations leads to two linear equations in terms of c_1 and c_2. Solving the above two equations, we get $c_1 = 0.2314 \times 10^{-4}$ and $c_2 = -0.50 \times 10^{-6}$. The solution is then approximated by $u(y) = c_1 + 2c_2 y^2$.

Note that the WRM and the Galerkin methods are very popular methods used in finite-element analysis to generate the approximate solution to the problem. One can see that these methods require numerics to be able to carry the integration further. If one leaves the loads as a variable P, then the solution is one that relates the deformation to the load. What follows is the introduction of FEM to trusses, where we can make use of the element displacement/force relation and extend it to the entire truss.

INTRODUCTION TO TRUSS ANALYSIS

Trusses are used in many engineering applications, including bridges, buildings, and towers and support structures. In a truss, we are faced with a structure where the displacements, translations, or compressions of any truss member vary linearly with the applied forces. That is, any increment in displacement is proportional to the force causing it to deform. All deformations are assumed small, so that the resulting displacements do not significantly affect the geometry of the structure and hence do not alter the forces in the members. In this case Hooke's law is preserved and the theory of elasticity is used to search for solutions of the truss. Most often, the truss design requires that its member be tested for tension, compression, stress, and strain relations. The applied loads are then tested against the possible yield stress to determine their evaluated limits and the overall stability of the truss.

For large and complicated truss structures, manual computation is often impractical to analyze the static equilibrium conditions, therefore a digital computer has to be used to accommodate the required computations. Over the past two decades, finite-element method codes have been developed for a large number of engineering applications, as trusses have always been a favorite topic for demonstrating FEM's usefulness. Consider the truss shown in Fig. 20.4.8, a 2-D planar truss with vertical loads.

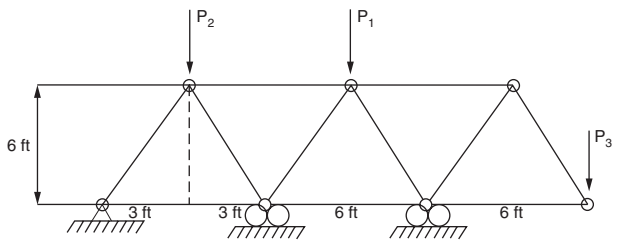

Fig. 20.4.8 A planar truss subject to vertical loads (P_1, P_2, P_3 represent arbitrary loads).

Finite-Element Formulation for a Truss

Trusses are typical structures in which the finite-element method can be best illustrated. We know that FEM relies on (1) discretizing the finite elements of the system; (2) developing the mathematical relationships between the forces and displacements, stresses and strains, etc., for a given element; and (3) formulating the general problem through an assembly procedure of all the elements to solve the given problem.

Consider an element of an arbitrary truss, as shown in Fig. 20.4.9. It is subjected to either tension or compression, as is the case for all the truss elements. Let us label the element's ends 1 and 2, and, consequently, call the corresponding forces f_1 and f_2.

We also know from static analysis that, for the element to be in a state of equilibrium, the following equation must be the true one:

$$f_1 + f_2 = 0 \tag{20.4.40}$$

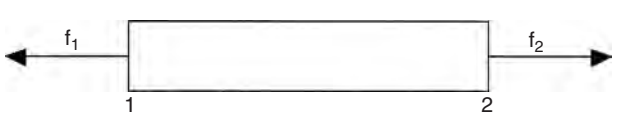

Fig. 20.4.9 A typical truss element.

This simply says that the forces at both ends are equal and opposite in direction. This is true for both tension and compression of the element. Using Hooke's law, we can write the force displacement relation as

$$u = f_{1,2}\frac{L}{AE} \tag{20.4.41}$$

or

$$f_{1,2} = ku \tag{20.4.42}$$

where $k = AE/L$ is the stiffness constant when the element is under tension or compression. Note that $f_{1,2}$ denotes either f_1 or f_2. The relative displacement between the nodal points of this truss element can be written as

$$u = u_2 - u_1 \tag{20.4.43}$$

where u_1 and u_2 are the displacements at ends 1 and 2, respectively. We also refer to ends 1 and 2 as nodes 1 and 2 of the truss element.

Using Eq. (20.4.43), we can write

$$f_1 = ku_1 - ku_2 \tag{20.4.44}$$

and

$$f_2 = -ku_1 + ku_2 \tag{20.4.45}$$

Using matrix notation, we write Eq. (20.4.44) and (20.4.45) in combined form as

$$\begin{bmatrix} f_1 \\ f_2 \end{bmatrix} = \begin{bmatrix} k & -k \\ -k & k \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} \tag{20.4.46}$$

or simply

$$\{f\} = [k]\,\{u\} \tag{20.4.47}$$

where

$$\{f\} = \begin{Bmatrix} f_1 \\ f_2 \end{Bmatrix} = \text{the nodal force vector for the element}$$

$$\{u\} = \begin{Bmatrix} u_1 \\ u_2 \end{Bmatrix} = \text{the nodal displacement vector}$$

$$[k] = k\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} = \text{the element stiffness matrix}$$

Thus, Eq. (20.4.46) shows that the nodal displacements and nodal forces are related by the element (local) **stiffness matrix**. As the orientation and loading of various elements in the structure (a truss in this case) vary from each other, we need to develop the local stiffness that will apply to any element orientation.

In the sequel, a more general local stiffness (2-D) will be developed. A uniform system for symbol notation will be adopted that is crucial for easy reading and understanding and subsequent computer implementation.

Let us consider an orientation of a truss element, as shown in Fig. 20.4.10. For $\theta = 0$, we develop a relationship between the forces

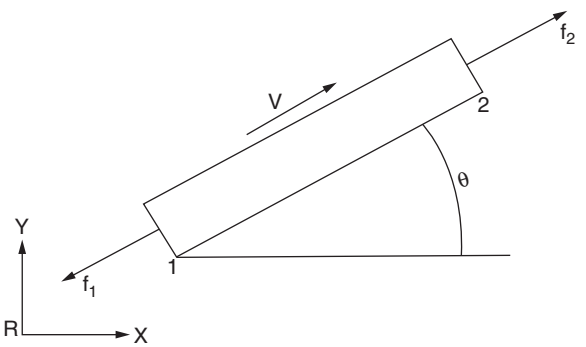

Fig. 20.4.10 A truss element making an angle θ with the x axis.

and the displacements given by Eq. (20.4.46), where v is a unit vector along the line of action of the forces.

Because we have to express all forces (tension or compression) in the global axes (x, y) given by the fixed inertial frame R, we define the element force components as follows:

$$\begin{aligned} f_{1x} &= f_1 \cos\theta \qquad f_{1y} = f_1 \sin\theta \\ f_{2x} &= f_2 \cos\theta \qquad f_{2y} = f_2 \sin\theta \end{aligned} \tag{20.4.48}$$

Given that the relative displacement u is along the unit vector v, then

$$u = (u_2 - u_1)v \tag{20.4.49}$$

where

$$v = (\cos\theta)i + (\sin\theta)j \tag{20.4.50}$$

and

$$u_1 = u_{1,x}i + u_{1,y}j \qquad u_2 = u_{2,x}i + u_{2,y}j \tag{20.4.51}$$

Then by substituting Eqs. (20.4.51) and (20.4.52) into Eq. (20.4.49) and making use of Eqs. (20.4.42), (20.4.48), and (20.4.49), we obtain an expression for each nodal force in terms of the local displacement, the orientation θ and the element stiffness K.

$$\begin{aligned} f_{1,x} = {} & (k\cos^2\theta)u_{1,x} + (k\sin\theta\cos\theta)u_{1,y} \\ & - (k\cos^2\theta)u_{2x} - (k\sin\theta\cos\theta)u_{2y} \end{aligned} \tag{20.4.52}$$

$$\begin{aligned} f_{1,y} = {} & (k\sin\theta\cos\theta)u_{1,x} + (k\sin^2\theta)u_{1,y} \\ & - (k\sin\theta\cos\theta)u_{2x} - (k\sin^2\theta)u_{2y} \end{aligned} \tag{20.4.53}$$

$$\begin{aligned} f_{2,x} = {} & (-k\cos^2\theta)u_{1,x} - (k\sin\theta\cos\theta)u_{1,y} \\ & + (k\cos^2\theta)u_{2x} + (k\sin\theta\cos\theta)u_{2y} \end{aligned} \tag{20.4.54}$$

$$\begin{aligned} f_{2,y} = {} & (k\sin\theta\cos\theta)u_{2x} - (k\sin^2\theta)u_{2,y} \\ & + (k\sin\theta\cos\theta)u_{2x} + (k\sin^2\theta)u_{2y} \end{aligned} \tag{20.4.55}$$

Writing Eqs. (20.4.52) through (20.4.55) in matrix form yields

$$\begin{bmatrix} f_{1,x} \\ f_{1,y} \\ f_{2,x} \\ f_{2,y} \end{bmatrix} = k \begin{bmatrix} c^2 & sc & -c^2 & -sc \\ sc & s^2 & -sc & -s^2 \\ -c^2 & -sc & c^2 & sc \\ -sc & -s^2 & sc & s^2 \end{bmatrix} \begin{bmatrix} u_{1x} \\ u_{1y} \\ u_{2x} \\ u_{2y} \end{bmatrix} \tag{20.4.56}$$

where s and c are abbreviations for $\sin\theta$ and $\cos\theta$, respectively, and k is the stiffness constant. We can write Eq. (20.4.56) in more compact form as

$$[f] = [k]\,[u] \tag{20.4.57}$$

where the local forces, local displacement, and local stiffness are defined as follows:

$$[f] = \begin{bmatrix} f_{1,x} \\ f_{1,y} \\ f_{2,x} \\ f_{2,y} \end{bmatrix} \qquad [u] = \begin{bmatrix} u_{1x} \\ u_{1y} \\ u_{2x} \\ u_{2y} \end{bmatrix} \tag{20.4.58}$$

$$[k] = \frac{AE}{L} \begin{bmatrix} c^2 & sc & -c^2 & -sc \\ sc & s^2 & -sc & -s^2 \\ -c^2 & -sc & c^2 & sc \\ -sc & -s^2 & sc & s^2 \end{bmatrix} \tag{20.4.59}$$

For $\theta = 0$, the truss element reduces to the one shown in Fig. 20.4.9. The local stiffness matrix is simply

$$[k] = \frac{AE}{L} \begin{bmatrix} 1 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{20.4.60}$$

Which checks with Eq. (20.4.46). Note how the zero rows and columns are simply used to expand the local stiffness matrix given by Eq. (20.4.60) to account for the zero forces and displacements along the y axis.

Global Stiffness Matrix

The **global stiffness matrix** relates the global forces (external forces) and the global displacements (displacements associated with each joint). We developed the local stiffness matrix for an arbitrary element of the truss—what remains is to assemble all the local stiffness matrices associated with the truss elements. Later it will be apparent in our analysis that the efficiency of the computer program is greatly dependent on the technique developed to formulate the global stiffness matrix.

The classical approach for a truss is to take a free-body diagram of each joint and, using the equilibrium equations, group all the equations together and isolate the global stiffness matrix. This approach is tedious and requires a large computational effort from the computer. The method that is illustrated in what follows to obtain the global stiffness matrix is one that Huston and Passerelo developed. It shows how the building of the global stiffness matrix can be done by a simple strategy in which connectivity tables are used to identify the truss elements and their joints. The method is as follows.

Step 1. Consider an arbitrary truss. First, label the **truss elements** and joints in an arbitrary fashion, as shown in Fig. 20.4.11. There are four joints (1, 2, . . . , 4) and five elements ([1], [2], . . . , [5]).

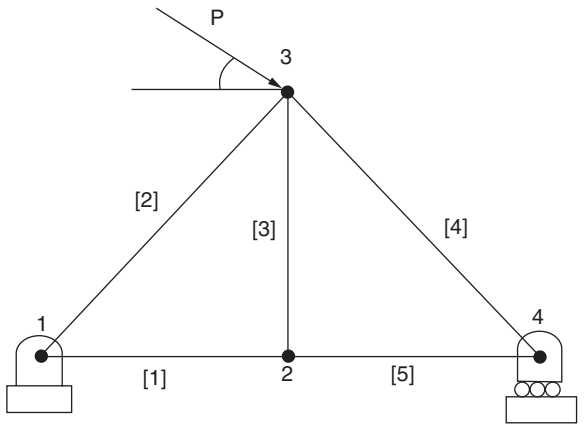

Fig. 20.4.11 A two-dimensional truss.

Step 2. We proceed to develop three tables that basically store geometrical information about the truss. Table 20.4.1 has the truss-joint/matrix-column matching, where pairs starting from 1 develop the column numbers, 2. Table 20.4.2 identifies the connection joints to all the elements of the truss. Using Tables 20.4.1 and 20.4.2, we construct Table 20.4.3, which will be used to assemble the global matrix.

Table 20.4.1 Truss-Joint/Matrix-Column Matrix

Joint	Column	Numbers
1	1	2
2	3	4
3	5	6
4	7	8

Table 20.4.2 Elements versus Joint Numbers

Truss element e	N_1	N_2
1	1	2
2	1	3
3	2	3
4	3	4
5	2	4

Table 20.4.3 Truss Elements versus k_{ij}

i, j from k_{ij}^e	Truss elements e				
	1	2	3	4	5
1	1	1	3	5	3
2	2	2	4	6	4
3	3	5	5	7	7
4	4	6	6	8	8

To see how Table 20.4.3 is constructed, consider truss element 1. From Table 20.4.2, we read the connecting joints to element 1, which are 1 and 2; with these joint numbers, we use Table 20.4.1 to extract the corresponding column numbers, which are 1, 2 and 3, 4. Therefore, in Table 20.4.3 number 1 (referring to the element number), we insert the values 1, 2, 3, and 4, as shown. We repeat the procedure for the remaining elements 2 to 7. Table 20.4.3 plays an important role in identifying the location where the local stiffness matrix terms will be inserted in the global matrix.

For the whole truss system, we write the equation relating the global forces and displacements:

$$\{F\} = [K]\,\{U\} \tag{20.4.61}$$

where

$$\{F\} = \begin{bmatrix} F_{1x} \\ F_{1y} \\ F_{2x} \\ F_{2y} \\ F_{3x} \\ F_{3y} \\ F_{4x} \\ F_{4y} \end{bmatrix} \quad \text{and} \quad \{U\} = \begin{bmatrix} U_{1x} \\ U_{1y} \\ U_{2x} \\ U_{2y} \\ U_{3x} \\ U_{3y} \\ U_{4x} \\ U_{4y} \end{bmatrix} \tag{20.4.62}$$

and

$$[K] = \begin{bmatrix} K_{1,1} & K_{1,2} & K_{1,3} & \cdots & K_{1,8} \\ K_{2,1} & K_{2,2} & K_{2,3} & \cdots & K_{2,8} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ K_{8,1} & K_{8,2} & K_{8,3} & \cdots & K_{8,8} \end{bmatrix} \tag{20.4.63}$$

Note that the size of the global stiffness matrix $[K]$ is 10 by 10. This is equal to the number of nodal points (joints in this case) in the truss multiplied by the degrees of freedom permitted at each node (2 for the planar truss shown). Thus, the $[K]$ in Eq. (20.4.27) is the assembled global stiffness matrix obtained from the assembly of individual element stiffness matrices, that is,

$$f_i^e = k_{ij}^e \mu_j \qquad (e = 1, \ldots, \text{number of elements};\ i, j = 1, 4) \tag{20.4.64}$$

where k_{ij}^e is the local element stiffness matrix and is given by Eq. (20.4.56).

For $\theta = 0$, k_{ij}^1 is given by Eq. (20.4.57). For $\theta = 90$, k_{ij}^3 is

$$k_{ij}^3 = \frac{AE}{L}\begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 1 \end{bmatrix} \tag{20.4.65}$$

In order to construct the global stiffness matrix, first evaluate all the local element stiffness matrices. Then Table 20.4.3 is used to transfer the terms from the local stiffness matrices to the locations in the global stiffness matrix.

For example, consider element 1 from Table 20.4.3.The element column identifies the location in the global stiffness matrix of its local stiffness. The variation by pair of the column numbers identifies the i, j entries of the local stiffness matrix in the global stiffness matrix, K_{ij}. For example, the column numbers for element 1 basically correspond to the local stiffness matrix for element 1 when transferred to the location in the assembled global stiffness matrix looks like

$$K^1 = \begin{bmatrix} k_{11}^1 & k_{12}^1 & k_{13}^1 & k_{14}^1 & 0 & 0 & 0 & 0 \\ k_{21}^1 & k_{22}^1 & k_{23}^1 & k_{24}^1 & 0 & 0 & 0 & 0 \\ k_{31}^1 & k_{32}^1 & k_{33}^1 & k_{34}^1 & 0 & 0 & 0 & 0 \\ k_{41}^1 & k_{42}^1 & k_{43}^1 & k_{44}^1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \tag{20.4.66}$$

For element 2, we read the row and column entries, which are 1, 2, 5, and 6, from Table 20.4.3. Hence, its contribution to the global stiffness is given by

$$K^2 = \begin{bmatrix} k_{11}^2 & k_{12}^2 & 0 & 0 & k_{13}^2 & k_{14}^2 & 0 & 0 \\ k_{21}^2 & k_{22}^2 & 0 & 0 & k_{23}^2 & k_{24}^2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ k_{31}^2 & k_{32}^2 & 0 & 0 & k_{33}^2 & k_{34}^2 & 0 & 0 \\ k_{41}^2 & k_{42}^2 & 0 & 0 & k_{43}^2 & k_{44}^2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \tag{20.4.67}$$

Once all the elements are completed and their local stiffness matrices are inserted into the global stiffness matrix $[K]$, the general global matrix of the system is then obtained by adding all the entries in different locations if they are more than one.

$$K_{ij} = K_{ij}^1 + K_{ij}^2 + K_{ij}^3 + \cdots K_{ij}^5 \tag{20.4.68}$$

The above outlined procedure for developing the global stiffness matrix could be automated by using computer coding.

Solution of the Truss Problem

The global force and displacement vectors are related through the global stiffness matrix:

$$[F] = [K]\,[U] \tag{20.4.69}$$

After the development of $[K]$, the global stiffness matrix, the identification of the boundary forces and displacements is important. These are to be substituted into the $[F]$ and $[U]$ vectors.

For the truss shown in Fig. 20.4.12, the reaction forces at joint 1 in the x and y directions are the reaction forces R_{1x} and R_{1y}, respectively. The reaction at joint 2 is only in the y direction as it is the roller joint, that is, R_{2y}. Also, force P acts as an external force in the x direction at joint 3.

$$\text{Thus,} \quad \begin{aligned} &F_{1x} = R_{1x} \quad F_{1y} = R_{1y} \quad F_{4y} = R_{4y} \\ &F_{3x} = P_x \quad F_{3y} = P_y \end{aligned} \tag{20.4.70}$$

Except for these, all other forces are equal to zero.

Substituting these values into force vector $[F]$, we get Eq (20.4.71):

$$[F] = \begin{bmatrix} R_{1x} \\ R_{1y} \\ 0 \\ 0 \\ P_x \\ P_y \\ 0 \\ R_{4y} \end{bmatrix} \tag{20.4.71}$$

Similarly, the displacement boundary condition can be identified, where for joints 1 and 2 we have Eq. (20.4.72)

$$\begin{aligned} U_{1x} &= 0 \\ U_{1y} &= 0 \\ U_{4y} &= 0 \end{aligned} \tag{20.4.72}$$

All others are nonzero. Substituting these zero displacements into the displacement vector $[U]$, we get Eq. (20.4.73)

$$[U] = \begin{bmatrix} 0 \\ 0 \\ U_{2x} \\ U_{2y} \\ U_{3x} \\ U_{3y} \\ U_{4x} \\ 0 \end{bmatrix} \tag{20.4.73}$$

Substituting $[F]$ and $[U]$ from Eqs. (20.4.71) and (20.4.73) into Eq. (20.4.69), we obtain the general equations governing the truss force/displacement equilibrium conditions.

$$\begin{bmatrix} R_{1x} \\ R_{1y} \\ 0 \\ 0 \\ P_x \\ P_y \\ 0 \\ R_{4y} \end{bmatrix} = \begin{bmatrix} K_{1,1} & K_{1,2} & \dots & K_{1,8} \\ K_{2,1} & K_{2,2} & \dots & K_{2,8} \\ \vdots & \vdots & \dots & \vdots \\ \vdots & \vdots & \dots & \vdots \\ \vdots & \vdots & \dots & \vdots \\ \vdots & \vdots & \dots & \vdots \\ \vdots & \vdots & \dots & \vdots \\ K_{8,1} & K_{8,1} & \dots & K_{8,8} \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ U_{2x} \\ U_{2y} \\ U_{3x} \\ U_{3y} \\ U_{4x} \\ 0 \end{bmatrix} \tag{20.4.74}$$

Note how in Eq. (20.4.39) the unknowns are in the global force array as well as in the joint displacement vector. A typical strategy to solve such a problem in which the unknowns are on both sides of the equation is to solve for the U's first by partitioning the matrices such that the force vector is completely in terms of the known forces. Eliminating the reaction forces does the partitioning. The resulting equation is Eq. (20.4.75)

$$\begin{bmatrix} 0 \\ 0 \\ P_x \\ P_y \\ 0 \end{bmatrix} = [K'] \begin{bmatrix} U_{2x} \\ U_{2y} \\ U_{3x} \\ U_{3y} \\ U_{4x} \end{bmatrix} \tag{20.4.75}$$

where $[K']$ is the new stiffness matrix resulting from the global stiffness after eliminating the rows and columns corresponding to the zero displacements. Equation (20.4.75) constitutes a set of seven equations and seven unknowns, which can be solved using the gaussian elimination method, Cramer's rule, or simply the inverse of $[K']$ as Eq. (20.4.76)

$$\begin{bmatrix} U_{2x} \\ U_{2y} \\ U_{3x} \\ U_{3y} \\ U_{4x} \end{bmatrix} = [K']^{-1} \begin{bmatrix} 0 \\ 0 \\ P_x \\ P_y \\ 0 \end{bmatrix} \tag{20.4.76}$$

Once the equations are solved for the displacements, reactions R_{1x}, R_{1y}, and R_{2y} can be evaluated by premultiplying the corresponding terms of $[K]$ and $[U]$ in Eq. (20.4.74). The solutions are found to be

$$R_{1x} = -P_x \qquad R_{4y} = \frac{P_y}{2} - \frac{b}{2a}P_x \qquad R_{1y} = \frac{P_y}{2} - \frac{b}{2a}P_x \tag{20.4.77}$$

The answers obtained from the FEM analysis as described before can be checked by simply taking the free-body diagram for the truss as shown in Fig. 20.4.12. Writing the equilibrium equations

$$\sum F_x = 0 \qquad \sum F_y = 0 \qquad \sum M = 0 \tag{20.4.78}$$

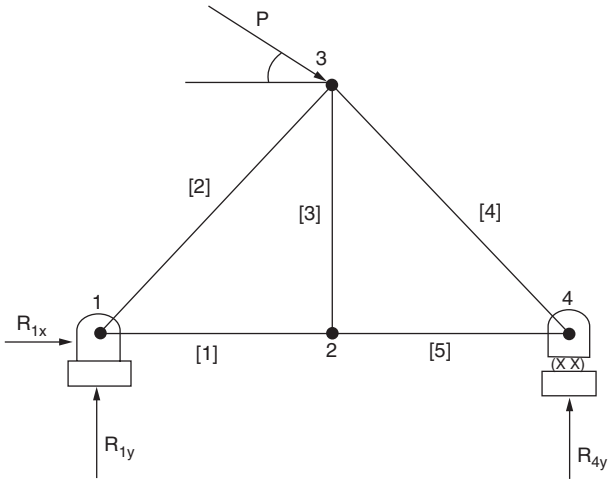

Fig. 20.4.12 A simple free-body diagram of 2-D truss subject to loading.

we get

$$\begin{aligned} \sum F_x &= R_{1x} + P_x = 0 \\ \sum F_y &= R_{1y} + R_{4y} + P_y = 0 \\ \sum M_1 &= R_{4y}2a - P_x b - P_y a = 0 \end{aligned} \tag{20.4.79}$$

which checks with the FEM solution.

Evaluation of the Local Forces

The internal forces are those that are either compressing or tensioning the truss elements. To find the components of the forces acting at each end, we use the previously computed global displacements and local stiffness matrix.

From Eq. (20.4.56), we have

$$\begin{bmatrix} f^e_{1x} \\ f^e_{1y} \\ f^e_{2x} \\ f^e_{2y} \end{bmatrix} = \frac{AE}{l} \begin{bmatrix} c_e^2 & s_e c_e & -c_e^2 & -s_e c_e \\ s_e c_e & s_e^2 & -s_e c_e & -s_e^2 \\ -c_e^2 & -s_e c_e & c_e^2 & s_e c_e \\ -s_e c_e & -s_e^2 & s_e c_e & s_e^2 \end{bmatrix} \begin{bmatrix} u^e_{1x} \\ u^e_{1y} \\ u^e_{2x} \\ u^e_{2y} \end{bmatrix} \tag{20.4.80}$$

The stiffness matrix in this equation (for the particular element at hand) is known. The nodal displacements are also known from the global displacement vector. The relationship between the global and local displacement is explained below.

Let the local displacement be written as u^e_{if}, where e is the element number of the truss, i denotes either end 1 or end 2 of the element, and j assigns the direction x or y to the end displacements. Assuming that all elements of the truss undergo the same displacements at each joint, we then write the following.

For joint 1: $U_{1x} = u^1_{1x} = u^2_{1x} = u^4_{1x} \qquad U_{1y} = u^1_{1y} = u^2_{1y} = u^4_{1y}$ (20.4.81)

For joint 2: $U_{2x} = u^1_{2x} = u^5_{1x} = u^7_{1x} \qquad U_{2y} = u^1_{2y} = u^5_{1y} = u^7_{1y}$ (20.4.82)

For joint 3: $U_{3x} = u^2_{2x} = u^3_{1x} \qquad U_{3y} = u^2_{2y} = u^3_{1y}$ (20.4.83)

For joint 4: $U_{4x} = u^3_{2x} = u^4_{2x} = u^6_{1x} = u^5_{2x}$

$$U_{4y} = u^3_{2y} = u^4_{2y} = u^6_{1y} = u^5_{2x} \tag{20.4.84}$$

For joint 5: $U_{5x} = u^7_{2x} = u^6_{2x} \qquad U_{5y} = u^7_{2y} = u^6_{2y}$ (20.4.85)

The nodal displacements for any particular element can be found from the relationships between the global displacements and the local displacement by using Eqs. (20.4.81) to (20.4.85). Subsequent substitution of these values for a particular element in Eq. (20.4.80) and multiplication by the corresponding stiffness matrix terms yields the nodal forces. The signs of these forces indicate whether the member is in tension or compression.

EXAMPLE: ANALYSIS OF A THREE-ELEMENT TRUSS Use the finite-element method on the truss in Fig. 20.4.13. (1) Find the global stiffness matrix. (2) Solve for the reaction forces. (3) Solve for the member forces and determine whether a truss element is in tension or compression.

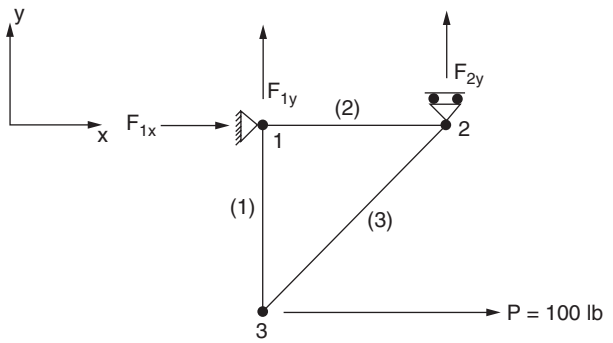

Fig. 20.4.13 A three-element truss subject to loading.

Solution: The first step in our analysis is to label the truss for the joint numbers and link numbers as shown in the figure. The second step is to compute the local stiffness matrices for each member, using Eq. (20.4.59) which gives

$$[k_{ij}^1] = \frac{A_1E}{l}\begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 1 \end{bmatrix} \qquad [k_{ij}^2] = \frac{A_2E}{l\sqrt{3}}\begin{bmatrix} 1 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

$$[k_{ij}^3] = \frac{A_3E}{8l}\begin{bmatrix} 3 & \sqrt{3} & -3 & -\sqrt{3} \\ \sqrt{3} & 1 & -\sqrt{3} & -1 \\ -3 & -\sqrt{3} & 3 & \sqrt{3} \\ -\sqrt{3} & -1 & \sqrt{3} & 1 \end{bmatrix}$$

where A_1, A_2, A_3 and L_1, L_2, L_3 are the areas of cross section and lengths of the members of the truss, respectively, and E is Young's modulus of elasticity. $A_1 = A_2 = A_3 = A$ and $L_1 = l$, such that $L_2 = l\sqrt{3}$ and $L_3 = 2l$.

Now let us construct Tables 20.4.4 to 20.4.6 (see earlier Tables 20.4.1 to 20.4.3), which help in arriving at the global stiffness matrix [K]. Using the local stiffness matrices and transferring the entries with the help of Table 20.4.6 we can arrive at the global stiffness matrix:

4	6	4	6

$$\frac{AE}{L}\begin{bmatrix} \frac{1}{\sqrt{3}} & 0 & -\frac{1}{\sqrt{3}} & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & -1 \\ -\frac{1}{\sqrt{3}} & 0 & \frac{8+3\sqrt{3}}{8\sqrt{3}} & \frac{\sqrt{3}}{8} & -\frac{3}{8} & -\frac{\sqrt{3}}{8} \\ 0 & 0 & \frac{\sqrt{3}}{8} & \frac{1}{8} & -\frac{\sqrt{3}}{8} & -\frac{1}{8} \\ 0 & 0 & -\frac{3}{8} & -\frac{\sqrt{3}}{8} & \frac{3}{8} & \frac{\sqrt{3}}{8} \\ 0 & -1 & -\frac{\sqrt{3}}{8} & -\frac{1}{8} & \frac{\sqrt{3}}{8} & \frac{9}{8} \end{bmatrix} \begin{bmatrix} U_{1x} \\ U_{1y} \\ U_{2x} \\ U_{2y} \\ U_{3x} \\ U_{3y} \end{bmatrix} = \begin{bmatrix} F_{1x} \\ F_{1y} \\ 0 \\ F_{2y} \\ P \\ 0 \end{bmatrix}$$

Zeros in the force vector indicate that the forces in the x and y directions at joints 2 and 3 are zeroes because of the roller and free joint, respectively.

Applying the displacement boundary conditions, $U_{1x} = 0$, $U_{1y} = 0$, $U_{2y} = 0$, and eliminating the corresponding rows and columns, we get

$$\begin{bmatrix} 0.952 & -0.375 & -0.2165 \\ -0.375 & 0.375 & 0.2165 \\ -0.2165 & 0.2165 & 1.125 \end{bmatrix} \begin{bmatrix} U_{2x} \\ U_{3x} \\ U_{3y} \end{bmatrix} = \begin{bmatrix} 0 \\ 100 \\ 0 \end{bmatrix}$$

Solving for the unknowns, we obtain

$$U_{2x} = 173.31\frac{l}{AE} \qquad U_{3x} = 473.13\frac{l}{AE} \qquad U_{3y} = -57.57\frac{l}{AE}$$

The reaction forces can be computed using Eq. (20.4.43) as

$$F_{1x} = \left(\frac{1}{\sqrt{3}}U_{1x} - \frac{1}{\sqrt{3}}U_{2x}\right)\frac{AE}{l} = -100.0 \text{ lb}$$

$$F_{1y} = (1.U_{1y} - 1.U_{3y})\frac{AE}{l} = 57.57 \text{ lb}$$

$$F_{2y} = \left(-\frac{\sqrt{3}}{8}U_{2x} + \frac{\sqrt{3}}{8}U_{3y} - \frac{1}{8}U_{3y}\right) = -57.57 \text{ lb}$$

These results can be verified by using the free-body diagram of the truss (Fig. 20.4.12)

$$\sum F_x = 0 \qquad \sum F_y = 0 \qquad \sum M = 0$$

$\sum F_x = 0$ gives $F_{1x} + 100.0 = 0$, that is, $F_{1x} = -100.0$ lb

$\sum F_y = 0$ gives $F_{1y} + F_{2y} = 0$, that is, $F_{1y} = -F_{2y}$

$\sum M = 0$ gives $pl + F_{2y}\sqrt{3}l = 0.0$, that is, $F_{2y} = \begin{cases} -57.57 \\ -F_{1y} \end{cases}$

Therefore, members 1 and 3 are in tension, whereas member 2 is in compression.

The member forces are obtained from the local element force-displacement relationship:

$$\begin{Bmatrix} f_{1x}^e \\ f_{1y}^e \\ f_{2x}^e \\ f_{2y}^e \end{Bmatrix} = \frac{AE}{l}\begin{bmatrix} c^2 & sc & -c^2 & -sc \\ sc & s^2 & -sc & -s^2 \\ -c^2 & -sc & c^2 & sc \\ -sc & -s^2 & sc & s^2 \end{bmatrix} \begin{Bmatrix} u_{1x}^e \\ u_{1y}^e \\ u_{2x}^e \\ u_{2y}^e \end{Bmatrix}$$

The global and local displacement at each joint are related as follows:

$$U_{1x} = u_{1x}^0 = 0 \qquad U_{1y} = u_{1y}^1 = 0 \qquad U_{3x} = u_{2x}^1 \qquad U_{3y} = u_{2y}^1$$

Using the local stiffness already computed, we obtain

$$\begin{Bmatrix} f_{1x}^1 \\ f_{1y}^1 \\ f_{2x}^1 \\ f_{2y}^1 \end{Bmatrix} = \frac{AE}{l}\begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 1 \end{bmatrix} \begin{Bmatrix} 0 \\ 0 \\ U_{3x} \\ U_{3y} \end{Bmatrix}$$

$$\Rightarrow f_{1y}^1 = -\left(\frac{AE}{l}\right)U_{3y} = -\left(\frac{AE}{l}\right)57.57\frac{l}{AE} = 57.57 \text{ lb}$$

$$f_{2y}^1 = \left(\frac{AE}{l}\right)U_{3y} = -57.57 \text{ lb}$$

The forces acting on element 1 clearly show that it is in tension as predicted. Similarly, we can obtain the magnitude of the forces and directions for elements 2 and 3.

$$F_{1x} = F_{2x} = 0$$

Stress Analysis

In the analysis of a truss, the main objective is to decide whether the truss elements are designed to sustain the load they support. For that we need to evaluate the stress or average stress in each element. The latter is an indication as to whether the tension or compression can be sustained.

Let the element stress be given by

$$\begin{aligned}\sigma^{(e)} &= E\varepsilon^{(e)} \\ &= E^{(e)}\frac{u_2^{(e)} - u_1^{(e)}}{l}\end{aligned} \tag{20.4.86}$$

Now we can compute the stress for each element of the truss in the previous example. For each element we can write

$$\sigma^{(1)} = E^{(1)}\frac{u_2^{(1)} - u_1^{(1)}}{l} = E^{(1)}\frac{U_{3y} - U_{1y}}{l}$$

$$\sigma^{(2)} = E^{(2)}\frac{u_2^{(2)} - u_1^{(2)}}{l} = E^{(2)}\frac{U_{2x} - U_{1x}}{\sqrt{3}l}$$

$$\sigma^{(3)} = E^{(3)}\frac{u_2^{(3)} - u_1^{(3)}}{l} = E^{(3)}\frac{U_{3x} - U_{2x}}{2l}$$

and the results are

$$\sigma^{(1)} = E\frac{U_{3y}}{l} = \frac{E}{l}\left(-57.57\frac{l}{AE}\right)$$

$$\sigma^{(2)} = E\frac{U_{2x}}{l\sqrt{3}} = \frac{E}{l\sqrt{3}}\left(173.31\frac{l}{AE}\right)$$

$$\sigma^{(3)} = E\frac{U_{2x} - U_{3x}}{2l} = -\frac{E}{2l}\left(299.82\frac{l}{AE}\right)$$

HEAT CONDUCTION ANALYSIS AND FEM

In most instances, the important problems of engineering involving an exchange of energy by the flow of heat are those in which there is a transfer of internal energy between two systems. In general, the internal energy transfer is called *heat transfer*. When such exchanges of internal energy or heat take place, the first law of thermodynamics requires that the heat given up by one body must equal that taken up by the other. The second law of thermodynamics demands that the transfer of heat take place from the hotter system to the colder system. It is customary to categorize the various heat transfer processes into three basic types or modes, although it is certainly a rare instance when one encounters a problem of practical importance that does not involve at least two, and sometimes all three, of these modes occurring simultaneously. The three modes are conduction, convection, and radiation. Heat conduction will be the focus of this section. Heat conduction is the term applied to the mechanism of internal energy exchange from one body to another, or from one part of a body to another part, by the exchange of kinetic energy.

When the relationship between force and displacement can be approximated by a linear function, the problem reduces to a one-dimensional analysis. This is seen in the study of trusses where the element deformation is expressed as a linear function in terms of the element force. A number of engineering problems, and heat conduction in particular, can be solved by using one-dimensional element and linear functions to approximate the solution. Here, we will extend the one-dimensional solution to heat conduction problems, and define the concept of shape functions for one and two dimensions in the finite-element method.

One-Dimensional Elements

Now we apply the finite-element method to the solution of heat flow in some simple one-dimensional steady-state heat conduction systems. Several physical shapes fall into the one-dimensional analysis, such as spherical and cylindrical systems, in which the temperature of the body is a function only of radial distance. Consider the straight bar of Fig. 20.4.14, where the heat flows across the end surfaces. Heat is also assumed to be generated internally by a heat source at a rate f per unit volume. The temperature varies only along the axial direction x, and we want to formulate a finite-element technique that would yield the temperature $T = T(x)$ along the position x in the steady-state condition.

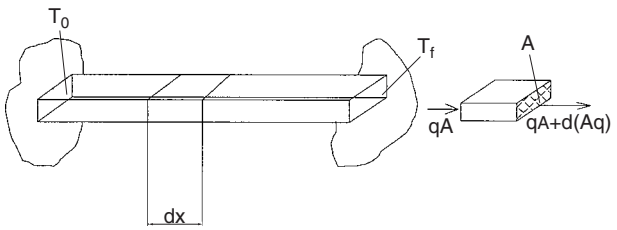

Fig. 20.4.14 A typical bar with temperatures T_0 and T_f at each end.

In steady-state conditions, the net rate of heat flow into any differential element is zero. We know that for heat conduction analysis, the Fourier heat conduction equation is

$$q = -\kappa\frac{dT}{dx} \tag{20.4.87}$$

This equation states that the heat flux q in direction x is proportional to the gradient of temperature in direction x. The conductivity constant is defined by κ.

From the differential element in Fig. 20.4.14, we can write the heat flux balance:

$$qA + fA\,dx - [qA + d(Aq)] = 0 \tag{20.4.88}$$

With the differentiation of q, the heat flux equation becomes

$$qA + fA\,dx - \left[qA + \frac{dq}{dx}dx\,A\right] = 0 \tag{20.4.89}$$

This reduces to a first-order differential equation of the form

$$\frac{dq}{dx} = f \tag{20.4.90}$$

where A = cross-sectional area; f = heat source/unit volume; q = heat flux; T = temperature.

Substituting Eq. (20.4.87) into Eq. (20.4.90), we get the governing differential equation for the temperature:

$$\kappa\frac{d^2T}{dx^2} = -f \tag{20.4.91}$$

The boundary conditions for the physical problem described in Fig. 20.4.14 are $T = T_0$ at $x = 0$ and $T = T_f$ at $x = L$.

Integrating (20.4.4) we get an explicit solution for the temperature at any point along the bar.

$$T(x) = \frac{fL}{2\kappa}\left(x - \frac{x^2}{L}\right) + \left(\frac{T_f - T_0}{L}\right)x + T_0 \tag{20.4.92}$$

For one-dimensional problem the temperature at any point x can be found by using Eq. (20.4.91). Finite-element analysis is tailored for engineering problems where the closed-form solution can't be evaluated and numerical approximation is required. There are a number of scenarios in which the governing heat equation is nonlinear and the closed form is unattainable. What follow are the initial steps in applying

finite-element methods to heat conduction problems. First we develop the solution to one-dimensional heat conduction problems and compare that to the solution given by Eq. (20.4.91).

Finite-Element Formulation

We must use either the principle of virtual work or energy to derive the necessary governing equations in the finite-element method. The method as shown in the previous two sections leads to the formulation of the element stiffness and stiffness matrix. We first develop the following energy equation as

$$I = \int \left[kA \frac{d^2T}{dx^2} + fA \right] dx \tag{20.4.93}$$

which yields Eq. (20.4.91) for $dI = 0$ after the standard manipulation of calculus of variations. Equation (20.4.93) could be expressed further in two parts, I_1 and I_2, as

$$I = \underbrace{\int \frac{d}{dx}\left[Ak \frac{dT}{dx} \right] T\, dx}_{I_1} + \underbrace{\int fAT\, dx}_{I_2} \tag{20.4.94}$$

Integrating the function I_1 by parts, we get

$$I_1 = TAk \frac{dT}{dx}\bigg|_0^L - \int_0^L \frac{dT}{dx} Ak \frac{dT}{dx} dx \tag{20.4.95}$$

The first term defines the boundary conditions' contributions. If we assume that the boundary conditions are such that

$$T_{(x=0)} = T_L \qquad \text{and} \qquad q|_{x=L} = h(T_L - T_\infty)$$

then the functional I becomes

$$I = -\int_0^L \frac{dT}{dx} Ak \frac{dT}{dx} dx - \int fAT\, dx + \frac{1}{2} h (T_L - T_\infty)^2 \tag{20.4.96}$$

We have an expression for I ready to use if the temperature $T = T(x)$ has an explicit form in x that can be substituted into the equation so that we can carry on the integration.

Next, consider the function $I^{(e)}$ for an element rather than for the total system:

$$I^{(e)} = -\int_{x_1}^{x_2} \frac{dT}{dx} A\kappa \frac{dT}{dx} dx + TA\kappa \frac{dT}{dx}\bigg|_{x_1}^{x_2} + \int_{x_1}^{x_2} fAT\, dx \tag{20.4.97}$$

$$I^{(e)} = I_1^{(e)} + I_2^{(e)} + I_3^{(e)} \tag{20.4.98}$$

where $I_1^{(e)}$, $I_2^{(e)}$, and $I_3^{(e)}$ correspond to the three terms of element $I^{(e)}$, respectively. To develop all the $I_1(e)$ terms we need to find an expression for the temperature T. Assume a linear interpolation for the temperature between x_1 and x_2, as the distance between these two points is assumed small. A representation of the temperature is shown in Fig. 20.4.15, where the temperature varies linearly as

$$T = ax + b \tag{20.4.99}$$

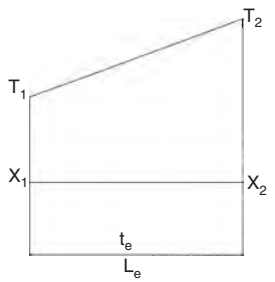

Fig. 20.4.15 Linear interpolation of the temperature.

At each node, the temperature is assumed to be T_1 and T_2, respectively. We can write the temperature equation for each node as

$$T_1 = ax_1 + b \qquad \text{and} \qquad T_2 = ax_2 + b \tag{20.4.100}$$

from which we can solve for a and b:

$$a = \frac{T_2 - T_1}{L_e} \qquad \text{and} \qquad b = T_1 - \frac{T_2 - T_1}{L_e} x_1$$

where L_e denotes the length of the element $(x_2 - x_1)$. Substituting the values of a and b into Eq. (20.4.100), we write an expression for T by introducing shape functions:

$$T = T_1 N_1 + T_2 N_2 \tag{20.4.101}$$

where

$$N_1 = \frac{x_2 - x}{L_e} \qquad \text{and} \qquad N_2 = \frac{x - x_1}{L_e} \tag{20.4.102}$$

The latter are known as shape functions. These functions are linear in x and represent the characteristic of the function assumed in representing the temperature between x_1 and x_2.

In matrix form, the temperature from Eq. (20.4.101) can be expressed as

$$T = [T_1 \quad T_2] \begin{bmatrix} N_1 \\ N_2 \end{bmatrix} \tag{20.4.103}$$

We note in Eq. (20.4.97) that the time derivative of T is also required, hence the derivative of T as given by Eq. (20.4.103) takes on the following form:

$$\frac{dT}{dx} = [T_1 \quad T_2] \begin{bmatrix} \dfrac{dN_1}{dx} \\ \dfrac{dN_2}{dx} \end{bmatrix} \tag{20.4.104}$$

$$\frac{dN_1}{dx} = -\frac{1}{L_e} \qquad \text{and} \qquad \frac{dN_2}{dx} = \frac{1}{L_e} \tag{20.4.105}$$

The functional $I^{(e)}$ then becomes

$$I^{(e)} = \int_{x_1}^{x_2} [T_1 \quad T_2] \begin{bmatrix} dN_1/dx \\ dN_2/dx \end{bmatrix} A\kappa \begin{bmatrix} \dfrac{dN_1}{dx} & \dfrac{dN_2}{dx} \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} dx - \int_{x_1}^{x_2} fA[T_1 \quad T_2] \begin{bmatrix} N_1 \\ N_2 \end{bmatrix} dx + \frac{1}{2} h(T_L - T_\infty) \tag{20.4.106}$$

Here the boundary conditions at both ends are defined by the last term in the above equation.

Let the first term be I_1^e and defined by

$$I_1^e = A\kappa \int_{x_1}^{x_2} [T_1 \quad T_2] \begin{bmatrix} \left(\dfrac{dN_1}{dx}\right)^2 & \dfrac{dN_1}{dx}\dfrac{dN_2}{dx} \\ \dfrac{dN_2}{dx}\dfrac{dN_1}{dx} & \left(\dfrac{dN_2}{dx}\right)^2 \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} dx \tag{20.4.107}$$

Substituting the Eq. (20.4.105) derivatives into Eq. (20.4.107) and integrating yields

$$I_1^e = A\kappa \; [T_1 \quad T_2] \begin{bmatrix} \dfrac{1}{L_e} & -\dfrac{1}{L_e} \\ -\dfrac{1}{L_e} & \dfrac{1}{L_e} \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} \tag{20.4.108}$$

Similarly, let $I_2^{(e)}$ denote the term defined in Eq. (20.4.108). Evaluating this term we obtain the term that involves the contribution of the heat source f:

$$I_2^{(e)} = \int_{x_1}^{x_2} fA[T_1 \quad T_2] \begin{bmatrix} N_1 \\ N_2 \end{bmatrix} dx = \frac{fAL_c}{2} [T_1 \quad T_2] \begin{bmatrix} 1 \\ 1 \end{bmatrix} \tag{204.109}$$

Next, writing the steady-state condition for an element we get

$$\left\{\frac{\partial I^{(e)}}{\partial T_e}\right\} = \{0\} \qquad \text{which yields} \qquad k_c = \frac{kA}{L_e}\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \tag{20.4.110}$$

and the element loading vector from the second term $I_2^{(e)}$,

$$f_Q = \frac{fAL_e}{2}\begin{bmatrix} 1 \\ 1 \end{bmatrix} \tag{20.4.111}$$

Combining the last equations, we obtain the first step in the finite-element formulation where

$$[k_c]\{T_{X\text{out}}\} = f_2 \tag{20.4.112}$$

Note how $[k_c]$ is analogous to a local stiffness matrix (we refer to it as the conductivity matrix), how $\{T\}$ is analogous to nodal displacements, and how $\{f_e\}$ is analogous to nodal forces. With this in mind, we can use a table analogous to Table 20.4.3 in the analysis of trusses, to develop the connectivity relations between elements. The latter will assist us in the formulation of the global stiffness matrix and the heat source array. The global problem can be stated as

$$[K]\{T\} = \{F\} \tag{20.4.113}$$

where $[K]$ is the global conductivity matrix (equivalent to the global stiffness) assembled from the element conductivity matrix k_c, $\{T\}$ the nodal temperatures, and $\{F\}$ the heat source contribution.

Boundary Condition Contribution

The term in the function I in Eq. (20.4.93) dealing with the convection can be written further as $\frac{1}{2}T_L hT_L - (hT_\infty)T_L + \frac{1}{2}hT_\infty^2$, where we see the last term drop out from the variational $\partial I/\partial T$.

We see that the hT_L term will be added to the K matrix at the (L, L) location and hT_∞ will be added to the F vector at the Lth location. The way the K and F will be formulated is shown below:

$$\begin{bmatrix} K_{11} & \cdots & \cdots & K_{1L} \\ K_{21} & \cdots & \cdots & K_{2L} \\ \vdots & & & \vdots \\ K_{L1} & & & K_{LL} + hT_L \end{bmatrix}\begin{Bmatrix} T_1 \\ T_2 \\ \vdots \\ T_L \end{Bmatrix} = \begin{Bmatrix} F_1 \\ F_2 \\ \vdots \\ F_L + hT_\infty \end{Bmatrix} \tag{20.4.114}$$

Handling of Additional Constraints

The handling of specified temperature boundary conditions such as $T_L = T_0$ can be accompanied by either the elimination or penalty approach. The procedure for elimination is demonstrated below.

Elimination Approach This technique consists of eliminating rows and columns of the corresponding temperature and then modifying the force vector to include the boundary force displacement relation as described in the finite-element solution of trusses. In general, we write the global problem as

$$KU = F \tag{20.4.115}$$

Consider the constraint where the displacement is defined by $U_1 = c_1$. The global displacement vector is array of order $1 \times n$. $U = [U_1 \quad U_2 \quad U_3 \quad \cdots \quad U_n]^T$, and similarly the global force vector is $F = [F_1 \quad F_2 \quad F_3 \quad \cdots \quad F_n]^T$.

We first start by defining the potential energy π as function of elastic energy and the work associated with F:

$$\pi = \frac{1}{2}U^T KU - U^t F \tag{20.4.116}$$

This is one way of obtaining the balance equation of force/displacement as stated previously. The energy explicit matrix form is further shown to be expressed as

$$\pi = \frac{1}{2}\begin{pmatrix} U_1K_{11}U_1 + U_1K_{12}U_2 + \cdots + U_2K_{1N}U_N \\ U_2K_{21}U_1 + U_2K_{22}U_2 + \cdots + U_2K_{2N}U_N \\ \vdots \\ U_NK_{N1}U_1 + U_NK_{N2}U_2 + \cdots + U_NK_{NN}U_N \end{pmatrix} - (U_1F_1 + U_2F_2 + \cdots + U_NF_N) \tag{20.4.117}$$

Let us substitute the boundary condition $U_1 = C_1$. Then we get

$$\pi = \frac{1}{2}\begin{pmatrix} C_1K_{11}C_1 + C_1K_{12}U_2 + \cdots + C_1K_{1N}U_N \\ U_2K_{21}C_1 + U_2K_{22}U_2 + \cdots + U_2K_{2N}U_N \\ \vdots \\ U_NK_{N1}C_1 + U_NK_{N2}U_2 + \cdots + U_NK_{NN}U_N \end{pmatrix} - (C_1F_1 + U_2F_2 + \cdots + U_NF_N) \tag{20.4.118}$$

To solve the problem at hand we need to minimize π, hence $\partial\pi/\partial U_i = 0$, where $i = 1, 2, 3, \ldots, N$, which yields

$$\begin{bmatrix} K_{22} & K_{23} & \cdots & K_{2N} \\ K_{32} & K_{33} & \cdots & K_{3N} \\ \vdots & & & \\ K_{N2} & K_{N3} & & K_{NN} \end{bmatrix}\begin{Bmatrix} U_2 \\ U_3 \\ \vdots \\ U_N \end{Bmatrix} = \begin{Bmatrix} F_2 - K_{21}C_1 \\ F_3 - K_{31}C_1 \\ \\ F_N - K_{N1}C_1 \end{Bmatrix} \tag{20.4.119}$$

The above matrix equation represents a set of $(N-1) \times (N-1)$ equations with the original K matrix being reduced by eliminating the first row and first column as well as the first element of the vector F. We see that the boundary conditions are subtracted from the force vector array by premultiplying it with the elements of the first row of K. This technique will be used in the solutions of heat transfer problems.

Penalty Approach An alternative to the elimination approach is the **penalty approach.** In handling constraints, this might be easier to implement and works well for multiple constraints. The methods are designed to handle the boundary conditions once the global problem has been formulated. Once more, let the boundary conditions be given by the displacement at node 1 such that $U_1 = C_1$.

The total potential energy is then defined by adding an extra term to account for the additional boundary condition or simply to account for the additional energy contribution from the boundary conditions:

$$\pi = \frac{1}{2}u^T ku - u^T F + \frac{1}{2}Q(u_1 - c_1)^2 \tag{20.4.120}$$

So, the energy term $\frac{1}{2}Q(U_1 - C_1)^2$ is significant only if the value of Q is large enough to emphasize the contribution of $(U_1 - C_1)$.

Minimization of π results in

$$\begin{bmatrix} K_{11} + Q & K_{12} & \cdots & K_{1N} \\ K_{21} & K_{22} & \cdots & K_{2N} \\ \vdots & \vdots & \vdots & \vdots \\ K_{N1} & K_{N2} & & K_{NN} \end{bmatrix}\begin{Bmatrix} U_1 \\ U_2 \\ \vdots \\ U_N \end{Bmatrix} = \begin{Bmatrix} F_1 + QC_1 \\ F_2 \\ \vdots \\ F_N \end{Bmatrix} \tag{20.4.121}$$

On examining the above equation, it is apparent that Q is added to K_{11} in the global K matrix and Q_c is added to the element force vector F_1. We can view Q as a stiffness value whose numerical values can be defined or selected by noting that

$$(K_{11} + Q)u_1 + K_{12}U_2 + K_{13}U_3 + \cdots + K_{1N}U_N = F_1 + QC_1 \tag{20.4.122}$$

If we divide by Q we obtain

$$\left(\frac{K_{11}}{Q} + 1\right)U_1 + \frac{K_{12}}{Q}U_2 + \cdots + \frac{K_{1N}}{Q}U_N = \frac{F_1}{Q} + C_1 \tag{20.4.123}$$

Observe how, if Q is chosen to be a large volume, the equation reduces to $U_1 = C_1$, which is the desired boundary condition. We also see further that Q is large in comparison to $K_{11}, K_{12}, \ldots, K_{1N}$, hence we need

to select Q large enough to satisfy the condition of the equation above. A suggested value in previous work is K_{ij}, $Q = \max|K_{1j}| \times 10^4$.

EXAMPLE Determine the temperature distribution in the composite wall used to isolate the outside (Fig. 20.4.16). Convection heat transfer on the inner surface of the wall with $T_\infty = 500°C$ is given by $h = 25$ W/m^{2}C. The conductivity constants for each wall are $K_1 = 20$ W/m · °C, $K_2 = 30$ W/m · °C and $K_3 = 40$ W/m · °C respectively. Let the cross-sectional area $A = 1$ m^2 and $L_1 = 0.4$ m, $L_2 = 0.3$ m, $L_3 = 0.1$ m.

This example is used to demonstrate not only how to build the conductivity stiffness matrices and the loading vector F but how to implement the technique that describes how the boundary conditions are employed.

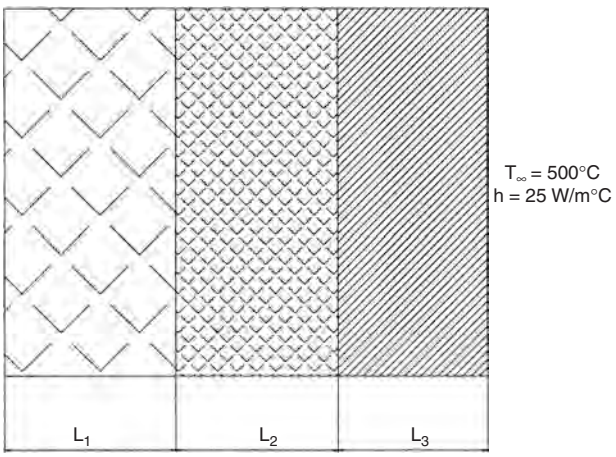

Fig. 20.4.16

Solution: Let the temperature at each wall be denoted by T_1 and let the width of the wall represent the length of each element.

We need to compute the local conductivity stiffness for each element. Since the conductivity constant is given per unit length, we write

$$K^{(1)} = \frac{\kappa_1}{L_1}\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \quad K^{(2)} = \frac{\kappa_2}{L_2}\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \quad K^{(3)} = \frac{\kappa_3}{L_3}\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \tag{20.4.124}$$

The global K is found by assembling $K^{(1)}$, $K^{(2)}$, and K$^{(3)}$, which results in

$$K = 50\begin{bmatrix} 1 & -1 & 0 & 0 \\ -1 & 3 & -2 & 0 \\ 0 & -2 & 10 & -8 \\ 0 & 0 & -8 & 8 \end{bmatrix}$$

Since convection occurs at node 1, we add $h = 25$ to the (1, 1) location in K, which results in

$$K = 50\begin{bmatrix} 1.5 & -1 & 0 & 0 \\ -1 & 3 & -2 & 0 \\ 0 & -2 & 10 & -8 \\ 0 & 0 & -8 & 8 \end{bmatrix}$$

We have no heat source in the problem, so the F vector consists only of hT_∞: $\{F\} = [25 \times 500,0,0,0]$.

Applying the boundary condition $T_4 = 10°C$ can be handled by the penalty approach. Let us choose a value for Q from the previously proposed procedure, where $Q = \max|K_{ij}| \times 10^4 = 50 \times 10 \times 10^4$. As stated, in the penalty function we add the Q value to the K matrix in the (4×4) location, and QT_4 to the (4×1) location of the F vector, resulting in

$$K = 50\begin{bmatrix} 1.5 & -1 & 0 & 0 \\ -1 & 3 & -2 & 0 \\ 0 & -2 & 10 & -8 \\ 0 & 0 & -8 & 100008 \end{bmatrix}\begin{Bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \end{Bmatrix} = \begin{Bmatrix} 25 \times 500 \\ 0 \\ 0 \\ 5 \times 10^7 \end{Bmatrix}$$

The solution of which is found to be

$$T = [229.6559 \quad 94.4839 \quad 26.8979 \quad 10.0014]°C$$

Finite-Difference Approach

Finite difference is discussed briefly in the following example for the purpose of validating the one-dimensional solution we have derived.

EXAMPLE A special design for a building wall consists of three studs containing the materials siding, sheathing, and insulation batting. The inside room temperature is maintained at 85°F and the outside air temperature is measured at 15°F. The area of the wall exposed to air is 180 ft^2. Determine the temperature distribution through the wall.

Table 20.4.7 Characteristics of the Wall

Items	Resistance, h · ft^2 · F/Btu	U factor, Btu/h · ft^2 · °F
Outside film resistance	0.17	5.88
Siding	0.81	1.23
Sheathing	1.32	0.76
Insulation	11.0	0.091
Inside film resistance	0.68	1.47

The steady-state condition of this system can be explained through Fourier's law: $q_x = -kA\,\partial T/\partial X$. We can express the gradient of temperature by $(T_{i+1} - T_i)/l$, and the heat transfer rate becomes $q = [kA(T_{i+1} - T_i)]/l$, or $q = UA(T_{i+1} - T_i)$, where U is defined by k/l.

The heat transfer between the surface and fluid is due to convection. Newton's law of cooling governs the heat transfer rate between the fluid and the surface: $q = hA(T_s - T_f)$, where h is the convection coefficient.

The heat loss through the wall due to conduction must equal the heat loss to the surrounding cold air by convection. That is, $-kA\,\partial T/\partial X = hA(T_s - T_f)$.

Expanding the equation on the temperature distribution at the edge of each wall leads to the following equations:

$$U_2A(T_3 - T_2) = U_1A(T_2 - T_1) \qquad U_3A(T_4 - T_3) = U_2A(T_3 - T_2)$$
$$U_4A(T_5 - T_4) = U_3A(T_4 - T_3) \qquad U_5A(T_6 - T_5) = U_4A(T_5 - T_4)$$

Expressing the above in a matrix form, we get

$$A\begin{bmatrix} u_1 + u_2 & -u_2 & 0 & 0 \\ -u_2 & u_2 + u_3 & -u_3 & 0 \\ 0 & -u_3 & u_3 + u_4 & -u_4 \\ 0 & 0 & -u_4 & u_4 + u_5 \end{bmatrix}\begin{bmatrix} T_2 \\ T_3 \\ T_4 \\ T_5 \end{bmatrix} = \begin{bmatrix} u_1AT_1 \\ 0 \\ 0 \\ u_5AT_6 \end{bmatrix}$$

For the numerical values given, we define the four equations in four unknown as

$$180\begin{bmatrix} 7.11 & -1.23 & 0 & 0 \\ -1.23 & 1.99 & -0.76 & 0 \\ 0 & -0.76 & 0.851 & -0.091 \\ 0 & 0 & -0.091 & 1.561 \end{bmatrix}\begin{bmatrix} T_2 \\ T_3 \\ T_4 \\ T_5 \end{bmatrix} = \begin{bmatrix} 15876 \\ 0 \\ 0 \\ 22491 \end{bmatrix}$$

The solution is found to be

$$[T_2 \quad T_3 \quad T_4 \quad T_5] = [15.8523 \quad 19.9266 \quad 26.5205 \quad 81.5909]°C$$

FORMULATION OF GLOBAL STIFFNESS MATRIX FOR *N* ELEMENTS

Let us consider a body discreditized into N one-dimensional elements, as shown in Fig. 20.4.17. Let the boundary conditions be such that

$$T_1 = T_{N+1} = 0 \tag{20.4.124}$$

The connectivity of the rod elements, which is determined by the same procedure outlined in Table 20.4.3 for trusses is used to define the

Fig. 20.4.17 Discretization of a heat conduction rod into N elements.

global conductivity matrix, which is of order $(N + 1) \times (N + 1)$. The ascending order of the elements helps the global K take a special form with a predictable bandwidth.

$$N\begin{bmatrix} 1 & -1 & 0 & & & 0 \\ -1 & 1+1 & -1 & & & \\ 0 & -1 & 1+1 & -1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ & & & -1 & 1+1 & -1 \\ 0 & & & 0 & -1 & 1 \end{bmatrix}\begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ \vdots \\ T_{N+1} \end{bmatrix} = \begin{bmatrix} \frac{1}{2N} \\ \frac{1}{2N}+\frac{1}{2N} \\ \frac{1}{2N}+\frac{1}{2N} \\ \vdots \\ \frac{1}{2N} \end{bmatrix} \tag{20.4.125}$$

where f is assumed 1 for simplicity. Applying the boundary conditions reduces the problem to

$$\begin{bmatrix} 2 & -1 & 0 & & & 0 \\ -1 & 2 & -1 & & & \\ 0 & -1 & 2 & -1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ & & -1 & 2 & & -1 \\ & & 0 & -1 & & 2 \end{bmatrix}\begin{bmatrix} T_2 \\ T_3 \\ \vdots \\ T_{N-1} \\ T_N \end{bmatrix} = \frac{1}{N^2}\begin{bmatrix} 1 \\ 1 \\ 1 \\ \vdots \\ 1 \\ 1 \end{bmatrix} \tag{20.4.126}$$

EXAMPLE For the one-dimensional heat transfer problem given by $d^2T/dx^2 = -10$, where $A = 1$ $(0 \le x \le 1$ with $T(0) = 0)$, find the temperature at $x = 0.2$, 0.4, 0.6, 0.8 and 1.0 m (Fig. 20.4.18).

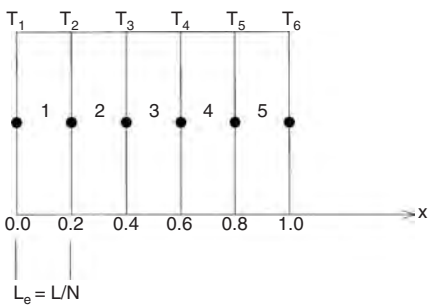

Fig. 20.4.18

Solution: Each element has an element conductivity matrix K_e of the form:

$$K_e = \frac{kA}{L_e}\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}$$

Substituting $A = 1$ m^2 and $L_e = L/N = \frac{1}{5} = 0.2$ m, and assuming the conductivity constant to be $k = 1$, we evaluate the element conductivity matrix:

$$K_e = 5\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}$$

Using the connectivity table, we expand the local matrices K_s^e to an order of 5×5, and the global matrix $[K]$ is obtained by summation:

$$[K] = 5\begin{bmatrix} 1 & -1 & 0 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 & 0 \\ 0 & 0 & -1 & 2 & -1 & 0 \\ 0 & 0 & 0 & -1 & 2 & -1 \\ 0 & 0 & 0 & 0 & -1 & 1 \end{bmatrix} \qquad T = \begin{bmatrix} 0 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \\ 0 \end{bmatrix}$$

With application of the boundary conditions, the global temperature vector becomes $\{T\}$, shown above.

The forcing vector for an element is shown to be

$$F_e = \frac{fAL_e}{2}\begin{bmatrix} 1 \\ 1 \end{bmatrix}$$

where f is the heat generation per unit volume and is obtained from the relation $\kappa\, d^2T/dx^2 = -f$. Substituting $\kappa = 1$ and $d^2T/dx^2 = -10$ yields $f = 10$. Substituting into F^e those values, we get

$$F_e = \begin{bmatrix} 1 \\ 1 \end{bmatrix}$$

Assembling the global forcing vector, using the connectivity table, yields F, and using the relation $[K]\{T\} = \{F\}$, we write

$$5\begin{bmatrix} 1 & -1 & 0 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 & 0 \\ 0 & 0 & -1 & 2 & -1 & 0 \\ 0 & 0 & 0 & -1 & 2 & -1 \\ 0 & 0 & 0 & 0 & -1 & 1 \end{bmatrix}\begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \\ T_6 \end{bmatrix} = \begin{bmatrix} 1 \\ 2 \\ 2 \\ 2 \\ 2 \\ 1 \end{bmatrix} = F = \begin{bmatrix} 1 \\ 1+1 \\ 1+1 \\ 1+1 \\ 1+1 \\ 1 \end{bmatrix}$$

By deleting the first and last rows together with their corresponding columns, and modifying the force vector, we obtain

$$\begin{bmatrix} 2 & -1 & 0 & 0 \\ -1 & 2 & -1 & 0 \\ 0 & -1 & 2 & -1 \\ 0 & 0 & -1 & 2 \end{bmatrix}\begin{bmatrix} T_2 \\ T_3 \\ T_4 \\ T_5 \end{bmatrix} = \begin{bmatrix} 0.4 \\ 0.4 \\ 0.4 \\ 0.4 \end{bmatrix}$$

Note that $T_2 = T_5$ and $T_3 = T_4$. From symmetry, we can solve the equation very easily. The solutions are as follows:

$$\begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \\ T_6 \end{bmatrix} = \begin{bmatrix} 0 \\ 0.8 \\ 1.2 \\ 1.2 \\ 0.8 \\ 0 \end{bmatrix} ^\circ\text{C}$$

2-D HEAT CONDUCTION ANALYSIS

In a fashion similar to the one-dimensional analysis, the finite-element method can be used to analyze 2-D and 3-D heat conduction problems. Let us examine the 2-D case and bear in mind that, first, we need to develop the element temperature relationship and then expand it to the global problem.

