The above formulas have been successfully applied in the past as a convenient tool for the initial assessment of strength requirements for various designs. At present, computer programs are routinely used in ship structural design. Empirical formulas for the individual calculation of both still water and wave-induced bending moments have been derived by the classification societies. They are based on ship length, breadth, block coefficient, and effective wave height (for the wave-induced bending moment). Similarly, permissible bending stresses are calculated from formulas as a function of ship length and its service environment. Finite element techniques in the form of commercially available computer software packages combined with statistical reliability methods are being applied with increasing frequency.

For ships, the maximum longitudinal bending stresses occur in the vicinity of the midship section at the deck edge and in the bottom plating. Maximum shear stresses occur in the shell plating in the vicinity of the quarter points at the neutral axis. For long, slender girders, such as ships, the maximum shear stress is small compared with the maximum bending stress.

The structure of a ship consists of a grillage of stiffened plating supported by longitudinals, longitudinal girders, transverse beams, transverse frames, and web frames. Since the primary stress system in the hull arises from longitudinal bending, it follows that the longitudinally continuous structural elements are the most effective in carrying and distributing this stress system. The strength deck, particularly at the side, and the keel and turn of bilge are highly stressed regions. The shell plating, particularly deck and bottom plating, carry the major part of the stress. Other **key longitudinal elements,** as shown in Fig. 11.3.5, are longitudinal deck girders, main deck stringer plate, gunwale angle, sheer strake, bilge strake, inner bottom margin plate, garboard strake, flat plate keel, center vertical keel, and rider plate.

Transverse elements include deck beams and transverse frames and web frames which serve to support and transmit vertical and transverse loads and resist hydrostatic pressure.

Good structural design minimizes the structural weight while providing adequate strength, minimizes interference with ship function, includes access for maintenance and inspection, provides for effective continuity of the structure, facilitates stress flow around deck openings and other stress obstacles, and avoids square corner discontinuities in the plating and other stress concentration "hot spots."

A longitudinally framed ship is one which has closely spaced longitudinal structural elements and widely spaced transverse elements. A transversely framed ship has closely spaced transverse elements and widely spaced longitudinal elements. Longitudinal framing systems are generally more efficient structurally, but because of the deep web frames supporting the longitudinals, it is less efficient in the use of internal space than the transverse framing system. Where interruptions of open internal spaces are unimportant, as in tankers and bulk carriers, longitudinal framing is universally used. However, modern practice tends increasingly toward longitudinal framing in other types of ships also.

Stability

A ship afloat is in vertical equilibrium when the force of **gravity,** acting at the ship's **center of gravity** G, is equal, opposite, and in the same vertical line as the force of **buoyancy,** acting upward at the **center of buoyancy** B. Figure 11.3.6 shows that an upsetting, transverse couple acting on the ship causes it to rotate about a longitudinal axis, taking a list ϕ. G does not change; however, B moves to B_1, the centroid of the new underwater volume. The resulting couple, created by the transverse separation of the two forces ($\overline{GZ}$) opposes the upsetting couple, thereby righting the ship. A static stability curve (Fig. 11.3.7), consisting of

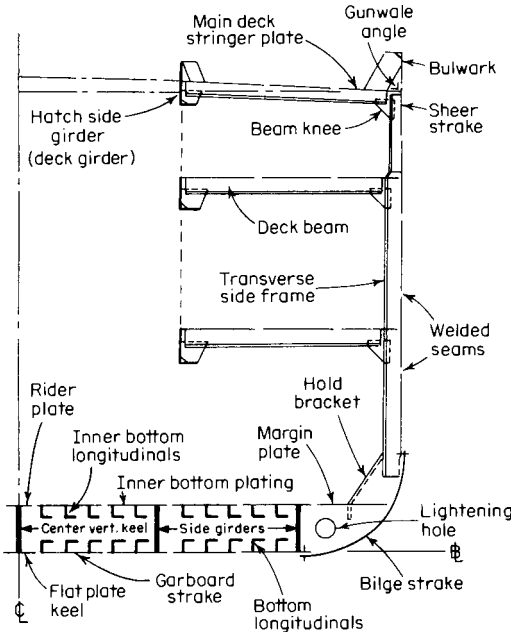

Fig. 11.3.5 Key structural elements.

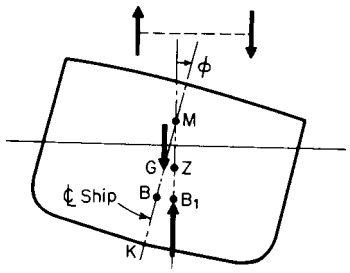

Fig. 11.3.6 Ship stability.

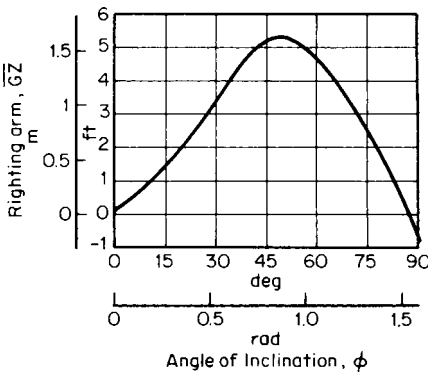

Fig. 11.3.7 Static stability curve.

values for the righting arm $\overline{GZ}$ plotted against angles of inclination (ϕ), gives a graphic representation of the static stability of the ship. The primary indicator for the safety of a ship is the maximum righting arm it develops and the angle heel at which this righting arm occurs.

For small angles of inclination ($\phi < 10°$), centers of buoyancy follow a locus whose instantaneous center of curvature M is known as the transverse **metacenter**. When M lies above G ($\overline{GM} > 0$), the resulting gravity-buoyancy couple will right the ship; the ship has positive stability. When G and M are coincident, the ship has neutral stability. When G is above M($\overline{GM} < 0$), negative stability results. Hence $\overline{GM}$, known as the **transverse metacentric height,** is an indication of **initial stability** of a ship.

The transverse **metacentric radius** $\overline{BM}$ and the vertical location of the center of buoyancy are determined by the design of the ship and can be calculated. Once the vertical location of the ship's center of gravity is known, then $\overline{GM}$ can be found. The vertical center of gravity of practically all ships varies with the condition of loading and must be determined either by a careful calculation or by an inclining experiment.

Minimum values of $\overline{GM}$ ranging from 1.5 to 3.5 ft (0.46 to 1.07 m), corresponding to small and large seagoing ships, respectively, have been accepted in the past. The $\overline{GM}$ of passenger ships should be under 6 percent of the beam to ensure a reasonable (comfortable) rolling period. This relatively low value is offset by the generally large range of stability due to the high freeboard of passenger ships.

The question of **longitudinal stability** affects the trim of a ship. As in the transverse case, a longitudinal metacenter exists, and a longitudinal metacentric height $\overline{GM}_L$ can be determined. The moment to alter trim 1 in, $\overline{MT1}$, is computed by $\overline{MT1} = \Delta\overline{GM}_L/12L$, ft · tons/in and moment to alter trim 1 m is $\overline{MT1} = 10^6\Delta\overline{GM}_L/L$,N · m/m. Displacement Δ is in tons and MN, respectively.

The **location of a ship's center of gravity** changes as small weights are shifted within the system. The vertical, transverse, or longitudinal component of movement of the center of gravity is computed by $\overline{GG}_1 = w \times d/\Delta$, where w is the small weight, d is the distance the weight is shifted in a component direction, and Δ is the displacement of the ship, which includes w.

Vertical changes in the location of G caused by **weight addition** or **removal** can be calculated by

$$KG_1 = \frac{\Delta\,\overline{KG} \pm w\overline{K}g}{\Delta_1}$$

where $\Delta_1 = \Delta \pm w$ and $\overline{K}g$ is the height of the center of gravity of w above the keel.

The free surface of the liquid in fuel oil, lubricating oil, and water storage and service tanks is deleterious to ship stability. The weight shift of the liquid as the ship heels can be represented as a virtual rise in G, hence a reduction in $\overline{GM}$ and the ship's initial stability. This virtual rise, called the **free surface effect,** is calculated by the expression

$$GG_v = \gamma_i i/\gamma_w \nabla$$

where γ_i, γ_w = specific gravities of liquid in tank and sea, respectively; i = moment of inertia of free surface area about its longitudinal centroidal axis; and ∇ = volume of displacement of ship. The ship designer can minimize this effect by designing long, narrow, deep tanks or by using baffles.

Seakeeping

Seakeeping is how a ship moves in response to the ocean's wave motion and determines how successfully the ship will function in a seaway. These motions in turn directly affect the practices of marine engineers. The motion of a floating object has six degrees of freedom. Figure 11.3.8 shows the conventional ship coordinate axes and ship motions. Oscillatory movement along the x axis is called **surge**; along the y axis, **sway**; and along the z axis, **heave**. Rotation about x is called **roll**; about y, **pitch**; and about z, **yaw**.

Rolling has a major effect on crew comfort and on the structural and bearing requirements for machinery and its foundations. The natural period of roll of a ship is $T = 2\pi K/\sqrt{g\overline{GM}}$, where K is the radius of gyration of virtual ship mass about a longitudinal axis through G. K varies from 0.4 to 0.5 of the beam, depending on the ship depth and transverse distribution of weights.

Angular acceleration of roll, if large, has a very distressing effect on crew, passengers, machinery, and structure. This can be minimized by increasing the period or by decreasing the roll amplitude. Maximum angular acceleration of roll is

$$d^2\phi/dt^2 = -4\pi^2(\phi_{max}/T^2)$$

where ϕ_{max} is the maximum roll amplitude. The period of the roll can be increased effectively by decreasing $\overline{GM}$; hence the lowest value of $\overline{GM}$ compatible with all stability criteria should be sought.

Pitching is in many respects analogous to rolling. The natural period of pitching, bow up to bow down, can be found by using the same expression used for the rolling period, with the longitudinal radius of gyration K_L substituted for K. A good approximation is $K_L = L/4$, where L is the length of the ship. The natural period of pitching is usually between one-third and one-half the natural period of roll. A by-product of pitching is **slamming,** the reentry of bow sections into the sea with heavy force.

Heaving and **yawing** are the other two principal rigid-body motions caused by the sea. The amplitude of heave associated with head seas, which generate pitching, may be as much as 15 ft (4.57 m); that arising

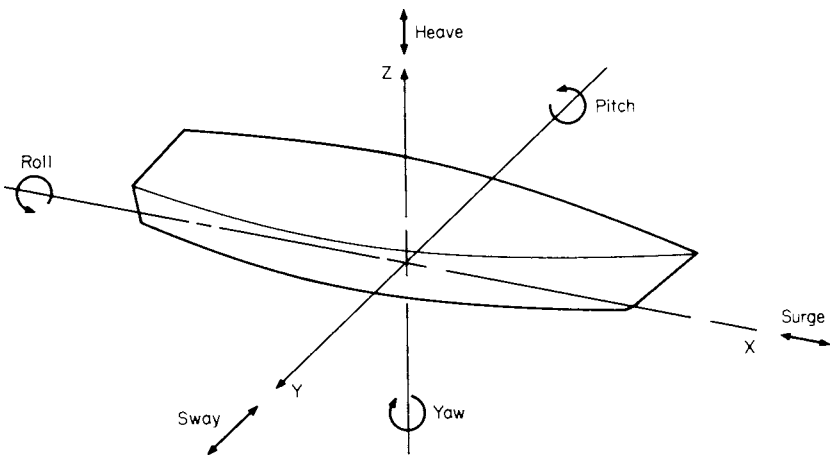

Fig. 11.3.8 Conventional ship coordinate axes and ship motions.

from beam seas, which induce rolling, can be even greater. Yawing is started by unequal forces acting on a ship as it quarters into a sea. Once a ship begins to yaw, it behaves as it would at the start of a rudder-actuated turn. As the ship travels in a direction oblique to its plane of symmetry, forces are generated which force it into heel angles independent of sea-induced rolling.

Analysis of ship movements in a seaway is performed by using probabilistic and statistical techniques. The seaway is defined by a mathematically modeled wave energy density spectrum based on data gathered by oceanographers. This wave spectrum is statistically calculated for various sea routes and weather conditions. One way of determining a ship response amplitude operator or transfer function is by linearly superimposing a ship's responses to varying regular waves, both experimentally and theoretically. The wave spectrum multiplied by the ship response transfer function yields the ship response spectrum. The ship response spectrum is an energy density spectrum from which the statistical character of ship motions can be predicted. (See Edward V. Lewis, Motions in Waves, "Principles of Naval Architecture," SNAME, 1989.)

Resistance and Powering

Resistance to ship motion through the water is the aggregate of (1) wave-making, (2) frictional, (3) pressure or form, and (4) air resistances.

Wave-making resistance is primarily a function of Froude number, $\text{Fr} = v/\sqrt{gL}$, where v = ship speed, ft/s (m/s); g = acceleration of gravity, ft/s^2 (m/s^2); and L = ship length, ft (m). In many instances, the dimensional speed-length ratio $V/\sqrt{L}$ is used for convenience, where V is given in knots. A ship makes at least two distinct wave patterns, one from the bow and the other at the stern. There also may be other patterns caused by abrupt changes in section. These patterns combine to form the total wave system for the ship. At various speeds there is mutual cancellation and reinforcement of these patterns. Thus, a plot of total resistance of the ship versus Fr or $V/\sqrt{L}$ is not smooth but shows humps and hollows corresponding to the wave cancellation or reinforcement. Normal procedure is to design the operating speed of a ship to fall at one of the low points in the resistance curve.

Frictional resistance is a function of Reynolds number (see Sec. 3). Because of the size of a ship, the Reynolds number is large and the flow is always turbulent.

Pressure or **form resistance** is a viscosity effect but is different from frictional resistance. The principal observed effects are boundary-layer separation and eddying near the stern.

It is usual practice to combine the wave-making and pressure resistances into one term, called the **residuary resistance,** assumed to be a function of Froude number. The combination, although not strictly legitimate, is practical because the pressure resistance is usually only 2 to 3 percent of the total resistance. The frictional resistance is then the only term which is considered to be a function of Reynolds number and can be calculated. Based on an analysis of the water resistance of flat, smooth planes, Schoenherr gives the formula

$$R_f = 0.5\rho S v^2 C_f$$

where R_f = frictional resistance, lb (N); ρ = mass density, lb/s^2 · ft^4 (kg/m^3); S = wetted surface area, ft^2 (m^2); v = velocity, ft/s (m/s); and C_f is the frictional coefficient computed from the ITTC formula

$$C_f = \frac{0.075}{(\log_{10} \text{Re} - 2)^2}$$

and Re = Reynolds number = vL/ν.

Through towing tests of ship models at a series of speeds for which Froude numbers are equal between the model and the ship, **total model resistance** (R_{tm}) is determined. Residuary resistance (R_{rm}) for the model is obtained by subtracting the frictional resistance (R_{fm}). By **Froude's law of comparison,** the residuary resistance of the ship (R_{rs}) is equal to R_{rm} multiplied by the ratio of ship displacement to model displacement. Total ship resistance (R_{ts}) then is equal to the sum of R_{rs}, the calculated ship frictional resistance (R_{fs}), and a correlation allowance that allows for the roughness of ship's hull opposed to the smooth hull of a model.

$$\begin{aligned} R_{tm} &= \text{measured resistance} \\ R_{rm} &= R_{tm} - R_{fm} \\ R_{rs} &= R_{tm}(\Delta s/\Delta m) \\ R_{ts} &= R_{rs} + R_{fs} + R_a \end{aligned}$$

A nominal value of 0.0004 is generally used as the correlation allowance coefficient C_a. $R_a = 0.5\rho S v^2 C_a$.

From R_{ts}, the **total effective power** P_E required to propel the ship can be determined:

$$P_E = \frac{R_{ts} v}{550} \quad \text{ehp} \qquad \left(P_E = \frac{R_{ts} v}{1{,}000} \quad \text{kW}_\text{E} \right)$$

where R_{ts} = total ship resistance, lb (N); v = velocity, ft/s (m/s); and $P_E = P_s \times$ P.C., where P_s is the shaft power (see Propulsion Systems) and P.C. is the propulsive coefficient, a factor which takes into consideration mechanical losses, propeller efficiency, and the flow interaction with the hull. *P.C.* = 0.45 to 0.53 for high-speed craft; 0.50 to 0.60, for tugs and trawlers; 0.55 to 0.65, for destroyers; and 0.63 to 0.72, for merchant ships.

Figure 11.3.9 illustrates the specific effective power for various displacement hull forms and planing craft over their appropriate speed regimes. Figure 11.3.10 shows the general trend of specific resistance versus Froude number and may be used for coarse powering estimates.

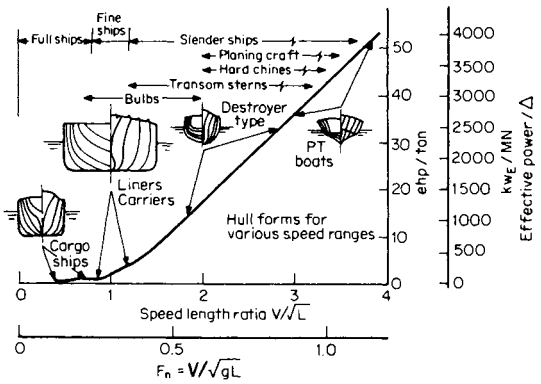

Fig. 11.3.9 Specific effective power for various speed-length regimes. *(From "Handbook of Ocean and Underwater Engineering," McGraw-Hill, 1969.)*

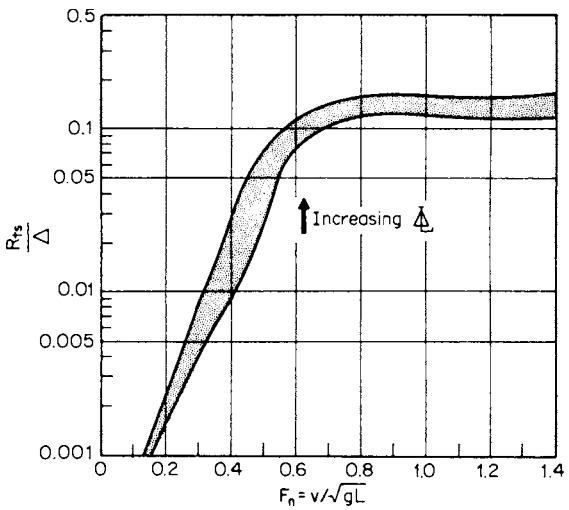

Fig. 11.3.10 General trends of specific resistance versus Froude number.

In early design stages, the hull form is not yet defined, and model testing is not feasible. Reasonably accurate power calculations are made by using preplotted series model test data of similar hull form, such as from Taylor's Standard Series and the Series 60. The Standard Series data were originally compiled by Admiral David W. Taylor and were based on model tests of a series of uniformly varied twin screw, cruiser hull forms of similar geometry. Revised Taylor's Series data are available in "A Reanalysis of the Original Test Data for the Taylor Standard Series," Taylor Model Basin, Rept. no. 806.

Air Resistance The air resistance of ships in a windless sea is only a few percent of the water resistance. However, the effect of wind can have a significant impact on drag. The wind resistance parallel to the ship's axis is roughly 30 percent greater when the wind direction is about 30° ($\pi/6$ rad) off the bow vice dead ahead, since the projected above-water area is greater. Wind resistance is approximated by $R_A = 0.002B^2V_R^2$ lb ($0.36B^2V_R^2$ N), where B = ship's beam, ft (m) and V_R = ship speed relative to the wind, in knots (m/s).

Powering of Small Craft The American Boat and Yacht Council, Inc. (ABYC) provides guidance for determining the maximum power for propulsion of outboard boats, to evaluate the suitability of power installed in inboard boats, and to determine maneuvering speed. Figures 11.3.11 and 11.3.12 demonstrate such data. The latest standard review dates are available at www.abycinc.org.

The development of high-power lightweight engines facilitated the evolution of planing hulls, which develop dynamic lift.

Small high-speed craft primarily use gasoline engines for powering because of weight and cost considerations. However, small high-speed diesel engines are commonly used in pleasure boats.

ENGINEERING CONSTRAINTS

The constraints affecting marine engineering design are too numerous, and some too obvious, to include in this section. Three significant categories, however, are discussed. The geometry of the hull forms immediately suggests **physical constraints.** The interaction of the vehicle with the marine environment suggests **dynamic constraints,** particularly vibration, noise, and shock. The broad topic of **environmental protection** is one of the foremost engineering constraints of today, having a very pronounced effect on the operating systems of a marine vehicle.

Physical Constraints

Formerly, tonnage laws in effect made it economically desirable for the propulsion machinery spaces of a merchant ship to exceed 13 percent of the gross tonnage of the ship so that 32 percent of the gross tonnage could be deducted in computing net tonnage. In most design configurations, however, a great effort is made to minimize the space required for the propulsion plant in order to maximize that available to the mission or the money-making aspects of the ship.

Specifically, **space** is of extreme importance as each component of support equipment is selected. Each component must fit into the master compact arrangement scheme to provide the most efficient operation and maintenance by engineering personnel.

Weight constraints for a main propulsion plant vary with the application. In a tanker where cargo capacity is limited by draft restrictions, the weight of machinery represents lost cargo. Cargo ships, on the other hand, rarely operate at full load draft. Additionally, the low weight of propulsion machinery somewhat improves inherent cargo ship stability deficiencies. The weight of each component of equipment is constrained by structural support and shock resistance considerations. Naval shipboard equipment, in general, is carefully analyzed to effect weight reduction.

Dynamic Constraints

Dynamic effects, principally mechanical vibration, noise, shock, and ship motions, are considered in determining the dynamic characteristics of a ship and the dynamic requirements for equipment.

Vibration (See Sec. 9.) Vibration analyses are especially important in the design of the propulsion shafting system and its relation to the excitation forces resulting from the propeller. The main propulsion **shafting** can vibrate in longitudinal, torsional, and lateral modes. Modes of **hull vibration** may be vertical, horizontal, torsional, or longitudinal; may occur separately or coupled; may be excited by synchronization with periodic harmonics of the propeller forces acting either through the shafting, by the propeller force field interacting with the hull afterbody, or both; and may also be set up by unbalanced harmonic forces from the main machinery, or, in some cases, by impact excitation from slamming or periodic-wave encounter.

It is most important to reduce the excitation forces at the source. Very objectionable and serious vibrations may occur when the frequency of the exciting force coincides with one of the hull or shafting-system natural frequencies.

Vibratory forces generated by the propeller are (1) alternating pressure forces on the hull due to the alternating hydrodynamic pressure fields of the propeller blades; (2) alternating propeller-shaft bearing forces, primarily caused by wake irregularities; and (3) alternating forces transmitted throughout the shafting system, also primarily caused by wake irregularities.

The most effective means to ensure a satisfactory level of vibration is to provide adequate clearance between the propeller and the hull surface and to select the propeller revolutions or number of blades to avoid synchronism. Replacement of a four-blade propeller, for instance, by a three- or five-blade, or vice versa, may bring about a reduction in vibration. Singing propellers are due to the vibration of the propeller blade edge about the blade body, producing a disagreeable noise or hum. Chamfering the edge is sometimes helpful.

Vibration due to variations in **engine torque reaction** is hard to overcome. In ships with large diesel engines, the torque reaction tends to

produce an athwartship motion of the upper ends of the engines. The motion is increased if the engine foundation strength is inadequate.

Foundations must be designed to take both the thrust and torque of the shaft and be sufficiently rigid to maintain alignment when the ship's hull is working in heavy seas. Engines designed for foundations with three or four points of support are relatively insensitive to minor working of foundations. Considerations should be given to using flexible couplings in cases when alignment cannot be assured.

Torsional vibration frequency of the prime mover–shafting-propeller system should be carefully computed, and necessary steps taken to ensure that its natural frequency is clear of the frequency of the main-unit or propeller heavy-torque variations; serious failures have occurred. Problems due to resonance of engine torsional vibration (unbalanced forces) and foundations or hull structure are usually found after ship trials, and correction consists of local stiffening of the hull structure. If possible, engines should be located at the nodes of hull vibrations.

Although more rare, a **longitudinal vibration** of the propulsion shafting has occurred when the natural frequency of the shafting agreed with that of a pulsating axial force, such as propeller thrust variation.

Other forces inducing vibrations may be vertical inertia forces due to the acceleration of reciprocating parts of an unbalanced reciprocating engine or pump; longitudinal inertia forces due to reciprocating parts or an unbalanced crankshaft creating unbalanced rocking moments; and horizontal and vertical components of centrifugal forces developed by unbalanced rotating parts. Rotating parts can be balanced.

Noise The noise characteristics of shipboard systems are increasingly important, particularly in naval combatant submarines where remaining undetected is essential, and also from a human-factors point of view on all ships. Achieving significant reduction in machinery noise level can be costly. Therefore desired noise levels should be analyzed. Each operating system and each piece of rotating or reciprocating machinery installed aboard a submarine are subjected to intensive airborne (noise) and structureborne (mechanical) vibration analyses and tests. Depending on the noise attenuation required, similar tests and analyses are also conducted for all surface ships, military and merchant.

Shock In naval combatant ships, shock loading due to noncontact underwater explosions is a major design parameter. Methods of qualifying equipment as "shock-resistant" might include "static" shock analysis, "dynamic" shock analysis, physical shock tests, or a combination.

Motions Marine lubricating systems are specifically distinguished by the necessity of including list, trim, roll, and pitch as design criteria. The American Bureau of Shipping requires satisfactory functioning of lubricating systems when the vessel is permanently inclined to certain angles athwartship and fore and aft. In addition, electric generator bearings must not spill oil under momentary roll specifications. Military specifications are similar, but generally add greater requirements for roll and pitch.