The heat conduction problem is formulated by a variational boundary value problem as

$$\delta I = 0 \tag{20.4.127}$$

where

$$I = \frac{1}{2}\int_\Omega [k(\nabla T)^2 + 2fT]\, d\Omega \tag{20.4.128}$$

and where k = thermal conductivity, which we assume is constant; f = heat source; ∇T = temperature gradient; $(\nabla T)^2 = \nabla T \cdot \nabla T$ (a dot product); Ω = domain of interest. Note that the heat convection

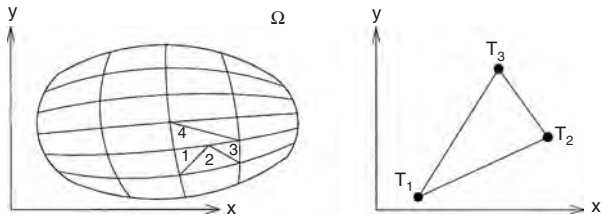

Fig. 20.4.19

part is neglected. If domain Ω is divided into N elements, as shown in Fig. 20.4.19, then

$$I = \sum_{e=1}^{N} I^e \tag{20.4.129}$$

where

$$I^e = \frac{1}{2}\int_e [k(\nabla T^e)^2 + 2f^e T^e]\, d\Omega \tag{20.4.130}$$

Let us consider the triangular element shown in Fig. 20.4.19. The local representation of the temperature can be expressed as

$$T(x,y) = T_1N_1 + T_2N_2 + T_3N_3 \tag{20.4.131}$$

where $N_i(x, y)$ $(i = 1, 2, 3)$ are the shape functions given by

$$N_i^e = a_i^e + b_i^e x + c_i^e y \tag{20.4.132}$$

The shape functions must satisfy the following conditions:

1. N_i^e (x, y) are linear in both x and y.
2. N_i^e (x, y) have the value 1 at node i and zero at other nodes.
3. N_i^e (x, y) are zero at all points in Ω, except those of N_i^e (x, y) can be written as

$$N_i(x, y) = [a_i \quad b_i \quad c_i]\begin{bmatrix}1\\ x\\ y\end{bmatrix} \tag{20.4.133}$$

and for the three nodes of the triangular element, we can write

$$\begin{bmatrix}N_1\\ N_2\\ N_3\end{bmatrix} = \begin{bmatrix}a_1 & b_1 & c_1\\ a_2 & b_2 & c_2\\ a_3 & b_3 & c_3\end{bmatrix}\begin{bmatrix}1\\ x\\ y\end{bmatrix} \tag{20.4.134}$$

For node 1, following condition 1, Eq. (20.4.134) yields

$$\begin{aligned} N_1 &= 1 = a_1 + b_1x_1 + c_1y_1\\ N_2 &= 0 = a_1 + b_1x_2 + c_1y_2\\ N_3 &= 0 = a_1 + b_1x_3 + c_1y_3 \end{aligned} \tag{20.4.135}$$

Which can be written in matrix form as

$$\begin{bmatrix}1\\ 0\\ 0\end{bmatrix} = [A]\begin{bmatrix}a_1\\ b_1\\ c_1\end{bmatrix} \tag{20.4.136}$$

where

$$[A] = \begin{bmatrix}1 & x_1 & y_1\\ 1 & x_2 & y_2\\ 1 & x_3 & y_3\end{bmatrix} \tag{20.4.137}$$

Solving for coefficients a, b, and c, we get

$$\begin{bmatrix}a_1\\ b_1\\ c_1\end{bmatrix} = \begin{bmatrix}1 & x_1 & y_1\\ 1 & x_2 & y_2\\ 1 & x_3 & y_3\end{bmatrix}^{-1}\begin{bmatrix}1\\ 0\\ 0\end{bmatrix} = [A]^{-1}\begin{bmatrix}1\\ 0\\ 0\end{bmatrix} \tag{20.4.138}$$

Similarly, for the interpolation functions N_2 and N_3, we get

$$\begin{bmatrix}a_2\\ b_2\\ c_2\end{bmatrix} = [A]^{-1}\begin{bmatrix}0\\ 1\\ 0\end{bmatrix} \quad \text{and} \quad \begin{bmatrix}a_3\\ b_3\\ c_3\end{bmatrix} = [A]^{-1}\begin{bmatrix}0\\ 0\\ 1\end{bmatrix} \tag{20.4.139}$$

The inverse of matrix A is

$$[A]^{-1} = \frac{1}{2a}\begin{bmatrix}(x_2y_3 - x_3y_2) & (y_2 - y_3) & (x_3 - x_2)\\ (x_3y_1 - x_1y_3) & (y_3 - y_1) & (x_1 - x_3)\\ (x_1y_2 - x_2y_1) & (y_1 - y_2) & (x_2 - x_1)\end{bmatrix} \tag{20.4.140}$$

where a is the area of the triangle. By combining Eqs. (20.4.138) and (20.4.139), we obtain the inverse of A as

$$[A]^{-1} = \begin{bmatrix}a_1 & b_1 & c_1\\ a_2 & b_2 & c_2\\ a_3 & b_3 & c_3\end{bmatrix} \tag{20.4.141}$$

Then the triangle element functions can be written in a more general form:

$$\{N^e\} = \begin{bmatrix}N_1\\ N_2\\ N_3\end{bmatrix} = [A]^{-1}\begin{bmatrix}1\\ x\\ y\end{bmatrix} \tag{20.4.142}$$

where

$$\begin{aligned} N_1 &= \frac{1}{2a}[(x_2y_3 - x_3y_2) + x(y_2 - y_3) + y(x_3 - x_2)]\\ N_2 &= \frac{1}{2a}[(x_3y_1 - x_1y_3) + x(y_3 - y_1) + y(x_1 - x_3)]\\ N_3 &= \frac{1}{2a}[(x_1y_2 - x_2y_1) + x(y_1 - y_2) + y(x_2 - x_1)] \end{aligned} \tag{20.4.143}$$

Now that we have defined the shape function, we can proceed in the evaluation of the conductivity matrix of individual elements.

Element Conductivity Matrix

From Eq. (20.4.130), we write the variational equation in terms of elements. This defines the element equation as

$$I^e = \frac{1}{2}\int [k^e(\nabla T)^2 + f^eT^e]\, d\Omega \tag{20.4.144}$$

The temperature at the nodes of the triangle element is expressed following the triangular element assumption developed in a previous section where

$$T(x, y) = T_1N_1 + T_2N_2 + T_3N_3 \tag{20.4.145}$$

From Eq. (20.4.143), we define the partial derivatives with respect to x and y as

$$\frac{\partial N_i}{\partial x} = b_i \quad \text{and} \quad \frac{\partial N_i}{\partial y} = c_i \tag{20.4.146}$$

Hence, we can write the gradient of the temperature as follows

$$\nabla T = \begin{bmatrix}\dfrac{\partial T}{\partial x}\\ \dfrac{\partial T}{\partial y}\end{bmatrix} = \begin{bmatrix}\dfrac{\partial N_1}{\partial x} & \dfrac{\partial N_2}{\partial x} & \dfrac{\partial N_3}{\partial x}\\ \dfrac{\partial N_1}{\partial y} & \dfrac{\partial N_2}{\partial y} & \dfrac{\partial N_3}{\partial y}\end{bmatrix}\begin{bmatrix}T_1\\ T_2\\ T_3\end{bmatrix} \tag{20.4.147}$$

which, expressed in compact form, yields $\Delta T = BT$, where

$$B = \begin{bmatrix}b_1 & b_2 & b_3\\ c_1 & c_2 & c_3\end{bmatrix} \quad \text{and} \quad T = \begin{bmatrix}T_1\\ T_2\\ T_3\end{bmatrix} \tag{20.4.148}$$

Note how the coefficients of B are obtained from the partial derivatives of the shape functions given by Eq. (20.4.149).

Now we can define the $(\nabla T)^2$ needed in Eq. (20.4.150).

$$(\nabla T)^2 = \begin{bmatrix} \frac{\partial T}{\partial x} & \frac{\partial T}{\partial y} \end{bmatrix} \begin{bmatrix} \frac{\partial T}{\partial x} \\ \frac{\partial T}{\partial y} \end{bmatrix} \tag{20.4.149}$$

For a given element, this equation can be expressed as

$$[\nabla T^e]^2 = \{T^e\}^T [B^e]^T [B^e] \{T^e\} \tag{20.4.150}$$

This yields

$$I_1^e = \frac{1}{2} k \int_e \{T^e\}^T [B^e]^T [B^e] \{T^e\} \, d\Omega \tag{20.4.151}$$

Because $[B]$ and $[T]$ are constant matrices, Eq. (20.4.151) reduces to

$$I_1^e = \frac{1}{2} k \{T^e\}^T [B^e]^T [B^e] \{T^e\} \int_e d\Omega \tag{20.4.152}$$

or simply

$$I_1^e = \frac{1}{2} \{T^e\}^T [k^e] \{T^e\} \tag{20.4.153}$$

where $[k^e]$ denotes the element conductivity matrix:

$$[K^e] = \kappa a [B^e]^T [B^e] \tag{20.4.154}$$

This takes the final form

$$[K^e] = \kappa a \begin{bmatrix} (b_1^2 + c_1^2) & (b_1 b_2 + c_1 c_2) & (b_1 b_3 + c_1 c_3) \\ (b_2 b_1 + c_2 c_1) & (b_2^2 + c_2^2) & (b_2 b_3 + c_2 c_3) \\ (b_3 b_1 + c_3 c_1) & (b_3 b_2 + c_3 c_2) & (b_3^2 + c_3^2) \end{bmatrix} \tag{20.4.155}$$

and a is the area of the triangular element.

Element-Forcing Function

To complete the integration of Eq. (20.4.144), we need to evaluate the second term, I_2^e.

$$I_2^e = \int f^e T^e d\Omega \tag{20.4.156}$$

As we have done with temperature, the heat source f can be expressed in a similar fashion:

$$f = f_1 N_1 + f_2 N_2 + f_3 N_3 = \begin{bmatrix} f_1 & f_2 & f_3 \end{bmatrix} \begin{bmatrix} N_1 \\ N_2 \\ N_3 \end{bmatrix} \tag{20.4.157}$$

For an arbitrary element, this equation can be written in compact matrix form:

$$f^e = \{f^e\}\{N^e\} \tag{20.4.158}$$

Recall that

$$T = T_1 N_1 + T_2 N_2 + T_3 N_3 = \begin{bmatrix} N_1 & N_2 & N_3 \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \\ T_3 \end{bmatrix} \tag{20.4.159}$$

or

$$T^e = \{N^e\}^T \{T^e\} \tag{20.4.160}$$

Therefore, I_2^e after substitution becomes

$$I_2^e = \int \{f^e\}\{N^e\}\{N^e\}^T \{T^e\} \, d\Omega = \{g^e\}\{T^e\} \tag{20.4.161}$$

where

$$\{g^e\}^T = \{f^e\}^T \int \{N^e\}\{N^e\}^T d\Omega \tag{20.4.162}$$

The integrand $\{N^e\}\{N^e\}^T$ yields

$$\{N^e\}\{N^e\}^T = [A]^{-1} \begin{bmatrix} 1 \\ x \\ y \end{bmatrix} \begin{bmatrix} 1 & x & y \end{bmatrix} [A^T]^{-1}$$

$$= [A]^{-1} \begin{bmatrix} 1 & x & y \\ x & x^2 & xy \\ y & xy & y^2 \end{bmatrix} [A^T]^{-1} \tag{20.4.163}$$

Note that $[A]$, given by Eq. (20.4.137), is a constant matrix, therefore the integral of $\{g\}$ depends only on the matrix with variables x and y. Integrating each element of the matrix is rather tedious and time-consuming. An alternative is to use a method developed by Eisenberg and Malvern.

From this method, we have the following statement of the integral:

$$\int_e N_1^m N_2^n N_3^p \, d\Omega = \frac{m!n!p!}{(m + n + p + 2)!} 2a \tag{20.4.164}$$

$$\{g^e\} = \left[\int_e \{N^e\}\{N^e\}^T d\Omega \right] \{f^e\} \tag{20.4.165}$$

Hence,

$$\{g^e\} = \left\{ \int \begin{bmatrix} N_1^2 & N_1 N_2 & N_1 N_3 \\ N_2 N_1 & N_2^2 & N_2 N_3 \\ N_3 N_1 & N_3 N_2 & N_3^2 \end{bmatrix} d\Omega \right\} \{f^e\} \tag{20.4.166}$$

which yields

$$\{g^e\} = \frac{a}{12} \begin{bmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{bmatrix} \{f^e\} \tag{20.4.167}$$

The element integral of the variational formulation is broken into two parts:

$$I^e = I_1^e + I_2^e \tag{20.4.168}$$

Which simplifies to

$$I^e = \frac{1}{2} \{T^e\}^T [k^e] \{T^e\} + \{g^e\}^T \{T^e\} \tag{20.4.169}$$

The "global integral" over the domain Ω of the entire body becomes

$$I = \sum_{e=1}^{N} I^e = \sum \left\{ \frac{1}{2} \{T^e\}^T [k^e] \{T^e\} + \{g^e\}^T \{T^e\} \right\} \tag{20.4.170}$$

or

$$I = \frac{1}{2} \{T\}^T \left[\sum_{3=1}^{N} [k^e] \right] \{T\} - \left[\sum_{e=1}^{N} \{F^e\}^T \right] \{T\} \tag{20.4.171}$$

where $\{F^e\}^T = -\{g^e\}^T$ and $\{T\} = [T_1 T_2 \ldots T_n]^T$. Hence,

$$I = \frac{1}{2} \{T\}^T [k] \{T\} - \{F\}^T \{T\} \tag{20.4.172}$$

where the global conductivity matrix is defined by

$$[k] = \sum_{e=1}^{N} [k^e] \tag{20.4.173}$$

and the global function (equivalent to the global force in the analysis of a truss) is

$$\{F\} = \sum_{e=1}^{N} \{F^e\} \tag{20.4.174}$$

The variation $\delta I = 0$ is equivalent to

$$\frac{\partial I}{\partial T_i} = 0 \qquad (i = 1, \ldots, n) \tag{20.4.175}$$

Applying Eq. (20.4.175) to Eq. (20.4.171) gives the global equation governing the temperature distribution and the heat source:

$$[k]\{T\} = \{F\} \tag{20.4.176}$$

This equation is similar to our FEM application to the truss and the one-dimensional heat flow problems.

Analysis of 2-D heat conduction problems can be done by using the FEM procedures developed herein. One proceeds by identifying the element shape functions and then evaluate the corresponding local conductivity (stiffness) matrices. The global $[K]$ is then assembled, using Eq. (20.4.173), and the elements' forcing functions are computed, using Eq. (20.4.167). Finally the global array $\{F\}$ is assembled according to Eq. (20.4.174).

20.5 COMPUTER-AIDED DESIGN, COMPUTER-AIDED ENGINEERING, AND VARIATIONAL DESIGN

by Farid Amirouche

INTRODUCTION

Computer-aided design (CAD) has gained tremendous popularity in the past decade, and it is becoming an absolutely necessary tool for any engineering task. Its application is broadening, and its success is due mostly to the mass production of powerful microprocessors and their low cost.

Computer-aided design is the blending of human and machine, working together to achieve the optimum design and manufacture of a product. The computer's graphics capability and computing power allow designers to fashion and test their ideas interactively in real time without having to create real prototypes as in conventional approaches to design.

CAD has revolutionized engineering over the past two decades, and engineering design has become the engine to a successful company. The road between the product in its initial design stages and the mature design ready to go into production is lined with a series of prototypes needed to evaluate the ongoing design. **Virtual reality** offers a novel

approach in product development, especially in the early stages of a development process. Virtual models are CAD prototypes that can be displayed on a computer screen for the purpose of getting a view into what reality might be and how to prepare for the product use.

PARAMETRIC AND VARIATIONAL DESIGN

Designing and drafting are the preliminary steps carried out in the manufacture of a component. Traditional mechanical CAD systems are effective tools in improving the efficiency of the drafting process, but they cannot handle the task of design and drafting at the same time. This forces the engineer to think simultaneously about all the design requirements and engineering relationships for each design approach.

Several new CAD systems claim to meet the needs of engineers engaged in the preliminary design of mechanical products. These systems should enhance the level of productivity of engineers in creating or modifying designs. Two approaches that are gaining popularity for providing flexibility in the design process are parametric design and variational design.

Parametric Design Systems

In a parametric design, the engineer selects a set of geometric constraints that can be applied for creating the geometry of the component. The geometric elements include lines, arcs, circles, and splines. A set of engineering equations can also be used to define the dimensions of the component.

From a given set of geometric constraints, the basic dimensions of the component can be defined. The set of geometric constraints would be regarded as a set of instructions that when executed would create the desired geometry. Hence any change to the known entities would yield a different picture altogether. So the objective is to create a geometric relationship between entities to minimize time and effort spent on design.

Parametric design systems help users manipulate the length, angle, and pitch of a particular component. These systems also have the ability to record engineering relationships within a design: they enable users to pinpoint the complex relationships that exist among parts of an assembly. A simple example would be the meshing of two gears. Thus the use of parametric design clarifies users' understanding of the engineering aspects of a component. Moreover, the parametric system can produce designs that are more meaningful than those generated by traditional CAD systems. Designers, analysts, and production engineers can work with the same solid model, extracting and adding information according to need.

A drawback of this system is that it is constrained to the set of geometric or engineering relationships provided by the engineer for creating the design of a component. The limited set of geometric constraints can make it difficult to change a parametric design model once the initial conditions have been set. These systems are best suited for design tasks that do not involve many variations in the design approach. Software equipped with such an option is therefore an excellent tool for design. Such software gives the designer flexibility to avoid redrawing objects and minimizes the time involved in arriving at a final product design.

Variational Design Systems

This technique can simultaneously solve a set of geometric constraints and engineering equations with important relationships among the elements of design. Essentially, the design is governed by a set of engineering equations relating its geometry and functions.

Unlike the parametric approach, a variational system is able to determine the positions of geometric elements and constraints. In addition, it is structured to handle the coupling between parameters in the geometric constraints and the engineering equations. The variational design concept helps the engineer evaluate the design of a component in depth instead of considering only the geometric aspects to satisfy the design relationships. This can be illustrated by the following example.

In design, one knows the performances and characteristics wanted for a developing product but does not know the geometric dimensions, material characteristic, etc. A good design starts with an appropriate set of parameters. The process of finding a set of parameters is done through optimization. Variational design has the ability to incorporate optimization into the design environment. The engineer can specify both equality and inequality design constraints. The objective function is a set of both dependent and independent variables that are optimized (minimized or maximized) relative to one or more independent variables.

Variational Design Applications

In their work Hofer and Pottmann[12] presented a solution for variational motion design of a rigid body in the presence of rigid obstacles of arbitrary shape that fully employs the available degrees of freedom in the design process. The main idea is to reduce the problem to a curve design task on a suitable barrier surface embedded in an appropriate kinematic image space (see Fig. 20.5.1).

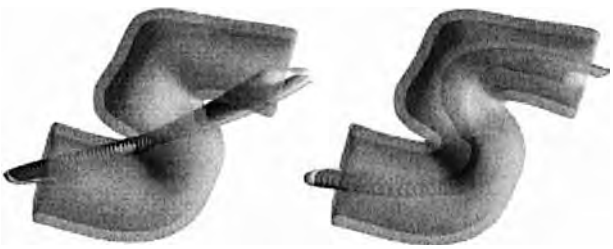

Fig. 20.5.1 Motion of a rigid body passing through a narrow channel.

This is an investigation of a 3-D shape reconstruction from measurement data in the presence of constraints. The constraints may fix the surface type or set geometric relations between parts of an object's surface, such as orthogonality, parallelity, and others. The authors of this work (see Fig. 20.5.2) have proposed to use a combination of surface fitting and registration within the geometric optimization framework of **squared distance minimization** (SDM). In this way, one obtains a **quasi-Newtonian** like optimization algorithm, which in each iteration simultaneously registers the data set with a rigid motion to the fitting surface and adapts the shape of the fitting surface. Figure 20.5.2 highlights the applicability of the method to constrained 3-D shape fitting for reverse engineering of CAD models and to high-accuracy fitting with kinematic surfaces, which include surfaces of revolution (reconstructed from fragments of archeological pottery) and spiral surfaces, which are fitted to 3-D measurement data of shells.

Innovative Process in Product Development

The focus and ultimate goal of an engineer is to be able to answer the following questions: Does my design (geometry) and my choices of material allow my product to achieve the performance required by the technical specifications? What is the optimum achievable performance? Will my design be sensitive to manufacturing tolerances? Answering the first question requires us to solve a set of equations relating output

Fig. 20.5.2 Approximation of a broken archeological finding by using inverse engineering.

and input conditions. The known quantities are the various targeted performances of a **product** (for example, static or modal behavior), and the unknowns of that problem are of various kinds: geometric dimensions, material characteristics, shell thickness, number of stiffeners, and density of weld spots, for example. A good design is a design where parameters have the appropriate values. Usually, these good values are not unique. The conventional way to solve the inverse problem is to use optimization techniques. The solution of an optimization problem is one set of parameter values that satisfies mathematical criteria. Even if simple criteria such as maximum stress or first Eigen frequency are mathematical criteria, these criteria rarely take into account manufacturing process constraints or the invaluable know-how of the engineer. Furthermore, finding the best point does not give any information on the global quality of the solution and its stability. Most of the optimization algorithms used in common practice are local algorithms that only find the closest point to the initial design.

ENGINEERING ANALYSIS AND CAD

Analysis is of two types: analytical and experimental. Both are performed to assess product performance.

Analytical Methods

In the analytical approach, different types of analysis can be carried out by using various software packages available for computer-aided design. These include finite-element analysis, kinematics analysis and synthesis, and static and dynamic analysis.

Finite-Element Analysis Finite-element analysis (FEA) is a computer-assisted technique for determining stresses and deflections in a structure. The method divides a structure into small elements with known shapes for which a mathematical solution can be found; then the global problem is solved by using an assembly procedure (see Sec. 20.4).

The first step in FEA is the creation of a model that breaks the structure into simple standardized shapes and plots it on a common coordinate grid system. The coordinate points are called *nodes* and serve as the locations in the model where output data is provided. Nodal stiffness properties are then calculated by the finite-element program for each element and arranged into matrices within the computer. These parameters are then processed with applied loads and boundary conditions or calculations of displacement, natural frequencies, strains, and engineering functions useful in interpreting the results. An application of FEA is biomechanics, as shown in Fig. 20.5.3.

In most cases, finite-element models are developed for prototype designs for which experimental data exist so that FEA results can be cross-checked and design modifications can be made. Modifications are also tested for actual prototypes.

Kinematics and Synthesis Mechanisms are devices used to transfer motion and/or force from a given source to an output device. The efficiency with which this transfer is accomplished depends on the mechanism design. General-purpose programs like Linkages, IMP, ADAMS, Unigraphics, and MCADA are available today to assist engineers in the kinematic analysis and synthesis of those systems. Kinematics starts with the mechanism design. It calculates large displacements, velocities, and accelerations of mechanisms without regard to the forces acting on them. The mechanism assumes zero degrees of freedom. This means that each degree of freedom (coordinate) is constrained to a particular type of motion. The advantages of combining the study of mechanisms with CAD are that it enables the design's output to be optimized and it eliminates interferences between links.

Synthesis analysis is concerned with arriving at the best characteristics of a mechanism through a set of computer iterations. The designer provides the parameters of the mechanism and the program develops the alternatives.

The first step before doing a synthesis analysis is deciding various parameters of the mechanism, such as number of links, joints, joint types, and connectivity of links by specifying which links are fixed. The basic linkage types are defined as kinematic chains within the program. The synthesis analysis is then carried out, and the mechanism structures satisfying the design objectives are determined. These programs are generally used to design four-bar linkages, although they can be used to design six-bar linkages.

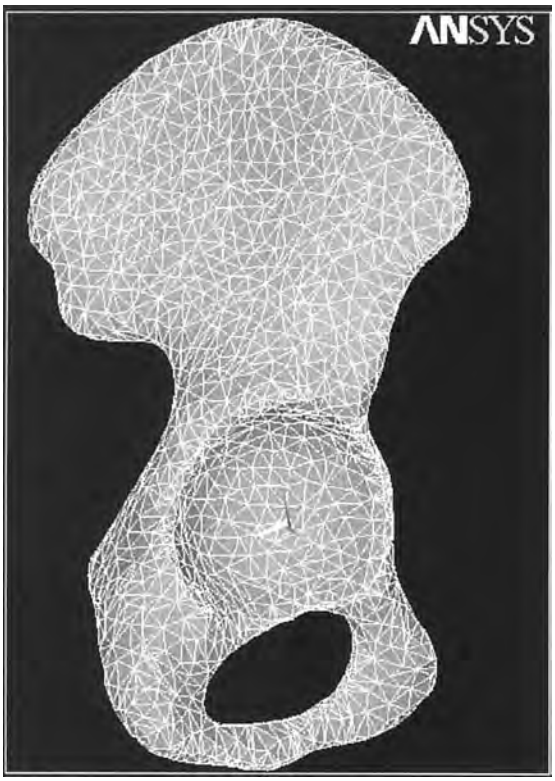

Fig. 20.5.3 Application of FEA in biomechanics. Figure illustrates finite-element model of right half of human pelvic bone.

Some kinematic synthesis programs use graphics to make the software user-friendly. The user specifies points and motion vectors via interactive graphics that can be easily moved about the screen. After a number of points have been specified, the program displays all possible locations of additional points to complete the mechanism. Some software also allows the user to animate the mechanism on the screen to check for criteria such as clearances of moving links.

Static Analysis and Dynamic Analysis Static analysis combines motion analysis with mass properties and force input data to determine positions and joint reaction forces of mechanisms at rest. Static analysis can also be done on mechanisms at various points in their range of movement if zero velocity is assumed. Static models can have multiple degrees of freedom. Motion and force are uncoupled in this type of analysis. In static analysis, we are mostly concerned with the reaction forces on the mechanical systems and their joints' interconnection forces. Knowing these latter forces is useful in stress analysis to determine engineering criteria such as performance, reliability, and fatigue.

Dynamic analysis uses mass properties and forces to calculate positions, velocities, accelerations, and joint and constraint reaction forces of all model parts when motion is coupled to forces in the system. Analysis is done in discrete steps within a specified time interval. Each degree of freedom in a dynamic model is associated with an independent coordinate for which the analyst has to specify both the initial position and velocity. The computer models for dynamic analysis include geometric data and mass properties of the structure as well as applied forces. The model is generally created through part, joint, marker, force, and generator statements that are input by the user.

Part statements define the geometry, mass, and moment of inertia of each rigid part of the structure. Joint statements describe contacts between moving parts that hold the assembly together. Joints can be specified as providing translational and rotational movement, including that of revolute, screw, spherical, universal, cylindrical, and translational joints. Marker statements provide a point or coordinate system fixed on each part, orienting it to other parts and together defining the overall configuration of the system. Internal reaction forces are selected from a library of standard force elements such as dampers and linear springs. User-written routines can also be used to define additional parameters. Basic geometric data from CAD programs can be sent through direct interfaces. Because complete geometric description is not required, mechanical analysis can be used early in the design cycle, before the final configuration is known. Engineers can design the system knowing only mass and inertia characteristics.

The dynamic analysis output is typically available in tabular form. Graphics can be produced showing output such as force-versus-time or force-versus-displacement characteristics. In some cases, animation is reproduced from the combination of dynamic analysis data and geometry representation of the object. Software capable of performing such a task includes ADAMS, DADS, DISCOS, DYAMUS, DARS, and DYNACOMBS.

Experimental Testing The second aspect of analysis deals with experimental methods in which testing is conducted on prototypes and models either to extract material properties or to validate performance characteristics of a particular design.

Testing in the conventional design process is done to qualify the design after manufacturing. The goal in computer-aided design is to use testing throughout the development cycle and to make better use of the test data through more advanced analysis techniques and to integrate these with other disciplines involved in design.

Initial testing can be done on a prototype or on different components to understand model response to certain loading conditions. Experimental data are extremely useful in the analysis of models where analytical solutions are not reliable. The data can also be used to refine finite-element models for large-scale analysis. The integration of experimental testing with analytical tools results in more effective engineering analysis. Computer-aided design provides the ultimate tool for combining such methods with the graphics capabilities to allow the designer to arrive at realistic and effective designs in a minimum span of time.

Additional experimental analyses include fatigue testing to estimate part life from strain gage measurements and modal testing to extract natural frequency and mode shapes, response functions, and a number of engineering functions in heat transfer, fluid dynamics, and thermodynamics.

COMPUTER-AIDED ENGINEERING (CAE)

According to J. R. Lemon, computer-aided engineering (CAE) is a product design and development philosophy, which combines three key engineering elements in an integrated environment for all engineering functions within each stage of the product development cycle. These elements are applications (performance, structural integrity, reliability, costs, etc.), facilities (hardware/software), and technology (data and information management). Thus, the CAE approach results in the restructuring and streamlining of the entire engineering process itself instead of the automation of specific steps in the current process such as has been the case in computer-aided design (CAD) and computer-aided manufacturing (CAM) activities.

The CAE approach places emphasis in terms of time and money on the initial conceptual design phases. This revised allocation of resources results in extensive analysis and testing to guide product design iterations in the computer as opposed to making physical prototypes. This is a major departure from current methods in most mechanical industries, where prototype manufacture and tests are the fundamental means of evaluating product performance and quality. However, the need for prototypes is not eliminated, but the reduction in the number of prototypes needed before full production can go ahead results in significant time and cost savings.

The CAE approach to mechanical product development emphasizes system analytical modeling and analysis techniques at the earliest phase of design, that is, conceptual design. The process starts with an integrated set of total system simulations of the entire product. Each alternative product concept is mathematically modeled as an entire system. At this point, overall product designers have the flexibility of defining significantly varying concepts in order to minimize weight, reduce energy consumption and maximize performance for acceptable product concepts.

Detailed component and subassembly design specifications are derived from system models by exercising computer simulations under severe environmental conditions and external product loadings. In addition, internal loads, duty cycles, and constraints acting on components and subassemblies at interfaces and connection points are derived from system models. System modeling and early development of product alternatives within the computer are essential differences compared with today's developments that rely on physical prototypes and build-and-test methods.

The new CAE approach attempts to integrate and automate various engineering functions in the entire product development process, which includes the following: (1) design, (2) analysis, (3) testing, (4) drafting, (5) documentation, (6) project management, (7) data management, (8) process planning (9) tool design, (10) numerical control, and (11) quality assurance. Improved product quality, increased market share, and greater profitability depend upon efficient and effective CAE integration and implementation. This is why CAE implementation has become a strategic issue in mechanical-related industries worldwide.

CAE IMPLEMENTATION

Implementation of an overall CAE system and its associated technologies must be planned carefully. Implementation should proceed step by step because it is not possible to switch off today's design, development, and manufacturing processes and switch on the CAE approach at the same time. As a first step toward CAE implementation, existing problems should be solved to gain knowledge and familiarity with the CAE system's capabilities and behavior.

A design audit is not simply a learning exercise; it is an important step to extend a basic product to a family of new products or to fix problems that may have developed. The next phase involves new product design and development. The CAE tools should be applied to a new and unique product design for which new concepts have the potential of providing strategic product quality and market share advantages. An optimum hardware system along with a similar integrated and distributed database management system should be configured for in-house usage and expected long-range expansion requirements. Software that performs efficiently should also be brought in house if it is economically justified.

Along with these tasks, outside CAE consultants are recommended to help guide and develop an overall CAE implementation plan. Educational programs and seminars in all aspects of CAE implementation are essential for all levels within an organization. Once CAE tools are implemented and the in-house organization structured to suit the particular CAE implementation philosophy, the outside consultant's role can be reduced to solving difficult problems.

VIRTUAL REALITY AND ITS APPLICATIONS TO PRODUCT DESIGN AND DEVELOPMENT

Virtual reality (VR) is a human-computer interface that aims at creating a realistic in-depth 3-D environment where manipulation and interaction of objects provides the user with an insight of the environment at the micro and macro scales through graphics and hepatics, providing the user a unique experience of a simulated reality.

Virtual reality has been used to visualize engineering and scientific concepts and offers new ways of training, enhancing the human

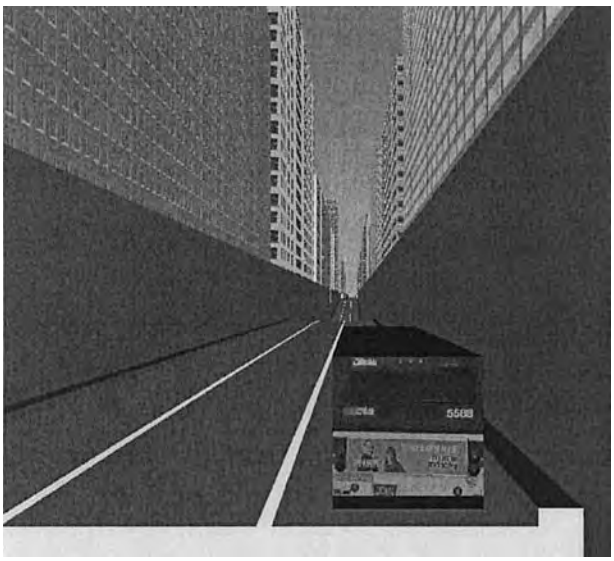

Fig. 20.5.4 Virtual reality simulation is used to develop an automated bus system and analyze the benefits of the automation process, such as decreased travel times and proper adherence to schedule.

computer interface and constructing graphically supported real-time simulation systems. An example of VR simulation is shown in Fig. 20.5.4.

Virtual reality technology is defined by three major qualities: **immersion, presence,** and **interactivity:** The user perceives the presence of the environment as real and at any time can travel through space, exploring and navigating through the environment without fear of collision. Feedback can be provided on making sensors and controls to provide the necessary information to the human to measure his or her interaction with the environment.

Computer simulation has for years been the backbone for all input/output displays by means of graphics. With the advent of CAD software, realistic models are created and simulation represents the execution of mathematical algorithms based on the models developed under some conditions described in the problem at hand. Simulation, unlike virtual reality, does not allow the user to interact but to observe an executed dynamic situation.

VR Application to Engineering

The typical VR display is a wall-projection display that uses either a large computer screen or a rear projection display. These systems can provide a good sense of depth but the feeling of immersion is very low. They are relatively inexpensive and nonintrusive. A greater impression of immersion may be achieved through **head-mounted** or **helmet-mounted displays (HMDs),** which consist of a pair of liquid-crystal display or cathode-ray tube display devices, mounted on a helmet worn by the user. In some HMDs there is only one display that is connected to a system of lenses and mirrors that conveys the image into the retinas of the eyes.

The **Cave Automatic Virtual Environment** (CAVE) was developed at the University of Illinois at Chicago, provides the illusion of **immersion** by projecting **stereo images** on the walls and floor of a room-sized cube. Several persons wearing lightweight stereo glasses can enter and walk freely inside the CAVE. A head tracking system continuously adjusts the stereo projection to the current position of the leading viewer.

In the example illustrated in Fig. 20.5.5, three networked users at different locations (anywhere in the world) meet in the same virtual world by using a BOOM device (a video display counterbalanced on a boom

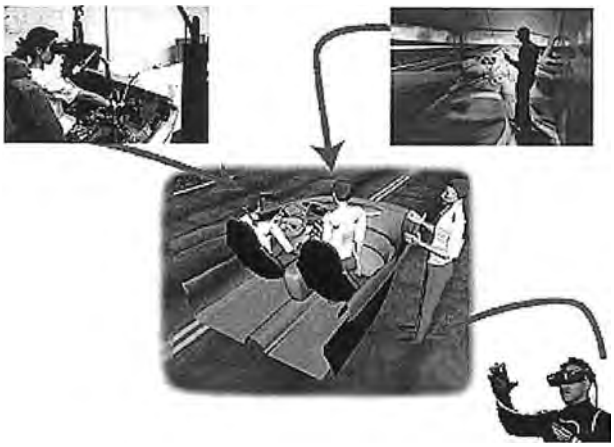

Fig. 20.5.5 Shared virtual environments.

support), a CAVE system, and a head-mounted display, respectively. All users see the same virtual environment from their respective points of view. Each user is presented as a virtual human (avatar) to the other participants. The users can see each other, communicate with each other, and interact with the virtual world as a team.

As the technologies of virtual reality evolve, the applications of VR become literally unlimited. It is assumed that VR will reshape the interface between people and information technology by offering new ways for the communication of information, the visualization of processes, and the creative expression of ideas.

Note that a virtual environment can represent any three-dimensional world that is either real or abstract. This includes real systems such as buildings, landscapes, underwater shipwrecks, spacecraft, archaeological excavation sites, human anatomy, sculptures, crime scene reconstructions, and solar systems. Of special interest is the visual and sensual representation of abstract systems like magnetic fields, turbulent-flow structures, molecular models, mathematical systems, auditorium acoustics, stock market behavior, population densities, information flows, and any other conceivable system including artistic and creative work of abstract nature. These virtual worlds can be animated, interactive and shared, and can expose behavior and functionality.

Useful applications of VR include training in a variety of areas (military, medical, equipment operation, etc.), education, design evaluation (virtual prototyping), architectural walk-through, human factors and ergonomic studies, simulation of assembly sequences and maintenance tasks, assistance for the handicapped, study and treatment of phobias (e.g., fear of height), entertainment, and much more. An application of immersive virtual reality is shown in Fig. 20.5.6.

Applying Virtual Environments to Manufacturing

Even though virtual environment technologies are still difficult and expensive to use, people are doing real work. The following case studies represent examples of recent state of the art work that exemplifies the application of virtual environments in one or several aspects of manufacturing. Manufacturing, in this case, is taken to encompass issues relating to maintenance and training as well as the actual creation of parts and the assembly of systems. These examples are actual systems, not simply speculative fantasies.

Boeing The Research and Technology organization of Boeing Computer Services is actively pursuing two projects using VR technology. Boeing uses a concept known as augmented reality.

Augmented reality is a term that refers to the ability to see through a computer-generated display. The generated images are superimposed

Fig. 20.5.6 Viewing a concept car in immersive virtual reality using the CAVE.

on top of reality. This is accomplished by projecting a computer image onto a half-silvered mirror that the user looks through. This technique provides an effective and intuitive way of **"annotating"** reality. The Boeing team is using a headset configured for augmented reality, which they call a HUD set (heads-up, see-through, head-mounted display).

The assembly of aircraft is a highly complex task that is difficult to automate. Many of the skills required demand dexterity not easily accomplished by robots. In addition, airplanes consist of many small-lot-size parts, and reprogramming robots for these quantities is an expensive prospect. Someone once said that a Boeing 747 is not really an airplane, but 5 million parts flying in close formation.

Caterpillar Caterpillar uses VR in its design and evaluation of heavy vehicles (Fig. 20.5.7). This technology allows the company to dramatically shorten the amount of time it takes to analyze a new design concept and incorporate it into the production process. It also represents a sizable cost savings because it eliminates the need to build prototype machines or make last-minute design changes. It takes 6 to 9 months to build full-scale models and make design changes, using conventional design methods. However, with the virtual reality approach, designs usually can be evaluated in less than 1 month. Such methods are currently being employed, and a number of other companies are fully invested in VR research and development. Today customers can "field-test" new products by putting on a special helmet and operating the vehicles in a VR environment.

PROTOTYPING ANALYSIS

A pioneering application of virtual reality was the NASA wind tunnel. A 3-D workstation generates flow-field visualizations. The user interacts with the simulation via a BOOM display and a data glove. (A BOOM is a video display counterbalanced on a boom support which the user easily moves with the head.) The data glove effectively acts as a source of "smoke," allowing the user to observe local flow lines. The computation of unsteady flow visualization occurs in real time and the user can view the dynamic scene from many points of view and scales. Since fluid dynamic phenomena occur over a large range of scales (several orders of magnitude in space), navigation through the virtual environment is more difficult than, say, architectural walk-through. Thus, in addition to "standard" viewing capabilities sensitive to head position and head orientation, our virtual environment lets the user rapidly change his or her scale, or the scale of the environment. Relative to the environment, a user can shrink to become completely surrounded by some small vortex or grow so that the entire flow field fits in one hand.

The role of a CAD workstation is to provide the means of graphically displaying the huge amount of data for visual inspection and quick review of the analysis. Finite-element programs have two types of data: the input required to run the program and the generated output that describes the behavior of the system under the assumed conditions. To further enhance communication between the user and the machine in which a particular finite-element program resides, many vendors of CAD software are developing pre- and postprocessors that allow the user to graphically visualize their input and output (see Fig. 20.5.8). Therefore, CAD workstations equipped with such software assist the user to interact with finite-element programs, thus minimizing the time required to learn how to use the FEM program. Most important, the graphics capability of CAD workstations provides the user the means of visual display of huge amounts of output, making the interpretation faster and more convenient.

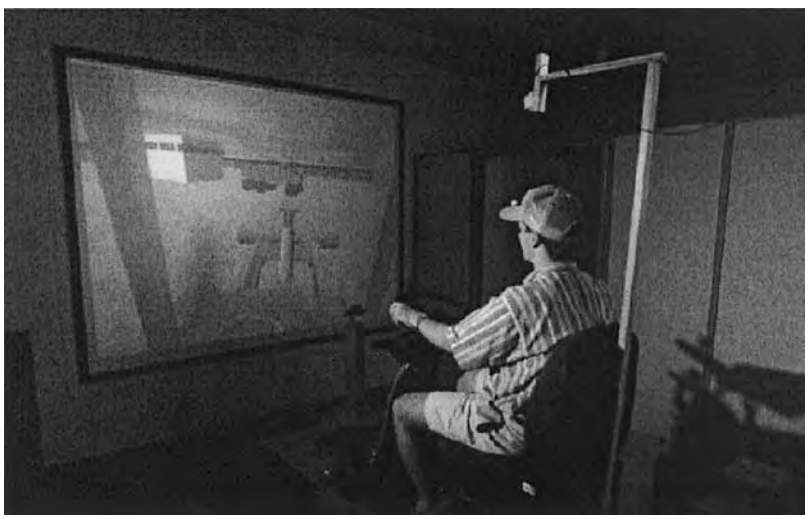

Fig. 20.5.7 Virtual backhoe project illustrates an "operator" driving the virtual equipment at the National Center for Supercomputing Applications. VR lab.

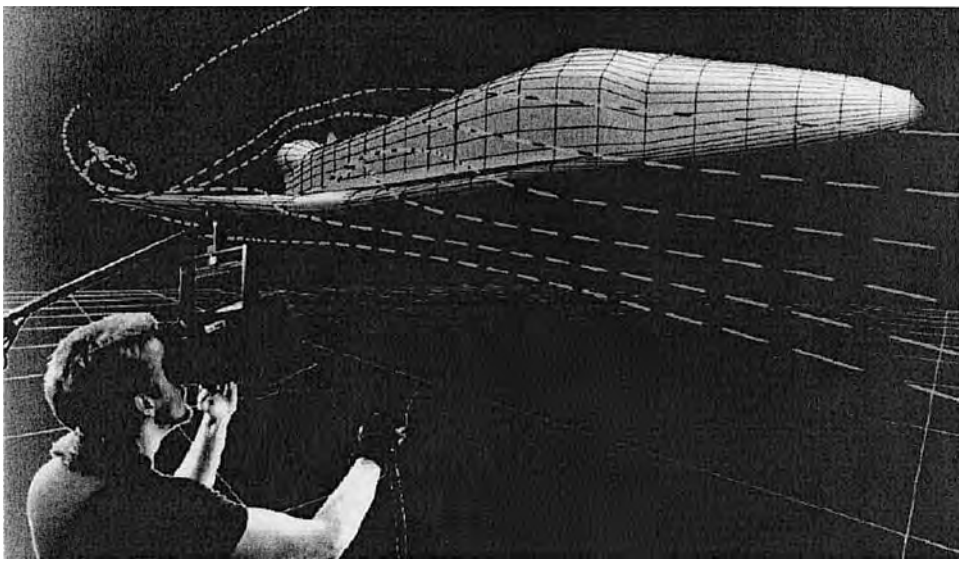

Fig. 20.5.8 NASA virtual wind tunnel product design.

THE USE OF VIRTUAL REALITY IN INTERACTIVE FINITE-ELEMENT ANALYSIS

Combining virtual reality (VR) with finite-element analysis (FEA) and executing interactive FEA provides an interface to implement comprehensive and intuitive analysis. A study of related research on and application of VR for interactive FEA has been completed. An overview of available VR systems and graphics APIs, and their suitability for interactive FEA/CAD, is presented here. FEA is quite developed in calculation with the improvement of computer techniques. There are two important procedures for FEA: preprocessing and the postprocessing. The preprocessor is used for setting up the model; the postprocessor is used for viewing the results. Three-dimensional visualization is already supported by currently available software, but 2-D is commonly used.

Engineers still need to imagine what is happening in a real 3-D world. Using VR in interactive FEA gives the preprocessor and the postprocessor a good method to describe the model and results in a 3-D world, which leads to a more intuitive and accurate understanding of design and construction. VR offers a real-time, full-scale interaction technique in the design period. For the iterative design procedure, real-time interactive FEA offers an excellent way to adjust the design. Apart from using VR in interactive FEA in the building and construction industry, it can also be used in the education of engineering students, to give students an intuitive understanding of the FEA technique.

20.6 INTRODUCTION TO COMPUTATIONAL FLUID DYNAMICS

by Doyle Knight

INTRODUCTION

Computational fluid dynamics (CFD) is one of the three branches of modern fluid dynamics, the other two being analytical and experimental. CFD emerged in the 1950s with the advent of digital computers, although a number of scientific papers appeared earlier in the twentieth century which constitute a not insignificant part of its theoretical foundation. Richardson's 1910 paper (Richardson, 1910) is generally cited as the progenitor of modern CFD because of its presentation of numerical methods for classical equations, some of which have found application in fluid dynamics (e.g., Laplace's equation), and Courant et al. (1928) established the concept of the domain of dependence of a numerical solution and its relationship to the stability of the numerical scheme. Roache (1972, 1988) provides additional historical detail. The appearance of major textbooks [e.g., Richtmyer and Morton (1957), Roche (1972), Kovenya and Yanenko (1981), and Peyret and Taylor (1983)] firmly established the role of CFD in modern fluid dynamics research and engineering.

Computational fluid dynamics is the science of solving the partial differential equations of fluid motion by discrete approximation. Although a formal development of CFD methodology is beyond the scope of this section, it is worthwhile to identify the principal theoretical concepts that form the foundation of CFD algorithms. *Accuracy* is the formal order of approximation of an individual discrete approximation to a partial derivative. Consider, for example, a uniformly spaced set of grid points $x_i = (i-1)\Delta x$ for $i = 1, \ldots, n$ where Δx is a constant, and a function $f(x)$ defined at each point x_i. The discrete approximation to the derivative $\partial f/\partial x$, denoted as $\delta f/\delta x$, given by

$$\frac{\delta f}{\delta x} = \frac{f_{i+1} - f_{i-1}}{2\Delta x} \tag{20.6.1}$$

can be shown by Taylor's series expansion to approximate the derivative of $f(x)$ as

$$\frac{f_{i+1} - f_{i-1}}{2\Delta x} = \frac{\partial f}{\partial x} + \mathbb{O}(\Delta x)^2 \tag{20.6.2}$$

where $\mathbb{O}(\Delta x)^2$ indicates that the remaining terms are proportional to $(\Delta x)^2$ and therefore vanish as $\Delta x \to 0$. The discrete approximation $\delta f/\delta x$ is said to be second-order accurate (since the error is proportional to the second power of the grid spacing Δx). *Consistency* is the equivalence of the discrete approximation of the partial derivative to the partial derivative itself in the limit of $\Delta x \to 0$, irrespective of its order of accuracy. *Convergence* is the equivalence of the *solution* of the partial differential equation(s) (not merely the equivalence of an individual term) to the exact solution in the limit of vanishing grid spacing. There are examples of accurate but nonconvergent numerical algorithms for the partial differential equations of fluid dynamics (Roache, 1972). *Stability* is the property that the solution must remain bounded (Lax and Richtmyer, 1956).

The remainder of the section is organized into the following topics: (1) the governing equations of incompressible homogeneous fluid mechanics, (2) the concept of potential flow and the conditions for its existence, (3) a detailed development of the vortex panel method for solution of potential flow, (4) a numerical algorithm for solution of the boundary layer equations, and (5) an algorithm for the Navier-Stokes equations. Items (3) to (5) represent, therefore, the sequence of increasing complexity of fluid motions, and also represent a chronology of major advances in CFD. A list of references concludes the section.

GOVERNING EQUATIONS

The governing equations of an incompressible, laminar, constant-property, Newtonian viscous fluid in differential, dimensional form, using the Einstein summation convention,* are (Wilcox, 1997):

$$\frac{\partial \tilde{u}_i}{\partial \tilde{x}_i} = 0 \tag{20.6.3}$$

$$\tilde{\rho}\frac{\partial \tilde{u}_i}{\partial \tilde{t}} + \tilde{\rho}\tilde{u}_j\frac{\partial \tilde{u}_i}{\partial \tilde{x}_j} = -\frac{\partial \tilde{p}}{\partial \tilde{x}_i} + \frac{\partial \tilde{\tau}_{ij}}{\partial \tilde{x}_j} \tag{20.6.4}$$

where $\tilde{u}_i$ are the dimensional Cartesian velocity components in the $\tilde{x}_i$ directions, $\tilde{\rho}$ is the density, $\tilde{p}$ is the static pressure, and $\tilde{\tau}_{ij}$ is the viscous stress tensor,

$$\tilde{\tau}_{ij} = \mu\left(\frac{\partial \tilde{u}_i}{\partial \tilde{x}_j} + \frac{\partial \tilde{u}_j}{\partial \tilde{x}_i}\right) \tag{20.6.5}$$

where μ is the molecular dynamic viscosity.

The equation may be made nondimensionalized by using a reference velocity U_∞ and length L,

$$\frac{\partial u_i}{\partial x_i} = 0 \tag{20.6.6}$$

$$\frac{\partial u_i}{\partial t} + u_j\frac{\partial u_i}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{\partial \tau_{ij}}{\partial x_j} \tag{20.6.7}$$

where

$$\begin{aligned} u_i &= \frac{\tilde{u}_i}{U_\infty} \\ x_i &= \frac{\tilde{x}_i}{L} \\ t &= \frac{\tilde{t}U_\infty}{L} \\ p &= \frac{\tilde{p}}{\rho U_\infty^2} \\ \tau_{ij} &= \frac{\tilde{\tau}_{ij}}{\rho U_\infty^2} \end{aligned} \tag{20.6.8}$$

In particular, the viscous stress tensor becomes

$$\tau_{ij} = \frac{1}{\mathrm{Re}}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{20.6.9}$$

where $\mathrm{Re} = \rho U_\infty L/\mu$ is the *Reynolds number*.

VORTICITY AND KELVIN'S THEOREM

The cartesian components of the vorticity ω_i are defined as†

$$\omega_i = \epsilon_{ijk}\frac{\partial u_k}{\partial x_j} \tag{20.6.10}$$

*The Einstein summation convention uses repeated indices to indicate summation over all values of the index. This, for example, Eq. (20.6.3) is

$$\frac{\partial \tilde{u}_1}{\partial \tilde{x}_1} + \frac{\partial \tilde{u}_2}{\partial \tilde{x}_2} + \frac{\partial \tilde{u}_3}{\partial \tilde{x}_3} = 0$$

† The indices *i, j, k* are cyclic if they are in increasing order. The possible combinations are (*i, j, k*) = (1, 2, 3), (2, 3, 1), and (3, 1, 2). The indices are anticyclic if they are in decreasing order. The possible combinations are (*i, j, k*) = (3, 2, 1), (2, 1, 3), and (1, 3, 2).

where ε_{ijk} is the cyclic tensor defined as

$$\varepsilon_{ijk} = \begin{cases} 1 & \text{if } i, j, k \text{ are cyclic} \\ -1 & \text{if } i, j, k \text{ are anticyclic} \\ 0 & \text{otherwise} \end{cases} \tag{20.6.11}$$

The vorticity is twice the effective local angular velocity of the fluid (Batchelor, 1970).

A flow field where $\omega_i = 0$ everywhere is denoted *irrotational flow* or *potential flow,* and the velocity u_i may be represented as the gradient of a scalar potential ϕ (Batchelor, 1970),

$$u_i = \frac{\partial \phi}{\partial x_i} \tag{20.6.12}$$

Kelvin's theorem (Wilcox, 1997) states that an inviscid, incompressible fluid with zero vorticity at some instant of time remains irrotational for all time.

IRROTATIONAL FLOW

At high Reynolds number Re, the viscous stresses [Eq. (20.6.9)] are negligible outside of a narrow region (denoted the *boundary layer*) adjacent to solid surfaces. Figure 20.6.1 shows an airfoil in cross section (without the boundary layer). Provided that the angle of attack of the airfoil is sufficiently small, the boundary layer at high Re remains affixed to the airfoil and the vorticity generated therein is convected downstream into a narrow wake. Thus, the flow field domain is almost entirely inviscid and the boundary layer can be ignored in determining the pressure distribution on the airfoil. Assuming the flow upstream is uniform (and hence has zero vorticity), the flow field outside the boundary layer is irrotational.

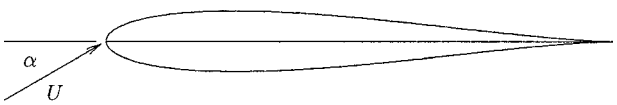

Fig. 20.6.1 Airfoil.

For irrotational flow, the governing Eqs. (20.6.3) and (20.6.4) become (with ¯ omitted for clarity),

$$\frac{\partial u_i}{\partial x_i} = 0 \tag{20.6.13}$$

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{1}{\rho} \frac{\partial p}{\partial x_i} \tag{20.6.14}$$

Using Eq. (20.6.12), we find the conservation of mass becomes

$$\frac{\partial^2 \phi}{\partial x_i^2} = 0 \tag{20.6.15}$$

which is known as *Laplace's equation*. The boundary conditions are

$$\begin{aligned} \frac{\partial \phi}{\partial x_i} &= U_i \qquad \text{as } |x_i| \to \infty \\ \frac{\partial \phi}{\partial n} &= 0 \qquad \text{on the surface} \end{aligned} \tag{20.6.16}$$

The first boundary condition states that the fluid velocity approaches the free-stream velocity with cartesian components U_i as the distance from the body becomes large. The second boundary condition states that the velocity normal to the surface is zero (assuming the airfoil is at rest in the frame of reference). In addition, the Zhukovsky (Joukowski) hypothesis must be applied to achieve a unique solution (Milne-Thompson, 1958),

Joukowski's hypothesis is that the circulation* in the case of a properly designed aerofoil, in its working range of incidence, always adjusts itself so that the airspeed at the trailing edge is finite.

* See "Elementary Solutions," below.

Using the identities

$$u_j \frac{\partial u_i}{\partial x_j} = \frac{\partial}{\partial x_i}\left(\frac{1}{2} u_j u_j\right) - \epsilon_{ijk} u_j \omega_k \tag{20.6.17}$$

and

$$\frac{\partial u_i}{\partial t} = \frac{\partial}{\partial t}\left(\frac{\partial \phi}{\partial x_i}\right) = \frac{\partial}{\partial x_i}\left(\frac{\partial \phi}{\partial t}\right) \tag{20.6.18}$$

and noting that $\omega_i = 0$ for an irrotational flow, we can rewrite the conservation of momentum [Eq. (20.6.7)] as

$$\frac{\partial}{\partial x_i}\left(\frac{\partial \phi}{\partial t} + \frac{1}{2} u_j u_j + \frac{p}{\rho}\right) = 0 \tag{20.6.19}$$

and thus

$$\frac{\partial \phi}{\partial t} + \frac{1}{2} u_j u_j + \frac{p}{\rho} = g(t) \tag{20.6.20}$$

where $g(t)$ is a function of time. This is *Bernoulli's equation* and provides an expression for the pressure p in terms of the velocity potential and its gradient.

Elementary Solutions

Laplace's equation (and its inhomogenous counterpart, Poisson's equation) have been studied extensively because of their broad application in physics and engineering (Kellogg, 1953). For simplicity, we consider Laplace's equation in two-dimensional cartesian or cylindrical coordinates where $(x_1, x_2) = (x, y)$, $r = \sqrt{x_1^2 + x_2^2}$, and $\theta = \tan^{-1}(x_2/x_1)$. The cartesian and cylindrical polar forms of Laplace's equation are

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0 \qquad \text{cartesian} \tag{20.6.21}$$

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r \frac{\partial \phi}{\partial r}\right) + \frac{\partial^2 \phi}{\partial \theta^2} = 0 \qquad \text{cylindrical} \tag{20.6.22}$$

There are three fundamental solutions of Eq. (20.6.15) that are commonly used in computational methods. The first is *uniform flow,* defined by

$$\phi = U_i x_i \qquad \text{uniform flow} \tag{20.6.23}$$

where U_i is the component of the velocity along the x_i axis and $U = \sqrt{U_i U_i}$. The second is a two-dimensional *source/sink* defined by

$$\phi = \frac{q}{2\pi} \log r \qquad \text{source/sink} \tag{20.6.24}$$

It may be directly verified that the volume flux of fluid crossing a circular boundary enclosing a source at $r = 0$ is

$$\int_0^{2\pi} u_i n_i r \, d\theta = \int_0^{2\pi} \frac{q}{2\pi r} r \, d\theta = q \tag{20.6.25}$$

where n_i are the cartesian components of the outward normals. The third is a *line vortex* defined by

$$\phi = \frac{\Gamma \theta}{2\pi} \qquad \text{line vortex} \tag{20.6.26}$$

It may be directly verified that the line integral of the velocity about a contour enclosing the line vortex is

$$\int_0^{2\pi} u_i s_i r \, d\theta = \int_0^{2\pi} \frac{\Gamma}{2\pi r} r \, d\theta = \Gamma \tag{20.6.27}$$

where s_i are the components of the unit tangent vector (taken in the counterclockwise direction). The quantity Γ is denoted the *circulation*.

Panel Methods

The elementary solutions may be combined in a discrete manner to generate the solution for irrotational flow past an arbitrary number of closed boundaries (Hess and Smith, 1986; Hess, 1975). For simplicity,

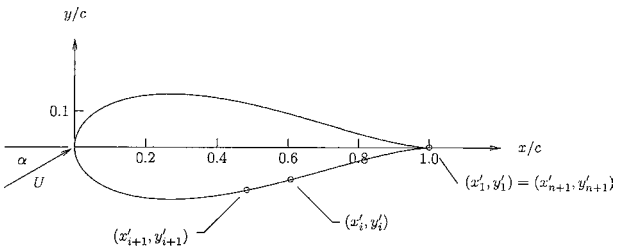

Fig. 20.6.2 Airfoil.

we consider a single body represented by the airfoil in Fig. 20.6.2. The airfoil surface is discretized into n segments with endpoints* (x'_i, y'_i), $i = 1, \ldots, n+1$. Note that $(x'_1, y'_1) = (x'_{n+1}, y'_{n+1})$. The slope of the ith segment relative to the x axis is

$$\delta_i = \tan^{-1}\left[\frac{(y'_{i+1} - y'_i)}{(x'_{i+1} - x_i)}\right] \qquad -\frac{\pi}{2} \le \delta_i \le \frac{\pi}{2} \tag{20.6.28}$$

In particular, it is noted that δ_n is not necessarily equal to δ_1 (i.e., the trailing edge of the airfoil may have a finite angle).

Nonlifting Airfoil

Consider an infinite number of sources/sinks on the ith segment (Fig. 20.6.3) with strength per unit length q_i and length ds_i. From Eq. (20.6.24), the velocity potential is

$$d\phi_i = \frac{q_i\, ds_i}{2\pi} \log r_i \tag{20.6.29}$$

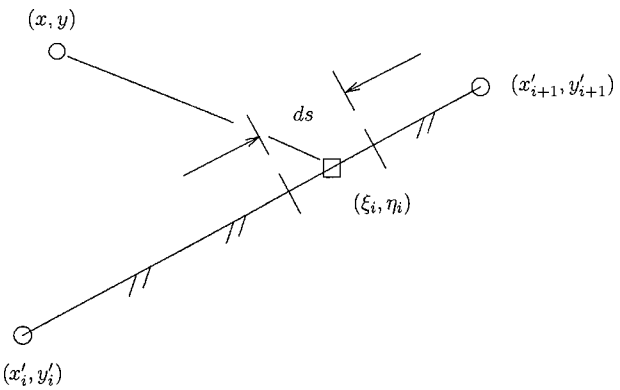

Fig. 20.6.3 Sources/sinks on segment.

where the summation on i is not performed and r is measured from the center of the infinitesimal segment (ξ_i, η_i) to the field point

$$r_i = \sqrt{(x - \xi_i)^2 + (y - \eta_i)^2} \tag{20.6.30}$$

The velocity potential for the ith source/sink segment is therefore

$$\phi = \frac{q_i}{2\pi}\int \log r_i\, ds_i \qquad \text{(no sum on } i\text{)} \tag{20.6.31}$$

*Note that the subscript i indicates the ith point, and should not be confused with the earlier cartesian notation.

Since Laplace's equation is linear, a linear superposition of elementary solutions is also a solution, and therefore the velocity potential is

$$\phi(x, y) = Ux\cos\alpha + Uy\sin\alpha + \sum_{j=1}^{j=n} \frac{q_j}{2\pi}\int \log r_j\, ds_j \tag{20.6.32}$$

where U is the amplitude of the free-stream velocity and α is the angle of the free-stream velocity with respect to the x axis.

Define n control points (x_i, y_i) for $i = 1, \ldots, n$, where

$$\begin{aligned} x_i &= \tfrac{1}{2}(x'_{i+1} + x'_i) \\ y_i &= \tfrac{1}{2}(y'_{i+1} + y'_i) \end{aligned} \tag{20.6.33}$$

and apply the boundary condition that the velocity normal to the boundary at each control point is zero. The resultant equations are (Kellogg, 1953):

$$\frac{q_i}{2} + \sum_{j=1}^{j=n} \frac{q_j}{2\pi}\int \frac{\partial}{\partial n_i}\log r_j\, ds_j = -\frac{\partial}{\partial n_i}(Ux\cos\alpha + Uy\sin\alpha) \qquad \text{for } i = 1, \ldots, n \tag{20.6.34}$$

where n_i is the outward (i.e., into the fluid) normal direction at the ith control point and the derivative is evaluated at (x_i, y_i). Define the unit normal (n_{1_i}, n_{2_i}) and tangential vectors (t_{1_i}, t_{2_i}) at each segment i for $i = 1, \ldots, n$ by (no sum on i)

$$\begin{aligned} n_{1_i} &= -(y'_{i+1} - y'_i)\Delta s_i^{-1} \\ n_{2_i} &= +(x'_{i+1} - x'_i)\Delta s_i^{-1} \\ t_{1_i} &= +(x'_{i+1} - x'_i)\Delta s_i^{-1} \\ t_{2_i} &= +(y'_{i+1} - y'_i)\Delta s_i^{-1} \end{aligned} \tag{20.6.35}$$

where Δs_i is the length of the ith segment

$$\Delta s_i = \sqrt{(x'_{i+1} - x'_i)^2 + (y'_{i+1} - y'_i)^2} \tag{20.6.36}$$

Equation (20.6.34) can be rewritten as (Kellogg, 1953):

$$\frac{Q_i}{2} + \sum_{j=1, j\ne i}^{j=n} \frac{Q_j}{2\pi}(n_{1_i}G_{ij} + n_{2_i}H_{ij}) = -(n_{1_i}\cos\alpha + n_{2_i}\sin\alpha) \qquad \text{for } i = 1, \ldots, n \tag{20.6.37}$$

where

$$Q_i = \frac{q_i}{U} \tag{20.6.38}$$

Equation (20.6.37) represents n linear equations for the n unknowns q_i. The $n \times n$ influence matrices G_{ij} and $H_{i,j}$ are defined as follows. Define the following (no sum on i or j):

$$\begin{aligned} a_{ij} &= (x_i - x_j)t_{1_j} + (y_i - y_j)t_{2_j} \\ b_{ij} &= \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2 - a_{ij}^2} \\ c_{ij} &= x_i - x_j - a_{ij}t_{1_j} \\ d_{ij} &= \tfrac{1}{2}\Delta s_j - a_{ij} \\ e_{ij} &= \tfrac{1}{2}\Delta s_j + a_{ij} \\ f_{ij} &= (x_i - x_j)^2 + (y_i - y_j)^2 + \Delta s_j a_{ij} + \tfrac{1}{4}\Delta s_j^2 \\ g_{ij} &= y_i - y_j - a_{ij}t_{2_j} \end{aligned} \tag{20.6.39}$$

The influence matrices are

$$\begin{aligned} G_{ij} &= \frac{c_{ij}}{b_{ij}}\left[\tan^{-1}\frac{d_{ij}}{b_{ij}} + \tan^{-1}\frac{e_{ij}}{b_{ij}}\right] - \tfrac{1}{2}t_{1_j}\log\frac{f_{i,j+1}}{f_{ij}} \\ H_{ij} &= \frac{g_{ij}}{b_{ij}}\left[\tan^{-1}\frac{d_{ij}}{b_{ij}} + \tan^{-1}\frac{e_{ij}}{b_{ij}}\right] - \tfrac{1}{2}t_{2_j}\log\frac{f_{i,j+1}}{f_{ij}} \end{aligned} \tag{20.6.40}$$

The solution of Eq. (20.6.37) yields the source/sink values q_i. The velocity at the midpoint of the ith segment on the airfoil is tangential to the airfoil and given by

$$V_i = U(t_{1_i}\cos\alpha + t_{2_i}\sin\alpha) + \sum_{j=1, j\neq i}^{j=n} \frac{q_i}{2\pi}(t_{1_i}G_{ij} + t_{2_i}H_{ij}) \qquad (20.6.41)$$

Evaluating Eq. (20.6.20) in the free stream and assuming steady flow, we obtain

$$\frac{1}{2}U^2 + \frac{p_\infty}{\rho} = \frac{1}{2}(u^2 + v^2) + \frac{p}{\rho} \qquad (20.6.42)$$

Thus, the pressure coefficient c_p, defined by

$$c_p = \frac{p - p_\infty}{\frac{1}{2}\rho U^2} \qquad (20.6.43)$$

becomes

$$c_p = 1 - \left(\frac{u^2 + v^2}{U^2}\right)^2 \qquad (20.6.44)$$

and on the airfoil surface at the midpoint of the ith segment,

$$c_{p_i} = 1 - \left(\frac{V_i}{U}\right)^2 \qquad (20.6.45)$$

The above method is applied to the flow past a cylinder as illustrated in Fig. 20.6.4. The computed pressure distribution using $n = 50$ segments is shown in Fig. 20.6.5 together with the exact solution (Anderson, 2001)

$$c_p(\theta) = 1 - 4\sin^2\theta \qquad (20.6.46)$$

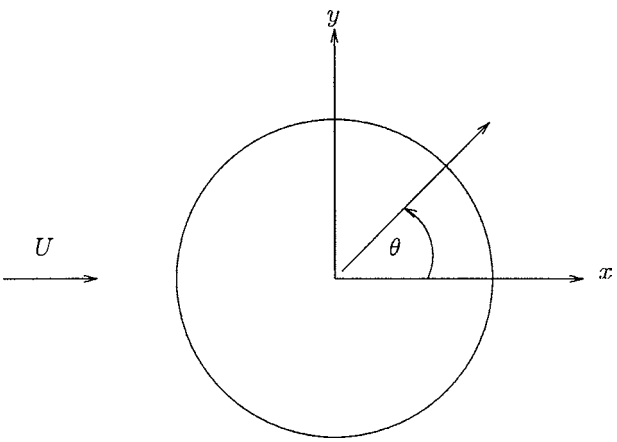

Fig. 20.6.4 Flow past a cylinder.

Lifting Airfoil

For a two-dimensional airfoil in steady flow, the Kutta-Zhukovsky theorem (Milne-Thompson, 1958) states

$$l = -\rho U\Gamma \qquad (20.6.47)$$

where l is the lift per unit span, U is the free-stream velocity, and Γ is the circulation defined by Eq. (20.6.27). The lift is the force on the airfoil in a direction perpendicular to the free-stream velocity. It is therefore evident that the solution of Laplace's equation for a lifting airfoil must include distributed vortices.

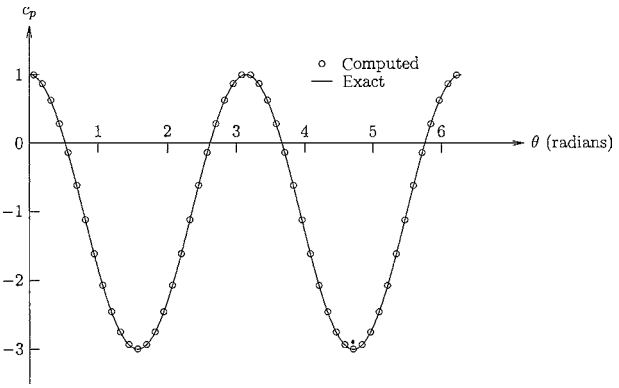

Fig. 20.6.5 Pressure coefficient on cylinder.

Consider an infinite number of line vortices on the ith segment (Fig. 20.6.6). For simplicity, the origin of the coordinate system is taken to be at the center of the segment. Each vortex has a circulation $\gamma d\xi$. The cartesian velocity components at point (x, y) due to the vortex at $(\xi, 0)$ are

$$u = -\frac{\gamma\, d\xi}{2\pi r}\sin\theta$$
$$v = +\frac{\gamma\, d\xi}{2\pi r}\cos\theta \qquad (20.6.48)$$

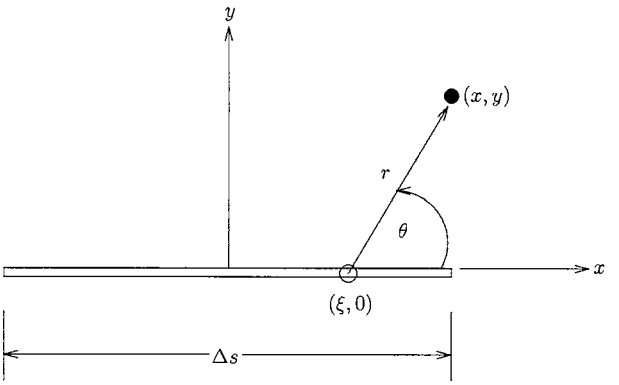

Fig. 20.6.6 Vortex on segment.

where

$$r = \sqrt{(x - \xi)^2 + y^2}$$
$$\theta = \tan^{-1}\left(\frac{y}{x - \xi}\right) \qquad (20.6.49)$$

Thus, the cartesian velocity components at point (x, y) due to the distribution of vortices on the segment is

$$u = -\frac{\gamma}{2\pi}\int_{-\frac{1}{2}\Delta s}^{+\frac{1}{2}\Delta s} \frac{y\, d\xi}{[(x - \xi)^2 + y^2]}$$

$$v = +\frac{\gamma}{2\pi}\int_{-\frac{1}{2}\Delta s}^{+\frac{1}{2}\Delta s} \frac{(x - \xi)\, d\xi}{(x - \xi)^2 + y^2} \qquad (20.6.50)$$

These equations may be integrated to obtain

$$u = -\frac{\gamma}{2\pi}\,\text{sign}(y)\left\{\tan^{-1}\left(\frac{\frac{1}{2}\Delta s - x}{|y|}\right) + \tan^{-1}\left(\frac{\frac{1}{2}\Delta s + x}{|y|}\right)\right\}$$

$$v = -\frac{\gamma}{4\pi}\log\left[\frac{x^2 + y^2 - x\Delta s + (\frac{1}{2}\Delta s)^2}{x^2 + y^2 + x\Delta s + (\frac{1}{2}\Delta s)^2}\right] \tag{20.6.51}$$

where sign (y) is the sign of y. Evaluating Eq. (20.6.51) at the midpoint of the segment yields

$$\lim_{x=0,\,y\downarrow 0} u(x, y) = -\frac{\gamma}{2}$$
$$\lim_{x=0,\,y\downarrow 0} v(x, y) = 0 \tag{20.6.52}$$

Therefore, the vectoral velocity at the midpoint of the ith segment due to the jth vortex segment is

$$\vec{v}_{ij_v} = -\frac{\gamma_j}{2\pi}\frac{h_{ij}}{b_{ij}}\left[\tan^{-1}\frac{d_{ij}}{b_{ij}} + \tan^{-1}\frac{e_{ij}}{b_{ij}}\right]\vec{t}_j - \frac{\gamma_j}{4\pi}\log\frac{f_{i,j+1}}{f_{ij}}\vec{n}_j \tag{20.6.53}$$

where

$$h_{ij} = (x_i - x_j')n_{1_j} + (y_i - y_j')n_{2_j} \tag{20.6.54}$$

Applying the boundary condition that the velocity normal to the boundary at each control point is zero yields

$$\frac{Q_i}{2} + \sum_{j=1,\,j\neq i}^{j=n}\frac{Q_j}{2\pi}(n_{1_i}G_{ij} + n_{2_i}H_{ij}) + \frac{1}{U}\sum_{j=1,\,j\neq i}^{j=n}\vec{v}_{ij_v}\cdot\vec{n}_i = -(n_{1_i}\cos\alpha + n_{2_i}\sin\alpha) \qquad \text{for } i = 1, \ldots, n \tag{20.6.55}$$

The additional boundary condition is the Zhukovsky hypothesis described above.

It is evident that Eq. (20.6.55) provides n equations. Together with the Zhukovsky hypothesis, there are $n + 1$ equations for the $2n$ unknowns q_i and γ_i. It is evident, therefore, that a functional form must be assumed for γ_j involving only a single unknown variable (Hess and Smith, 1966; Hess, 1975). At a trailing edge, the vortex strength must vanish, otherwise the tangential velocity will be infinite. Thus, we assume the form

$$\gamma_i = U\Lambda S_i \qquad \text{for } i = 1, \ldots, n \tag{20.6.56}$$

where

$$S_i = s_i(1 - s_i) \tag{20.6.57}$$

with $s_1 = 0$ and

$$s_i = \left[\sum_{j=2}^{j=i}\sqrt{(x_j - x_{j-1})^2 + (y_j - y_{j-1})^2}\right] \times \left[\sum_{j=2}^{j=n}\sqrt{(x_j - x_{j-1})^2 + (y_j - y_{j-1})^2}\right]^{-1} \tag{20.6.58}$$

Thus, $S_1 = 0$ and $S_n = 0$.

Define the influence matrices

$$A_{ij} = S_j\left\{-\frac{h_{ij}t_{1_j}}{b_{ij}}\left[\tan^{-1}\frac{d_{ij}}{b_{ij}} + \tan^{-1}\frac{e_{ij}}{b_{ij}}\right] - \frac{1}{2}n_{1_j}\log\frac{f_{i,j+1}}{f_{ij}}\right\}$$

$$B_{ij} = S_j\left\{-\frac{h_{ij}t_{2_j}}{b_{ij}}\left[\tan^{-1}\frac{d_{ij}}{b_{ij}} + \tan^{-1}\frac{e_{ij}}{b_{ij}}\right] - \frac{1}{2}n_{2_j}\log\frac{f_{i,j+1}}{f_{ij}}\right\} \tag{20.6.59}$$

Equation (20.6.55) becomes

$$\frac{Q_i}{2} + \sum_{j=1,\,j\neq i}^{j=n}\frac{Q_i}{2\pi}(n_{1_i}G_{ij} + n_{2_i}H_{ij}) + \frac{\Lambda}{2\pi}\sum_{j=1,\,j\neq i}^{j=n}(n_{1_i}A_{ij} + n_{2_i}B_{ij}) = -(n_{1_i}\cos\alpha + n_{2_i}\sin\alpha) \tag{20.6.60}$$

The tangential velocity at the ith control point becomes

$$V_i = U(t_{1_i}\cos\alpha + t_{2_i}\sin\alpha) + \sum_{j=1,\,j\neq i}^{j=n}\frac{q_j}{2\pi}(t_{1_i}G_{ij} + t_{2_i}H_{ij}) + U\Lambda\left[-\frac{1}{2}S_i + \frac{1}{2\pi}\sum_{j=1,\,j\neq i}^{j=n}(t_{1_i}A_{ij} + t_{2_i}B_{ij})\right] \tag{20.6.61}$$

The Zhukovsky hypothesis indicates that the velocity at the training edge is finite (Fig. 20.6.7). For a sharp trailing edge, this implies that the velocity vector must be aligned with the bisector of the trailing edge. In order for this to occur, the pressure at control points $i = 1$ and $i = n$ must be the same, and therefore, by Bernoulli's equation, $V_1^2 = V_n^2$. Since the velocity is tangent to the surface at all control points, and since the tangential vectors $\vec{t}_1$ and $\vec{t}_n$ point toward and away from the trailing edge, respectively,

$$V_1 = -V_n \tag{20.6.62}$$

Thus,

$$\sum_{j=2}^{j=n}\frac{Q_i}{2\pi}(t_{1_1}G_{1j} + t_{2_1}H_{1j}) + \sum_{j=1}^{j=n-1}\frac{Q_i}{2\pi}(t_{1_n}G_{nj} + t_{2_n}H_{nj}) + \Lambda\left[-\frac{1}{2}(S_1 + S_n) + \frac{1}{2\pi}\sum_{j=2}^{j=n}(t_{1_1}A_{1j} + t_{2_1}B_{1j}) + \frac{1}{2\pi}\sum_{j=1}^{j=n}(t_{1_n}A_{nj} + t_{2_n}B_{nj})\right] = -(t_{1_1} + t_{1_n})\cos\alpha - (t_{2_1} + t_{2_n})\sin\alpha \tag{20.6.63}$$

Equations (20.6.55) and (20.6.63) are solved for the source/sink strengths q_i and vortex sheet parameter Λ.

The lift on the airfoil is obtained from the Kutta-Zhukovsky theorem [Eq. (20.6.47)]. The circulation is defined by Eq. (20.6.27), which yields

$$l = -\rho U^2\Lambda\sum_{i=1}^{i=n}S_i\Delta s_i \tag{20.6.64}$$

and the corresponding lift coefficient

$$c_l = \frac{l}{\frac{1}{2}\rho U^2 c} = -\frac{2\Lambda}{c}\sum_{i=1}^{i=n}S_i\Delta s_i \tag{20.6.65}$$

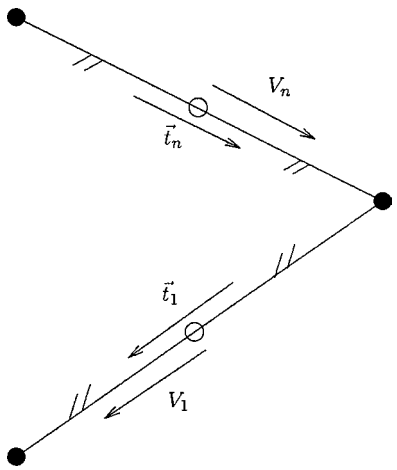

Fig. 20.6.7 Velocities at trailing edge.

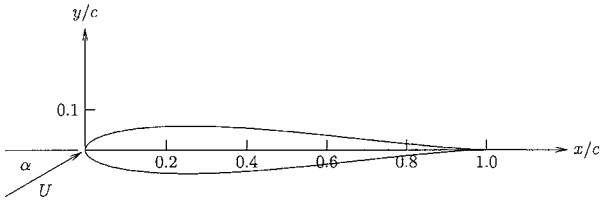

Fig. 20.6.8 Zhukovsky airfoil.

where c is the airfoil chord. The drag on the airfoil (i.e., the component of force acting in the direction of the freestream velocity) is zero.

The above method is applied to the flow past a Zhukovsky airfoil (Houghton and Carpenter, 1993) as illustrated in Fig. 20.6.8. The airfoil coordinates are defined as

$$x = \frac{1}{4\kappa_1}\left[\xi\left(1 + \frac{1}{\xi^2 + \eta^2}\right) + 2\kappa_2\right]$$
$$y = \frac{1}{4\kappa_1}\left[\eta\left(1 - \frac{1}{\xi^2 + \eta^2}\right)\right] \tag{20.6.66}$$

where

$$\begin{aligned}\xi &= -e + (1 + e)\cos\theta' \\ \eta &= (1 + e)\sin\theta' \\ \kappa_1 &= (1 + 2e + e^2)(1 + 2e)^{-1} \\ \kappa_2 &= (1 + 2e + 2e^2)(1 + 2e)^{-1}\end{aligned} \tag{20.6.67}$$

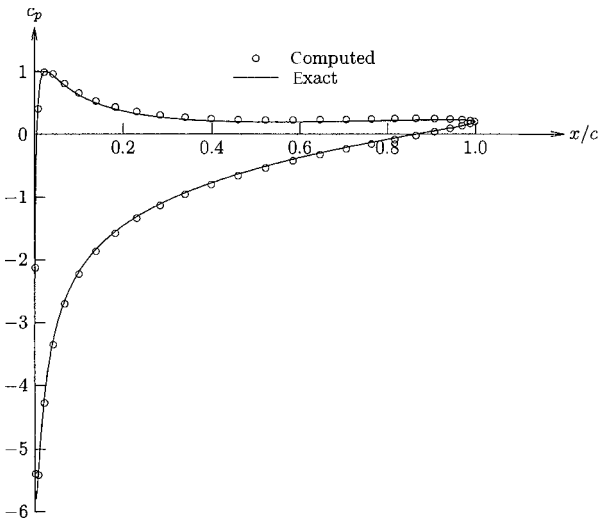

Fig. 20.6.9 Pressure coefficient on airfoil.

where e is the *eccentricity*. Note that the airfoil leading edge is located at $(x, y) = (0, 0)$ and the trailing edge at $(x, y) = (1, 0)$. The computed pressure distribution for a Zhukovsky airfoil with $e = 0.1$ an angle of attack $\alpha = 10°$ using $n = 50$ segments is shown in Fig. 20.6.9 together with the exact solution*

$$c_p = 1 - 4\kappa_3[\sin(\theta' - \alpha) + \sin\alpha]^2 \tag{20.6.68}$$

*The pressure coefficient at the trailing edge $(x, y) = (1, 0)$, corresponding to $\theta' = 0$, is obtained by two successive applications of L'Hospital rule to yield

$$c_p|_{\theta'=0} = 1 - (1 + e)^{-2}\cos^2\alpha$$

where

$$\begin{aligned}\kappa_3 &= \left[1 - 2\frac{(1 - 2\sin^2\theta)}{\kappa_4} + \frac{1}{\kappa_4^2}\right]^{-1} \\ \kappa_4 &= [-e + (1 + e)\cos\theta']^2 + [(1 + e)\sin\theta']^2 \\ \sin^2\theta &= \frac{(1 + e)^2\sin^2\theta'}{\kappa_4}\end{aligned} \tag{20.6.69}$$

BOUNDARY LAYER FLOW

At high Reynolds number Re and in the absence of strong pressure gradients,† the viscous stresses generate a thin *boundary layer* adjacent to solid surfaces wherein the flow velocity decreases to zero at the surface. A detailed history of the development of boundary layer theory is presented by Tani (1977).

Consider a body-oriented coordinate system (Fig. 20.6.10) where the x and y coordinates are locally tangential and normal to the surface, respectively. For laminar, steady, two-dimensional flow, the boundary layer equations are obtained from Eqs. (20.6.3) and (20.6.4) under the assumption that the normal y derivatives are large compared to the streamwise x derivatives.‡ The steady boundary layer equations are (with ˜ omitted for clarity):

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \tag{20.6.70}$$

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{1}{\rho}\frac{dp}{dx} + \nu\frac{\partial^2 u}{\partial y^2} \tag{20.6.71}$$

where $\nu = \mu/\rho$ is the kinematic viscosity. The boundary conditions are

$$\begin{aligned}u &= 0 \qquad \text{on } y = 0 \\ v &= 0 \qquad \text{on } y = 0 \\ u &= U_e(x) \qquad \text{as } y \to \infty\end{aligned} \tag{20.6.72}$$

where $U_e(x)$ is the velocity outside of the boundary layer at the streamwise location x, and dp/dx is the streamwise pressure gradient. Both $U_e(x)$ and $dp(x)/dx$ are obtained from the solution of the irrotational flow (see "Irrotational Flow," above).

Mangler-Levy-Lees Transformation

The boundary layer equations may be rewritten by using the Mangler-Levy-Lee transformation (Cebeci and Cousteix, 1999):

$$d\xi = \rho\mu U_e(x)\,dx \tag{20.6.73}$$

$$d\eta = \frac{\rho U_e(x)}{\sqrt{2\xi}}\,dy \tag{20.6.74}$$

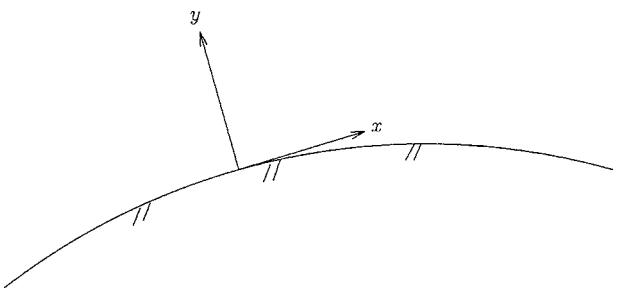

Fig. 20.6.10 Coordinate system.

† A sufficiently strong pressure gradient will cause the boundary layer to *separate* from the body surface. Under such circumstances, the boundary layer equations are no longer valid and the full Navier-Stokes equations (see "Navier-Stokes Flow," below) must be solved.

‡In addition, it is assumed that the local boundary layer thickness $\delta(x)$ is small compared to the local radius of curvature R of the boundary.

which may be integrated to obtain

$$\xi = \rho\mu \int_0^x U_e(x')\,dx' \tag{20.6.75}$$

$$n = \frac{\rho U_e(x) y}{\sqrt{2\xi}} \tag{20.6.76}$$

By introducing the stream function ψ according to

$$\rho u = \frac{\partial \psi}{\partial y} \qquad \rho v = -\frac{\partial \psi}{\partial x} \tag{20.6.77}$$

the conservation of mass, [Eq. (20.6.70)] is exactly satisfied. Introducing the dimensionless function $f(\xi, \eta)$ according to

$$\psi(\xi, \eta) = \sqrt{2\xi} f(\xi, \eta) \tag{20.6.78}$$

we see that the velocity components become

$$u = U_e \frac{\partial f}{\partial n} \tag{20.6.79}$$

$$v = -\left[\frac{f}{\sqrt{2\xi}} + \sqrt{2\xi}\frac{\partial f}{\partial \xi}\right]\mu U_e - \frac{\sqrt{2\xi}}{\rho}\frac{\partial f}{\partial \eta}\left[\frac{\eta}{U_e}\frac{dU_e}{dx} - \frac{\eta\rho\mu U_e}{2\xi}\right] \tag{20.6.80}$$

The momentum equation (20.6.71) becomes

$$\frac{\partial^3 f}{\partial \eta^3} + f\frac{\partial^2 f}{\partial \eta^2} + \beta\left[1 - \left(\frac{\partial f}{\partial \eta}\right)^2\right] - 2\xi\left[\frac{\partial f}{\partial \eta}\frac{\partial^2 f}{\partial \eta\,\partial \xi} - \frac{\partial^2 f}{\partial \eta^2}\frac{\partial f}{\partial \xi}\right] = 0 \tag{20.6.81}$$

where $\beta(\xi)$ is the dimensionless pressure gradient parameter

$$\beta = \frac{2\xi}{U_e}\frac{dU_e}{d\xi} \tag{20.6.82}$$

The boundary conditions [Eq. (20.6.72)] become

$$\begin{aligned} \frac{\partial f}{\partial \eta} &= 0 \quad \text{at } \eta = 0 \\ f &= 0 \quad \text{at } \eta = 0 \\ \frac{\partial f}{\partial \eta} &= 1 \quad \text{as } \eta \to \infty \end{aligned} \tag{20.6.83}$$

Keller Box Scheme

Given the pressure gradient parameter $\beta(\xi)$, the momentum equation (20.6.81) can be solved by using Keller's box scheme (Keller, 1975). A grid of points is defined by

$$\xi_i = \xi_{i-1} + \Delta\xi_i \qquad \text{for } i = 2, \ldots, m \tag{20.6.84}$$

$$\eta_j = \eta_{j-1} + \Delta\eta_j \qquad \text{for } j = 2, \ldots, n \tag{20.6.85}$$

where $\xi_1 = \eta_1 = 0$ (Fig. 20.6.11). Note that $\Delta\xi_i$ and $\Delta\eta_j$ may be taken to be arbitrary positive values consistent with adequate resolution of the boundary layer in the streamwise and normal directions. The boundary layer momentum equation (20.6.81) is rewritten as a system of first-order partial differential equations

$$\frac{\partial f}{\partial \eta} = g \tag{20.6.86}$$

$$\frac{\partial g}{\partial \eta} = h \tag{20.6.87}$$

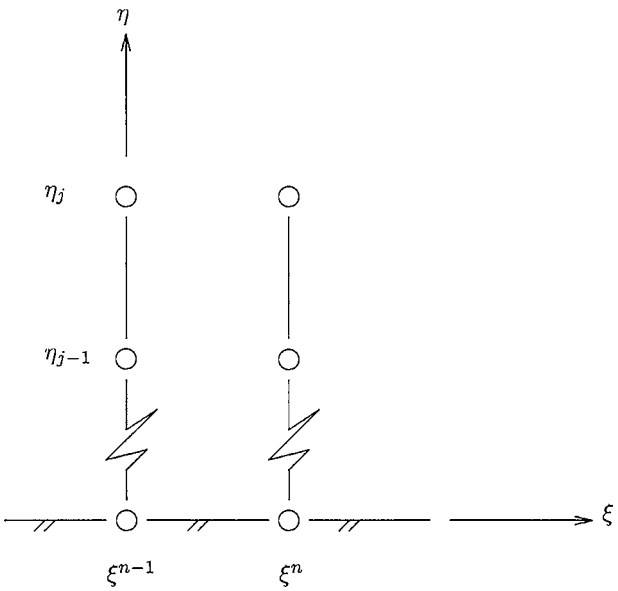

Fig. 20.6.11 Finite-difference grid.

$$\frac{\partial h}{\partial \eta} + fh + \beta(1 - g^2) - 2\xi\left(g\frac{\partial g}{\partial \xi} - h\frac{\partial f}{\partial \xi}\right) = 0 \tag{20.6.88}$$

where Eq. (20.6.88) is recognized as the boundary layer momentum equation (20.6.81). The function $f(\xi, \eta)$, $g(\xi, \eta)$, and $h(\xi, \eta)$ are defined at the discrete grid points by using the notation $f_{i,j} = f(\xi_i, \eta_j)$, etc. Equations (20.6.86) and (20.6.87) are discretized as

$$f_{i,j} - f_{i,j-1} - \tfrac{1}{2}\Delta\eta_j(g_{i,j} + g_{i,j-1}) = 0 \tag{20.6.89}$$

$$g_{i,j} - g_{i,j-1} - \tfrac{1}{2}\Delta\eta_j(h_{i,j} + h_{i,j-1}) = 0 \tag{20.6.90}$$

Equation (20.6.88) is discretized about the centroid of the cell (Fig. 20.6.12) to yield

$$\begin{aligned} &h_{i,j} + h_{i-1,j} - h_{i,j-1} - h_{i-1,j-1} + \tfrac{1}{2}\Delta\eta_j\overline{fh}_{i,j} + \Delta\eta_j\overline{\beta}_i\left(1 - \tfrac{1}{4}\overline{g^2}_{i,j}\right) \\ &-\tfrac{1}{4}\frac{\Delta\eta_j}{\Delta\xi_i}\overline{\xi}_i\left[\overline{g}_{i,j}(g_{i,j} + g_{i,j-1} - g_{i-1,j} - g_{i-1,j-1})\right. \\ &\qquad \left. - \overline{h}_{i,j}(f_{i,j} + f_{i,j-1} - f_{i-1,j} - f_{i-1,j-1})\right] = 0 \end{aligned} \tag{20.6.91}$$

where

$$\overline{fh}_{i,j} = f_{i,j}h_{i,j} + f_{i-1,j}h_{i-1,j} + f_{i,j-1}h_{i,j-1} + f_{i-1,j-1}h_{i-1,j-1}$$

$$\overline{\xi}_i = (\xi_i + \xi_{i-1})$$

with similar expressions for $\overline{g}_{i,j}$, $\overline{g^2}_{i,j}$, $\overline{h}_{i,j}$, and $\overline{\beta}_i$. The boundary conditions are

$$\begin{aligned} f_{i,1} &= 0 \\ g_{i,1} &= 0 \\ g_{i,n} &= 1 \end{aligned} \tag{20.6.92}$$

for $i = 2, \ldots, m$. The third boundary condition assumes η_n is outside the boundary layer.

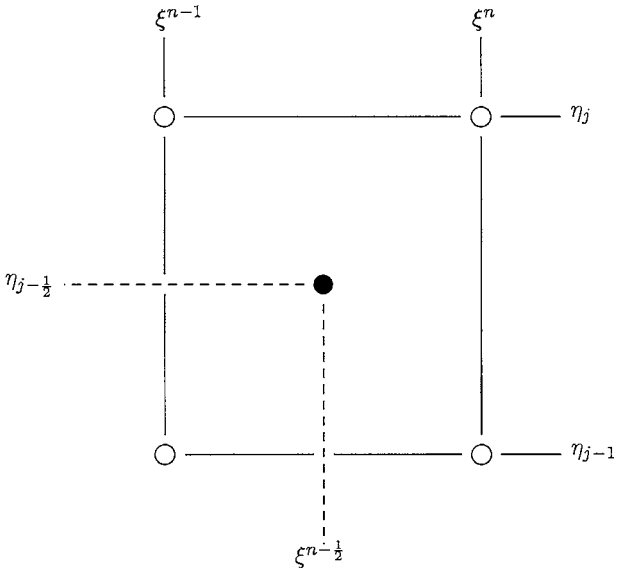

Fig. 20.6.12 Computational cell.

The discrete equations (20.6.89), (20.6.90), and (20.6.91) are second-order accurate in ξ and η, and may be solved by using an implicit technique. Define

$$G_{i,j} = f_{i,j} - f_{i,j-1} - \tfrac{1}{2}\Delta\eta_j (g_{i,j} + g_{i,j-1}) \tag{20.6.93}$$

$$H_{i,j} = g_{i,j} - g_{i,j-1} - \tfrac{1}{2}\Delta\eta_j (h_{i,j} + h_{i,j-1}) \tag{20.6.94}$$

$$\begin{aligned} F_{i,j} = {} & h_{i,j} + h_{i-1,j} - h_{i,j-1} - h_{i-1,j-1} + \tfrac{1}{2}\Delta\eta_j \overline{fh}_{i,j} \\ & + \Delta\eta_j \overline{\beta}_i \left(1 - \tfrac{1}{4}\overline{g^2}_{i,j}\right) - \frac{1}{4}\frac{\Delta\eta_j}{\Delta\xi_i}\overline{\xi}_i [\overline{g}_{i,j}(g_{i,j} + g_{i,j-1} - g_{i-1,j} - g_{i-1,j-1}) \\ & - \overline{h}_{i,j}(f_{i,j} + f_{i,j-1} - f_{i-1,j} - f_{i-1,j-1})] \end{aligned} \tag{20.6.95}$$

for $j = 2, \ldots, n$. Then the discrete equations become

$$\begin{aligned} f_{i,1} &= 0 \\ g_{i,1} &= 0 \\ F_{i,j} &= 0 \qquad \text{for } j = 2, \ldots, n \\ G_{i,j} &= 0 \qquad \text{for } j = 2, \ldots, n \\ H_{i,j} &= 0 \qquad \text{for } j = 2, \ldots, n \\ g_{i,n} - 1 &= 0 \end{aligned} \tag{20.6.96}$$

for $i = 2, \ldots, m$. These constitute $3n$ equations in $3n$ unknowns and may be solved by Newton's method. Define the vector of equations

$$R_i = (R_{i,1} R_{i,2}, \ldots, R_{i,n})^{\mathrm{T}} \tag{20.6.97}$$

where $^{\mathrm{T}}$ denotes the vector transpose and $R_{i,j}$ are column vectors of length three defined by

$$\begin{aligned} R_{i,1} &= (f_{i,1}, g_{i,1}, F_{i,2})^{\mathrm{T}} \\ R_{i,2} &= (G_{i,2}, H_{i,2}, F_{i,3})^{\mathrm{T}} \\ &\ldots \\ R_{i,j} &= (G_{i,j}, H_{i,j}, F_{i,j+1})^{\mathrm{T}} \\ R_{i,n} &= (G_{i,n}, H_{i,n}, g_{i,n} - 1)^{\mathrm{T}} \end{aligned} \tag{20.6.98}$$

Define the vector of unknowns

$$U_i = (U_{i,1}, U_{i,2}, \ldots, U_{i,n})^{\mathrm{T}} \tag{20.6.99}$$

where

$$U_{i,j} = (f_{i,j}, g_{i,j}, h_{i,j})^{\mathrm{T}} \tag{20.6.100}$$

Equations (20.6.97) are solved by Newton's method. The current iterate for U_i^k is updated:

$$\frac{\partial R_i}{\partial U_i}\delta U_i^k = -R_i \tag{20.6.101}$$

and

$$U_i^{k+1} = U_i^k + \delta U_i^k \tag{20.6.102}$$

The Jacobian matrix is block tridiagonal,

$$\frac{\partial R_i}{\partial U_i} = \begin{Bmatrix} A_1 & C_1 & & & & \\ B_2 & A_2 & C_2 & & & \\ & B_3 & A_3 & C_3 & & \\ & & \ddots & \ddots & \ddots & \\ & & & B_{n-1} & A_{n-1} & C_{n-1} \\ & & & & B_n & A_n \end{Bmatrix} \tag{20.6.103}$$

The diagonal matrices are

$$A_1 = \begin{Bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ a_{3,1_1} & a_{3,2_1} & a_{3,3_1} \end{Bmatrix} \qquad \text{for } j = 1$$

$$A_j = \begin{Bmatrix} 1 & -\frac{1}{2}\Delta\eta_j & 0 \\ 0 & 1 & -\frac{1}{2}\Delta\eta_j \\ a_{3,1_j} & a_{3,2_j} & a_{3,3_j} \end{Bmatrix} \qquad \text{for } j = 2, \ldots, n-1$$

$$A_n = \begin{Bmatrix} 1 & -\frac{1}{2}\Delta\eta_n & 0 \\ 0 & 1 & -\frac{1}{2}\Delta\eta_n \\ 0 & 1 & 0 \end{Bmatrix} \qquad \text{for } j = n \tag{20.6.104}$$

where

$$a_{3,1_j} = \tfrac{1}{2}\Delta\eta_{j+1} h_j + \frac{1}{4}\frac{\Delta\eta_{j+1}}{\Delta\xi_i}\overline{\xi}_i \overline{h}_{i,j+1}$$

$$a_{3,2_j} = -\tfrac{1}{2}\Delta\eta_j \overline{\beta}_i g_{i,j} - \frac{1}{4}\frac{\Delta\eta_{j+1}}{\Delta\xi_i}\overline{\xi}_i (g_{i,j+1} + g_{i,j} - g_{i-1,j+1} - g_{i-1,j} + \overline{g}_{i,j+1})$$

$$a_{3,3_j} = -1 + \tfrac{1}{2}\Delta\eta_{j+1} f_{i,j} + \frac{1}{4}\frac{\Delta\eta_{j+1}}{\Delta\xi_i}\overline{\xi}_i (f_{i,j+1} + f_{i,j} - f_{i-1,j+1} - f_{i-1,j}) \tag{20.6.105}$$

The off-diagonal matrices are

$$B_j = \begin{Bmatrix} -1 & -\frac{1}{2}\Delta\eta_j & 0 \\ 0 & -1 & -\frac{1}{2}\Delta\eta_j \\ 0 & 0 & 0 \end{Bmatrix} \qquad \text{for } j = 2, \ldots, n \tag{20.6.106}$$

$$C_j = \begin{Bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ c_{3,1_j} & c_{3,2_j} & c_{3,3_j} \end{Bmatrix} \qquad \text{for } j = 1, \ldots, n-1 \tag{20.6.107}$$

where

$$c_{3,1_j} = \tfrac{1}{2}\Delta\eta_{j+1} h_{i,j+1} + \frac{1}{4}\frac{\Delta\eta_{j+1}}{\Delta\xi_i}\overline{\xi}_i \overline{h}_{i,j+1}$$

$$c_{3,2_j} = -\tfrac{1}{2}\Delta\eta_j \overline{\beta}_i g_{i,j+1} - \frac{1}{4}\frac{\Delta\eta_{j+1}}{\Delta\xi_i}\overline{\xi}_i (g_{i,j+1} + g_{i,j} - g_{i-1,j+1} - g_{i-1,j} + \overline{g}_{i,j+1})$$

$$c_{3,3_j} = 1 + \tfrac{1}{2}\Delta\eta_{j+1} f_{i,j+1} + \frac{1}{4}\frac{\Delta\eta_{j+1}}{\Delta\xi_i}\overline{\xi}_i (f_{i,j+1} + f_{i,j} - f_{i-1,j+1} - f_{i-1,j}) \tag{20.6.108}$$

The above method is applied to the flow past a flat plate in the absence of a pressure gradient; i.e., $dp/dx = 0$ and $U_e(x) = U_\infty$. For this case, Eqs. (20.6.75) and (20.6.76) become

$$\xi = \rho\mu U_\infty x \tag{20.6.109}$$

$$\eta = y\sqrt{\frac{U_\infty}{2\nu x}} \tag{20.6.110}$$

and a self-similar solution (the *Blasius solution*) is obtained, wherein the dimensionless function f depends only on η, and

$$u = U_\infty \frac{df}{d\eta} \tag{20.6.111}$$

$$v = U_\infty\left(\frac{U_\infty x}{\nu}\right)^{-1/2}\frac{1}{\sqrt{2}}(-f + g\eta) \tag{20.6.112}$$

The computed streamwise and normal velocities are displayed in Figs. 20.6.13 and 20.6.14, respectively, for a grid of 50 points in the η direction with $\Delta\eta = 0.2$, together with the exact solution (Schlichting, 1968).

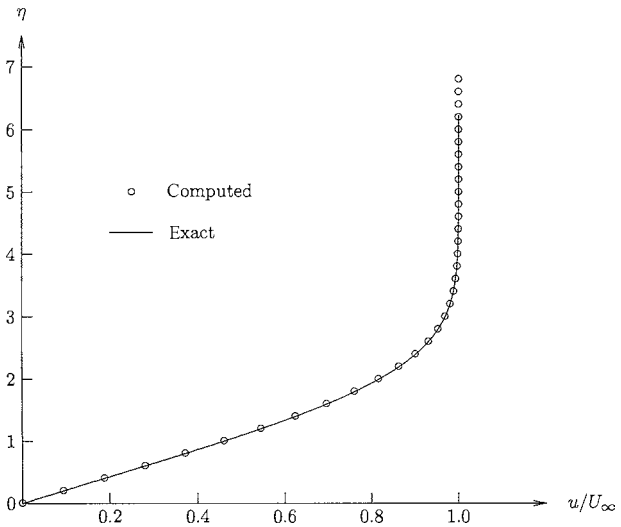

Fig. 20.6.13 Velocity at x direction.

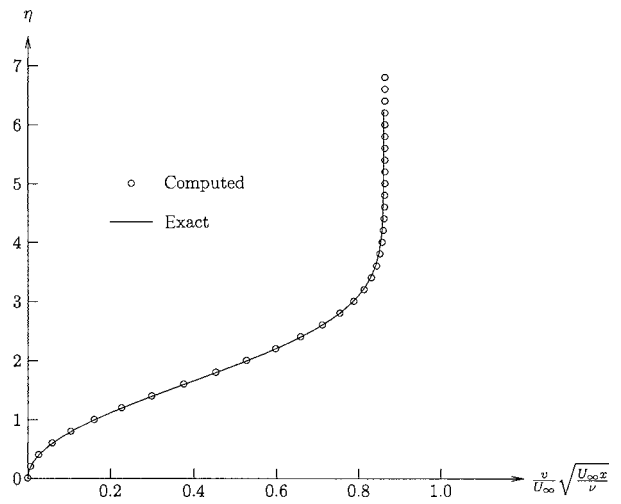

Fig. 20.6.14 Velocity in y direction.

NAVIER-STOKES FLOW

The unsteady Navier-Stokes equations are (with ˜ omitted for clarity):

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \tag{20.6.113}$$

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \hat{\nu}\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right) \tag{20.6.114}$$

$$\frac{\partial v}{\partial t} + u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \hat{\nu}\left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2}\right) \tag{20.6.115}$$

where $\hat{\nu} = \mu/\rho$ is the kinematic viscosity. The first boundary condition is

$$u = u_b \quad \text{and} \quad v = v_b \quad \text{on solid boundary} \tag{20.6.116}$$

where u_b and v_b are the x and y components of the velocity of the boundary. Equation (20.6.116) is the *no-slip condition*. The second boundary condition is

u and v approach their freestream values away from the solid boundary (20.6.117)

SIMPLE Algorithm

The Navier-Stokes equations (20.6.113) to (20.6.115) can be solved by using Patankar's SIMPLE algorithm (Patankar, 1980). A staggered grid (Harlow and Welch, 1965) is used to avoid unphysical oscillations in the pressure. Consider a uniform grid with constant spacing Δx and Δy, as illustrated in Fig. 20.6.15. The x and y components of velocity are defined on adjacent sides of the computational cell, and the pressure is defined at the center of the cell.

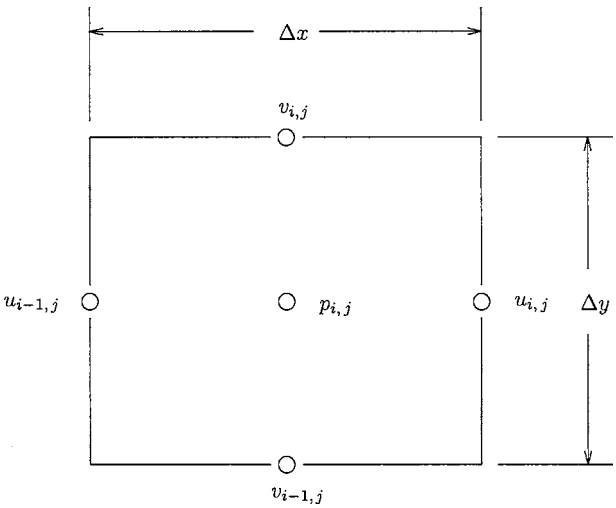

Fig. 20.6.15 Staggered grid.

The conservation of mass is applied to the finite volume in Fig. 20.6.15 to obtain

$$\left(u_{i,j}^{n+1} - u_{i-1,j}^{n+1}\right) + \left(v_{i,j}^{n+1} - v_{i-1,j}^{n+1}\right) = 0 \tag{20.6.118}$$

where i and j indicate the indices in the x and y directions, respectively, and n indicates the time level. The conservation of x momentum

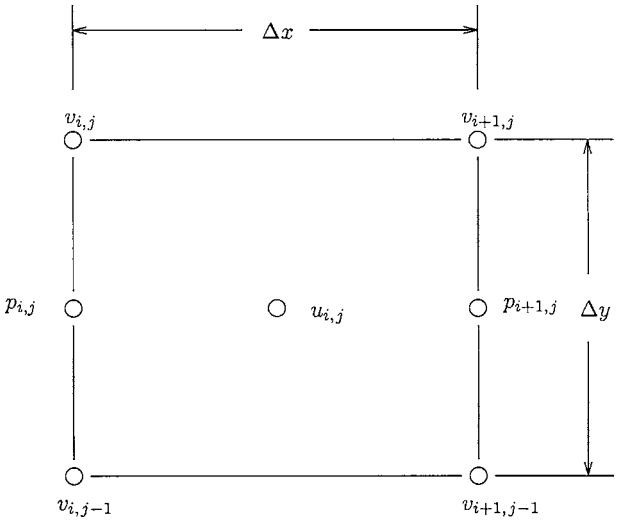

Fig. 20.6.16 Finite volume for x-momentum equation.

[Eq. (20.6.114)] is applied to the finite volume illustrated in Fig. 20.6.16 to obtain

$$\frac{\Delta x\,\Delta y}{\Delta t}\left(u_{i,j}^{n+1}-u_{i,j}^{n}\right)+\left(F_{i+\frac{1}{2},j}^{(1)}-F_{i-\frac{1}{2},j}^{(1)}\right)\Delta y + \left(G_{i,j+\frac{1}{2}}^{(1)}-G_{i,j-\frac{1}{2}}^{(1)}\right)\Delta x+\left(p_{i+1,j}^{n+1}-p_{i,j}^{n}\right)\Delta y=0 \tag{20.6.119}$$

where

$$F^{(1)}=u^2-\hat{\nu}\frac{\partial u}{\partial x} \tag{20.6.120}$$

$$G^{(1)}=uv-\hat{\nu}\frac{\partial u}{\partial y} \tag{20.6.121}$$

Similarly, the conservation of y momentum [Eq. (20.6.115)] is applied to the finite volume illustrated in Fig. 20.6.17 to obtain

$$\frac{\Delta x\,\Delta y}{\Delta t}\left(v_{i,j}^{n+1}-v_{i,j}^{n}\right)+\left(F_{i+\frac{1}{2},j}^{(2)}-F_{i-\frac{1}{2},j}^{(2)}\right)\Delta y + \left(G_{i,j+\frac{1}{2}}^{(2)}-G_{i,j-\frac{1}{2}}^{(2)}\right)\Delta x+\left(p_{i,j+1}^{n+1}-p_{i,j}^{n}\right)\Delta x=0 \tag{20.6.122}$$

where

$$F^{(2)}=uv-\hat{\nu}\frac{\partial v}{\partial x} \tag{20.6.123}$$

$$G^{(2)}=v^2-\hat{\nu}\frac{\partial v}{\partial y} \tag{20.6.124}$$

We consider the development of a discrete expression for $F^{(1)}$. Consider the one-dimensional steady analog of Eqs. (20.6.113) and (20.6.114) in the absence of a pressure gradient,

$$\frac{\partial u}{\partial x}=0 \tag{20.6.125}$$

$$\frac{\partial}{\partial x}\left(u^2-\hat{\nu}\frac{\partial u}{\partial x}\right)=0 \tag{20.6.126}$$

with boundary conditions

$$\begin{aligned} u&=u_1 \quad \text{at } x=x_1\\ u&=u_2 \quad \text{at } x=x_2 \end{aligned} \tag{20.6.127}$$

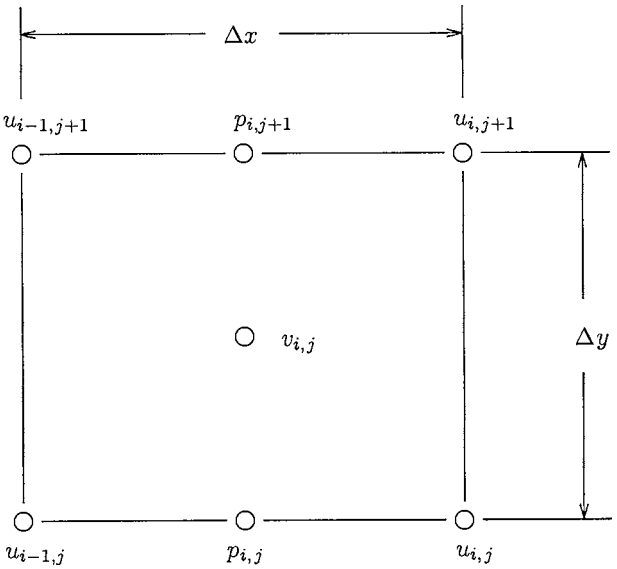

Fig. 20.6.17 Finite volume for y-momentum equation.

Linearizing the quadratic term in Eq. (20.6.126) as $u^2 \approx \bar{u}u$, where $\bar{u}$ is a suitable approximation to u, Eq. (20.6.126) can be solved to obtain

$$u=u_1+(u_2-u_1)\left[e^{\bar{u}(x-x_1)/\hat{\nu}}-1\right]\left[e^{\bar{u}(x_2-x_1)/\hat{\nu}}-1\right]^{-1} \tag{20.6.128}$$

which yields

$$\bar{u}u-\hat{\nu}\frac{\partial u}{\partial x}=\bar{u}\left\{u_1+(u_1-u_2)\left[e^{\bar{u}(x_2-x_1)}-1\right]^{-1}\right\} \tag{20.6.129}$$

Considering Eq. (20.6.129) as the expression for $F_{i+\frac{1}{2},j}^{(1)}$ in Eq. (20.6.119) and identifying points 1 and 2 to be (i, j) and $(i+1, j)$, we obtain

$$F_{i+\frac{1}{2}}^{(1)}=u_{i+\frac{1}{2},j}^{n+1}\left[u_{i,j}^{n+1}+\left(u_{i,j}^{n+1}-u_{i+1,j}^{n+1}\right)\left[e^{R_{i+\frac{1}{2},j}}-1\right]^{-1}\right] \tag{20.6.130}$$

where

$$R_{i+\frac{1}{2},j}=\frac{u_{i+\frac{1}{2},j}^{n+1}\Delta x}{\hat{\nu}} \tag{20.6.131}$$

Using a similar expression for $F_{i-\frac{1}{2},j}^{(1)}$ yields

$$\left(F_{t+\frac{1}{2},j}^{(1)}-F_{i-\frac{1}{2},j}^{(1)}\right)\Delta y=a_P u_{i,j}^{n+1}-a_E u_{i+1,j}^{n+1}-a_W u_{i-1,j}^{n+1} \tag{20.6.132}$$

where

$$a_E=u_{i+\frac{1}{2},j}^{n+1}\Delta y\left[e^{R_{i+\frac{1}{2},j}}-1\right]^{-1} \tag{20.6.133}$$

$$a_W=u_{i-\frac{1}{2},j}^{n+1}\Delta y\left[1+\left[e^{R_{i-\frac{1}{2},j}}-1\right]^{-1}\right] \tag{20.6.134}$$

$$a_P=a_E+a_W+\left(u_{i+\frac{1}{2},j}^{n+1}-u_{i-\frac{1}{2},j}^{n+1}\right)\Delta y \tag{20.6.135}$$

The subscripts E, W, and P are mnemonics for east, west, and point, respectively. Defining a diffusion conductance D according to

$$D=\frac{\hat{\nu}}{\Delta x} \tag{20.6.136}$$

we obtain

$$a_E=\frac{D_{i+\frac{1}{2},j}R_{i+\frac{1}{2},j}\Delta y}{e^{R_{i+\frac{1}{2},j}}-1} \tag{20.6.137}$$

Since the exponential is costly to evaluate computationally, Patankar (1980) developed the *Power Law* approximation

$$\frac{a_E}{\Delta y D_{i+\frac{1}{2},j}} = \begin{cases} -R_{i+\frac{1}{2},j} & R_{i+\frac{1}{2},j} < 10 \\ \left(1 + 0.1R_{i+\frac{1}{2}j}\right)^5 - R_{i+\frac{1}{2},j} & -10 \le R_{i+\frac{1}{2},j} < 0 \\ \left(1 - 0.1R_{i+\frac{1}{2},j}\right)^5 & 0 \le R_{i+\frac{1}{2},j} < 10 \\ 0 & R_{i+\frac{1}{2},j} \ge 10 \end{cases} \tag{20.6.138}$$

Additional approximation (e.g., central difference, hybrid, upwind) are also possible (Patankar, 1980). The coefficients may be written as

$$a_E = D_{i+\frac{1}{2},j}\Delta y\left[\max(0,(1 - 0.1|R_{i+\frac{1}{2},j}|)^5) + \max(-R_{i+\frac{1}{2},j}, 0)\right] \tag{20.6.139}$$

$$a_W = D_{i-\frac{1}{2},j}\Delta y\left[R_{i-\frac{1}{2},j} + \max(0, (1 - 0.1|R_{i-\frac{1}{2},j}|)^5) + \max(-R_{i-\frac{1}{2},j}, 0)\right] \tag{20.6.140}$$

$$a_P = a_E + a_W + \left(u_{i+\frac{1}{2},j} - u_{i-\frac{1}{2},j}\right)\Delta y \tag{20.6.141}$$

Similarly,

$$\left(G^{(1)}_{i,j+\frac{1}{2}} - G^{(1)}_{i,j-\frac{1}{2}}\right)\Delta x = b_P u^{n+1}_{i,j} - b_N u^{n+1}_{i,j+1} - b_S u^{n+1}_{i,j-1} \tag{20.6.142}$$

where

$$b_N = D_{i,j+\frac{1}{2}}\Delta x\left[\max(0,(1 - 0.1|R_{i,j+\frac{1}{2}}|)^5) + \max(-R_{i,j+\frac{1}{2}}, 0)\right] \tag{20.6.143}$$

$$b_S = D_{i,j-\frac{1}{2}}\Delta x\left[R_{i,j-\frac{1}{2}} + \max(0,(1 - 0.1|R_{i,j-\frac{1}{2}}|)^5 + \max(-R_{i,j-\frac{1}{2}}, 0)\right] \tag{20.6.144}$$

$$b_P = b_N + b_S + \left(v_{i,j+\frac{1}{2}} - v_{i,j-\frac{1}{2}}\right)\Delta x \tag{20.6.145}$$

with

$$R_{i,j+\frac{1}{2}} = \frac{v_{i,j+\frac{1}{2}}\Delta y}{\hat{\nu}} \tag{20.6.146}$$

The x- and y-momentum equations become

$$\frac{\Delta x\,\Delta y}{\Delta t}\left(u^{n+1}_{i,j} - u^n_{i,j}\right) + a_P u^{n+1}_{i,j} - a_E u^{n+1}_{i+1,j} - a_W u^{n+1}_{i-1,j} + b_P u^{n+1}_{i,j} - b_N u^{n+1}_{i,j+1} - b_S u^{n+1}_{i,j-1} + \Delta y\left(p^{n+1}_{i+1,j} - p^{n+1}_{i,j}\right) = 0 \tag{20.6.147}$$

$$\frac{\Delta x\,\Delta y}{\Delta t}\left(v^{n+1}_{i,j} - v^n_{i,j}\right) + c_P v^{n+1}_{i,j} - c_E v^{n+1}_{i+1,j} - c_W v^{n+1}_{i-1,j} + d_P v^{n+1}_{i,j} - d_N v^{n+1}_{i,j+1} - d_S v^{n+1}_{i,j-1} + \Delta x\left(p^{n+1}_{i,j+1} - p^{n+1}_{i,j}\right) = 0 \tag{20.6.148}$$

where the coefficients c_E, c_W, c_P and d_N, d_S, d_P are given by Eqs. (20.6.139) to (20.6.141) and (20.6.143) to (20.6.145) with due consideration to the expressions for $R_{i\pm\frac{1}{2},j}$ and $R_{i,j\pm\frac{1}{2}}$.

Equations (20.6.147) and (20.6.148) are solved by iteration, using the pressure field at the previous time step $p^n_{i,j}$. The resultant expressions for the velocity components, denoted $\hat{u}^{n+1}_{i,j}$ and $\hat{v}^{n+1}_{i,j}$, therefore satisfy

$$\frac{\Delta x\,\Delta y}{\Delta t}\left(\hat{u}^{n+1}_{i,j} - u^n_{i,j}\right) + a_P\hat{u}^{n+1}_{i,j} - a_E\hat{u}^{n+1}_{i+1,j} - a_W\hat{u}^{n+1}_{i-1,j} + b_P\hat{u}^{n+1}_{i,j} - b_N\hat{u}^{n+1}_{i,j+1} - b_S\hat{u}^{n+1}_{i,j-1} + \Delta y\left(p^n_{i+1,j} - p^n_{i,j}\right) = 0 \tag{20.6.149}$$

$$\frac{\Delta x\,\Delta y}{\Delta t}\left(\hat{v}^{n+1}_{i,j} - v^n_{i,j}\right) + c_P\hat{v}^{n+1}_{i,j} - c_E\hat{v}^{n+1}_{i+1,j} - c_W\hat{v}^{n+1}_{i-1,j} + d_P\hat{v}^{n+1}_{i,j} - d_N\hat{v}^{n+1}_{i,j+1} - d_S\hat{v}^{n+1}_{i,j-1} + \Delta x\left(p^n_{i,j+1} - p^n_{i,j}\right) = 0 \tag{20.6.150}$$

However, $\hat{u}_{i,j}$ and $\hat{v}_{i,j}$ do not satisfy conservation of mass [Eq. (20.6.118)]. Consequently, a correction $u'_{i,j}$ and $v'_{i,j}$ must be determined, Writing

$$u^{n+1}_{i,j} = \hat{u}^{n+1}_{i,j} + u'_{i,j} \tag{20.6.151}$$

$$v^{n+1}_{i,j} = \hat{v}^{n+1}_{i,j} + v'_{i,j} \tag{20.6.152}$$

$$p^{n+1}_{i,j} = p^n_{i,j} + \delta p_{i,j} \tag{20.6.153}$$

and subtracting (20.6.149) from (20.6.147) and (20.6.150) from (20.6.148) yields

$$\left(\frac{\Delta x\,\Delta y}{\Delta t} + a_P + b_P\right)u'_{i,j} - a_W u'_{i-1,j} - a_E u'_{i+1,j} - b_S u'_{i,j-1} - b_N u'_{i,j+1} + \Delta y\,(\delta p_{i+1,j} - \delta p_{i,j}) = 0 \tag{20.6.154}$$

$$\left(\frac{\Delta x\,\Delta y}{\Delta t} + c_P + d_P\right)v'_{i,j} - c_W v'_{i-1,j} - c_E v'_{i+1,j} - d_S v'_{i,j-1} - d_N v'_{i,j+1} + \Delta x(\delta p_{i,j+1} - \delta p_{i,j}) = 0 \tag{20.6.155}$$

These equations are simplified (Patankar, 1980) to

$$\left(\frac{\Delta x\,\Delta y}{\Delta t} + a_P + b_P\right)u'_{i,j} = -\Delta y(\delta p_{i+1,j} - \delta p_{i,j}) \tag{20.6.156}$$

$$\left(\frac{\Delta x\,\Delta y}{\Delta t} + c_P + d_P\right)v'_{i,j} = -\Delta x(\delta p_{i,j+1} - \delta p_{i,j}) \tag{20.6.157}$$

The expressions in Eqs. (20.6.151) and (20.6.152), together with Eqs. (20.6.156) and (20.6.157), are substituted into the conservation of mass [Eq. (20.6.118)] to obtain an equation for the pressure correction:

$$g_{i,j}\delta p_{i,j} = \left(\hat{u}^{n+1}_{i-1,j} - \hat{u}^{n+1}_{i-1,j}\right)\Delta y + \left(\hat{v}^{n+1}_{i,j} - \hat{v}^{n+1}_{i,j-1}\right)\Delta x + (e_{i,j}\delta p_{i+1,j} + e_{i-1,j}\delta p_{i-1,j})\,\Delta y + (f_{i,j}\delta p_{i,j+1} + f_{i,j-1}\delta p_{i,j-1})\,\Delta x \tag{20.6.158}$$

where

$$e_{i,j} = -\Delta y\left[\frac{\Delta x\,\Delta y}{\Delta t} + a_P + b_P\right]^{-1} \tag{20.6.159}$$

$$f_{i,j} = -\Delta x\left[\frac{\Delta x\,\Delta y}{\Delta t} + c_P + d_P\right]^{-1} \tag{20.6.160}$$

$$g_{i,j} = (e_{i,j} + e_{i-1,j})\,\Delta y + (f_{i,j} + f_{i,j-1})\,\Delta x \tag{20.6.161}$$

The algorithm is known as SIMPLE (Semi-Implicit Method for Pressure-Linked Equations) (Patankar, 1980). The solution procedure is:

1. The approximate solution $\hat{u}^{n+1}_{i,j}$ and $\hat{v}^{n+1}_{i,j}$ is obtained from Eqs. (20.6.149) and (20.6.150) by iteration. This can be achieved in a two-step procedure. First, each equation is written as scalar tridiagonal system along each y grid line and solved by the Thomas algorithm (Anderson et al., 1984). Second, each equation is written as a tridiagonal system along each x grid line and solved. The two-step procedure is iterated until converged.
2. The correction to the pressure δp_{ij} is obtained by solution of Eq. (20.6.158), using, for example, successive overrelaxation (Anderson et al., 1984).

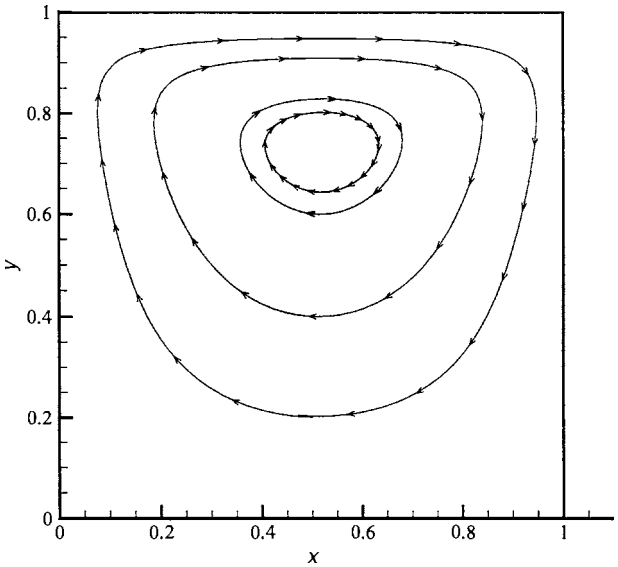

Fig. 20.6.18 Driven flow in cavity.

3. The pressure is updated according to $p_{i,j}^{n+1} = p_{i,j}^{n} + \omega_p \, \delta p_{i,j}$

4. The correction to the velocity, $u'_{i,j}$ and $v'_{i,j}$, is obtained from Eqs. (20.6.156) and (20.6.157) and the velocity is updated according to Eqs. (20.6.151) and (20.6.152).

5. The process is repeated until steady state is achieved (if appropriate) or the unsteady solution is obtained for the desired period of time

Several improvements to the SIMPLE algorithm have also been developed as described in Fletcher (1988b).

The above method is applied to the driven flow in a cubic cavity as shown in Fig. 20.6.18. The upper surface moves to the right at a constant speed U. The three remaining walls are stationary. The Reynolds number $\mathrm{Re} = UL/\nu$ is 100. The streamlines display the convective motion generated by the shearing force exerted by the movement of the upper surface.

20.7 EXPERIMENTAL FLUID DYNAMICS

by Yiannis Andreopoulos

INTRODUCTION

Experimental fluid dynamics (EFD) is a branch of fluid dynamics that complements the analytical and computational fluid dynamics branches. Although the complete equations describing fluid motions were derived several decades ago, today there are only a few solutions of particular problems of those nonlinear, partial differential equations. For turbulent flows, for instance, these solutions are limited to very low Reynolds number flows, which are not applicable to present data technological flows that are mostly in the high Reynolds number regime. Consequently, physical and numerical experiments will increasingly be employed to provide guidance and solutions to many engineering and technological problems.

The major objective of this section is to introduce the subject of experimental fluid dynamics broadly to readers, to provide an up-to-date view of the fundamentals of some key methods, and to present emerging needs and trends in current technological applications. The field of EFD is rather large and extends over the entire range of fluid dynamics, including not only the customary fields of aeronautics and hydraulics, but also diverse topics as biological and biomedical flows, including insect flight mechanics and pulmonary and blood flows, meteorology, oceanography, granular flows, and metallurgy.

Laboratory experiments require two very important processes: (1) designing or selecting the flow simulation platform and (2) selecting and designing the measurement system. The objectives of the experimental work will determine whether a new experimental setup is needed or an existing facility can be used. The measurement system has to be built around the flow simulation platform by accommodating possible operating restrictions and to fulfill the specific objectives of the experiments. In cases of direct measurements in the field with actual moving objects or in nature, designing the measurement system is the most critical aspect of the work.

Fluid mechanical quantities to be measured can range from forces and flow rates to dissipation rates of kinetic energy and enstrophy. Measurements of lift and drag forces of a body moving in air or water or the power attainable in a turbomachine are typical tasks in engineering applications, while the measurements of the rate-of-strain tensor and vorticity are typical of research-oriented problems that can provide better understanding of the physics of the flows and lead to analytical and computational tools that can predict the efficiency of fluid systems more accurately than existing methods.

EFD encompasses single- and multicomponent fluids, multiphase flows, newtonian and non-newtonian flows, chemically reacting flows, and biological fluid mechanics. We will restrict our description to single-component, chemically nonreactive flows. In that context, issues related to incompressible and compressible flows will be discussed in detail. Particular emphasis will be given to techniques related to applications in emerging technologies and to measurements of quantities that are not in the mainstream, such as spatially and temporarily resolved vorticity, rate-of-strain tensor, and dissipation rate of kinetic energy, which are essential in describing the efficiency of fluid systems. The scope of the present contribution excludes the description of facilities used to simulate specific flow phenomena. Extensive coverage of items like wind tunnels and water tunnels, towing tanks and wave tanks, and shock tubes is provided in Refs. 1 to 7 and at NASA Web sites.

BACKGROUND INFORMATION

The relative importance of each of the measurable fluid mechanical quantities and their relationship can be appreciated by considering the application of conservation laws of mass, momentum, and energy, which leads to expressions in the form of integral or differential equations. The continuum approximation will be assumed to be valid in the present description. The fluid flow is inside a control volume V bounded by a control surface ∂V with n, the unit vector, normal in the outside direction. Here $U(x, t) = (U_1, U_2, U_3)$ is the **velocity field** as a function of location x and time t, ρ is the density, E is the **total specific energy** $E_t = (e + \frac{1}{2} U_i U_i)$ and e is the specific internal energy. Einstein's summation convention of repeated indices is applied here.

Conservation of Mass

$$\frac{d}{dt}\int_V \rho\, dV + \int_{\partial V} \rho U_k n_k\, dA = 0 \tag{20.7.1}$$

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_k}(\rho U_k) = 0 \tag{20.7.2}$$

Conservation of Momentum: Newton's Second Law

$$\frac{d}{dt}\int_V \rho U_i\, dV + \int_{\partial V} \rho (U_k n_k) U_i\, dA = -\int_{\partial V} \sigma_{ki} n_k\, dA + \int_V \rho f_i\, dV \tag{20.7.3}$$

where σ_{ki} is the second-order stress tensor and f_i represents the components of the specific external forces acting on this control volume.

$$\frac{\partial}{\partial t}(\rho U_i) + \frac{\partial}{\partial x_k}(\rho U_k U_i) = \frac{\partial \sigma_{ki}}{\partial x_k} + \rho f_i \tag{20.7.4}$$

where $\sigma_{ki} = -p\delta_{ki} + \tau_{ki} = -p\delta_{ki} + 2\mu S_{ki}$ and S_{ki} is the rate-of-strain tensor.

Conservation of Energy

$$\frac{d}{dt}\int_V \rho E_t\, dV + \int_{\partial V} \rho E_t U_k n_k\, dA = \int_{\partial V} U_i \sigma_{ki} n_k\, dA - \int_{\partial V} q_k n_k\, dA + \int_V \rho U_i f_i\, dV \tag{20.7.5}$$

$$\frac{\partial}{\partial t}(\rho E_t) + \frac{\partial}{\partial x_k}(\rho U_k E_t) = \frac{\partial U_i \sigma_{ki}}{\partial x_k} + \rho U_i f_i \tag{20.7.6}$$

Velocity Gradient Tensor, Strain-Rate, Vorticity, and Dissipation Rate

The velocity gradient tensor A_{ij} can be decomposed, not uniquely, into a symmetric and antisymmetric part. Specifically, these two parts are the rate-of-strain tensor $S_{ij} = \frac{1}{2}(\partial U_i/\partial x_j + \partial U_j/\partial x_i)$ and the-rate-of rotation tensor $R_{ij} = \frac{1}{2}(\partial U_i/\partial x_j - \partial U_j/\partial x_i) = \frac{1}{2}\varepsilon_{ijk}\Omega_k$, where Ω_k is the vorticity vector. Ω_k is defined as the curl of the velocity vector

$$\Omega_k = \epsilon_{ijk}\frac{\partial U_i}{\partial x_j} \tag{20.7.7}$$

and ϵ_{ijk} is the alternating unit vector. At each point in the flow field we may imagine a spherical fluid particle whose motion can be decomposed into translation, expansion, shearing, and rotation. The vorticity can be interpreted as just twice the instantaneous solid-body-like rotation

rate of the fluid particles along the principal axes in the fluid where there exists no shear deformation. We may alternatively interpret the **vorticity** as the circulation per unit area of a surface perpendicular to the vorticity field.

Why is vorticity so important in understanding the dynamics of turbulent fluid flow? Insight into this may be gained by looking at the equation describing the transport of vorticity[8]

$$\frac{d\Omega_i}{dt} = S_{ik}\Omega_k - \Omega_i S_{kk} + \epsilon_{iqn}\frac{1}{\rho^2}\frac{\partial\rho}{\partial x_q}\frac{\partial p}{\partial x_n} + \epsilon_{iqn}\frac{\partial}{\partial x_q}\left(\frac{1}{\rho}\frac{\partial\tau_{nj}}{\partial x_j}\right) \tag{20.7.8}$$

This transport equation indicates that, for an observer moving with the flow, the rate of change of vorticity component Ω_i of a particle is provided by four dynamically significant processes: (1) stretching or compression and reorientation or tilting by the strain S_{ik}, (2) vorticity generation through dilatation, (3) baroclinic generation through the interaction of pressure and density gradients, and (4) viscous effects expressed by the viscous stress term. The term $S_{ik}\Omega_k$ consists of one stretching or compression component and two tilting components. This term has been illuminated mostly through numerical work and it appears to play an important role in the various physical processes involved in turbulent flows. If the viscous term can be ignored when its magnitude is small, then the change of vorticity of a fluid element in a lagrangian frame of reference can be entirely attributed to vortex stretching and/or tilting, to dilatational effects, and to baroclinic torque.

If the above equation is multiplied by Ω_i, then the transport equation for the enstrophy $\frac{1}{2}\Omega_i\Omega_i$ can be obtained:

$$\frac{d(\frac{1}{2}\Omega_i\Omega_i)}{dt} = S_{ik}\Omega_k\Omega_i - \Omega_i\Omega_i S_{kk} + \epsilon_{iqn}\frac{1}{\rho^2}\Omega_i\frac{\partial\rho}{\partial x_q}\frac{\partial p}{\partial x_n} + \epsilon_{iqn}\frac{\partial}{\partial x_q}\left(\Omega_i\frac{1}{\rho}\frac{\partial\tau_{nj}}{\partial x_j}\right) - \epsilon_{iqn}\frac{1}{\rho}\frac{\partial\Omega_j}{\partial x_q}\frac{\partial\tau_{nj}}{\partial x_j} \tag{20.7.9}$$

The physical meaning of the terms associated with the time-dependent changes of enstrophy of a fluid element in a lagrangian frame of reference are similar with those responsible for the generation or destruction of vorticity. The physical mechanisms involved in these complex processes are not fully understood. Enstrophy is a very significant quantity in fluid dynamics because it is not only related to the solenoidal dissipation, but also to several of the invariants of the rate-of-strain matrix S_{ij}, which may lead to detection of vortex tubes and shear layers in the flow field. In addition, enstrophy is a source term in the **transport equation** of **dilatation** S_{kk}:

$$\frac{dS_{kk}}{dt} = -S_{ik}S_{ki} + \frac{1}{2}\Omega_k\Omega_k + \frac{1}{\rho^2}\frac{\partial\rho}{\partial x_k}\frac{\partial p}{\partial x_k} - \frac{1}{\rho}\frac{\partial^2 p}{\partial x_k\partial x_k} + \frac{\partial}{\partial x_k}\left(\frac{1}{\rho}\frac{\partial\tau_{kq}}{\partial x_q}\right) \tag{20.7.10}$$

This transport equation relates the change of dilatation along a particle path, which can be caused by the straining action of the dissipative motions ($S_{ik}S_{ik}$) as well as by the rotational energy of the spinning motions as it is expressed by the enstrophy $\frac{1}{2}\Omega_i\Omega_i$. Pressure and density gradients as well as viscous diffusion can also affect dilatation. It should be noted that the above transport equation reduces to the well-known Poisson equation for incompressible flows of constant density ($S_{kk} = 0$).

The dissipation rate of kinetic energy, defined as $E = \tau_{ij}S_{ij}$, is a key quantity in determining viscous losses in fluid systems. It can be expanded[9] as:

$$E = \tau_{ij}S_{ij} = 2\mu S_{ij}S_{ij} - \frac{2}{3}\mu S_{kk}S_{kk} \tag{20.7.11}$$

The second term in the right-hand side of the above relation represents the additional contribution of compressibility to the dissipation rate of kinetic energy. This term disappears in the cases of **incompressible flow.** Since this term is always positive, the negative sign in front may erroneously suggest that compressibility reduces dissipation. This is incorrect because the term $S_{ij}S_{ij}$ also contains contributions from dilatation effects, which can be revealed if one considers that

$$S_{ij}S_{ij} = \frac{1}{2}\Omega_k\Omega_k + \frac{\partial U_i}{\partial x_j}\frac{\partial U_j}{\partial x_i} \tag{20.7.12}$$

The second term in the right-hand side represents the inhomogeneous contribution in the case of incompressible flows. In the case of compressible flows, terms related to dilatation can be extracted, and the instantaneous total dissipation rate then becomes

$$E = \mu\Omega_k\Omega_k + 2\mu\left[\frac{\partial U_i}{\partial x_j}\frac{\partial U_j}{\partial x_i} - S_{kk}S_{kk}\right] + \frac{4}{3}\mu S_{kk}S_{kk} \tag{20.7.13}$$

The third term on the right-hand side describes the direct effects of compressibility, i.e., dilatation on the dissipation rate. The first and the last terms on the right-hand side of the last relation are quadratic with positive coefficients and positive signs and they are, therefore, always positive. The second term on the right-hand side indicates the contributions to the dissipation rate by the purely nonhomogeneous part of the flow. Its time-averaged contribution disappears in homogeneous flows. This term, in principle, can obtain negative values, and thus it can reduce the dissipation rate. This does not violate the second thermodynamic law as long as the total dissipation remains positive at any point in space and time

The above description indicates that velocity, pressure, and temperature are the primary measurable quantities that can determine the local stresses acting on a body inside a flow field and therefore can be used to estimate the resultant forces and possibly torques exerted on various parts of a fluid system. The availability of this type of information will help determine the performance of the fluid system. However, if estimates of the efficiency of the system are required, determination of kinetic energy dissipation rate is essential. This demand is more critical in the case of turbulent flows, where viscous losses are substantially larger than in laminar flows.