Bearing loads are also affected by ship roll and pitch accelerations, and thus rotating equipment often must be arranged longitudinally.

Environmental Constraints

The **Refuse Act of 1899** (33 U.S.C. 407) prohibits discharge of any refuse material from marine vehicles into navigable waters of the United States or into their tributaries or onto their banks if the refuse is likely to wash into navigable waters. The term **refuse** includes nearly any substance, but the law contains provisions for sewage. The Environmental Protection Agency (EPA) may grant permits for the discharge of refuse into navigable waters.

The **Oil Pollution Act of 1961** (33 U.S.C. 1001-1015) prohibits the discharge of oil or oily mixtures (over 100 mg/L) from vehicles generally within 50 mi of land; some exclusions, however, are granted. (The Oil Pollution Act of 1924 was repealed in 1970 because of supersession by subsequent legislation.)

The **Port and Waterways Safety Act of 1972** (PL92-340) grants the U.S. Coast Guard authority to establish and operate mandatory vehicle traffic control systems. The control system must consist of a VHF radio for ship-to-shore communications, as a minimum. The Act, in effect, also extends the provisions of the Tank Vessel Act, which protects against hazards to life and property, to include **protection of the marine environment.** Regulations stemming from this Act govern standards of tanker design, construction, alteration, repair, maintenance, and operation.

The most substantive marine environmental protection legislation is the **Federal Water Pollution Control Act (FWPCA),** 1948, as amended (33 U.S.C. 466 et seq.). The 1972 and 1978 Amendments contain provisions which greatly expand federal authority to deal with **marine pollution,** providing authority for control of pollution by oil and hazardous substances other than oil, and for the assessment of penalties. **Navigable waters** are now defined as ". . . the waters of the United States, including territorial seas."

"Hazardous substances other than oil" and harmful quantities of these substances are defined by the EPA in regulations. The Coast Guard and EPA must ensure removal of such discharges, costs borne by the responsible vehicle owner or operator if liable. **Penalties** now may be assessed by the Coast Guard for any discharge. The person in charge of a vehicle is to notify the appropriate U.S. government agency of any discharge upon knowledge of it.

The Coast Guard regulations establish **removal procedures** in coastal areas, contain regulations to **prevent discharges** from vehicles and transfer facilities, and regulations governing the **inspection of cargo vessels** to prevent hazardous discharges. The EPA regulations govern inland areas and non-transportation-related facilities.

Section 312 of the FWPCA as amended in 1972 deals directly with **discharge of sewage**. The EPA must issue standards for marine sanitation devices, and the Coast Guard must issue regulations for implementing those standards. In June, 1972, EPA published standards that now prohibit discharge of any sewage from vessels, whether it is treated or not. Federal law now prohibits, on all inland waters, operation with marine sanitation devices which have not been securely sealed or otherwise made visually inoperative so as to prevent overboard discharge.

The **Marine Plastic Pollution Control Act of 1987** (PL100-220) prohibits the disposal of plastics at sea within U.S. waters.

The **Oil Pollution Act of 1990** (PL101-380) provides extensive legislation on liability and includes measures that impact the future use of single-hull tankers.

PROPULSION SYSTEMS

(See Sec. 9 for component details.)

The basic operating requirement for the main propulsion system is to propel the vehicle at the required sustained speed for the range or endurance required and to provide suitable maneuvering capabilities. In meeting this basic requirement, the marine propulsion system integrates the power generator/prime mover, the transmission system, the propulsor, and other shipboard systems with the ship's hull or vehicle platform. Figure 11.3.13 shows propulsion system alternatives with the most popular drives for fixed-pitch and controllable-pitch propellers.

Definitions for Propulsion Systems

Brake power P_B, bhp (kW_B), is the power delivered by the output coupling of a prime mover before passing through speed-reducing and transmission devices and with all continuously operating engine-driven auxiliaries in use.

Shaft power P_s, shp (kW_s), is the net power supplied to the propeller shafting after passing through all reduction gears or other transmission devices and after power for all attached auxiliaries has been taken off. Shaft power is measured in the shafting within the ship by a torsionmeter as close to the propeller or stern tube as possible.

Delivered power P_D, dhp (kW_D), is the power actually delivered to the propeller, somewhat less than P_s because of the power losses in the stern tube and other bearings between the point of measurement and the propeller. Sometimes called **propeller power,** it is also equal to the effective power P_E, ehp (kW_E), plus the power losses in the propeller and the losses in the interaction between the propeller and the ship.

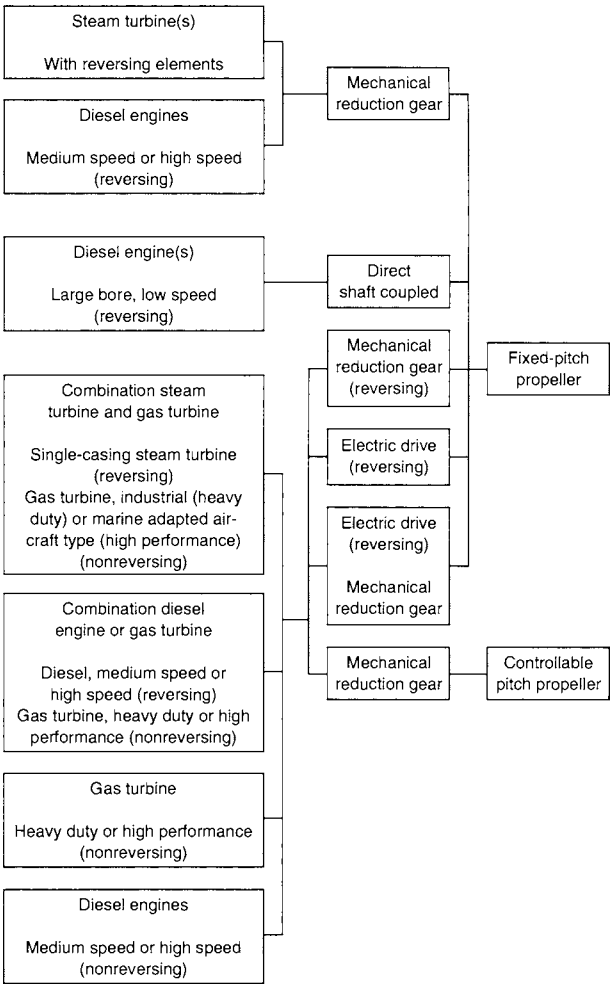

Fig. 11.3.13 Alternatives in the selection of a main propulsion plant. *(From "Marine Engineering" SNAME, 1992.)*

Normal shaft power or **normal power** is the power at which a marine vehicle is designed to run most of its service life.

Maximum shaft power is the highest power for which propulsion machinery is designed to operate continuously.

Service speed is the actual speed maintained by a vehicle at load draft on its normal route and under average weather and sea conditions typical of that route and with average fouling of bottom.

Designed service speed is the speed expected on trials in fair weather at load draft, with clean bottom, when machinery is developing a specified fraction of maximum shaft power. This fraction may vary but is of order of 0.8.

MAIN PROPULSION PLANTS

Steam Plants

The basic steam propulsion plant contains main boilers, steam turbines, a condensate system, a feedwater system, and numerous auxiliary components necessary for the plant to function. A heat balance calculation, the basic tool for determining the effect of various configurations on plant thermal efficiency, is demonstrated for the basic steam cycle. Both fossil-fuel and nuclear energy sources are successfully employed for marine applications.

Main Boilers (See Sec. 9.) The pressures and temperatures achieved in steam-generating equipment have increased steadily over recent years, permitting either a higher-power installation for a given space or a reduction in the size and weight of a given propulsion plant.

The **trend in steam pressures** and **temperatures** has been an increase from 600 psig (4.14 MN/m^2) and 850°F (454°C) during World War II to 1,200 psig (8.27 MN/m^2) and 950°F (510°C) for naval combatants in and since the postwar era. For merchant ships, the progression has been from 400 psig (2.76 MN/m^2) and 750°F (399°C) gradually up to 850 psig (5.86 MN/m^2) and 850°F (454°C) in the 1960s, with some boilers at 1,500 psig (10.34 MN/m^2) and 1,000°F (538°C) in the 1970s.

The **quantity of steam** produced by a marine boiler ranges from approximately 1,500 lb/h (680 kg/h) in small auxiliary boilers to over 400,000 lb/h (181,500 kg/h) in large main propulsion boilers. Outputs of 750,000 lb/h (340,200 kg/h) or more per boiler are practical for high-power installations.

Most marine boilers are **oil-fired.** Compared with other fuels, oil is easily loaded aboard ship, stored, and introduced into the furnace, and does not require the ash-handling facilities required for coal firing.

Gas-fired boilers are used primarily on power or drill barges which are fixed in location and can be supplied from shore (normally classed in the Ocean Engineering category). At sea, tankers designed to carry liquefied natural gas (LNG) may use the natural boil-off from their cargo gas tanks as a supplemental fuel **(dual fuel system).** The cargo gas boil-off is collected and pumped to the boilers where it is burned in conjunction with oil. The quantity of boil-off available is a function of the ambient sea and air temperatures, the ship's motion, and the cargo loading; thus, it may vary from day to day.

For economy of space, weight, and cost and for ease of operation, the trend in **boiler installations** is for fewer boilers of high capacity rather than a large number of boilers of lower capacity. The minimum installation is usually two boilers, to ensure propulsion if one boiler is lost; one boiler per shaft for twin-screw ships. Some large ocean-going ships operate on single boilers, requiring exceptional reliability in boiler design and operation.

Combustion systems include forced-draft fans or blowers, the fuel oil service system, burners, and combustion controls. Operation and maintenance of the combustion system are extremely important to the efficiency and reliability of the plant. The best combustion with the least possible excess air should be attained.

Main Turbines (See Sec. 9.) Single-expansion (i.e., single casing) marine steam turbines are fairly common at lower powers, usually not exceeding 4,000 to 6,000 shp (2,983 to 4,474 kW$_s$). Above that power range, the turbines are usually double-expansion (cross-compound) with high- and low-pressure turbines each driving the main reduction gear through its own pinion. The low-pressure turbine normally contains the reversing turbine in its exhaust end. The main condenser is either underslung and supported from the turbine, or the condenser is carried on the foundations, with the low-pressure turbine supported on the condenser.

The inherent **advantages** of the steam turbine have favored its use over the reciprocating steam engine for all large, modern marine steam propulsion plants. Turbines are not size-limited, and their high temperatures and pressures are accommodated safely. Rotary motion is simpler than reciprocating motion; hence unbalanced forces can be eliminated in the turbine. The turbine can efficiently utilize a low exhaust pressure; it is lightweight and requires minimum space and low maintenance.

The **reheat cycle** is the best and most economical means available to improve turbine efficiencies and fuel rates in marine steam propulsion plants. In the reheat cycle, steam is withdrawn from the turbine after partial expansion and is passed through a heat exchanger where its temperature is raised; it is then readmitted to the turbine for expansion to condenser pressure. Marine reheat plants have more modest steam conditions than land-based applications because of lower power ratings and a greater reliability requirement for ship safety.

The reheat cycle is applied mostly in high-powered units above 25,000 shp (18,642 kW$_s$) and offers the maximum economical thermal

efficiency that can be provided by a steam plant. Reheat cycles are not used in naval vessels because the improvement in efficiency does not warrant the additional complexity; hence a trade-off is made.

Turbine foundations must have adequate rigidity to avoid vibration conditions. This is particularly important with respect to periodic variations in propeller thrust which may excite longitudinal vibrations in the propulsion system.

Condensate System (See Sec. 9.) The condensate system provides the means by which feedwater for the boilers is recovered and returned to the feedwater system. The major components of the condensate system of a marine propulsion plant are the **main condenser,** the **condensate pumps,** and the **deaerating feed tank** or **heater.** Both singlepass and two-pass condenser designs are used; the single-pass design, however, allows somewhat simpler construction and lower water velocities. The single-pass condenser is also adaptable to scoop circulation, as opposed to pump circulation, which is practical for higher-speed ships. The deaerating feedwater heater is supplied from the condensate pumps, which take suction from the condenser hot well, together with condensate drains from steam piping and various heaters.

The deaerating feed heater is normally maintained at about 35 psig (0.241 MN/m^2) and 280°F (138°C) by auxiliary exhaust and turbine extraction steam. The condensate is sprayed into the steam atmosphere at the top of the heater, and the heated feedwater is pumped from the bottom by the feed booster or main feed pumps. In addition to removing oxygen or air, the heater also acts as a surge tank to meet varying demands during maneuvering conditions. Since the feed pumps take suction where the water is almost saturated, the heater must be located 30 to 50 ft (9.14 to 15.24 m) above the pumps in order to provide enough positive suction head to prevent flashing from pressure fluctuations during sudden plant load change.

Feedwater System The feedwater system comprises the pumps, piping, and controls necessary to transport feedwater to the boiler or steam generator, to raise water pressure above boiler pressure, and to control flow of feedwater to the boiler. **Main feed pumps** are so vital that they are usually installed in duplicate, providing a standby pump capable of feeding the boilers at full load. Auxiliary steam-turbine-driven centrifugal pumps are usually selected. A typical naval installation consists of three main feed booster pumps and three main feed pumps for each propulsion plant. Two of the booster pumps are turbine-driven and one is electric. Additionally, an electric-motor-driven emergency booster pump is usually provided. The total capacity of the main feed pumps must be 150 percent of the boiler requirement at full power plus the required recirculation capacity. Reliable feedwater regulators are important.

Steam Plant—Nuclear (See Sec. 9.) The compact nature of the energy source and not requiring air for combustion are the most significant characteristics of nuclear power for marine applications. The fission of one gram of uranium per day produces about one megawatt of power. (One pound produces about 600,000 horsepower.) In other terms, the fission of 1 lb of uranium is equivalent to the combustion of about 86 tons (87,380 kg) of 18,500 Btu/lb (43.03 MJ/kg) fuel oil. This characteristic permits utilization of large power plants on board ship without the necessity for frequent refueling or large bunker storage. Economic studies, however, show that nuclear power, as presently developed, is best suited for military purposes, where the advantages of high power and endurance override the pure economic considerations. As the physical size of nuclear propulsion plants is reduced, their economic attractiveness for commercial marine application will increase.

Major differences between the nuclear power and fossil-fuel plants are: (1) The **safety aspect** of the nuclear reactor system—operating personnel must be shielded from fission product radiation, hence the size and weight of the reactor are increased and maintenance and reliability become more complicated; (2) the steam produced by a pressurized-water reactor plant is saturated and, because of the **high moisture content** in the turbine steam path, the turbine design requires more careful attention; (3) the steam pressure provided by a pressurized-water reactor plant varies with output, the maximum pressure occurring at no load and decreasing approximately linearly with load to a minimum at full power; hence, **blade stresses** in a nuclear turbine increase more rapidly with a decrease in power than in a conventional turbine. Special attention must be given to the design of the control stage of a nuclear turbine. The *N.S. Savannah* was designed for 700 psig (4.83 MN/m^2) at no load and 400 psig (2.76 MN/m^2) at full power.

Steam Plant—Heat Balance The heat-balance calculation is the basic analysis tool for determining the effect of various steam cycles on the thermal efficiency of the plant and for determining the quantities of steam and feedwater flow.

The thermal arrangement of a **simple steam cycle,** illustrated in Fig. 11.3.14, and the following simplified analysis are taken from "Marine Engineering," SNAME, 1992.

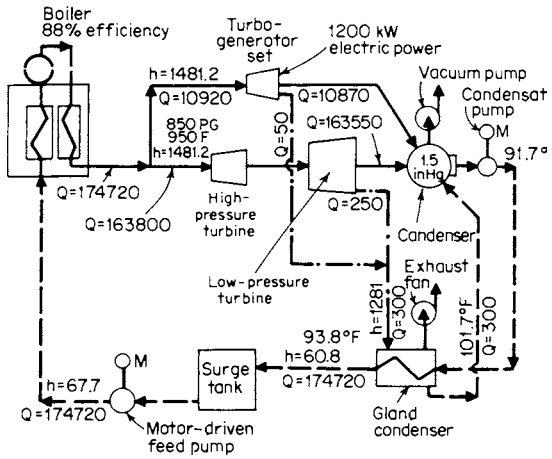

Fig. 11.3.14 Simple steam cycle. *(From "Marine Engineering," SNAME, 1992.)*

The unit is assumed to develop 30,000 shp (22,371 kW$_S$). The steam rate of the main propulsion turbines is 5.46 lb/(shp · h) [3.32 kg/ (kW$_S$ · h)] with throttle conditions of 850 psig (5.86 MN/m^2) and 950°F (510°C) and with the turbine exhausting to the condenser at 1.5 inHg abs (5,065 N/m^2). To develop 30,000 shp (22,371 kW$_S$), the throttle flow must be 163,800 lb/h (74,298 kg/h).

The generator load is estimated to be 1,200 kW, and the turbogenerator is thus rated at 1,500 kW with a steam flow of 10,920 lb/h (4,953 kg/h) for steam conditions of 850 psig (5.86 MN/m^2) and 950°F (510°C) and a 1.5 inHg abs (5,065 N/m^2) back pressure. The total steam flow is therefore 174,720 lb/h (79,251 kg/h).

Tracing the steam and water flow through the cycle, the flow exhausting from the main turbine is 163,800 − 250 = 163,550 lb/h (74,298 − 113 = 74,185 kg/h), 250 lb/h (113 kg/h) to the gland condenser, and from the auxiliary turbine is 10,870 lb/h (4,930 kg/h), 50 lb/h (23 kg/h) to the gland condenser. The two gland leak-off flows return from the gland leak-off condenser to the main condenser. The condensate flow leaving the main condenser totals 174,720 lb/h (79,251 kg/h).

It is customary to allow a 1°F (0.556°C) hot-well depression in the condensate temperature. Thus, at 1.5 inHg abs (5,065 N/m^2) the condenser saturation temperature is 91.7°F (33.2°C) and the condensate is 90.7°F (32.6°C). Entering the gland condenser there is a total energy flow of 174,720 × 59.7 = 10,430,784 Btu/h (11,004,894,349 J/h). The gland condenser receives gland steam at 1,281 Btu/lb (2,979,561 J/kg) and drains at a 10°F (5.6°C) terminal difference or 101.7°F (38.6°C). This adds a total of 300 × (1,281 − 69.7) or 363,390 Btu/h (383,390,985 J/h) to the condensate, making a total of 10,794,174 Btu/h (11,388,285,334 J/h) entering the surge tank. The feed leaves the surge tank at the same enthalpy with which it enters.

The feed pump puts an amount of heat into the feedwater equal to the total power of the pump, less any friction in the drive system. This friction work can be neglected but the heat from the power input is a significant quantity. The power input is the total pump head in feet of feedwater, times the quantity pumped in pounds per hour, divided by the mechanical equivalent of heat and the efficiency. Thus,

Heat equivalent of feed pump work

$$= \frac{144 \Delta P v_f Q}{778 E} \quad \text{Btu/h} \quad \left(\frac{\Delta P v_f Q}{E} \quad \text{J/h} \right)$$

where ΔP = pressure change, lb/in^2 (N/m^2); v_f = specific volume of fluid, ft^3/lb (m^3/kg); Q = mass rate of flow, lb/h (kg/h); and E = efficiency of pump.

Assuming the feed pump raises the pressure from 15 to 1,015 lb/in^2 abs (103,421 to 6,998,178 N/m^2), the specific volume of the water is 0.0161 ft^3/lb (0.001005 m^3/kg), and the pump efficiency is 50 percent, the heat equivalent of the feed pump work is 1,041,313 Btu/h (1,098,626,868 J/h). This addition of heat gives a total of 11,835,487 Btu/h (12,486,912,202 J/h) entering the boiler. Assuming no leakage of steam, the steam leaves the boiler at 1,481.2 Btu/lb (3,445,219 J/kg), with a total thermal energy flow of 1,481.2 × 174,720 = 258,795,264 Btu/h (273,039,355,300 J/h). The difference between this total heat and that entering [258,795,264 − 11,835,487 = 246,959,777 Btu/h (260,552,443,098 J/h)] is the net heat added in the boiler by the fuel. With a boiler efficiency of 88 percent and a fuel having a higher heating value of 18,500 Btu/lb (43,030,353 J/kg), the quantity of fuel burned is

$$\text{Fuel flow rate} = 246{,}959{,}777/(18{,}500)(0.88) = 15{,}170 \text{ lb/h}$$

or $$260{,}552{,}443{,}098/(43{,}030{,}353)(0.88) = 6{,}881 \text{ kg/h}$$

The specific fuel rate is the fuel flow rate divided by the net shaft power [15,170/30,000 = 0.506 lb/(shp · h) or 6881/22,371 = 0.308 kg/(kW_S · h)]. The heat rate is the quantity of heat expended to produce one horsepower per hour (one kilowatt per hour) and is calculated by dividing the net heat added to the plant, per hour, by the power produced.

Heat rate

$$= (15{,}170 \text{ lb/h})(18{,}500 \text{ Btu/lb})/30{,}000 \text{ shp} = 9{,}335 \text{ Btu/(ship} \cdot \text{h)}$$

or $$296{,}091{,}858{,}933/22{,}371 = 13{,}235{,}522 \text{ J/(kW}_S \cdot \text{h)}$$

This simple cycle omits many details that must necessarily be included in an actual steam plant. A continuation of the example, developing the details of a complete analysis, is given in "Marine Engineering," SNAME, 1992. A heat balance is usually carried through several iterations until the desired level of accuracy is achieved. The first heat balance may be done from approximate data given in the SNAME Technical and Research Publication No. 3-11, "Recommended Practices for Preparing Marine Steam Power Plant Heat Balances," and then updated as equipment data are known.

Diesel Engines

(See Sec. 9.)

While steam plants are custom-designed, diesel engines and gas turbines are selected from commercial sources at discrete powers. Diesel engines are referred to as being high, medium, or low speed. Low-speed diesels are generally categorized as those with engine speeds less than about 300 r/min, high-speed in excess of 1,200 r/min. Low-speed marine diesel engines are directly coupled to the propeller shaft. Unlike steam turbines and gas turbines, which require special reversing provisions, most direct-drive diesel engines are readily reversible.

Slow-speed diesel engines are well-suited to marine propulsion. Although larger, heavier, and initially more expensive than higher-speed engines, they generally have lower fuel, operating, and maintenance costs. Slow-speed engine parts take longer to wear to the same percentage of their original dimension than high-speed engine parts. Largebore, low-speed diesel engines have inherently better combustion performance with lower-grade diesel fuels. However, a well-designed high-speed engine which is not overloaded can give equally good service as a slow-speed engine.

Medium- and High-Speed Diesels The number of medium- and high-speed diesel engines used in marine applications is relatively small compared to the total number of such engines produced. The medium- and high-speed marine engine of today is almost universally an adaptation of engines built in quantities for service in automotive and stationary applications. The automotive field contributes high-speed engine applications in the 400-hp (298-kW) range, with engine speeds commonly varying from 1,800 to 3,000 r/min, depending on whether use is continuous or intermittent. Diesels in the 1,200- to 1,800-r/min range are typical of off-highway equipment engines at powers from 500 to upward of 1,200 hp (373 to 895 kW). Medium-speed diesel engines in units from 6 to 20 cylinders are available at ratings up to and exceeding 8,000 hp (5,966 kW) from both locomotive and stationary engine manufacturers. These applications are not all-inclusive, but only examples of the wide variety of diesel ratings commercially available today.

Some of the engines were designed with **marine applications** in mind, and others require some modification in external engine hardware. The changes are those needed to suit the engine to the marine environment, meaning salt-laden air, high humidity, use of corrosive seawater for cooling, and operating from a pitching and rolling platform. It also may mean an installation made in confined spaces. In order to adapt to this environment, the prime requisite of the marine diesel engine is the ability to resist corrosion. Because marine engines may be installed with their crankshafts at an angle to the horizontal and because they are subjected to more motion than in many other applications, changes are also necessary in the lubricating oil system. The air intake to a marine engine may not be dust-free and dirt-free when operating in harbors, inland waters, or close offshore; therefore, it is as important to provide a good air cleaner as in any automotive or stationary installation.

Diesel engines are utilized in all types of marine vehicles, both in the merchant marine and in the navies of the world. The power range in which diesel engines have been used has increased directly with the availability of higher-power engines. The line of demarcation in horsepower between what is normally assigned to diesel and to steam has continually moved upward, as has the power installed in ships in general.

Small boats in use in the Navy are usually powered by diesel engines, although the gas turbine is being used in special boats where high speed for short periods of time is the prime requirement. Going a little higher in power, diesels are used in many kinds of workboats such as fishing boats, tugs, ferries, dredges, river towboats and pushers, and smaller types of cargo ships and tankers. They are used in the naval counterparts of these ships and, in addition, for military craft such as minesweepers, landing ships, patrol and escort ships, amphibious vehicles, tenders, submarines, and special ships such as salvage and rescue ships and icebreakers. In the nuclear-powered submarine, the diesel is relegated to emergency generator-set use; however, it is still the best way to power a nonnuclear submarine when not operating on the batteries. This will likely change, giving way to the new technology of air-independent propulsion systems for nonnuclear submarines.

Diesel engines are used either singly or in multiple to drive propeller shafts. For all but high-speed boats, the rpm of the modern diesel is too fast to drive the propeller directly with efficiency, and some means of speed reduction, either mechanical or electrical, is necessary. If a single engine of the power required for a given application is available, then a decision must be made whether it or several smaller engines should be used. The decision may be dictated by the available space. The diesel power plant is flexible in adapting to specific space requirements. When more than one engine is geared to the propeller shaft, the gear serves as both a speed reducer and combining gear. The same series of engines could be used in an electric-drive propulsion system, with even greater flexibility. Each engine drives its own generator and may be located independently of other engines and the propeller shaft.