CLASSIFICATION OF MEASUREMENTS

A typical block diagram of the measuring system of an experimental technique is shown in Fig. 20.7.1. It includes a probe, a transducer, a signal processing unit with an amplifier, an interface to the data processing unit such as an analog to digital converter, a data processing unit with a CPU, and a storage or a display unit. This type of block diagram is very useful in estimating and reducing uncertainties along the line with the various stages of the measurement system.

The output of instruments measuring fluid mechanical quantities can be purely mechanical, electrical, or optical. Most of the techniques used in EFD include probes and transducers that convert the measured value of a fluid mechanical quantity into an electrical output, which, through an appropriate interface, can feed the CPU of a computer or the local processing unit of the instrument with a display, as shown in Fig. 20.7.1. Substantial effort has been devoted in the past to develop transducers and instrumentation that convert the measured quantity into an electrical signal, which carries the information. Optical

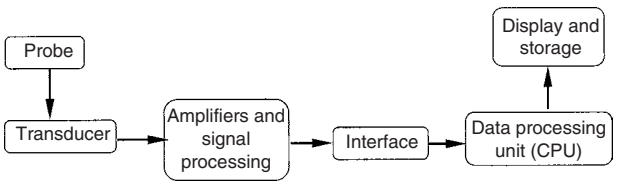

Fig. 20.7.1 Typical block diagram of a measurement system.

carriers and optical techniques, however, have the advantage of faster transmission and processing of information because light travels faster than electricity. In that respect the use of light and the development of optical converters in the future may provide an incentive to replace electrical converters of mechanical quantities.

In most optical techniques the use of flow tracers or flow markers is required. Flow tracers are solid particles that are introduced into the flow and scatter light when they are illuminated. These particles should have a dynamic response comparable to the dynamics of the flow; i.e., they should follow a temporally fluctuating flow very closely, and therefore their density has to match that of the fluid. This problem is more critical in gas flows than in liquid flows. In addition the presence of these particles should not interfere with the flow and change its structure. Flow markers, on the other hand, are molecules of the same fluid of the flow field or foreign molecules that emit light and can be detected when they are excited by photons. In that respect, inertia effects similar to those found in flow tracers are not present here because of the molecular nature of the flow markers.

Flow rate of information from one block to the next (see Fig. 20.7.1) can be hampered by the limited processing speed and storage capability in each of the blocks. This may have an effect on the spatial and/or temporal resolution of the measurement.

Experimental techniques used in EFD can provide qualitative and/or quantitative information about the flow field. Flow visualization techniques, for instance, although qualitative in nature can provide substantially useful information on the flow structure that could not be revealed even through detailed quantitative measurements.

Another way to classify experimental techniques is by considering whether they provide single-point measurement or multipoint measurements. The latter can be on a plane inside the flow field or in a volume that is part of the flow field. These techniques are usually referred as *global measurement techniques*.

GENERAL REQUIREMENTS

The first requirement of every experimental technique is to avoid interference with the flow itself because any disturbance introduced by the probe, the probe-volume or flow tracers needed in the particular technique can alter the flow field substantially. Consider, for instance, an intrusive technique which is using a probe holder to support the sensor. If the sensor is located far upstream of the probe holder and the whole system is designed so that all disturbances introduced into the flow field travel downstream, the flow at the sensor will not be affected. In separated flows, however, where flow reversals take place, disturbances propagate upstream and the use of intrusive measurement techniques is prohibited. In these cases, which are characterized by partial differential equations [see Eq. (20.7.4)] that are elliptical, the use of nonintrusive, mostly optical techniques is recommended.

The second requirement is that the technique should be sensitive to small spatial and temporal changes of the measured quantity in the flow field. This brings the issues of spatial and temporal resolution of the probe. In a steady state laminar flow, for instance, the probe size should be small enough to be able to resolve spatial gradients of the quantity inside the flow field. The case of measurement of a quantity Q_i that varies drastically in the x_j direction is shown in Fig. 20.7.2. If we assume that the size of the sensing area has a linear scale Δx_s, then the change of Q_i along the x_j direction will be $\Delta Q_i = (\partial Q_i/\partial x_j)\Delta x_s$, and since most sensors are not able to measure the variation of Q_i in the x_j direction, the sensor will measure an area-weighed average of $Q_i + \overline{\Delta Q_i}$. The question for the experimentalist is whether this uncertainty in ΔQ_i is acceptable or not. Further reducing the size of the sensing area Δx_s will reduce the error. However, this is not always attainable even if fabrication of small size sensors were possible, because electronic or optical interference noise may increase the uncertainty.

In case of temporal flow variations, the sensor should have adequate frequency response to resolve variations in the measured quantity within the smallest time scale acceptable. Usually separate tests with temporal step change in the measured quantity are needed to determine the frequency response of the sensor. For dynamic measurements of pressure, velocity, temperature, or density the shock tube is an ideal platform for frequency response tests.

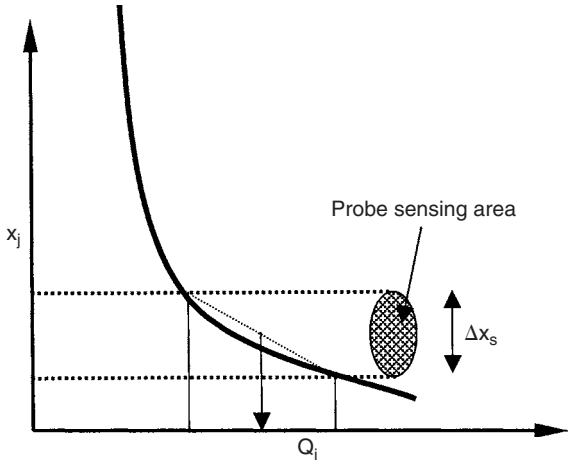

Fig. 20.7.2 Spatial resolution of sensing area.

Spatial and Temporal Resolution in Turbulent Flows

Turbulent flows are characterized by a large range of spatial and temporal scales and the sensors are not only required to have adequate **spatial and temporal response** and resolution but also good response to suddenly changing flow directions (yaws and pitch response).

The spatial and temporal resolution of any probe affects the accuracy of measurements of time-dependent velocity U_i, velocity gradients A_{ij}, or vorticity components Ω_k. This resolution depends on the arrangement of the sensors used in the technique, the hardware used to generate the measuring probe volume and to process the signals, the particles used as flow tracers to scatter light, and their arrival rate in the measuring locations. Thus the technique has a typical characteristic length scale L_p, which is usually associated with the separation distance between the sensing areas, and a time scale T_p, which depends mostly on the speed of data acquisition or burst processor. The technique should be able to resolve the small scales that exist in a given flow, which appear to be the Kolmogorov viscous scales $\eta = \nu^{3/4}\epsilon^{-1/4}$ for length and $T_\epsilon = \nu^{1/2}\epsilon^{-1/2}$ for time, where ϵ is the dissipation rate of turbulent kinetic energy and ν is the kinematic viscosity. The quantity ϵ is the time-averaged value of the fluctuating part of E in Eqs. (20.7.11) and (20.7.13). L_p and T_p should be less than η and T_ϵ, respectively, in order to capture contributions from the smallest eddies of the flow field. In the case of vorticity or velocity gradients, the small scales are responsible for most of the content of vorticity or velocity gradient fluctuations, since small eddies are uncorrelated. Wyngaard[10] was the first to evaluate the problem of spatial resolution of **hot-wire** based vorticity techniques and found that no attenuation occurred for $L_p/\eta = 1$, while substantial attenuation of vorticity was evident for $L_p/\eta > 3.3$. The review by Wallace and Foss[11] concludes that reasonable estimates of velocity gradients can be obtained without attenuation with $L_p/\eta < 2$ to 4.

Although L_p has to be as small as possible, it cannot be minimized independently from other parameters such as the speckle noise. Errors due to noise in the measurements amplify as the length scale decreases. There is certainly an optimum length intermediate between attenuation and amplification of noise.

Determining η requires a good estimate of turbulent kinetic energy dissipation rate ϵ or the total dissipation rate E, which is very difficult to measure directly in a laboratory. Previous studies obtained the value

of E by making assumptions to reduce some of the terms in the expression of the total dissipation rate:[9]

The estimates that usually are provided for E, particularly those based on indirect methods, may be very misleading. An experiment with poor spatial resolution will result in attenuation of all measured turbulent quantities, including the dissipation rate, which will indicate high η and therefore high resolution.

It should be mentioned here, however, that there is increasing evidence provided in Refs. 12 and 13 that the Taylor micro scale λ should be used to determine the spatial resolution in vorticity measurements. It has been shown that in the limit of vanishing separation Δx_j between the measurement locations, the root mean square (rms) of the fluctuations of one velocity gradient $\partial U_i/\partial x_j$ is given by

$$\lim_{\Delta x_j \to 0} \overline{\left[\frac{\Delta U_i}{\Delta x_j}\right]^2} = \frac{\overline{u_i^2}}{\lambda_{ij}^2}\left[1 + \lambda_{ij}^2\left[\frac{\partial \rho}{\partial(\Delta x_j)}\right]^2\right]$$

where λ_{ij} is the Taylor micro scale. If the gradient $\partial\rho/\partial\Delta x_j$, which indicates the degree of variation of the rms of velocity fluctuations, is much smaller than $1/\lambda_{ij}^2$, then the relation

$$\lim_{\Delta x_j \to 0} \overline{\left[\frac{\Delta U_i}{\Delta x_j}\right]^2} = \frac{\overline{u_i^2}}{\lambda_{ij}^2}$$

provides the best estimate for ideal resolution when Δx_j tends to zero. In that respect the ratio L_p/λ_{ij} should be less than 1.

An example of the effect of temporal resolution on the statistical results of vorticity flux $\partial\Omega_z/\partial y$, for instance, is obtained from the data of Andreopoulos and Agui.[82] Artificial sampling times Δt were produced by skipping by various numbers of equally sampled data digitized at rates substantially faster than the Kolmogorov frequency $1/T_\epsilon$. The results, plotted in Fig. 20.7.3, show a substantial dependence of the rms of vorticity flux on temporal resolution Δt.

Although statistics of fluctuations of individual velocity components do not require increased temporal resolution, cross-correlation/shear stress and velocity gradients/vorticity measurements by optical techniques using particles as flow tracers require a high degree of coincidence of these particles at different locations inside the probe volume. This can be achieved by providing a high rate of particles, which results in practically continuous signals. The resolution in time depends basically on the rate of arrivals of particles in the probe volume and on the data processing rate of the hardware.

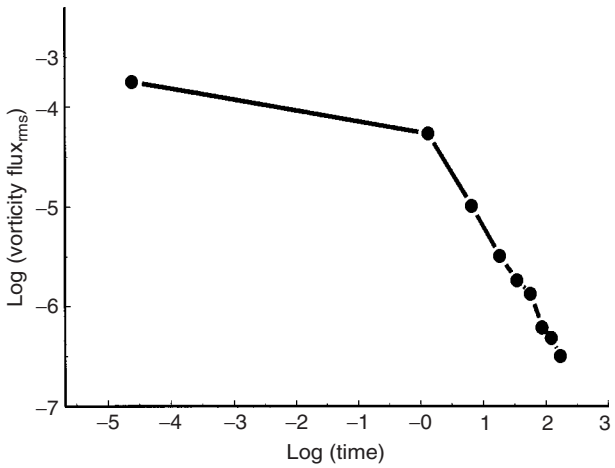

Fig. 20.7.3 Effect of temporal resolution on vorticity flux rms data from Andreopoulos and Agui[82,83] are made nondimensional by inner wall scaling.

As the Reynolds number of the flow increases, its spatial and temporal scales decrease, and therefore, if the size of the measuring volume and data acquisition rate remain unchanged, then it is expected that the spatial and temporal resolution of the measuring technique will deteriorate.

MEASUREMENTS OF PRESSURE AND TEMPERATURE

There is an extensive description of probes and instrumentation used to measure pressure in textbooks[1,14,15] or in handbooks.[16, 17] Manometers, gages, transducers and microphones are used to measure pressure at single points inside the flow field or at its boundaries.

Pressure-sensitive paint (PSP) can provide useful quantitative and qualitative information on the pressure field on a solid surface, i.e., at more than one point. In that respect, PSP has the advantage of being a field pressure measurement. The technique is based on the phenomena of photoluminescence and oxygen quenching of fluorescent dyes.[18–22]

In its simplest terms, the PSP method is based on the sensitivity of some luminescent dye to molecular oxygen. After absorbing a photon, a luminescent molecule is placed in an excited state. The molecule then returns to its ground state by emitting a new photon at a longer wavelength, as illustrated in Fig. 20.7.4. For some luminescent molecules, however, oxygen quenching allows the molecule to return to a ground state without emitting a photon. Hence, for a given level of excitation, the emitted light intensity from the luminescent molecules varies inversely with the local oxygen partial pressure. Since the mole fraction of oxygen in air is fixed, the oxygen partial pressure is easily converted into the air pressure.

PSP simply consists of luminescent molecules suspended in some type of oxygen permeable binder. Currently, most of these binders are some form of silicone polymer. The vast majority of PSP formulations to date come in a liquid form that is suitable for use with normal spray-painting equipment and methods. Typically, in its simplest application, PSP is the topmost layer of a multilayer coating on a model surface. The PSP is usually applied over a white undercoat, which provides two related benefits. The white undercoating reflects a large portion of the light that is incident upon it, which results in the benefits of amplifying not only the excitation illumination, but the emission illumination as well.

One of the characteristics of PSP is that the response of the luminescent molecules in the coating degrades with time of exposure to the excitation illumination. This degradation occurs because of a photochemical reaction that occurs when the molecules are excited. Eventually, this degradation of the molecules determines the useful life of the PSP coating. This characteristic becomes more important for larger models, as the cost and time of PSP reapplication becomes a significant factor. A second undesirable characteristic of PSP is that the emission intensity is affected by the local temperature. This behavior is due to the effect temperature has on the energy state of the luminescent

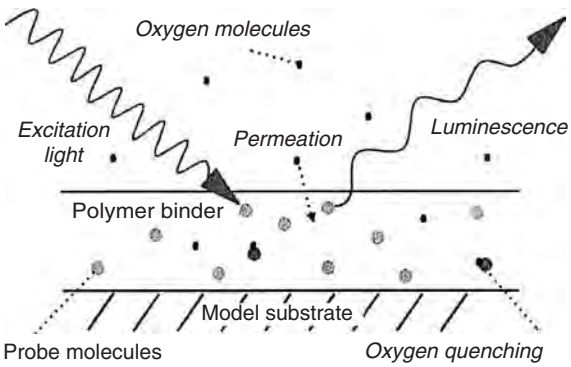

Fig. 20.7.4 Excitation an illumination in a typical pressure-sensitive paint.

molecules, and the oxygen permeability of the binder. This temperature dependence becomes even more significant in compressible flow tests, where the recovery temperature over the model surface is not uniform.

For the measurement of temperature the classical techniques using thermocouples, resistive and solid-state thermometers, pyrometers, constant-current anemometers, liquid crystals, interferometers, and infrared imaging are described in Refs. 1 and 23, as well as in several textbooks.

Temperature-sensitive paint is used in a global measurement technique that is very similar to PSP except that the coating is temperature sensitive rather than pressure sensitive. In the case of TSP, changes in the free volume in the binder affect the luminescence; as the temperature increases, the luminescence decreases. As in PSP, a ratio of two images provides the measured quantity. In this case, one image is taken at a known, constant temperature, and the other is taken at the unknown conditions. The ratio of the two images is then converted to temperature by using the appropriate calibration. As in PSP testing, during the acquisition of the images, the test surface is exposed to excitation light in only a narrow frequency band. The detector is then notch-filtered to pass only the luminescence band for the particular probe molecule. Of course, these two bands must not overlap.

MEASUREMENTS OF VELOCITY

The measurement of flow velocity at single or multiple points may be accomplished by direct measurement of the speed of the flow or indirectly by a variety of techniques that can be in general classified as pressure-based methods using pitot or pitot static tubes, thermal anemometry, laser Doppler anemometry (LDA), **particle image velocimetry (PIV)**, planar **Doppler velocimetry (PDV)**, **molecular tagging velocimetry (MTV)**, which appear to be the most commonly used techniques. Pressure-based methods are adequately explained in several textbooks and they will be excluded from the present description.

Thermal Anemometry

Thermal anemometry has been used extensively for many years in fluid mechanics to measure instantaneous fluid velocity. The technique depends on the convective heat loss to the surrounding fluid from an electrically heated sensing element or probe. If only the fluid velocity varies, then the heat loss can be interpreted as a measure of that variable. There are several textbook on the subject[24–26] that cover comprehensively the associated techniques.

Cylindrical sensors (hot wires and hot films) are most commonly used to measure the fluid velocity, while flush sensors (hot films) are employed to measure the wall shear stress. Hot-wire sensors are, as the name implies, made from short lengths of resistance wire and are circular in cross section. **Hot-film** sensors consist of a thin layer of conducting material that has been deposited on a nonconducting substrate. Hot-film sensors may also be cylindrical but may also take other forms, such as those that are flush-mounted.

Thermal anemometry is very popular among researchers because the technique involves the use of very small probes that offer very high spatial resolution and excellent frequency response characteristics. The basic principles of the technique are relatively straightforward and the probes are relatively easy to fabricate. The sensors can be operated in the constant-temperature mode (CTA) or constant-current mode (CCA).

Hot-wire anemometry has been used for many years in the study of laminar, transitional, and turbulent boundary layer flows, and much of our current understanding of the physics of boundary layer transition has come solely from hot-wire measurements. Thermal anemometers are also ideally suited to the measurement of unsteady flows such as those that arise behind rotating blade rows when the flow is viewed in the stationary frame of reference. Until the advent of laser anemometry, this was the only available technique for the acquisition of data. In present times, thermal anemometry remains one of the primary tools used in experimental fluid mechanical work.

A hot-wire probe consists of the sensor itself, which is supported on prongs that are embedded in nonconducting (often ceramic) material.

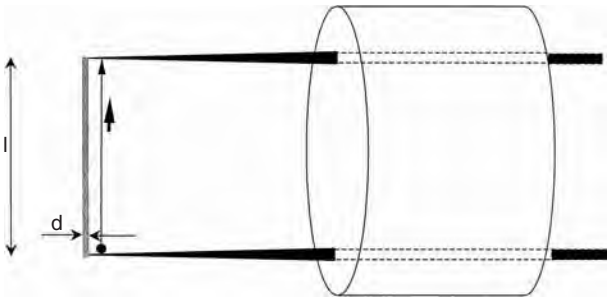

Fig. 20.7.5 Basic hot-wire probe.

Figure 20.7.5 shows the main components of a basic hot-wire probe. The sensing element is heated by a current I under a voltage. A hot-wire sensor has to have several characteristics to make it a useful device:

- Its thermal capacity/inertia should be small so that it provides good frequency response.
- It should have a high temperature coefficient of resistance.
- Its electrical resistance should be such that it can be easily heated with an electrical current at practical voltage and current levels.

The most common wire materials are tungsten, platinum, and a platinum-iridium alloy. Tungsten wires are strong and have a high temperature coefficient of resistance (0.004/°C). However, they cannot be used at high temperatures in many gases because of poor oxidation resistance. Platinum has good oxidation resistance and temperature coefficient (0.003/°C), but is very weak, particularly at high temperatures. The platinum-iridium wire is a compromise between tungsten and platinum with good oxidation resistance, and more strength than platinum, but it has a low temperature coefficient of resistance (0.00085/°C). Tungsten is presently the more popular hot-wire material. The choice of diameter of the sensors, d, depends on the particular application. It can vary from 0.8 μm to 5 μm, while its length is between 0.7 mm and 1 mm. Since these elements are sensitive to heat transfer between the element and its environment, temperature and composition changes can also be sensed. Figure 20.7.6 shows a photograph of a hot-wire probe used for near-wall measurements.

The heat transfer rate from the sensor to the fluid can be, to a certain extent, simulated by considering a heated cylinder at uniform

Fig. 20.7.6 Photograph of boundary-layer-type hot-wire probe.

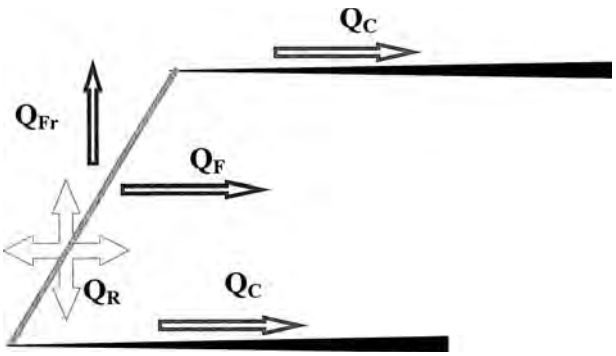

Fig. 20.7.7 Thermal energy balance in hot wires.

temperature T_w inside a steady flow field. Part of the electrically generated heat along the sensor will be transferred to the fluid by force and free convection, part of it will be transferred to the prongs by conduction, and the remaining will be radiated (see Fig. 20.7.7). For relatively long sensors with $l/d > 200$, heat rate by conduction Q_C can be ignored. For the usual hot-wire anemometry temperature range of a few hundred degrees Celsius, radiation heat transfer Q_R is less than 0.1 percent of the convective heat rate Q_C and may be disregarded. Free convection can be also ignored if $\mathrm{Re} > \mathrm{Gr}^{1/3}$, where Gr is the Grashof number, defined as $\mathrm{Gr} = g\beta(T_w - T)d^3/\nu^2$, where β is the thermal expansion coefficient of the fluid.

The temperature of the fluid in the immediate vicinity of the cylinder will have values between the fluid temperature T and T_w, and the fluid properties will vary accordingly. By convention, gas flow properties such as thermal conductivity, density, kinematic viscosity, and thermal diffusivity will be evaluated at the average film temperature defined as $T_f = \frac{1}{2}(T + T_w)$.

If Q_F is the heat flux convected from the wire to the fluid, the Nusselt number is defined as $\mathrm{Nu} = Q_F/\pi lk(T_w - T)$, with k being the thermal conductivity of the fluid. If one restricts the analysis to air only, the Prandtl number is constant, and then Nu depends on $\mathrm{Re} = \rho Ud/\mu$, $\mathrm{Nu} = \mathrm{Nu}\,(\mathrm{Re})$

Under the above assumptions Nu appears to be

$$\mathrm{Nu} = (C + D\mathrm{Re}^n)(T_w + T_\infty)^{0.17} \tag{20.7.14}$$

where C, D, and n are constants. The heat flux rate Q_F is provided by the electrical heating and therefore is $Q_F = IE = I^2/R = E^2/R$, where I and E are the current through and the voltage across the sensor, respectively, and R is the resistance of the wire. The technique then can provide $Q_F = f(E)$ under constant I for the CCA-mode operation or $Q_F = f(R)$ under constant resistance/temperature for is the CTA-mode operation.

In the CTA mode the above relation becomes

$$E^2 \frac{R_w}{(R_w + R_a)^2 (T_w - T)} = X + YU_{\mathrm{eff}}^n \tag{20.7.15}$$

where U_{eff} is the effective cooling velocity of the fluid. This relation is known as King's law.[27] If we ignore the variation of fluid properties and since T_w is constant, then the partial sensitivities of voltage on velocity and fluid temperature are

$$\frac{\partial E}{\partial U} = \frac{nYU_{\mathrm{eff}}^{n-1}}{2}\left[\frac{(R_w + R_a)^2}{R_w}\frac{T_w - T}{X + YU_{\mathrm{eff}}^n}\right]^{1/2} \tag{20.7.16}$$

$$\frac{\partial E}{\partial T} = -\frac{1}{2}\left[\frac{(R_w + R_a)^2}{R_w}\frac{X + YU_{\mathrm{eff}}^n}{T_w - T}\right]^{1/2} \tag{20.7.17}$$

Then $\Delta E = (\partial E/\partial U)\Delta U + (\partial E/\partial T)\Delta T$, and, if the objective is to measure velocity and velocity fluctuations, the partial sensitivity $\partial E/\partial U$ has to be maximized and the partial derivative $\partial E/\partial T$ has to be minimized in comparison or completely eliminated. In order to achieve this, the operating wire temperature T_w has to be large, since the term $(T_w - T)$ is the nominator of $\partial E/\partial U$ and in the denominator of $\partial E/\partial T$. For accurate measurements an overheat ratio $(R_w - R_a)/R_a = \alpha(T_w - T_a)$ of 0.80 is recommended, where R_a is the cold resistance and α is the coefficient temperature.

Frequency Response The response of a hot-wire sensor of mass m_w and specific heat c_w is governed by the first-order differential equation given in Ref. 28 as

$$m_w c_w \frac{\partial T_w}{\partial t} = I^2 R_a[1 + \alpha(T_w - T_a)] - \pi k(T_w - T)\mathrm{Nu} \tag{20.7.18}$$

which is the unsteady heat equation with the first term on the left-hand side representing the accumulated heat rate by the wire mass. The solution of this equation contains the exponential term $e^{-t/M}$, where M is the time constant

$$M = \frac{m_w c_w}{I^2 R_a \alpha - \pi k l \mathrm{Nu}} = \frac{\rho_w c_w d^2}{k\mathrm{Nu}}\frac{R_w}{R_a} \tag{20.7.19}$$

In order to minimize M, small values of wire diameter d are used; in fact, wire size is the only control a user can have. However, the mechanical strength of the wire under aerodynamic load limits the reduction in d. Reductions in M, at the expense of sensitivity, can be also obtained by reducing the ratio R_w/R_a.

Angular Sensitivity Unfortunately the output of a hot-wire anemometer depends on the yaw and pitch angles of the incoming velocity vector. This angular response of the probe can be found through appropriate yaw and pitch angle calibration, which is usually carried out at constant free-stream velocity. This angular sensitivity is modeled in the expression of the sensor cooling velocity U_{eff} in various ways by decomposing the local velocity vector into the wire coordinates (see Fig. 20.7.8):

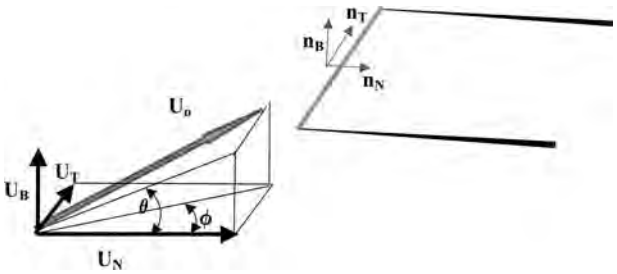

Fig. 20.7.8 Components of velocity vector in wire coordinates.

1. Cosine law with $U_{\mathrm{eff}} = U_o \cos\phi$ (see Ref. 28). This is the simplest of the expressions, and it is valid for small yaw angle ϕ.
2. According to Champagne, Schleicher, and Weherman,[29] U_{eff} includes a fraction of the tangential component of the local velocity vector U_T, and the expression becomes $U_{\mathrm{eff}} = (U_N^2 + k^2U_T^2)^{1/2}$ where k is a coefficient with values $k = 0.2$ for $l/d = 200$ and $k = 0$ for $ld = 600$.
3. A more general expression for U_{eff}, due to Jörgersen,[30] includes cooling in the binormal direction from the component U_B: $U_{\mathrm{eff}} = (U_N^2 + h^2U_B^2 + k^2U_T^2)^{1/2}$ where h is another coefficient with values of the order of 1. Apparently this is the most complete expression for U_{eff} and it can be applied in principle to any three-dimensional flow field with reasonable turbulence intensities.

The coefficients k and h can be determined through individual calibration wire and may include the unavoidable effects of prong and probe holder interference.

Multisensor Probes A single-sensor probe oriented perpendicularly to the flow direction can yield information of one velocity component only, under the assumption that the lateral components are considerably smaller than the longitudinal one. If measurements of two velocity components are required, then a probe with two sensors independently oriented at ±45° each to the mean direction should be used. Triple wires consisting of three sensors are recommended for use in three-dimensional flows.

Laser Doppler Anemometry

The laser Doppler anemometry (LDA) technique, which is also known as laser Doppler velocimetry (LDV), is based on light scattering off flow tracers that exist in the flow or are introduced by the user. The flow field is illuminated by a laser beam and the particle tracer that follows the flow produces a Doppler frequency shift due to its velocity.

This is a nonintrusive optical technique to measure the **Doppler frequency shift** contained in scattered light. The idea of measuring the Doppler shift due to the motion of particles inside a flow was originated by Cummins et al.[31] after the discovery of narrow line width lasers. Cummins, a professor of physics at City College, demonstrated in Yeh and Cummins[32] that the Doppler frequency shift Δv is related to the velocity vector of the light scattering particle **V** through

$$\Delta v = v_s - v_i = 1/\lambda(\mathbf{k}_s - \mathbf{k}_i) \cdot \mathbf{V} \qquad (20.7.20)$$

where $\mathbf{k}_s$ and $\mathbf{k}_i$ are the unit vectors in the scattered and incident light directions and λ is the wavelength of the incident light. Because of the inability of existing photodetectors to measure directly the extremely high frequencies of the original laser beam, several arrangements have been used to offset this problem. The most common arrangement is shown in Fig.(20.7.9). The original laser beam is split into two beams that intersect in an interference pattern of standing waves consisting of high- and low-intensity surfaces called *fringes.* As micrometre-sized liquid or solid particles entrained in a fluid pass through the intersection of the two laser beams, the scattered light received from the particles fluctuates in intensity. The laser frequency of the two beams cancels out and the Doppler frequency is independent of the scattered light direction $\mathbf{k}_s$, which is the observation angle:

$$v_D = v_{s1} - v_{s2} = 1/\lambda(\mathbf{k}_{i1} - \mathbf{k}_{i2}) \cdot \mathbf{V} = 2 \sin\theta \, U_i/\lambda \qquad (20.7.21)$$

This last feature is a great advantage of this arrangement, since it provides some flexibility in the placement of the frequency detector, which is usually a photomultiplier that converts the light intensity into photocurrent. Then Eq. (20.7.21) is transformed into the simple form

$$U_i = v_D\lambda/2 \sin\theta \qquad (20.7.22)$$

Another advantage of linear equation (20.7.22) is that it contains no undetermined constants, thus eliminating the need for calibration and errors due to instrumentation drifting. The proportionality coefficient $\lambda/(2 \sin \theta)$ is the calibration factor, although no calibration is actually necessary (see Refs. 33, 34, and 35 for more details).

The velocity direction can be fixed if one of the laser beams has a frequency slightly different from that of the other. All three components of velocity can be measured by crossing four or six laser beams of different wavelenths or polarization in the same measuring volume, and separating out the scattered light with filters. The frequency is measured by digital counters (if data rates are above 50 per second) or photon correlators (low data rates and signal level) or spectral analyzers (Doppler shift frequency not over a few megahertz).

A laser power source is required, with excellent frequency stability, narrow linewidth, small beam diameter, and a gaussian beam intensity profile (bright at the center). Typically, helium, neon, or argon ion lasers are used, with power levels from 10 mW to 20 W.

LDA techniques have provided spatially precise point measurements, at speeds from millimetres per second to supersonic. In some cases, measurement point distances of up to 7 m have been used in large wind tunnels.

The limitation of this technique is that it provides single-point measurement only. Data rates are dictated by particle arrival in the measuring volume, not when the user wants to sample data. Particles should follow the flow closely. However, particles cannot enter all flows through turbulent diffusion, and simple viscous diffusion is not adequate to provide particles inside the laminar cores of vortices, for instance. Particles should be small enough to follow the flow, but reducing their size may produce a signal below the noise threshold. There is also greater noise at higher speeds. The signal level depends on detector solid angle, posing problems of optical access. Mie scattering intensity is much better in the forward direction, but it is difficult to set up forward receiving optics which remains aligned to the moving measurement volume. Time to alignment of emitting optics can range from 3 hours for a one-component system to a day for a three-component system. The setup may be also sensitive to vibrations. These problems may be alleviated with fiber optic probes, at the cost of signal level because of fiber power loss.

LDA techniques have been used in a variety of flow applications that include low- and high-speed boundary layers, combustion studies, and turbomachinery and rotorcraft flows. They have been also used in atmospheric turbulence measurement, and in air data systems for aircraft. In periodic flows, phase-resolved averaging is used to construct 3-D velocity fields with high accuracy.

Particle Image Velocimetry

Particle image velocimetry (PIV) is a whole-flow-field, nonintrusive optical technique that provides instantaneous velocity vector measurements in a cross-section of a flow. Two velocity components are usually measured on the illumination plane. The use of a stereoscopic arrangement provides all three velocity components to be recorded, resulting in instantaneous 3-D velocity vectors for the whole area. The use of modern CCD cameras and dedicated computing hardware results in real-time velocity maps. In PIV, the velocity vectors are derived from subsections

of the target area of the particle-seeded flow by measuring the movement of particles between two light pulses. The technique is nonintrusive and measures the velocities of micrometre-sized particles following the flow. It has been tested in flows with velocity range from zero to supersonic.

The flow is illuminated by a laser sheet in the target area. A camera lens images the target area onto the CCD array of a digital camera. Two sequential images of the flow field are captured by the CCD array, produced by two light pulses in separate image frames. Once a sequence of two light pulses is recorded, the images are divided into small subsections called *interrogation areas*. These interrogation areas from each image frame are cross-correlated with each other, pixel by pixel. The correlation produces a signal peak, identifying the common particle displacement.[36–40] In PIV, the velocity vectors are derived from subsections of the target area of the particle-seeded flow by measuring the movement of particles between two light pulses, $\overline{V} = \overline{\Delta x_i}/\Delta t$.

A typical experimental setup of a PIV system is shown in Fig. 20.7.10. This system has been used to measure the velocity in the near field of a compressible jet at CCNY (see Wang[41]). Talcum flow tracer particles of $1\,\mu$m in diameter have been added to the flow. A plane (light sheet), about 1 mm thick, within the flow is illuminated by means of a dual laser system (the time delay between pulses depending on the mean

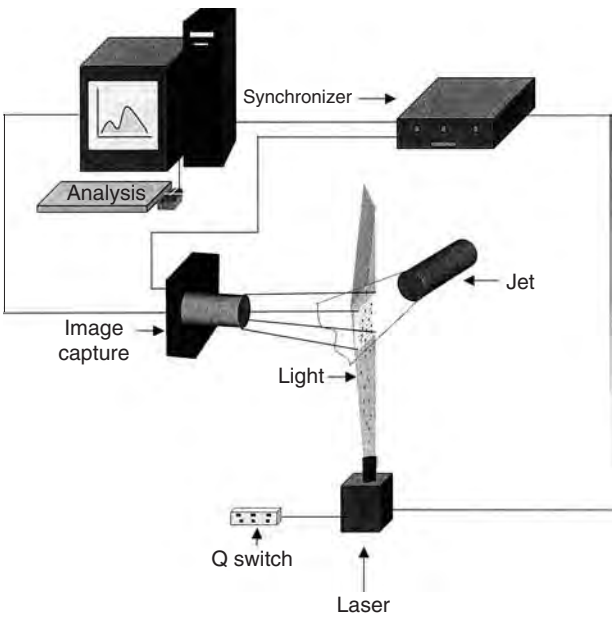

Fig. 20.7.10 Experimental setup for particle image velocimetry measurements in a compressible jet flow facility.

flow velocity and the magnification at imaging). It is assumed that the tracer particles move with local flow velocity between the two illuminations. The light scattered by the tracer particles is recorded via a high-quality lens either on a single frame or on two separate frames on a special cross-correlation CCD sensor. It is assumed that all particles within one interrogation area have moved homogeneously between the two illuminations. The projection of the vector of the local flow velocity into the plane of the light sheet (two-component velocity vector) is calculated, taking into account the time delay between the two illuminations and the magnification at imaging.

The process of interrogation is repeated for all interrogation areas of the PIV recording. It was possible to capture 100 PIV dual frames per minute with the present 1k × 1k PIVCAM 10-30 cameras. The duration of processing of one PIV recording with 3600 instantaneous velocity vectors (depending on the size of the recording and of the interrogation area) is of the order of a few seconds with present PCs.

Prior to the detailed velocity measurement in the jet flow facility, the overall structure of the flow was captured by the high-resolution PIVCAM 10-30 camera. This is shown in Fig. 20.7.11 for the case of a nitrogen jet issuing in ambient still air. On the left side of this figure, the 7-mm jet exit nozzle is shown. The flow as it exits the nozzle starts to mix with the ambient air and decelerates. A few diameters downstream of the jet exit, the flow starts to spread out.

The two images shown in Fig. 20.7.12 correspond to the flow described above with the Mach 0.6 nitrogen jet. If these two images were overlapped, the same particle displacement could be revealed. Cross correlation of the two frames provided the velocity vectors shown in Fig. 20.7.13.

Planar Doppler Velocimetry Techniques

Planar Doppler velocimetry (PDV), also known as global Doppler velocimetry (GDV), is a relatively new nonintrusive planar optical technique that utilizes molecular filters to measure the Doppler frequency shift contained in scattered light. As mentioned earlier, the idea of measuring the Doppler shift due to the motion of particles inside a flow was originated by Cummins et al.[31] after the discovery of narrow linewidth lasers. The Doppler frequency shift Δv is related to the velocity vector of the light-scattering particle, $\mathbf{V}$ (see[32]) through

$$\Delta v = v_s - v_i = 1/\lambda(\mathbf{k}_s - \mathbf{k}_i) \cdot \mathbf{V}$$

where $\mathbf{k}_s$ and $\mathbf{k}_i$ are the unit vectors in the scattered and incident light directions and λ is the wavelength of the incident light.

A laser sheet is formed inside the flow field and global measurements can be obtained by recording the light intensity, which is related to the Doppler frequency shift. The measurement of the frequency shift is made spectroscopically by using a high-resolution iodine gas cell, which acts as a frequency-dependent filter with very high sensitivity. The edge of an absorption line in molecular iodine is used to determine the frequency of the Doppler shift of the scattered light. Image data are acquired via digital cameras, which have to be placed appropriately for each axis of interest. The intensity of the light from a given point in the object plane is attenuated in proportion to its Doppler shift. The image plane then contains gray levels proportional to the product of the local intensity of the illuminating light sheet and the Doppler shift. To eliminate the problem of both scattering signal and illumination intensity variations spatially in the measurement window, the Doppler signal intensity map is normalized by a reference intensity map from the same view of the flow. The camera is split into two halves to record the unshifted image field, and the Doppler-shifted image is normalized by the unshifted image, pixel by pixel.

The technique was first described in a U.S. patent by Komine[42] and by Komine et al.[43] and Meyer and Komine,[44] who used an iodine filter. At about the same time Miles and Lempert[45] and Miles et al.[46] used an I_2 molecular filter with Rayleigh scattering to demonstrate the feasibility of measuring mean velocity, density, and temperature in high-speed flows. A good review article on the subject can be found in Samimy and Wernet.[47] Further information can be found in Refs. 48 to 55.

Figure 20.7.14 shows a typical scan of a typical transfer function of the I_2 vapor filter. The laser is tuned at the middle point of the range of the normalized light intensity. Any scattered light of flow tracers inside the flow field will cause a Doppler frequency shift depending on the velocity magnitude which corresponds to a normalized light intensity. This spectroscopic transfer function is obtained in advance and it is typical of the filter used and the tuned frequency of the laser.

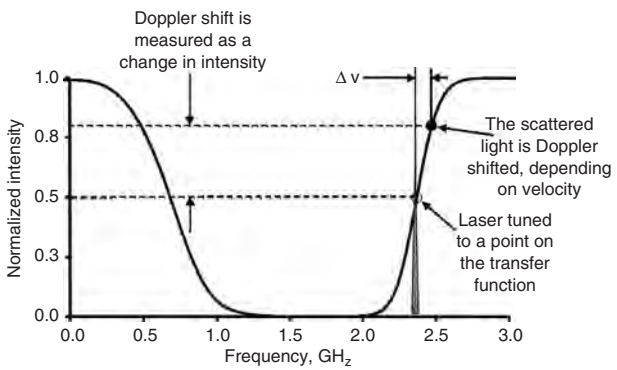

Fig. 20.7.14 Typical transfer function of I_2 vapor filter.

Figure 20.7.15 shows a typical arrangement currently used at CCNY to measure the velocity field within a shock wave interacting with an isotropic and homogeneous turbulence generated by metallic

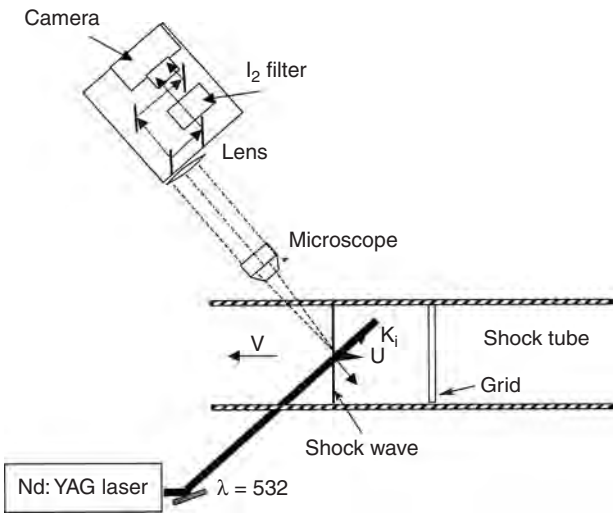

Fig. 20.7.15 Experimental setup for one-component micro PDV measurements inside a shock wave in the large-scale shock tube facility at CCNY.

rectangular grids. The major hardware components are a Nd:YAG laser, a CCD camera, and an absorption filter. Presently a *Q*-switched Quanta Ray GRC-14s Nd:YAG laser with 250-mJ pulse energy is available in the laboratory. This laser is equipped with a LightWave injection seeder. A Princeton Instruments (Roper Scientific) back-illuminated camera, model MicroMax 1024B with 1k × 1k pixels and an ultraviolet ASROMED camera with a chip of 540 × 650 pixels are used for imaging. An I_2 absorption filter provided by Innovative Scientific Solutions Inc. has a typical absorption spectrum shown in Fig. 20.7.16. These hardware pieces are adequate to provide measurements of one-velocity components only. Measurements of three velocity components by using PDV have been already made successfully in supersonic jets by combining the pair of filtered and unfiltered images on the same CCD chip.[47]

Implementation of the PDV techniques to the present flow in the shock-tunnel environment is not straightforward. Particle seeding is one of the major issues in flow measurements based on Doppler frequency shift. In the past, acetone has been used to provide light scatterers in flows

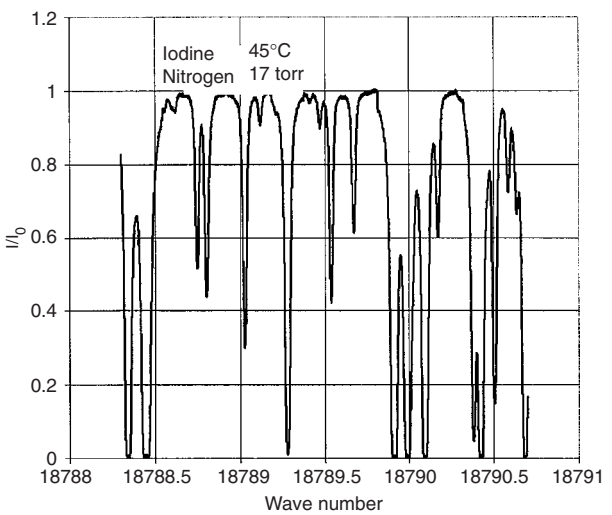

Fig. 20.7.16 Absorption spectrum of I_2 vapor filter.

configured in high-speed wind tunnels where temperatures are rather low. In the present flow case, the use of acetone is not certain because the temperature in the shock tunnel is higher than the flow temperature in supersonic wind tunnels. Submicrometre talcum powder particles have been used successfully in our work in the past. The scales of this flow can be adequately resolved with a magnification of about 200, or less. The pixel-to-pixel distance is 9 μm, and with this magnification the flow scales resolution is about 45 nm. For a shock thickness of about 3λ, where λ is the molecular mean free path, and helium as a driven gas at one-fifth atmospheric pressure with $\lambda = 3.75\,\mu$m, the shock thickness can be resolved by 90 pixels. Talcum powder with particle size less than 0.2 μm is used for light scattering.

Unfortunately the pulsed **Nd:YAG lasers** are known for long-term frequency drifts and pulse-to pulse fluctuations in frequency and power. The variation in the power can be remedied by normalization of the filtered signal with the unfiltered one. Frequency variations, however, require a frequency monitoring system. The system described by Mosedale et al.[56] is a good remedy to this problem. This system requires a small cut-out portion of the laser beam to focus on two fast-response photo detectors after it is split in two and after one of the two parts passes through a second I_2 filter. This system can be also used to characterize the frequency-transmission relation of each filter.

Currently, however, PDV is considered to be more suitable for the measurement of high-speed flows (estimated to be above 30 m/s) because of the limit on velocity resolution, which is approximately equal to 1 m/s, which is the uncertainty of a very good DGV system. It is one of the very few Mie-scattering whole-field velocimetry techniques that could be truly regarded as instantaneous with the use of a short-duration (~10 ns) pulsed laser.

Other Techniques

In molecular tagging velocimetry (MTV), the flowing medium is premixed with molecules that can be turned into long-lifetime flow markers upon excitation by photons. Typically a pulsed laser is used to "tag" small regions of interest. The tagged regions are then imaged at two successive instants within the lifetime of the tracer. The measured displacement vectors provide estimates of the average velocity for each small region during the brief interval between exposures. The fluid is water in this case, premixed with a water-soluble phosphorescent triplex compound. The corresponding velocity field is determined by a spatial correlation technique.[57, 58] One advantage of the MTV technique over other commonly used whole-field velocimetry techniques that rely on light scattering from particles is its molecular nature. In that respect, the issues related to flow tracers that are particularly important in gas flows are eliminated. The molecular nature of MTV also makes it suitable for obtaining other flow variables, such as pressure, temperature, and concentration, along with the velocity field.

There are several "unseeded" tagging methods where gas tags are produced from molecules naturally occurring in air (i.e., nitrogen, oxygen, water vapor). Examples of molecular tags produced from air are N_2 + ion,[59] ozone,[60] hydroxyl,[61] nitric oxide,[62,63] and vibrationally excited oxygen.[64, 65] Many of the methods use nonlinear laser excitation[59, 62–65] to produce these tags from air and the tag is produced only in a small region near the laser focus.

MEASUREMENTS OF VORTICITY, RATE OF STRAIN, AND DISSIPATION

The measurement of one or more components of vorticity in turbulent flows of research and technical interest has been a long-held, but elusive, goal of fluid mechanics instrument developers and researchers. The review article by Wallace and Foss[11] provides a detailed account of the available techniques, as of that date, used to measure vorticity and compare existing data. A majority of the techniques are based on thermal anemometry or on optical methods. Optical techniques are nonintrusive, are sensitive to large changes in velocity direction, and most of them do not require any calibration. These characteristics make them ideal for use in separated flows and flows with large turbulence intensities where the use of intrusive methods is prohibited and recirculating effects are present. Most of the optical techniques are based on detecting light scattered by particles imbedded in the flow. In that respect, seeding the flow with appropriate particles that follow the fluid motion very closely is critical. It should be noted here that, for gas flows in which seed must be added and in which the flow does not recirculate, adding particles can be far more intrusive than a hot-wire probe.

There is a need for a formal definition of the measured quantities, either vorticity components Ω_k or velocity gradient tensor terms A_{ij}. Specifically, there are two common ways to derive vorticity. In the first method, measurements of velocity components at nearby locations are obtained and used in a finite-difference scheme to derive vorticity. In the second method measurements of microcirculation around a small area are obtained and vorticity is computed as circulation density.

The first definition is based on a Taylor's series expansion of velocity in a nearby location, which to a first-order approximation becomes $U_i(r_j + \Delta r_j) = U_i(r_j) + \Delta r_j(\partial U_i/\partial r_j) + \cdots$

For r_j in the y direction and $\Delta r_j = (0, \Delta y, 0)$, the above equation becomes $U_i(y + \Delta y) \approx U_i(y) + \Delta y(\partial U_i/\partial y)$, which yields the following relation to compute the velocity gradient:

$$\frac{\partial U_i}{\partial y} \approx \frac{U_i(y + \Delta y) - U_i(y)}{\Delta y}$$

This relation will also define the uncertainties in the measurement of the velocity gradient.

The second method of estimating vorticity is due to Foss and his coworkers,[66–68] who have developed a hot-wire technique for the measurement of the transverse vorticity component. The technique involves the measurement of microcirculation Γ around a small finite domain of area ΔS normal to the flow. The estimated vorticity appears to be computed through the relation $< \Omega_z > = \Gamma/\Delta S$.

These two methods are not the only ones that are used. There is no need to have a computational formalism for vorticity when it is estimated explicitly. For instance, direct estimate of vorticity through measurements of fluid rotation does not require vorticity computation through an implicit scheme.[69]

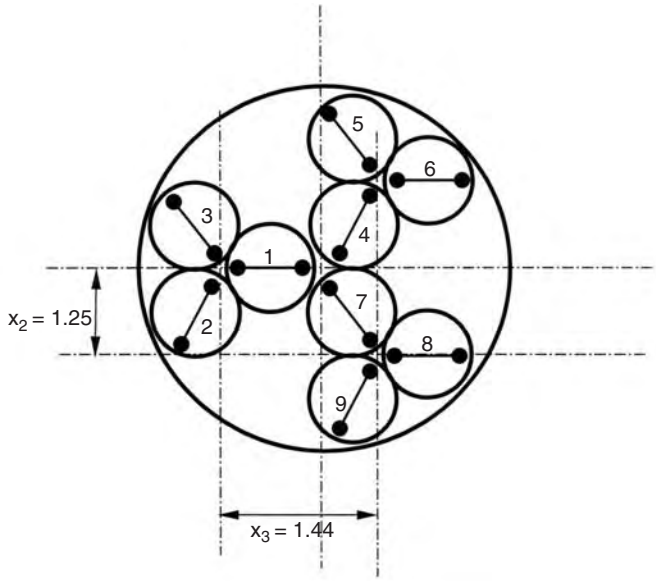
The inherent difficulties of velocity gradient/vorticity measurements, which require high spatial and temporal resolution in turbulent flow fields, have only recently been substantially overcome.

Hot-Wire-Based Vorticity Probes

Several multi-hot-wire probes have been developed that are capable of measuring velocity-gradient-related quantities. The difference among them is the orientation and number of wires used. One of the first papers to provide well-documented data on vorticity in low-speed adiabatic boundary layers is by Vukoslavcevic, Wallace, and Balint.[70] Honkan and Andreopoulos[71] fabricated one probe consisting of nine individual single-wire sensors. The probe, shown schematically in Fig. 20.7.17, consists of a set of three individual triple-hot-wire sensors put together so that the probe remains geometrically axisymmetric. Two photographs of the entire probe assembly together the probe dimensions are shown in Fig. 20.7.17.

In designing a vorticity probe, several considerations have to be taken into account. (1) The individual wire length l_w should be as small as possible so that small scales can be resolved adequately. (2) The size of the individual triple-hot-wire probe, l_p, should be as small as possible to satisfy the assumption that the velocity does not change substantially across the probe. Small wire spacing, however, can lead to thermal interference and cross talk between the wires. (3) Since vorticity or strain rate will be computed from velocity gradients, spacing of the individual probes should be finite so that velocity gradients do not "disappear." If this spacing becomes small, the effect of noise may overwhelm the signal.[11] (4) Each of the wires should be controlled independently of the others. The use of one common prong as in the case of Ref. 70 may create problems such as imbalance under dynamic conditions. (5) The transfer function of the hot-wire anemometer system should be a three-dimensional one. This suggests that the probe should be able to respond to yaw and pitch angle variations of the velocity vector in addition to its magnitude.

Detailed lookup tables were created through velocity, pitch, and yaw calibrations, which are subsequently used to reduce the acquired data.



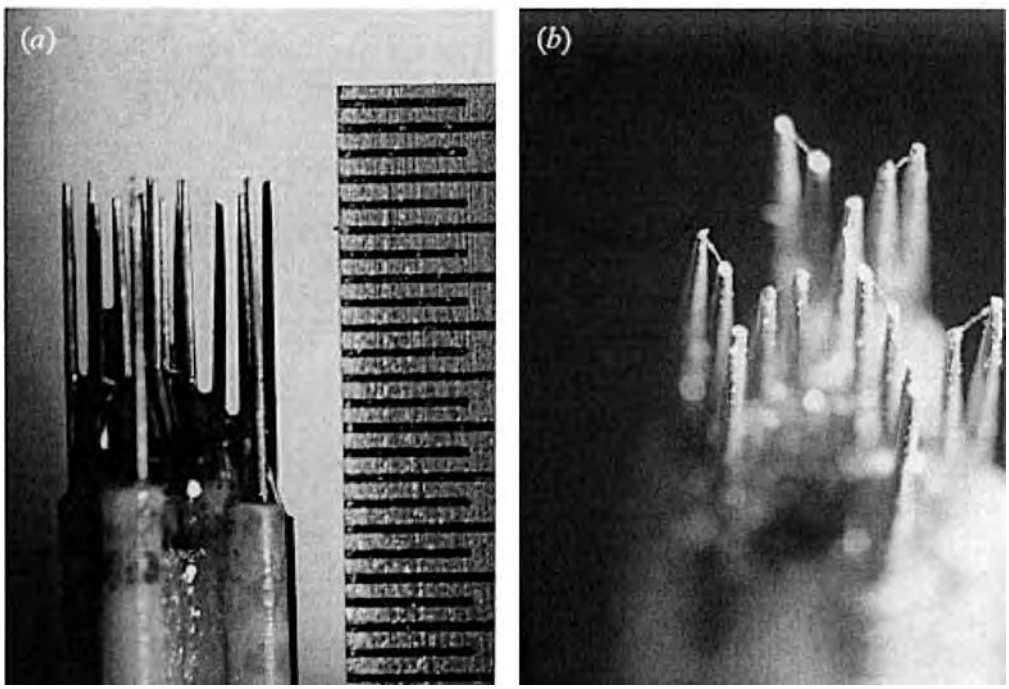


Fig. 20.7.17 Sensor arrangement and photographs of the probe (dimensions in millimetres).

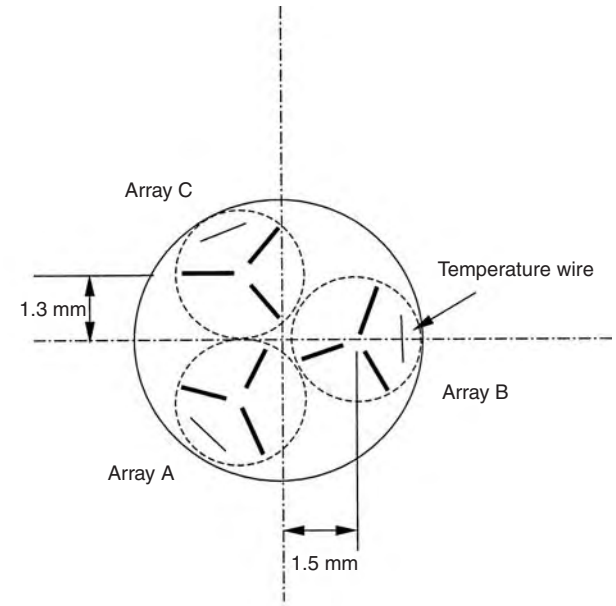
A new vorticity probe designed for use in nonisothermal flows or in compressible flows is described by Agui et al.[72] and Briassulis et al.[73] The probe consists of 12 wires, which is a modification of the original design with nine wires by Honkan and Andreopoulos.[71] The three additional wires were operated in the so-called constant-current mode and used to measure time-dependent total temperature.

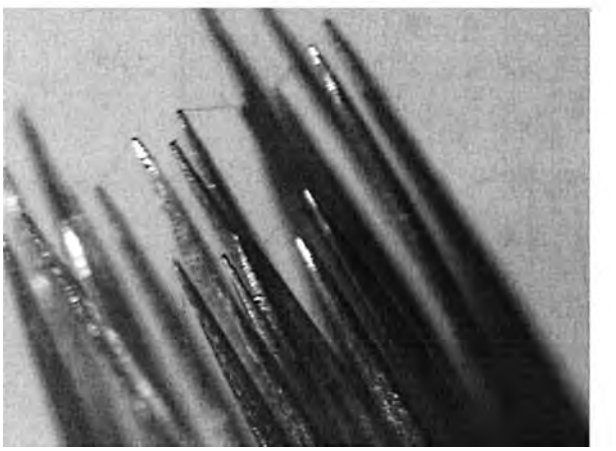
Since the probe essentially consists of a set of three modules or arrays (see Fig. 20 7.18), it is necessary to provide several key features of the individual hot-wire modules. Each module contains three hot wires operated in the constant-temperature mode (CTM) and one cold-wire sensor operated in the constant-current mode (CCM). Each wire of the triple-wire submodule is mutually orthogonal to the others, thus oriented at 54.7° to the probe axis. Each of the 5-μm-diameter tungsten sensors is welded on two individual prongs, which have been tapered at the tips. Each sensor is operated independently, since no common prongs are used. Each of the 2.5-μm-diameter cold wires is located on the outer part of the submodule.

The hot-wire output voltage *Ei* of the *i*th sensor is related to the effective cooling velocity, $U_{i,\,\mathrm{eff}}$ through Eq. (20.7.15), known as King's law[27]:

$$\frac{E_i^2}{T_w - T_0} = A_i \left[\frac{T_0}{T_r}\right]^a + B_i \left[\frac{T_0}{T_r}\right]^b (\rho U_{i,\,\mathrm{eff}})^n$$



(a)



(b)

Fig. 20.7.18 Vorticity probe: (*a*) probe sensor geometry and arrays; (*b*) close-up view of the probe.

where T_w is the hot-wire temperature, T_0 is the total temperature of the flow, and T_r is a reference temperature, the ambient temperature in the present case. The values of the exponents a and b were taken as suggested by Kovasznay[77]: $a = b = 0.768$. The effective velocity $U_{i,\,\text{eff}}$ is related to the normal, tangential, and binormal components of the velocity vector in reference to the ith sensor, respectively, by

$$U_{\text{eff}} = (U_N^2 + h^2 U_B^2 + k^2 U_T^2)^{1/2}$$

where k and h are coefficients that, for a given probe, depend on the yaw and pitch angle of the velocity vector. Details of the techniques associated with the use of triple wire arrays can be found in Ref. 74, while estimates of errors related to probe geometry and turbulence intensity are described in Ref. 75.

Mass fluxes ρU_i can be further separated into density and velocity by using the method adopted in Ref. 76. Decoupling density from mass fluxes assumes that static pressure fluctuations are small. This is the so-called weak version of the original "strong Reynolds analogy" hypothesis of Morkovin.[78] The original hypothesis is based on the assumption that pressure and total temperature fluctuations are very small. In the present work, total temperature was measured directly and therefore no corresponding assumptions were needed. The pressure, however, was measured at the wall and not at the location of the hot-wire measurement. The mean value of this pressure signal was used to separate the density and velocity signals since no mean pressure variation has been detected across a given section of the flow. The procedure involves an expression for mass flux m_i in terms of total temperature T_0 and pressure p at the centroid of each array: $m_i = \rho U_i = pU_i/RT = pU_i/[R(T_0 - U_k U_k/2c_p)]$, where U_i is the instantaneous velocity component, $i = 1, 2,$ or 3 and $U_k U_k = U_1^2 + U_2^2 + U_3^2$. The velocity can be decomposed into $U_i = \bar{U}_i + u_i$. An iterative scheme can be used to decouple density and velocity. During the first iteration it was assumed that the quantity $(u_2^2 + u_3^2)/2c_p$, where u_2 and u_3 are the velocity components in the spanwise and normal directions, respectively, is substantially smaller that the quantity $T_0 - U_1^2/2c_p$. Then the above relation can be rearranged to obtain a quadratic equation for U_i, $(Rm_i/2c_p)U_i^2 + pU_i - m_i RT_0 = 0$.

Optical Techniques

Laser speckle strophometry (LSS) or particle image velocimetry (PIV) techniques are nonintrusive but cannot in general provide adequate time-history information. In addition a slight out-of-plane motion of scattering particles due to flow three dimensionality results in different speckle patterns (speckle decorrelation).

Laser speckle strophometric methods have been developed.[79–81] In these techniques, the speckle pattern, which is the result of the diffraction of a plane wave produced by random grating, is basically affected by the flow velocity gradient while the translation of the grating caused by the constant flow velocity will not affect the pattern.

These authors applied their double pulse strophometric technique to obtain direct measurements of the quantities $\partial U/\partial x + \partial U/\partial y$, $\partial U/\partial x - \partial U/\partial y$, and $\partial U/\partial z$ in a channel flow with Reynolds number based on the channel width in the range of 2,250 to 6,700. This information was used to obtain statistics of the $\partial U/\partial y$ gradient.

One of the first direct measurements of vorticity were obtained by measuring the solid rotations of tiny transparent spherical beads of 25 μm in diameter,[69] each containing embedded planar crystal mirrors specially developed for this purpose, which were suspended in a refractive index-matched liquid.

LDA-Based Vorticity Techniques The techniques used to obtain indirect measurements of vorticity take advantage of the Doppler effect and they have configurations similar to those used in laser Doppler anemometry (LDA). In typical dual-beam configurations for velocity measurements, two laser beams cross each other to form the measuring/probe volume with the fringe pattern. Receiving optics can be aligned in any direction since the Doppler frequency shift Δf_D is independent of the k_s direction. The velocity component normal to the fringe orientation $U_i(x_j)$ can be obtained by measuring the Δf_D as

$$\Delta f_D = \frac{\vec{V}}{2\pi} \cdot \left[\vec{k}_{01} - \vec{k}_{02} \right]$$

where $\vec{k}_{01}$ and $\vec{k}_{02}$ are the wave number vectors along the two incident beams forming the measurement volume.

A natural extension of the traditional single-point LDA measurement of one velocity component shown in Fig. 20.7.9 to obtain one velocity gradient is possible by forming two independent probe volumes at a distance Δx_j apart to measure two velocity components in the same direction, $U_i(x_j)$ and $U_i(x_j + \Delta x_j)$. The velocity gradient $\partial U_i/\partial x_j$ can be estimated through the finite difference relation

$$\frac{\partial U_i}{\partial x_j} \approx \frac{\Delta U_i}{\Delta x_j} \approx \frac{U_i(x_j + \Delta x_j) - U_i(x_j)}{\Delta x_j}$$

For one component vorticity measurements, simultaneous measurements of the two velocity gradients are required.

The LAVOR method described by Agui and Andreopoulos[82,83] uses two parallel laser beams focused with a long-focal-length lens to generate a moderately narrow probe volume defined by the region of intersection of the two beams. The velocity at two different locations inside the probe volume has been measured. There are several advantages to this approach as compared to the "sheet" beam approach. These include fewer optical components, simple alignment of the optics, smaller windows for optical access, and better use of laser intensity.

A second category of single-point velocity gradient/vorticity measurement techniques exists that are not based on the interference of two laser beams and the scattering light of a particle moving through the fringes that is realized on the surface of the photodetector. This category includes techniques that use laser-Doppler signals from two particles illuminated by two different light beams. The idea of heterodyning of the scattered light from two particles originally proposed by Durst, Melling, and Whitelaw[33] was explored by Hanson[85] and more recently by Ötügen, Su, and Papadopoulos[86] and Yao et al.[87] Hanson's heterodyning arrangement uses an optical filter to define the relative separation of two particles, which requires fabrication of miniature spatial gratings and rings with geometries tailored to the specific flows under investigation. His technique, which has been tested in a cylindrical laminar Couette flow, is insensitive to the sign of velocity gradient. The technique in Ref. 86 resolves the sign of the velocity gradient by using a Bragg cell to shift the frequency of one laser beam, and it has been tested in the laminar flow formed between two concentric cylinders with one of them rotating. The technique of Yao et al.,[87] which is quite similar to that of Ötügen et al., has been tested successfully in a laminar channel flow.

In all these techniques that estimate the velocity gradient through the heterodyning of the scattered light from two different particles, the velocity field cannot be measured simultaneously with the velocity gradient; it requires separate measurements. In that respect, the inability of these methods to provide information of the velocity field at the same time with the velocity gradient measurements may be considered a drawback.

PIV-Based Vorticity Techniques In particle image velocimetry, crossing of the flowing particle paths in highly fluctuating flows may cause ambiguity in the detection scheme. PIV is also limited by spatial resolution loss due to averaging from the correlation schemes. Although the resolution of a typical CCD camera may be typically 1k $\times$ 1k pixels, subregions of 32 $\times$ 32 pixels known as *interrogation zones* are usually considered to validate a local velocity measurement. According to Arik,[88] in a typical PIV setup approximately 10 particles are needed to validate a velocity vector measurement and 10 more velocity vectors are needed to evaluate a vorticity vector. Thus approximately 100 particles are needed to evaluate a vorticity vector, a number that results in 30 to 40 particles for each of the three vorticity components.

Lourenco et al.[89] used PIV techniques to obtain one-component vorticity measurements in a jet flow. Meinhart and Adrian[90] used PIV to measure the near wall vortical structure of low-speed boundary layers with reasonable spatial resolution.

Holographic particle image velocimetry (HPIV) was used by Zhang et al.[91] to obtain velocity gradient measurements in a square duct flow with moderate resolution.

A polarization-based approach with dual-plane particle image velocimetry (DSPIV) has been used by Kähler,[92] Ganapathisubramani et al.[93] and Hu et al.[94] to obtain vorticity measurements in boundary layer flows and in lobed jet mixers. A two-frequency DSPIV was applied in jet flows to measure all nine components of the velocity gradient tensor with resolution of about 6 Kolmogorov length scales.[95] This recent work, which is based on PIV techniques, have demonstrated the potential to provide measurements of vorticity with excellent spatial resolution. At the moment, their temporal resolution is rather limited, which, however, does not affect the process of statistical averaging. In the following, a description is provided of optical techniques that have been used to measure one velocity gradient/vorticity at a single point with reasonable success. These techniques can be classified as direct or indirect, depending on whether vorticity is obtained from the measurement of fluid particle rotation or from the measurement of individual velocity gradients inside the flow field.

MICRO- AND NANOSENSORS AND ASSOCIATED TECHNIQUES

Over the past 5 to 12 years, there has been an increasing interest in understanding fluid phenomena at the micrometre- and nanometre-length scales. This has been evident in both basic and applied fluid mechanics research. The application of microscale fluid mechanics to MEMS and BioMEMS represents one of the most significant practical applications. In addition, there is a need to resolve smaller scales in measurements of mainstream macroscopic flows.

These two needs led to the development of microsensors and nanosensors. It is very encouraging to see that, in general, as the physical size of the probes is reduced, their frequency response increases. Reduction in probe dimensions is expected to improve spatial and temporal resolution.

Thermal anemometry–based **micromachined** probes have been explored by Tai[96] and Lofdahl et al.,[97] but they were never ready for practical use. Jiang, Tai, Ho, and Li[98] developed new micrometre-sized polysilicon wires and demonstrated the potential for batch fabrication. Jiang, Tai, Ho, Karan, and Garstenauer[99] have implemented these hot wires into anemometers and performed calibration of them in wind tunnels. The micromachined anemometers (Fig. 20.7.19*a*) consist of a sensing wire, two parallel support shanks, a silicon beam, and a thick (500-μm) Si handle. The silicon beam is like the probe body and is 1 μm long, 200 μm wide, and 75 μm thick. The two parallel support shanks are 100 μm long, 20 μm wide, and 0.5 μm thick. Various sizes of the sensing wires have been made, and they are 10 to 160 μm long, 1 μm wide, and 0.5 μm thick. This structure is similar to that of the conventional anemometers, so direct comparison can be made. The package of the anemometers is a ceramic tube a few centimetres long and 3 mm in diameter (Fig. 20.7.19*b*). The anemometer handle is soldered with electrical cables, placed inside the tube, and then epoxy-fixed. During handling, all mechanical vibrations have to be avoided in order to prevent damage of the wires.

Ebefors et al.[100] used doped silicon for both the prongs and the hot-wire sensor, along with a polyamide hinge, to make a three-component sensor, shown schematically in Fig. 20.7.20. An SEM photograph is shown in Fig. 20.7.21.

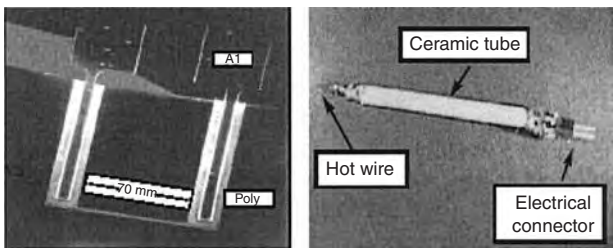


Fig. 20.7.19 (*a*) SEM of a micromachined hot wire. (*b*) Micrograph of the anemometer packaging from Jiang et al.[99]

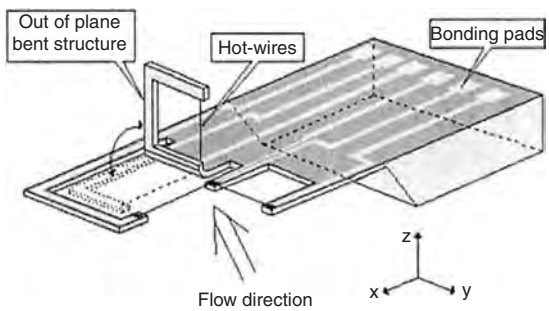

Fig. 20.7.20 Schematitic view of the 3-D hot-wire probe based on a polyamide joint. Silicon chip is 3.5 mm $\times$ 3 mm $\times$ 0.5 mm and the three wires are 500 mm $\times$ 5 mm $\times$ 2 mm. From Ebefors et al.[100]

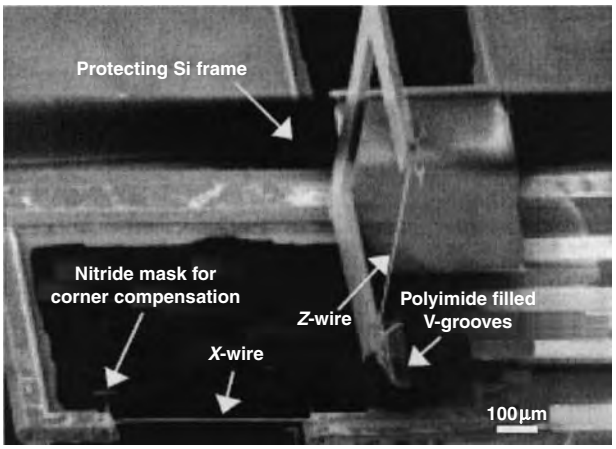

Fig. 20.7.21 SEM photo of the *x*- and *z*-hot-wire resistance elements with electrical connection through the poluamide joint. From Ebefors et al.[100]

Non-silicon-based hot wires with a thermal element size of 2.7 μm × 50 μm have been fabricated by Chen and Liu[101] (Fig. 20.7.22).

Micrometre-resolution particle image velocimetry (μ**PIV**) refers to the application of PIV to measure velocity fields of fluid motion with length scales of the order 100 μm, and with spatial resolution of individual velocity measurements of order 1 to 10 μm. The PIV technique is limited to maximal spatial resolutions of 0.2 to 1.0 mm because of fundamental physical limitations as well as practical implementation difficulties. In μPIV, emphasis is placed on the ability to accurately and reliably measure fluid velocity with micrometre spatial resolution. In order to achieve microscale velocity measurements, novel developments in PIV image recording hardware, flow-tracing particles, system design, and analysis software are required. The theoretical background of μPIV is based on the interactions between the flow fluid and the seed particles, which occur at nanometre length scales. μPIV can be thought of as a practical, application of nanotechnology to perform science and engineering at micrometre-length scales.

The main component of a typical μPIV setup like that shown in Fig. 20.7.23 is the microscope lens and epifluorescent prism/filter which are typical in microscopy imaging. This system was adopted originally by Meinhart et al.[102] for μPIV measurements. A pulsed monochromatic light source, such as a pulsed Nd:YAG laser system is used. The laser system is similar to those used in PIV applications. It consists of two Nd:YAG laser cavities, beam-combining optics, and a frequency-doubling crystal. The illumination light is delivered to the microscope through beam-forming optics, which can consist of a variety of optical elements that will sufficiently modify the light so that it will fill the back of the objective lens, and thereby broadly illuminate the microfluidic device. The beam-forming optics can consist of a liquid-filled optical fiber to direct the light into the microscope. Recently, light has been delivered into the microfluidic device by using total reflection through a transparent wall. This instrument is called a total internal reflection fluorescence (TIRF) microscope.

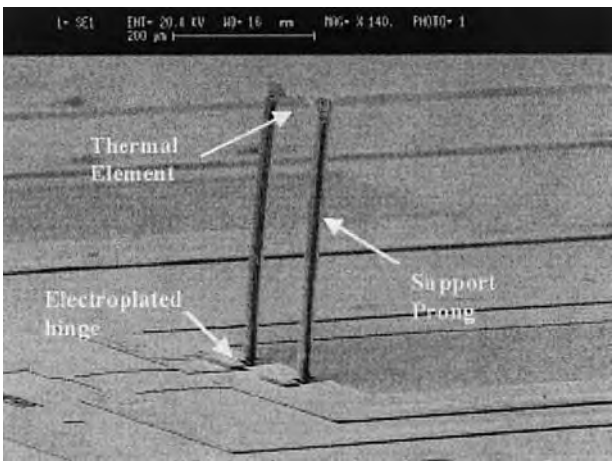

Fig. 20.7.22 SEM micrographs of a hot-wire anemometer after postrelease strengthening by electroplating. From Chen and C. Liu.[101]

Typically, the working fluid is directed through the microfluidic device by pressure, or induced electrokinetically. The working fluid can be of any visibly transparent fluid, such as water. Liquids are most commonly used. It is conceivable to use gaseous fluids, such as air, but μPIV experiments using air have not been demonstrated successfully to date. The working fluid should be seeded with fluorescent particles, which can be manufactured from a variety of materials, such as polystyrene. It is important that the particles have a specific gravity closely matched to the working fluid, and less than, say, 1 μm, preferably 200 to 700 nm.

A sensitive large-format interline-transfer CCD camera is commonly used to record the particle image fields. A large-format CCD array is desirable because it allows for more particle images to be recorded, and increases the spatial dynamic range of the measurements. The interline transfer feature of the CCD camera allows for two particle image frames to be recorded back to back to within a 500-ns time delay.

These techniques can be extended to provide three-dimensional information on the entire flow field by changing the focal plane of the objective lens with piezoelectric positioners to scan the whole depth.

In μPIV, fluorescent particles with diameters typically in the range 200 to 300 nm are used to obtain velocity data with an out-of-plane spatial resolution typically of order 1 μm. Near-wall measurements with this method have so far been obtained no closer than 450 nm from the surface.

Recently, **nano-PIV** (nPIV) has been introduced as a technique specifically designed for near-surface interrogation of flow[103,104,105] where near-wall measurements with μPIV have so far been obtained no closer than 450 nm from the surface. The new nPIV method relies on an evanescent wave illumination generated by the total internal reflection (TIR) of light at the interface between two materials of different refractive indices,[106] e.g., a glass-liquid interface. With this method, the motion of particles within a region of order 100 nm of the surface is measured. In nPIV studies, to date, the size of the seed particles are in the 100- to 300-nm range; i.e., they are of the same order of, or larger than, the illuminated region. It would be desirable to use much smaller seed particles to reduce some of the complications that can be caused by larger particles, such as the modification of the evanescent wave field and particle–fluid interactions that compromise the accuracy of fluid velocity measurement and the ability of particles to move close to the surface.

The use of **quantum dot** (QD) nanoparticles for near-surface measurements of velocity has been introduced by Pouya et al.[107] These particles are an order of magnitude smaller than what has been used to date in nPIV. Nanocrystal QDs are semiconductor nanoparticles that are chemically synthesized with precisely controlled sizes in the range of 1 to 10 nm.[108–112] Among the most developed QDs for fluorescence imaging are the coreshell dots composed of an optically active nanocrystal core of CdSe surrounded by a protective shell of ZnS. The surface of QD is covered with a ligand shell that can be functionalized for broad chemical flexibility. Several properties of QDs make them extremely attractive for fluid flow studies. By modifying the functional groups in the ligand shell, QDs may be dispersed in specific chemical environments such as polar and nonpolar liquids. Since QDs can be solubilized within the fluid, they are expected to behave more like molecules and some of the near-wall issues of "solid" particles should not manifest themselves to QD tracers (e.g., particle-fluid and particle-wall interactions). The emission wavelength of a QD depends on its size, and

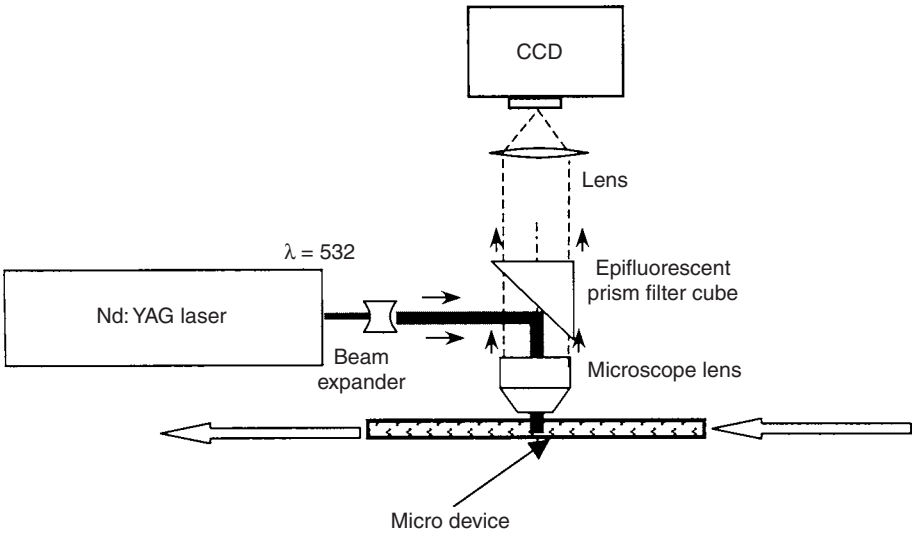

Fig. 20.7.23 Experimental setup for μPIV measurements.

can be tuned across the entire visible spectrum by varying the diameter of the particle. The excitation band is very broad, and the emission is independent of the excitation wavelength. Thus, a size series of QDs with different emissions can be excited with the same light source.

The experimental setup is similar to that of μPIV. Pouya et al.[107] indicated that QDs showed large enough displacement to be discernible with the naked eye.

Nuclear magnetic resonance (NMR), one of the most powerful analytic tools for studying chemical composition, is opening the door to microfluidic applications. NMR is a phenomenon involving a property found in atomic nuclei of almost every molecule called *spin,* which gives rise to a magnetic moment, meaning that the nuclei behave like bar magnets with north and south poles. When a magnetic filed is applied, these magnets align their axes along the lines of the magnetic field. This alignment is not perfect and it results in a wobbly rotation about the magnetic lines that is characteristic for each type of nucleus. Hilty et al.[113] developed a remote NMR technique that provided a strong signal to overcome the sensitivity limitation of NMR by introducing hyperpolarized xenon nuclei, which have a very long spin-relaxation time (several minutes). In this technique, signal encoding and detection are carried out independently while in a conventional setup the two processes take place within a single device. In addition to the magnetic field, the nuclei of the sample are also subjected to a sequence of radio-frequency pulses during the encoding phase, and because of this they absorb and re-emit energy at characteristic frequencies. In the detection phase the frequencies of these encoded signals are used to obtain an NMR spectrum that contains distinct information to characterize the sample.

20.8 INTRODUCTION TO BIOMECHANICS

by Ali M. Sadegh

GLOSSARY

In describing the relationship of body parts or the location of an external object with respect to the body, the use of directional terms is necessary. The following are commonly used directional terms; see Fig. 20.8.1.

Superior: Closer to the head
Inferior: Farther away from the head
Anterior: Toward the front of the body
Posterior: Toward the back of the body
Medial: Toward the midline of the body
Lateral: Away from the midline of the body
Proximal: Closer to the trunk
Distal: Away from the trunk

INTRODUCTION—WHAT IS BIOMECHANICS?

The concepts of biomechanics were implicitly reflected in medical literatures since the nineteenth century and later in mechanics literatures. For example, von Helmholtz, who was a professor of physiology, pathology, and anatomy at Bonn and later professor of physics in Berlin (1871), had contributed to the mechanism of hearing and theory of color vision and optics and velocity of nerve pulses. Then, in the twentieth century, some researchers employed mechanics principles to explain some phenomena in human physiology. In the early 1970s, the international community adopted the term *biomechanics* to describe biological systems from mechanical perspectives.

By definition, **biomechanics** is the application of mechanics in biology and physiology, i.e., utilization of physics laws to study and to analyze the anatomical and functional aspects of living organisms.

Biomechanics has been involved in virtually every facet of modern medical science and technology. Biomechanics has helped in solving all kinds of clinical problems associated with virtually all human organs from the cardiovascular system to prosthetic devices. Even the molecular biology field, which may seem far from biomechanics, utilizes physics principles to understand the mechanics of the formation, design, function, and production of the molecules. Orthopedics has profoundly relied on biomechanics research to treat patients with musculoskeletal problems. Orthopedic surgeons employ biomechanics as their clinical tools. Rehabilitation and healing are intimately related to the stress and strain in the tissues. Injury biomechanics in automotive accidents and other trauma is becoming more important to modern society since it has an economic impact. Therefore, it is no surprise that biomechanics researchers may have academic backgrounds in all engineering and medical disciplines, including orthopedic, cardiac, sports medicine, physical therapy, and many other fields.

Similar to an engineering approach, biomechanics problems should be solved through the following steps.

1. Acquire knowledge of the geometry and configuration of an organ; anatomy, morphology, and histology of the organ should be studied first.
2. Determine the mechanical properties. Unlike with engineering materials, the mechanical properties of living tissues are very difficult to ascertain due to the size of the tissue, or large deformation and nonlinearity of the constitutive equation.
3. Derive the governing equation. The fundamental laws of physics, e.g., conservation of mass, momentum, and energy, should be employed, and the governing differential or integral equation for the living tissue should be determined.
4. Determine proper boundary conditions of the organ.
5. Solve the boundary value problem analytically or numerically.
6. Similar to engineering, physiological experiments including animals (in vivo or in vitro) are needed to verify or to compare with the analytical/numerical solutions.

The body spatial coordinate system, which is frequently referred to in this section, is shown in Fig. 20.8.1.

BIOMECHANICS OF BONE

Bones are the main load-bearing tissue in the skeletal system, the purpose of which is to protect internal organs, to provide rigid links and muscle attachment sites, and to facilitate muscle action and body movement. There are 206 bones in the human body that are categorized in four groups according to their general shapes and functions: Short bones provide gliding motion and serve as shock absorbers (e.g., carpals); flat bones provide protection for underlying organs (e.g., scapulae or shoulder blades);

irregular bones have different shapes to fulfill specific functions in the body (e.g., vertebrae in the spine); and long bones, provide movements for upper and lower extremities (Fig. 20.8.2).

After the enamel of the teeth, bone is the second-hardest structure of the body. Bone is a highly vascular tissue with excellent remodeling capability. That is, it can repair, alter its properties, and change its geometry in response to changes in mechanical loading. For example, when bone is not subjected to mechanical loading, its density changes; or when it is subjected to new and repeated mechanical loads, then its shape, architecture, and density change.

Bone is composed of inorganic and organic phases and water. Based on the weight, bone is approximately 60 percent inorganic, 30 percent organic, and 10 percent water. On a volume basis, bone is approximately 40 percent inorganic, 35 percent organic, and 25 percent water. The inorganic portion of the bone, which is in the form of small ceramic crystalline-type mineral, consists of calcium and phosphate, resembling synthetic hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$. The organic phase of the bone consists primarily of type I collagen (90 percent by weight), some other collagen of types III and IV, and a variety of noncollagenous proteins.

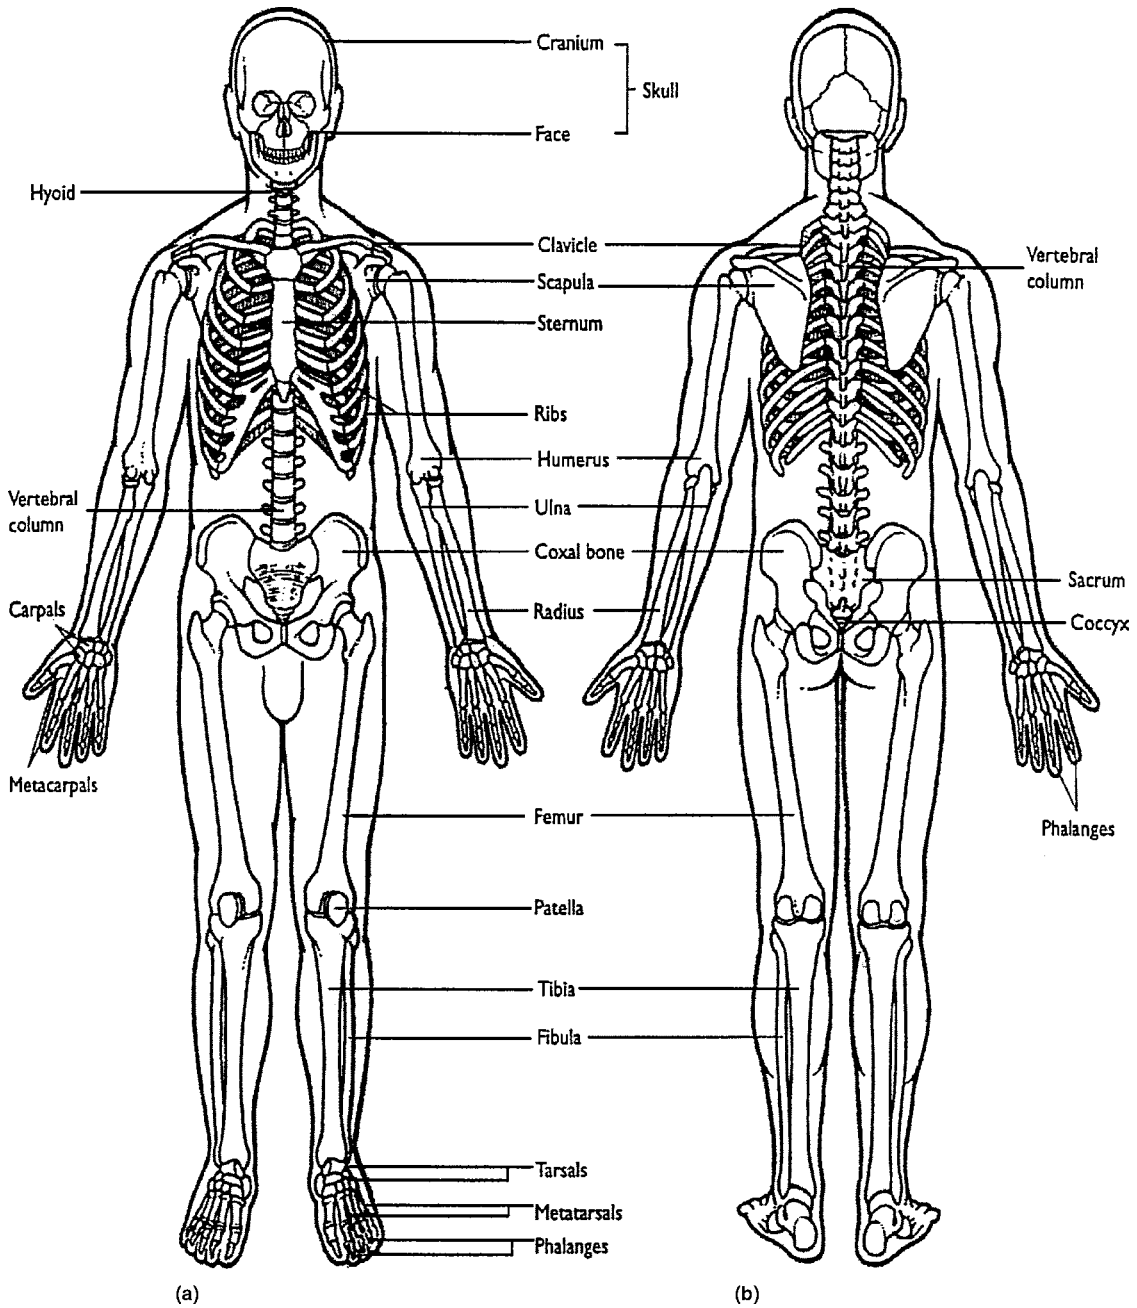

Fig. 20.8.2 The human skeleton. (*From Hall, 2003.*)

Bone Structure

Macroscopically, there are two types of bone: cortical, or compact, bone and cancellous, or trabecular, bone. This is called the highest level of bone porosity. Cortical bone forms the outer shell or cortex of the bone and has a dense structure, while cancellous bone is within this shell and is composed of thin plates, or rods (known as trabeculae), in a mesh structure (Fig. 20.8.3). The interstices between the trabeculae are filled with red marrow. The porosity of cortical bone ranges from 5 to 30 percent, and that of cancellous (trabecular) bone ranges from 30 to 90 percent. Except for the joint surfaces, which are covered with articular cartilage, a dense fibrous membrane called the periosteum surrounds all bones.

Microscopically, the osteon or haversian system is the main structural unit of bone. This is called the second level of bone porosity. At the center of each osteon is a small channel, called the haversian canal, that contains blood vessels and nerve fibers. The osteon itself consists of a concentric series of layers (lamellae) of mineralized matrix surrounding the central canal, similar to growth rings on a tree (Fig 20.8.4). Along the boundaries of each layer, or lamella, are small cavities known as lacunae, each containing one bone cell, or osteocyte. Osteon is typically about 200 μm in diameter, which varies with age, and has a length of 1 to 3 mm. The lacunae of adjacent lamellae are connected by numerous small channels, or canaliculi, which ultimately reach the haversian canal.

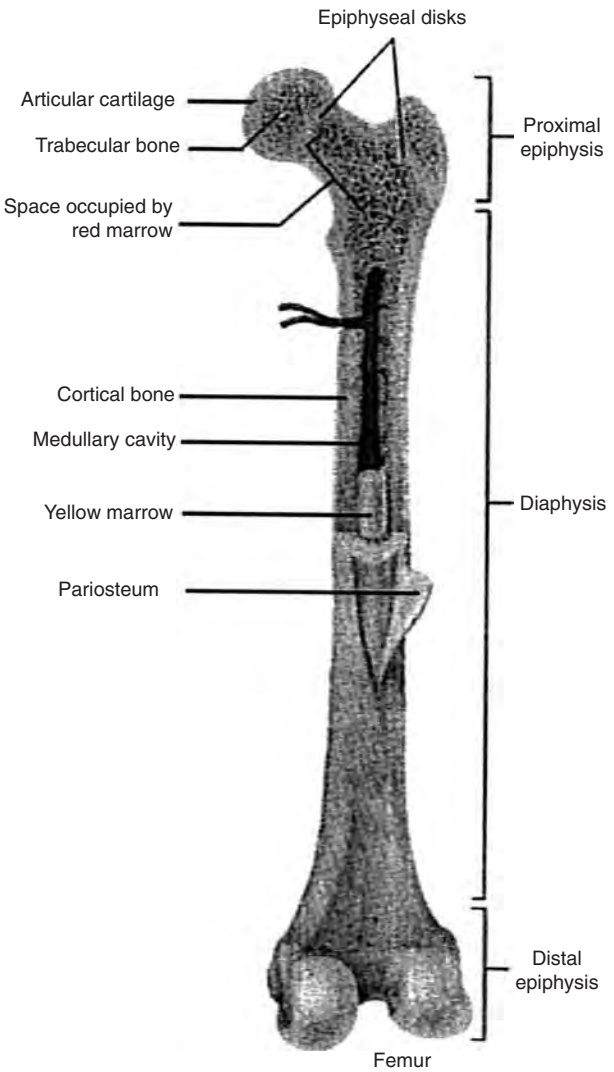

Fig. 20.8.3 Femur, showing cortical and trabecular bones. (*From "Hole's Human Anatomy and Physiology" and Hall, 2003.*)

Mechanical Properties of Bone

Cortical Bone

Based on the anisotropy of bone microstructure, the elastic and strength properties of human cortical bone are anisotropic. In diaphysis of long bones, cortical bone is both stronger and stiffer in the longitudinal direction than in the radial or circumferential directions (Table 20.8.1). Cortical bones are stronger in compression than in tension (Table 20.8.1). Mechanical properties of human cortical bone change (decrease) as age increases (Fig. 20.8.6). While the modulus does not reduce much, if at all, the strength is reduced at a rate of about 2 percent per decade.

As with all biological materials, bone is viscoelastic and nonlinear. It has been shown that cortical bone is moderately strain-rate-dependent. That is, over a six order of magnitude increase in strain rate, modulus changes by only a factor of 2 and strength by a factor of 3 (Fig. 20.8.5). The majority of physiological activities occur in the range of 0.01 to 1.0 percent strain per second, where the changes in bone strength are negligible.

In some simple failure analyses of bone, cortical bone has been considered as simple isotropic materials and the von Mises criterion has been employed. This approach is not capable of describing multiaxial failure of cortical bone. However, the Tsai-Wu criterion, commonly used for composite materials, has been applied to cortical bone using transversely isotropic and orthotropic properties of bone.

Trabecular Bone

The modulus of elasticity and the strength of trabecular bone vary depending on the anatomic site, loading direction, loading mode, and age and health of the donor. In compression, the anisotropy of trabecular bone, both modulus and strength, decreases with age, falling approximately 10 percent per decade (Fig. 20.8.6). The trabecular bone is stronger in compression and is weaker in shear loading mode. Both the modulus and the strength of the trabecular bone depend heavily on the apparent density, yet they depend on the anatomic site. Note that the density of the bone is the ratio of mass to volume of the actual bone tissue; however, the **apparent density** is defined as the ratio of the mass of the bone tissue to the bulk volume of the specimen, including the volume associated with the vascular channels. The density of the trabecular bone also decreases with age. The apparent density of cortical bone is about 1.85 g/cm^3, which does not vary much with anatomic sites or species. However, the apparent density of trabecular bone is as low as 0.10 g/cm^3 for the spine (vertebra) (Kopperdahl and Keaveny, 1998), about 0.3 g/cm^3 for the human tibia (Linde et al., 1989), and up to 0.6 g/cm^3 for the load-bearing portion of the proximal femur (Morgan and Keaveny, 2001).

Bone Remodeling

Bone, as a living tissue, has the ability to remodel, by altering its size, shape, architecture, density, and structure to accommodate the mechanical loadings placed on it. According to Wolff's law, bone remodeling is a function of the magnitude and direction of the mechanical stresses that act on the bones (Wolff, 1892). In other words, Wolff's law states that bone is laid down (deposition) where needed and is resorbed where not needed. Bone remodeling particularly occurs around implants and prostheses where the mechanical stresses to the bone have been altered (Sadegh et al., 1993; Cowin et al., 1992; Luo et al., 1995). In a bone fracture repair process, an implant is firmly attached to the bone to stabilize the fracture site. After the fracture has healed, if the implant is not extracted, the strength and stiffness of the bone may be diminished. This is due to the fact that the material of implants is about 10 times stiffer than the bone, and thus the majority of the loading will be carried

out by the implant. This is called **stress shielding** where an implant may cause bone resorption.

BIOMECHANICS OF ARTICULAR CARTILAGE

Articular cartilage is a tough, dense, white connective elastic tissue, about 1 to 5 mm thick, that covers the ends of bones in joints and enables the bones to move smoothly over one another. Articular cartilage is an isolated tissue without blood vessels, lymph channels, and nerves; yet it withstands the rigorous joint environment without failing during the average lifetime. However, when articular cartilage is damaged through injury or a lifetime of use, it does not heal as rapidly or effectively as other tissues in the body. Instead, the damage tends to spread, allowing the bones to rub directly against each other and resulting in pain and reduced mobility.

The primary function of articular cartilage is to distribute joint loads over a wide area and to reduce the stress concentration on the joint. Its secondary function is to provide a contacting surface with minimal friction and wear.

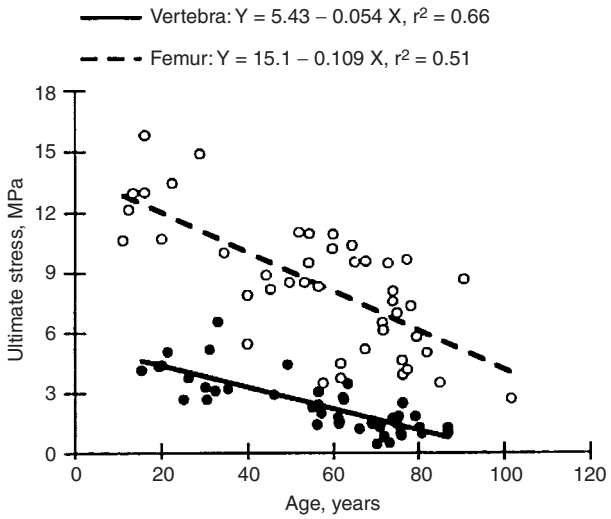

Fig. 20.8.6 Variation of ultimate stress of trabecular bone (from the human vertebra and femur) with age. (*From Kutz, 2003; data from Mosekilde et al., 1987 and McCalden et al., 1997.*)

Chondrocytes are mature cartilage cells. They are sparsely distributed and account for less than 10 percent of the tissue's volume. Chondrocytes are arranged in three zones through the thickness of cartilage (Fig. 20.8.7). The first zone is close to the articular surface where chondrocytes' long axes are parallel to the articular surface. In the second, middle zone, the chondrocytes are round and randomly distributed. In the third, deep zone, the chondrocytes are arranged in columnar fashion perpendicular to the articular surface.

The organic matrix of cartilage is composed of a dense network of fine collagen fibrils enmeshed in a concentrated solution of proteoglycans (PGs). The collagen content of cartilage tissue ranges from 10 to 30 percent by net weight, and the PG content from 3 to 10 percent by wet weight; the remaining 60 to 87 percent is water, inorganic salts, and small amounts of other matrix proteins, glycoproteins, and lipids.

Cartilage is predominantly loaded in compression and is biphasic (solid-fluid) and viscoelastic. When cartilage is compressively loaded, the water within the proteoglycan matrix is extruded. The stiffness of cartilage is a function of its permeability, and the fluid pressure within the matrix supports approximately 20 times more load than the underlying material during physiological loading (Mankin et al., 1994). Cartilage material properties are given in Table 20.8.2.

Table 20.8.2 Representative Properties of the Human Articular Cartilage Taken from the Lateral Condyle of the Femur

Property	Value

BIOMECHANICS OF TENDONS AND LIGAMENTS

Tendons and ligaments, along with the joint capsule, surround, connect, and stabilize the joints of the skeletal system. Ligaments and joint capsules, which connect bone to other bones, provide stability to joints by guiding joint motion and preventing excessive joint motion. The function of the tendons is to attach muscle to bone and to transmit tensile loads from muscle to bone. Tendons and ligaments are sparsely vascularized and are composed of a combination of collagen and elastin fibers arranged primarily in parallel along the axis of loading. They have relatively few fibroblast cells and abundant extracellular matrix. In general, the cellular material occupies about 20 percent of the total tissue volume, while the extracellular matrix accounts for the remaining 80 percent. About 70 percent of the matrix consists of water, and approximately 30 percent is solids.

Both tendons and ligaments are passive tissues, and they do not have the ability to contract as muscle tissue does; however, they are extensible in tensile loading, and will return to their original length after being stretched, when they are extended within their elastic limits. In the unloaded state, the fibers are slightly crimpled, and thus at the initial stage of tensile loading the structure acts only to straighten out the component fibers and exhibits low stiffness, i.e., in the toe region in Fig. 20.8.8*a*. The straightened fibers exhibit linear deformation under further tensile loading, resulting in this load-deformation curve of Fig. 20.8.8*a*. Typical tensile properties of ligament and tendon are shown in Table 20.8.3. Tendons are generally stiffer than ligament due to the higher concentration of collagen. Tendons and ligaments are highly viscoelastic and rate-dependent; i.e., they will fail at lower extensions when loaded at high rates. That is, rapid motion (stretching) of ligaments or tendons may result in tear or rupture. For the whole ligaments and tendons the linear response can extend above 20 percent (Fig. 20.8 8*b*).

BIOMECHANICS OF MUSCLES

Skeletal muscle is the most abundant tissue in the human body, accounting for 40 to 45 percent of the total body weight. There are 430 skeletal muscles, found in pairs on the right and left sides of the body. There are three types of muscles: (1) cardiac muscles which compose the heart,

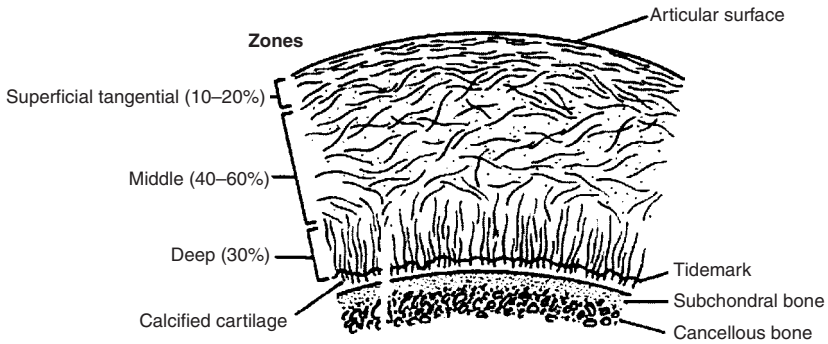

Fig. 20.8.7 Collagen fibrils of chondrocyte arrangement through the thickness of cartilage, with three distinct zones: surface tangential, middle, and deep. (*From Nordin and Frankel, 1989, by permission.*)

(2) smooth or involuntary muscles which line the hollow internal organs, and (3) skeletal or voluntary muscles which are attached to the skeleton through the tendons, and cause it to move.

Muscles are molecular machines that convert chemical energy to a force (mechanical energy). The structural unit of skeletal muscle is the fiber, a long cylindrical cell with hundreds of nuclei, ranging from about 10 to 100 μm in thickness and about 1 to 30 cm in length. Individual muscle fibers are connected by three levels of collagenous tissue: endomysium, which surrounds individual muscle fibers; perimysium, which collects bundles of fibers into fascicles; and epimysium, which encloses the entire muscle belly (see Fig. 20.8.9). The functional unit of skeletal muscle is the motor unit, which is the smallest part of the muscle that can be made to contract independently. The motor unit consists of a single motor neuron and all the muscle fibers that are to be stimulated by it. Note that when stimulated, all muscle fibers in the motor unit respond as one (Fig. 20.8.10).

The tendons and the connective tissues in and around the muscle belly are viscoelastic structures that help determine the mechanical characteristics of whole muscle during contraction and passive extension. In simulating musculotendon actuation, Hill (1970) showed that the tendons represent a springlike elastic component located in series with the contractile component (element) CC (or CE), which is in parallel with parallel elastic element (PEE) and in series with the series elastic element (SEE) (Fig. 20.8.11).

The mechanism of muscle contraction is as follows. After stimulation by the motor nerve, there is an interval of a few milliseconds, known as the latency period, before the tension in the muscle fibers begins to rise and contraction starts. Physiologically, according to the sliding filament theory, active shortening of the muscle results from the relative movement of the actin and myosin filaments past one another. This mechanical response of muscle fibers is known as twitching. Some muscle fibers contract with a speed of only 10 ms, while others may take 100 ms or longer.

During muscle contraction, a tension load is exerted on the bone to overcome the external load of the body. The muscle tension is generally applied at a distance from the center of rotation of a joint, to create a moment (torque) on the involved joint.

There are three types of muscle contraction. First, when muscles develop sufficient tension to overcome the resistance of the body segment, the muscles shorten and cause joint movement in the same direction as the net torque generated by the muscles. This contraction is called a **concentric.** Second, when muscle tension is developed but no change in muscle length occurs, the contraction is said to be **isometric.** In this case due to the developed contraction the diameter of the muscles is increased. Third, when a muscle cannot develop sufficient tension and the opposing joint torque exceeds that produced by the tension, the muscle progressively lengthens instead of shortens. In this case the muscle is said to contract **eccentrically.** Note that concentric and eccentric contractions involve dynamic work, in which the muscle moves a joint or controls the movement, while isometric contractions involve static work, in which the joint position is maintained (Fig. 20.8.12).

BIOMECHANICS OF JOINTS

Anatomically, there are three types of joints: immovable joints, such as sutures of the skull; slightly movable joints, such as cartilaginous joints (discs) where applied forces are attenuated to the adjacent bones; and freely movable (synovial) joints such as articular joints in the upper and lower extremities. In this section the biomechanics of articular joints in upper and lower extremities is discussed.

Biomechanics of the Knee

The human knee is the largest and one of the most complex joints in the body. The knee joint is situated between the body's two longest bones, the femur and tibia, and bears tremendous loads. The fact that the knee joint provides the mobility required for locomotor activities makes it one of the high weight-bearing joints of the body. Anatomically, the knee joint comprises (1) two condylar articulations of the tibiofemoral, with the third articulation being the patellofemoral joint; (2) medial and lateral menisci cartilaginous disc located between the tibial and femoral condyles; (3) articular capsule which is a double-layered membrane that surrounds the joint; (4) the synovial fluid, which is a clear, slightly yellow liquid that provides lubrication inside the articular capsule at the joint; and (5) the patella, also known as kneecap (Fig. 20.8.13). In addition, there are several ligaments in the knee joint; the two important

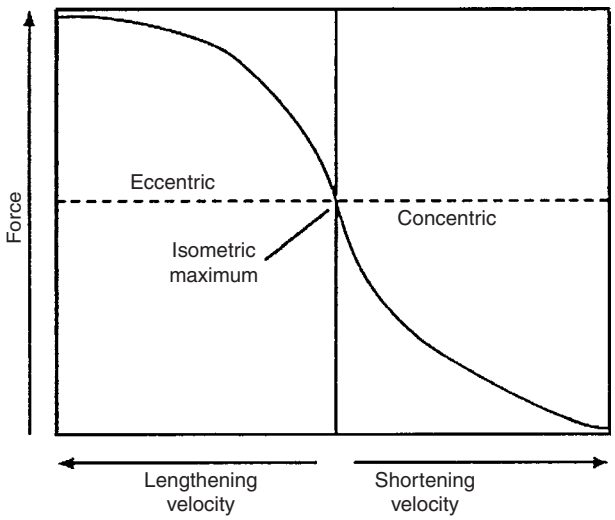

Fig. 20.8.12 The three types of muscle contraction are shown schematically. (*From Hall, 2003.*)

ones are the anterior cruciate ligament (ACL) and the posterior cruciate ligament (PCL) (Fig. 20.8.13).

Knee Kinematics

The knee joint motion takes place in all three planes; however, the range of motion is greatest in the sagittal plane. Motion in this plane is from full extension to full flexion of the knee, which is approximately 140°. When the knee is fully extended, its rotation is almost completely restricted by the interlocking of the femoral and tibial condyles. However, when the knee reaches about 90° flexion, the external rotation ranges from 0° to approximately 45°. During flexion/extension, in addition to the rolling contact between the femoral and tibial condyles, there is tangential gliding between the two condyles as well. Also, in flexion/extension motion, the patella glides inferiorly and superiorly against the distal end of the femur in the vertical direction. The anterior and posterior cruciate ligaments (ACL and PCL) limit the forward and backward sliding of the femur on the tibial plateaus during knee flexion and extension and also limit knee hyperextension. They both play an important role in knee stability.

Knee Loads

In flexing the knee, the three hamstring muscles are the primary flexors acting on the knee. However, during extension the quadriceps muscles provide the primary force for the knee. During daily activities, the tibiofemoral joint is subjected to compression and shear forces. Specifically, during the stance phase of gait, the compressive force at the tibiofemoral joint exceeds 3 times the body weight; or during stair climbing the compressive force is approximately 4 times the body weight. Figure 20.8.14 shows the static load diagram of the knee during stair climbing. Figure 20.8.15 shows the joint reaction force, in terms of body weight transmitted through the tibial plateau during walking, in one gait cycle. During the gait cycle the joint reaction force shifts from the medial to the lateral tibial plateau. In stance phase, when the force reached its peak value, the medial plateau mainly carried the load; and in the swing phase, when the force was minimal, the load was carried by the lateral plateau. The contact area of the medial tibial plateau is approximately 50 percent larger than that of the lateral tibial plateau.

Although the tibial plateaus are the main load-bearing structures in the knee, the menisci act as force absorption and distribute loads at the tibiofemoral joint over a larger area, thus reducing the magnitude of contact stress at the joint. The joint cartilages and ligaments also contribute to load bearing.

Biomechanically, the patella serves two important functions. First, it aids knee extension by producing anterior displacement of the quadriceps tendon throughout the entire range of motion, thereby lengthening the lever arm of the muscle force. Second, it allows wider distribution of compressive stress on the femur by increasing the area of contact. During normal walking gait, compressive force at the patellofemoral joint is about one-half of body weight, and during the stair climbing, it increases up to over 3 times body weight.

Biomechanics of the Hip

The hip joint is a ball-and-socket joint and is one of the largest and most stable joints (less likely to be dislocated) in the body with a great deal

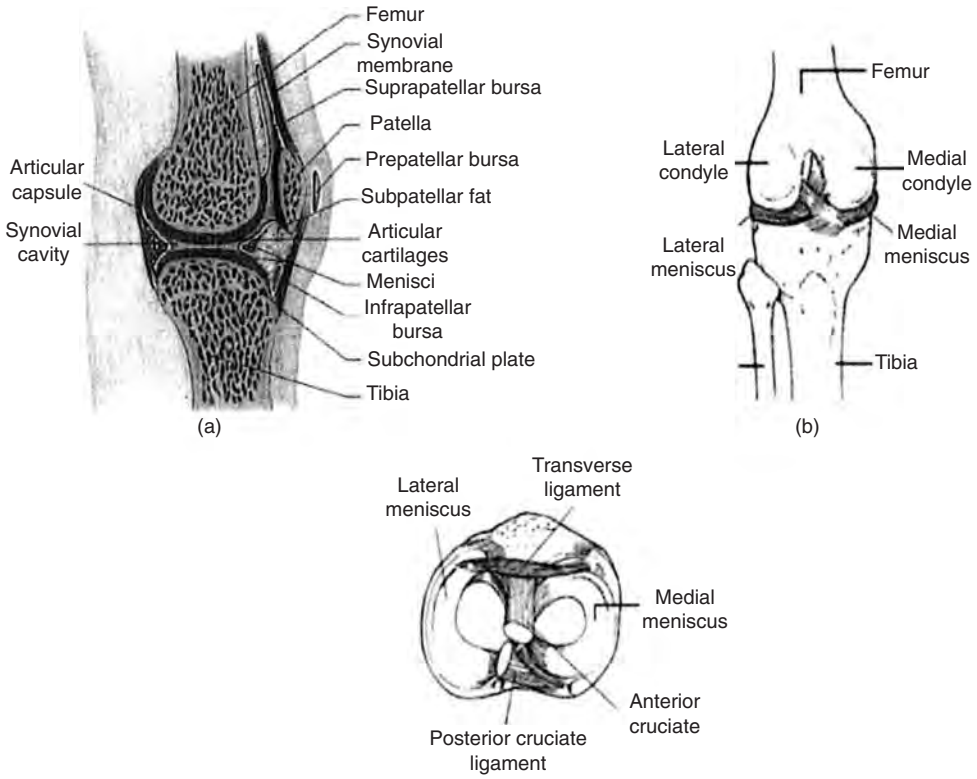

Fig. 20.8.13 The knee joint. (*a*) Sagittal cross-sectional view (*"Hole's Human Anatomy and Physiology," 1996; Hall, 2003.*) (*b*) Posterior view. (*Hall, 2003.*) (*c*) Top view. (*Hall, 2003.*)

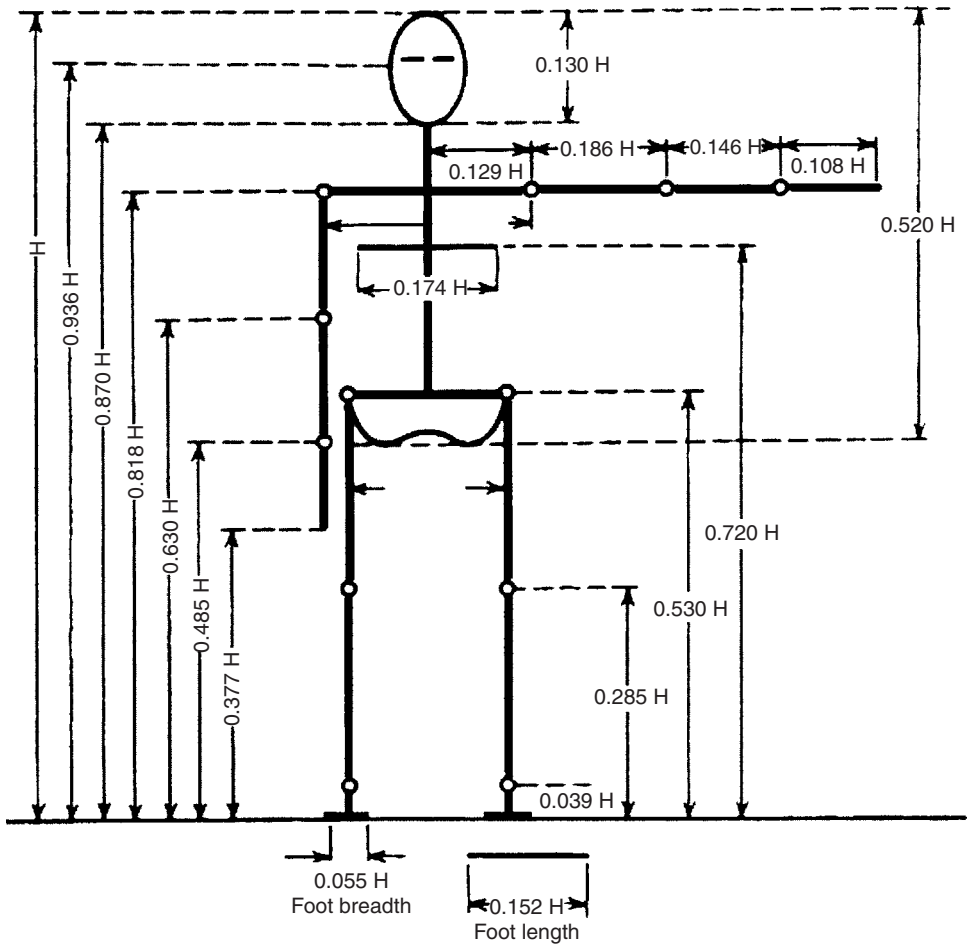

Fig. 20.8.18 Body segment length expressed as a fraction of body height *H*. (*From Drillis and Contini, 1966.*)

of mobility. Anatomically, the hip joint is composed of the head of the femur, which forms approximately two-thirds of a sphere, and the acetabulum of the pelvis, which is a socket (see Fig. 20.8.16).

The acetabular surface and the head are covered with articular cartilages. The femur is a major weight-bearing bone and is the longest, largest, and strongest bone in the body. The femoral neck is its weakest component and is primarily composed of trabecular bone. The hip joint cartilage covers both articulating surfaces. Several large and strong ligaments provide the stability of the hip.

Hip Kinematics

The hip joint, due to its ball-and-socket nature, moves in all three planes. In the sagittal plane it flexes or extends, in the transverse plane it rotates internally and externally, and in the frontal plane it has abduction and adduction motions. The maximum range of motion is in the sagittal plane where the range of flexion is from 0° to approximately 140° and the range of extension is from 0° to 15°. The range of abduction is from 0° to 30°, whereas that of adduction is from 0° to 25°. Its external rotation ranges from 0° to 90°, and its internal rotation ranges from 0° to 70° when the hip is flexed. The average range of hip joint motion in the sagittal plane during normal walking, in one gait cycle, is shown in Fig. 20.8.17. The joint was maximally flexed during late swing phase of gait, as the limb moved forward for heel strike. Maximum tension was reached at heel-off.

Hip Loads

During flexion six muscles that cross the joint anteriorly (the iliacus, psoas major, pectineus, rectus femoris, sartorius, and tensor fascia latae) are primarily responsible for the motion. However, during extension, the three hamstring muscles (the biceps femoris, semitendinosus, and semimembranosus) and the gluteus provide the motion. These muscles are the knee flexors as well.

The hip is the major weight-bearing joint. During upright standing on both feet the body weight is evenly distributed to each of the hip joints. To calculate the forces and torques in each joint or muscle of the body, the dimensions and length of each body segment are needed. The length between each joint of the human body varies with body build, gender, and racial origin. However, an average set of segment lengths expressed as a percentage of body height was prepared by Drillis and Contini (1966) and is shown in Fig. 20.8.18. To determine the mechanism of balance during quiet standing, Winter et al. (1998) modeled the body as 14 segments with 21 markers, as shown in Fig. 20.8.19. The location of the markers and the accompanying table give the definition of each of the 14 segments, along with the mass fraction of each segment.

During a single-leg stance, the force of the abductor muscle is calculated as follows. The weight of the body above the hip joint is approximately equal to five-sixths of the total body weight. The moment arising from the weight above the hip joint must be balanced by a moment occurring from the force of the abductor muscles, as shown in

Fig. 20.8.20. A simple balance of moment with respect to the center of the femoral head reveals that the abductor muscle force M is $M = \frac{5}{6}Wb/c$, where c is the radius of the ball (femoral head) and b is the distance between the center of the ball and the center of gravity (CG) of mass of the body, without the right hip (minus the one leg). Substitution of the values of b and c leads to the abductor muscle force, which is about 2 times the body weight. The reaction force of the hip joint during a single-leg stance is approximately 3 times the body weight. This magnitude varies as the position of the upper body changes.

During dynamic activities several investigators [Paul, 1967; Andriacchi et al., 1980; Bergmann et al., 1997 and 2001] have studied the loads on the hip joint. Figure 20.8.21 shows the hip joint reaction force in units of body weight during walking, one gait cycle. In both men and women, the largest peak of about 7 times the body weight was reached just before toe-off. An increase in gait velocity increases the magnitude of the hip joint reaction force in both swing and stance phases.

BIOMECHANICS OF THE SPINE

The human spine is a complex and functionally significant structure of the human body. The principal function of the spine is to protect the spinal cord and transfer loads from the upper body, head, and trunk to the lower extremities. The spine is capable of motion in all three planes

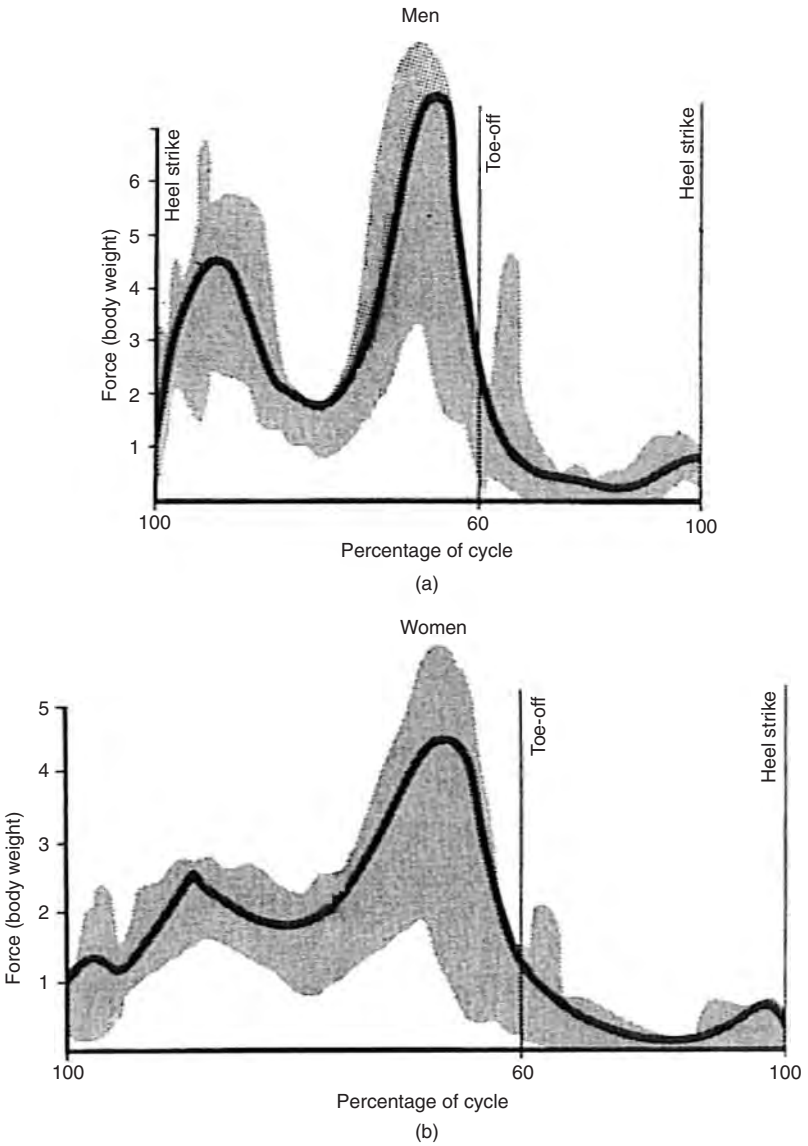

Fig. 20.8.21 Hip joint reaction forces in units of body weight during walking one gait cycle. Shaded area indicates variations among subjects. (*Adapted from Paul 1967; Nordin and Frankel, 1989, by permission.*)

through its 24 vertebrae which are articulated by intervertebral discs. The discs, surrounding ligaments and muscles, gain the spine stability. The spinal column is structurally divided into four regions. Starting from superior to inferior, there are 7 cervical vertebrae (C1 to C7), 12 thoracic vertebrae (T1 to T12), 5 lumbar vertebrae (L1 to L5), and 5 fused sacral vertebrae (S1 to S5) (Fig. 20.8.22).

The spine contains four normal curves. The thoracic and sacral curves, which are concave anteriorly, are present at birth and are referred to as primary curves. The lumbar and cervical curves, which are concaved posteriorly, are developed from supporting the body in an upright position when young children begin to sit up and stand. These curves are known as secondary spinal curves.

Because of the anatomical changes of vertebrae throughout the spinal column, the amount of movement between adjacent vertebrae is varied. In this subsection, the biomechanics of the lumbar spine and the cervical spine are discussed.

Biomechanics of the Lumbar Spine

The vertebral bodies are designed to bear mainly compressive loads. Anatomically, the vertebral bodies of the lumbar region are thicker and wider than those in the thoracic and cervical regions. A typical vertebra consists of a body, a hollow ring known as the neural arch, and several bony processes (Fig. 20.8.23). The spinous and transverse processes serve as outriggers to improve the mechanical advantage of the attached muscles.

The functional unit of the spine, known as the motion segment, consists of two vertebrae and their intervening soft tissues (Fig. 20.8.24). The intervertebral discs in adults account for approximately one-fourth of the height of the spine. The intervertebral disc bears and distributes loads and restrains excessive motion. The intervertebral disc is composed of two functional structures: a thick outer ring composed of fibrous cartilage, called annulus fibrosus, and a central gelatinous material known as the nucleus pulposus, or nucleus

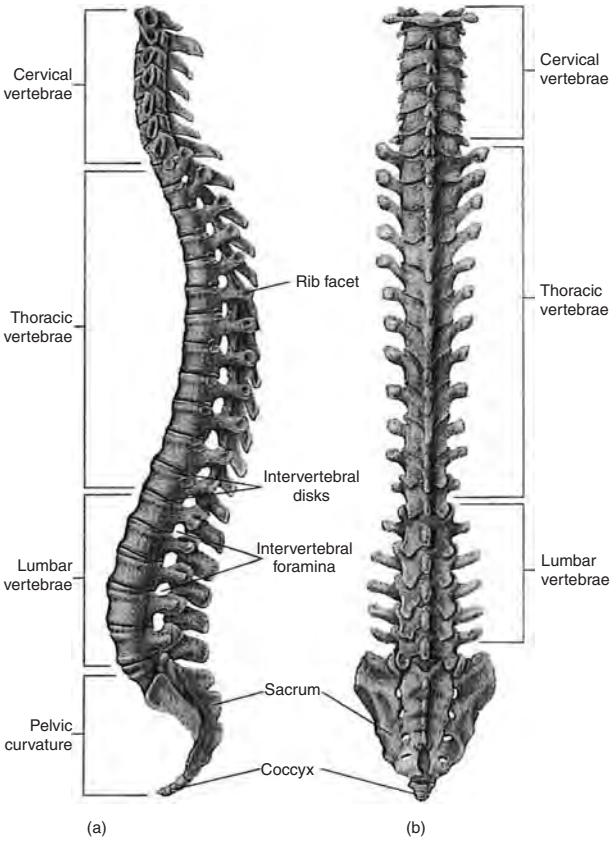

Fig. 20.8.22 The spine. (*a*) Lateral view; and (*b*) the posterior view. (*From "Hole's Human Anatomy and Physiology," 1996; Hall, 2003.*)

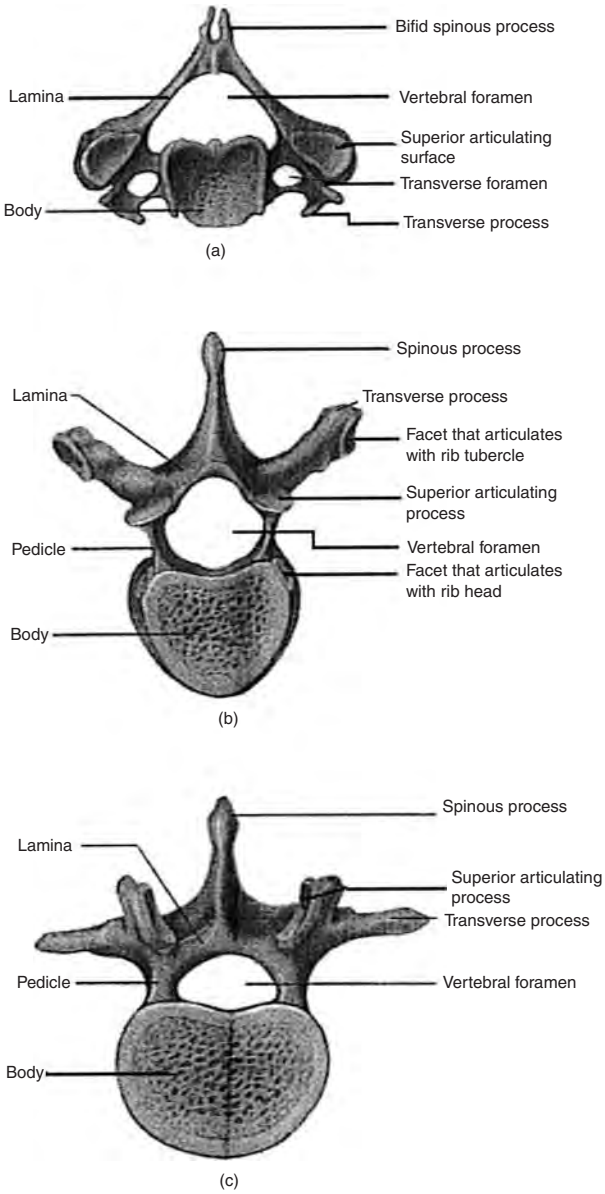

Fig. 20.8.23 Superior views of the typical vertebrae. (*a*) Cervical vertebra, (*b*) thoracic vertebra, and (*c*) lumbar vertebra. (*From "Hole's Human Anatomy and Physiology," 1996*; *Hall, 2003.*)

(Fig. 20.8.25). The annulus surrounds the nucleus pulposus. The annulus fibrosus, composed of fibrocartilage which is in crisscross arrangement of the coarse collagen fiber bundles within the fibrocartilage, allows the annulus fibrosus to withstand high bending and torsional loads. The nucleus pulposus lies directly in the center of all discs except those in the lumbar segment, where it has a slightly posterior position (Fig. 20.8.25*c*). In young adults, the nucleus is rich in hydrophilic (water-binding) glycosaminoglycans, and it diminishes in glycosaminoglycan content with age and becomes less hydrated. The disc is separated from the vertebral body by the end plate, composed of hyaline cartilage.

The vertebral body is comprised of a thin outer cortical shell and the encompassed cancellous or trabecular bone. The cortical shell and the cancellous bone with the ratio of 45:55 share the load transmitted through the vertebral body, respectively, for an adult of 45 years or younger (Goal and Weinstein, 2000). For subjects over 40 years, the cortical bone shell transmits about 65 percent of the total load exerted on the body, due to an increase in the porosity of the cancellous bone. Table 20.8.4 shows the mechanical properties of the cortical shell and the cancellous bone in the vertebral body. The mechanical properties of ligaments surrounding the vertebrae are given in Table 20.8.5.

Spine Kinematics

The ranges of motion of individual motion segments of the spine have been measured by investigators. The represented values on the relative amount of motion at different levels of the spine are presented by White and Panjabi (1978) in Fig. 20.8.26. The range of flexion and extension is approximately 4° in the upper thoracic motion segments, about 6° in the middle thoracic region, and about 12° in the two lower thoracic segments. This range progressively increases in the lumbar motion segments, reaching a maximum of 20° at the lumbosacral level. The range of motion is strongly age-dependent, decreasing by about 50 percent from youth to old age. The first 50° to 60° of spine flexion occurs in the lumbar spine, mainly in the lower motion segments. The thoracic spine contributes little to flexion of the total spine because of the oblique orientation of the facets. Significant axial rotation occurs at the thoracic and lumbosacral levels.

Spinal Load

During daily activities the disc is subjected to a combination of compression, bending, and torsional loads. While the facets appear to

function as a guide for the relative movement of adjacent vertebrae, they in fact carry about 30 percent of the total load when the spine is hyperextended (El-Bohy and King, 1986). The vertebral arches and intervertebral joints play an important role in resisting shear forces. The abdominal muscles and the vertebral portion of the psoas muscle initiate flexion. The weight of the upper body produces further flexion.

During the standing position, the center of gravity of the total body is anterior to the spinal column (passes through L4), which makes the postural muscles active. That is, the spine is under a constant forward bending moment. Therefore, the extensor muscles in the back provide a tension, which counteracts the torque (Fig. 20.8.27). The relative loads on the third lumbar disc for various postures are shown in Fig. 20.8.28. As the body continues to flex, the moment arm of the trunk, arm, head, and neck is increased which leads to the increase in tension in the back extensor muscles. Figure 20.8.29 illustrates the back muscle tension, with approximately a 6-cm lever arm counter to torque created by the weight of the body and the external load. When the body is flexed (forward inclination), the spine makes the disc bulge on the concave side of the spine and retracts on the convex side. That is, the disc protrudes anteriorly and is retracted posteriorly.

When a disc is subjected to a compressive load, in a standing position, the compressive stress predominates in the inner portion of the disc, the nucleus pulposus, and tensile stress predominates in the annulus fibrosus. While a person is lifting an object, the increase in abdominal pressure, contributes to the stiffness of the lumbar spine and thus helps in lifting. While a person is in a sitting position, the loads on the lumbar spine are less if the back is supported, since part of the weight of the upper body is supported by the backrest. The trunk muscles involved in motion contribute to the stability of the spine and maintenance of the posture in an upright position.

During slow walking the increase in loads on the lumbar spine is relatively modest. However, the loads increase with an increase in speed of walking. In his study, Cappozzo (1984) showed that the loads were maximal around toe-off and increased approximately linearly with walking speed. Figure 20.8.30 revealed the axial load on the L3-L4 motion segment in terms of body weight during walking at four speeds. The solid horizontal line in the figure shows the upper body weight (UBW), and the maximum load occurred about the left heel strike (LHS) and right heals strike (RHS).

Biomechanics of Cervical Spine

The cervical spine consists of seven vertebrae. The first two vertebrae, C1 and C2, are atypical, each having a unique structure and role; and the rest of them, C3 through C7, have similar structure and function to those of thoracic and lumbar spine.

The first vertebra in the cervical spine is called the **atlas**, which has no vertebral body and is composed of a ring within which an oval fossa articulates anteriorly with the dens of C2. The superior facets of C1, which form the base of the atlanto-occipital joint, bear the weight of the skull. The second vertebra is called *axis* and is composed of dens, superior facets, pedicle, and spinous process (Fig. 20.8.31). The dens is an articular process that protrudes superiorly from the vertebral body and around which C1 rotates. This configuration allows significant rotation of the head.

The five typical cervical vertebrae C3-C7, each has a body that is elliptical with a transversely concave upper surface, two pedicles, two laminae, and a spinous process. A motion segment consists of two adjacent vertebrae is shown in Fig. 20.8.32 where the ligaments and the intervertebral disc are shown. The intervertebral disc, similar to the lumbar disc, consists of a central gelatinous mass, known as nucleus pulposus, surrounded by a tough outer covering, the annulus fibrosus.

CERVICAL SPINE KINEMATICS

The cervical spine is the most mobile region of the spine. The range of motion of the cervical spine in flexion-extension is about 145°, about

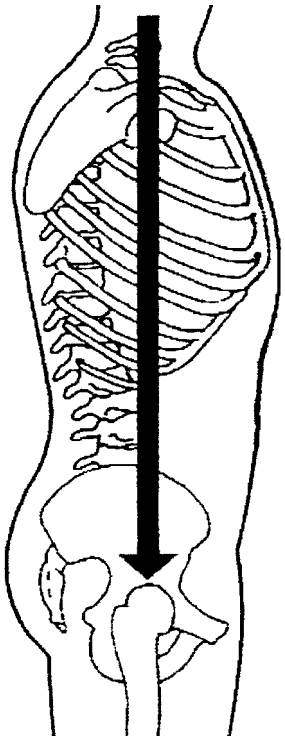

Fig. 20.8.27 Schematic lateral view of the human body; the line of gravity passes through L4. (*From Hall, 2003.*)

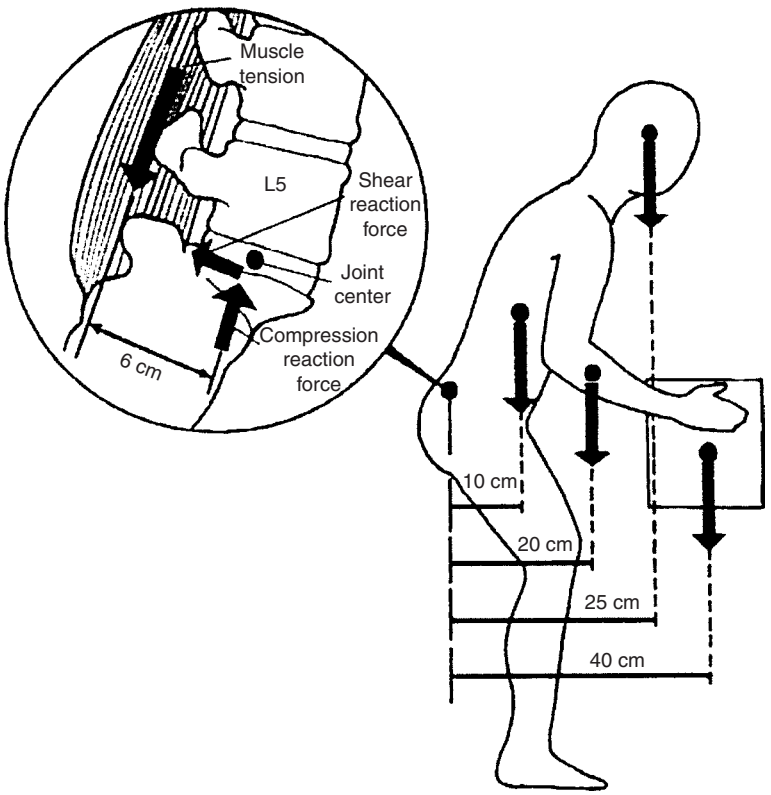

Fig. 20.8.29 Free-body diagram of spine and body loads when subject lifts an external load. The back muscle with a moment of arm of approximately 6 cm must support the moment produced by the body and the load. (*From Hall, 2003.*)

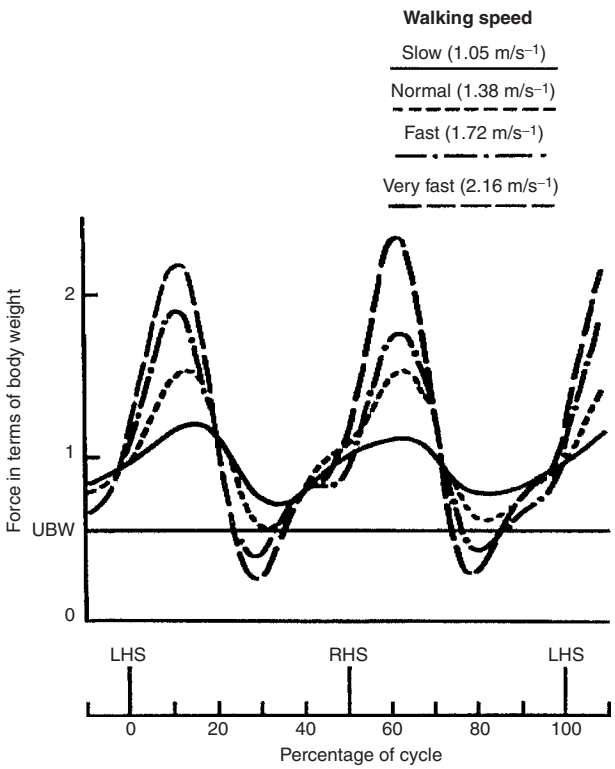

Fig. 20.8.30 Variation of axial load on L3-L4 motion segment based on the body weight during walking at four speeds. The horizontal line shows the upper body weight (UBW), which represents the gravitational component of the load. (*From Nordin and Frankel, 1989, by permission.*)

180° in axial rotation, and about 90° in lateral bending. Specifically, motion at the atlanto-occipital articulation, between C1 and the skull, consists of 10° to 15° of flexion-extension and 8° of lateral flexion, with no rotation. The skull rotation is transferred into motion at the C1-C2 articulation, the atlantoaxial joint. The C1-C2 joint is the most mobile segment of the cervical spine, having up to 47° of axial rotation, representing 50 percent of the axial rotation of the whole cervical spine. However, at this joint, about 10° of flexion and extension takes place with minimal lateral flexion (White and Panjabi, 1978). Flexion, extension, lateral flexion, and axial rotation occur at the joints below C2. A total of +/−45° of axial rotation takes place in C3-C7. Note that the range of motions varies widely among individuals.