Low-Speed, Direct-Coupled Diesels Of the more usual prime mover selections, only low-speed diesel engines are directly coupled to the propeller shaft. This is due to the low rpm required for efficient propeller operation and the high rpm inherent with other types of prime movers.

A rigid hull foundation, with a high resistance to vertical, athwartship, and fore-and-aft deflections, is required for the low-speed

diesel. The engine room must be designed with sufficient overhaul space and with access for large and heavy replacement parts to be lifted by cranes.

Because of the low-frequency noise generated by low-speed engines, the operating platform often can be located at the engine itself. Special control rooms are often preferred as the noise level in the control room can be significantly less than that in the engine room.

Electric power may be produced by a generator mounted directly on the line shafting. Operation of the entire plant may be automatic and remotely controlled from the bridge. The engine room is often completely unattended for 16 h a day.

Gas Turbines

(See Sec. 9.)

The gas turbine has developed since World War II to join the steam turbine and the diesel engine as alternative prime movers for various shipboard applications.

In gas turbines, the efficiency of the components is extremely important since the compressor power is very high compared with its counterpart in competitive thermodynamic cycles. For example, a typical marine propulsion gas turbine rated at 20,000 bhp (14,914 kW_B) might require a 30,000 hp (22,371 kW) compressor and, therefore, 50,000 hp (37,285 kW) in turbine power to balance the cycle.

The basic **advantages** of the gas turbine for marine applications are its simplicity, small size, and light weight. As an internal-combustion engine, it is a self-contained power plant in one package with a minimum number of large supporting auxiliaries. It has the ability to start and go on line very quickly. Having no large masses that require slow heating, the time required for a gas turbine to reach full speed and accept the load is limited almost entirely by the rate at which energy can be supplied to accelerate the rotating components to speed. A further feature of the gas turbine is its low personnel requirement and ready adaptability to automation.

The relative simplicity of the gas turbine has enabled it to attain outstanding records of reliability and maintainability when used for aircraft propulsion and in industrial service. The same level of reliability and maintainability is being achieved in marine service if the unit is properly applied and installed.

Marine units derived from aircraft engines usually have the gas generator section, comprising the compressor and its turbine, arranged to be removed and replaced as a unit. Maintenance on the power turbine, which usually has the smallest part of the total maintenance requirements, is performed aboard ship. Because of their light weight, small gas turbines used for auxiliary power or the propulsion of small boats, can also be readily removed for maintenance.

Units designed specifically for marine use and those derived from industrial gas turbines are usually maintained and overhauled in place. Since they are somewhat larger and heavier than the aviation-type units, removal and replacement are not as readily accomplished. For this reason, they usually have split casings and other provisions for easy access and maintenance. The work can be performed by the usual ship repair forces.

Both **single-shaft** and **split-shaft** gas turbines can be used in marine service. Single-shaft units are most commonly used for generator drives. When used for main propulsion, where the propeller must operate over a very wide speed range, the single-shaft unit must have a controllable-pitch propeller or some equivalent variable-speed transmission, such as an electric drive, because of its limited speed range and poor acceleration characteristics. A multishaft unit is normally used for main propulsion, with the usual arrangement being a split-shaft unit with an independent variable-speed power turbine; the power turbine and propeller can be stopped, if necessary, and the gas producer kept in operation for rapid load pickup. The use of variable-area nozzles on the power turbine increases flexibility by enabling the compressor to be maintained at or near full speed and the airflow at low-power turbine speeds. Nearly full power is available by adding fuel, without waiting for the compressor to accelerate and increase the airflow. Where low-load economy is of importance, the controls can be arranged to reduce the compressor speed at low loads and maintain the maximum turbine inlet and/or exhaust temperature for best efficiency. Since a gas turbine inherently has a poor part-load fuel rate performance, this variable-area nozzle feature can be very advantageous.

The **physical arrangement** of the various components, i.e., compressors, combustion systems, and turbines, that make up the gas turbine is influenced by the thermodynamic factors (i.e., the turbine connected to a compressor must develop enough power to drive it), by mechanical considerations (i.e., shafts must have adequate bearings, seals, etc.), and also by the necessity to conduct the very high air and gas flows to and from the various components with minimum pressure losses.

In marine applications, the gas turbines usually **cannot be mounted rigidly** to the ship's structure. Normal movement and distortions of the hull when under way would cause distortions and misalignment in the turbine and cause internal rubs or bearing and/or structural failure. The turbine components can be mounted on a subbase built up of structural sections of sufficient rigidity to maintain the gas-turbine alignment when properly supported by the ship's hull.

Since the gas turbine is a high-speed machine with output shaft speeds ranging from about 3,600 r/min for large machines up to 100,000 r/min for very small machines (approximately 25,000 r/min is an upper limit for units suitable for the propulsion of small boats), a **reduction gear is necessary** to reduce the speed to the range suitable for a propeller. Smaller units suitable for boats or driving auxiliary units, such as generators in larger vessels, frequently have a reduction gear integral with the unit. Larger units normally require a separate reduction gear, usually of the double- or triple-reduction type.

A gas turbine, in common with all turbine machinery, is **not inherently reversible** and must be reversed by external means. Electric drives offer ready reversing but are usually ruled out on the basis of weight, cost, and to some extent efficiency. From a practical standpoint there are two alternatives, a reversing gear or a controllable reversible-pitch (CRP) propeller. Both have been used successfully in gas-turbine-driven ships, with the CRP favored.

Combined Propulsion Plants

In some shipboard applications, diesel engines, gas turbines, and steam turbines can be employed effectively in various combinations. The prime movers may be combined either mechanically, thermodynamically, or both. The leveling out of specific fuel consumption over the operating speed range is the goal of most combined systems.

The gas turbine is a very flexible power plant and consequently figures in most possible combinations which include combined diesel and gas-turbine plants **(CODAG);** combined gas- and steam-turbine plants **(COGAS);** and combined gas-turbine and gas-turbine plants **(COGAG).** In these cycles, gas turbines and other engines or gas turbines of two different sizes or types are combined in one plant to give optimum performance over a very wide range of power and speed. In addition, combinations of diesel or gas-turbine plants **(CODOG),** or gas-turbine or gas-turbine plants **(COGOG),** where one plant is a diesel or small gas turbine for use at low or cruising powers and the other a large gas turbine which operates alone at high powers, are also possibilities. Even the combination of a small nuclear plant and a gas turbine plant **(CONAG)** has undergone feasibility studies.

COGAS Gas and steam turbines are connected to a common reduction gear, but thermodynamically are either independent or combined. Both gas- and steam-turbine drives are required to develop full power. In a thermodynamically independent plant, the boost power is furnished by a lightweight gas turbine. This combination produces a significant reduction in machinery weight.

In the thermodynamically combined cycle, commonly called STAG (steam and gas turbine) or COGES (used with electric-drive systems), energy is recovered from the exhaust of the gas turbine and is used to augment the main propulsion system through a steam turbine. The principal advantage gained by the thermodynamic interconnection is the potential for improved overall efficiency and resulting fuel savings. In this arrangement, the gas turbine discharges to a heat-recovery boiler where a large quantity of heat in the exhaust gases is used to generate

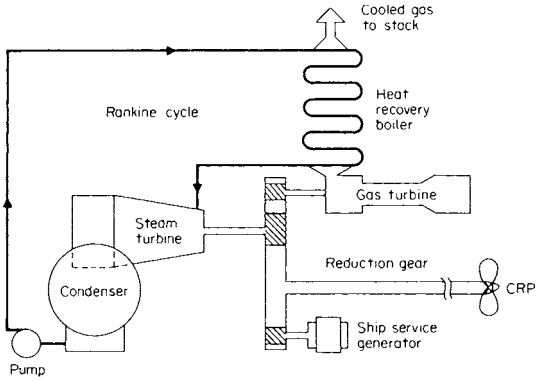

Fig. 11.3.15 COGAS system schematic.

steam. The boiler supplies the steam turbine that is geared to the propeller. The steam turbine may be coupled to provide part of the power for the gas-turbine compressor. The gas-turbine may be used to provide additional propulsion power, or its exhaust may be recovered to supply heat for various ship's services (Fig. 11.3.15).

Combined propulsion plants have been used in several applications in the past. **CODOG** plants have serviced some Navy patrol gunboats and the Coast Guard's Hamilton class cutters. Both **COGOG** and **COGAS** plants have been used in foreign navies, primarily for destroyer-type vessels.

PROPULSORS

The force to propel a marine vehicle arises from the rate of change of momentum induced in either the water or air. Since the force produced is directly proportional to the mass density of the fluid used, the reasonable choice is to induce the momentum change in water. If air were used, either the cross-sectional area of the jet must be large or the velocity must be high. A variety of propulsors are used to generate this stream of water aft relative to the vehicle: screw propellers, controllable-pitch propellers, water jets, vertical-axis propellers, and other thrust devices. Figure 11.3.16 indicates the type of propulsor which provides the best efficiency for a given vehicle type.

Screw Propellers

The screw propeller may be regarded as part of a helicoidal surface which, as it rotates, appears to "screw" its way through the water, driving water aft and the vehicle forward. A propeller is termed **"right-handed"** if it turns clockwise (viewed from aft) when producing ahead thrust; if

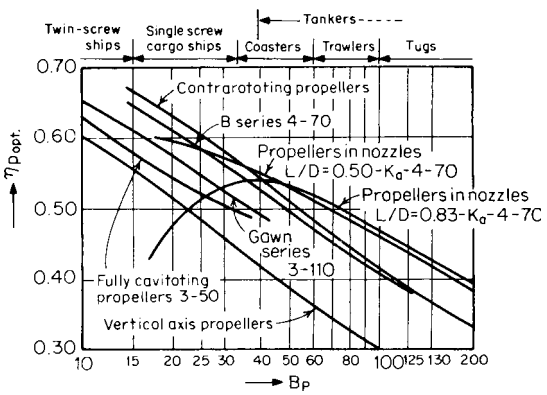

Fig. 11.3.16 Comparison of optimum efficiency values for different types of propulsors. *(From "Marine Engineering," SNAME, 1992.)*

counterclockwise, **"left-handed."** In a twin-screw installation, the starboard propeller is normally right-handed and the port propeller left-handed. The surface of the propeller blade facing aft, which experiences the increase in pressure, producing thrust, is the **face** of the blade; the forward surface is the **back.** The face is commonly constructed as a true helical surface of constant pitch; the back is not a helical surface. A **true helical surface** is generated by a line rotated about an axis normal to itself and advancing in the direction of this axis at constant speed. The distance the line advances in one revolution is the **pitch.** For simple propellers, the pitch is constant on the face; but in practice, it is common for large propellers to have a reduced pitch toward the hub and less usually toward the tip. The pitch at 0.7 times the maximum radius is usually a representative mean pitch; maximum lift is generated at that approximate point. Pitch may be expressed as a dimensionless ratio, *P/D.*

The **shapes** of blade outlines and sections vary greatly according to the type of ship for which the propeller is intended and to the designer's ideas. Figure 11.3.17 shows a typical design and defines many of the terms in common use. The **projected area** is the area of the projection of the propeller contour on a plane normal to the shaft, and the **developed area** is the total face area of all the blades. If the variation of helical cord length is known, then the true blade area, called **expanded area,** can be obtained graphically or analytically by integration.

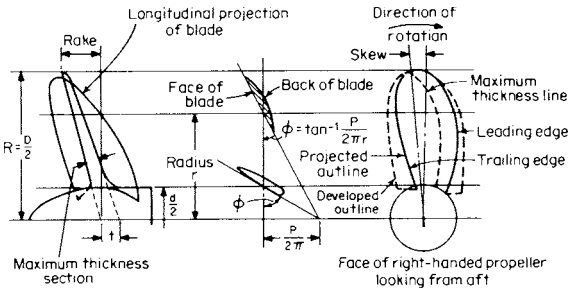

Fig. 11.3.17 Typical propeller drawing. *(From "Principles of Naval Architecture," SNAME, 1988.)*

Diameter = D Pitch ratio = P/D Pitch = P
Blade thickness ratio = t/D No. of blades = 4
Pitch angle = ϕ
Disk area = area of tip circle = $\pi D^2/4 = A_O$
Developed area of blades, outside hub = A_D
Developed area ratio = DAR = A_D/A_O
Projected area of blades (on transverse plane) outside hub = A_P
Projected area ratio = PAR = A_P/A_O
Blade width ratio = BWR = (max. blade width)/D
Mean width ratio = MWR = [A_D/length of blades (outside hub)]/D

Consider a section of the propeller blade at a radius r with a pitch angle ϕ and pitch P working in an unyielding medium; in one revolution of the propeller it will advance a distance P. Turning n revolutions in unit time it will advance a distance $P \times n$ in that time. In a real fluid, there will be a certain amount of yielding when the propeller is developing thrust and the screw will not advance $P \times n$, but some smaller distance. The difference between $P \times n$ and that smaller distance is called the **slip velocity. Real slip ratio** is defined in Fig. 11.3.18.

A wake or a frictional belt of water accompanies every hull in motion; its velocity varies as the ship's speed, hull shape, the distance from the ship's side and from the bow, and the condition of the hull surface. For ordinary propeller design the **wake velocity** is a fraction w of the ship's speed. Wake velocity = wV. The **wake fraction** w for a ship may be obtained from Fig. 11.3.19. The velocity of the ship relative to the ship's wake at the stern is $V_A = (1 - w)V$.

The **apparent slip ratio** S_A is given by

$$S_A = (Pn - V)/Pn = 1 - V/Pn$$

Although real slip ratio, which requires knowledge of the wake fraction, is a real guide to ship performance, the apparent slip ratio requires

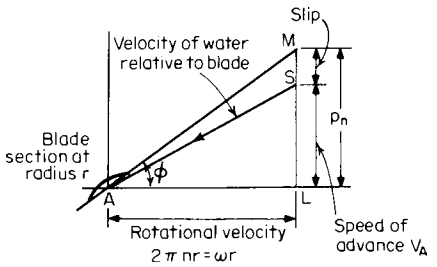

Fig. 11.3.18 Definition of slip. *(From "Principles of Naval Architecture," SNAME, 1988.)*

$$\tan \varphi = Pn/2\pi nr = P/2\pi r$$

$$\text{Real slip ratio} = S_R = MS/ML = (Pn - V_A)/Pn = 1 - V_A/Pn$$

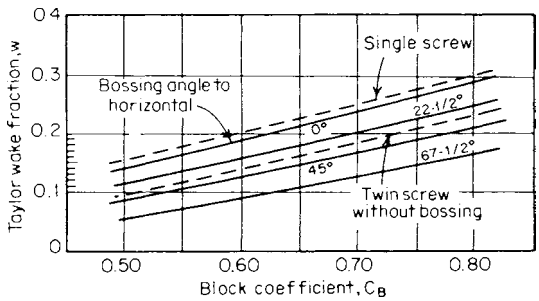

Fig. 11.3.19 Wake fractions for single- and twin-screw models. *(From "Principles of Naval Architecture," SNAME, 1988.)*

only ship speed, revolutions, and pitch to calculate and is therefore often recorded in ships' logs.

For P in ft (m), n in r/min, and V in knots, $S_A = (Pn - 101.3\ V)/Pn$; $[S_A = (Pn - 30.9V)/Pn]$.

Propeller Design The design of a marine propeller is usually carried out by one of two methods. In the first, the design is based upon charts giving the results of open-water tests on a series of model propellers. These cover variations in a number of the design parameters such as pitch ratio, blade area, number of blades, and section shapes. A propeller which conforms with the characteristics of any particular series can be rapidly designed and drawn to suit the required ship conditions.

The second method is used in cases where a propeller is heavily loaded and liable to cavitation or has to work in a very uneven wake pattern; it is based on purely theoretical calculations. Basically this involves finding the chord width, section shape, pitch, and efficiency at a number of radii to suit the average circumferential wake values and give optimum efficiency and protection from cavitation. By integration of the resulting thrust and torque-loading curves over the blades, the thrust, torque, and efficiency for the whole propeller can be found.

Using the first method and **Taylor's propeller** and **advance coefficients** B_P and δ, a convenient practical design and an initial estimate of propeller size can be obtained

$$B_P = \frac{n(P_D)^{0.5}}{(V_A)^{2.5}} \qquad \left[\frac{1.158n(P_D)^{0.5}}{(V_A)^{2.5}}\right]$$

$$\delta = \frac{nD}{V_A} \qquad \left(\frac{3.281nD}{V_A}\right)$$

$$\eta_O = \frac{TV_A}{325.7P_D\eta_R} \qquad \left(\frac{TV_A}{1{,}942.5P_D\eta_R}\right)$$

where B_p = Taylor's propeller coefficient; δ = Taylor's advance coefficient; n = r/min; P_D = delivered power, dhp (kW_D); V_A = speed of advance, knots; D = propeller diameter, ft (m); T = thrust, lb (N); η_O = open-water propeller efficiency; η_R = relative rotative efficiency ($0.95 < \eta_R < 1.0$, twin-screw; $1.0 < \eta_R < 1.05$, single-screw), a factor which corrects η_O to the efficiency in the actual flow conditions behind the ship.

Assume a reasonable value for n and, using known values for P_D and V_A (for a useful approximation, $P_D = 0.98P_S$), calculate B_p. Then enter Fig. 11.3.20, or an appropriate series of Taylor or Troost propeller charts, to determine δ, η_O, and P/D for optimum efficiency. The charts and parameters should be varied, and the results plotted to recognize the most suitable propeller.

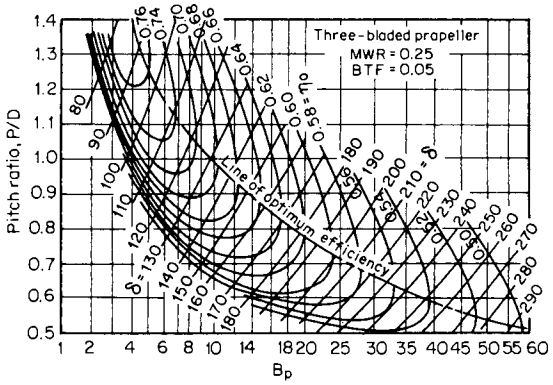

Fig. 11.3.20 Typical Taylor propeller characteristic curves. *(From "Handbook of Ocean and Underwater Engineering," McGraw-Hill, 1969.)*

Propeller cavitation, when severe, may result in marked increase in rpm, slip, and shaft power with little increase in ship speed or effective power. As cavitation develops, noise, vibration, and erosion of the propeller blades, struts, and rudders are experienced. It may occur either on the face or on the back of the propeller. Although cavitation of the face has little effect on thrust and torque, extensive cavitation of the back can materially affect thrust and, in general, requires either an increase in blade area or a decrease in propeller rpm to avoid. The erosion of the backs is caused by the collapse of cavitation bubbles as they move into higher pressure regions toward the trailing edge.

Avoidance of cavitation is an important requirement in propeller design and selection. The Maritime Research Institute Netherlands (MARIN) suggests the following **criterion** for the minimum blade area required **to avoid cavitation:**

$$A_P^2 = \frac{T^2}{1{,}360(p_0 - p_v)^{1.5}V_A} \qquad \text{or} \qquad \left[\frac{T^2}{5.44(p_0 - p_v)^{1.5}V_A}\right]$$

where A_p = projected area of blades, ft^2 (m^2); T = thrust, lb (N); p_0 = pressure at screw centerline, due to water head plus atmosphere, lb/in^2 (N/m^2); p_v = water-vapor pressure, lb/in^2 (N/m^2); and V_A = speed of advance, knots (1 knot = 0.515 m/s); and

$$p_0 - p_v = 14.45 + 0.45h \qquad lb/in^2$$

or

$$(p_0 - p_v = 99{,}629 + 10{,}179h \qquad N/m^2)$$

where h = head of water at screw centerline, ft (m).

A four-blade propeller of 0.97 times the diameter of the three-blade, the same pitch ratio, and four-thirds the area will absorb the **same power** at the same rpm as the three-blade propeller. Similarly, a two-blade propeller of 5 percent greater diameter is approximately equivalent to a three-blade unit. Figure 11.3.20 shows that propeller efficiency increases with decrease in value of the propeller coefficient B_p. A low value of B_p in a slow-speed ship calls for a large-diameter (optimum) propeller. It is frequently necessary to limit the diameter of the propeller and accept the accompanying loss in efficiency.

The number of propeller blades is usually three or four. Four blades are commonly used with single-screw merchant ships. Recently five, and

even seven, blades have been used to reduce vibration. Alternatively, highly skewed blades reduce vibration by creating a smoother interaction between the propeller and the ship's wake. Highly loaded propellers of fast ships and naval vessels call for large blade area, preferably three to five blades, to reduce blade interference and vibration.

Propeller fore-and-aft clearance from the stern frame of large single-screw ships at 70 percent of propeller radius should be greater than 18 in. The stern frame should be streamlined. The clearance from the propeller tips to the shell plating of twin-screw vessels ranges from about 20 in for low-powered ships to 4 or 5 ft for high-powered ships. U.S. Navy practice generally calls for a propeller tip clearance of $0.25D$. Many high-speed motorboats have a tip clearance of only several inches. The immersion of the propeller tips should be sufficient to prevent the drawing in of air.

EXAMPLE. Consider a three-blade propeller for a single-screw installation with $P_s = 2{,}950$ shp (2,200 kW_s), $V = 17$ knots, and $C_B = 0.52$. Find the propeller diameter D and efficiency η_O for $n = 160$ r/min.

From Fig. 11.3.19, the wake fraction $w = 0.165$. $V_A = V(1 - 0.165) = 14.19$ knots. $P_D = 0.98P_s = 2{,}891$ dhp (2,156 kW_D). At 160 r/min, $B_P = 160(2{,}891)^{0.5}/(14.19)^{2.5} = 11.34$. [$1.158 \times 160\,(2{,}156)^{0.5}/(14.19)^{2.5} = 11.34$.] From Fig. 11.3.20, the following is obtained or calculated:

r/min	B_p	P/d	η_O	δ	D, ft (m)	P, ft (m)
160	11.34	0.95	0.69	139	12.33 (3.76)	11.71 (3.57)

For a screw centerline submergence of 9 ft (2.74 m) and a selected projected area ratio PAR = 0.3, investigate the cavitation criterion. Assume $\eta_R = 1.0$.

Minimum projected area:

$$T = 325.7\,\eta_O\eta_R P_D/V_A = 325.7 \times 0.69 \times 1.0 \times 2{,}891/14.19 = 45{,}786 \text{ lb}$$
$$(T = 1{,}942.5 \times 0.69 \times 2{,}156/14.19 = 203{,}646 \text{ N})$$
$$p_0 - p_v = 14.45 + 0.45(9) = 18.5 \text{ lb/in}^2$$
$$(p_0 - p_v = 99{,}629 + 10{,}179(2.74 = 127{,}519 \text{ N/m}^2)$$
$$A_p^2 = (45{,}786)^2/1{,}360(18.5)^{1.5}(14.19) = 1{,}365, A_p = 36.95 \text{ ft}^2 \text{ minimum}$$
$$A_p^2 = (203{,}646)^2/5.44(127{,}519)^{1.5}(14.19) = 11.79, A_p = 3.43 \text{ m}^2 \text{ minimum}$$

Actual projected area: PAR $= A_p/A_0 = 0.3$, $A_p = 0.3A_0 = 0.37\pi\,(12.33)^2/4 = 35.82$ ft^2 (3.33 m^2).

Since the selected PAR does not meet the minimum cavitation criterion, either the blade width can be increased or a four-blade propeller can be adopted. To absorb the same power at the same rpm, a four-blade propeller of about $0.97\,(12.33) = 11.96$ ft (3.65 m) diameter with the same blade shape would have an $A_p = 35.82 \times 4/3 \times (11.96/12.33)^2 = 44.94$ ft^2 (4.17 m^2), or about 25 percent increase. The pitch $= 0.95\,(11.96) = 11.36$ ft (3.46 m). The real and apparent slip ratios for the four-blade propeller are:

$$S_R = 1 - (101.3)(14.19)/(11.36)(160) = 0.209$$
$$S_A = 1 - (30.9)(17.0)/(3.46)(160) = 0.051$$

that is, 20.9 and 5.1 percent (S_A calculated using SI values).

Since the projected area in the three-blade propeller of this example is only slightly under the minimum, a three-blade propeller with increased blade width would be the more appropriate choice.

Controllable-Pitch Propellers

Controllable-pitch propellers are screw propellers in which the blades are separately mounted on the hub, each on an axis, and in which the pitch of the blades can be changed, and even reversed, while the propeller is turning. The pitch is changed by means of an internal mechanism consisting essentially of hydraulic pistons in the hub acting on crossheads. Controllable-pitch propellers are most suitable for vehicles which must meet different operating conditions, such as tugs, trawlers, ferries, minesweepers, and landing craft. As the propeller pitch is changed, the engine can still run at its most efficient speed. Maneuvering is more rapid since the pitch can be changed more rapidly than could the shaft revolutions. By use of controllable-pitch propellers, neither reversing mechanisms are necessary in reciprocating engines, nor astern turbines in turbine-powered vehicles, especially important in gas-turbine installations. Except for the larger hub needed to house the pitch-changing mechanism, the controllable-pitch propeller can be made almost as efficient as the solid, fixed-blade propeller. Gas turbines and controllable reversible-pitch propellers (CRPs) are generally used in all recent U.S. Navy surface ship designs (except carriers).

Water Jet

This method usually consists of an impeller or pump inside the hull, which draws water from outside, accelerates it, and discharges it astern as a jet at a higher velocity. It is a reaction device like the propeller but in which the moving parts are contained inside the hull, desirable for shallow-water operating conditions and maneuverability. The overall efficiency is lower than that of the screw propeller of diameter equal to the jet orifice diameter, principally because of inlet and ducting losses. Other disadvantages include the loss of volume to the ducting and impeller and the danger of fouling of the impeller. Water jets have been used in several of the U.S. Navy's hydrofoil and surface-effect vehicles.

Vertical-Axis Propellers

There are two types of vertical-axis propulsor systems consisting of one or two vertical-axis rotors located underwater at the stern. Rotor disks are flush with the shell plating and have five to eight streamline, spade-like, vertical impeller blades fitted near the periphery of the disks. The blades feather during rotation of the disk to produce a maximum thrust effect in any direction desired. In the **Kirsten-Boeing** system the blades are interlocked by gears so that each blade makes a half revolution about its axis for each revolution of the disk. The blades of the **Voith-Schneider** system make a complete revolution about their own axis for each revolution of the disk. A bevel gear must be used to transmit power from the conventional horizontal drive shaft to the horizontal disk; therefore, limitations exist on the maximum power that can be transmitted. Although the propulsor is 30 to 40 percent less efficient than the screw propeller, it has obvious maneuverability advantages. Propulsors of this type have also been used at the bow to assist in maneuvering.

Other Thrust Devices

Pump Jet In a pump-jet arrangement, the rotating impeller is external to the hull with fixed guide vanes either ahead and/or astern of it; the whole unit is enclosed in a duct or long shroud ring. The duct diameter increases from the entrance to the impeller so that the velocity falls and the pressure increases. Thus the impeller diameter is larger, thrust loading less, and the efficiency higher; the incidence of cavitation and noise is delayed. A penalty is paid, however, for the resistance of the duct.

Kort Nozzles In the Kort nozzle system, the screw propeller operates in a ring or nozzle attached to the hull at the top. The longitudinal sections are of airfoil shape, and the length of the nozzle is generally about one-half its diameter. Unlike the pump-jet shroud ring, the Kort nozzle entrance is much bigger than the propeller, drawing in more water than the open propeller and achieving greater thrust. Because of the acceleration of the water into the nozzle, the pressure inside is less; hence a forward thrust is exerted on the nozzle and the hull. The greatest advantage is in a tug, pulling at rest. The free-running speed is usually less with the nozzle than without. In some tugs and rivercraft, the whole nozzle is pivoted and becomes a very efficient steering mechanism.

Tandem and Contrarotating Propellers Two or more propellers arranged on the same shaft are used to divide the increased loading factor when the diameter of a propeller is restricted. Propellers turning in the same direction are termed **tandem,** and in opposite directions, **contrarotating.** In tandem, the rotational energy in the race from the forward propeller is augmented by the after one. Contrarotating propellers work on coaxial, contrary-turning shafts so that the after propeller may regain the rotational energy from the forward one. The after propeller is of smaller diameter to fit the contracting race and has a pitch designed for proper power absorption. Such propellers have been used for years on torpedoes to prevent the torpedo body from rotating. Hydrodynamically, the advantages of contrarotating propellers are increased propulsive efficiency, improved vibration characteristics, and higher blade frequency. Disadvantages are the complicated gearing, coaxial shafting, and sealing problems.

Supercavitating Propellers When cavitation covers the entire back of a propeller blade, an increase of rpm cannot further reduce the pressure at the back but the pressure on the face continues to increase as does the total thrust, though at a slower rate than before cavitation began. Advantages of such fully cavitating propellers are an absence of back erosion and less vibration. Although the characteristics of such propellers were determined by trial and error, they have long been used on high-speed racing motor boats. The blade section design must ensure clean separation of flow at the leading and trailing edges and provide good lift-drag ratios for high efficiency. Introducing air to the back of the blades (**ventilated propeller**) will ensure full cavitation and also enables use at lower speeds.

Partially Submerged Propellers The appendage drag presented by a propeller supported below high-speed craft, such as planing boats, hydrofoil craft, and surface-effect ships, led to the development of partially submerged propellers. Although vibration and strength problems, arising from the cyclic loading and unloading of the blades as they enter and emerge from the air-water interface, remain to be solved, it has been demonstrated that efficiencies in partially submerged operation, comparable to fully submerged noncavitating operation, can be achieved. The performance of these propellers must be considered over a wide range of submergences.

Outboard Gasoline Engine Outboard gasoline engines of 1 to 300 bhp (0.75 to 225 kW_B), combining steering and propulsion, are popular for small pleasure craft. Maximum speeds of 3,000 to 6,000 r/min are typical, as driven by the propeller horsepower characteristics (see Sec. 9).

PROPULSION TRANSMISSION

In modern ships, only large-bore, slow-speed diesel engines are directly connected to the propeller shaft. Transmission devices such as mechanical speed-reducing gears or electric drives (generator/motor transmissions) are required to convert the relatively high rpm of a compact, economical prime mover to the relatively low propeller rpm necessary for a high propulsive efficiency. In the case of steam turbines, medium and high-speed diesel engines, and gas turbines, speed reduction gears are used. Gear ratios vary from relatively low values for medium-speed diesels up to approximately 50 : 1 for a compact turbine design. Where the prime mover is unidirectional, the drive mechanism must also include a reversing mechanism, unless a CRP is used.

Reduction Gears

Speed reduction is usually obtained with reduction gears. The simplest arrangement of a marine reduction gear is the **single-reduction,** single-input type, i.e., one pinion meshing with a gear (Fig. 11.3.21). This arrangement is used for connecting a propeller to a diesel engine or to an electric motor but is not used for propelling equipment with a turbine drive.

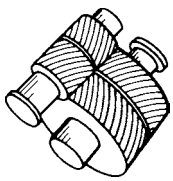

Fig. 11.3.21 Single-reduction, single-input gear. *(From "Marine Engineering," SNAME, 1992.)*

The usual arrangement for turbine-driven ships is the **double-reduction,** double-input, articulated type of reduction gear (Fig. 11.3.22). The two input pinions are driven by the two elements of a cross-compound turbine. The term *articulated* applies because a flexible coupling is generally provided between the first reduction or primary gear wheel and the second reduction or secondary pinion.

The **locked-train** type of double-reduction gear has become standard for high-powered naval ships and, because it minimizes the total weight and size of the assembly, is gaining increased popularity for higher-powered merchant ships (Fig. 11.3.23).

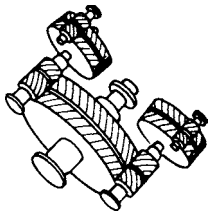

Fig. 11.3.22 Double-reduction, double-input, articulated gear. *(From "Marine Engineering," SNAME, 1992.)*

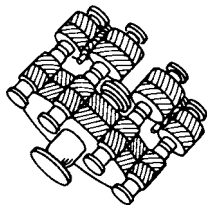

Fig. 11.3.23 Double-reduction, double-input, locked-train gear. *(From "Marine Engineering," SNAME, 1992.)*

Electric Drive

Electric propulsion drive is the principal alternative to direct- or geared-drive systems. The prime mover drives a generator or alternator which in turn drives a propulsion motor which is either coupled directly to the propeller or drives the propeller through a low-ratio reduction gear.

Among its **advantages** are the ease and convenience by which propeller speed and direction are controllable; the freedom of installation arrangement offered by the electrical connection between the generator and the propulsion motor; the flexibility of power use when not used for propulsion; the convenience of coupling several prime movers to the propeller without mechanical clutches or couplings; the relative simplicity of controls required to provide reverse propeller rotation when the prime mover is unidirectional; and the speed reduction that can be provided between the generator and the motor, hence between the prime mover and the propeller, without mechanical speed-reducing means.

The disadvantages are the inherently higher first cost, increased weight and space, and the higher transmission losses of the system. The advent of **superconductive electrical machinery** suitable for ship propulsion, however, has indicated order-of-magnitude savings in weight, greatly reduced volume, and the distinct possibility of lower costs. Superconductivity, a phenomenon occurring in some materials at low temperatures, is characterized by the almost complete disappearance of electrical resistance. Research and development studies have shown that size and weight reductions by factors of 5 or more are possible. With successful development of superconductive electrical machinery and resolution of associated engineering problems, monohulled craft, such as destroyers, can benefit greatly from the location flexibility and maneuverability capabilities of superconductive electric propulsion, but the advantages of such a system will be realized to the greatest extent in the new high-performance ships where mechanical-drive arrangement is extremely complex.

In general, electric propulsion drives are employed in marine vehicles requiring a high degree of maneuverability such as ferries, icebreakers, and tugs; in those requiring large amounts of special-purpose power such as fireboats, and large tankers; in those utilizing nonreversing, high-speed, and multiple prime movers; and in deep-submergence vehicles. Diesel-electric drive is ideally adapted to bridge control.

Reversing

Reversing may be accomplished by stopping and reversing a reversible engine, as in the case of many reciprocating engines, or by adding reversing elements in the prime mover, as in the case of steam turbines. It is impracticable to provide reversing elements in gas turbines; hence a reversing capability must be provided in the transmission system or in the propulsor itself. Reversing reduction gears for such transmissions are available up to quite substantial powers, and CRP propellers are also used with diesel or gas-turbine drives. Electrical drives provide reversing by dynamic braking and energizing the electric motor in the reverse direction. Waterjets reverse inserting reversing thrust buckets into the discharge stream.

Marine Shafting

A main propulsion shafting system consists of the equipment necessary to transmit the rotative power from the main propulsion engines to the

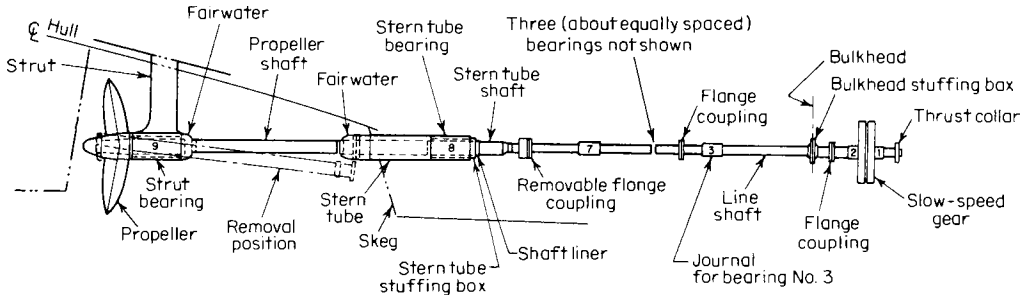

Fig. 11.3.24 Shafting arrangement with strut bearings. *(From "Marine Engineering," SNAME, 1992.)*

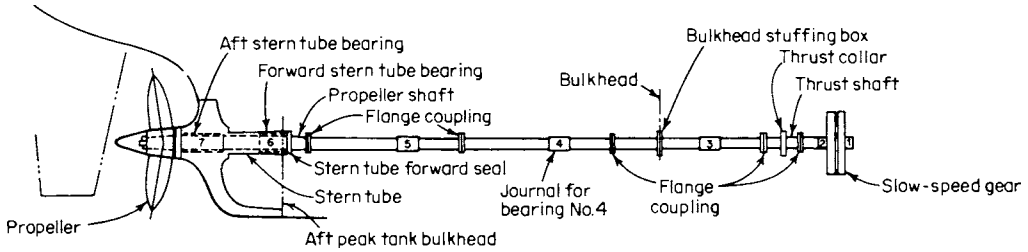

Fig. 11.3.25 Shafting arrangement without strut bearings. *(From "Marine Engineering," SNAME, 1992.)*

propulsor; support the propulsor; transmit the thrust developed by the propulsor to the ship's hull; safely withstand transient operating loads (e.g., high-speed maneuvers, quick reversals); be free of deleterious modes of vibration; and provide reliable operation.

Figure 11.3.24 is a shafting arrangement typical of multishaft ships and single-shaft ships with transom sterns. The shafting must extend outboard a sufficient distance for adequate clearance between the propeller and the hull. Figure 11.3.25 is typical of single-screw merchant ships.

The shafting located inside the ship is **line shafting.** The outboard section to which the propeller is secured is the **propeller shaft** or **tail shaft.** The section passing through the stern tube is the **stern tube shaft** unless the propeller is supported by it. If there is a section of shafting between the propeller and stern tube shafts, it is an **intermediate shaft.**

The principal dimensions, kind of material, and material tests are specified by the classification societies for marine propulsion shafting. The American Bureau of Shipping Rules for Steel Vessels specifies the minimum diameter of propulsion shafting, tail shaft bearing lengths, bearing liner and flange coupling thicknesses, and minimum fitted bolt diameters.

Tail or propeller shafts are of larger diameter than the line or tunnel shafting because of the propeller-weight-induced bending moment; also, inspection during service is possible only when the vessel is drydocked.

Propellers are fitted to shafts over 6 in (0.1524 m) diameter by a taper fit. Aft of the propeller, the shaft is reduced to 0.58 to 0.68 of its specified diameter under the liner and is fitted with a relatively fine thread, nut, and keeper. Propeller torque is taken by a long flat key, the width and total depth of which are, respectively, about 0.21 and 0.11 times the shaft diameter under the liner. The forward end of the key slot in the shaft should be tapered off in depth and terminate well aft of the large end of the taper to avoid a high concentrated stress at the end of the keyway. Every effort is made to keep saltwater out of contact with the steel tail shaft so as to prevent failure from corrosion fatigue.

A cast-iron, cast-steel, or wrought-steel-weldment **stern tube** is rigidly fastened to the hull. In single-screw ships it supports the propeller shaft and is normally provided with a packing gland at the forward end as seawater lubricates the stern-tube bearings. The aft stern-tube bearing is made four diameters in length; the forward stern-tube bearing is much shorter. A bronze liner, ¾ to 1 in (0.0191 to 0.0254 m) thick, is shrunk on the propeller shaft to protect it from corrosion and to give a good journal surface. Lignum-vitae inserts, epoxy applications, or rubber linings have been used for stern-tube bearings; the average bearing pressure is about 30 lb/in^2 (206,842 N/m^2). Rubber and phenolic compound bearings, having longitudinal grooves, are also extensively used. White-metal oil-lubricated bearings and, in Germany, roller-type stern bearings have been fitted in a few installations.

The line or tunnel shafting is laid out, in long equal lengths, so that, in the case of a single-screw ship, withdrawal of the tail shaft inboard for inspection every several years will require only the removal of the next inboard length of shafting. For large outboard or water-exposed shafts of twin-screw ships, a bearing spacing up to 30 shaft diameters has been used. A greater ratio prevails for steel shafts of power boats. Bearings inside the hull are spaced closer—normally under 15 diameters if the shaft is more than 6 in (0.1524 m) diameter. Usually, only the bottom half of the bearing is completely white-metaled; oil-wick lubrication is common, but oil-ring lubrication is used in high-class installations.

Bearings are used to support the shafting in essentially a straight line between the main propulsion engine and the desired location of the propeller. Bearings inside the ship are most popularly known as lineshaft bearings, steady bearings, or spring bearings. Bearings which support outboard sections of shafting are stern-tube bearings if they are located in the stern tube and strut bearings when located in struts.

The propeller thrust is transmitted to the hull by means of a main thrust bearing. The main thrust bearing may be located either forward or aft of the slow-speed gear.

HIGH-PERFORMANCE SHIP SYSTEMS

High-performance ships have spawned new hull forms and propulsion systems which were relatively unknown just a generation ago. Because of their unique characteristics and requirements, conventional propulsors are rarely adequate. The prime thrust devices range from those using water, to water-air mixtures, to large air propellers.

The total propulsion power required by these vehicles is presented in general terms in the Gabrielli and Von Karman plot of Fig. 11.3.26. Basically, there are those vehicles obtaining lift by displacement and those obtaining lift from a wing or foil moving through the fluid. In

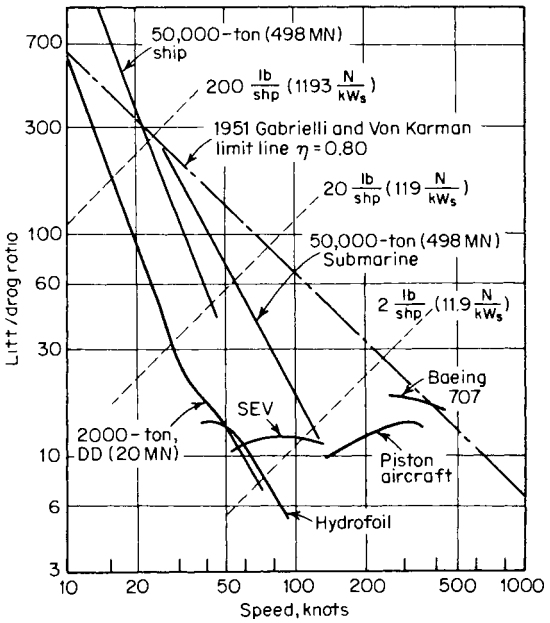

Fig. 11.3.26 Lift-drag ratio versus calm weather speed for various vehicles.

order for marine vehicles to maintain a reasonable lift-to-drag ratio over a moderate range of speed, the propulsion system must provide increased thrust at lower speeds to overcome low-speed wave drag. The weight of any vehicle is converted into total drag and, therefore, total required propulsion and lift power.

Lightweight, compact, and efficient propulsion systems to satisfy extreme weight sensitivity are achieved over a wide range of power by the marinized aircraft gas-turbine engine. Marinization involves addition of a power turbine unit, incorporation of air inlet filtration to provide salt-free air, addition of silencing equipment on both inlet and exhaust ducts, and modification of some components for resistance to salt corrosion. The shaft power delivered is then distributed to the propulsion and lift devices by lightweight shaft and gear power transmission systems.

A comparison of high-performance ship propulsion system characteristics is given in Table 11.3.3.

Hydrofoil Craft

Under foilborne conditions, the support of the hydrofoil craft is derived from the dynamic lift generated by the foil system, and the craft hull is lifted clear of the water. Special problems relating to operation and directly related to the conditions presented by waves, high fluid density, surface piercing of foils and struts, stability, control, cavitation, and

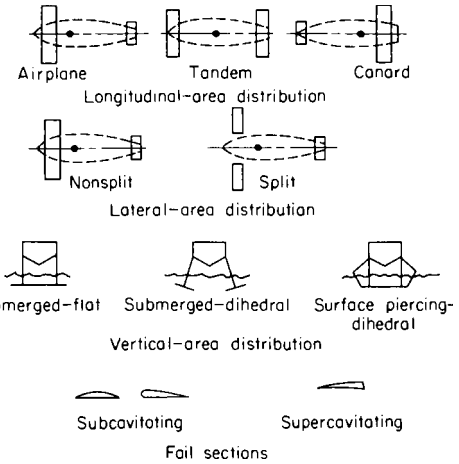

Fig. 11.3.27 Some foil arrangements and sections.

ventilation of foils have given rise to foil system configurations defined in Fig. 11.3.27.

The hydrofoil craft has three modes of operation: **hullborne, takeoff,** and **foilborne.** The thrust and drag forces involved in hydrofoil operation are shown in Fig. 11.3.28. Design must be a compromise between the varied requirements of these operating conditions. This may be difficult, as with propeller design, where maximum thrust is often required at takeoff speed (normally about one-half the operating speed).

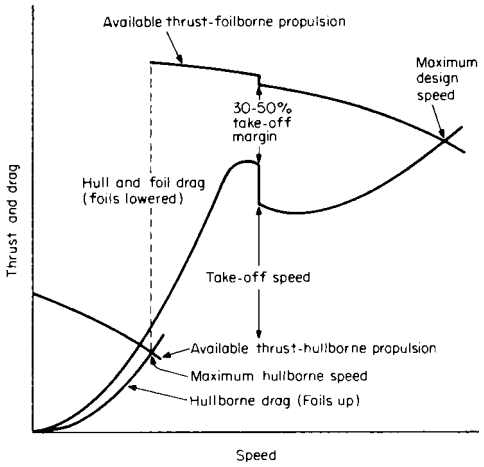

Fig. 11.3.28 Thrust and drag forces for a typical hydrofoil.

Table 11.3.3 U.S. Navy High-Performance Ship Propulsion System Characteristics

Ship	Engine	Propulsor/lift
Hydrofoil, PHM, 215 tons (2.1 MN), 50 knots	Foilborne: one LM-2500 GT, 22,000 bhp (15,405 kW_B), 3,600 r/min	Foilborne: one 2-stage axial-flow waterjet, twin aft strut inlets
Surface-effect ship, SES-200, 195 tons (1.94 MN), 30 + knots	Propulsion: two 16V-149TI diesel, 1,600 bhp (1,193 kW_B)	Two waterjet units
	Lift: two 8V-92TI diesel, 800 bhp (597 kW_B)	Two double-inlet centrifugal lift fans
Air-cushion vehicle, LCAC, 150 tons (1.49 MN), 50 knots	Propulsion and lift: four TF-40B GT, 3,350 bhp (2,498 kW_B), 15,400 r/min	Two ducted-air propellers, 12 ft (3.66 m) dia., 1,250 r/min; four double-entry centrifugal lift fans, 1,900 r/min
SWATH, SSP, 190 tons (1.89 MN), 25 knots	Propulsion: two T-64 GT, 3,200 bhp (2,386 kW_B), 1,000 r/min at output of attached gearbox	Two subcavitating controllable-pitch propellers, 450 r/min

A propeller designed for maximum efficiency at takeoff will have a smaller efficiency at design speeds, and vice versa. This is complicated by the need for supercavitating propellers at operating speeds over 50 knots. Two sets of propellers may be needed in such a case, one for hull-borne operation and the other for foilborne operation. The selection of a surface-piercing or a fully submerged foil design is determined from specified operating conditions and the permissible degree of complexity. A **surface-piercing system** is inherently stable, as a deviation from the equilibrium position of the craft results in corrective lift forces. **Fully submerged foil** designs, on the other hand, provide the best lift-drag ratio but are not stable by themselves and require a depth-control system for satisfactory operation. Such a control system, however, permits operation of the submerged-foil design in higher waves.

Surface-Effect Vehicles (SEV)

The air-cushion-supported **surface-effect ship (SES)** and **air-cushion vehicle (ACV)** show great potential for high-speed and amphibious operation. Basically, the SEV rides on a cushion of air generated and maintained in the space between the vehicle and the surface over which it moves or hovers. In the SES, the cushion is captured by rigid sidewalls and flexible skirts fore and aft. The ACV has a flexible seal or skirt all around. Figure 11.3.29 illustrates two configurations of the surface-effect principle.

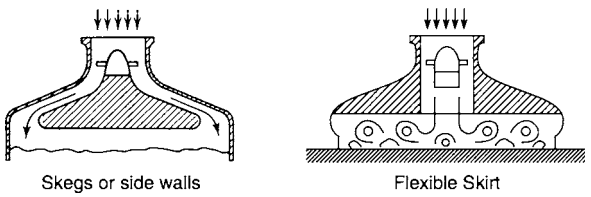

Fig. 11.3.29 Two configurations of the surface-effect principle.

Since the ACV must rise above either land or water, the propulsors use only air for thrust, requiring a greater portion of the total power allocated to lift than in the SES design as shown in Fig. 11.3.30.

While SES technology has greatly improved the capability of amphibious landing vehicles, it is rapidly being developed for high-speed large cargo vessels.

Small Water-Plane Area Twin Hull

The **SWATH,** configured to be relatively insensitive to seaway motions, gains its buoyant lift from two parallel submerged, submarinelike hulls which support the main hull platform through relatively small vertical struts. The small hull area at the waterline lowers the response of the hull to waves. The same small waterplane area makes the SWATH hull form sensitive to changes in weight and load distribution. In this configuration, a propulsion arrangement choice must be with regard to the location of the main engines. In the U.S. Navy's SSP, power from two independently operated gas turbines is transmitted down each aft strut by a group of three wide-belt chain drives with speed reduction to the propellers. By contrast, the T-AGOS 19 series SWATH vessels employ diesel-electric drive, with both motors and propulsors in the lower hull.

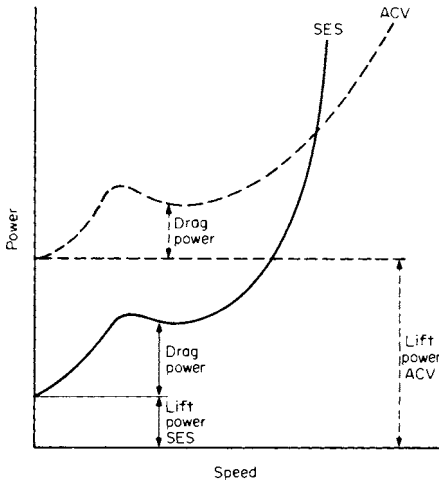

Fig. 11.3.30 Comparison of power requirements: SES versus ACV.

CARGO SHIPS

The development of containerization in the 1950s sparked a growth in ship size. More efficient cargo-handling methods and the desire to reduce transit time led to the emergence of the high-speed container vessel.

The Container Vessel

Because of low fuel costs in the 1950s and 1960s, early container vessel design focused on higher speed and container capacity. Rising fuel costs shifted emphasis toward ship characteristics which enhanced reduced operating costs, particularly as affected by fuel usage and trade route capacity. By the early 1980s, ships were generally sized for TEU (twenty-foot-equivalent-unit) capacity less than 2,500 and speeds of about 20 knots, lower if fuel was significant in the overall operating costs. Largely a function of the scale of trade route capacity, container ships carrying in excess of 5,000 TEUs are common today. The larger the trade capacity, the larger the containerships operating the route. However, many trade route scales do not support even moderately sized containership service.

The **on deck** and **under deck** container capacity varies with the type of vessel, whether a **lift on/lift off** vessel, a bulk carrier equipped for containers, or a **roll on/roll off** vessel. Extensive studies have been conducted to optimize the hull form and improve the operating efficiency for the modern containership.