The cervical spine stability has been discussed extensively in White and Penjabi's publications. Instability is defined as excessive relative movements of adjacent vertebrae where there is a need for clinical procedure to return the vertebrae to their normal positions. They suggested that the adult cervical spine is unstable, or on the brink of instability, when any of the following conditions is present: more than 3.5 mm of transverse (horizontal) relative displacement of two adjacent vertebrae, or more than an 11° difference in rotation from that of either adjacent vertebra. These cervical conditions need clinical attention to be corrected.

Cervical Spine Load

Distribution of loads throughout the vertebra is a complex issue, which has been studied by several investigators. The results of these studies indicate that the facets bear a portion of the load (King et al., 1975; Miller et al., 1978). In particular, in extension, the facets bear up to

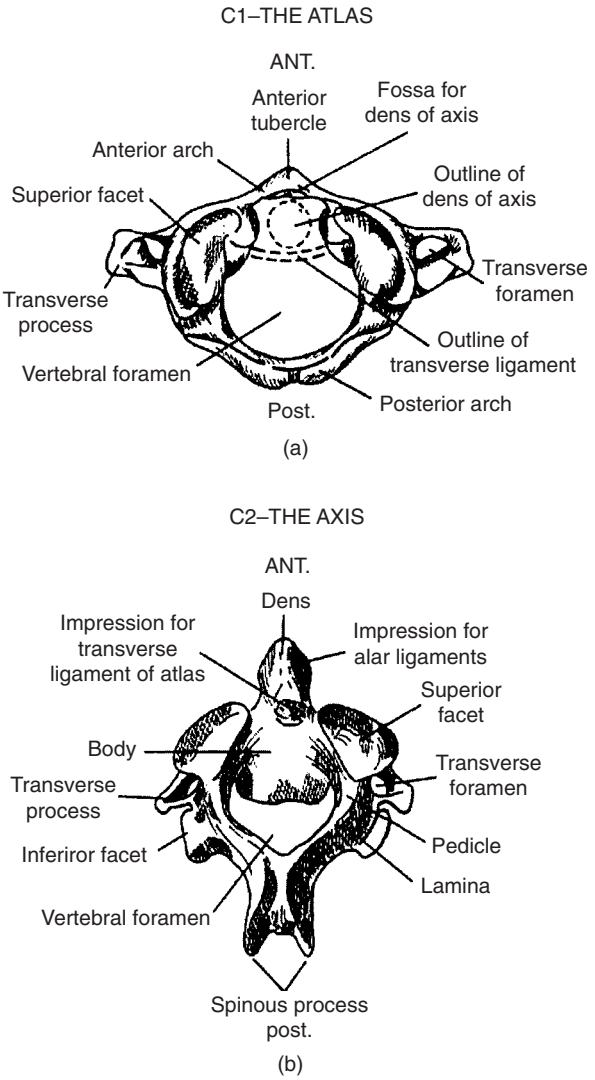

Fig. 20.8.31 Superior views of the atypical cervical vertebrae (*a*) C1 and (*b*) C2. (*From Nordin and Frankel, 1989, by permission.*)

33 percent of the total load, reducing substantially the load of the discs. Harms-Ringdahl (1986) calculated the bending moment generated around the axes of motion of the atlanto-occipital joint (Occ-C1) and at the C7-T1 motion segments. Figure 20.8.33 shows the extension and flexion moments at these joints in a variety of head positions. During extreme flexion the maximum bending moment in the neck occurs at the C7-T1 joint, while the moment at the Occ-C1 joint is relatively high. As the head moves to its natural position, the moment at the Occ-C1 joint slightly decreases while the moment at C7-T1 significantly decreases so that both joints carry approximately equal amounts of load. As the head continues to rotate and approaches the extreme extension, the moment on the Occ-C1 is further reduced while that of C7-T1 increases in the negative direction.

The head and neck, due to their structures, i.e., a large mobile ball atop a column, are particularly vulnerable to dynamic injuries. Excessive loading and motion of the head can easily create stresses and bending moments that exceed the strength of the structure, which leads into subluxation and destabilization of the neck.

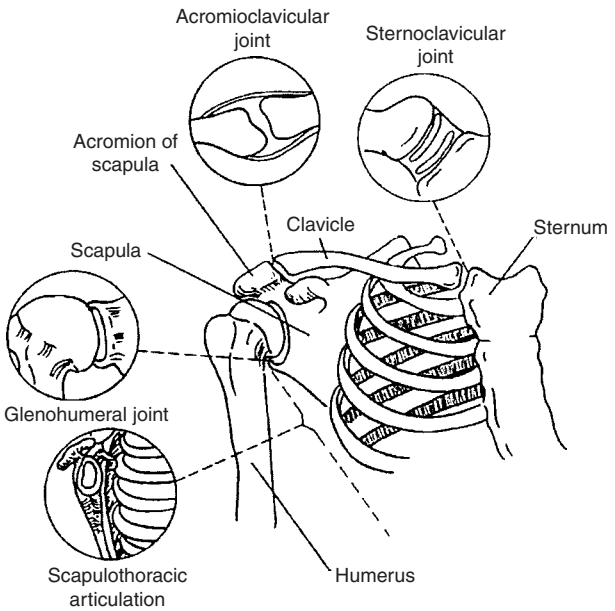

Fig. 20.8.34 Biomechanics of the shoulder. Schematic view of the shoulder joint and the four articulations. (*Adapted from DePalma, 1983; Nordin and Frankel, 1989, by permission.*)

During normal axial rotation the size of the canal is significantly decreased because the oval shape of the central foramen of C1 does not coincide with that of C2.

BIOMECHANICS OF THE SHOULDER

The shoulder is the most complex joint in the human body. It consists of four major separate articulations, as described below, and is shown in Fig. 20.8.34.

1. At the sternoclavicular joint, the proximal end of the clavicle articulates with the clavicular notch of the sternum along with the cartilage of the first rib.
2. At the acromioclavicular joint, the acromion process of the scapula (shoulder blade) articulates with the distal end of the clavicles.
3. At the glenohumeral joint, the hemispherical head of the humerus articulates with the glenoid fossa of the scapula. This is a ball-and-socket configuration joint and is the most freely moving joint in the human body, enabling flexion, extension, hyperextension, abduction, adduction, horizontal abduction and adduction, and medial and lateral rotation of the humerus. There are four major muscles on the posterior, superior, and anterior sides of the joint, providing the joint movements; they are called rotator cuff muscles. The capsule of the joint is surrounded and is stabilized by several ligaments and the tendons of four muscles, as well as the biceps. Negative pressure within the capsule of the glenohumeral joint also helps to stabilize the joint.
4. At the scapulothoracic joint, the anterior scapula is articulated with the thoracic wall. This is due to the movement of the scapula in the sagittal and frontal planes.

Shoulder Loads

The ball-and-socket configuration of glenohumeral joint provides mainly the rotation of the shoulder; however, it includes some rolling and gliding motion as well. The rotator cuff muscles are oriented such that their tendons and muscle masses may push on the head of the humerus, thereby stabilizing the joint.

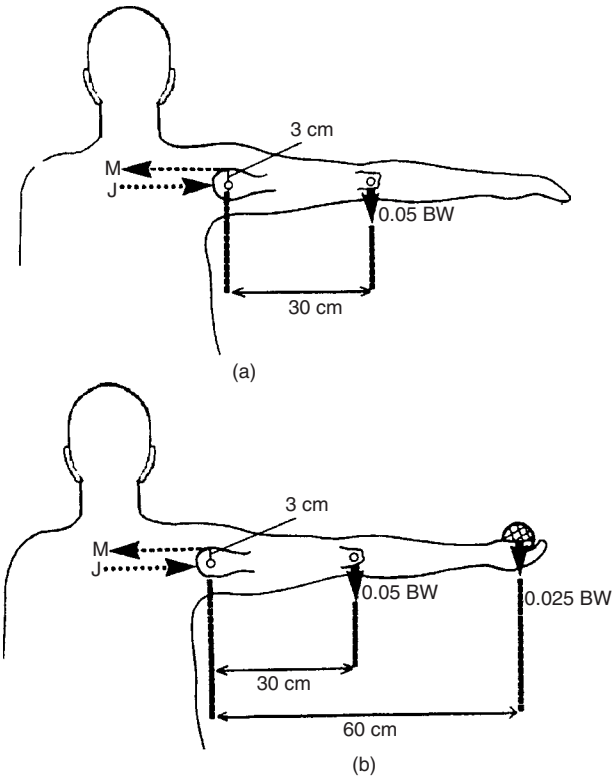

Fig. 20.8.35 Free-body diagram of the shoulder joint, showing the reaction force and the deltoid muscle force. (*a*) Without the load; (*b*) with a load in the hand. (*Adapted from Nordin and Frankel, 1989, by permission.*)

When the arm is in 90° of abduction (extended horizontally in the frontal plane), the deltoid muscle (superior of the shoulder joint) provides a tension of about one-half of the body weight. This can be calculated by a simple static equilibrium of the joint, as shown in Fig. 20.8.35. When a light weight of about 0.025 times the body weight (BW) is held in the hand, the muscle force is approximately equal to the body weight. In these cases the joint reaction force, which is equal and opposite to the muscle force, is as high as the body weight. Therefore, the glenohumeral joint is a major load-bearing joint.

THE ELBOW

At the elbow joint, three bones are joined: humerus, ulna, and radial. The elbow joint consists of three articulations: the humeroulnar, humeroradial, and proximal radioulnar. All these articulations are enclosed in the same joint capsule, which is reinforced by the anterior and posterior radial collateral and ulnar collateral ligaments. The elbow joint allows 2° of freedom in motion: flexion-extension and pronation-supination (rotation of the radius around the ulna).

Elbow Load

The elbow is not considered a weight-bearing joint; however, it is regularly subjected to large loads during our daily activities. Two simple diagrams of Fig. 20.8.36 show the muscle forces and joint reaction forces, which could be calculated by a simple static equilibrium. The research has shown that the compressive loads during activities such as dressing and eating could reach as high as 300 N (67 lb), and during rising from a chair when the body is supported by the arms, the load could reach as high as 1,700 N (382 lb). During push-up exercises peak forces on the elbow could reach as high as 45 percent of the body weight.

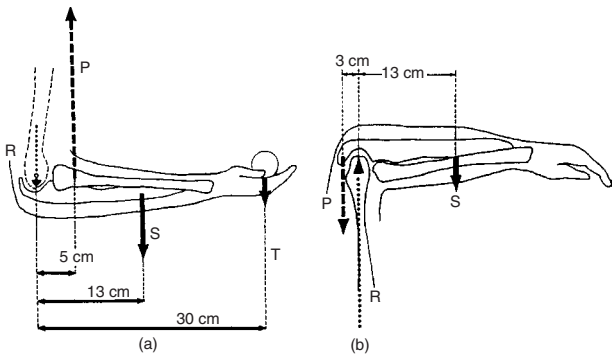

Fig. 20.8.36 Free-body diagram of the elbow joint showing (*a*) the reaction force in flexion and the tendons of the biceps and the brachialis muscle forces and (*b*) the tendon of the extensor (triceps) muscle tendon. (*From Nordin and Frankel, 1989, by permission.*)

BIOMATERIALS

By definition, **biomaterial** is a biocompatible material suitable for inclusion, augmentation, or replacement of the function of bodily tissues or organs. Biomaterials science is a multidisciplinary field that brings together researchers from diverse academic backgrounds, such as bioengineering, chemistry, chemical engineering, electrical engineering, mechanical engineering, materials science, biology, microbiology, and medicine. Biomaterials can be synthetic and natural, solid and sometimes liquid. Solid biomaterials can be metals, ceramics, polymers, glasses, carbons, and composite materials. Such materials are used as molded or machined parts, coatings, fibers, films, foams, and fabrics. Biomaterials are generally integrated into medical devices and implants and are rarely used on their own.

Historically, in the early 1900s bone plates were successfully implemented to stabilize bone fractures and to accelerate their healing, and since 1960s blood vessel replacement and artificial heart valves and joint replacements have been used. Since then, with the advent of new materials and prostheses, the field of biomaterials has rapidly expanded and has saved many lives.

Key factors in the design and use of biomaterials are biocompatibility, toxicology, biofunctionality, and, to a lesser extent, availability of biomaterials. Except for their brittle characteristics, ceramic materials are ideal candidates as biomaterials. Most biomaterials and medical devices perform satisfactorily, improving the quality of life for the recipient or saving lives; however, they have exhibited some failures. This is due to the fact that manufactured materials and devices have a failure rate. Other factors such as genetic differences, gender, body chemistries, living environment, and physical activity as well as physicians' "talent" for implanting devices may contribute to the success or failure of the biomaterials and implants.

Biocompatibility

The understanding and measurement of the biocompatibility of biomaterials are not fully understood. It has been accepted that no foreign material placed within a living body is completely compatible. Only those materials (natural tissues) manufactured by the body itself (autogenous) are compatible, and any other substance that is recognized as foreign initiates some type of reaction (host-tissue response). Natural material that is obtained from an individual and will be implanted into the same person is called an **autograft.** However, if the donor is a different individual, the material is called an **allograft.**

Toxicity

Toxicology in biomaterials has evolved into a sophisticated science, which deals with the substances that migrate out of biomaterials. For example, for polymers, many low-molecular-weight materials have shown some level of physiologic activity and cell toxicity. It is reasonable to say that a biomaterial should not give off anything from its mass unless it is specifically designed to do so, e.g., cancer drug delivery systems to destroy specific cells.

In terms of tissue response to the biomaterials and implants, there are three types of biomaterials: bioinert, bioresorbable, and bioactive. (Buddy, Ratner et al., 1996).

Bioinert Any material that once placed in the human body has minimal interaction with its surrounding tissue is called **bioinert.** For example, stainless steel, titanium, alumina, partially stabilized zirconia, and ultrahigh-molecular-weight polyethylene (UHMWPE) (to some degree) are bioinert. A fibrous capsule that might form around bioinert implants may compromise the biofunctionality of bioinert materials. In addition, the tissue remodeling around the implant (bone ingrowth or architectural changes such as resorption or depositon of bone) may alter the functionality of the implant.

Bioresorbable Materials that upon placement within the human body start to dissolve (are resorbed) and slowly are replaced by advancing tissue (such as bone) are **bioresorbable.** Common examples of bioresorbable materials are tricalcium phosphate $[Ca_3(PO_4)_2]$ and polylactic–polyglycolic acid copolymers. Calcium oxide, calcium carbonate, and gypsum are other common materials that have been utilized during the last three decades.

Bioactive Materials that upon placement in the human body interact with the surrounding bone and in some cases even soft tissue are **bioactive.** This occurs through a time-dependent kinetic modification of the surface, triggered by their implantation within the living bone. An ion-exchange reaction between the bioactive implant and the surrounding body fluids results in the formation of a biologically active carbonate apatite layer on the implant. For example, coating an implant with synthetic hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$ triggers bone ingrowth.

OCCUPATIONAL BIOMECHANICS

Human Factors in Design

In interacting with machines and devices, the human musculoskeletal system often has to provide forces to power a product or actuate a controller. The designs of machines and devices are influenced by humans' ability to supply the force and their ability to interact with the machine. The interface between humans and machines requires that humans sense the state of the device and be able to control it. That is, a product must be comfortable for a person to use. Thus products and devices must be designed with human factors in mind [see Bridger (1995)]. The geometric properties of humans (i.e., their height, reach, and seating requirements; the size of the holes they can fit through; and the forces that they can exert in specific directions with their body segments) are called anthropometric data. The armed forces in Military Standard MIL-STD-1472 have collected the majority of these data. A sample of these data is shown in Fig. 20.8.37 and Table 20.8.6. In addition, occupational biomechanics researchers have studied measures for humans' ability to perform various activities. Figure. 20.8.38 shows the average human strength for differing body positions (Dreyfuss, 1967). For example, in the standing position, the push and pull force of the hand in the position slightly lower than the torso region is higher than that of the hand position at the neck level. More detailed information is available in MIL-HDBK (Military Handbook) 759A and books in occupational biomechanics.

PROSTHESES AND IMPLANTS

There are implants and prostheses for virtually every member and organ of the human body. Being among the oldest implants, hip and knee prostheses are discussed in this subsection.

Hip Implants

The hip prosthesis has been the most active area of joint replacement research since **total hip** joint **replacement (THR)** among the most common orthopedic procedures. The hip joint is called a ball-and-socket

joint because the spherical head of the femur moves inside the cup-shaped hollow socket (acetabulum) of the pelvis. To duplicate this action, a total hip replacement implant has three parts: the stem, which fits into the femur and provides stability; the ball, which replaces the spherical head of the femur; and the cup, which replaces the worn-out hip socket (Fig. 20.8.39). There are many designs of hip implant parts based on age, weight, bone quality, activity level, and health of the recipient. The stem portions of most hip implants are made of titanium- or cobalt/chromium-based alloys; they come in different shapes and degrees of roughness. Cobalt/chromium-based alloys or ceramic materials (aluminum oxide or zirconium oxide) are used in making the ball portions, which are polished smooth to allow easy rotation within the prosthetic socket. The acetabular socket can be made of metal, with a liner made of ultrahigh-molecular-weight

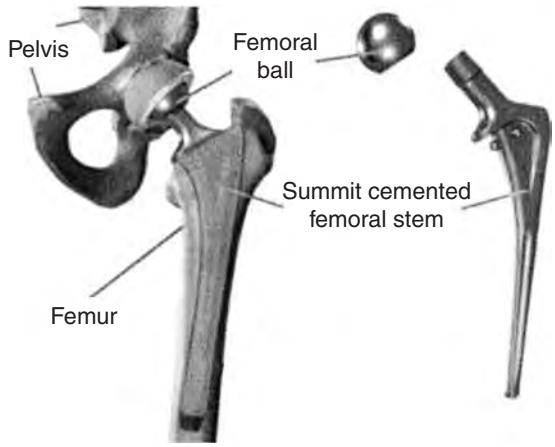

Fig. 20.8.39 Total hip implant.

polyethylene (UHMWPE) or a combination of polyethylene backed by metal. All together, these components weigh between 14 and 18 oz, depending on the size needed. The chance of a hip replacement lasting 20 years is about 80 percent.

There are many hip implant designs (such as modular stems) and a variety of surface textures (such as sintered beads, meshes, and etched). For more information the reader is referred to manufacturers' Web sites.

Implant Fixation

To hold the femoral and acetabular components in place, two methods, cemented and cementless (bone ingrowth or osseointegration), are used. The cement, an acrylic polymer called polymethylmethacrylate (PMMA), is used for older patients. However, the cementless method is used for younger patients (under 50 years of age) who are active and have good bone quality. Cemented fixation relies on a stable interface between the prosthesis and the cement and a solid mechanical bond between the cement and the bone.

Cementless implants were introduced in the 1980s, and the implant is directly attached to bone without the use of cement. The surface topography of the implant is textured or has porous regions, and the implant is generally coated with hydroxyapatite so that the new bone actually grows into the surface of the implant. In general, these designs are larger and longer than those used with cement. The surgeon's accuracy in placing the implant is an important factor in the stability of the implant since the channel (bone cavity) must match the shape of the implant precisely. Intimate contact between the component and bone is crucial to permit bone ingrowth. New bone growth cannot bridge gaps larger than 1 to 2 mm.

Hybrid THR, which was introduced in the early 1980s, has one component, usually the acetabular socket, inserted without cement and the other component, usually the femoral stem, inserted with cement. A hybrid hip takes advantage of the excellent track records of cementless hip sockets and cemented stems.

Loosening of hip implants may occur due to several factors.

1. Cracks (fatigue fractures) in the cement that occur over time can cause the prosthetic stem to loosen and become unstable. This is more often the case with patients who are very active or very heavy.
2. The action of the metal ball against the polyethylene cup of the acetabular component creates polyethylene wear debris. The microscopic debris particles are absorbed by cells around the joint and initiate an inflammatory response from the body, which tries to remove them.
3. Micromotion between the implant and the bone prevents bone ingrowth into the implant.

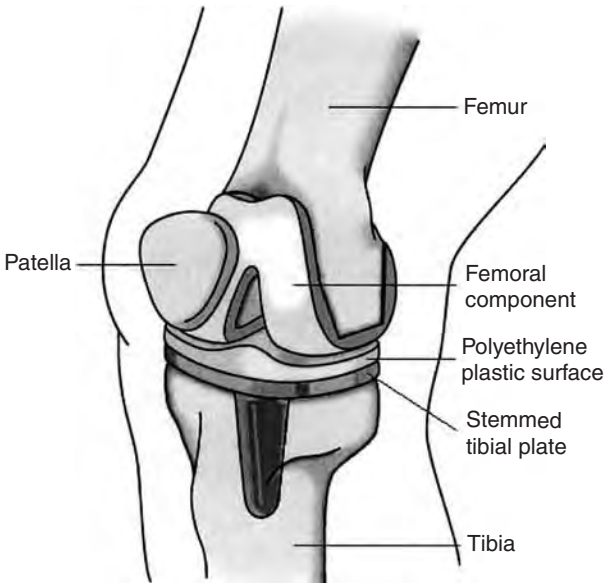

Fig. 20.8.40 Components of the total knee arthroplasty implant.

The hip implants could be made of two or three types of materials, namely, metal, ceramic, and polyethylene. The crucial part of the implant is the contact between the ball and the acetabular liner. The ball could be made of metal or ceramic, and the liner could be made of ceramic, metal, and UHMWPE. The metal and plastic implants wear at a rate of about 0.1 mm/yr. Metal-on-metal implants wear at a rate of about 0.01 mm/yr about 10 times less than that of metal and plastic. There are also concerns about the wear debris generated from the metal-on-metal implants. Ceramics are the most resistant to wear of all available hip replacement implants. However, due to low fracture toughness, ceramic implants can break inside the body.

The Knee Implants

The **total knee arthroplasty (TKA)** implants are more complex because of the articulation of three bones—distal femur, proximal tibia, and patella (the kneecap)—where the surfaces actually roll and glide as the knee bends. There are many knee implant designs in the market having the following major components (Fig. 20.8.40).

1. **Femoral component.** The metal femoral component curves around the distal end of the femur and has an interior groove so the kneecap can move up and down smoothly against the bone as the knee bends and straightens. In some designs, a smaller piece may be used (unicompartmental knee replacement) to resurface just the medial or lateral part of the condyle.
2. **Tibial component.** The tibial component is a flat metal platform.
3. **Polyethylene cushion.** The cushion may be part of the platform (fixed) or separate (mobile).
4. **Patellar component.** The patellar component is a dome-shaped piece of polyethylene that duplicates the shape of the kneecap anchored to a flat metal plate.

The metal parts of the implant are made of titanium- or cobalt/chromium-based alloys. The plastic parts are made of ultrahigh-molecular-weight polyethylene. All together, the components weigh between 15 and 20 oz, depending on the size selected.

Due to its continuous sliding and rolling, knee implant wear is a major problem where microscopic particulate debris are generated.

Similar to the hip implants, the knee implants may be cemented, cementless, or hybrid, depending on the type of fixation used to hold the implant in place.

Other Implants

The majority of orthopedic implants are made of metals. There is considerable mismatch between the metal and bone properties, which can lead to stress shielding and bone resorption. New composite implants or graded materials are being developed to closely match the bone properties and thereby reduce the risk of bone resorbtion.

There are many other orthopedic implants and prostheses for virtually every joint in the body as well as plates and rods for bone repair and fracture fixations. In addition, there are many types of screws for different locations and varieties of bones. For these topics the reader is referred to specialized orthopedic books, journals, and manufacturers' Web sites.

Dental implants have been widely used in recent years. There are two categories of dental implants: endosteal implants, which enter the bone tissue, and subperiosteal systems, which contact the exterior bone surfaces (Lemons, 1988).

Mechanical or tissue **prosthetic heart valves** are used to replace the natural heart valves (miteral, tricuspid, aortic, and pulmonic) when these no longer perform their normal functions because of disease (Gidden et al., 1993). Mechanical valves are of two types: caged ball and tilting disk. The materials most widely used are silicone elastomer, cobalt/chrome-based alloys, titanium, and pyrolytic carbon.

A **stent** is a device made of inert materials and designed to serve as a temporary or permanent internal scaffold to maintain or increase the lumen of a vessel. For further information see Schatz (1989).

20.9 HUMAN INJURY TOLERANCE AND ANTHROPOMETRIC TEST DEVICES

by Srirangam Kumaresan and Anthony Sances, Jr.

HUMAN INJURY TOLERANCE RELATED TO AUTOMOTIVE SAFETY

This section discusses an overview of injury tolerance of various body components relevant to the design of automotive vehicles. For the sake of brevity, the chapter provides a brief definition of injury criteria and tabulates the tolerance values proposed by the **National Highway Safety Traffic Administration** (NHTSA) at different time periods. The injury criteria are proposed both for adult and pediatric populations. The injury values for the pediatric population were based on scaling procedures.[1]

Head Injury Criteria

A blunt force or load applied to the head may result in injury to the skull, the brain, or both. Early work sought to establish a relationship between skull fracture and brain injury through head acceleration. Lissner et al. found that the time required to produce a fracture was smaller for higher levels of acceleration, using four cadavers.[2] Later on, Gadd developed the **severity index** (SI) to fit published literature to assess **head injury.**[3] Versace noted some shortcomings of SI and proposed an alternative index, the **head injury criterion (HIC)**.[4] This index was adopted by **NHTSA,** and in 1972 a proposal was advanced to replace the SI with the following expression:

$$\text{HIC} = \left[\left(\frac{1}{t_2 - t_1}\right)\int_{t_1}^{t_2} a(t)\,dt\right]^{2.5}_{\text{maximum}} (t_2 - t_1) \le 1{,}000$$

where $t_2 - t_1$ is the time for integration and $a(t)$ is the acceleration at the center of the head of the dummy. A value of 1,000 over a maximum period of 36 ms was chosen as the threshold of injury in the **Federal Motor Vehicle Safety Standards** (FMVSS 208). Table 20.9.1 summarizes the head injury values.

Neck Injury Criteria

The force applied to the head may result in an injury to the neck. The neck injuries occur when the range of motion or force exceeds the limit of human tolerance. The neck injury results in the form of fracture or dislocation of vertebra, ligamentous damage, or a combination. The current **FMVSS** No. 208 injury criteria for the neck using the alternative sled test include individual tolerance limits for compression (4,000 N), tension (3,300 N), shear (3,100 N), flexion (190 N · m), and extension (57 N · m). The concept that neck injury criteria should be a linear combination of axial tension loads and extension-bending moments was developed by Prasad and Daniel and was based on their results from experimental tests on porcine subjects.[8] In 1996, Klinich et al. presented a composite neck injury indicator based on a linear combination of neck forces and moments.[9] The neck injury criterion, called N_{ij}, incorporates critical limits for all possible modes of neck loading: tension or compression combined with either flexion (forward) or extension (rearward) bending moment:

$$N_{ij} = F_z/F_{\text{int}} + M_y/M_{\text{int}}$$

where F_z is the axial load, F_{int} is the critical intercept value of load used for normalization, M_y is the flexion/extension bending moment, and M_{int} is the critical intercept value for moment used for normalization. Tables 20.9.2 to 20.9.4 summarize the neck injury tolerance.

Chest Injury Criteria

The acceleration and deflection applied individually or in combination to the chest in excess would injure the rib cage and underlying organs. The current FMVSS No. 208 stipulates that during the specified crash test, the chest deflection of the 50th percentile **Hybrid III** male dummy cannot exceed 76 mm (3 in) and its chest acceleration cannot exceed 60 *g*. Using the probability of injury curve reported in literature, lines of equal probability of injury for the linear combination of deflection and spinal acceleration were generated and the **combined thoracic injury criteria** (CTI) was proposed in 1998 with the following equation:

$$\text{CTI} = A_{\max}/A_{\text{int}} + D_{\max}/D_{\text{int}}$$

where $A_{\max}$ is the maximum value of 3-ms clip spinal acceleration (A_s), $D_{\max}$ is the maximum value of the dummy deflection D, and A_{int} and D_{int} are the respective intercepts. Table 20.9.5 summarizes the chest injury tolerance values.

Lower Extremity Criteria

The femur load tolerance is proposed to represent the lower extremity injuries. Currently the tolerance limit is recommended for the adult population. Table 20.9.6 summarizes the limit values.

BIOMECHANICAL BASIS TO DEVELOP ANTHROPOMETRIC TEST DUMMIES FOR AUTOMOBILE CRASH TESTS

This section focuses on the biomechanical basis for anthropometric test dummies to assess head and neck injuries in accident environments with specific attention to the development of **Federal Motor Vehicle Safety Standard** (FMVSS).

Head Injury Assessment

In 1966 Gadd proposed a **severity index** (SI) based upon the Wayne State Tolerance Curve (WSTC).[1] In 1971, the **head injury criterion** (HIC) was proposed by Versace.[2] The HIC attempted to incorporate the observation that higher peak acceleration was tolerable if presented in a shorter period of time. Versace emphasized that the WSTC represented only the boundary between acceptable and unacceptable levels, and that it did not provide a scaling for injury. In 1984, Mertz again emphasized that injury assessment values should be used only to interpret the response of dummies and thereafter only as a guide to design.[3] Nevertheless, a graph relating HIC to the percentage of population expected to experience life-threatening brain injury was advanced. The basis for the curve was a series of 54 cadaver impacts.[4] The result of the impact was scored on the presence or absence of a skull fracture. By using the lowest **HIC** for which a fracture was observed (450) and the highest HIC resulting in a nonfracture (2,351), a normal curve was generated between the two. The appearance of a skull fracture was equated to life-threatening brain injury. Kleinberger reviewed the literature on head injury and the origin of HIC for the **National Highway Transportation Safety Administration** (NHTSA).[5] Since the agents directly responsible for brain injury (e.g., pressure, force, stress, inertial movement) are difficult to measure, a surrogate was sought. It was apparent that peak acceleration and impulse-area measurements, although they are related to head injury, are not easily related to experimental data. Energy absorption calculations were found to be difficult to apply, and, therefore, a simple relationship between energy absorption and brain injury was not possible. Sances has given a review of the various theories of skull fracture and human head injury tolerance.[6] A review of the recent HIC for child and adult dummies has also been given.[7] The value of HIC $\leq$ 1,000 for an integration duration of up to 36 ms is recommended in the **Federal Motor Vehicle Safety Standards** (FMVSS) Standard 208 for the midsized male (50% **Hybrid III**). The value of 1,000 has been adopted for the midsized male, small female, and 6-year-old child. This decision was made after reviewing a large quantity of test data available in the NHTSA databases.[8] It has been noted that the presence or absence of a skull fracture does not have much significance on the course of brain injury.[9] The question of the survivability of a fall may be addressed by observing the results of documented accidental falls onto hard surfaces. The variability of humans to the effects of falls onto unyielding surfaces was investigated by Snyder in 1977.[10] It was found that falls from low heights can be fatal, while falls from significant heights are not necessarily so.

The HIC is useful in setting standards and comparing the relative effectiveness of different methods of head protection to differing levels of translational acceleration and the occurrence of skull fracture. However, the HIC does not measure the presence or absence of other injury mechanisms such as rotational acceleration, internal pressure, and differential movement of tissue within the brain leading to shearing or tearing of tissue.

Neck Injury Assessment

The early studies by Patrick and Mertz are used to determine the injury values for tension and flexion of the Hybrid III 50% male dummy, which is routinely used for rear impact and frontal flexion analysis.[11,12] However, the cadavers that were used by Patrick and Mertz in the 1960 and 1970 studies had been used prior to the studies in windshield and steering wheel studies or for chest experiments.[13] Because CT and MRI equipment was not available, plain X-rays were used to evaluate injury. Consequently, the ligamentous damage could not be evaluated. In another study involving vehicle rollover tests with dummies, the authors have indicated that injury occurs at the neck when the Hybrid III 50% male dummy (Fig. 20.9.1) neck transducer measured 2,000 N[14]. In this study, measured axial neck loads above 7,000 N were 4 for the production vehicle and 0 for the roll cage vehicle. There were five force levels for the production vehicle and two for the roll cage above 6,000 N. At 5,000 N, there were six for the production vehicle and three for the roll cage. But this study is severely limited by the inability to predict injury values. In a laboratory study, a clinical-burst-type fracture was produced when forces of approximately 8,000 N were applied at speeds of 4.0 to 4.5 m/s to the head of a cadaver.[15] This study shows that four potentially injurious neck loads occurred in the production vehicles when the threshold is set at 7,000 N for neck injury and none in the roll cage vehicles.

Human head and neck axial tension studies in the intact human cadaver indicate injury values in the region of 3,400 N.[16] There are marked differences between the Hybrid III neck and the human neck. One important missing characteristic of the Hybrid III is the lack of head lag when the neck goes into flexion and/or extension.[17]

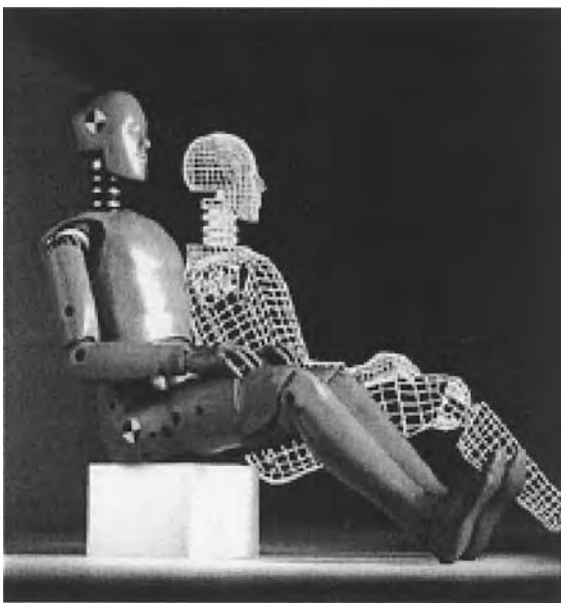

Fig. 20.9.1 Picture of 50th percentile male dummy. (*Source*: http://www.ftss.com.)

Differences in axial compression, dynamic, and static loading of the **Hybrid III** head and neck system has shown that the dynamic and static characteristics of the Hybrid III are 3 to 5 times stiffer than those of the human. A comparison of the Hybrid III 50% male and the cadaveric neck at slow rates showed that dummy necks had a stiffness of about 5,600 N/mm while the human head neck, which averaged about 2,000 N/mm in the axial compression mode.[18] Parallel axial compression studies in the intact human cadaver head-neck system at rates of 3 to 8 m/s were done.[19] Weights represented the muscles; impacts were made on the top of the Hybrid III 50% male head-neck and the cadaveric head-neck system. Forces and moments were measured at the C7/T1 level. This preparation produced clinical-type burst and flexion compression injuries to the cervical spine. The flexion and extension bending moments measured at C7/T1 were 2 to 3 times greater in the human tissue compared with the Hybrid III. Studies on 20 human cervical columns in vertical compression at velocities from 2.5 to 8 m/s showed that the initial force deflection curve was very low until the soft tissue loaded up to about 12 mm of compression.[20] The average level of injury was at 3,326 N with an average stiffness of 555 N/mm. Subsequent dynamic studies of the Hybrid III 50% neck showed markedly greater stiffness compared with the human cadaveric neck with values up to 2,160 N/mm at velocities of 7.6 m/s. The Hybrid III does not exhibit head lag similar to the human.[21]

Scaling approaches have been done to provide injury assessment values for the 6-month, 12-month, 3-year, and 6-year old, the small female, the midsized male, and large male dummies.[22] The major source for the child biomechanical data is a series of tests conducted on pigs by General Motors and the Ford Motor Company with a simulated airbag inflating in front of an out-of-position occupant in the passenger seat. Scaling from these studies, assuming that a 10-week-old pig represents a 3-year-old child, matched tests were then conducted with the 3-year old airbag dummy. These studies were then advanced to the child and adult dummies. Unfortunately, little information is available for the material properties of pediatric tissue except for a study performed over 100 years ago by Duncan.[23] It is well known that there are substantial differences between the 3-year old child and the porcine geometry and development.[24]

20.10 AIR-INFLATED FABRIC STRUCTURES

by Paul V. Cavallaro and Ali M. Sadegh

INTRODUCTION

Air-inflated fabric structures fall within the category of tensioned structures and provide unique advantages in their use over traditional structures. These advantages include lightweight designs, rapid and self-erecting deployment, enhanced mobility, large deployed-to-packaged volume ratios, fail-safe collapse, and possible rigidification.

Most of the research and development pursued in air-inflated structures can be traced to space, military, commercial, marine engineering, and recreational applications. Examples include airships, weather balloons, inflatable antennas and radomes, temporary shelters, pneumatic muscles and actuators, inflatable boats, temporary bridging, and energy absorbers such as automotive air bags. However, the advent of today's high-performance fibers combined with continuous textile manufacturing processes has produced an emerging interest in air-inflated structures. Air-inflated structures can be designed as viable alternatives to conventional structures.

Because these structures combine both the textile and the structural engineering disciplines, the structural designer should become familiar with the terminology used in textile materials and their manufacturing processes. A glossary is provided in Ref. 1.

DESCRIPTION OF AIR-INFLATED FABRIC STRUCTURES

Air-inflated fabric structures are constructed of lightweight fabric skins that enclose a volume of pressurized air. The fabric is typically formed in a variety of textile architectures including those shown in Fig. 20.10.1. Each architecture has its own design, manufacturing, tooling, and cost implications. Structurally, these architectures will behave differently when subjected to loads.

The plain-weave architecture provides orthogonal yarn placement, resulting in extensional stiffness along the two **yarn** axes; however, it lacks shear stiffness for off-axis loads. While the braided architecture provides the fabric with shear stiffness due to the nonorthogonality of the yarns, it lacks extensional stiffness. The angle between the braid axis and the yarns θ is referred to as the braid angle or bias angle. Both the triaxial braid and axial strap reinforced braid architectures behave similarly in that they impart to the fabric extensional and shear stiffnesses.

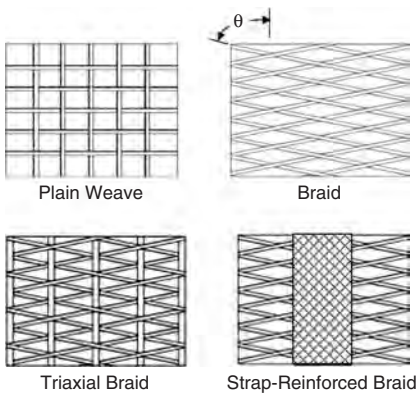

Fig. 20.10.1 Various fabric architectures used in air-inflated fabric structures.

The air pressure develops a biaxial pretensioning stress throughout the fabric. This pretensioning stress enables the structure to generate its intended shape, provides stiffness to resist deflections, and affords stability against collapse from external loads. Fabric materials can often be idealized as tension-only materials for design purposes; i.e., their in-plane compressive moduli and bending moduli are considered negligible.

Stiffness of the structure is primarily a function of the inflation pressure. As the inflation pressure increases, the pretensioning stresses throughout the fabric increase and, in turn, stiffen the structure. Once external loads are applied, stresses from these loads superimpose with the pretensioning stresses in the fabric. As a result, a complete redistribution of stress occurs. This stress redistribution balances the loads and maintains the structure in a state of static equilibrium. Depending upon the type of air-inflated fabric structure (i.e., beam, arch, etc.) and applied loads (i.e., tension, compression, shear, bending, torsion, etc.), the redistribution of stresses can either increase or decrease the net tension stresses in the fabric skin. However, stability of the structure is only ensured when no regions of the fabric experience a net loss in tensile stress. Otherwise, if the stresses from applied loads begin to relax the pretensioning stress (i.e., the tension approaches zero), the onset of wrinkling is said to have occurred within the structure. Wrinkling decreases the structure's load-carrying capability, and upon further loading, eventual buckling or collapse will result.

There are two significant and unique characteristics that air-inflated fabric structures provide over conventional structures. First, upon an overload condition, a collapse of an air-inflated structure does not necessarily damage the fabric membrane. When the overload condition is removed, the air-inflated fabric structure simply restores itself to its design load configuration. Second, since wrinkling can be visually detected, it can serve as a warning indicator prior to collapse.

FIBER MATERIALS AND YARN CONSTRUCTIONS

Proper selection of fiber materials and yarn constructions are important factors that must be considered in the design of air-inflated fabric structures. Both should be optimized together to achieve the desired performance characteristics at the fabric and structural levels.

Many of today's air-inflated fabric structures use yarns constructed of high-performance continuous fibers such as **Vectran**® (thermoplastic liquid-crystal polymer), **PEN** (polyethylene naphthalate), DSP (dimensionally stable polyester), and others. These fibers provide improved structural performance (high strength, low elongation, fatigue, flex-fold, cyclic loadings, creep, etc.) and enhanced environmental resistance (ultraviolet rays, heat, humidity, moisture, abrasion, chemicals, etc.). Other fibers used in air-inflated fabric structures include Kevlar, Dacron, nylon, Spectra, and polyester. Hearle[2] provides additional information on fiber materials and their mechanical properties.

Yarns are constructed from fibers that may be aligned unidirectionally or arranged in a number of twisted bundles. Twist is used to improve the handling susceptibility of the yarns by grouping the fibers together, especially during textile processing. Twist, which is measured in turns per unit yarn length, affects the yarn tensile properties. For discontinuous or staple fiber yarns, twist can increase the yarn breaking strength because the internal forces at the ends of a fiber can transfer to neighboring fibers via interfiber shear forces. However, twist in continuous fiber yarns can reduce the yarn breaking strength as observed by Hearle et al.[3] Therefore, a minimal twist is recommended for providing adequate handling protection to continuous fiber yarns.

Hearle et al.[3] experimentally investigated the effects of twist on the tensile behavior of several continuous fiber yarns. Results showed that

Fig. 20.10.2 Yarn tensile testing using Instron textile grips.

yarn tenacity (defined as tensile strength measured in grams force per denier or grams force per tex) decreased with increasing twist for three prescribed yarn tensions used during twist formation. In general, the yarn modulus decreased with increasing twist, yarn elongation at break increased with increasing twist, and yarn elongation decreased with increasing yarn tension. A difference in the load extension behavior of twisted and nontwisted yarns is that a twisted yarn subjected to tension will undergo compaction of its cross section through migration of its fibers and will develop greater interfiber frictional forces than a nontwisted yarn. As with fabrics, the structural performance of yarns can be tailored by changes in their architecture and processing.

Once the yarns are processed into the fabric (i.e., by weaving, braiding, etc.), it is recommended that tensile tests be performed on sample yarns removed from the fabric. This will allow the as-processed yarn properties to be compared to the design requirements. For example, the as-woven tensile properties of continuous fiber, nontwisted yarns removed from a **plain-woven fabric** air beam were measured[4] using an Instron machine configured with textile grips, as shown in Fig. 20.10.2. The cross-sectional areas of the yarns were computed based on fiber diameter and quantity. The tests revealed that the average breaking stress of the weft yarns was nearly 20% less than that of the warp yarns. The reduction in breaking stress of the weft yarns was due to fiber damage caused by the use of higher tensions in these yarns during weaving.

EFFECTS OF FABRIC CONSTRUCTION ON STRUCTURAL BEHAVIOR

Fabric materials are constructed from yarns that cross over and under each other in a repetitive, undulating pattern. The undulations shown in Fig. 20.10.3 are referred to as *crimp,* which is based on Pierce's geometric fabric model.[5]

Pierce geometric model relates these parameters as they are coupled among yarn families. The crimp height h is related to the crimp angle α

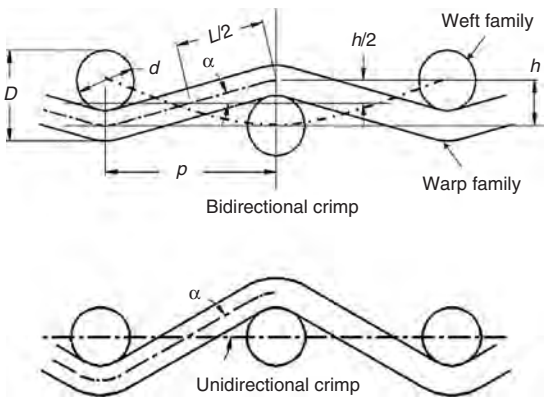

Fig. 20.10.3 Examples of Pierce's geometric model for plain-woven fabrics with bi-directional and unidirectional crimp.

and yarn length L, as measured between yarns, and the sum of yarn diameters at the crossover points by the following equations, described by Hearle et al.[3]

$$\begin{aligned} p &= (L - D\alpha)\cos\alpha + D\sin\alpha \\ h &= (L - D\alpha)\sin\alpha + D\,(L - \cos\alpha) \\ D &= h_1 + h_2 \end{aligned} \qquad (20.10.1)$$

These equations were based on idealized geometry and assumptions such as restricting the yarns to circular cross sections and no consideration of force or stiffness effects.

Plain-woven and braided fabrics behave differently under load because their yarn families are aligned at different angles. Plain-woven fabrics utilize a nearly orthogonal yarn placement of **warp** and **weft** (or **fill**) yarns. By general textile definitions, **warp yarns** are identified as those yarns running parallel to the selvage and are virtually unlimited in their length. **Weft yarns** are at right angles to the selvage and are limited in length by the width of the weaving equipment. On the other hand, braided fabrics have a $+\theta/-\theta$ yarn placement, where θ is commonly referred to as the *bias angle,* with respect to the braid axis.

The biaxial stress-strain behavior of plain-woven fabrics is initially dominated by **crimp interchange** rather than yarn elasticity. Because the factors of safety used in air-inflated fabric structures are typically within the range of 4 to 6, the operating stresses are designed to be low with respect to fabric strength. Therefore, the structural performance of fabrics must address the influences of crimp interchange. The relative yarn motions (slip and rotation) affect the stiffness properties. The **crimp ratio,** which is denoted as C, is defined as the waviness of the yarns and is obtained by measuring the length of a yarn in its fabric state L_{fabric} and the length of that same yarn after it has been extracted from the fabric L_{yarn} and straightened out according to Eq. (20.10.2).

$$C = \frac{L_{\text{yarn}} - L_{\text{fabric}}}{L_{\text{fabric}}} \qquad (20.10.2)$$

The following equation described by Hearle et al. relates the crimp height to C.

$$\frac{h}{p} = \frac{4}{3}\left(\frac{L}{p} - 1\right)^{1/2} \equiv \frac{4}{3}C^{1/2} \qquad (20.10.3)$$

Consider a plain-woven fabric subject to a tensile load along the direction of one yarn family. The loaded yarns will attempt to straighten, decrease their crimp heights, and elongate their effective lengths. However, the yarns of the crossing family are forced to increase their crimp heights, resulting in contractions of their effective lengths. This coupling effect associated with changes in crimp is referred to as **crimp interchange** and is similar to Poisson's effect exhibited in metals. In tests of plain-woven fabrics along the direction of a given yarn family, crimp interchange can be easily observed by reducing the width of the specimen. Crimp interchange is a source of nonlinear load extension behavior for fabrics.

Hearle et al.[3] describe a limiting phenomenon to crimp interchange. As the biaxial tensile loads continually increase for a given loading ratio, a configuration results in which yarn kinematics (i.e., slip at the crossover points) cease and the spacing between yarns converges to minimum values. This configuration is referred to as the **extensional jamming point,** which can prevent a family of yarns from straightening and thereby not achieve its full strength. Crimp interchange depends upon the ratio of initial crimp between yarn axes and the ratio of stress between yarn axes rather than the levels of stress. Crimp interchange introduces significant nonlinear effects in the mechanical response of the fabric.

Now consider the plain-woven fabric subjected to shearing by applying a uniaxial load at $\pm 45°$ to either yarn family. The yarn families will rotate at the crossover points with respect to each other and become

increasingly skewed as the angle between the yarns changes. The change in angle is referred to as the **shear angle.** At larger shear angles, the available space between yarn families decreases, and rotational jamming (locking) of the yarn families occurs. This phenomenon is known as shear jamming, and the angle at which the yarn families become jammed is referred to as the **shear-jamming** angle. The shear-jamming angle decreases with increasing yarn density ratio and can be estimated from Pierce's geometric fabric model or obtained experimentally with various trellising or biaxial test fixtures. Continued loading beyond the onset of shear jamming will produce shear wrinkles leading to localized out-of-plane deformations.

It is important to determine the extension and **shear jamming** points for both fabric manufacturing and structural stiffness concerns. In general, jamming is related to the maximum number of weft yarns that can be woven into a fabric for a given warp yarn size and spacing.

OPERATION

Today's air-inflated fabric structures can be operated at various pressure levels depending upon the fabric architecture, service loads, and ambient temperatures. Woven structures are generally designed to operate at pressures up to 20 psi while triaxial braided and strap-reinforced braided structures are generally capable of higher inflation pressures. Blowers, which may be used for inflation pressures up to 3 psi, provide a high volumetric airflow rate. However, air compressor systems will be required for higher inflation pressures. Air compressors are available in single- and dual-stage configurations. The single-stage air compressor delivers a high-pressure capability but at a low volumetric airflow rate. The volumetric flow rate is measured in standard cubic feet per minute (scfm). Dual-stage air compressors are designed to provide an initial high volumetric airflow rate at low pressures in the first stage and can be followed by a low volumetric airflow rate at high pressure. When a dual-stage air compressor is used, the first stage is most beneficial to erecting the braided structure. At this time, no appreciable resistance to the design loads is available. However, the second-stage mode of the compressor is used to fully inflate the braided structure to its proper operating pressure so that the design loads can be supported. Because the dual-stage compressor can achieve the desired inflation pressure much more rapidly than the single-stage compressor, it is more appropriate for those applications in which the need for rapid deployment justifies the additional cost.

INFLATION AND PRESSURE RELIEF VALVES

Valves designed for use in air-inflated fabric structures must be chosen according to several criteria including locations, orifice size, pressure relief controls, and potential strength degradation in the surrounding fabric regions. Ideally, valves should be positioned in structural elements that interface with the fabric and bladder, such as metal clamps, discs, or end plates at the end termination zones of the structure. This avoids the need for cutting additional penetration holes through the fabric or repositioning the yarns to accommodate holes, thus preventing stress concentrations. When fibers must be removed to accommodate insertion of valves, fabric reinforcement layers should be bonded and stitched to the main fabric in the surrounding region. The valves should be readily accessible for user access but should not jeopardize the integrity of the fabric when the structure is subjected to handling events (such as drops and impacts). Valve locations should be further optimized to mitigate the effects of interference with other objects when the structure is deployed or stowed.

A variety of pneumatic valve designs including threaded valves, quick connect disconnect valves, check valves (one-way, two-way), and pressure relief valves are readily available. The use of pressure relief valves is recommended to avoid accidental overpressures and pressure increases due to changes in ambient temperatures. Valves can also be configured to manifold inflation lines in air-inflated structures containing multiple pressure chambers. This also provides capabilities for self-erecting and controlled deployments by sequencing the inflation timing of multiple chambers. Sizing of the valve orifices should be matched to provide the optimal inflation and deflation times for the air volumes and operating pressures required by the structure.

CONTINUOUS MANUFACTURING AND SEAMLESS FABRICS

Prior to continuous circular weaving and braiding processes in use today, air-inflated fabric structures were constructed by using adhesively bonded, piece-cut manufacturing methods. These methods were limited to relatively low pressures because of fabric failures and air leakage through the seams. Continuous weaving and braiding processes can eliminate or minimize the number of seams, resulting in improved reliability, increased pressure capacities, and greater structural load-carrying capability. However, when seams cannot be avoided, the seam construction should be designed in such a way that failure of the surrounding fabric occurs rather than of the seam. For the safe and reliable use of air-inflated fabric structures, sufficient factors of safety against burst and seam failures must be provided. To guard against burst, e.g., a minimum factor of safety of 6 is used on yarn strength for each yarn family.

High fiber densities within the fabric and rip-stop weave constructions afford improved resistance to punctures, impacts, tears, and abrasion. Rip-stop fabrics have periodic inclusions of stronger, larger yarns along both yarn axes that contain the tear or rupture.

Like traditional composite materials, fabrics can be tailored to meet specific structural performance requirements. Fiber placement can be optimized for air-inflated fabric structures by varying the denier of the yarns (defined as the mass in grams of a 9,000-m yarn) and yarn counts along each direction. For instance, consider a pressurized fabric cylinder. The ratio of hoop stress per unit length to axial stress per unit circumference is 2:1. One can ensure equal factors of safety against yarn burst in the weft (hoop) and warp (longitudinal) yarns by weaving twice as many weft yarns per unit length of air beam as the number of warp yarns per unit circumference. Alternatively, the same can be accomplished by doubling the denier of the weft yarns in comparison to the denier of the warp yarns.

IMPROVED DAMAGE TOLERANCE

Assorted methods are used to enhance the reliability of air-inflated fabric structures against various damage mechanisms. Resistance to punctures, impacts, tears, and abrasion can be improved by using high-density weaves, rip-stop fabrics, and coatings. High-density weaves are less susceptible to penetrations and provide greater coverage protection for bladders. Rip-stop fabrics have periodic inclusions of high-strength yarns woven in a cellular arrangement used to prevent fractures of the basic yarns from propagating across cells.

Additionally, coatings protect the fabric against environmental exposure to ultraviolet rays, moisture, fire, chemicals, etc. Coating such as urethane, PVC (polyvinyl chloride), neoprene, EPDM (ethylene propylene diene monomer) are commonly used. Additives such as Hypalon further enhance a coating's resistance to ultraviolet light and abrasion. Coatings can be applied in two stages. First, coating the yarns prior to forming the fabric by a liquid bath immersion provides the best treatment to the fibers. Second, coatings can be applied by spraying, painting or laminating directly to the fabric after forming. This stage coats the yarns and bridges the gaps formed between adjacent yarns. The maximum protection is achieved when both stages are utilized. While protective coatings have been shown to increase the stiffness of the fabric by restricting relative yarn motions, they remain flexible enough to not adversely impact the stowing and packaging operations of the structure. Additional information on coating materials and processes is provided by Fung.[6]

RIGIDIFICATION

Air-inflated fabric structures can be rigidified by coating the fabric with resins such as thermoplastics, thermosets, and shape memory polymers. Prior to inflation, these particular coatings are applied to the fabric and remain initially uncured, thus acting as flexible coatings. After the structure is inflated and properly erected, a phase change is triggered in the coating by a controlled chemical reaction (curing process) activated by exposure to elevated temperature, ultraviolet light, pressure, diffusion, etc. Once the phase change is fully developed, the coatings bind the yarns together; stiffen the fabric in tension, compression, and

shear; and behave similar to a matrix material found in traditional fiber-reinforced composites. The air-inflated fabric structure is now rigidified and no longer requires the inflation pressure to maintain its shape and stiffness. Depending upon the coating used, the transition process may be permanent or reversible (except where thermoset plastics are used). Reversible rigidification is especially suited for those applications requiring multiple long-term deployments.

The performance of the rigidified fabric structure can be assessed by using **classical lamination theory (CST)** as described by Jones.[7] Unlike in the inflated version of the structure, the elastic and shear moduli of the rigidified structure are based on the constituent properties of the fibers and cured coating. As such, the elastic and shear moduli can be readily estimated by using CST. However, the rigidified structure may have different failure modes than its pressurized counterpart. The designer must guard against new failure modes including localized shell buckling and compression rather than wrinkling.

Rigidification is of particular interest for space structures because of restrictions on payload weights and stowage volumes. Cadogan et al.[8,9] have pursued the use of shape memory composites for rigidizing deployable space frames.

AIR BEAMS

Fabric air beams are examples of air-inflated structural elements that are capable of supporting a variety of loads, similar to conventional beams. To date, seamless air beams have been constructed using continuous manufacturing methods that have produced diameters ranging up to 42 in. They are constructed of an outer fabric skin that contains an internally sealed film or bladder made of an impermeable elastomerlike material. The bladder contains the air, prevents leakage, and transfers the pressure to the fabric. The air beam has a cylindrical cross section, and its length can be configured to a straight or curved shape such as an arch. The ends are closed using a variety of end termination methods consisting of bonding, stitching, mechanical clamps, etc., depending upon the inflation pressure and loading requirements. Clamping methods are available to permit disassembly, repair, and replacement of the bladder and fabric layers.

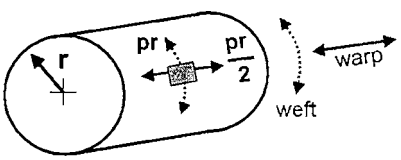
Once an air beam is sufficiently pressurized, the fabric becomes pretensioned and provides the air beam with a plurality of stiffnesses including axial, bending, shear, and torsion. Upon inflation, the ratio of hoop (cylindrical) stress per unit length of beam to the longitudinal stress per unit circumference is 2:1, as shown in Fig. 20.10.4.

In the context of plain-woven air beams, the warp yarns are aligned parallel to the longitudinal axis of the air beam and resist axial and bending loads. The weft yarns spiral through the weave and are located at nearly 90° to the warp axis, thus lying along the hoop direction of the air beam. Weft yarns provide stability against collapse by maintaining the circular cross section of the air beam.

For braided air beams, the braid axis is aligned with the longitudinal axis of the air beam. If the ends of a braided air beam are unconstrained from moving in the longitudinal direction, the fibers will exhibit a scissoring effect, causing the length of the beam to expand or shorten with pressure depending upon the selection of θ. Eventually, the braided yarns will achieve a maximum rotation, and the fabric will become fully jammed. This phenomenon can be easily demonstrated with the well-known Chinese finger trap toy. Unlike in plain-woven fabric structures, the bias angle of braided fabric structures can be controlled to allow expansion or contraction of the structure when inflated. For an unconstrained braided air beam to resist axial tension, longitudinal reinforcements such as distributed axial yarns (i.e., triaxial braid) or axial straps, webbing, belts, etc., must bonded on at multiple locations around the circumference. Various design methods for constructing strap-reinforced and axial yarn-reinforced braided fabric air beams were developed by Brown[10] and Brown and Sharpless.[11,12]

The bending stiffness EI for metal beams is written as the product of elastic modulus E and area moment of inertia I and has units of (force × distance^2). However, in air-inflated fabric structures, the fabric elastic modulus E_f is commonly denoted in units of force per unit length, and therefore, $E_f I$ is denoted in units of (force × distance^3). Likewise, fabric strengths are denoted in units of force per unit length.

Now, consider the air beam subjected to transverse loads. Upon loading, the pretension stresses and the bending stresses will algebraically add. That is, the compressive bending stresses will subtract (relax) from the pretension on the compressive surface of the air beam while the tensile bending stresses will add to the pretension along the tensile surface, as shown in Fig. 20.10.5. The instant at which any point along the length of the air beam develops a net zero longitudinal tensile stress, the structure is said to have reached the onset of wrinkling. The corresponding bending moment is referred to as the **wrinkling moment** M_w. Prior to wrinkling, the moment-curvature relationship is expectedly linear in the absence of both material nonlinearities and notable changes in air pressure and volume. A stress balance analysis based on strength-of-materials equations can generally be used to compute M_w. Such a stress balance analysis was used to show the variation of warp yarn tensions for a 2-in-diameter plain-woven air beam subjected to four-point bending loads, as depicted in Fig. 20.10.6. Once wrinkling has occurred, the air beam moment-curvature relation behaves nonlinearly because with further loading, the cross section loses bending stiffness, the neutral axis displaces away from the centroidal axis of the cross section, and eventual collapse occurs. The spread of wrinkling around the circumference is similar to the flow of plasticity in metal beams subjected to bending. Loading beyond the wrinkling onset will result in an



Weft yarn tension per unit length of cylinder = pr

Warp yarn tension per unit circumference = pr/2

Fig. 20.10.4 Yarn tensions in a plain-woven pressurized fabric cylinder, and definition of yarn density ratio.

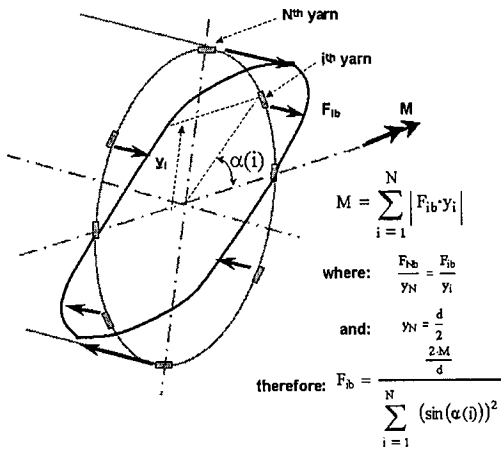

Fig. 20.10.5 Idealized distribution of warp yarn forces due to bending of a plain-woven fabric air beam.

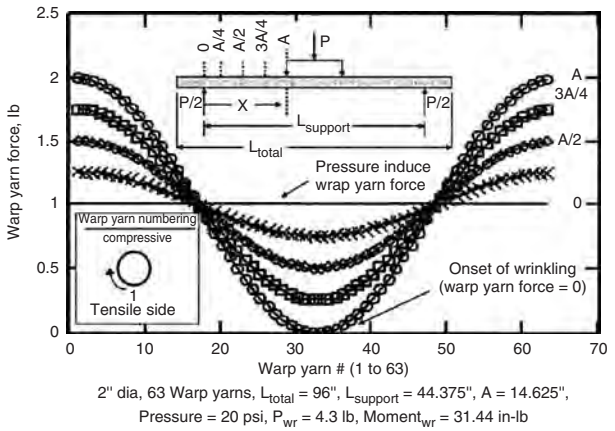

Fig. 20.10.6 Combined pressure- and bending-induced forces in warp yarns at various distances along a plain-woven air beam based on a simple stress balance analysis.

increase of pressure due to loss of volume, and the work done on the air will affect the postwrinkled bending stiffness. Thus, the postwrinkled response becomes nonlinear. The superposition of the pressure and bending-induced forces is shown for each architecture in Fig. 20.10.7.

Consider now a plain-woven air beam subjected to inflation pressure P. The force in the warp yarns F_{warp}, is shown in Eq. (20.10.4) as simply the pressure times the cross-sectional area divided by the number of warp yarns N_{warp}. The force in the weft yarns F_{weft} was idealized by the assumption of orthogonal yarn placement and is shown in Eq. (20.10.5). The Wrinkling moment M_W for a woven air beam was derived from a simple force balance of the pressure- and bending-induced yarn forces

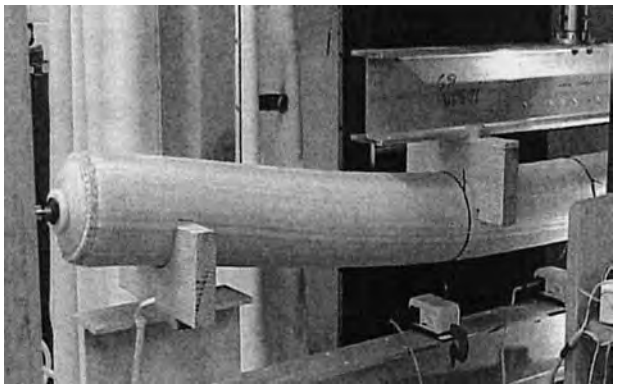

Fig. 20.10.8 Four-point flexure test on a 6-in-diameter plain-woven air beam constructed of 3,000-denier, 2:1 YDR Vectran fabric.

and is shown in Eq. (20.10.6).

$$F_{warp} = P\pi r^2/N_{warp} \tag{20.10.4}$$

$$F_{weft} = P\pi rL/N_{weft} \tag{20.10.5}$$

$$M_W = P\pi r^3/2 \tag{20.10.6}$$

Note that M_W is independent of the fabric material properties.

The global flexure response of plain-woven air beams was experimentally investigated for use in inflatable military shelters.[13,14] The air beams were constructed of nontwisted yarns and were inflated to various operating pressures. Operating pressures were considered to be safe when the resulting yarn tensions did not exceed 30 percent of their breaking strength. The experimental setup is shown in Fig. 20.10.8. A plot of the experimental load versus deflection is shown in Fig. 20.10.9.

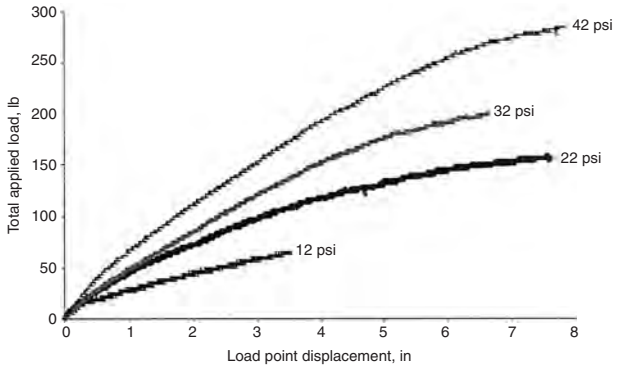

Fig. 20.10.9 Experimental load versus deflection plot for an uncoated 6-in-diameter air beam constructed of 3,000-denier nontwisted Vectran yarns in a plain-woven 2:1 yarn density ratio fabric using a 37-in span between load points and an 85-in span between support points.

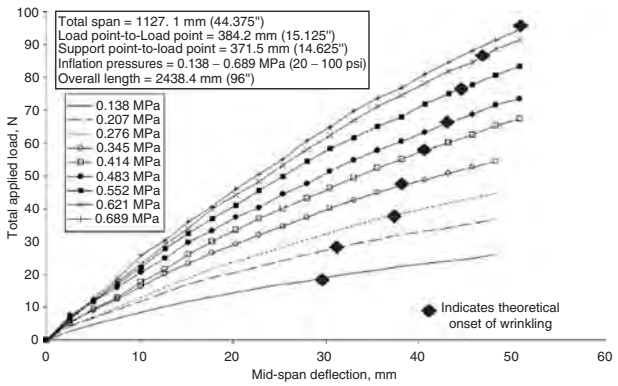

Fig. 20.10.10 Plot of total load versus midspan deflection for a 2-in-diameter plain-woven air beam constructed of 1,500-denier, 2:1 YDR Vectran fabric.

A second series of four-point bending tests[4] was conducted on a 2-in-diameter, uncoated plain-woven Vectran air beam to measure the midspan deflections as a function of inflation pressures ranging from 10 to 100 psi. The load versus midspan deflection curves are shown in Fig. 20.10.10.

In a third series of tests,[4] the flexure behavior of uncoated plain-woven Vectran and PEN air beams was compared for two pressures using a constant load point displacement rate. Both air beams had identical crimp in the warp and weft yarns, yarn density ratios (YDRs), deniers, diameters, and lengths. [The **yarn density ratio** is defined as the number of weft (hoop) yarns per unit beam length divided by the number of warp (longitudinal) yarns per unit circumference.] The graph of Fig. 20.10.11 shows the total applied load versus the midspan deflection responses.

Although the ratio of the as-woven elastic moduli of the Vectran and PEN yarns obtained through as-woven yarn tensile tests was 4.7:1.0, there were minimal differences in deflections of these air beams at the inflation pressures used. It was observed that the global bending behavior of the air beams was (1) invariant with E_{yarn} for the range of inflation pressures considered, (2) dominated by the kinematics of crimp interchange, and (3) subjected to considerable transverse shearing deformations. The effects of crimp interchange and shearing deformations precluded the use of traditional strength-of-materials design methods for plain-woven fabric air beams.

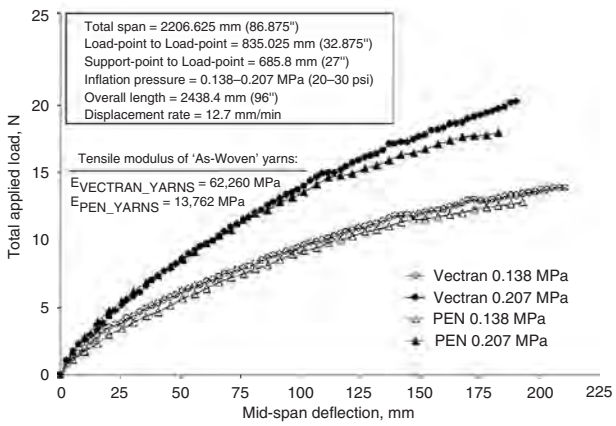

Fig. 20.10.11 Comparison of 2-in-diameter Vectran and PEN plain-woven air beams subjected to four-point bending tests at various load point displacement rates.

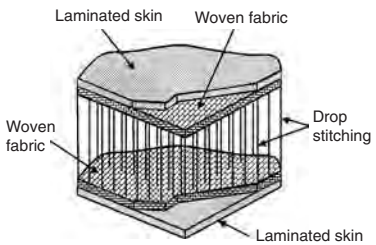

Fig. 20.10.12 Section view of an example drop-stitch construction for air-inflated fabrics.

DROP-STITCH FABRICS

Drop-stitch technology was originally pursued by the aerospace community and is now frequently used in inflatable boats. It extends the available shapes and configurations that air-inflated fabric structures can achieve to include flat and curved panels having moderate to large aspect ratios and variable thickness. Drop-stitch construction consists of external skins laminated to a pair of intermediate woven fabric layers separated by a length of perpendicularly aligned fibers as shown in Fig. 20.10.12. During weaving of the intermediate layers, fibers are "dropped" between these layers. Upon inflation, the skins separate and form a panel of thickness controlled by the effective stitch lengths. Air-inflated fabric structures that incorporate drop-stitch technologies include floors for inflatable boats, energy-absorbing walls, temporary barriers, lightweight foundation forms, and a variety of recreational products.

EFFECTS OF AIR COMPRESSIBILITY ON STRUCTURAL STIFFNESS

The load-deflection response of air-inflated fabric structures may depend upon additional stiffening influences other than the initial inflation pressure. These may include contributions from nonlinearities in the fabric stress-strain behavior, the work done on the air by external loads, and other phenomena. If appreciable changes in pressure or volume occur during loading, as in the case of energy absorbers, work is performed on the air through compressibility,

which stiffens the structure. Air compressibility can be modeled from thermodynamic principles in accordance with the ideal gas law shown in Eq. (20.10.7).

$$PV = mRT \tag{20.10.7}$$

where P = absolute pressure
V = volume
m = mass
R = gas constant for air
T = temperature, K

For a quasi-static, isothermal process, the work done on the air by compression is

$$W_{\text{air}} = -\int_{V_1}^{V_2} P\,dV = -\int_{V_1}^{V_2} \frac{mRT}{V}\,dV = -mRT \ln \frac{V_2}{V_1} \tag{20.10.8}$$

The total energy of the structure E_{total} is the work done by all external forces W_{ext}, which is related to the total strain energy of the fabric U_f and W_{air} as shown in the energy balance of Eq. (20.10.8).

$$E_{\text{total}} = W_{\text{ext}} = U_f - W_{\text{air}} \tag{20.10.9}$$

For homogeneous films and membranes, the elastic and shear moduli are readily determined by standardized tests. However, for the case of plain-woven and braided fabrics, the elastic and shear moduli can vary not only with pressure but also with fabric architecture (plain weave, harness weave, braid, yarn densities, etc.), external loads (**crimp interchange**), and coatings, if present. With increasing pressure, slack within the yarns is removed, the yarns begin to straighten (**decrimp**), and contact between intersecting yarns at the crossover points causes compaction.

EXPERIMENTS ON PLAIN-WOVEN FABRICS

Hearle[3] identified three distinct regions of stiffness for tensile loading of a plain-woven fabric, as shown in Fig. 20.10.13. For safe practice, air-inflated fabric structures are designed to operate with yarn forces ranging between regions I and II.

This ensures that the yarns are loaded well below their breaking strengths to provide sufficient factors of safety against burst. Once the fabric is biaxially stressed and subjected to an in-plane shear stress, the yarns will shear (rotate) with respect to their original orientations. The shear stiffness (i.e., resistance to yarn rotations) results from interyarn friction and compaction at the crossover points. Hence, the shear modulus is actually a system property rather than a constitutive (i.e., material) property. As the shear rotations increase, an upper bound is reached when yarns of both directions become kinematically locked, resulting in what is referred to as **shear jamming.** For pure shear loading, the trellising fixture shown in Fig. 20.10.14 can be used. Figure 20.10.15 shows

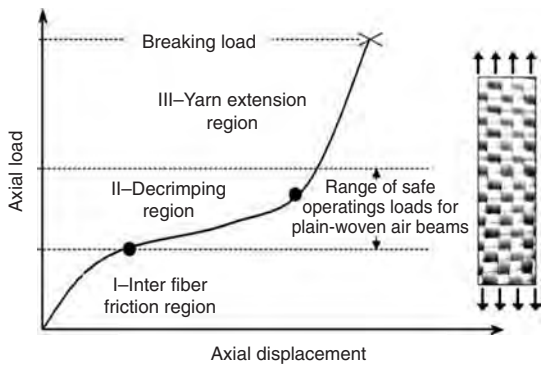

Fig. 20.10.13 Stages of axial stiffness for woven fabric subjected to tension.

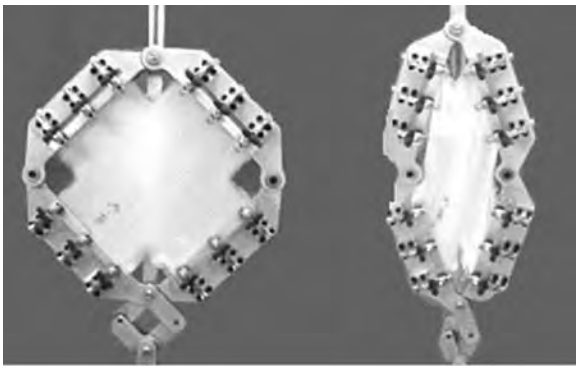

Fig. 20.10.14 Picture frame test fixture for pure shear loading of fabrics.

the shear force versus shear angle plot of an uncoated Vectran fabric. Further shear loading induces localized shear wrinkling instabilities that lead to increased out-of-plane deformations.

Farboodmanesh et al.[15] conducted shear tests on rubber-coated, plain-woven fabrics and established that the initial shear response was dominated by the coating, and with increased shearing the behavior of a coated fabric transitions to that of an uncoated fabric.

Unlike in fabric structures, the homogeneity of membranes excludes the kinematic motions associated with crimp interchange, and strain energy is developed throughout all stages of biaxial tensile loading. However, membrane structures composed of homogeneous materials are also susceptible to both bending and shear wrinkling instabilities.

Many testing methods have been developed for evaluating the mechanical properties of yarns and fabrics including ASTM standards, Kawabata Evaluation System, military specifications (MIL-Spec), British standards, etc. It is recommended that the structural engineer become familiar with the applicability of these standards to the design and testing of fabric materials as applicable to air-inflated fabric structures. Saville[16] provides a description of many standard tests used in evaluating fiber, yarns, and fabrics.

Recently a multiaxial tension and shear test fixture[13] was developed to permit simultaneous measuring of E_{warp}, E_{weft}, and G_f for structural fabrics. The fixture, as shown in Fig. 20.10.16, was designed for use with conventional tension/torsion machines to characterize the elastic and shear moduli of fabrics as functions of biaxial loads. It utilizes a cruciform-shaped specimen and was designed to evaluate both strength

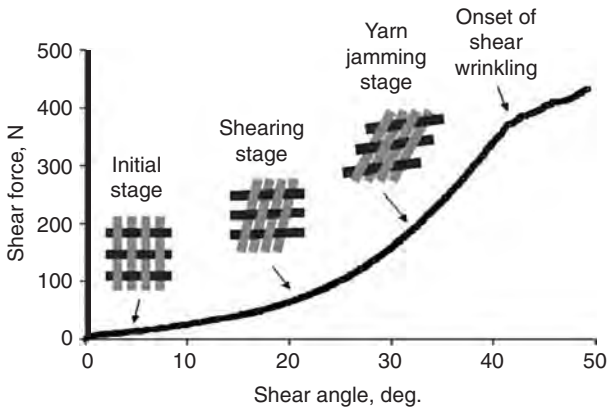

Fig. 20.10.15 Stages of shear stiffness for pure shear loading of a 2:1 yarn density ratio woven fabric.

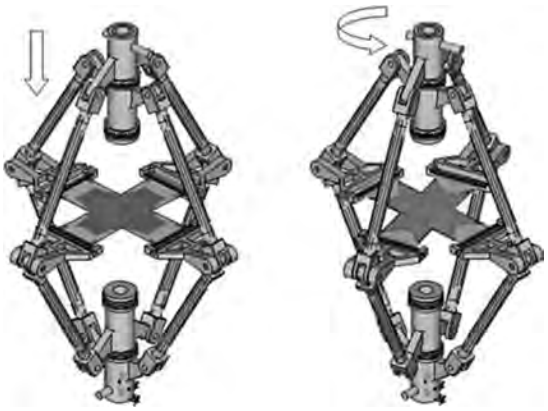

Fig. 20.10.16 Combined biaxial tension and in-plane shear test fixture. (U.S. Patent No. 6,860,156.)

and stiffness properties of various fabric architectures such as weaves, braids, and knits subjected to biaxial loads, shear loads, or **combined biaxial** and shear loads. For fabrics constructed of two principal fiber directions, the fixture utilizes two rhombus-shaped frames connected with rotary joints, as shown in Fig. 20.10.16 with the biaxial tension and shear modes illustrated for a plain-woven fabric. For triaxial braided fabrics, the fixture uses a third rhombus-shaped frame with additional rotary joints.

A STRAIN ENERGY–BASED DEFLECTION SOLUTION FOR BENDING OF AIR BEAMS WITH SHEAR DEFORMATIONS

The air beam bending experiments exhibited that deflections are functions of internal pressure and transverse shear deformations may be significant. If shearing deformations become appreciable, they will increase the total deflection of air-inflated fabric structures. Therefore, a shear-deformable theory such as that developed by Timoshenko[17] must be employed in place of the Euler-Bernoulli[18] theory to compute air beam deflections.

This section simulates the four-point bending experiments and analytically estimates the fabric shear modulus when changes in pressure and volume are negligible. Fabric shearing deformations, which were evident for each of the four-point bending tests shown in Figs. 20.10.9 through 20.10.11, were observed to decrease with increasing pressure. It will be shown that the shear modulus of the fabric is not a function of the warp yarn's elastic modulus. This was accomplished by deriving a shear-deformable air beam deflection equation for the four-point loading arrangement described by Fig. 20.10.17. From that equation, and using experimentally obtained air beam deflections, the fabric shear modulus G_f can be computed. This equation captured both the bending and transverse shear deformations that comprise the total midspan deflection.

The nearly orthogonal yarn directions were assumed to be truly orthogonal, with the warp axis being parallel to the longitudinal axis of the air beam. This uncoupled the bending stresses from the weft (hoop) yarns. The warp yarns were assumed to exclusively support the bending stresses. In a truly orthogonal fabric air beam, the weft yarns can be considered as parallel rings rather than continuously spiraled yarns with small lead angles. Also an equivalent cylinder having a cross-sectional area equal to the total cross-sectional areas of all the warp yarns A_{total} was used to represent the actual air beam. The inner radius of the equivalent cylinder r_i was taken as the nominal air beam radius, and the outer radius of the equivalent cylinder r_o was computed by

$$r_o = \sqrt{\frac{A_{\text{total}}}{\pi} + r_i^2} \tag{20.10.10}$$

Castigliano's second theorem[18] was used and considered the strain energies from both bending and shearing for the equivalent cylinder. The total strain energy U_{total} was expressed as the sum of the bending and shearing strain energies:

$$U_{\text{total}} = \int_0^L \frac{M(x)^2}{2E_f I_{\text{cyl}}}\,dx + \int_0^L FS\,\frac{V(x)^2}{2A_{\text{cyl}}G_f}\,dx \tag{20.10.11}$$

where A_{cyl} = cross-sectional area of equivalent cylinder (equal to total area of warp yarns A_{total})
E_f = fabric elastic modulus along warp (longitudinal) axis measured from biaxial tests
FS = shear strain correction factor (for tube = 2.0)
G_f = pressure-dependent fabric shear modulus
I_{cyl} = area moment of inertia of equivalent cylinder about bending axis
L = length of air beam
$M(x)$ = bending moment
$V(x)$ = transverse shear force along longitudinal axis
x = longitudinal position along air beam

For thin-walled cylinders of outer radius r_o and thickness t_{cyl}, I_{cyl} is computed as shown in Eq. (20.10.10) by neglecting terms containing higher-order forms of t_{cyl}.

$$I_{\text{cyl}} = \pi r_o^3 t_{\text{cyl}} \tag{20.10.12}$$

The total midspan deflection δ_{total} due to the total applied P_{total} is derived from minimizing the total strain energy U_{total}. This leads to

$$\delta_{\text{total}} = \frac{1}{48}\frac{8a^3P_{\text{total}} + 12ca^2P_{\text{total}} + 3c^2aP_{\text{total}}}{E_f I_{\text{cyl}}} + \frac{1}{4}FS\frac{2aP_{\text{total}}}{G_f A_{\text{cyl}}} \tag{20.10.13}$$

where a = distance between support point and adjacent load point and c = distance between load points. The first and second terms of Eq. (20.10.13) represent the bending component δ_{bend} and the shearing component δ_{shear} of the total midspan deflection, respectively. The fabric elastic modulus E_f is measured from biaxial tension tests performed on the fabric using the 2:1 weft-to-warp loading ratio. The magnitudes of the warp yarn tension used in the biaxial tests must match the warp yarn

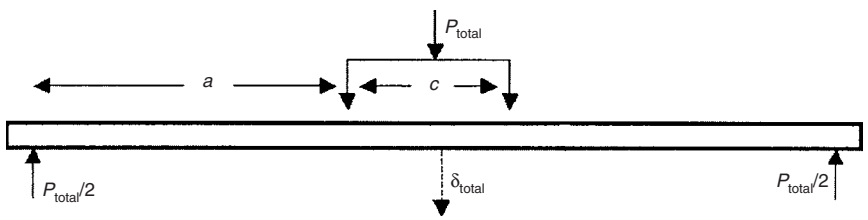

Fig. 20.10.17 Four-point bending arrangement for shear-deformable beam deflection equation.

forces of the air beam at the inflation pressure of interest. By using the second term d_{shear} the fabric shear modulus G_f may be calculated from

$$G_f = \frac{aP_{total}FS}{2\delta_{shear}A_{cyl}} \tag{20.10.14}$$

Equation (20.10.14) indicates that G_f is not a function of the fabric elastic modulus E_f whereas P_{total} and δ_{shear} are functions of inflation pressure. Alternatively, by determining the shear jamming angle of the fabric and the corresponding δ_{shear}, a lower bound value of G_f can be determined.

ANALYTICAL AND NUMERICAL MODELS

A variety of analytical and numerical models have been developed to predict the load deflection behavior for inflatable structures[4,13,19–26] and for the load extension behavior of the fabrics themselves.[27,28]

Unit Cell Numerical Models

One could create a finite element model of an air beam with all its discrete yarns, bladder, contact surfaces, friction etc.; however, research has shown that solutions to such a model would exceed the computational limits of today's hardware. The need to obtain a computationally efficient model that would not exceed hardware limits or encounter convergence problems led to the development of localized yarn interaction models for plain-woven fabrics. These models are commonly referred to as unit cell models.

Unit cell models are used to develop the constitutive behavior on the material scale rather than the structural scale. All sources of influence on constitutive behavior are present on the material scale. Once this behavior is known, it can be applied to the structural scale by using homogenization methods. **Homogenization methods** simply employ the as-established constitutive behavior from the unit cell models in global structural models constructed of homogeneous membranes. This two-step approach reduces the necessary computations and runtime for full-structure modeling while preserving the effects of yarn interactions on material behavior.

A unit cell of a plain-woven fabric generally consists of several rows of warp and weft yarns. Since the yarns exhibit relative displacements and rotations with respect to each other, researchers have investigated two options for treating yarn kinematics: (1) rotation-only (pinned centers at the yarn crossover points) and (2) rotation and translation at the yarn crossover points, as shown in Fig. 20.10.18. In the rotation-only condition, the centers of the contact areas are hinged and remain coincident. Friction is due only to the relative rotation of the yarns and no sliding is allowed. This kinematic condition is appropriate for modeling pneumatic muscles[29] where the fabric is braided and the relative angle of rotation at the yarn crossover points is significantly large. In the rotation and translation condition, no kinematic constraints are imposed at the yarn crossover points. This enables interacting yarns to slide and rotate with respect to each other. Therefore, contact-induced friction forces at the yarn crossover points provide resistance to both relative rotations and translations.

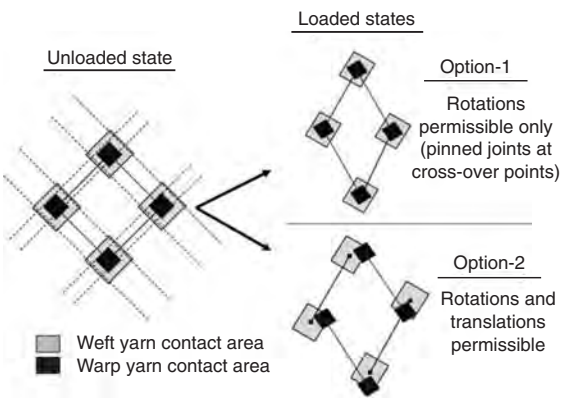

Fig. 20.10.18 Treatment of yarn kinematics in unit cell models.

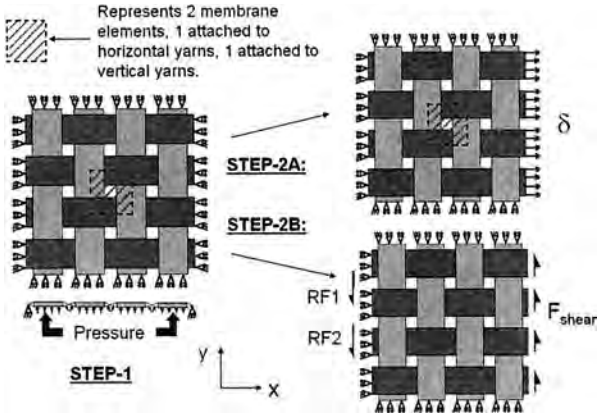

Fig. 20.10.19 Example unit cell model and loading procedure.

The bladder generally does not contribute any structural stiffness to the fabric, nor is it necessary to include the bladder as a contacting medium. In addition, the inclusion of a bladder contact surface was found to create unnecessary convergence difficulties and added computational expenses. Since the bladder was eliminated from these models, the unit cell should be subjected to a uniform pressure representing the air beam pressure. There are several methods of applying the internal pressure to the unit cell model, depending on individual preferences.

Example of a Unit Cell Model

In a specific example of the **unit cell,** each yarn was represented by an isotropic thin shell with material properties of either Vectran or PEN, depending on the fabric being studied. The shell unit cell model consisted of four warp yarns and four weft yarns, as shown in Fig. 20.10.19. The model was subjected to internal pressures ranging from 0.0138 MPa (1 psi) to 0.276 MPa (20 psi). Contact surfaces were permitted to allow yarn translation and rotations as described by option 2. Two compliant membrane elements ($E_{membrane} << E_{yarn}$) connecting the center points of the contact regions were created. These membrane elements were used to determine the overall stress and strain of the shell unit cell model and did not contribute to the structural stiffness of the model.

A three-step computational procedure was employed to determine the elastic and shear moduli of the unit cell. First, the vertical yarns were restrained and the horizontal yarns (x direction) were subjected to +1 percent displacement. The model was solved, and the stress in the x direction and the strains in the x and y directions were determined. Then the elastic modulus $E_1 = \sigma_1/\varepsilon_1$ and Poisson's ratio $\nu_{21} = -\varepsilon_2/\varepsilon_1$ were determined. Second, the horizontal yarns were restrained, and the vertical yarns (y direction) were subjected to +1 percent displacement in the y direction. The model was solved, and the stress in the y direction and the strains in the x and y directions were determined. Then the elastic modulus $E_2 = \sigma_2/\varepsilon_2$ and Poisson's ratio $\nu_{21} = -\varepsilon_1/\varepsilon_2$ were determined.

Finally, the third step was to calculate the shear modulus. This is difficult because the elastic and shear moduli of a plain-woven fabric structure are highly dependent on the internal pressure; furthermore, the elastic and shear moduli are independent. Two methods are suggested. The first method is for the case where the fabric is coated and there is no relative motion between the yarns. Then the following approach is recommended.

In this approach the fabric is assumed to be a continuum with orthotropic material properties. The unit cell model in this case was subjected to a +1 percent nodal displacement at a 45° angle (not shown).

The model was solved, and the stresses and strains of the unit cell at the 45° angle were determined. The shear modulus was calculated according to Jones[7] by

$$G_f = \left(\frac{4}{E_x} - \frac{1}{E_1} - \frac{1}{E_2} + \frac{2\nu_{12}}{E_1} \right)^{-1} \qquad (20.10.15)$$

where E_x is the elastic modulus in the direction of the 45° load. This expression may be appropriate for fabrics with stiff coatings.

The second approach to calculating G_f assumes that the woven fabric is not a continuum and that each yarn independently responds to the external load. In this case, the horizontal yarns were subjected to a shear force F_{shear}. The shear modulus was then calculated based on the equilibrium of the horizontal yarn and its shear deformation as

$$G_f = G_{12} = \frac{\tau}{\gamma} \qquad (20.10.16)$$

where $\tau_{\text{shear}} = \Sigma F_{\text{reaction}}/\Sigma A$, $\gamma = \arctan(\delta_{\text{shear}}/L)$, and $\Sigma F_{\text{reaction}}$ is the sum of reaction forces at the support, δ_{shear} is the nodal transverse displacement, A is the yarn cross section, and L is the yarn length.

It is recommended that a number of tests on the unit cell model be performed in which the coefficient of friction is varied and the changes in the elastic and shear moduli are determined. Therefore, the results of the shell unit cell model will be parametric in both friction and pressure.

Structural Air Beam Models

Once the elastic and shear moduli of the membrane elements are determined from the unit cell model, a global structural finite element model of the air beam, using membrane elements, can be created such as the one shown in Fig. 20.10.20. Here, the fabric skin would be discretized using membrane elements. However, nine elastic material constants (E_1, E_2, E_3, ν_{12}, ν_{13}, ν_{23}, G_{12}, G_{13}, and G_{23}) are required, of which only E_1, E_2, and G_{12} had been calculated from the beam unit cell model. Because a membrane formulation is used for the fabric skin, the elastic modulus E_3 would not influence the global beam deflection and was therefore chosen to be of the same order of magnitude as E_1 and E_2 (in the order of E_3 = 64,000 MPa for the current example). It was also noted that any load applied in the direction of one yarn is decoupled from all orthogonal yarns. That is, the Poisson's ratio is nearly 0; therefore, the condition that $\nu_{12} = \nu_{13} = \nu_{23} = 0.0$ may be applied. No method was developed to determine G_{13} and G_{23}. It is hypothesized that neither value had a significant effect on the beam deflection. One could examine this hypothesis by a parametric study of values for G_{13} and G_{23}.

In the above-mentioned example, using the analytical strain energy solution, the equivalent in-plane fabric shear modulus G_f for the 50.8-mm (2.0-in) diameter Vectran beam pressurized to 0.689 MPa (100 psi) was calculated as 86.06 MPa (12,480 psi). The computed bending and shear components of the midspan deflection were 12.39 mm (0.488 in) and 39.54 mm (1.557 in), respectively. The elastic and shear moduli in the beam unit cell model were calculated for an internal pressure of 0.137 MPa (20 psi) as E_1 = 64,033 MPa, E_2 = 64,098 MPa, and $G_f = G_{12}$ = 60.96 MPa. Similarly, for an internal pressure of 0.207 MPa (30 psi), the elastic moduli were calculated as E_1 = 64,045 MPa, E_2 = 64,049 MPa, and $G_f = G_{12}$ = 80.64 MPa.

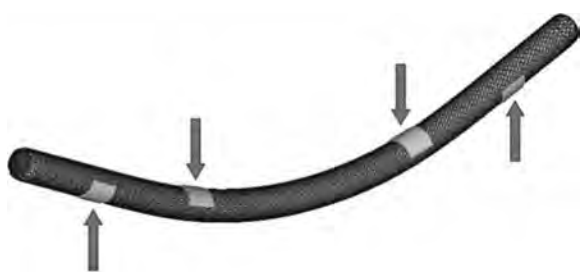

Fig. 20.10.20 Example of an air beam global finite-element model subjected to four-point bending.

Concluding Remarks

The unit cell modeling method was used to determine the influence of pressure, weave architecture (including yarn density ratio), crimp interchange, coefficients of friction and biaxial loading ratios on the effective fabric elastic and shear moduli. These moduli were shown to increase with increasing pressure. The coefficient of friction between yarns did not influence the elastic and shear moduli significantly because the relative displacements of the interacting yarns were small compared to their cross sections. The shear modulus of plain-woven fabrics was shown to be a system property; it is a kinematic property of the yarn assemblage in fabric form and is independent of the yarn elastic moduli. The use of yarns with higher elastic modulus may not significantly influence the deflection of air beams because crimp interchange can prevent the as-woven yarns from developing elastic behavior. It has also been shown that coatings can stiffen the fabric material, resulting in smaller air beam deflections.

Homogenization is particularly suitable for developing computationally efficient global models of air-inflated fabric structures in conjunction with unit cell methods. The unit cell method captures the nonlinear constitutive behavior of the plain-woven fabric in response to applied loads. This behavior is transferred to a homogeneous material in a global model of the air-inflated fabric structure.

The studies have shown that air-inflated fabric structures differ fundamentally from conventional metal structures and fiber/matrix composite structures. While the plain-woven fabric may appear to be an orthotropic material, its mechanical behavior indicated otherwise. It does not behave as a continuum, but rather as a discrete yarn assembly.

20.11 ROBOTICS, MECHATRONICS, AND INTELLIGENT AUTOMATION

by Andrew A. Goldenberg

OVERVIEW

Description of the Fields

In the 1950s engineering schools used to teach students the subjects related to mechanical and electrical engineering in the same department, usually named electromechanical engineering. This approach was considered suitable to provide the required level of professional knowledge that would allow graduates to work effectively in this branch of engineering.

As the technology, in particular electronics, begun to unravel significant advances, and the industrial requirements became more focused, engineering schools started splitting up the electromechanical departments as independent entities into electrical and mechanical, respectively, with scope, aims, and objectives that were not necessarily similar.

In 1954 a U.S. patent was filed by G. Devol for a programmable universal manipulator arm (PUMA). It constituted the first registered patent in the field of robotics. Soon thereafter, together with John Engelberger and others, they set up Unimation Inc., acquired the rights to this patent, and started a business of manufacturing robots. Unimation was the first company solely dedicated to the business of robots. The first Unimation robot was used at GM, Trenton, New Jersey, in 1961. Eventually, an entire industry as we know it today emerged.

The paradox was that as the departments of electrical and mechanical engineering became independent, the new field of robotics was calling for a merger of these two now established solitudes. Furthermore, the third major disciplinary component of robotics was emerging, that is, the computer science, which provides the capability of software development that is required in robotic systems.

In the 1970s a large number of important industrial projects in the field of robotics took off. The most prominent was the Shuttle Space Remote Manipulator System, developed by Rockwell, NASA, Spar Aerospace of Toronto, Ontario, and National Research Council in Canada. In parallel, the automotive industry embraced the use of robots in earnest. As a result, the industry began requiring skills that combined electronics, mechanical, and software engineering. Many engineering schools set up robotics programs in late 1970s and early 1980s. Usually these programs were hosted by one of the three constituent departments, and the programs they offered reflected the departmental basic discipline. One of the few institutions that started offering a multidisciplinary program in robotics was the Institute of Robotics at Carnegie-Mellon University in the early 1980s.

In parallel an industrial association was formed, the Robotics Institute of America (RIA). RIA had the mandate to standardize the use of robotics. It issued a formal definition that is still used widely to qualify automatic equipment as a **robot**—a mechanical device that can be programmed to perform some task of manipulation or locomotion under automatic control. This definition provided a basis for the interdisciplinary nature of robotics.

At that time the above definition and the use of robotics in general were limited to manipulator arms. All robotic manufacturers in the 1980s were offering manipulator arms. The teaching and research were also confined to robotic arms, and major applications such as in the space sector were also focused entirely on manipulator arms. The robotic arm was generically an open kinematic chain consisting of a base, shoulder, elbow joints, and a three-dimensional wrist, ending with an end effector in the form of a gripper. There were many variations to this basic robot configuration, nonetheless they were all classified as arms.

Robotic applications in late 1980s and early 1990s evolved from automotive welding and painting to assembly in electronics manufacturing. Also, new applications emerged in the medical, security, mining, and other sectors. These applications required more complex robotics structures than the common manipulator arms. In terms of design and development, they were developed using the same basic disciplines and engineering design principles. These applications led to the emergence of a new field: mechatronics.

The term was actually used in the 1970s in Japan. **Mechatronics** is defined as the synergistic combination of precision mechanical engineering, electronic control, and systems thinking in the design of products and manufacturing processes. It extended the scope of automation from robotic arms to intelligent systems. Mechatronics was integrating mechanical, electronics, and software engineering in a more aggressive way than robotics. The major difference was the emphasis on microelectronics, nonexistent in the 1960s, and the use of new materials in mechanical design of small, miniature, portable devices, leading to the emergence of ultraminiature or microsystems, and their fabrication methods, as defined by the new field that emerged in the 1980s: MEMS, or microelectromechanical systems. MEMS is a branch of mechatronics that addresses microsystems. It has further evolved into systems designed based on particle components: nanotechnology.

Today, the teaching and research of mechatronics and robotics often overlap, as more people have embraced both fields of study and professional work. To attempt to precisely differentiate between the two entities is fruitless at this point of technological development. The expertise is overlapping, but most practitioners see robotics as a subentity of mechatronics. However, there are peculiar issues in each of the fields requiring distinct specialization, and both fields belong to the area of intelligent automation.

Robotics

Based on the single-axis servomechanism methods of control system design that were well developed by late 1960s, the development of industrial automation for machine tools began with **numerically controlled (NC) machines.** These tools were designed in the 1960s to perform unstaffed operations of cutting, lathing, drilling, and polishing using primarily two-dimensional positioning devices. The devices were the result of integrating two or three axes of motion, usually perpendicular to each other. Each axis was driven by a standard servomechanism. The NC machines were programmed using logic circuits such that the motions of the servomechanisms were coordinated. These automatic units were machining profiles in two and three dimensions.

The typical **servomechanism** was operated using available hardware (analog) and software (logic circuits). The underlined control system design was based on PID controller and later on optimal and adaptive control. The coordination of the motion of two or three axes was realized by effecting simultaneously very small steps of motion of the axial servomechanisms. The frequency of these steps was selected to correspond to the required speed of motion. The coordination was provided

by ensuring that all axes start and stop at the same instant of time. By ensuring that arbitrarily small steps of motion can be performed, limited only by the servomechanism's ability to monitor its own axial motion online by feedback, high-precision motion was generated. In modern machining the repeatability can be guaranteed to a hundredth of a thousand of an inch, or 0.00254 mm.

The control of NC machining along with design, programming, and language used for programming have dominated the industrial automation sector until the mid-1960s. At that time it was recognized that the operations of the NC machine are limited to standard machining operations. Any task that would require more than two or three axes of motion, including translational and rotational motion, could not be executed. At this stage the notion of articulated motion, i.e., the handling of a tool, tracking a path with the tool, and also orienting the tool arbitrarily in three-dimensional space, became intriguing enough, such that the impetus started shifting from the linear NC machines to new devices that could be programmed to deliver the tool motion over an arbitrary path and with arbitrary orientation.

This generated the birth of robotics as a domain of engineering research and design. The robotics were multidegree-of-freedom devices with a capability similar to that of NC machines, but with a higher number of axes active that move based on coordinated motion plans. The purpose was to handle and operate a tool over a workpiece while following specific paths (contours). The robotics provided the domain of development of radically more complex mechanisms. Furthermore, the advent of microelectronics provided a new technology of hardware and software that became the cornerstone in the proliferation of robotics in industry.

The field of mechatronics started to become acknowledged in the 1980s. It was providing a different approach to automation, and it generalized the robotics technology. The mechatronics approach is different from that of robotics in the sense that it does not regard the arm as the central piece of an automated system. Both domains are regarded as an all-encompassing effort to eliminate human involvement in order to provide the industry with the capability of supplying more consistent, more economical products, and compete worldwide on equal footing without concern that the cost of production is significantly dependent on local wages. This reason for introducing automation is more powerful today than it was late in the last century.

Mechatronics

Mechatronics is a multidisciplinary field that is the synergistic combination of mechanical systems, electronics, sensors, actuators, and software. Mechatronics is in essence the integration of these areas. In practice as well as education the division along the classical disciplines is no longer effective, as this emerging branch of engineering generates the most appropriate vehicle for interdisciplinary work. Integration must be done *concurrently,* unlike in the classical approach to design whereby the work in each domain is done in solitude, and the integration is referred to at the last stage before testing and verification of the whole system. In mechatronics, integration is elevated to the position of most relevant stage of design. Mechatronics as a theoretical subject deals with the interaction between various disciplines and their expression in the context of system design. In principle, mechatronics is a methodology for product design. Therefore, education of mechatronics must be based on real problems, product design, and teamwork.

There has been already a certain amount of soul-searching to answer the question, What is mechatronics? It is recognized that there are many designs in which electronics and mechanical systems are integrated, but poorly from a technical perspective and thus ineffectively. In mechatronics the design of an intelligent system begins with the conceptual design that involves the participation of all the members by discipline in an integrated effort to formulate solutions that are feasible and efficient based on considerations of all technological branches involved in the project. The next stage of development is to delegate the various members by disciplines to define their subsystems specifications in coordination with the other members, to ensure that the various discipline's input can be related and associated effectively. Last, but not least, the detailed design phase is undertaken, which is concerned with the independent work of each discipline team. Following this stage and the manufacturing, the assembled team again resumes the collaborative work on integration and testing. At all times the development work demands interaction, and it actually provides the basis for intense collaboration between the various disciplines involved.

Mechatronics identity as a collection of disciplines required to formulate a common approach to development of intelligent systems is also a novel but resurrected way of providing education. A mechatronics engineer is expected to be proficient in mechanical design, electronics design, software development, testing, and integration. It provides the best opportunity for a true technology-oriented training of systems engineers. Whereas the classical version of system engineering was limited to concepts and system specifications, the modern interpretation is also embedding the subsystem development in the context of system design. In other words, there is less of a hierarchy, or vertical integration, and more of an equally valued teamwork, or horizontal integration. The mechatronics engineering is inherently interdisciplinary.

The emergence of this paradigm facilitates innovation and, more importantly, transfer of innovative technology to the use of humanity. Innovation is the product of out-of-the-ordinary ideas that usually emerge in contradiction with the state-of-the-art way of thinking. Many innovative ideas do not progress to becoming relevant ideas because they do not cover the necessary ground to identify their usefulness. In reality, ideas are better appreciated when there is a correlation to their use. However, usefulness is not necessarily associated with immediacy. But the modern society is less inclined to serve as a recipient if the usefulness is hidden. This would indicate that ideas that can be shown to have the capability to become products will be better received. Mechatronics is an excellent vehicle to provide innovation in intelligent automation with a much better way of determining the benefits to the society that are emerging from supporting endeavors related to this field.

In terms of formal definition of mechatronics, it may be wiser not to seek to refine the definition while the field is still emerging. Too early revision would jeopardize future attempts to encompass new paradigms. Moreover, one could point out that the robotics domain has been struggling with its own definition since mid-1980s. Robotics was defined by the RIA so rigidly that immediate repercussions followed with regard to the interpretation of "what mechanism qualifies as a robot." Japan, the United States, and the rest of the world had different views of what constituted a robot. As a result, statistics that were compiled to assess the number of robots worldwide became political tools in the hands of those who benefited from claiming that the numbers in the United States are much lower than those in Japan. However, they were using different definitions of robots; hence the comparisons of robot populations were meaningless.

In terms of expertise, know-how, and education, mechatronics covers a variety of topics in the aforementioned disciplines. There is a danger, already prevailing, that research and development would begin in the basic disciplines, allowing the field to evolve as an integrative one, instead of consolidating a basis that would allow the field to be defined independent of its constituent disciplines. Again from robotics, some lessons could be learned. Early on in the 1980s most of, if not all, the research had connotations with the basic disciplines that were contributing to its integrative nature. In particular, control systems theory, mechanical CAD and FEM design, computer architecture, and electronic hardware design have contributed most to robotics research and development. There were many attempts to open forums for discussing the fundamentals of robotics, but they failed to make convincing arguments. Today, there is a large community of researchers who identify themselves as robotics fundamentalists, as well as at least as large a community in each of the constituting disciplines, who are arguing that robotics is an integration of fundamental engineering science disciplines and thus does not qualify to be regarded as a fundamental field. This conundrum does not seem to get abated by the progress of the field, yet one could argue that some stagnation is perceivable, and the opportunity of explaining it is provided by the fact that advances in the constituent technologies have not been

created equally. Some domains are further off, such as microelectronics and computer architectures; others are somewhat behind, such as materials and mechanical design.

It is timely to consider these historical facts in the context of mechatronics. Undoubtedly, if no effort is allocated to these issues, one could argue that at least, similar to robotics, mechatronics is an integrative field, whose progress will be dependent on the advances of the constituent technologies. This issue has an impact on education as well as on training of mechatronics engineers. The argument has already been stated. It is necessary to build a basis that would identify unequivocally the field as fundamental. The most assured way of achieving this goal is to educate in the context of a, yet to be formulated, fundamental discipline. Many schools have taken serious steps in this direction. In parallel many journals and conferences bearing the word *mechatronics* in their brand name have been started; some have already achieved notoriety and are regarded as "archival journals." Unfortunately, a quick review of teaching curriculum and journals content would only reemphasize the ambiguity that already existed at the onset. Many schools teach mechatronics as a reproduction of earlier curricula in robotics and controls. As to some journals, they do not publish content that is different from that of robotics, control, and control technology publications. It begs the question, What is the identity?

Clearly the identity could be found in the interdisciplinary interaction between subsystems. The field identity is strongly related to these issues; however, they have not achieved a predominant role in the literature and education. To attain this goal, it is necessary to shift the teaching from the fundamental topics of electronics, sensors, actuators, control, and mechanical structure design to teaching integration and product design. This implies focusing on implementation and means of fulfilling required system specifications, instead of development of subsystems. This would lead to education based on problem solving, case studies, and real industrial product development. But this approach is impeded by the inherent tendency to teach subjects close to the basic disciplines. It is necessary to promote education in new departments of mechatronics where equal emphasis can be allocated to all the constituent disciplines in order to homogenize their contribution toward a systematic approach to this emerging discipline. A possible approach to this goal is to educate by deengineering "black boxes," thus allowing the unknown to be explored and basic science be understood by exploration of existing benchmark systems. They offer the opportunity to correlate rapidly the basic science to the practice, as well as to unveiling the interactions between the various disciplines.

Another issue is the prevalence of opportunity presented by the Internet. It is well known that many terms of reference—books, papers, parts, devices, components—are available on the Internet. This provides a phenomenal source of information that was not available at the onset of robotics. It is possible to carry many courses in engineering by reviewing material published on the Web, perhaps with some qualified guidance from a more experienced person in the field. In terms of understanding basic concepts as well as learning about new devices and components, the Web provides the best source. It contains and provides what is typically taught in the classroom. It would be beneficial to focus the teaching on such aspects that do not have adequate representation on the Web. This category includes mechatronics integration and subsystems interactions, which by and large are dependent on the professional experience and less so on material available in textbooks. It would be ideal if mechatronics were taught by practitioners instead of nonpracticing Ph.D.s, similar to the medical profession where surgery is taught by surgeons instead of biologists.

The mechatronics field presents a unique opportunity to engage the professional community as a whole comprising experts, practitioners, academics, and the socioeconomic sector as well.

Intelligent Automation

Originating in the fields of robotics, mechatronics, and automation, the research and industrial communities have generated a new term of reference: **intelligent automation.** There have been some initial attempts to define this new entity formally, but not all efforts have generated a satisfactory result because of terms of reference that are ambiguous and significant overlap, mainly with the predecessors robotics and mechatronics.

A close and detailed investigation of systems that are classified as robotics or mechatronics would reveal that the boundaries between these fields are not at all easily and clearly defined. Based on common fundamental physics and engineering science principles that provide the underpinning of these fields, it could be argued that a complete abolition of the need to define them separately is in order. However, the research community seems to be more inclined to maintain distinctions between these domains, whereas the practical/professional domain is less concerned with the definitions as long as the systems that are created work and fulfill required specifications.

Intelligent automation could be understood as an extension of mechatronics and robotics. There is a great deal of uncertainty as to where systems that could be defined as robotics or mechatronics begin their journey as "intelligent." Some serious arguments were made to distinguish between the mechanical design of ordinary robotics and mechatronics and that of intelligent automation systems. It was found that the inclusion of new technology such as micro- and nanotechnology could provide the way to render them intelligent. Other attempts focused on software. It is common practice to consider adaptive and learning systems as intelligent. An example is fuzzy-logic-based expert systems, a new domain of research and business activities.

In the next section examples of robotic-based and mechatronic systems are given. No attempt was made to underline their intelligence, although they could be considered "practically intelligent."

TYPICAL APPLICATIONS

In an attempt to illustrate the emerging technologies of robotics and mechatronics, and their combined by-product intelligent automation, a number of examples of niche applications are presented in this section. The purpose is to facilitate the understanding of these fields via examples instead of taking the usual route of presenting the underlining theory and tools that support design and developments in these areas. The examples should elucidate two issues: (1) complexity of the design of some robotics and mechatronics applications and (2) proliferation of intelligent automation in new areas that have not been addressed so far.

The examples are given in two sections: robotics and mechatronics. As indicated in the previous section, it was not considered useful to segregate some of the systems to the intelligent automation category. The design of most of the provided examples is of high complexity, leading to advanced methods of control, microelectronics, sensing, and custom-developed software. These are the main elements of intelligent automation. Furthermore, the distinction between robotics and mechatronics could be also difficult to draw if functionality is the only concern. Although commonly perceived as "arms" or "manipulators," robotics could really encompass any system that has a number of degrees of freedom either activated in automatic closed loop or when the loop is closed by the human operator. The existence of an arm that may or may not be the main element of the system does not warrant a separate classification. However, to follow the accepted norms, in some of the examples although there is a robotic arm involved, the system is much more complex, and therefore it was categorized as mechatronic.

The provision for separate categories seems to hinder rather than support the efforts in technology development in both academic and industrial domains. Some see mechatronics and intelligent automation as new fields, whereas practically they are significantly overlapping.

Robotics

In robotics the applications usually involve a manipulator arm. They encompass industrial operations such as welding and painting in car manufacturing, pick-and-place of parts and subassemblies, parts mating and assembly in the electronics industry, and machine shop operations. They are based on stationary robotics. In the late 1980s, mobile robotics emerged mainly as remote-controlled devices for operations in

hazardous environments. The mobility issues rendered robotics as more complex systems, but as integration of such systems began to dominate, they were viewed as mechatronics. We are addressing this field in the section "Mechatronics."

Another domain that has been gaining popularity in the last 10 to 15 years is *modular* robotics. They are ordinary robotics in terms of functionality; are offered in kits including joints, links, and controllers; and are differentiated by providing ways of reconfiguring the robot's arms for a wide variety of tasks.

The most notorious application of robotic arms is in the space sector. The most common use is in car manufacturing (welding, painting). Applications in electronics assembly of components and systems are also growing, pushing up the number of industrial robots in use today.

Applications of robotic arms encountered in the car manufacturing sector are well documented in the literature from the late 1970s to the mid-1980s. New applications in electronic industry are also well documented in the later publications.

To illustrate the use of robotics, we present a number of niche applications. The purpose is to highlight the use of robotics in areas that are less publicized. These examples could provide an impetus for consideration of robotic-based applications in new areas. There are no reasons for limiting the proliferation of robotics in all sectors of society, but the technology has still not matured, such that development and use of new applications in some areas are not economical and reliable.

Space Shuttle Remote Manipulator System

The **shuttle remote manipulator system** (**SRMS**) or "Canadarm" was a joint venture between the governments of the United States and Canada to supply the NASA Space Shuttle program with a robotic arm for the deployment/retrieval of space hardware to/from the payload bay of the orbiter. A schematic view of the SRMS is shown in the Fig. 20.11.1.

The SRMS is a robotic arm consisting of a shoulder, elbow, and wrist separated by an upper and lower arm boom, giving it a total of 6 degrees of freedom (shoulder pitch and yaw, elbow pitch and wrist pitch, yaw and roll). At a total weight of approximately 431 kg, the SRMS is capable of maneuvering payloads of up to 60,000 lb at a rate of 0.06 m/s with a maximum contingency operation payload weight of 256,000 lb. Under unloaded conditions the SRMS can achieve a maximum translational rate of 0.6 m/s. However, the SRMS is incapable of supporting its own weight on Earth. It must be supported by specialized ground handling equipment during its testing and packaging for shipment. Although the SRMS can handle very heavy payloads, movement of the tip is very accurately controlled, allowing precise handling of delicate payloads. The length of the SRMS is approximately 15 m. A control system is used to deploy payloads in automatic mode to a positional accuracy of ± 2.0 in and $\pm 1.0^\circ$ of a preprogrammed target point and orientation at the aforementioned rates and load conditions. The SRMS may also be operated manually (remote control) by the astronauts to the same accuracy with the use of hand controllers and closed-circuit televisions (CCTVs) mounted on the manipulator arm. The SRMS was designed to have a life of 10 years or 100 missions. The SRMS is comprised of the following component subsystems:

Joints There are two basic joints (Fig. 20.11.2) in the shoulder, which allow the whole arm to pitch (up-and-down motion) and yaw (side-to-side motion); there is one joint in the elbow to allow the lower arm to pitch; and there are three joints in the wrist to allow the tip of the arm to pitch, yaw, and roll (rotating motions). SRMS can accomplish very complex maneuvers. The motors are equipped with their own brakes, encoder, and speed control.

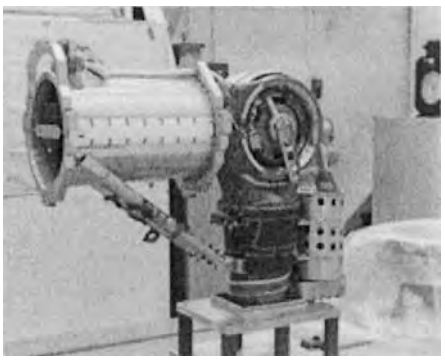

Fig. 20.11.2 SRMS's basic joint (Spar).

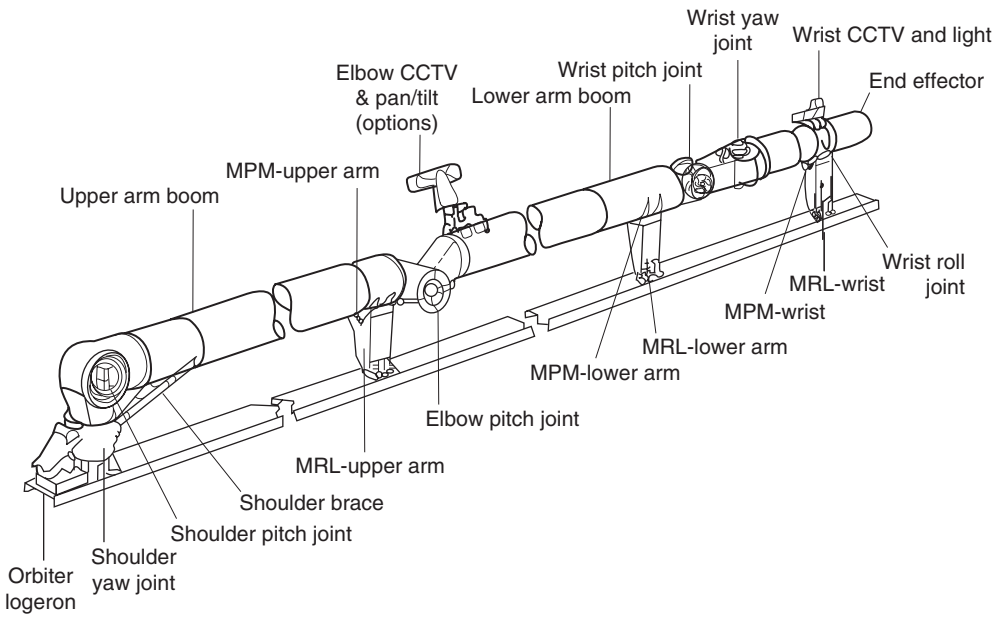

Fig. 20.11.1 SRMS mechanical subsystem. (*From Spar Aerospace Ltd., Toronto, Ontario.*)

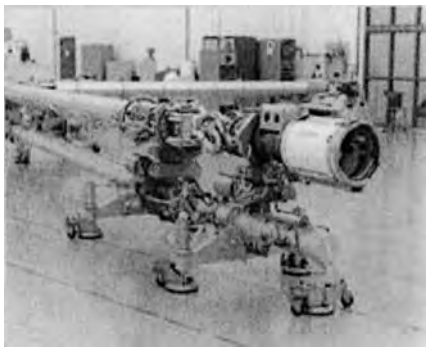

Fig. 20.11.3 SRMS's end effector. (*From Spar.*)

Booms Linking the shoulder, elbow, and wrist joints are the upper and lower arm booms. These booms are constructed of graphite epoxy. The upper arm boom is approximately 5 m long by 33 cm in diameter comprising 16 plies of graphite epoxy (each ply is 0.013 cm thick) for a total weight of just under 23 kg. The lower arm boom is approximately 5.8 m long by 33 cm in diameter comprising 11 plies of graphite epoxy for a total weight of just over 22.7 kg. Each boom is protected with a Kevlar bumper (the same material used in bulletproof vests) to preclude the possibility of dents or scratches on the carbon composite.

End Effector The end effector (Fig. 20.11.3) of the SRMS allows the arm to capture stationary or free-flying payloads (e.g., orbiting satellites) by providing a large capture envelope (a cylinder 20.3 cm in diameter and 10 cm deep) and a mechanism/structure capable of soft docking and rigidizing the payload/end effector interface. This action is accomplished by a two-stage mechanism in the end effector which closes three cables (like a snare) around a grapple probe (knobbed pin) bolted onto the payload and then draws it into the device until close contact is established and a load of approximately 499 kg is imparted to the grapple probe.

Control System The hand controllers used by the astronauts (one for arm linear motion and one for rotary motion) are generating the commands representing what the astronauts would like the arm to do. Built-in software calculates which joints to move, what direction to move them in, how fast to move them, and what angle to move to. The computer issues the commands every 80 ms. Any changes inputted by the astronauts to the initial trajectory commanded are reexamined and recalculated, and updated commands are then sent out to each of the joints.

Thermal Protection The SRMS is covered over its entire length with a multilayer insulation thermal blanket system, which provides passive thermal control. This material consists of alternate layers of Kapton, Dacron scrim cloth, and a beta cloth outer covering. In extreme cold conditions, thermostatically controlled electric heaters (resistance elements) attached to critical mechanical and electronic hardware can be powered on to maintain a stable operating temperature.

A Remote-Controlled Hydraulic Robot for Difficult and Hazardous Tasks

Utility companies must provide tree trimming in the vicinity of live aerial electrical distribution lines, to avoid outages due to ruptured cables which are caused by erratic motion of tree branches during storms and other natural causes. The operation of tree trimming is usually done with **hydraulic wood-cutting** tools by a trained operator stationed in a bucket mounted at the end of an aerial boom of approximately 45 ft in length (Fig. 20.11.4). The boom is a two-link hydraulic arm with up to four joints that is mounted on a specially retrofitted truck. Two sets of controllers for the aerial boom are used in parallel: one in the operator bucket and one on a panel aboard the truck, where a second operator (usually the driver) provides guidance and support from the ground. The operator has the ability to lift the bucket to a height of approximately 45 ft.

Fig. 20.11.4 Slave manipulator and aerial boom.[1]

The operator carries in the bucket a set of tools: **circular saw, linear saw, grappling hook,** etc. The operator can connect one tool at a time to the source of hydraulic power available on the bucket. The tools are handheld, and the operator can perform the cutting operations as needed.

The above-mentioned operations have proved to be dangerous for workers. Occasionally the operator's tool touches live cables, and due to grounding of the boom and bucket, serious injuries of the operator result. There are also cases where the bucket, the upper boom, or the operator come into contact with the cables. Note that in the majority of cases the cables carry 22.5 kV. While there is insulation, and grounding is assumed to be avoided, there are instances where the configuration of the system and the work of the operator generate electric shocks to the operator. In response to concerns for worker safety, a remote master-slave hydraulic manipulator was developed with the intent of relocating workers away from the hazardous tasks. The operator was provided with a handheld controller (the master) located on the platform of the track from where the operator can control the slave (a new five-joint hydraulic manipulator) that is attached at the end of the aerial boom, replacing the bucket where the operator used to be located. An assortment of hydraulic tools can be attached to the slave to enable its use in a variety of high-risk tasks.

The slave is a 5-degree-of-freedom **hydraulic manipulator arm,** and the master is a 5-degree-of-freedom electric arm shaped as a reduced-size replica of the slave. The master is instrumented to provide the operator with torque feedback with respect to two axes of rotation. This allows the operator to feel the forces and moments along and about certain directions at the contact between the tool and branches. Such capability could be extended to a complete (6-degree-of-freedom) force and moment reflection onto the master. The communication between the master and slave is via a fiber-optic cable to ensure electric isolation between the tools and the ground equipment.

The operator is comfortably seated on a swivel chair located on the track bed. The operator has two hand controllers. One is the master of the attached slave, operated with the right hand, and the other is a simpler master that allows the operator to control the aerial boom, operated by the left hand. To achieve this configuration, the aerial boom hydraulic control has been converted from the original hydraulic valves lever controller to a replica master to facilitate operation with only one hand.

The control system of the slave is an open-loop resolved rate controller that transforms commands from the task space (relative to a coordinate frame located at the interface between the tool and a hydraulic coupler that constitutes the end effector of the slave robot). The commands in task space are generated by the master in accordance with the operator's right-hand movements.

To perform the type of tasks described above, there is a need of a hydraulic coupler/adapter designed for quick connect and disconnect of

Fig. 20.11.5 Hydraulic tools.[1]

tools from hydraulic lines with one fitting. The coupler features two lines that can handle a flow at 3,000 psi in either direction and can withstand this pressure when disconnected. A hydraulic tool with tool adapter can be connected or disconnected automatically with a single linear motion simply by pulling or pushing on a locking ring. The same ring can be used for the automatic load/unload operation of the tools. Various hydraulic tools have been retrofitted with an adapter to allow the operator to connect the tools with minimum effort (Fig. 20.11.5). The only drawback is that the operator has to bring the slave down to ground every time a change of tooling is required. This is considered unproductive, and means to alleviate it are being researched.

The slave joints are the shoulder turret, shoulder lift, elbow, wrist pitch, and wrist roll. The base of the slave manipulator is located on a small platform attached to the end of the aerial boom. The platform is controlled in closed loop to maintain its plane perpendicular to the gravity vector. This allows the operator and controller to generate and control the arm movements, respectively, in an unambiguous way.

The slave is designed to carry a radial and axial load of up to 67.5 kg (150 lb). The coupler and the adapter of each tool are locked together with balls and locking ring. For safety, the coupler has an extra security pin which prevents the accidental disengagement of the adapter.

Long-Reach Manipulator Arm

In nuclear reactor installations, there is a need to inspect the structural integrity of supports of critical subsystems, such as the heavy-water boiler. Such a system is located in a closed vault that is not accessible by humans. The walls have a thickness of 7 ft to ensure that no radiation emanates from the vault. Any repair and maintenance operation inside the vault can be done with long-reaching tools that are transferred to the vault via a few cylindrical openings whose diameter is 10 in (25 cm).

To perform operations in the vault through the available openings, specially designed long-reach arms are required and must be fitted with suitable tools. An array of CCTV cameras are also required, mounted on the arm, to provide views of the vault interior, in order to help the operator guide the robot arm by remote control.

A long-reach manipulator arm was successfully designed for this purpose. The robot is modular in the sense that the long-reach arm is formed by a tandem of short linkages that are coupled together to provide different lengths for various tasks and sizes of tools. The maximum length is 21 ft. As the robot has to pass through 7 ft of wall thickness, and it has a base length outside the vault of about 2 ft, it provides 12 ft inside the vault. This was seen as sufficient for most tasks. The tools include various grippers, cameras, grinders, water blasters, and other modules.

In the specific application reported, the manipulator was used to carry ultrasonic equipment that was used to check the structural integrity of some of the support columns. The robot with the sensors attached was inserted into the vault. The robot had to perform two operations. One was to put a rubber cap on an opening at the bottom of the

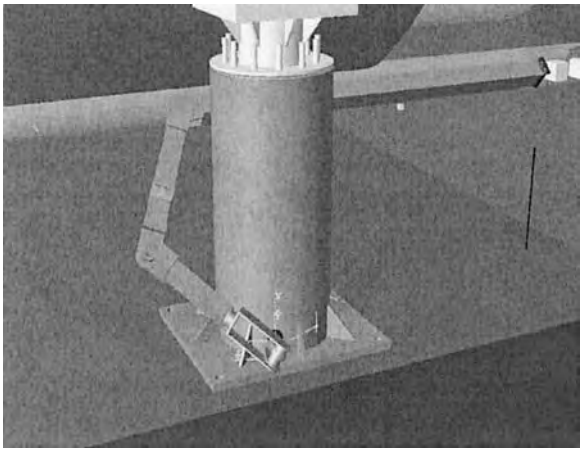

Fig. 20.11.6 Tip of arm reaching the opening of the cavity.[1]

column. This enables filling with water the cylindrical cavity surrounding the support column; it is necessary for ultrasonic inspection. The task of inserting the cup to close the cavity hermetically was very tedious. The operator required hours of training to perform this task. Six cameras were mounted on the arm to help guide the operator movements. After the cavity was sealed and water was used to fill the cavity, the actual inspection took place.

In terms of arm reach, the bottom of the column was the farthest point to be reached by the robot tool. As seen in the schematic Fig. 20.11.6, the robot had to be curled around the column. The operation of inspection also required the robot to traverse the surface of the column, starting from the bottom and advancing toward the top (Fig. 20.11.7). At least four columns needed inspection for every boiler.

Although the portion of the arm inside the cylindrical tunnel was supported by the wall structure, the 12 ft of arm inside the vault was in effect "nearly cantilevered" to the inside edge of the cylindrical opening. However, this cantilever was not rigid, as the arm was free to move around the pivot point at the edge of the opening. This presented a formidable challenge for the designers as well as operators. The designers have oriented each coupler, attaching two adjacent links in such a way that the moments around the axis of the coupler would be balanced by the structure, thus rigidizing as much as possible the arm against structural vibrations caused by the payload and arm links' mass moments of inertia. The result was visible in the camera's images. The robot arm

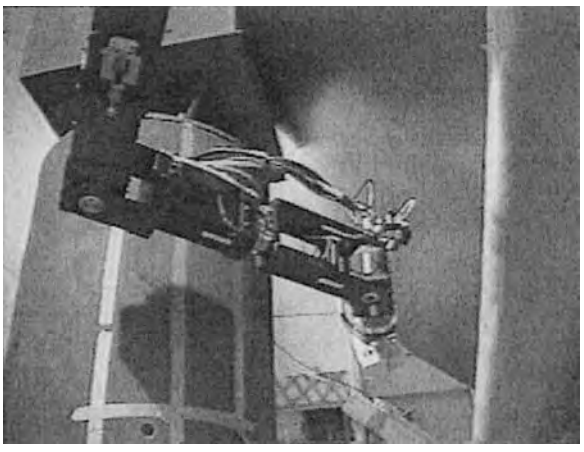

Fig. 20.11.7 Arm carrying the ultrasonic equipment.[1]

was stiff, and the operator could control very well the tip of the tool to perform the dexterous operations of inserting the plug and carrying the ultrasonic equipment at a fixed distance from the surface of the column. Note that if a surface scan was insufficient, then the alternative—drilling into the support to remove a sample—had to be carried out.

The long-reach arm has five joints with zero-backlash harmonic drives: joint 1, roll 360°; joint 2, pitch ±120°; joint 3, pitch ±120°; joint 3, pitch ±120°; joint 4, roll ±175°. Every link has a length between 0.25 and 1.8 m. The links are connected to the joints with quick-connect fittings. The cross section of the link is constrained to fit in a 0.2-m (8-in) diameter. The reach is 1.35 m from joint 2 axis and 4.00 m from the edge of the in-vault opening. The total weight of the arm is 55 kg, and the weight of the largest member of the modular arm is 23 kg.

The lift capacity of the gripper is 7 kg and of the arm at full extension is 10 kg, and the maximum lift is 25 kg. The maximum speed of arm joints 1 through 3 is 15°/s, and of the joints 4 through 6 is 90°/s. The arm motion resolution is 0.5 mm, which is very high for such a long arm.

Modular and Reconfigurable Robot

Industrial robots are used in many sectors of manufacturing and service industries. Other sectors are laboratory automation, mobile robots for security, and aerospace. In all these applications the robots have standard configurations, i.e., articulated, gantry, SCARA, cylindrical, etc. They possess any number of joints, usually between three and six. The mechanical structure is fixed; therefore the acquisition process must take into account present needs as well as future ones, to ensure that the robot can perform required future tasks. In this process it is inherent that the designer of the automatic robotic-based task must consider the requirements conservatively. Often the result is that the acquired robot may have more joints (degrees of freedom) than necessary for the task at hand, or the supplier cannot provide a suitable configuration without exceeding the minimum number of required joints.

As a solution to this problem, technology developers have introduced a new concept: **modular robots.** These robots can be disassembled into a set of modules: joints and links. The joints are usually each a rotary or linear 1 degree of freedom, and the links can have a multitude of cross sections and lengths. These robots can be had as one, two, three, etc., joint arms depending on the application. Implicitly the cost will be determined by the number of such joints that are acquired. Thus, the user can trim the cost to the minimum necessary. This concept allows also acquiring more joints at a later stage in the event that a new task is being automated that may require higher complexity of motion.

There are several published results on this technology. Some providers are limiting their scope to strictly mechanical modularity. Others are also introducing modularity in the computer architecture and embedded electronics. More recently software has been also modularized to allow independent integration of joint modules consisting of electromechanical structure (motor, drive, gear, encoder, brake, torque sensor, embedded controller) that can be easily coupled with links, thus forming an open- or closed-loop kinematic chain.

One technology of the **modular joint (MRJ)** is shown in Fig. 20.11.8 and is described below. The basic module is a single rotary joint. There are also multiple joint modules: three- and two-dimensional wrists.

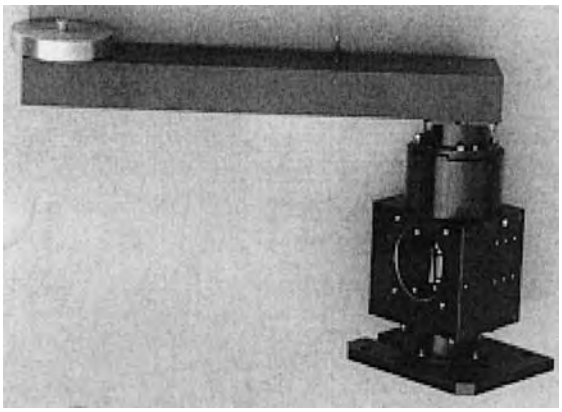

Fig. 20.11.8 Modular joint.

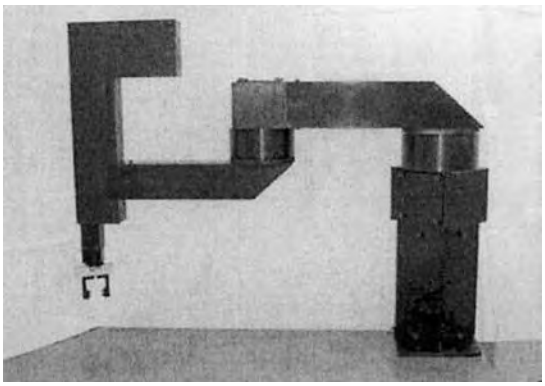

Fig. 20.11.9 Modular and reconfigurable robot (MRR).

The robot configurations that can be obtained from the modules are SCARA (Fig. 20.11.9), articulated, gantry, and various custom configurations of one to five joints. The modules can be assembled and reassembled, thus providing reconfigurability. For example, an articulated four-joint arm can be reassembled as a SCARA robot.

The joints are controlled using embedded software based on PID controls. The assembled robot can be taught points and paths for playback, or it can be programmed in closed loop in the task space, using an inverse kinematic routine that can be run online or based on a lookup table. The kinematics runs on a host PC that is interfaced with the embedded controller via RS-232. The basic specifications of some of the MRJ modules are shown in Table 20.11.1.

The modular wrist specification are shown in Table 20.11.2

Table 20.11.1 Modular Joint Specifications

Specs/Module	MRJ-0	MRJ-1	MRJ-2

Mechatronics

The technology of mechatronics is currently present in the following sectors: military, law enforcement, service food, manufacturing, etc. A few interesting examples are given in this section.

The systems presented are only a small set of niche applications that may inspire new applications to be considered. The main motivation in developing such systems was the need or desire to improve the execution, economics, and quality of human life. The systems presented are focused on hazardous environments where the human may be exposed to danger. The examples cover meat processing industry, tire industry, utilities, biotechnology, and security and defense.

The example from the meat processing industry is representative of situations where the human working conditions generate a reduction in human capability. The example from the tire industry expresses situations where the job difficulty may lead to poor performance. In both cases the result of the deterioration of the human performance on the job may lead to further problems, even to catastrophes. It was imperative to consider some form of automation in such cases.

The example from the domain of utilities provides a number of opportunities to consider automation. In this example repairs to underground gas pipelines are considered. Such operations involve serious disruptions because of excavations, hazard to the human operator because of gas leaks, and major costs that lead to increases in the price of gas distributed to consumers. All these factors could be alleviated by automation.

The examples from the security and defense are the most eloquent in terms of hazard encountered by human operators. The need of remote control tools to maintain standoffs is very timely in dealing with some of the terrorism-related threats in the world today.