11.4 AERONAUTICS

DEFINITIONS

Aeronautics is the science and art of flight and includes the operation of heavier-than-air aircraft. An **aircraft** is any weight-carrying device designed to be supported by the air, either by buoyancy or by dynamic action. An **airplane** is a mechanically driven fixed-wing aircraft, heavier than air, which is supported by the dynamic reaction of the air against its wings. An aircraft supported by buoyancy is called an **airship,** which can be either a balloon, a hot-air type, or of semirigid or rigid construction. These airships can be free floating or, if of semirigid or rigid design, propelled by fixed or vectoring propeller or jet propulsion. Ascent or descent is achieved primarily through helium gas or hot air, venting, and by the use of disposable ballast. A **helicopter** is a kind of aircraft lifted and moved by a large propeller mounted horizontally above the fuselage. It differs from the **autogiro** in that this propeller is turned by motor power and there is no auxiliary propeller for forward motion. A **ground-effect machine (GEM)** is a heavier-than-air surface vehicle which operates in close proximity to the earth's surface (over land or water), never touching except at rest, being separated from the surface by a cushion or film of air, however thin, and depending entirely upon aerodynamic forces for propulsion and control.

Aerodynamics is the branch of aeronautics that treats of the motion of air and other gaseous fluids and of the forces acting on solids in motion relative to such fluids. Aerodynamics falls into velocity ranges, depending upon whether the velocity is below or above the local speed of sound in the fluid. The velocity range below the local speed of sound is called the **subsonic** regime. Where the velocity is above the local speed of sound, the flow is said to be **supersonic.** The term **transonic** refers to flows in which both subsonic and supersonic regions are present. The **hypersonic** regime is that speed range usually in excess of five times the speed of sound.

STANDARD ATMOSPHERE

The U.S. Standard Atmosphere, 1976 of Table 11.4.1*a* is the work of the U.S. Committee on Extension to the Standard Atmosphere (COESA), established in 1953, which led to the 1958, 1962, 1966, and 1976 versions of this standard. It is an idealized, steady-state representation of the atmosphere and extends to approximately 621.4 miles (1000 kilometres) above the surface. It is assumed to rotate with the earth.

It is the same as COESA's "U.S. Standard Atmosphere—1962" below approximately 32 miles (51 km) but replaces this standard above this altitude. Figure 11.4.1 shows the variation of base temperature K with altitude Z up to approximately 76 miles (122 km). Above 281,952 feet, our distinct altitude zones are identified (Table 11.4.1*b*) in which

1000	3,280,992	1000.0	1340.3	—	2.907×10^{-15}	7.416×10^{-14}

temperature altitude relationships are defined relative to the base altitude of each zone. These four zones constitute the current standard atmosphere in terms of base temperature K from 53.4 miles to approximately 621.4 miles (1000 km). For further definition of the standard atmosphere in this four-zone region the reader is referred to U.S. Department of Commerce document "U.S. Standard Atmosphere, 1976," ADA035728.

The assumed sea-level conditions are: pressure, $p_0 = 29.91$ in (760 mm Hg) = 2,116.22 lb/ft^2; mass density, $\rho_0 = 0.002378$ slugs/ft^3 (0.001225 g/cm^3); $T_0 = 59°F$ (15°C).

UPPER ATMOSPHERE

High-altitude atmospheric data have been obtained directly from balloons, sounding rockets, and satellites and indirectly from observations of meteors, aurora, radio waves, light absorption, and sound effects. At relatively low altitudes, the earth's atmosphere is, for aerodynamic purposes, a uniform gas. Above 250,000 ft, day and night standards differ because of dissociation of oxygen by solar radiation. This difference in density is as high as 35 percent, but it is usually aerodynamically negligible above 250,000 ft since forces here will become less than 0.05 percent of their sea-level value for the same velocity.

Temperature profile of the COESA atmosphere is given in Fig. 11.4.1. From these data, other properties of the atmosphere can be calculated.

Speed in aeronautics may be given in knots (now standard for U.S Armed Forces and FAA), miles per hour, feet per second, or metres per second. The international nautical mile = 6,076.1155 ft (1,852 m). The basic relations are: 1 knot = 0.5144 m/s = 1.6877 ft/s = 1.1508 mi/h. For additional conversion factors see Sec. 1. Higher speeds are often given as **Mach number,** or the ratio of the particular speed to the speed of sound in the surrounding air. For additional data see "Supersonic and Hypersonic Aerodynamics" below.

Axes The forces and moments acting on an airplane (and the resultant velocity components) are referred to a set of three mutually perpendicular axes having the origin at the airplane center of gravity (cg) and moving with the airplane. Three sets of axes are in use. The basic difference in these is in the direction taken for the longitudinal, or x, axis, as follows:

Wind axes: The x axis lies in the direction of the relative wind. This is the system most commonly used, and the one used in this section. It is shown on Fig. 11.4.2.

Body axes: The x axis is fixed in the body, usually parallel to the thrust line.

Stability axes: The x axis points in the initial direction of flight. This results in a simplification of the equations of motion.

Absolute Coefficients Aerodynamic force and moment data are usually presented in the form of absolute coefficients. Examples of force coefficients are: lift $C_L = L/qS$; drag $C_D = D/qS$; side force $C_Y = Y/qS$; where q is the dynamic pressure $\frac{1}{2}\rho V^2$, ρ = air mass-density, and V = air speed. Examples of moment coefficients are $C_m = M/qSc$; roll $C_l = L/qSb$; and yaw $C_n = N/qSb$; where c = mean wing chord and b = wing span.

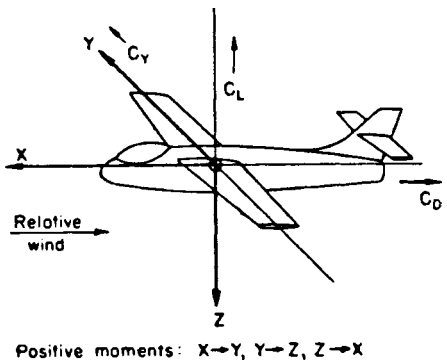

Fig. 11.4.2 Wind axes.

Section Coefficients Basic test data on wing sections are usually given in the form of section lift coefficient C_l and section drag coefficient C_d. These apply directly to an infinite aspect ratio or to two-dimensional flow, but aspect-ratio and lift-distribution corrections are necessary in applying to a finite wing. For a wing having an elliptical lift distribution, $C_L = (\pi/4)C_l$, where C_l is the centerline value of the local lift coefficient.

SUBSONIC AERODYNAMIC FORCES

When an airfoil is moved through the air, the motion produces a pressure at every point of the airfoil which acts normal to the surface. In addition, a frictional force tangential to the surface opposes the motion. The sum of these pressure and frictional forces gives the **resultant force** R acting on the body. The point at which the resultant force acts is defined as the **center of pressure,** c.p. The resultant force R will, in general, be inclined to the airfoil and the relative wind velocity V. It is resolved (Fig. 11.4.3) either along wind axes into

L = **lift** = component normal to V
D = **drag** or resistance = component along V, or along body axes into
N = **normal force** = component perpendicular to airfoil chord
T = **tangential force** = component along airfoil chord

Instead of specifying the center of pressure, it is convenient to specify the moment of the air forces about the so-called *aerodynamic center,* a.c. This point lies at a distance a (about a quarter-chord length) back of the leading edge of the airfoil and is defined as the point about which the moment of the air forces remains constant when the angle of attack α is changed. Such a point exists for every airfoil. The force R acting at the c.p. is equivalent to the same force acting at the a.c. plus a moment equal to that force times the distance between the c.p. and the a.c. (see Fig. 11.4.3). The location of the aerodynamic center, in terms of the chord c and the section thickness t, is given for NACA 4- and 5-digit series airfoils approximately by

$$a/c = 0.25 - 0.40(t/c)^2$$

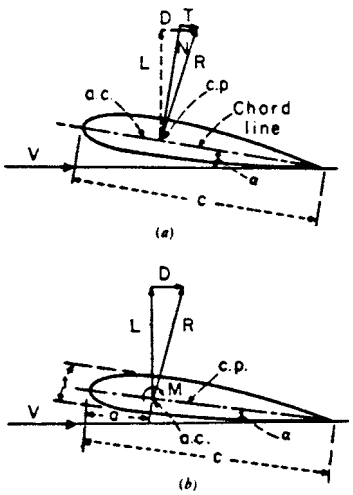

Fig. 11.4.3 Forces acting on an airfoil. (*a*) Actual forces; (*b*) equivalent forces through the aerodynamic center plus a moment.

The distance $x_{c.p.}$ from the leading edge to the center of pressure expressed as a fraction of the chord is, in terms of the moment $M_{c/4}$ about the quarter-chord point,

$$M_{c/4} = (¼ - x_{c.p.}) \cdot cN$$

$$x_{c.p.} = \frac{1}{4} - \frac{M_{c/4}}{cN}$$

From dimensional analysis it can be seen that the **air force on a body** of length dimension l moving with velocity V through air of density ρ can be expressed as

$$F = \varphi \cdot \rho V^2 l^2$$

where φ is a coefficient that depends upon all the dimensionless factors of the problem. In the case of a wing these are:

1. **Angle of attack** α, the inclination between the chord line and the velocity V
2. **Aspect ratio** $A = b/c$, where b is the span and c the mean chord of the wing
3. **Reynolds number** $\text{Re} = \rho V l/\mu$, where μ is the coefficient of dynamic viscosity of air
4. **Mach number** V/V_s, where V_s is the velocity of sound
5. Relative surface roughness
6. Relative turbulence

The dependence of the force coefficient φ upon α and A can be theoretically determined; the variation of φ with the other parameters must be established experimentally, i.e., by model tests.

AIRFOILS

Applying Bernoulli's equation to the flow around a body, if p represents the **static pressure,** i.e., the atmospheric pressure in the undisturbed air, and if V is superposed as in Fig. 11.4.4 and if p_1, V_1 represent the pressure and velocity at any point 1 at the surface of the body,

$$p + ½\rho V^2 = p_1 + ½\rho V_1^2$$

The maximum pressure occurs at a point s on the body at which the velocity is zero. Such a point is defined as the **stagnation point.** The maximum pressure increase occurs at this point and is

$$p_s - p = ½\rho V^2$$

This is called the stagnation pressure, or **dynamic pressure,** and is denoted by q. It is customary to express all aerodynamic forces in terms of $½\rho V^2$, hence

$$F = ½\varphi\rho V^2 l^2 = q\varphi l^2$$

For the case of a wing, the forces and moments are expressed as

$$\text{Lift} = L = C_L ½\rho V^2 S = C_L qS$$
$$\text{Drag} = D = C_D ½\rho V^2 S = C_D qS$$
$$\text{Moment} = M = C_M ½\rho V^2 Sc = C_M qSc$$

where S = wing area and c = wing chord.

The lift produced can be determined from the intensity of the circulatory flow or **circulation** Γ by the relation $L' = \rho V \Gamma$, where L' is the lift per unit width of wing. In a **wing of infinite aspect ratio,** the flow is two-dimensional and the lift reaction is at right angles to the line of relative motion. The **lift coefficient** is a function of the angle of attack α and by mathematical analysis $C_L = 2\pi \sin \alpha$, which for small angles becomes $C_L = 2\pi\alpha$. Experiments show that $C_L = 2\pi\eta(\alpha - \alpha_0)$, where α_0 is the angle of attack corresponding to zero lift. $\eta \approx 1 - 0.64(t/c)$, where t is airfoil thickness.

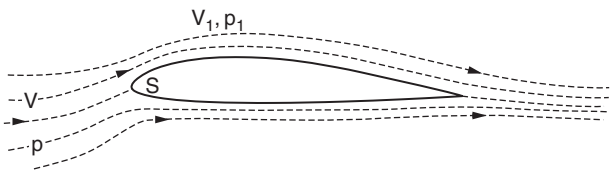

Fig. 11.4.4 Fluid flow around an airfoil.

In **a wing of finite aspect ratio,** the circulation flow around the wing creates a strong vortex trailing downstream from each wing tip (Fig. 11.4.5). The effect of this is that the direction of the resultant velocity at the wing is tilted downward by an **induced angle of attack** $\alpha_i = w_i/V$ (Fig. 11.4.6). If friction is neglected, the resultant force R is now tilted to the rear by this same angle α_i. The lift force L is approximately the same as R. In addition, there is also a drag component D_i, called the **induced drag,** given by

$$D_i = L \tan \alpha_i = Lw_i/V$$

For a given geometrical angle of attack a the **effective angle of attack** has been reduced by α_i, and thus

$$C_L = 2\pi\eta(\alpha - \alpha_0 - \alpha_i)$$

According to the Lanchester-Prandtl theory, for **wings having an elliptical lift distribution**

$$\alpha_i = w_i/V = C_L/\pi A \quad \text{rad}$$
$$D_i = L^2/\pi b^2 q \quad \text{and} \quad C_{Di} = D_i/qS = C_L^2/\pi A$$

where b = span of wing and $A = b^2/S$ = aspect ratio of wing. These results also apply fairly well to wings not differing much from the elliptical shape. For **square tips,** correction factors are required:

$$\left.\begin{aligned} \alpha_i &= \frac{C_L}{\pi A}(1 + \tau) \quad \text{where } \tau = 0.05 + 0.02A \\ C_{Di} &= \frac{C_L^2}{\pi A}(1 + \sigma) \quad \text{where } \sigma = 0.01A - 0.01 \end{aligned}\right\} \quad \text{for } A < 12$$

These formulas are the basis for transforming the characteristics of rectangular wings from an **aspect ratio** A_1 to an aspect ratio A_2:

$$\alpha_2 = \alpha_1 + \frac{57.3C_L}{\pi}\left(\frac{1 + \tau_2}{A_2} - \frac{1 + \tau_1}{A_1}\right) \quad \text{deg}$$

$$C_{D2} = C_{D1} + \frac{C_L^2}{\pi}\left(\frac{1 + \sigma_2}{A_2} - \frac{1 + \sigma_1}{A_1}\right)$$

For elliptical wings the values of τ and σ are zero. Most wing-section data are given in terms of aspect ratios 6 and ∞. For other values, the preceding formulas must be used.

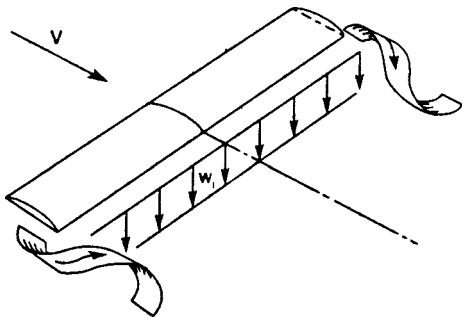

Fig. 11.4.5 Vortex formation at wing tips.

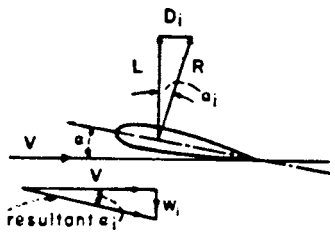

Fig. 11.4.6 Induced angle of attack.

Characteristics of Wings Wings have **airfoil sections** that can be constant from wing root to tip, or sections that vary across the wing to tailor the aerodynamic properties of the wing. Wing aerodynamic properties are expressed in terms of the dimensionless coefficients C_L, C_D, and C_M. **Airfoil** coefficients, termed section characteristics, are usually denoted as C_l, C_d, and C_m, and refer to wings of infnite aspect ratio. Figure 11.4.10 presents tunnel test results from early NACA studies on 6 percent and 12 percent thick two-dimensional sections.

The lift coefficient C_L is a linear function of the angle of attack up to a critical angle called the **stalling angle** (Fig. 11.4.7). The **maximum lift coefficient** $C_{L\max}$ which can be reached is one of the important characteristics of a wing because it determines the landing speed of the airplane.

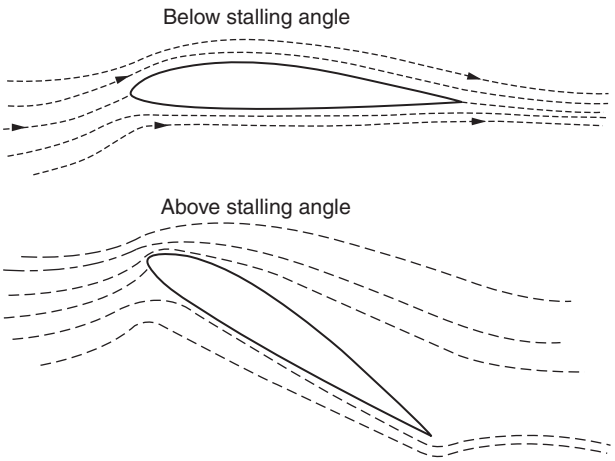

Fig. 11.4.7 Stalling angle of an airfoil.

The **drag of a wing** is made up of three components: the **profile drag** D_0, the **induced drag** D_i, and the **wave drag** D_W, near the speed of sound. The profile drag is due principally to surface friction. At aspect ratio ∞ or at zero lift the induced drag is zero, and thus the entire drag is profile drag. In Fig. 11.4.8 the coefficient of induced drag $C_{Di} = C_L^2/\pi A$ is also plotted for a wing. The difference $C_D - C_{Di} = C_{D0}$, the profile-drag coefficient. Among the desirable characteristics of a wing is a small value of the minimum profile-drag coefficient and a large value of C_L/C_D (L/D).

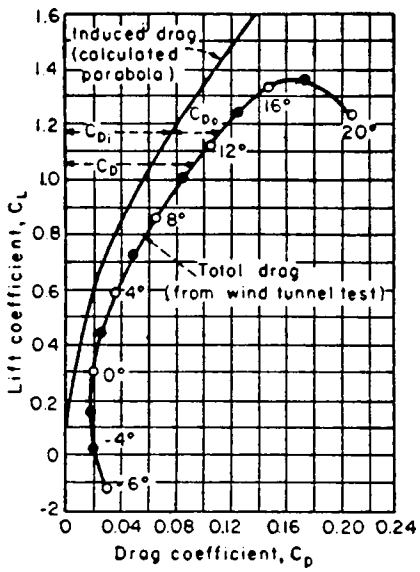

Fig. 11.4.8 Polar-diagram plot of airfoil data.

The moment characteristics of a wing are obtainable from the curve of the center of pressure as a function of α or by the **moment coefficient taken about the aerodynamic center** $C_{Ma.c.}$ as a function of C_L. A forward motion of the c.p. as α is increased corresponds to an unstable wing section. This instability is undesirable because it requires a large download on the tail to counteract it.

The characteristics of a wing section (Fig. 11.4.9) are determined principally by its **mean camber line,** i.e., the curvature of the median line of the profile, and secondly by the thickness distribution along the chord. In the NACA system of designation, when a four-digit number is used such as 2412, the significance is always first digit = maximum camber in percent of chord, second digit = location of position of maximum camber in tenths of chord measured from the leading edge (that is, 4 stands for 40 percent), and the last two figures indicate the maximum thickness in percent of chord. NACA also developed a 5-digit and 6-digit series of airfoils, the latter referred to as *laminar flow sections.* More recently, NASA work has centered on developing low-speed sections for general aviation aircraft. Today most major aerospace companies no longer use the early NACA section data and prefer to develop their own geometric and aerodynamic section properties, through either computational or experimental means. Extensive reshaping of airfoil leading edge geometries has yielded significant increases in maximum lift coefficients, and high-speed sections, termed "peaky" or "supercritical" sections have permitted cruise Mach numbers to increase significantly. These high-speed sections retain a large region of high pressure in front of the airfoil crest, resulting in a peak in pressure coefficient there at high speeds.

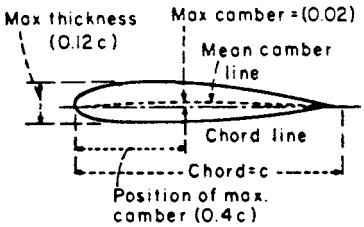

Fig. 11.4.9 Characteristics of a wing section.

Selection of Wing Section

In selecting a wing section for a particular airplane the following factors are generally considered:

1. Maximum lift coefficient $C_{L\max}$
2. Minimum drag coefficient $C_{D\min}$
3. Moment coefficient at zero lift C_{m0}
4. Maximum value of the ratio C_L/C_D

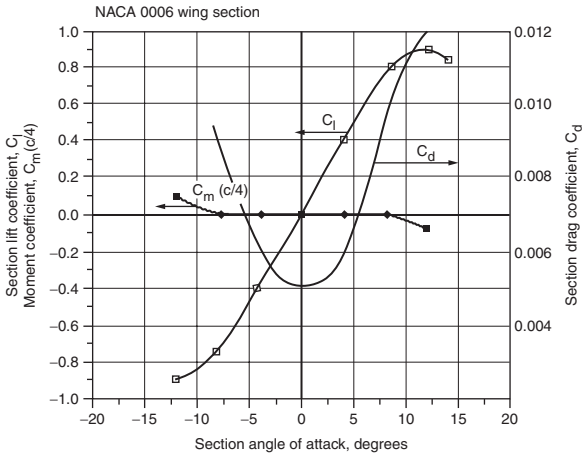
For certain special cases it is necessary to consider one or more factors from the following group:

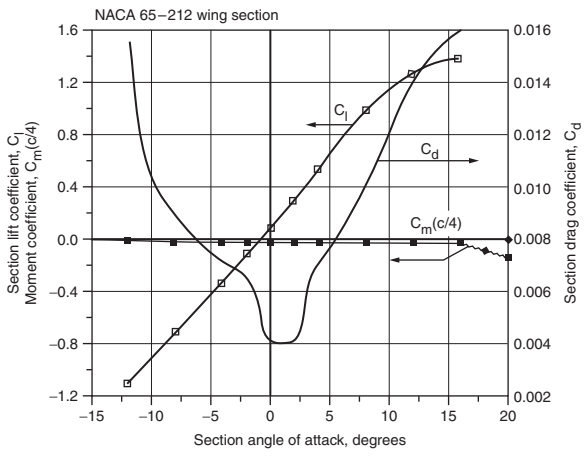
5. Value of C_L for maximum C_L/C_D
6. Value of C_L for minimum profile drag
7. Maximum value of $C_L^{3/2}/C_D$
8. Maximum value of $C_L^{1/2}/C_D$
9. Type of lift curve peak (stall characteristics)
10. Drag divergence Mach number M_{DD}

Characteristics of airfoil sections are given in *NACA-TR* 586, 647, 669, 708, and 824. Figure 11.4.10 gives data on two typical sections: 0006 is often used for tail surfaces, and $NACA_I$ 65-212 is especially suitable for the wings of subsonic airplanes. For Mach numbers greater than 0.6 thin wings must be used.

The dimensionless coefficients C_L and C_D are functions of the **Reynolds number** $\mathrm{Re} = \rho Vl/\mu$. For wings, the characteristic length l is taken to be the chord. In standard air at sea level

$$\mathrm{Re} = 6{,}378V_{\mathrm{ft/s}} \cdot l_{\mathrm{ft}} = 9{,}354V_{\mathrm{mi/h}} \cdot l_{\mathrm{ft}}$$





x, % c	0	1.25	2.5	5	7.5	10	15	20	25
y, % c(+/–)	0	0.947	1.307	1.777	2.1	2.341	2.673	2.869	2.971
x, % c	30	40	50	60	70	80	90	95	100

L.E. Radius: 0.40c									

Fig. 11.4.10 Properties of two airfoil sections. *(Courtesy of NACA.)*

For other heights, multiply by the coefficient $K = (\rho/\mu)/(\rho_0/\mu_0)$. Values of K are as follows:

Altitude, ft*	0	5,000	10,000	15,000	20,000	25,000	30,000	40,000	50,000	60,000
K	1.000	0.884	0.779	0.683	0.595	0.515	0.443	0.300	0.186	0.116

* × 0.305 = m.

The variation of C_L and C_D with the Reynolds number is known as **scale effect.** These are shown in Figs. 11.4.11 and 11.4.12 for some typical airfoils. Figure 11.4.12 shows in dashed lines also the theoretical variation of the drag coefficient for a smooth flat plate for laminar and turbulent flow, respectively, and also for the transition region.

In addition to the Reynolds number, airfoil characteristics also depend upon the **Mach number** (see "Supersonic and Hypersonic Aerodynamics" below).

Laminar-flow Wings NACA developed a series of **low-drag wings** in which the distribution of thickness along the chord is so selected as to maintain **laminar flow** over as much of the wing surface as possible.

The low-drag wing under controlled conditions of surface smoothness may have drag coefficients about 30 percent lower than those obtained on normal conventional wings. Low-drag airfoils are so sensitive to roughness in any form that the full advantage of laminar flow is unobtainable.

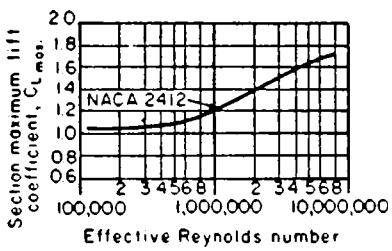

Fig. 11.4.11 Scale effect on section maximum lift coefficient.

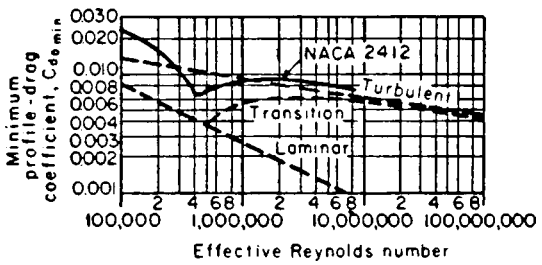

Fig. 11.4.12 Scale effect on minimum profile-drag coefficient.

Transonic Airfoils At airplane Mach numbers of about M = 0.75, normal airfoil sections begin to show a greater drag, which increases sharply as the speed of sound is approached. Airfoil sections known as **transonic airfoils** have been developed which significantly delay this **drag rise** to Mach numbers of 0.9 or greater (Fig. 11.4.13). Advantage may

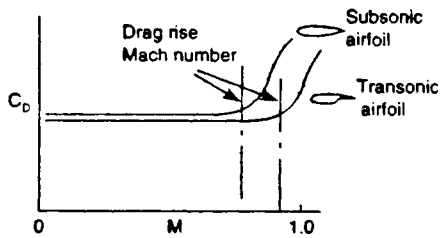

Fig. 11.4.13 Drag rise delay due to transonic section.

also be taken of these airfoil sections by increasing the thickness of the airfoil at a given Mach number without suffering an increase in drag.

Wing sweepback (Fig. 11.4.14) or sweepforward also delays the onset of the drag rise to higher Mach numbers. The flow component normal to the wing leading edge, M cos Γ determines the effective Mach number felt by the wing. The parallel component, M sin Γ, does not significantly influence the drag rise. Therefore for a flight Mach number M, the wing senses it is operating at a lower Mach number given by M cos Γ.

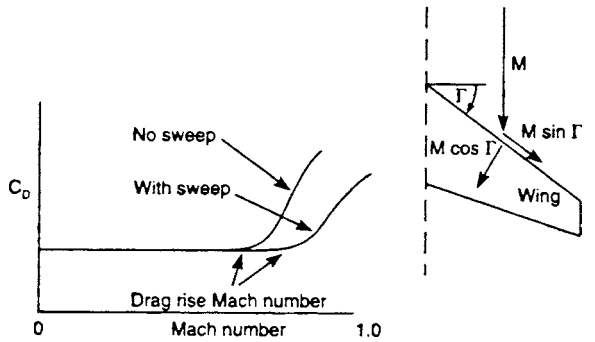

Fig. 11.4.14 Influence of wing sweepback on drag rise Mach number.

Flaps and Slots

The maximum lift of a wing can be increased by the use of **slots**, retractable or fixed slats on the leading edge, or **flaps** on the trailing edge. **Fixed slots** are formed by rigidly attaching a curved sheet of metal or a small auxiliary airfoil to the leading edge of the wing. The trailing-edge flap is used to give increased lift at moderate angles of attack and to increase $C_{L\max}$. Theoretical analyses of the effects are given in *NACA-TR* 938 and *Br. ARCR&M* 1095. Flight experience indicates that the four types shown in Fig. 11.4.15 have special advantages over other known types. Values of $C_{L\max}$ for these types are shown in Table 11.4.2. All flaps cause a diving moment $(-C_m)$ which must be trimmed out by a download on the tail, and this download reduces $C_{L\max}$. The correction is $\Delta C_{L\max}$ (trim) $= \Delta C_{mo}(l/c)$, where l/c is the tail length in mean chords.

Boundary-Layer Control (BLC) This includes numerous schemes for (1) maintaining laminar flow in the boundary layer in the flow over a wing or (2) preventing flow separation. Schemes in the first category try to obtain the lower frictional drag of laminar flow either by providing favorable pressure gradients, as in the NACA "low-drag" wings, or by removing part of the boundary layer. The boundary-layer thickness can be partially controlled by the use of suction applied either to spanwise slots or to porous areas. The flow so obtained approximates the laminar skin-friction drag coefficients (see Fig. 11.4.12). Schemes in the second category try to delay or improve the stall. Examples are the leading-edge slot, slotted flaps, and various forms of suction or blowing applied through transverse slots. The slotted flap is a highly effective form of boundary-layer control that delays flow separation on the flap.

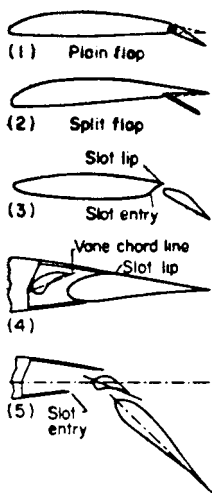

Fig. 11.4.15 Trailing-edge flaps: (1) plain flap; (2) split flap; (3) single-slotted flap; (4) double-slotted flap (retracted); (5) double-slotted flap (extended).

Table 11.4.2 Flaps*

Type of flap	Section $C_{L\max}$ (approx)	Finite wing $C_{L\max}$ (approx)	Remarks
Plain	2.4	1.9	$C_{f/c} = 0.20$. Sensitive to leakage between flap and wing.
Split	2.6	2.0	$C_{f/c} = 0.20$. Simplest type of flap.
Single slotted	2.8 3.0	2.2 2.4	$C_{f/c} = 0.25$. Shape of slot and location of deflected flap are critical.
Double slotted	3.0 3.4	2.4 2.7	$C_{f/c} = 0.25$. Shape of slot and location of deflected flap are critical.

* The data is for wing thickness $t/c = 0.12$ or 0.15. Lift increment is dependent on the leading-edge radius of the wing.

Spanwise Blowing Another technique for increasing the lift from an aerodynamic surface is spanwise blowing. A high-velocity jet of air is blown out along the wing. The location of the jet may be parallel to and near the leading edge of the wing to prevent or delay leading-edge flow separation, or it may be slightly behind the juncture of the trailing-edge flap to increase the lift of the flap. Power for spanwise blowing is sensitive to vehicle configuration and works most efficiently on swept wings. Other applications of this technique may include local blowing on ailerons or empennage surfaces (Fig. 11.4.16).

The **pressure distributions** on a typical airfoil are shown in Fig. 11.4.17. In this figure the ratio p/q is given as a function of distance along the chord. In Fig. 11.4.18 the effect of addition of an external airfoil flap is shown.

Airplane Performance

In **horizontal flight** the lift of the wings must be equal to the weight of the airplane, or $L = nW$, where W is the weight (lb or kg) of the airplane and n is 1.00. When the airplane is in a turn or is performing a pull-up, $n > 1.00$. The following equation determines the minimum or stall speed of the airplane at the appropriate value of n:

$$nW = C_{L\max}\frac{1}{2}\rho V_{\min}^2 S \quad \text{or} \quad V_{\min} = \sqrt{\frac{2nW}{C_{L\max}\rho S}} \qquad (11.4.1)$$

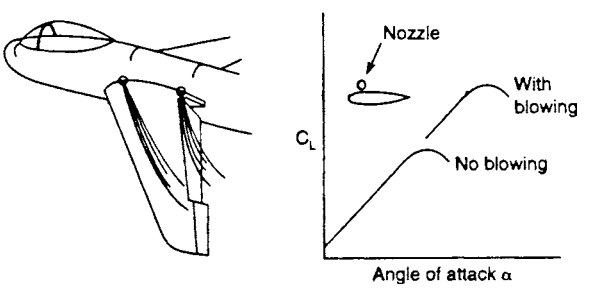

Fig. 11.4.16 Influence of spanwise blowing.

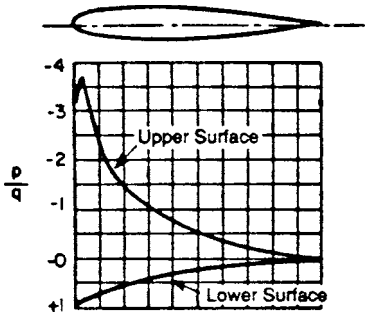

Fig. 11.4.17 Pressure distribution over a typical airfoil.

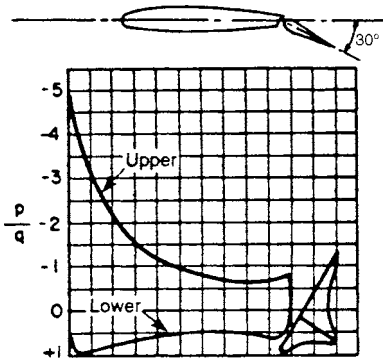

Fig. 11.4.18 Pressure distribution on an airfoil-flap combination.

This is called the *stalling speed* and when multiplied by a suitable safety factor, such as 1.2, can be termed the **minimum safe flight speed.**

The interplay of airplane **drag** D and **thrust** T dictates the airplane performance. Usually graphical means are used to display performance capability. Here the airplane **drag polar** and thrust available, at sea level, are superimposed as shown in Fig. 11.4.19. In level flight at constant speed $T = D$, where T can be generated either by propeller, rocket, or jet engine. For propeller-driven airplanes, T becomes TV and D becomes DV in performance analyses. Our discussion will center on **jet propulsion** with a summary showing significant propeller-induced equation changes.

Figure 11.4.19 shows that at maximum B and minimum A speeds, $T = D$. The minimum thrust-dictated speed is usually less than the stall speed; the latter then dictates the lower performance boundary speed. Between the maximum and minimum speeds $T > D$, and this excess in T available can be used to climb (dh/dt), or to accelerate in level flight. Similar curves can be constructed for a range of altitudes (a 30,000-foot set is shown), resulting in the performance boundaries as shown in Fig. 11.4.20. Here are minimum and maximum speeds, best climb speed, stall speed, and best cruise speed. Maximum and minimum speeds are equal at the absolute ceiling where $dh/dt = 0$.

Rate of climb, or airplane **vertical velocity,** is given by

$$\frac{dh}{dt} = V\left(\frac{T - D}{W}\right) \qquad \text{ft/s} \qquad (11.4.2)$$

where V is in ft/s.

Climb angle θ is given by

$$\theta = \sin^{-1}\left(\frac{T - D}{W}\right) \qquad \text{deg} \qquad (11.4.3)$$

Jet engine thrust reduces with increase in altitude approximately as density reduces. At some altitude $(T - D)$ becomes zero (therefore $dh/dt = 0$) and the **absolute ceiling** of the airplane is reached, beyond

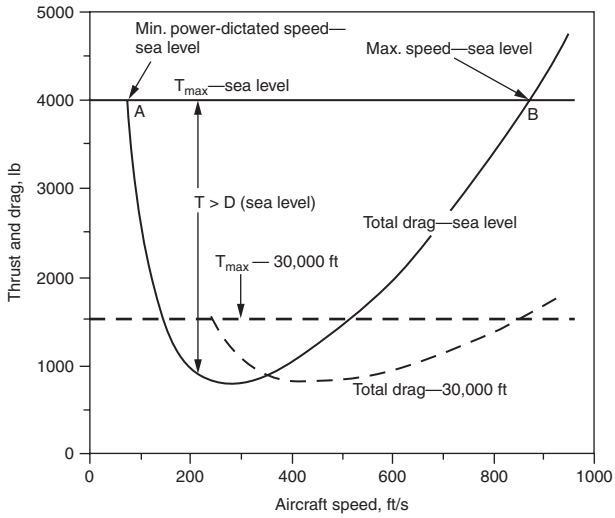

Fig. 11.4.19 Thrust-drag relationships for airplane performance at sea level and 30,000 ft.

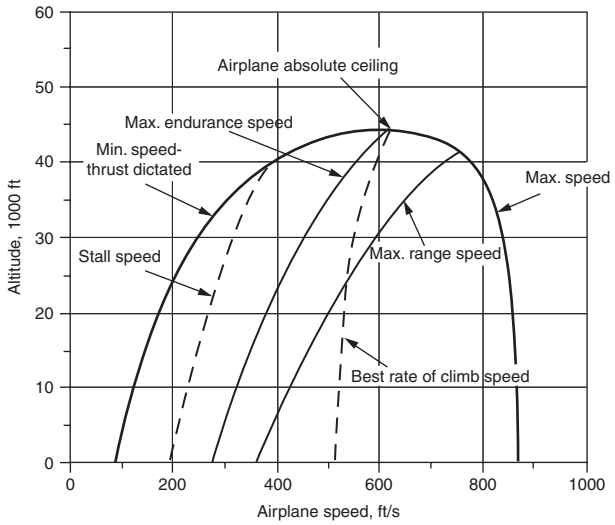

Fig. 11.4.20 Summary of airplane speed variations with altitude.

which the aircraft cannot fly in steady flight. Climb angle becomes zero also and the airplane can fly at one speed only. A practical maximum altitude, termed **service ceiling,** is assumed to occur when $dh/dt =$ 100 ft/min. The absolute ceiling can be determined from the curve of maximum rate of climb as a function of altitude when this is approximated by a straight line, usually accurate at the higher altitudes. See Fig. 11.4.21. For a linear decrease in the rate of climb the following approximations hold:

$$\text{Absolute ceiling } H = (r_0\, h)/(r_0 - r) \qquad \text{ft} \qquad (11.4.4)$$

where subscript 0 refers to sea level rate of climb and r is the rate of climb, in ft/min, at altitude h.

$$\text{Service ceiling } h_s = H\,(r_0 - 100)/r_0 \qquad \text{ft} \qquad (11.4.5)$$

Altitude climbed in t minutes is

$$h = H\,(1 - e^k) \qquad \text{ft} \qquad (11.4.6)$$

where $k = (-r_0\, t)/H$.

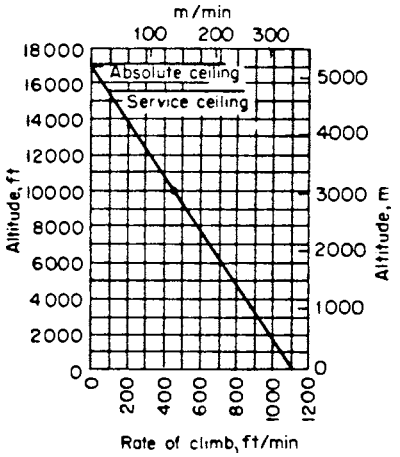

Fig. 11.4.21 Characteristic rate of climb curves.

Time to climb to altitude h is

$$t = 2.303\left(\frac{H}{r_0}\right)\log\left(\frac{H}{H-h}\right) \qquad \text{min} \qquad (11.4.7)$$

Power off **minimum glide angle** γ is given by

$$\gamma = \tan^{-1}\left(\frac{1}{(L/D)_{\max}}\right) \qquad \text{deg} \qquad (11.4.8)$$

The minimum glide angle corresponds to maximum straight line **glide distance measured along the ground,** s_g, given by

$$s_g = h_s(L/D)_{\max} \qquad \text{ft} \qquad (11.4.9)$$

where h_s is the start of glide altitude in feet.

For performance purposes, an airplane **drag polar** is required, which will vary with Mach number. This polar will also change when flaps and landing gears are extended, and is given by the generic equation,

$$C_D qS = (C_{D0} + C_L^2/A\,e\,\pi)\,q\,S \qquad (11.4.10)$$

where C_{D0} = profile drag coefficient, $[f(\text{Mach number})] = C_{D0}(\text{clean aircraft}) + \Delta C_{D0}$ (flaps) $+ \Delta C_{D0}$ (gear). A = wing aspect ratio, e = Oswald's span efficiency factor, $\pi = 3.14159$, $q = \frac{1}{2}\rho V^2$, S = wing reference area.

A typical clean aircraft drag variation with V, complete with the corresponding L/D is shown in Fig. 11.4.22 which shows that a maximum value of L/D occurs at a given velocity which is termed the best **endurance speed.** The **best range speed** occurs at 0.866 $(L/D)_{\max}$ as shown. Table 11.4.3 shows typical values of C_{D0} for various types of jet aircraft.

The ratio L/D, (C_L/C_D), is sometimes called the **aerodynamic efficiency** of the airplane. Mission requirements dictate the magnitude for competitive values of this ratio which is primarily controlled by the value of the **wing aspect ratio** and C_{D0}. Airliners usually have high aspect ratio values and fighter aircraft low values. See Fig. 11.4.23. As seen in the following equations, maximizing L/D will maximize range and endurance. Range, more accurately termed **maximum range,** is defined as the maximum **distance** flown on a given quantity of fuel. **Maximum endurance** is defined as the maximum **time** spent in the air on a given quantity of fuel.

Range R at constant altitude is

$$R = 2\sqrt{\frac{2}{\rho S}}\frac{1}{c}\frac{C_L^{1/2}}{C_D}(W_0^{1/2} - W_1^{1/2}) \qquad \text{ft} \qquad (11.4.11)$$

where ρ = air density in slugs/ft^3, c = specific fuel consumption in lb of fuel/lb thrust · s, V = aircraft velocity in ft/s. Subscript 0 refers to the segment weight at start of mission and subscript 1 to segment weight at end of mission.

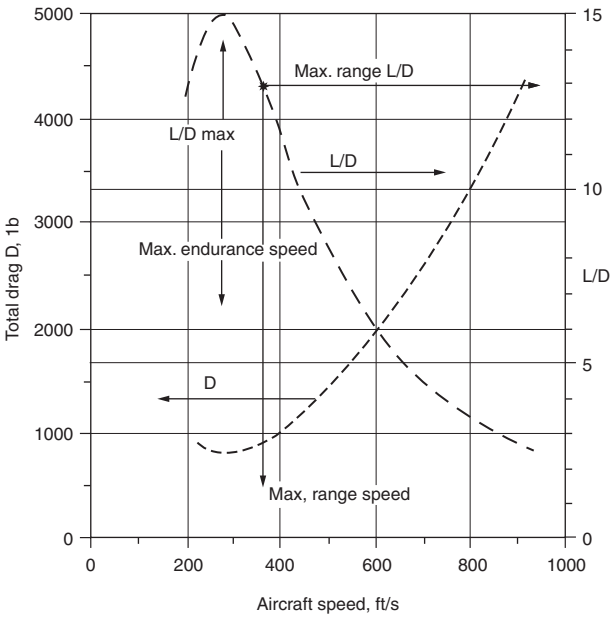

Fig. 11.4.22 Aircraft aerodynamic properties: drag polar and L/D ratio.

Table 11.4.3 Total C_{D0} Values for Typical Aircraft Types (Clean Aircraft)

Aircraft type	Subsonic C_{D0}
Supersonic twin-jet fighter	0.0237
Narrow-body twin-jet transport	0.0166
Wide-body four-jet transport	0.0170

Endurance E, in hours, is given by

$$E = \frac{1}{c}\left(\frac{C_L}{C_D}\right)\ln\left(\frac{W_0}{W_1}\right) \qquad \text{h} \qquad (11.4.12)$$

In each instance, c and (L/D) correspond to the appropriate altitude and speed, and $(W_0 - W_1)$ represents fuel used.

For **propeller-powered airplanes,** the above equations, starting at Eq. (11.4.2) become

$$\frac{dh}{dt} = \left(\frac{TV - DV}{W}\right) \qquad \text{ft/s} \qquad (11.4.13)$$

where V is in ft/s. If thrust horsepower available $P_{Ta} = \eta \cdot P_a$, where P_a = **available engine horsepower,** η is the propeller efficiency, and P_r = horsepower required, then

$$\frac{dh}{dt} = 550\left(\frac{P_{Ta} - P_r}{W}\right) \qquad \text{ft/s} \qquad (11.4.14)$$

$$\text{Range } R = \frac{\eta}{c}\left(\frac{C_L}{C_D}\right)\ln\left(\frac{W_0}{W_1}\right) \qquad \text{ft} \qquad (11.4.15)$$

where the units of c are (lb fuel)/ft · lb/s) · (s).

$$\text{Endurance } E = \left(\frac{\eta}{c}\right)\frac{C_L^{3/2}}{C_D}(2\rho S)^{1/2}(W_1^{-1/2} - W_0^{-1/2})\left(\frac{1}{3600}\right) \qquad \text{h} \qquad (11.4.16)$$

See Table 11.4.4 for dimensions and performance of selected airplanes.

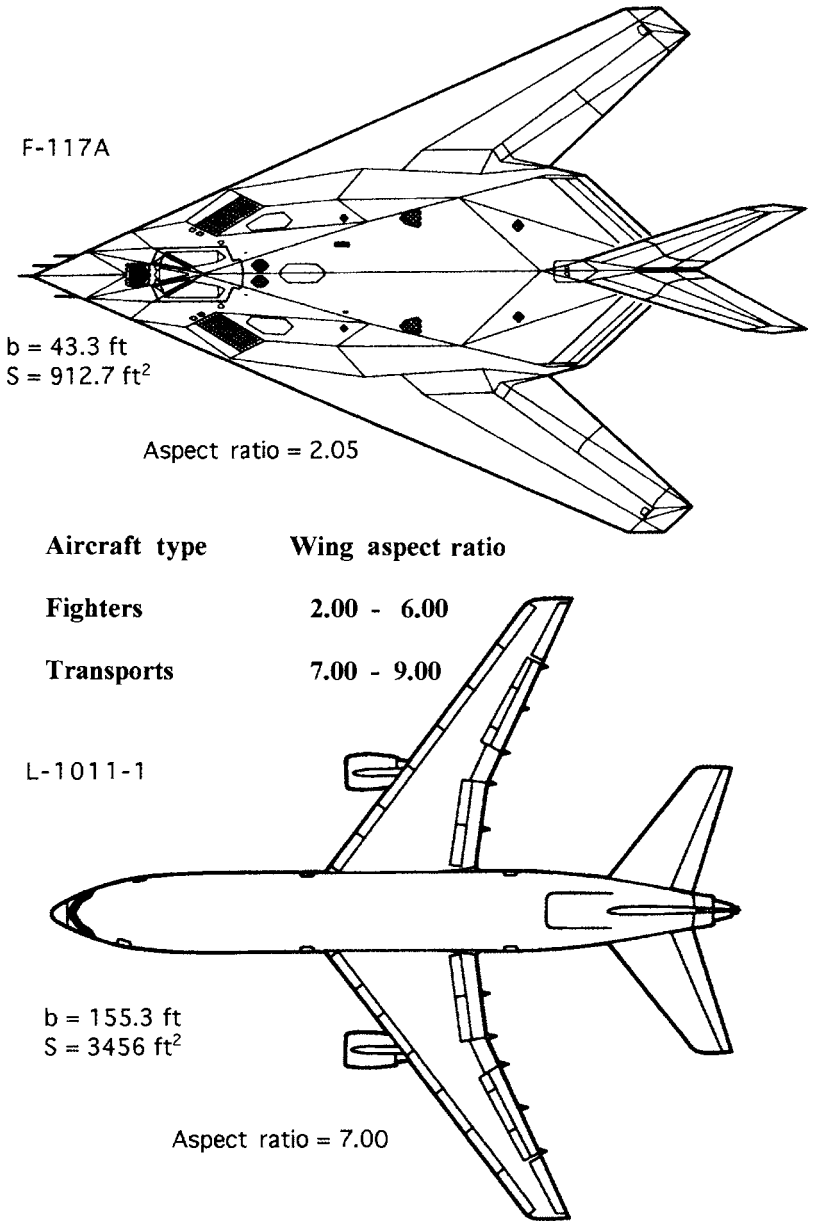

Fig. 11.4.23 Typical aircraft configurations. (*Drawings courtesy of Lockeed-Martin.*)

Power Available The maximum efficiency η_m and the diameter of a propeller to absorb a given power at a given speed and rpm are found from a propeller-performance curve. The thrust horsepower at maximum speed P_{Tm} is found from $P_{Tm} = \eta_m\, p_m$. The **thrust horsepower** at **any speed** can be approximately determined from the ratios given in the following table:

V/V_{max}		0.20	0.30	0.40	0.50	0.60
P_T/P_{TM}	Fixed-pitch propeller	0.29	0.44	0.57	0.68	0.77
	constant-rpm propeller	0.47	0.62	0.74	0.82	0.88
V/V_{max}		0.70	0.80	0.90	1.00	1.10
P_T/P_{Tm}	Fixed-pitch propeller	0.84	0.90	0.96	1.00	1.03
	constant-rpm propeller	0.93	0.97	0.99	1.00	1.00

The **brake horsepower** of an engine decreases with increase of altitude. The variation of P_T with altitude depends on engine and propeller characteristics with average values as follows:

h, ft	0	5,000	10,000	15,000	20,000	25,000
P_T/P_{T0} (fixed pitch)	1.00	0.82	0.66	0.52	0.41	0.30
P_T/P_{T0} (controllable pitch)	1.00	0.85	0.71	0.59	0.48	0.38

Parasite Drag

The drag of the nonlifting parts of an airplane is called the **parasite drag.** It consists of two components: the frictional and the eddy-making drag.

Frictional drag, or **skin friction,** is due to the viscosity of the fluid. It is the force produced by the viscous shear in the layers of fluid immediately

Table 11.4.4 Principle Dimensions and Performance of Typical Air Vehicles

adjacent to the body. It is always proportional to the wetted area, i.e., the total surface exposed to the air.

Eddy-making drag, sometimes called **form drag,** is due to the disturbance or wake created by the body. It is a function of the shape of the body.

The total drag of a body may be composed of the two components in any proportion, varying from almost pure skin friction for a plate edgewise or a good streamline form to 100 percent form drag for a flat plate normal to the wind. A **steamline form** is a shape having very low form drag. Such a form creates little disturbance in moving through a fluid.

When air flows past a surface, the layer immediately adjacent to the surface adheres to it, or the tangential velocity at the surface is zero. In the transition region near the surface, which is called the **boundary layer,** the velocity increases from zero to the velocity of the stream. When the flow in the boundary layer proceeds as if it were made up of laminae sliding smoothly over each other, it is called a **laminar boundary layer.** If there are also irregular motions in the layers normal to the surface, it is a **turbulent boundary layer.** Under normal conditions the flow is laminar at low Reynolds numbers and turbulent at high Re with a transition range of values of Re extending between 5×10^5 and 5×10^7. The profile-drag coefficients corresponding to these conditions are shown in Fig. 11.4.12.

For laminar flow the friction-drag coefficient is practically independent of surface roughness and for a flat plate is given by the Blasius equation,

$$C_{DF} = 2.656/\sqrt{\text{Re}}$$

The turbulent boundary layer is thicker and produces a greater frictional drag. For a smooth flat plate with a turbulent boundary layer

$$C_{DF} = 0.91/\log \text{Re}^{2.58}$$

For rough surfaces the drag coefficients are increased. The drag coefficients as given above are based on *projected area* of a double-surfaced plane. If *wetted* area is used, the coefficients must be divided by 2. The frictional drag is $D_F = C_{DF}\, qS$, where S is the *projected area,* or $D_F = \frac{1}{2} C_{DF}\, qA$, where A is the wetted area.