Automatic Robotic-Based Meat Grader System

In commercial abattoirs, **grading of meat** is performed routinely to establish the thickness of fat. The grading is performed at a federally legislated point on the back of the carcass. In the case of hogs, that is at 7 cm from the spine between the third and fourth ribs below the neck. The grading is performed with widely used electronic equipment that measures the thickness. The equipment has a long needle that gets inserted manually by the grader. The equipment measures the impedance of the tissue, and the differentiation between the impedance of the fat and that of the meat generates a reading of the thickness. The grading device, operated by a qualified grader, has to be inserted in every single carcass. In the abattoir the carcass are transported attached to an overhead conveyor. The operator must perform the task while the conveyor is moving, at a rate of maximum 700 to 800 carcasses per hour shift in large abattoirs. This work is performed along the cutting line, as one of several steps of preparing the meat for packaging. The work is tedious; the environment is hardened by odors and generally leads to serious fatigue. The operator works continuously only 20 min at a time and rest the next 20 min. Thus two operators are working in every 8-h shift. Large abattoirs have two or even three shifts. The fatigue of the operator leads to inconsistent grading. The insertion of the needle must be done in one stroke, at a certain speed, and the needle must be inserted perpendicular to the surface of the meat. When it arrives at the grading station, the carcass is already split along the spine from the tail down about halfway. The operator inserts an arm between the two parts of the carcass (the carcass back is facing the operator), finds the third rib, and presses a hand against the third and fourth ribs while he or she inserts the needle. Clearly, experience helps the operator to find the ribs, insert the needle between them, maintain the needle orthogonal to the surface, maintain the speed of insertion, and perform the insertion in one stroke. The equipment is connected to a PC, and it registers the carcass number and the grade automatically.[1]

The operation described above measures only the thickness of fat. The meat processing industry has been asked to perform additional measurements indicating the quality of the meat. There are developments currently underway to develop measurement devices for all sorts of meat properties. It is also desirable to effect grading in a noninvasive way. This would preserve the integrity of the carcass surface.

Grading operator fatigue, inconsistency in grading, the need to perform additional measurements, provision for both invasive or noninvasive grading, and the high cost of grading operations have led to considerations of robotic-based automation. A prototype system was built and labeled *Automatic Pork Grading System* (APGS). The choice of developing this system for hogs was the result of collaboration between the developers and a pork processing plant. The approach and methodology are applicable to the red meat industry as well.

APGS replaces the grader in the repetitive and tedious manual task of grading pork carcasses. Only manual grading of fat/lean thickness is performed. However, automatic grading can be performed for fat/lean thickness, PSE (paleness, softness, and exudativeness) characteristics, and marbling content of a fresh pork carcass.

Automatic grading can be performed (1) invasively, by the insertion of a grading probe, at a designated spot identified using ultrasound technology; (2) noninvasively, using ultrasound and infrared technology; and (3) as a combination of both. Manual grading of fat/lean thickness is representative of invasive grading. Noninvasive grading ensures that no cross contamination occurs.

APGS comprises three subsystems: robotic subsystem (Fig. 20.11.10), sensing and probing subsystem, and clamping subsystem (Fig. 20.11.11). The robotic subsystem carries the sensing and probing subsystem which scans the pork carcass, as the carcass is moving along the conveyor line, to (1) locate the designated spot for probing (invasive or noninvasive) and (2) perform the grading. The clamping subsystem automatically clamps the pork carcass as it enters the grading station and presents the carcass at a constant position and orientation during the grading operation performed by the robotic and probing subsystems. The sensor probing subsystem uses a dual-echo ultrasonic technology to detect the probing site and perform the probing.

The APGS is a modular robot. It provides simultaneous multiple probing at several sites on the carcass and/or complete continuous scanning of the carcass. It is flexible enough to be used with any type of commercially available grading probe. The system can work at a very high rate of 1,200 carcasses per hour or 3 s per carcass. The system does not require large floor space. The system is readily expandable to other species such as beef or lamb.

Automatic Robotic-Based Tire Casing Analyzer

Truck tire wear and tear generates a need for replacing them as often as needed. The industry of used tire retreading is growing for a number of reasons, in particular environmental concerns. Tire retreading is a growing business that requires effective detection of used tires that are candidates for retreading.

An **automatic** robotic-based **tire casing analyzer** (ATCA) has been developed. It detects defects and wear. It marks the locations of defects, and it provides a report on the state of the tire. The operator then decides if the tire could be retreaded. For many years, the tire industry has been searching for a nondestructive, simple way to inspect tires and tire casings for flaws. Good casings are presently being discarded and disposed of in landfill sites, causing a detrimental effect on the environment. Or, tires are often prepared for retreading only to discover that the casing has major irreparable flaws. The new technology of ATCA eliminates these problems, resulting in significant economic benefits. The technology is based on an intelligent controller that uses two robotic systems and carries 28 ultrasonic sensors. The controller provides autonomous positioning and guidance of the sensors which are delivered into a tested tire by a very compact foldable robot. The sensor's manifold conforms to the interior shape of the tested tire. Based on the ultrasonic signal, the sensors detect and evaluate defects in the tire. An intelligent algorithm has been developed to evaluate defects; classify them according to size, shape, etc.; and graphically zoom in on a detected defect to be displayed on a computer screen.

The robot arms and sensory arrays have been specifically designed to handle a variety of small and large tires. A sensor protection mechanism has been developed to prevent collisions of delicate sensor arrays with nails that may have penetrated the tire walls. Special low-noise material was used to achieve quality ultrasonic inspection.

The robotic arms are performing the ultrasonic inspection from within the cavity of the tire (carrying the emitters) and over the external surface (carrying the receivers) (Fig. 20.11.12). Loading and unloading of tires are done automatically by the operator using a lifting device.

After loading, the unit starts operating by pressing a set of disks onto the sides of the tire to enclose its inner cavity. Then a foldable robot arm that was stowed inside one of the disks gets deployed internally. The robot arm carries a manifold of ultrasonic sensors that have three segments. The segments get deployed in such a way that the center segment faces the inner side of the tire tread, and the two other face the inner sides of the tire. The manifold positions itself at a suitable distance from the internal surface of the tire to enable ultrasonic waves to penetrate and reach the receivers that are connected on an external manifold mounted on the other robot arm external to the tire. Emitters and receivers are automatically aligned for maximum efficiency. The operation of the ultrasonic sensors, including the positioning and alignment, is fully automatic.

After both the emitters and the receivers are positioned accurately, the tire starts rotating at a predetermined speed to perform the inspection (Fig. 20.11.13).

After the inspection of the tire is finished, the tire stops rotating, and the robotic arms retrieve the sensor manifolds to allow the tire to be removed. The inner robot folds itself into the cavity of the disk, and the outer robot arm lifts the sensors from the proximity of the tire. Immediately the tire is lowered to the load/unload plate, and the disks dislodge themselves from the tire. The operator now rolls the tire off the unit.

ATCA inspects all regular truck tire sizes, regardless of tread depth and pattern, design, or wear. It automatically detects various defects: air leaks, nail holes, ply separation. It can identify internal ply separation of 1 in. The robotic unit is fully automated and operator-friendly and has a short cycle (2.5 min per tire on average). The operator can define the flaw size to be detected, graphically displayed on the computer monitor, and printed out.

Defects are automatically marked on the tire using specially designed paint-based marking unit. Safety and protective devices are incorporated to prevent injury. The outer robot is designed to be compact, to enable fitting the system into a transportation container.

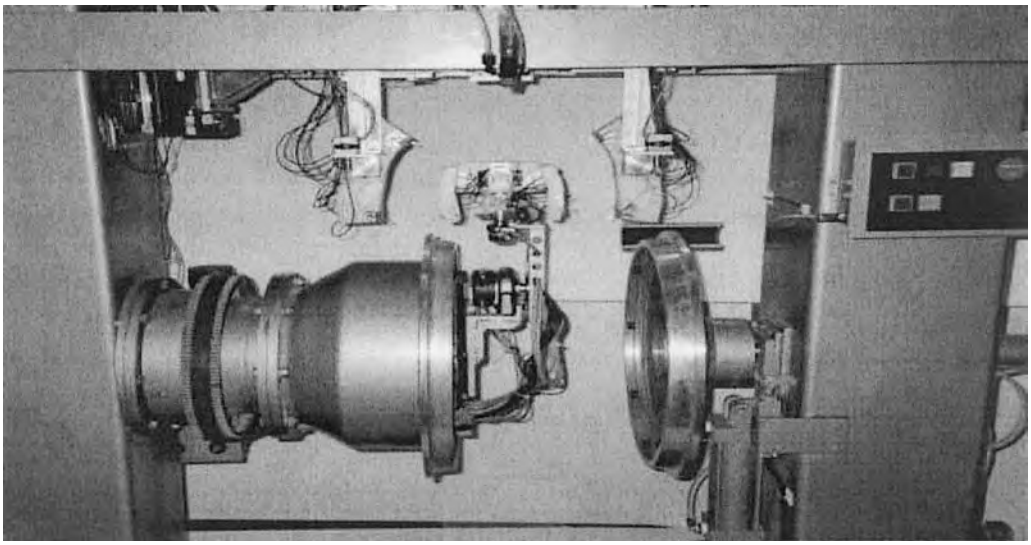

Fig. 20.11.12 View of internal and external robot arms carrying ultrasonic sensors.[1]

Robot for Internal Operations in Underground Gas Pipes

Underground cast iron gas pipes are made out of 12-ft-long sections connected by bell-and-spigot joints. A joint is generally filled with jute packing and sealed with lead. The joint can develop leaks over time and must be repaired. One current most frequently done repair procedure is to inject an anaerobic sealant into the jute packing. This procedure requires a 4-ft × 6-ft excavation at each joint to allow the utility to reach the pipe (in the northeastern United States and Canada the pipes are 8 ft deep in the ground), drill a hole through the bell into the jute, and inject a measured quantity of anaerobic sealant. Such a process is hazardous, laborious, and costly, and it interferes with transportation and pedestrians in urban areas.

To alleviate the above problems, a novel technique was developed to perform cast iron bell-and-spigot joint sealing from inside the pipe, using a remotely controlled robot. The robot is launched into the pipe through a special opening, travels inside the pipe until a desired joint is reached, and drills a hole into the joint spigot at the highest point. Then anaerobic sealant is injected into the jute packing to reseal the joint. This approach replicates the repair procedure currently done externally. The sealant flows under gravity and saturates the jute. The operation is done while the main is kept in service.

The new internal sealing system is capable of sealing several joints from a single excavation while keeping the main in service. The system has been designed for 6-in- (15-cm-) diameter pipes. It can be inserted into the main up to 150 ft (over 45 m) in each direction from the entry

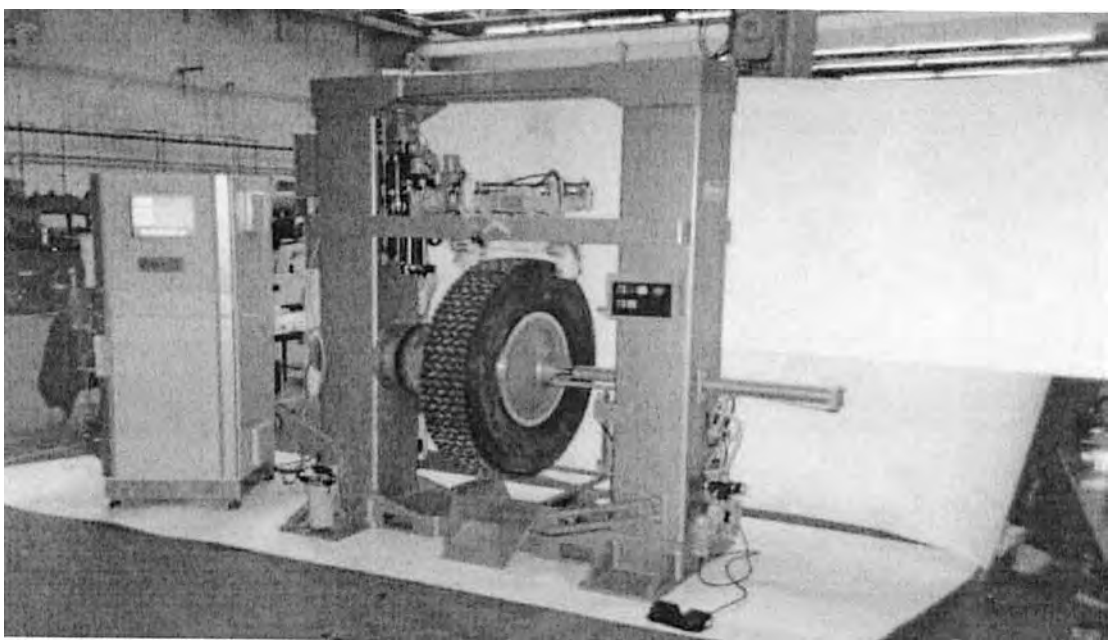

Fig. 20.11.13 General view of ATCA.

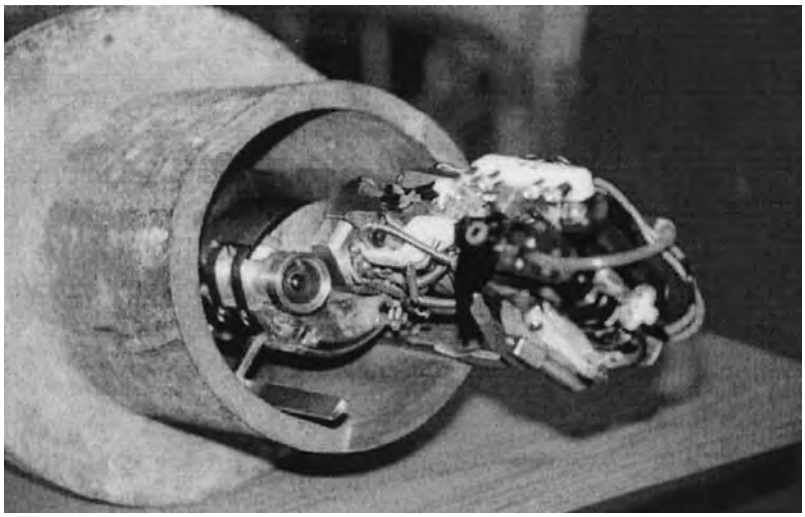

Fig. 20.11.14 View of the gas pipe robot end effector.[1]

point. Up to 24 joints can therefore be sealed from a single excavation. Adaptation of the concept to larger pipe diameters (up to 36 in) has also been performed using a different methodology of moving inside the pipe.

The joint sealing system consists of a small robotic working head (Fig. 20.11.14) equipped with a video camera for search and joint identification, an umbilical cable, cable insertion unit, system storage reel with the tool control components, and an operator's station that includes a control panel and video monitor. In operation, the robot head is inserted into the main through a small tap, and pushed along the pipe by its motorized umbilical cable. The operator visually locates the desired joint and positions the robot at the joint. The robot head is then raised into drilling position, and a small hole is drilled through the spigot into the joint cavity. Next the sealant head is rotated into position, and a measured amount of sealant is injected into the joint. The head is retrieved, and the unit is then moved to the next joint.

The robotic tool head is inserted through a small tap, using a custom-designed saddle. Semirigid umbilical cable is used to push and control the tool head position. The umbilical cable is stored on a custom-designed reel. A miniature video camera mounted on the tool head is used to locate each joint for sealing.

The operator's station is provided with a control panel and video monitor, allowing remote control of the tool head for drilling and sealant injection.

The operation of the robot is as follows. The excavation is performed by a crew designated by the gas company. Then the robot system operator crew takes over the operation. First it drills an opening of about 3-in in diameter into the pipe. This drilling is done nonrobotically with specialized equipment that prevents gas emission. This equipment has been also developed by the robotic design group. The drill unit is held within a cylindrical guide that is attached to a saddle that covers the pipe. The saddle has been designed for this task. The saddle is mounted first, followed by the cylindrical guide. The guide has a tap that closes one end of the guide to prevent the gas from emanating during the drilling. The same guide and valve are used to guide the robot head into the pipe and avoid emission during the operation of the robot.

Two openings are drilled side by side. Each is tilted toward one or the other side of the pipe. The tilt helps insertion of the robot head and umbilical cord. After the drilling operation is finished, the drilling equipment is removed, and the robot is inserted. The robot has skids to slide at the bottom of the pipe. These skids are folded during the insertion into the pipe, and they deploy automatically after the head has entered the pipe fully. The head is pushed into the pipe by the automatic umbilical cord. The cord is stiff longitudinally, and compliant radially, allowing it to curl on a storage drum for transportation. When the robot reaches a joint that needs to be sealed, the operator stops the robot and lifts a small drill vertically up. The operator positions the drill bit at a location convenient for anaerobic insertion. The drill bit is automatically lifted and pressed against the surface of the pipe. The drilling into the spigot takes approximately 2 to 3 min. The operator maintains a visual observation of the process. The drilling is monitored in closed loop by a force sensor. When the drill has penetrated the wall, the force decreases and the drill stops. Then the system retrieves the drill, rotates the end effector, and brings the anaerobic flow line (activated pneumatically) in line with the hole. The system lifts and presses the anaerobic flow line end onto the opening secured by a specially designed gasket that prevents backflowing, and the anaerobic starts flowing. The flow is controlled in closed loop by a pressure differential sensor. The sensor indicates that the pressure has reached a maximum which implies that the joint is filled with anaerobic material.

DNA Microarrayer

A **DNA array** is a generic name covering different molecular biology products and techniques. It can be described as a manifold of DNA fragments (spots) of oligonucleotides at low, medium, or high density. DNA arrays are used as research or diagnostic tools. The array of DNA fragments on a solid surface allows detection of the expression of thousands of genes in a single experiment. The gene array technology is becoming one of the most common techniques used in all molecular biology laboratories.

The advantages of DNA array technology include the simultaneous analysis of a large number of genes in a single experiment; quantitative and reproducible results; speeding up of basic biological research and disease diagnosis; reduction of time, cost, and risks associated with discovery and development.

In terms of technology used to make DNA arrays, there are three methods: (1) photolithography method that is based on site oligonucleotide synthesis; (2) microspotting with quill pins; and (3) ink jetting. The spotting tools are split/quill pins, solid pins, piezoelectric pins, capillary, and ring-and-pin systems. The support used for DNA arrays can be nylon membrane, polypropylene membrane, or glass slides. The methods of DNA binding to the support are based on electrostatic and hydrophobic interactions with covalent links. For detection of gene expression, first cDNA is spotted onto the slides, then the target DNA is hybridized with the cDNA, and the expression is identified through probe labeling: radioactivity (^{33}P) and fluorescence (CY 3 and CY 5), and subsequent detection (reading of color intensity).

The applications of the DNA array are in research and clinical use, such as mapping and genotyping of single-nucleotide polymorphism in the human genome; disease diagnosis: tracking mutation in genes involved in many cancers (p53, BRCA1, BRCA2, etc.); viral, bacterial, and fungal infections: species assignment and detection of drug-resistant strains (HIV, *Mycobacterium* sp, *Candida* sp, etc.).

Robot spotters have been developed for DNA spotting on glass slides. A particular spotter has a large spotting surface (75 or 126 slides), and modular and reconfigurable structure, is able to spot up to 83,000 spots per 25-mm × 75-mm slide, and is capable of performing other biolaboratory tasks such as arraying, gridding, rearraying, and pipetting. The robot is a cell based on a high-quality three-axis gantry robot, with 1.25-μm resolution of motion along each axis, and impedance control to avoid high impact forces at the contact between the slide and the pin. The system has a repeatability of 3 μm and high bandwidth communication with the controller. There is no heating or vibration, and the speed is 1 spot/slide/pin (61,000 genes are spotted in 3.5 h). The slides can be 25 × 75 mm, 20 × 25 mm, or 50 × 75 mm. Also 1 to 8 microtitter source plates and one to six small membrane holders can be used along with up to 126 slides. The cleaning of the pins between loads is done in a water bath that uses active water pump for cleaning.

A vacuum chamber is used to dry out excess material from the quill pins and dry off the water after washing them. A blotting pad is used to eliminate excess material from the pins before spotting. The quill pins have long life (1,000,000 spots). They generate 75- or 90-μm-diameter spots. Each pin can be replaced individually, and up to 250 dots per sample/one dip can be obtained.

Environmental control is provided with a positive-pressure HEPA Fun Filter and PPHC humidity controller (limits evaporation and fast drying of the spots).

The motion controller is based on an embedded PC-104/Pentium. A graphical-user interface is used to program the spotter and monitor the execution. The host computer is based on Pentium/Windows NT. The host controller module can be at a remote location. The graphical-user interface is intuitive and Windows-based for easy control of number of slides, rows, columns, array patterns, dots per row or column, speed, spotting order, type and direction of source plate or membranes, number of pins, etc. Simple robotic language is used for programming the robot.

There are specialized options such as electronic pipetting, colony picking, stacker for multiple source plates, etc.

The robot (Fig. 20.11.15) is designed to collect DNA from 96- and 384-well source plates; 1 to 48 pins (Fig. 20.11.16) can be used simultaneously.

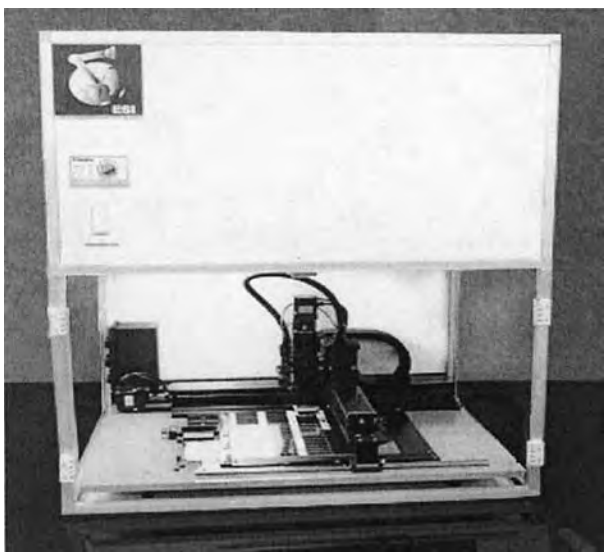

Fig. 20.11.15 DNA microarrayer.[1]

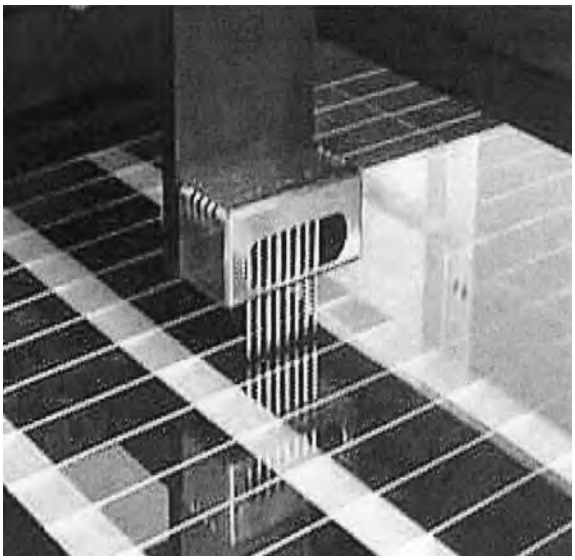

Fig. 20.11.16 Manifold of up to 48 quill pins.

Each pin collects 250 nL of solution and spots 0.6 nL per dot on 75 to 126 microscope glass slides. The center-to-center distance is 120 μm.

Gridding can be performed on up to 15 nylon filters. The filter is standard size equal to 96/384-well plate size. The number of spots per standard filter is maximum 6,144.

Pipetting to and from plates 96/384 can be executed with electronic pipetters in volumes from 0.2 to 200 mL with an accuracy of 10 percent. The pipetters are assembled on manifolds containing four pipetters.

Rearraying can also be performed on 96 and 384 plates also in volumes of 0.2 to 200 mL.

Mobile Robot for Explosive and Ordnance Disposal

Police, military, ERT, fire, nuclear, and other hazardous response personnel require remote-controlled equipment for standoff in dealing with explosives, ordnance, and other hazardous materials. The remote-controlled equipment consists of a mobile platform, video equipment, a robot arm mounted on the platform, and a series of auxiliary operational tools such as firearms, disrupters, and X-ray units and associated means of attaching them to the arm or platform. As well, such a system includes an **operator control unit (OCU)** that includes cable and wireless communication with the platform, video monitor, means of controlling the platform and arm, as well as activating the operational tools. The communication covers data, video, and audio links.

The platforms and arms come in various sizes. The platforms are usually anywhere from 60 to 135 cm in length and from 45 to 66 cm in width. The arms can have a reach from 0.8 cm to 2 to 3 m. The payload capacity varies from 5 to over 75 kg depending on the configuration of the arm. The total weight varies from 25 to 350 kg. The speed of the platform varies from 2 km/h to more than 10 km/h.

This class of robots is subdivided in three major groups: small, medium, and large. There are commercial suppliers for each category. The small category is mainly used for reconnaissance and surveillance. It is usually not used with an arm. The large category addressed large payloads, ammunition firing, and other hazardous tasks involving heavy payloads. The medium category is used for a mix of operations, some pertinent to the small robots and others to the large ones.

These **mobile robots** could be used for surveillance, reconnaissance, handling of hazardous items, manipulation of suspected packages, neutralizing and handling such items as improvised explosive devices (IEDs), hazardous chemicals, and radioactive materials. They are all-weather, all-terrain mobile robots that can be used indoors (buildings,

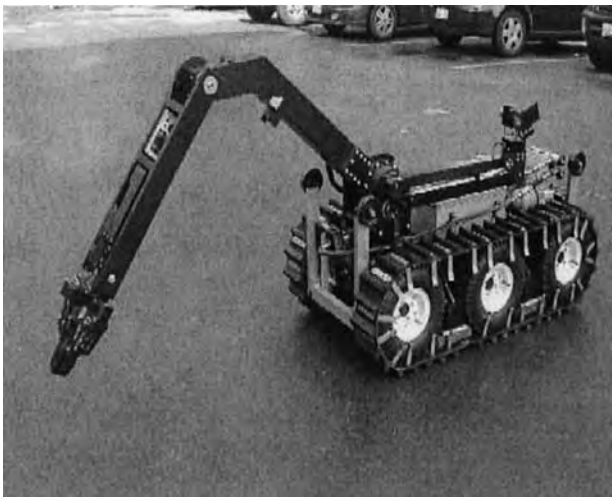

Fig. 20.11.17 Mobile robot with arm deployed.[1]

public institutions, airports, homes, etc.) and outdoor environments (terrain cluttered with obstacles, ditches, gravel, snow, mud, etc.).

The mobile robots have special features: some use only wheels for traction, others use tracks, yet others use quick-remove tracks that can be mounted or dismounted very easily. The tracks, permanent or removable, are necessary for climbing stairs and obstacles.

Other special features are related to precise independent joint control, high dexterity of arm (Fig. 20.11.17), long reach, high payload, open computer architecture for integrating biochemical sensors, and options for autonomous navigation. In terms of control, the operator has the choice to control the arm in joint or task space. The platform is always controlled in task space, by coordinating the motion of the wheels. Typically the platform has two motors, actuating two wheels, one on each side. The other wheels are rotated by chain or other means of transmission.

In terms of mobility the platform is equipped with four or six wheels (Fig. 20.11.18) and a set of fixed or removable tracks. The tracks are used for rough terrain and stair or slope climbing. The robot is able to turn on the spot and maneuver precisely in an obstacle-cluttered area.

Fig. 20.11.18 Mobile robot with arm stowed.[1]

The drives also feature a drive hub, which can disconnect the drive from the wheels to facilitate handling of the robot if necessary.

The robots are remotely controlled by a wireless or cable link; cable link has an onboard automatic winding cable system or an independent reeled cable system. Two-way data and audio and one-way video links are usually available. Up to four cameras and a microphone provide the operator with images and sounds of the environment. A surveillance camera can be mounted on the arm (low to the ground, high in the air, close or far from the gripper) or on a separate articulated boom (usually positioned vertically up).

The wrist/gripper of the arm can be configured to perform operations such as aiming and firing disrupters, pushing heavy payloads, reaching under cars or through car windows, and breaking windows. The robot can insert a car key to open car doors and turn on the car engine, unlock and open building doors, manipulate sensory devices for inspection and surveillance, and handle delicate or hazardous materials. A force-controlled high-quality gripper provides dexterous handling capability.

The robots are water-resistant. Some are even amphibious. All exposed surfaces are covered with anodizing or protective paint. All detector and electronics compartments are protected against water and contaminants. They can operate in all types of weather conditions, day and night, and various types of wet and dry surfaces. Operational temperature range is usually from -20 to $+45$°C. Environmental humidity can be up to 90 percent at 25°C. Storage temperature range is from 0 to 45°C.

This type of mobile robot was further developed as semi- and full autonomous vehicles. As well, certain arm movements can be automated. In terms of platform, features have been developed such as programmed motion (straight line, circular, pivoting), movement in reference to compass, GPS, and land markers. These movements can be controlled in closed-loop or in resolved rate control mode. For the arm, there are automatic movements such as deployment from stowage configuration and vice versa.

Mobile Robot for In-Ground Mine Detection

An articulated remote-controlled mobile manipulator has been developed to scan autonomously off-road and unstructured terrain for buried land mines and explosives. The robot consists of a dual-arm manipulator mounted on a six-wheel mobile platform, a mine or explosive detector, range sensors, terrain-mapping software, and hardware and software for communication, data transfer, and control. The platform can be used also with tracks mounted over the wheels. The tracks help in climbing steep slopes and moving over very rough terrain. The platform can be operated in remote control, semiautonomous, and autonomous modes. The terrain map is generated with respect to a range sensor frame to minimize the computational load in real time. Sensors scan and measure the range with respect to the terrain and relative to the reference coordinate frame. Also the normal direction to the terrain is computed in real time. Based upon the terrain map that is generated in real time, the mine detector's position and orientation are controlled such that a desired (constant) separation and orientation with respect to the terrain is maintained.

One of the dual arms, the *detector arm* (DA), holds the mine or explosive detector (e.g., metal detector, ground penetrating radar, or a nuclear quadripole resonance instrument) that is manipulated autonomously. A plurality of mine detectors can be mounted on the DA. The autonomous motion of the DA is synthesized and controlled online based on the three-dimensional map of the terrain. The map is generated in real time by fusion of sensory data acquired from a scanning laser range finder, an array of four ultrasonic sensors, and joint encoders of the dual arm.

The range finder, a motorized scanning mirror, and ultrasonic sensors are mounted on the other articulated arm, the *sensor Arm* (SA). The SA has a pan joint that allows it to be positioned relative to the DA such that it always scans "ahead" of the DA (Fig. 20.11.19).

The DA holding the detector can maintain it at a desired constant vertical distance from the ground irrespective of undulations of the a priori

Fig. 20.11.19 Mine detector arms: DA and SA.

unknown terrain profile. As well, the DA can maintain the detector orientation constant with respect to the unknown terrain.

The terrain map is generated in real time by using a laser range finder, an array of four ultrasonic sensors, and some joint encoders of the dual arm. The map is generated with respect to the range finder's reference frame (Fig. 20.11.20). The map generation is preceded by image registration that is a fusion of data acquired from the sensors. The map is used to generate the path of DA. Before being used, the map is filtered and enhanced algorithmically (statistically and via fuzzy logic). The fuzzy logic uses a database of terrain signatures. The path of the DA is used to generate the commands of the DA joints that would maintain the detector at the desired separation and orientation relative to the terrain. The DA performs the scanning autonomously.

The performance and reliability of the detection process largely depend on the scanner distance from the terrain, orientation with respect to the terrain, size, scanning speed, and associated filtering and data acquisition software. The scanning involves motion of the sensor manifold (usually a relatively large plate) at constant speed, while maintaining the plate at a constant distance from the ground and in fixed orientation relative to the ground (the detector plate's normal is parallel to the local terrain normal).

The scanning is difficult to perform autonomously because of uncertainties involved in detection of terrain undulations. The uncertainties are estimated in real time (map filtering).

A variety of mine or explosive detectors and terrain scanning sensors can be mounted and interfaced. The entire system (sensors, dual arms, and operational software) is portable to various mobile platforms and vehicles.

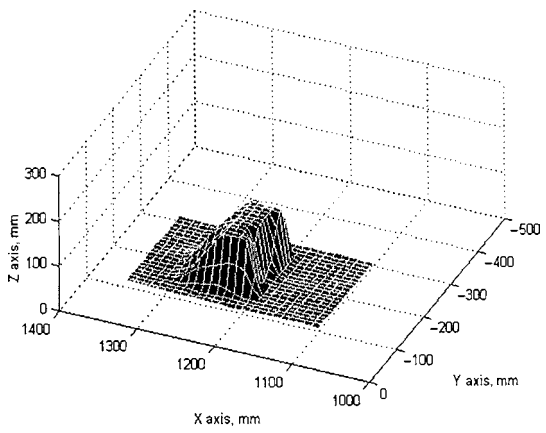

Fig. 20.11.20 Terrain map generated by the robot.

The detector arm is an articulated arm with 5 degrees of freedom. Four degrees of freedom are sufficient to move the detector along an arc (i.e., a side-to-side scan), at a constant distance from the ground and parallel to the terrain profile (i.e., the normal of the detector plate is parallel to the local normal of the terrain). The fifth degree of freedom corresponds to a linear motion that supersedes the mobile platform motion when the arms are advanced while the platform is stationary.

The sensor arm carries a laser range finder, two ultrasonic range finders mounted vertically, and two range finders mounted horizontally. The measurements of the latter are used to prevent the collision of the arms with sidewalls when the robot is scanning hallways and narrow passages. The laser range finder and the two vertical ultrasonic range finders measure the distance of the sensors from the ground. These measurements are fused to the joint encoder data to generate a range image of the terrain map. The map is generated locally and online by using a periodic map-building procedure. The ultrasonic range finders move along the arc of the side-to-side scan but do not scan the terrain across the arc. Moreover, the ultrasonic range finders measure the minimum distance of the terrain from the sensors in a region covered by the ultrasonic cones. Thus, the measurements of the ultrasonic range finders cannot be directly used in the range image, but they can be fused to the laser measurements to reduce the uncertainty.

TECHNOLOGICAL UPDATE ON SOME EMERGING APPLICATIONS

Emerging applications of intelligent automation can be found in several sectors such as space, medical, security, and biotechnology. They utilize (1) technology of robotic arms that are embedded in automatic cells, (2) cells that are integrated based on mechatronics technology, and (3) the capability of machine adaptation and learning, thus providing intelligent automation.

In the domain of space, a consortium of major players in the sector is currently developing the Space Mobile Station (SMS). On the station various docking ports and remote-controlled manipulators will be used. One such manipulator is the Special Purpose Dexterous Manipulator (SPDM). This has dual arms with two similar branches, each consisting of seven joints. Seven-joint arms are labeled in the literature as *redundant*. They provide excess degrees of freedom that allow one to effect a task in many ways (configurations). This property can be utilized to perform the tasks in an optimal way by selecting from the many configurations one that optimizes a certain criterion. For example, minimum energy consumption could be used as a criterion in selecting the robot configuration.

The SPDM will be used on the SMS to perform manipulation, assembly, and other tasks that require two arms working in coordination. The domain of coordinated arms is not new in the context of industrial robots, but it presents a new challenge in space robotics.

In the medical field, intelligent automation began being utilized in the 1980s in two domains: surgery and orderly help in hospitals. The latter is based on various mobile autonomous guided vehicles (AGVs), some with an arm mounted for delivery of food, medication, and other necessities to the hospital beds. The former is growing very rapidly by introduction of newly designed robotics in operating rooms. Initially robots were used to perform life-threatening procedures such as brain biopsy in neurological surgery. Later, knee and hip replacement surgery with robotics became standard. Currently laparoscopic surgery is performed in abdomen and thoracic-related surgery. As well, methodologies of surgery with robotic tools are being developed for the brain, heart, prostate, and breast. Some of these procedures will be performed under MRI inside close-bore MRI for best imaging. This requires the development of MRI-compatible equipment, as well as remote control of the surgical tools because of the location of the surgical team in a room adjacent to the MRI, and control of the procedure through computer monitors and master controllers, such as joysticks and pushbuttons.

In the security domain, new technology for standoff and inspection is being developed. There are developments related to inspecting, by

remote control, the interior of passenger cars and trucks. Other developments address the need to negotiate in the event of terrorist-related hostage situations. In the military, there is an acute need for remote devices that can detect and neutralize improvised explosive devices (IEDs). Various unstaffed ground and aerial devices are being developed that could detect IEDs, in-ground mines, and unexploded ammunition. Other technology is being developed for removing the hazardous material after detection.

In the domain of biotechnology, drug discovery and structural proteomics are leading the effort in research and development. There is a need for a wide range of automated equipment to accelerate the drug discovery processes via research in proteomics. Structural proteomics is a crucial domain of molecular biology in the context of drug discovery. Equipment that can perform reliably tens of thousands of experiments each day is being developed using robotic arms, mechatronics cells, and intelligent automation, such as fuzzy-logic-based identification of patterns in the genetic map of humans for detection of predisposition to certain chronic diseases.

In the general domain of intelligent automation, there are developments of mobile robots that climb walls to wash high-rise windows, autonomous vacuuming of floors, robot arms used in the construction industry, modular laboratory equipment that can be carried home by students for studying intelligent automation, automatic guidance of the visually impaired, etc.

TRENDS AND SUMMARY

This section has discussed the related fields of robotics, mechatronics, and intelligent automation, and illustrated them by presenting some selected niche applications. Many other applications would serve the same purpose. The aim was to support the view that these fields have a great impact on humanity, and the opportunities for further developments in these emerging domains are tremendous. Opportunities abound in this domain both scientifically and commercially. There is a great entrepreneurial spirit in conjunction with these areas, as the technological progress made in the last decade has generated extraordinary scientific and commercial activities. Education and research in colleges and universities also have been harnessed onto this wave of technological development, leading to a significant increase in the number of students, publications, patents, and commercial spinoffs.

The domain has achieved significant results, and it continues to evolve as new applications are emerging. The new applications mentioned in the section "Technological Update on Some Emerging Applications" are only representative of the thrust. They are only illustrating this exciting domain of science and engineering. Furthermore, they are demonstrating the interdisciplinary nature of this area of technology.

Nonetheless, there are some main issues that require more thorough consideration as to the best way to accomplish the proliferation of intelligent automation in every sector of life. Already, medicine, security, manufacturing, education, all major sectors of human life and economy, are subscribing to the era of intelligent automation. There is a need to extend this list to services, rehabilitation, entertainment, and other items. This may be possible only if opportunities are provided, human resources are available, and the economics are favorable for developing new technology to serve humanity in the most effective way.

20.12 RAPID PROTOTYPING

by Ali M. Sadegh

In the process of product development in a **computer-aided design** (CAD) environment, when a design concept has been tested and a virtual prototype (solid model) has been created, a physical prototype is needed for testing. This stage of the process is called **alpha prototype** testing. The alpha prototype is a replica of the part showing principal geometric features, such as all the dimensions, slots, cavities, and surface texture. In the case of a device or a machine, the interaction between parts of the device or the machine could be tested with the alpha prototype. The next step in the product development is **beta prototype** testing, where limited full-scale parts are made with planned manufacturing processes and are examined and tested by volunteers or customers in actual operation condition of the device. In the end, the parts or the devices are made with the final materials and processes and are tested in an independent laboratory or limited (selective) market.

Traditional alpha prototype manufacturing utilizes common materials including metal, woods, clay, ceramics, construction papers, and polymers with machining and metal forming. This method requires craftsmanship; it is time-consuming, labor-intensive, and costly.

During the last decade, a class of technologies known as **rapid prototyping** has emerged that can automatically construct physical models, the alpha prototype, from computer-aided design (CAD) data. Rapid prototyping is an alternative technology that uses computer-controlled equipment to automatically and rapidly fabricate prototypes. These technologies have dramatically reduced the time needed for the design and product development.

Rapid prototyping (RP), also referred to as **three-dimensional printing,** or 3-D printing, allows designers to quickly create tangible prototypes of their designs. These prototypes are excellent visual aids for communicating ideas with coworkers or customers and even testing the functionality of devices or machines. In addition to prototypes, RP techniques can also be used to make tooling for a manufacturing process (referred to as **rapid tooling**) and even production-quality parts (**rapid manufacturing**). For small production runs and complicated objects, rapid prototyping is often the best manufacturing process available.

Clearly the word *rapid* is a relative term, since most of the 3-D printing machines take from 1 h to more than 48 h to build, depending on the size and complexity of the part or the device. There is significant time saving compared to the few days or few months that is required for traditional prototyping.

The principal operation of a majority of rapid prototyping machines is the **layered manufacturing process.** That is, a software package "slices" the CAD model into a number of thin (about 0.003-in or 0.1-mm) layers, which are then built up one atop another. Of course, because of the machine dimensions, the size of the prototype is limited. Part volume is generally limited to 5,000 in^3.

RAPID PROTOTYPE PROCESS

The following steps are required to construct and build a prototype through rapid prototyping machines.

1. **The solid model.** Through the use of any computer-aided design software, the solid model of the object should be created. Then the solid object should be converted to the STL format, explained next.
2. **The STL format.** The software format of stereolithography (STL), which was the first RP technology, has been adopted as the standard of the rapid prototyping industry.

This format represents a three-dimensional surface as an assembly of planar triangles. The file contains the coordinates of the vertices and the direction of the outward normal of each triangle. The CAD file should be transferred to the **STL format** with the extension .stl, which is universal for all of the RP machines.

3. **Creating layers from STL file.** Rapid prototyping machines generally have a preprocessing program that slices the STL file. Each RP machine has its own solid modeler, which allows users to alter the scale or some dimensions of the model as well as place the object in a desired orientation to be built. The preprocessing software then slices the STL model into a number of layers from 0.01 to 0.7 mm thick, depending on the RP machine's precision. In case the solid model has overhangs, internal cavities, or very thin-walled sections, the program may also generate an auxiliary structure to support the model during the build. The materials used for the structural support are generally very fragile and could be taken out easily through a cleaning process.

4. **Construction of the object.** Through several techniques (presented below), each sliced layer will be constructed from different materials such as paper, plaster, polymer, or powdered metal. Each layer is glued, fused, or sintered to the previous layer. Finally the object is built when the construction of all the layers are completed. Almost all the RP machines are autonomous and build the object without intervention.

5. **Cleaning.** After the object is built, it is removed from the machine by detaching any support for the object. Some photosensitive materials need to be fully cured before use. Prototypes may also require detaching the structural supports through cleaning and surface treatment. In some cases, sanding, sealing, and/or painting the model will improve its appearance and durability.

RAPID PROTOTYPING TECHNIQUES

Since the early 1980s, several technologies have been patented and developed. However, most commercially available rapid prototyping machines use one the following techniques.

• **Stereolithographic apparatus (SLA).** The stereolithography technique, which was first patented in 1986 by 3D Systems of Valencia, CA, revolutionized the rapid prototyping technology. The commercial machine is called stereolithographic apparatus (SLA). It uses a high power laser to selectively solidify a liquid photopolymer, layer by layer, into the shape of the finished prototype. In essence, the SLA machine is a **material additive process** in nature where the polymer solidifies when exposed to ultraviolet laser. The model is built upon a platform situated just below the surface in a vat of liquid epoxy or acrylate resin.

Through a series of servocontrolled mirrors, as shown in Fig. 20.12.1, the laser is guided and shone on the liquid photosensitive polymers to solidify the top layer, leaving excess areas liquid. Then, an elevator incrementally lowers the platform into the liquid polymer. A sweeper recoats the solidified layer with liquid, and the laser traces the second layer atop the first. This process is repeated until the prototype is complete. Once the very top layer of the object is completed, the elevator raises the platform and the part is removed from the vat and rinsed clean of excess liquid. Supports are broken off and the model is then placed in an ultraviolet oven for complete curing. Figure 20.12.2 shows samples of final products.

• **Fused deposition modeling (FDM).** This is a process that deposits thin beads of melted (fused) thermoplastic materials (filament), and is generally extruded from a tip that moves in a horizontal plane. As the material solidifies, a prototype model is built, layer by layer, typically up to 10 in. by 10 in. in cross section and up to 16 in. high.

The platform is maintained at a lower temperature, so that the thermoplastic quickly hardens. After the platform lowers, the extrusion head deposits a second layer upon the first. Support structures are built along the way. Materials used in this process are high-strength ABS plastic, standard ABS, elastomers (96 durometer), polycarbonate, and polyphenylsulfone. To remove the supporting structure, parts are postprocessed by mechanical agitation in a warm water solution.

• **Laminated object manufacturing (LOM).** In this method each slice of the model is cut (from thin layers of paper, polymer, or sheet metal) using a numerically controlled laser. The slices are bonded together with adhesive materials to form a prototype. After each layer is put on top of the previous layer, a heated roller applies pressure to bond the material (paper) to the base. Then, the platform lowers the object to prepare for the next layer. This process is repeated as needed to build the part. LOM prototypes can be sanded to reduce jagged edges; however, they cannot be rigorously tested. This technique was developed by Helisys of Torrance, CA.

• **Selective laser sintering (SLS).** This technique employs a laser beam to selectively sinter together fusible materials such as powdered metal, nylon, and elastomer. **Sintering** is the heating and fusing of

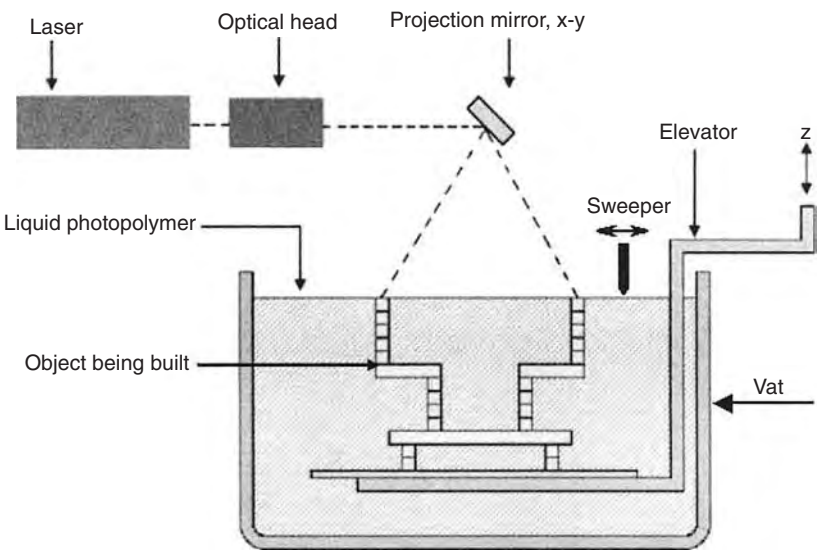

Fig. 20.12.1 Schematic diagram of stereolithography.

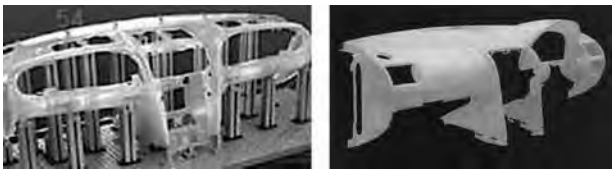

Fig. 20.12.2 Samples of products built by stereolithography.

small particles resulting in a hard bonded layer of material. The laser beam traces the pattern of the first layer, sintering it together. Then, the platform is lowered by the height of the next layer and powder is reapplied, and once again the laser beam traces the next layer, which is fused to the previous layer. This process continues layer by layer until the part is complete. The unsintered powder supports the part as the layers are sintered. The University of Texas first patented this method in 1989.

• **3-D Inkjet Printing.** In this process an inkjet printing head deposits or "prints" glue-like binder on a thin layer of powdered material. The binder fluid fuses the powder together in a desired area, to form a layer of the part. As the platform is lowered, more powder is added and leveled, and the inkjet head prints (despites) the binder to form another layer of the part. Layer by layer, the part is built. Unbounded powder remains to support the part. When the part is finished, it is removed from the container and the unbound (excess) powder is blown off. The resolution of each layer is about 0.1 mm. This process is relatively fast, and produces parts that are somewhat fragile, unless the part is coated with wax, Cyanoacrylate (CA) glue, or other sealants to improve durability and surface finish. This process was first developed by MIT. The ZCorp 3D printer, produced by Z Corp., uses two different materials: a starch-based powder (not as strong, but can be burned out, for investment casting applications) and a ceramic powder.

APPLICATIONS OF RAPID PROTOTYPING

Because of the time and cost savings, rapid prototyping machines have revolutionized product development processes in many industries such as automotive, aerospace, medical, and consumer products. Although the rapid prototyping applications are vast, almost all fall into one of the following categories: prototyping, rapid tooling, or rapid manufacturing.

Prototyping Rapid prototyping (RP) plays an important role in quickly making prototypes for communication and alpha prototyping testing purposes. While solid modeling of an object in computers and engineering drawings helps one to understand the function of an object, clearly, touching and feeling the actual prototype of the object dramatically improve communication among people, including engineers.

Rapid Tooling *Rapid tooling* (RT) is a process that employs rapid prototyping models, directly or indirectly, to create a mold quickly. The mold could be used for a limited volume of alpha or beta prototypes. Rapid tooling is less expensive and requires less time than conventional fabrication of tooling. Note that conventional tooling is one of the slowest and most expensive steps in the manufacturing process, since it requires a high level of precision. Typically with RT, the time needed for the fabrication of the first articles is below one-fifth that of conventional tooling and the cost is about 5 percent that of the conventional tooling. The disadvantage of rapid tooling is that the tool life is considerably less than that of a conventional tool.

Indirect Tooling RP parts are also used as patterns for making molds and dies. RP models can be indirectly used in a number of manufacturing processes:

Vacuum casting. This is the simplest and oldest rapid tooling technique. A RP positive pattern is suspended in a vat of liquid silicone or room temperature vulcanizing (RTV) rubber. Specifically, silicone liquid is cast around a master model that is typically made by a rapid prototyping machine (preferably SLAs). A partial vacuum is applied to avoid air bubbles that may be trapped in between the master and silicone. After curing, the mold is cut open and the master (SLA) is removed, leaving a cavity to make copies. The flexibility of the silicone allows limited undercuts, which might avoid slides or additional parting planes. Vacuum casting is a copying technique typically used for the production of small series (10 to 20) of functional plastic prototypes. An alternative approach, known as the Keltool powder metal sintering process, uses rubber molds to produce metal tools. When the binder cures, the "green" metal tool is removed from the rubber mold and then sintered. At this stage the metal is only 70 percent dense, so it is infiltrated with copper to bring it close to its theoretical maximum density. Note that vacuum molding is a different process where, through suction, a sheet of plastic or metal is forced to conform to a preset shaped mold.

Injection molding. To prepare a mold for an injection-molding machine, first a stereolithography machine is used to make a matchplate positive pattern of the desired molding. To form the mold, the SLA pattern is plated with nickel, which is then reinforced with a stiff ceramic material. The two mold halves are separated to remove the pattern, leaving a matched die set that can produce tens of thousands of injection moldings.

Other methods such as casting, including sand casting, may be employed for rapid tooling. In casting, an RP model is used as the positive pattern around which the sand mold is built.

Direct Tooling This technique, developed at Sandia National Laboratories and Stanford University, can create metal tools from CAD data. As in the rapid prototyping process, a laser beam melts the top layer of the part in areas where material is to be added. Powder metal is injected into the molten pool, which then solidifies. This process is repeated layer by layer until the part is built. Unlike traditional powder metal processing, this method produces fully dense parts, since the metal is melted, and not merely sintered. The resulting parts have exceptional mechanical properties. This method is appropriate for parts with simple geometry or a more uniform cross section.

In a different process, an RP machine selectively sinters polymer-coated steel pellets together to produce a metal mold. The mold is then placed in a furnace where the polymer binder is burned off and the part is infiltrated with copper.

Rapid Manufacturing When a limited number of products is needed, rapid manufacturing (RM) is much cheaper, since it does not require tooling. RM is also ideal for producing custom parts tailored to the user's exact specifications. Rapid manufacturing is a natural extension of rapid prototyping. RM will never completely replace other manufacturing techniques, especially in large production runs where mass production is more economical. However, when an object cannot be made by subtractive (machining, grinding) or compressive (forging, etc.) processes, such as internal voids or complex structures, rapid manufacturing is the solution.

Conclusion

Rapid prototyping has changed product development processes and the way companies design and build products. The most attractive feature of RP is the short prototyping time, which saves tremendous cost during product development.

As a result of the advent of computers, RP technology is constantly improving. For example the accuracy of the surface finish is improving and the laser optics and motor control (used in RP) have increased their accuracy in all three directions. In addition, RP companies are developing new polymers that will be less prone to curing and temperature-induced warpage.

RP machines using nonpolymeric materials, such as metals, ceramics, and composites, produce functional parts that could be used for testing. These machines expand the range of products that can be made by rapid manufacturing. Much of the RP research is focused on the development of new materials for the RP machines that make functional parts.

20.13 MISCELLANY

by E. A. Avallone

PREFERRED NUMBERS

REFERENCE: ANSI Standard Z17.1.

Many manufactured articles are made in several sizes which may be designated by some dimension, speed, capacity, or other feature. Each such series of products may be paralleled by a series of numbers.

It is generally agreed that such number series should be **geometric progressions;** i.e., each term should be a fixed percentage larger than the preceding. A geometric series provides small steps for small numbers, large steps for large numbers, and this best meets most requirements. The small steps in the diameter of the numbered twist drills would be absurd in drills of 1 in diameter and larger.

In the case of sized objects that are used principally as raw material, e.g., steel rod, an arithmetic progression may be preferable because it tends to reduce the cost of machining. It is desirable to be able to buy raw material a fixed amount (rather than a fixed percentage) larger than the finished article.

Preferred numbers is the name given to various series proposed for general use. These are either geometric progressions or approximations thereto. A geometric series is defined by one term and the ratio of each term to the preceding one. On the choice of these elements for a preferred number series, there is as yet no general agreement. The same value would hardly be satisfactory for all cases. The idea of preferred numbers is to provide a master series from which terms can be chosen to suit any needs. This would ultimately lead to a comprehensive plan in all fields of manufacture, so that, for example, the sizes of shafting would be in accord with the sizes of bearings, and indeed with all manner of cylindrical machine elements.

An advantage of a geometric series is that if linear dimensions are chosen in the series, areas, volumes, and other functions of powers of dimensions are also members of the same series.

In one of the most carefully considered systems of preferred numbers the base term is 1, and the ratio is $\sqrt[80]{10}$. In this series, the 81st term is 10, and accordingly the series from 10 to 100 or from 0.01 to 0.1, or, in general, from 10^n to 10^{n+1} is identical with the series from 1 to 10 with the decimal point shifted. This series will rarely be used in full; some will choose alternate terms, some every fourth, fifth, tenth, or twentieth term. The index of the root, 80, has as factors, 2^4 and 5, so that the series readily yields subseries having as ratios the roots of 10 with indices 2, 4, 8, 16, 5, 10, 20, 40, thus giving a wide range of choice. See Table 20.13.1.

The strict logic of this series has been somewhat impaired by the adoption of rounded values that are slightly different in the 1-to-10 and 10-to-100 intervals. For the United States, ANSI has adopted a Table of Preferred Numbers (ANSI Z17.1) which differs slightly from the system described in the preceding paragraph.

Another type of series is the **semigeometric series** consisting of a basic geometric series with 1 as the base term and a ratio of 2, giving a series . . . ⅛, ¼, ½, 1, 2, 4, ... Between consecutive terms are inserted arithmetic series of 2, 4, 8, or 16 terms, in general using different numbers of terms in different intervals.

A similar procedure is used to establish the numbers of teeth in a prescribed number of gears that are intended for use in a gear train to provide a stepped gradation of rotational speeds within an upper and lower bound.

Table 20.13.1 Basic Series of Preferred Numbers: R 80 Series

1.00	1.80	3.15	5.60
1.03	1.85	3.25	5.80
1.06	1.90	3.35	6.00
1.09	1.95	3.45	6.15
1.12	2.00	3.55	6.30
1.15	2.06	3.65	6.50
1.18	2.12	3.75	6.70
1.22	2.18	3.87	6.90
1.25	2.24	4.00	7.10
1.28	2.30	4.12	7.30
1.32	2.36	4.25	7.50
1.36	2.43	4.37	7.75
1.40	2.50	4.50	8.00
1.45	2.58	4.62	8.25
1.50	2.65	4.75	8.50
1.55	2.72	4.87	8.75
1.60	2.80	5.00	9.00
1.65	2.90	5.15	9.25
1.70	3.00	5.30	9.50
1.75	3.07	5.45	9.75

SOURCE: American National Standard Preferred Numbers Z17.1, reproduced with permission of ANSI.

Preferred sizes are different from preferred numbers, but when reduced to linear dimensions, they enjoy the convenience and simplicity of "whole" numbers. Metallic bar stock, e.g., may be supplied in diameters (in inches) of, say, 1, 1¼, 1½, 1¾, 2 , . . . , 8, 8½, 9.

PROFESSIONAL ENGINEERING PRACTICE

The regulatory engineering environment may be broadened to include the professional working environment in which engineers conduct their practice. Ultimately, the engineers' endeavors result in a product of some sort, be it a tangible item or drawings, specifications, inspection documents, research reports, and the like. Keeping that in mind, the subjects which follow address briefly some aspects pertinent to the practice of engineering.

Personnel

The engineer often will employ other persons, and as an employer, the engineer is subject to all applicable laws and regulations related to the employer-employee relationship. The administration of personnel matters will involve the engineer directly or will be delegated to a surrogate

within the organization. Among the things which relate to personnel are worker's compensation insurance; accident and health insurance; antidiscrimination laws related to hiring, termination, and promotion; general liability insurance; and so on. Depending upon the staffing and the type of work which is performed in the engineer's office, it may prove prudent to carry employer's liability insurance to cover situations which are excluded from worker's compensation and general liability insurance. In these regards, it is wise to seek legal counsel.

If the employees are affiliated with organized labor, collective bargaining will be involved with the one or more unions representing the employees, and it will encompass matters such as pay, fringe benefits, and working conditions.

The objective of good personnel administration is to have the entity run smoothly, with maximum interpersonal harmony and good will so that the organization will prosper.

Some other pertinent details related to personnel administration are discussed briefly in Sec. 17.1.

Professional Engineer Licensing and Registration

Many engineers, whether self-employed or employed by others, may seek to obtain a license as a registered professional engineer. Generally, the terms *licensed professional engineer* and *registered professional engineer* are synonymous.

The licensing of professional engineers (and of those in other professions and trades) falls under the aegis of the individual state education departments, which control and administer professional licensing within the state's jurisdiction. In years past, some states granted the license as a professional engineer to a few persons who, although lacking formal credentials (education and otherwise), had a demonstrated record of performance of the duties of a professional engineer. The licenses were granted under "grandfather" clauses. This is now very seldom the case.

The usual route to obtain a license as a professional engineer is via a combination of education, experience, and written examination. The successful attainment of an undergraduate degree in engineering will admit the applicant to a first examination, the successful completion of which results in the applicant being granted a certificate as Engineer in Training (EIT). Additional suitable experience for another 4 years admits the EIT into the final written examination for professional engineer. The successful completion of the final examination results in the award of a license as Professional Engineer.

Federal, state, and most local municipalities require that their key engineering personnel be licensed professional engineers. Engineering documents submitted to those bodies, likewise, will require that the signatory thereto be a licensed professional engineer.

There are minor variations from state to state as to acceptable experience, the degree to which academic experience may be acceptable as engineering experience, etc.; but by and large, there is a degree of uniformity among the state education departments in the matter of licensing professional engineers.

Professional engineers active in several state jurisdictions may be required to obtain a license as professional engineer in those different states. To that end, most states have established procedures to grant a license as professional engineer by comity, but usually this will be possible only if the original license was granted on the basis of a written examination. Comity is often initiated through the offices of the National Society of Professional Engineers as a service to its members.

The work bearing the professional engineer's seal is considered creative work and is so addressed in most stated education laws. The work carries an implicit copyright, even though a statement to that effect may not be placed on the documents. Said work is the property of the professional engineer; unauthorized copying of such documents is illegal, and violators are subject to legal action and redress.

The basic intent of formal licensing of professional engineers is to protect the public from incompetent practice. A licensed professional engineer whose competence is called into question is subject to formal investigative procedures, and when the circumstances warrant it, the license may be revoked or suspended.

Detailed information regarding license as a professional engineer can be obtained from the state education department having jurisdiction, and it will set forth the requirements, privileges, and responsibilities inherent in the granting of the license.

In recent years, there has been recognition that a licensed professional engineer provides services in a rapidly changing environment of evolving technology, with the concomitant necessary continual development of knowledge and skills. To that end, most jurisdictions now require that, as a prerequisite to license renewal, professional engineers accrue specified minimal amounts of continuing education, usually in the form of contact hours or continuing education units. Acceptable continuing education includes formal coursework and/or educational activities; teaching a course in an acceptable subject area; authoring an article in a peer-reviewed journal or a published book; making a technical presentation at an approved technical conference; obtaining a patent related to the practice of engineering; and completion of an approved self-study program.

Inquiries along these lines are made to the entity having jurisdiction over granting licenses and renewals.

Product Liability

In the current consumer and/or user climate, the matter of product liability has assumed a large role and often impacts upon the engineer's input to certain products. In some cases, the engineer may be held personally responsible and liable for some outcome even though the engineer may have been employed by others. The case reports of litigation involving product liability are voluminous, and it is not surprising that identical circumstances will result in verdicts different from one jurisdiction to another. The laws related to product liability are based principally on two concepts: negligence and strict liability. The details are not addressed here; suffice it to say that the engineer who faces product liability litigation must retain competent legal counsel to prepare and implement an appropriate defense.

Professional Liability Insurance

This type of insurance is often carried by engineers in private practice to protect the engineer as well as to provide relief to an injured party, when the latter may result from error(s) and/or omission(s) in the documents prepared by the engineer; hence, the term *errors and omissions insurance,* or E&O insurance. The nature of professional liability insurance is quite complex and is usually handled between the engineer and the insurer, often with the active participation of the engineer's legal counsel. Essentially, in obtaining professional liability insurance, the engineer enlists a broader financial entity (the insurance company) to absorb a portion of the costs of claims in exchange for a premium paid to the insurance company. Actions related to professional liability insurance evolve from the management decisions made by the engineer (or the firm), as part of the overall conduct of the engineering practice and consideration of the financial risks incurred thereby.

In many cases, before any work proceeds, the client will require that the engineer provide evidence that professional liability insurance is in effect, and that evidence often is incorporated into the contractual agreement between engineer and client.

Professional liability insurance policies are traditionally of the claims-made type. Claims arising out of work undertaken and performed while the policy is in effect will be covered. Claims arising from that work at a later date will **not** be covered unless the insurance has continued in effect to the time the claim is made. All coverage ceases when the policy is canceled or not renewed.

Insurance premiums depend on several factors: limits of liability, deductibles, type of work performed and the services rendered in connection therewith, experience of engineer and his or her "track record," and the geographic location of the work (there are low-risk states and high-risk states). There are other factors which may be subject to consideration by the insurer.

PUBLISHING AND EDITING

Sizes of Type

The unit of height of a line of printer's type is the "point." One point = 1/72 in. Six-point type is consequently 6/72 = 1/12 in high. The sizes generally employed in books and periodicals are 6-, 7-, 8-, 9-, 10-, 11-, and 12-point. These are shown in Fig. 20.13.1.

6-point
7-point
8-point
9-point
10-point

12-point

Fig. 20.13.1 Examples of type sizes.

Copy Preparation and Copy Fitting

It is recommended that manuscript material be printed double-spaced on 8½- by 11-in paper with 1½-in margins at the top and left side, 1-in margins on the bottom and right side, and with each page containing 25 lines, double-spaced. Thus a printed line will be 60 characters long. Nearly all printers can print at 10 characters to the inch and double-spaced (three lines to the inch). For convenience in copyediting, printed copy should be printed double-spaced. One manuscript page so printed is equivalent to about 250 words (assuming that each word averages six characters).

One way to determine approximately how many lines of manuscript copy are equivalent to how many lines of finished book type is to print, to the specifications given above, a number of lines from a book which has been printed in the desired type font. This will show the relationship between the number of manuscript-copy lines and lines set in type.

Nearly all word-processing programs will produce satisfactory manuscript. Authors working directly with a publisher will usually make arrangements to submit their manuscripts in computer-readable form. Some publishers require it. Publishers have very comprehensive format-conversion facilities. Authors working in groups or with intermediate editors, however, face the problem that others of their associates or editors may not have much conversion capability. In such cases, the editors or group leaders will make arrangements to accept such computer-readable copy as they can. In most cases, a printed copy should accompany all computer-readable material.

Proofreading

When correcting proof, use ink or pencil of a color different from the marks already on the proof. Put your marks in the right or left margin, whichever is nearer to the word corrected. If there are several corrections in a single line, place them in order from left to right, separated by a slant line (e.g., tr/cap/,). If the same correction is made several times in the same line with no intervening correction, make your correction once in the margin, followed by an appropriate number of slant lines. For instance, if you add an *s* to three words in a line, write in the margin s///. When you wish to insert words, put a caret at the point of insertion and write the additional words in the margin. To delete material without substituting anything, cross it out and put a delete sign in the margin. When you delete words and substitute other words, cross out the unwanted material, use a caret within the line, and write the new material in the margin; the delete sign is then unnecessary. Standard proofreader's marks are shown in Fig. 20.13.2.

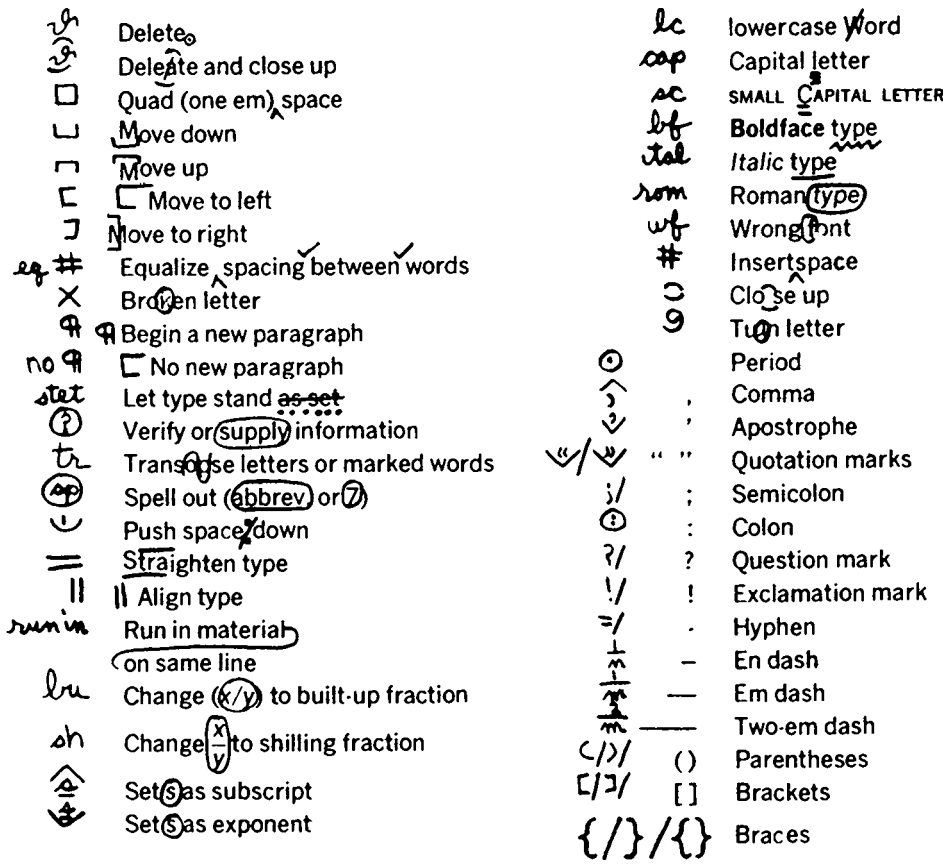

Fig. 20.13.2 Proofreader's marks.

Occasionally you may decide that material you have deleted should be restored. Place a row of dots under the crossed-out material, cross off the delete sign in the margin, and write "stet" (let it stand).

Special Alphabets

The primary alphabets used as symbols are Greek, script, and German. Examples of these are shown in Figs. 20.13.3 through 20.13.6.

Fig. 20.13.3 Greek alphabet.

Fig. 20.13.4 Boldface Greek alphabet.

Note that the capital Greek letters used by the printer are easily mistaken for the Roman letters A, B, E, Z, H, I, K, M, N, O, P, T, and X and may not be suitable as symbols. If they are used in a manuscript, they should be identified with a marginal note so they will not be improperly set. The form of many Greek boldface symbols is markedly different from the style of the lightface characters.

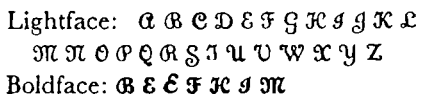

Fig. 20.13.5 Script alphabet.

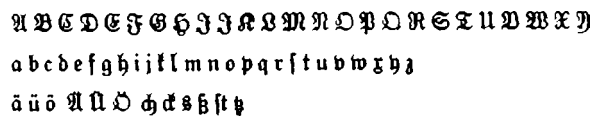

Fig. 20.13.6 German Fraktur alphabet.

Script and German symbols (Figs. 20.13.5 and 20.13.6) may be indicated by circling in a distinctive color the corresponding English letter.