Values of C_{DF} for double-surfaced planes may be estimated from the following tabulation:

Laminar flow (Blasius equation):

Re	10	10^2	10^3	10^4	10^5	10^6
C_{DF}	0.838	0.265	0.0838	0.0265	0.0084	0.0265

Turbulent flow:

Re	10^5	10^6	10^7	10^8	10^9	10^{10}
C_{DF}	0.0148	0.0089	0.0060	0.0043	0.00315	0.0024

These are double-surface values which facilitate direct comparison with wing-drag coefficients based on projected area. For calculations involving wetted area, use one-half of double-surface coefficients. Interpolations in the foregoing tables must allow for the logarithmic functions; i.e., the variation in C_{DF} is not linear with Re.

Drag Coefficients of Various Bodies

For **bodies with sharp edges** the drag coefficients are almost independent of the Reynolds number, for most of the resistance is due to the difference in pressure on the front and rear surfaces. Table 11.4.5 gives $C_D = D/qS$, where S is the maximum cross section perpendicular to the wind.

Table 11.4.5 Drag Coefficients

Object	Proportions	Attitude	C_D
Rectangular plate, sides a and b	$\frac{a}{b} =$ 1		1.16
	4		1.17
	8		1.23
	12.5		1.34
	25		1.57

Hemispherical cup, open front, parachute			1.35
Cone, closed base			$\alpha = 60°$, 0.51
			$\alpha = 30°$, 0.34

For **rounded bodies** such as **spheres, cylinders,** and **ellipsoids** the drag coefficient depends markedly upon the Reynolds number, the surface roughness, and the degree of turbulence in the airstream. A sphere and a cylinder, for instance, experience a sudden reduction in C_D as the Reynolds number exceeds a certain critical value. The reason is that at low speeds (small Re) the flow in the boundary layer adjacent to the body is laminar and the flow separates at about 83° from the front (Fig. 11.4.24). A wide wake thus gives a large drag. At higher speeds (large Re) the boundary layer becomes turbulent, gets additional energy from the outside flow, and does not separate on the front side of the sphere. The drag coefficient is reduced from about 0.47 to about 0.08 at a critical Reynolds number of about 400,000 in free air. Turbulence in the airstream reduces the value of the critical Reynolds number (Fig. 11.4.25). The Reynolds number at which the sphere drag $C_D = 0.3$ is taken as a criterion of the amount of turbulence in the airstream of wind tunnels.

Cylinders The drag coefficient of a cylinder with its axis normal to the wind is given as a function of Reynolds number in Fig. 11.4.26. Cylinder drag is sensitive to both Reynolds and Mach number. Figure 11.4.26 gives the Reynolds number effect for M = 0.35. The increase in C_D because of Mach number is approximately:

M	0.35	0.4	0.6	0.8	1.0
C_D increase, percent	0	2	20	50	70

(See *NACA-TN* 2960.)

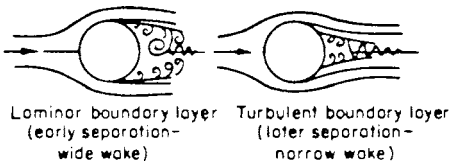

Fig. 11.4.24 Boundary layer of a sphere.

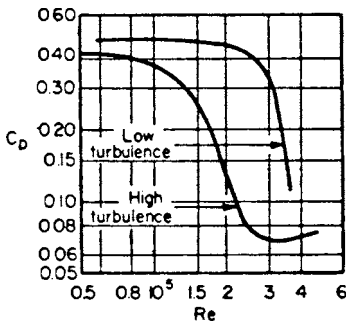

Fig. 11.4.25 Drag coefficients of a sphere as a function of Reynolds number and of turbulence.

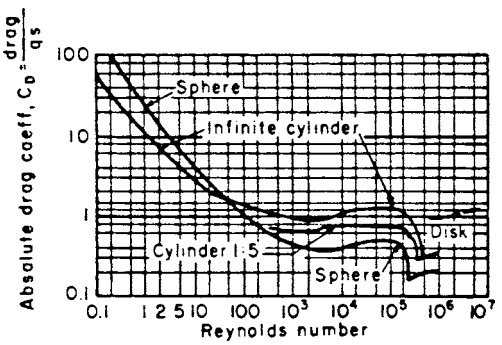

Fig. 11.4.26 Drag coefficients of cylinders and spheres.

Streamline Forms The drag of a streamline body of revolution depends to a very marked extent on the Reynolds number. The difference between extreme types at a given Reynolds number is of the same order as the change in C_D for a given form for values of Re from 10^6 to 10^7.

Tests reported in *NACA-TN* 614 indicate that the shape for minimum drag should have a fairly sharp nose and tail. At Re = 6.6×10^6 the best forms for a fineness ratio (ratio of length to diameter) 5 have a drag

$$D = 0.040qA = 0.0175qV^{2/3}$$

where A = max cross-sectional area and V = volume. This value is equivalent to about 1.0 lb/ft^2 at 100 mi/h. For Re $> 5 \times 10^6$, the drag coefficients vary approximately as $\mathrm{Re}^{0.15}$.

Minimum drag on the basis of cross-sectional or frontal area is obtained with a fineness ratio of the order of 2 to 3. Minimum drag on the basis of contained volume is obtained with a fineness ratio of the order of 4 to 6 (see *NACA-TR* 291).

The following table gives the ordinates for good streamline shapes: the **Navy strut,** a two-dimensional shape; and the Class C **airships,** a three-dimensional shape. Streamline shapes for high Mach numbers have a high fineness ratio.

Percent length		1.25	2.50	4.00	7.50	10.0	12.50
Percent of max ordinate	Navy strut	26	37.1	52.50	63.00	72.0	78.50
	Class C airship	20	33.5	52.60	65.80	75.8	83.50

Percent length		20	40	60	80	90
Percent of max ordinate	Navy strut	91.1	99.5	86.1	56.2	33.8
	Class C airship	94.7	99.0	88.5	60.5	49.3

Test data on the *RM*-10 shape are given in *NACA-TR* 1160. This shape is a parabolic-arc type for which the coordinates are given by the equation $r_x = X/7.5(1.0 - X/L)$.

Nonintrusive flow field measurements about airfoils can be made by laser Doppler velocimeter (LDV) techniques. A typical LDV measurement system setup is shown in Fig. 11.4.27*a*. A seeded airflow generates the necessary reflective particles to permit two-dimensional flow directions and velocities to be accurately recorded.

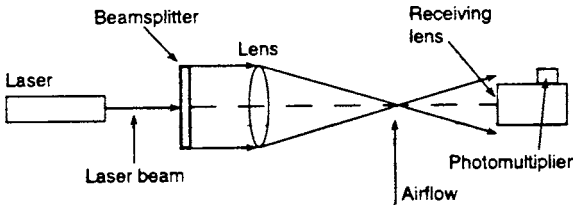

Fig. 11.4.27*a* Typical laser Doppler velocimeter measurement system.

CONTROL, STABILITY, AND FLYING QUALITIES

Control An airplane is controlled in flight by imposing yawing, pitching, and rolling moments by use of rudders, elevators, and ailerons. In some instances special airplane configurations will use mixtures or combinations of these control methods. It is possible to control aircraft through the use of two controls by suitable blending of aileron and rudder inputs.

Stability An airplane is **statically stable** if the airframe moments, due to a disturbance, tend to return the airplane to its original attitude. It is **dynamically** stable if the oscillations produced by the static stability are rapidly damped out. A **statically unstable** aircraft will produce upsetting moments instead of restoring moments. A **dynamically unstable** aircraft will generate oscillations increasing in amplitude with time. A statically unstable or a dynamically unstable aircraft can be made stable by the use of suitable automatic flight control systems.

Longitudinal static and dynamic stability, and longitudinal trim, are commonly achieved through the use of a suitable sized horizontal tail. Under these conditions the pitching moment equation, representing forces and moments on the airframe, is conditioned as follows: $C_m = 0$ for trim, and $(\partial C_m/\partial\alpha) < 0$ for stability, where C_m is the overall pitching moment coefficient about the aircraft center of gravity and α is the aircraft angle of attack. When a definitive value is chosen for $(\partial C_m/\partial\alpha)$ in the design process (such as -0.03), this is known as the design **static margin.** In a similar manner the vertical tail size is determined from lateral/directional stability and lateral trim requirements. The trim requirement is usually overriding in fixing vertical tail size for multiengine aircraft when critical engine-out design requirements are evaluated.

It can be shown that the forces and moments, inertial and aerodynamic, acting on an aircraft can be represented by six simultaneous, linear, small perturbation differential equations. These are called *the equations of motion of an aircraft,* and they represent the three forces and three moments assumed to act on the aircraft center of gravity (Fig. 11.4.27*b*). For conventional aircraft configurations, it is common practice to separate these into two sets of three each: one set representing longitudinal motions and one set the lateral-directional motions of the aircraft.

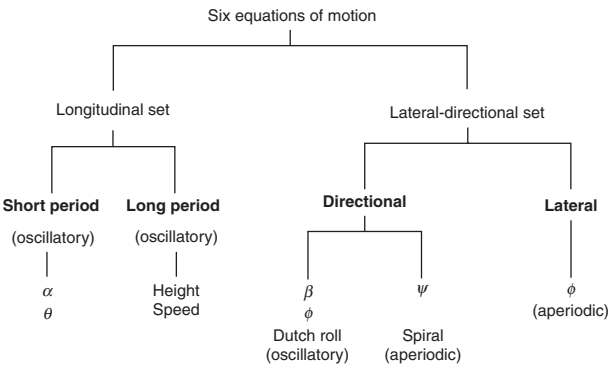

Fig. 11.4.27*b* Six equations of motion.

In this separation, the assumption is that these motions do not normally influence each other, therefore they can be solved separately to establish the separate dynamic behaviors. The longitudinal set is characterized by two distinct oscillations called *short period* and *long period.* Short period motions usually influence angle of attack and pitch angle θ, whereas the long period, called "phugoid," primarily influences the height excursions and small speed changes. The lateral-directional set characterizes the motions in spiral ψ, the so-called Dutch roll mode, a mixture of bank angle ϕ and sideslip β motions, and in the bank angle response. All response behavior is characterized by the oscillatory parameters, relative damping ratio ζ, and undamped natural frequency ω_n, as well as time to one-half amplitude ($t_{1/2}$), or time to double amplitude (t_2). It is the magnitudes of these parameters that establish the **flying** or **handling qualities** of an aircraft.

Flying Qualities Requirements These are for military aircraft and civil aircraft and are in the form of Federal Aviation Requirements (FARs) and Military Standards (Mil. STD). These imply certain levels for the response parameters to ensure that the aircraft will achieve satisfactory pilot acceptability in the operation of the aircraft. The response parameter requirements vary with mission segments. Typical longitudinal response values for two aircraft, in cruise, are:

Large Jet Transport, *W* = 630,000 lb, *V* = 460 knots, altitude = 40,000 ft

	$t_{1/2}$, s	ω_n, rad/s	ζ
Short period	1.86	1.00	0.39
Phugoid	211.00	0.07	0.05

Small Civil Propeller Aircraft, *W* = 2,800 lb, *V* = 104 knots, altitude = sea level

	$t_{1/2}$, s	ω_n, rad/s	ζ
Short period	0.28	3.6	0.69
Phugoid	40.3	0.22	0.08

Rolling (or **banking**) does not produce any lateral shift in the center of the lift, so that there is no restoring moment as in pitch. However, when banked, the airplane sideslips toward the low wing. A fin placed above the center of gravity gives a lateral restoring moment that can correct the roll and stop the slip. The same effect can be obtained by **dihedral,** i.e., by raising the wing tips to give a transverse *V.* An effective dihedral of 1 to 3° on each side is generally required to obtain stability in roll. In low-wing monoplanes, 2° effective dihedral may require 8° or more of geometrical dihedral owing to interference between the wing and fuselage.

In a **yaw** or **slip** the line of action of the lateral force depends on the size of the effective vertical fin area. Insufficient fin surface aft will allow the skid or slip to increase. Too much fin surface aft will swing the nose of the plane around into a tight spiral. Sound design demands sufficient vertical tail surface for adequate directional control and then enough dihedral to provide lateral stability.

When moderate positive effective dihedral is present, the airplane will possess **static lateral stability,** and a low wing will come up automatically with very little yaw. If the dihedral is too great, the airplane may roll considerably in gusts, but there is little danger of the amplitude ever becoming excessive. **Dynamic lateral stability** is not assured by static stability in roll and yaw but requires that these be properly proportioned to the damping in roll and yaw.

Spiral instability is the result of too much fin surface and insufficient dihedral.

HELICOPTERS

NACA, "Conference on Helicopters," May, 1954. Gessow and Myers, "Aerodynamics of the Helicopter," Macmillan.

Helicopters derive lift, propulsion force, and control effect from adjustments in the blade angles of the rotor system. At least two rotors are required, and these may be arranged in any form that permits control over the reaction torque. The common arrangements are main lift rotor; auxiliary torque-control or tail rotor at 90°; two main rotors side by side; two main rotors fore and aft; and two main rotors, coaxial and oppositely rotating.

The helicopter rotor is an actuator disk or momentum device that follows the same general laws as a propeller. In calculating the rotor performance, the major variables concerned are diameter D, ft (radius R); tip speed, $Vt = \Omega R$, ft/s; angular velocity of rotor $\Omega = 2\pi n$, rad/s; and rotor solidity q (= ratio of blade area/disk area). The rotor performance is usually stated in terms of coefficients similar to propeller coefficients. The rotor coefficients are:

$$\text{Thrust coefficient } C_T = T/\rho(\Omega R)^2\pi R^2$$
$$\text{Torque coefficient } C_Q = Q/\rho(\Omega R)^2\pi R^3$$
$$\text{Torque } Q = 5{,}250\ \text{bhp/rpm}$$

Hovering The **hovering flight** condition may be calculated from basic rotor data given in Fig. 11.4.28. These data are taken from full-scale rotor tests. Surface-contour accuracy can reduce the total torque coefficient 6 to 7 percent. The power required for hovering flight is greatly reduced near the ground. Observed flight-test data from various sources are plotted in Fig. 11.4.29. The ordinates are heights above the ground measured in rotor diameters.

Effect of Gross Weight on Rate of Climb Figure 11.4.30 from Talkin (*NACA-TN* 1192) shows the rate of climb that can be obtained by reducing the load on a helicopter that will just hover. Conversely, given

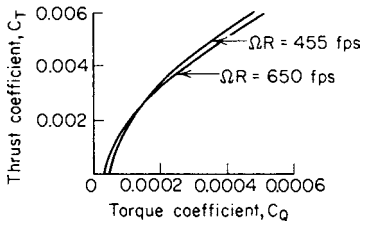

Fig. 11.4.28 Static thrust performance of NACA 8-H-12 blades.

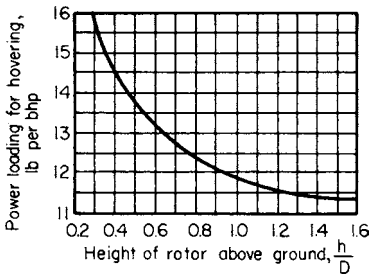

Fig. 11.4.29 Observed ground effect on Sikorsky-type helicopters.

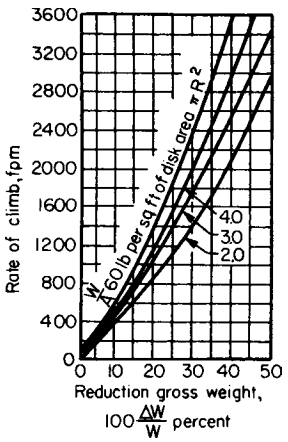

Fig. 11.4.30 Effect of gross weight on the rate of climb of a helicopter.

the rate of climb with a given load, the curves determine the increase in load that will reduce the rate of climb to zero; i.e., they determine the maximum load for which hovering is possible.

Performance with Forward Speed The performance of a typical single-main-rotor-type helicopter may be shown by a curve of C_{TR}/C_{QR} plotted against $\mu = v/\pi nD$, where v is the speed of the helicopter, as in Fig. 11.4.31. This curve includes the parasite-drag effects which are appreciable at the higher values of μ. It is only a rough approximation

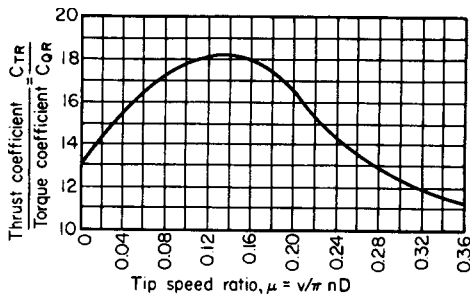

Fig. 11.4.31 Performance curve for a single-main-rotor-type helicopter.

to the experimentally determined values. C_{TR} may be calculated to determine C_{QR}, from which Q is obtained.

The performance of rotors at forward speeds involves a number of variables. For more complete treatment, see *NACA-TN* 1192 and *NACA Wartime Report* L-110.

SUPERSONIC AND HYPERSONIC AERODYNAMICS

REFERENCES: Liepmann and Roshko, "Elements of Gas Dynamics," Wiley. "High Speed Aerodynamics and Jet Propulsion" 12 vols., Princeton. Shapiro, "The Dynamics and Thermodynamics of Compressible Fluid Flow," Vols. I, II, Ronald. Howarth (ed.), "Modern Developments in Fluid Mechanics—High Speed Flow," Vols. I, II, Oxford. Kuethe and Schetzer, "Foundations of Aerodynamics," Wiley. Ferri, "Elements of Aerodynamics of Supersonic Flows," Macmillan. Bonney, "Engineering Supersonic Aerodynamics," McGraw-Hill.

The effect of the compressibility of a fluid upon its motion is determined primarily by the **Mach number M.**

$$\mathrm{M} = V/V_s \tag{11.4.17}$$

where V = speed of the fluid and V_s = speed of sound in the fluid which for air is $49.02\sqrt{T}$, where T is in °R and V_s in ft/s. The Mach number varies with position in the fluid, and the compressibility effect likewise varies from point to point.

If a *body moves through the atmosphere,* the overall compressibility effects are a function of the Mach number $\overline{\mathrm{M}}$ of the body, defined as

$$\overline{\mathrm{M}} = \text{velocity of body/speed of sound in the atmosphere}$$

Table 11.4.6 lists the useful **gas dynamics relations** between velocity, Mach number, and various fluid properties for isentropic flow. (See also Sec. 4, "Heat.")

$$V^2 = 2(h_0 - h) = 2C_P(T_0 - T)$$

$$\frac{V^2}{V_{s0}^2} = \frac{\mathrm{M}^2}{1 + \dfrac{\gamma - 1}{2}\mathrm{M}^2}$$

$$\left(\frac{p}{p_0}\right)^{(\gamma-1)/\gamma} = \frac{T}{T_0} = \left(\frac{\rho}{\rho_0}\right)^{\gamma-1} = \left(\frac{V_s}{V_{s0}}\right)^2 = \frac{1}{1 + \dfrac{\gamma - 1}{2}\mathrm{M}^2}$$

$$\frac{\frac{1}{2}\rho V^2}{p_0} = \frac{(\gamma/2)\mathrm{M}^2}{\left(1 + \dfrac{\gamma - 1}{2}\mathrm{M}^2\right)^{\gamma/(\gamma-1)}} \tag{11.4.18}$$

$$\left(\frac{A}{A^*}\right)^2 = \frac{1}{\mathrm{M}^2}\left[\frac{2}{\gamma + 1}\left(1 + \frac{\gamma - 1}{2}\mathrm{M}^2\right)\right]^{(\gamma+1)/(\gamma-1)}$$

where h = enthalpy of the fluid, A = stream-tube cross section normal to the velocity, and the subscript $_0$ denotes the isentropic stagnation condition reached by the stream when stopped frictionlessly and adiabatically (hence isentropically). V_{s0} denotes the speed of sound in that medium.

The superscript * denotes the conditions occurring when the speed of the fluid equals the speed of sound in the fluid. For M = 1, Eqs. (11.4.18) become

$$\frac{T^*}{T_0} = \left(\frac{V_s^*}{V_{s0}}\right)^2 = \frac{2}{\gamma + 1}$$

$$\frac{p^*}{p_0} = \left(\frac{2}{\gamma + 1}\right)^{\gamma/(\gamma-1)} \tag{11.4.19}$$

$$\frac{\rho^*}{\rho_0} = \left(\frac{2}{\gamma + 1}\right)^{1/(\gamma-1)}$$

For air $p^* = 0.52828p_0$; $\rho^* = 0.63394\rho_0$; $T^* = 0.83333T_0$.

SOURCE: Emmons, "Gas Dynamics Tables for Air," Dover Publications, Inc., 1947.

For subsonic regions flow behaves similarly to the familiar hydraulics or incompressible aerodynamics: In particular, an increase of velocity is associated with a decrease of stream-tube area, and friction causes a pressure drop in a tube. There are no regions where the local flow velocity exceeds sonic speed. For **supersonic regions,** an increase of velocity is associated with an increase of stream-tube area, and friction causes a pressure rise in a tube. $M = 1$ is the dividing line between these two regions. For **transonic flows,** there are regions where the local flow exceeds sonic velocity, and this mixed-flow region requires special analysis. For **supersonic flows,** the entire flow field, with the exception of the regime near stagnation areas, has a velocity higher than the speed of sound.

The hypersonic regime is that range of very high supersonic speeds (usually taken as $M > 5$) where even a very streamlined body causes disturbance velocities comparable to the speed of sound, and stagnation temperatures can become so high that the gas molecules dissociate and become ionized.

Shock waves may occur at locally supersonic speeds. At low velocities the fluctuations that occur in the motion of a body (at the start of the motion or during flight) propagate away from the body at essentially the speed of sound. At higher subsonic speeds, fluctuations still propagate at the speed of sound in the fluid away from the body in all directions, but now the waves cannot get so far ahead; therefore, the force coefficients increase with an increase in the Mach number. When the Mach number of a body exceeds unity, the fluctuations instead of traveling away from the body in all directions are actually left behind by the body. These cases are illustrated in Fig. 11.4.32. As the supersonic speed is increased, the fluctuations are left farther behind and the force coefficients again decrease.

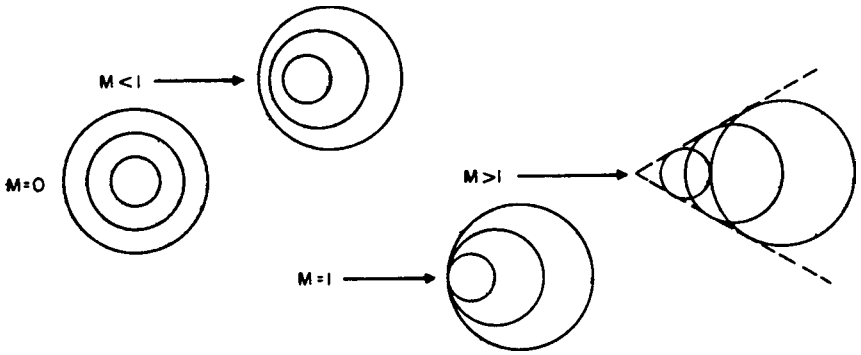

Fig. 11.4.32 Propagation of sound waves in moving streams.

Where, for any reason, waves form an envelope, as at $M > 1$ in Fig. 11.4.32, a wave of finite pressure jump may result.

The speed of sound is higher in a higher-temperature region. For a compression wave, disturbances in the compressed (hence high-temperature) fluid will propagate faster than and overtake disturbances in the lower-temperature region. In this way shock waves are formed.

For a **stationary normal shock wave** the following properties exist, where subscripts 1 and 2 refer to conditions in front of and behind the shock, respectively,

$$\left(\frac{V_{S2}}{V_{S1}}\right) = \sqrt{\left(\frac{T_2}{T_1}\right)} = \left(\frac{a_2}{a_1}\right) \tag{11.4.20a}$$

$$\left(\frac{V_2}{V_1}\right) = \left(\frac{M_2}{M_1}\right) \cdot \left(\frac{a_2}{a_1}\right) \tag{11.4.20b}$$

In the following equations, also for a normal shock, the second form shown is for air with $\gamma = 1.4$.

$$\left(\frac{p_2}{p_1}\right) = \frac{2\gamma M_1^2 - (\gamma - 1)}{\gamma + 1} = \left(\frac{7M_1^2 - 1}{6}\right) \tag{11.4.20c}$$

$$\left(\frac{\rho_2}{\rho_1}\right) = \frac{(\gamma + 1)M_1^2}{(\gamma - 1)M_1^2 + 2} = \left(\frac{6M_1^2}{M_1^2 + 5}\right) \tag{11.4.20d}$$

$$M_2 = \left[\frac{(\gamma - 1)M_1^2 + 2}{2\gamma M_1^2 - (\gamma - 1)}\right]^{1/2} = \left(\frac{M_1^2 + 5}{7M_1^2 - 1}\right)^{1/2} \tag{11.4.20e}$$

$$\left(\frac{p_{20}}{p_{10}}\right) = \left[\frac{(\gamma + 1)M_1^2}{(\gamma - 1)M_1^2 + 2}\right]^{\gamma/(\gamma-1)} \cdot \left[\frac{\gamma + 1}{2\gamma M_1^2 - (\gamma - 1)}\right]^{1/(\gamma-1)} = \left(\frac{6M_1^2}{M_1^2 + 5}\right)^{3.5} \cdot \left(\frac{6}{7M_1^2 - 1}\right)^{2.5} \tag{11.4.20f}$$

$$\left(\frac{T_2}{T_1}\right) = \frac{1 + \left(\frac{\gamma - 1}{2}\right)M_1^2}{1 + \left(\frac{\gamma - 1}{2}\right)M_2^2} = \left(\frac{1 + 0.2M_1^2}{1 + 0.2M_2^2}\right) \tag{11.4.20g}$$

The subscript 20 refers to the stagnation condition after the shock, and the subscript 10 refers to the stagnation condition ahead of the shock.

In a normal shock M, V, and p_0 decrease; p, ρ, T, and s increase, whereas T_0 remains unchanged. These relations are given numerically in Table 11.4.7.

If the shock is moving, these same relations apply *relative to the shock.* In particular, if the shock advances into stationary fluid, it does so at the speed V_1 which is always greater than the speed of sound in the stationary fluid by an amount dependent upon the shock strength.

When an air vehicle is traveling at high subsonic, transonic, or supersonic speeds, shock waves will form on it. A shock wave is a thin region of air through which air physical properties change. Shock waves can be normal or oblique to the air vehicle direction of flight. If oblique, it behaves exactly like a normal shock to the normal component of the stream. The tangential component is left unchanged. Thus the resultant velocity not only drops abruptly in magnitude but also changes discontinuously in direction. Figure 11.4.33 gives the relations between M_1, M_2, θ_W, and δ.

In **supersonic flow past a two-dimensional wedge** with semiangle δ, one **strong** and one **weak** oblique shock wave will theoretically form attached to the leading edge. See Fig. 11.4.34*a*. In practice only the weak one will be present and downstream of this oblique shock the resultant flow will be parallel to the wedge surface. It is possible to use Eqs. (11.4.20) to generate the flow characteristics about wedges with various wedge angles or more easily with the help of Fig. 11.4.33.

The relationship between δ, M_1, and θ_W is shown in Fig. 11.4.34*b*. These are related through the equation

$$\tan\delta = \left[\frac{2\cot\theta_W\,(M_1^2\sin^2\theta_W - 1)}{M_1^2(\gamma + \cos 2\theta_W) + 2)}\right]$$

The results of a numerical evaluation of the above equation for $1.5 < M_1 < 20$, $\gamma = 1.4$ (for air) are shown graphically in Fig. 11.4.35. The locus of the maximum wedge angle line differentiates between weak and strong shocks. For small wedge angles, the shock angle differs only slightly from $\sin^{-1}(1/M_1)$, the **Mach angle,** and the velocity component normal to this wave is the speed of sound. The pressure jump is small and is given approximately by

$$p - p_1 = \left[\frac{\gamma p_1 \overline{M}_1^2}{\sqrt{\overline{M}_1^2 - 1}}\right]\delta$$

where δ is the wedge semiangle.

For wedge semiangles that exceed the corresponding Mach number lines, a detached shock will form at the leading edge (Fig. 11.4.36). For example, if $\delta = 40°$ and $M_1 = 3.00$, then a detached bow wave will form in front of the wedge leading edge (see Fig. 11.4.35). Behind this detached shock there will be a region of subsonic flow reaching the wedge leading edge.

Exact solutions also exist for **supersonic flow past a cone.** Above a certain supersonic Mach number, a conical shock wave is attached to the apex of the cone. Figures 11.4.37 and 11.4.38 show these exact relations; they are so accurate that they are often used to determine the Mach number of a stream by measuring the shock-wave angle on a cone of known angle. For small cone angles the shock differs only slightly from the **Mach cone,** i.e., a cone whose semiapex angle is the Mach angle; the pressure on the cone is then given approximately by

$$p - p_1 = \gamma p_1 \overline{M}_1^2 \delta^2 (\ln 2/\delta\sqrt{\overline{M}_1^2 - 1}) \tag{11.4.21}$$

where δ is the cone semiangle.

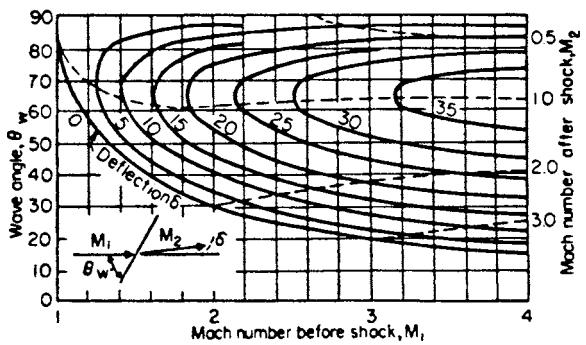

Fig. 11.4.33 Oblique shock wave relations.

A **nozzle** consisting of a single contraction will produce at its exit a jet of any velocity from M = 0 to M = 1 by a proper adjustment of the pressure ratio. For use as a subsonic wind-tunnel nozzle where a uniform parallel gas stream is desired, it is only necessary to connect the supply section to the parallel-walled or open-jet test section by a smooth gently curving wall. If the radius of curvature of the wall is nowhere less than the largest test-section cross-sectional dimension, no flow separation will occur and a good test gas stream will result.

When a **converging nozzle** connects two chambers with the pressure drop beyond the critical $[(p/p_0) < (p^*/p_0)]$, the Mach number at the exit of the nozzle will be 1; the pressure ratio from the supply section to the nozzle exit will be critical; and all additional expansion will take place outside the nozzle.

A nozzle designed to supply a supersonic jet at its exit must converge to a minimum section and diverge again. The area ratio from the minimum section to the exit is given in the column headed A/A^* in Table 11.4.6. A converging-diverging nozzle with a pressure ratio p/p_0 = (gas pressure)/(stagnation pressure), Table 11.4.6, gradually falling from unity to zero will produce shock-free flow for all exit Mach numbers from zero to the subsonic Mach number corresponding to its area ratio. From this Mach number to the supersonic Mach number corresponding to the given area ratio, there will be shock waves in the nozzle. For all smaller pressure ratios, the Mach number at the nozzle exit will not change, but additional expansion to higher velocities will occur outside of the nozzle.

To obtain a uniform parallel shock-free supersonic stream, the converging section of the nozzle can be designed as for a simple converging nozzle. The diverging or supersonic portion must be designed to produce and then cancel the expansion waves. These nozzles would perform as designed if it were not for the growth of the boundary layer. Experience indicates that these nozzles give a good first approximation to a uniform parallel supersonic stream but at a somewhat lower Mach number.

For **rocket nozzles** and other thrust devices the gain in thrust obtained by making the jet uniform and parallel at complete expansion must be balanced against the loss of thrust caused by the friction on the wall of the greater length of nozzle required. A simple conical diverging section, cut off experimentally for maximum thrust, is generally used (see also Sec. 11.5 "Jet Propulsion and Aircraft Propellers").

For transonic and supersonic flow, **diffusers** are used for the recovery of kinetic energy. They follow the test sections of supersonic wind tunnels and are used as inlets on high-speed planes and missiles for ram recovery. For the first use, the diffuser is fed a nonuniform stream from the test section (the nonuniformities depending on the particular body under test) and should yield the maximum possible pressure-rise ratio. In missile use the inlet diffuser is fed by a uniform (but perhaps slightly yawed) airstream. The maximum possible pressure-rise ratio is important but must provide a sufficiently uniform flow at the exit to assure good performance of the compressor or combustion chamber that follows.

In simplest form, a **subsonic diffuser** is a diverging channel, a nozzle in reverse. Since boundary layers grow rapidly with a pressure rise, subsonic diffusers must be diverged slowly, 6 to 8° equivalent cone angle, i.e., the apex angle of a cone with the same length and area ratio.

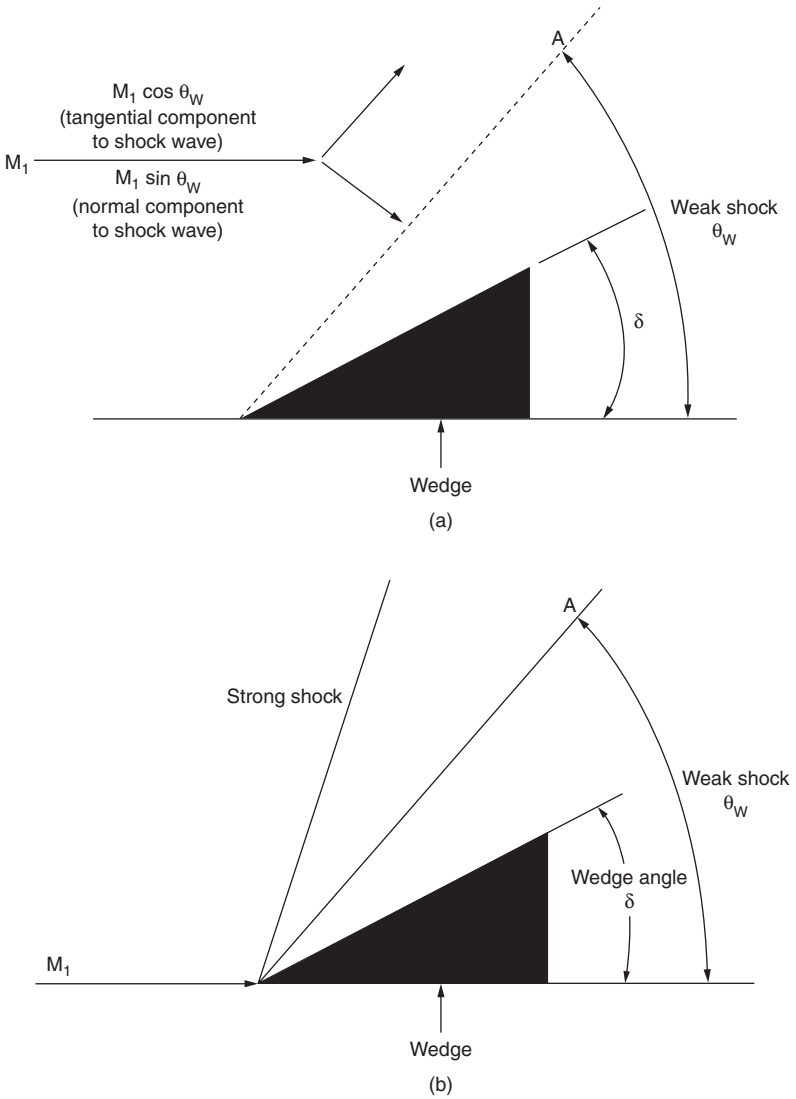

Fig. 11.4.34 Shock waves on a wedge.

Similarly, a **supersonic diffuser** in its simplest form is a supersonic nozzle in reverse. Both the convergent and divergent portions must change cross section gradually. In principle it is possible to design a shock-free diffuser. In practice shock-free flow is not attained, and the design is based upon minimizing the shock losses. Oblique shocks should be produced at the inlet and reflected a sufficient number of times to get compression nearly to M = 1. A short parallel section and a divergent section can now be added with the expectation that a weak normal shock will be formed near the throat of the diffuser.

For **a supersonic wind tunnel,** the best way to attain the maximum pressure recovery at a wide range of operating conditions is to make the diffuser throat variable. The ratio of diffuser-exit static pressure to the diffuser-inlet (test-section outlet) total pressure is given in Table 11.4.8. These pressure recoveries are attained by the proper adjustment of the throat section of a variable diffuser on a supersonic wind-tunnel nozzle.

A **supersonic wind tunnel** consists of a compressor or compressor system including precoolers or aftercoolers, a supply section, a supersonic nozzle, a test section with balance and other measuring equipment, a diffuser, and sufficient ducting to connect the parts. The **minimum pressure ratio** required from supply section to diffuser exit is given in Table 11.4.8. Any pressure ratio greater than this is satisfactory. The extra pressure ratio is automatically wasted by additional shock waves that appear in the diffuser. The compression ratio required of the compressor system must be greater than that of Table 11.4.8 by at least an amount sufficient to take care of the pressure drop in the ducting and valves. The latter losses are estimated by the usual hydraulic formulas.

After selecting a compressor system capable of supplying the required maximum pressure ratio, the test section area is computed from

$$A = 1.73 \frac{Q}{V_{s0}} \frac{A}{A^*} \frac{p_e}{p_0} \qquad \text{ft}^2 \tag{11.4.22}$$

where Q is the inlet volume capacity of the compressors, ft^3/s; V_{s0} is the speed of sound in the supply section, ft/s; A/A^* is the area ratio given in Table 11.4.6 as a function of M; p_e/p_0 is the pressure ratio given in Table 11.4.8 as a function of M.

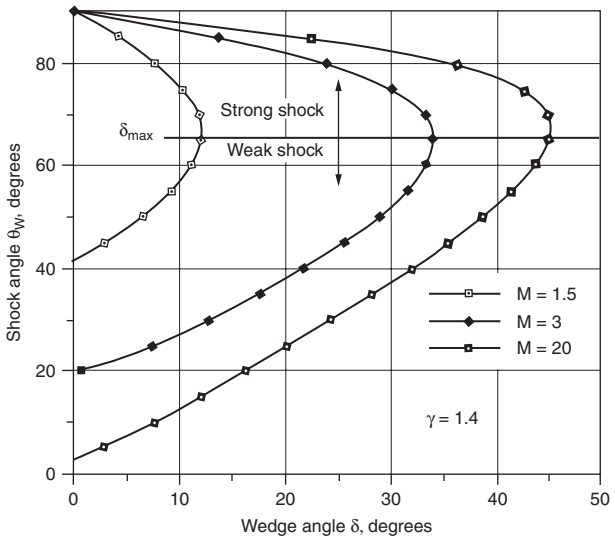

Fig. 11.4.35 Oblique shock properties for air: strong and weak shock variables.

The nozzle itself is designed for uniform parallel airflow in the test section. Since for each Mach number a different nozzle is required, the nozzle must be flexible or the tunnel so arranged that fixed nozzles can be readily interchanged.

The Mach number of a test is set by the nozzle selection, and the Reynolds number is set by the inlet conditions and size of model. The Reynolds number is computed from

$$\mathrm{Re} = \mathrm{Re}_0 D(p_0/14.7)(540/T_0)^{1.268} \qquad (11.4.23)$$

where Re_0 is the Reynolds number per inch of model size for atmospheric temperature and pressure, as given by Fig. 11.4.39, D is model diam, in; p_0 is the stagnation pressure, lb/in^2; T_0 is the stagnation temperature, °R.

For a closed-circuit tunnel, the Reynolds number can be varied independently of the Mach number by adjusting the mass of air in the system, thus changing p_0.

Intermittent-wind tunnels for testing at high speeds do not require the large and expensive compressors associated with continuous-flow tunnels. They use either a large vacuum tank or a large pressure tank (often in the form of a sphere) to produce a pressure differential across the test

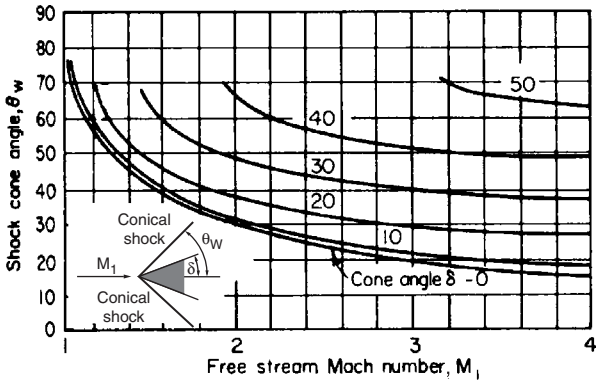

Fig. 11.4.37 Wave angles for supersonic flow around cones.

section. Such tunnels may have steady flow for only a few seconds, but by careful instrumentation, sufficient data may be obtained in this time. A **shock tube** may be used as an intermittent-wind tunnel as well as to study shock waves and their interactions; it is essentially a long tube of constant or varying cross section separated into two parts by a frangible diaphragm. High pressure exists on one side; by rupturing the diaphragm, a shock wave moves into the gas with the lower pressure. After the shock wave a region of steady flow exists for a few milliseconds. Very high stagnation temperatures can be created in a shock tube, which is not the case in a wind tunnel, so that it is useful for studying hypersonic flow phenomena.

Wind-tunnel force measurements are subject to errors caused by the model support strut. Wall interference is small at high Mach numbers for which the reflected model head wave returns well behind the model. Near M = 1, the wall interference becomes very large. In fact, the tunnel chokes at Mach numbers given in Table 11.4.6, at

$$\frac{A}{A^*} = \frac{1}{1 - \dfrac{\text{area of model projected on test-section cross section}}{\text{area of test-section cross section}}} \qquad (11.4.24)$$

There are two choking points: one subsonic and one supersonic. Between these two Mach numbers, it is impossible to test in the tunnel. As these Mach numbers are approached, the tunnel wall interference becomes very large.

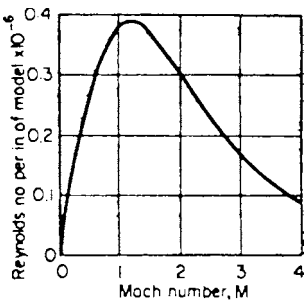

Fig. 11.4.39 Reynolds number–Mach number relation (for a fixed model size and stagnation condition).

For tests in this range of Mach number, specially constructed **transonic wind tunnels** with perforated or slotted walls have been built. The object here is to produce a mean flow velocity through the walls that comes close to that which would have existed there had the body been moving at that speed in the open. Often auxiliary blowers are needed to produce the necessary suction on the walls and to reinject this air into the tunnel circuit in or after the diffuser section.

Drag is difficult to predict precisely from wind-tunnel measurements, especially in the transonic regime. **Flight tests** of rocket-boosted models which coast through the range of Mach numbers of interest are used to obtain better drag estimates; from telemetered data and radar or optical sighting the deceleration can be determined, which in turn yields the drag.

LINEARIZED SMALL-DISTURBANCE THEORY

As the speed of a body is increased from a low subsonic value (Fig. 11.4.40*a*), the local Mach number becomes unity somewhere in the fluid along the surface of the body, i.e., the lower critical Mach number is reached. Above this there is a small range of transonic speed in which a supersonic region exists (Fig. 11.4.40*b*). Shock waves appear in this region attached to the sides of the body (Fig. 11.4.40*c*) and grow with increasing speed. At still higher transonic speeds a detached shock wave appears ahead of the body, and the earlier side shocks either disappear or move to the rear (Fig. 11.4.40*d*). Finally, for a sharp-nosed body, the head wave moves back and becomes attached (Fig. 11.4.40*e*). The flow is now generally supersonic everywhere, and the transonic regime is replaced by the supersonic regime. With the appearance of shock waves there occurs a considerable alteration of the pressure distribution, and the center of pressure on airfoil sections moves from the one-fourth chord point back toward the one-half chord point. There is an associated increase of drag and, often, flow separation at the base of the shock.

The redistribution of pressures and the motion of shock waves over the wing surfaces through the transonic regime demands special consideration in the design of control surfaces so that they do not become ineffective by separation or inoperative by excessive loading.

If a body is slender (i.e., planes tangent to its surface at any point make small angles with the flight direction), the disturbance velocities caused by this body will be small compared with the flight speed and, excluding the hypersonic regime, small compared with the speed of sound. This permits the use of linearized small-disturbance theory to predict the approximate flow past the body. This theory relates the steady flow past the body at subsonic speeds to the incompressible flow past a distorted version of this body (the "generalized Prandtl-Glauert rule"). For **thin airfoil sections** at subsonic speeds, this theory predicts

$$C_L = 2\pi\alpha/\sqrt{1 - \mathrm{M}^2} \quad \alpha \text{ in radians} \tag{11.4.25}$$

where $L = C_L qS$ and $q = (\gamma/2)p_0\mathrm{M}^2$.

An approximation to the **subsonic** lift curve slope for wings is given by:

$$C_{L\alpha} = \left(\frac{2\pi A}{\left[2 + \left\{ \left(\frac{A^2\beta^2}{0.90} \right) \left(1 + \frac{\tan^2 \Lambda_{c/2}}{\beta^2} \right) + 4 \right\}^{1/2} \right]} \right) \quad \text{per radian}$$

where A = aspect ratio, $\beta = (1 - \mathrm{M}^2)^{0.5}$, $\Lambda_{c/2}$ = semichord sweep angle. This can be applied to wings of all aspect ratios, taper ratios, and for quarter chord sweep angles of up to 60°.

The corresponding **induced** drag, or **drag due to lift,** is given by

$$C_{Di} = \frac{C_L^2}{\pi A e}$$

where e is the span efficiency factor, which is usually between 0.85 and 0.95.

At supersonic speeds, the Prandtl-Glauert rule is also applicable if we replace β by $\lambda = \sqrt{\mathrm{M}^2 - 1}$. For **thin airflow sections** (see Fig. 11.4.41) this theory predicts

$$C_L = 4\alpha/\sqrt{\mathrm{M}^2 - 1} \quad \alpha \text{ in radians} \tag{11.4.26}$$

$$C_D = \frac{2}{\lambda} \int_0^1 \left[\left(\frac{dy_u}{dx} \right)^2 + \left(\frac{dy_l}{dx} \right)^2 \right] d\left(\frac{x}{c} \right) + \frac{4a^2}{\lambda} + C_{DF} \tag{11.4.27}$$

where dy_u/dx and dy_l/dx are the slopes of the upper and lower surfaces of the airfoil, respectively, and C_{DF} is the skin-friction drag coefficient. Note that there is a drag due to thickness and a drag due to lift at supersonic speeds for an airfoil section where there is none at subsonic speeds. For symmetric double-wedge airfoil sections, the thickness drag coefficient becomes $(4/\lambda)(t/c)^2$, and for symmetric biconvex airfoil sections it is $(16/3\lambda)(t/c)^2$, where t is the maximum thickness.

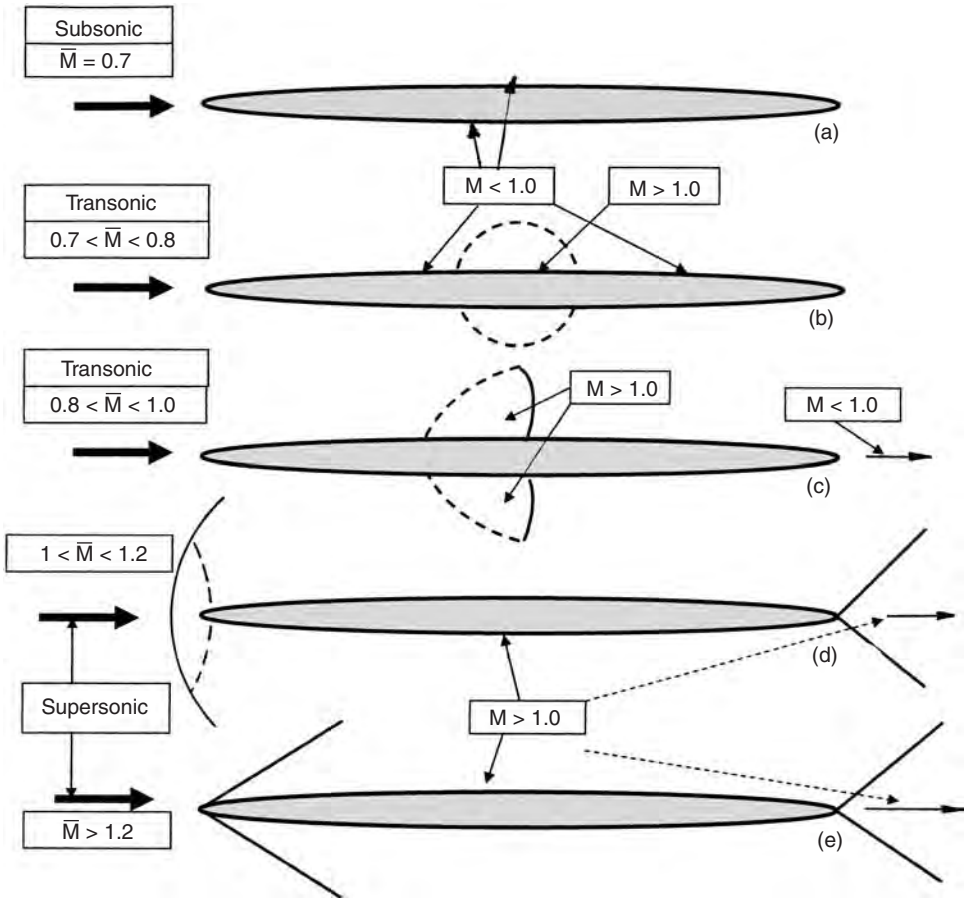

Fig. 11.4.40 Regions of flow about an airfoil (Mach numbers are approximate).

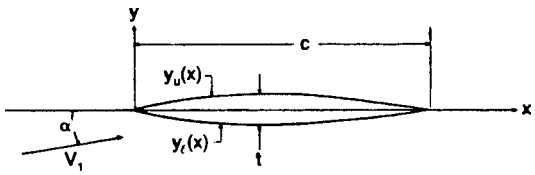

Fig. 11.4.41 Supersonic airfoil section.

Within the small disturbance approximation, a disturbance at a point in supersonic flow can affect only the points in the downstream **Mach cone**. Thus a rectangular wing with constant airfoil section has two-dimensional flow on all parts of the wing except the points within the Mach cones. At Mach numbers near unity these tip Mach cones cover nearly the entire wing, whereas at high Mach numbers they cover only a small part.

Research at NACA (NACA TR 839, NACA TR 900) established that for **supersonic** wings, swept and unswept, the relative location of the Mach lines and the wing planform (Fig. 11.4.42) is important in the determination of the magnitudes of the wing lift curve slopes and the drag due to lift. For swept wings, the wing possesses a **subsonic** leading edge when $\mu > \varepsilon$, (Fig. 11.4.43), and a **supersonic** leading edge when $\varepsilon > \mu$. When $\varepsilon = \mu$ the leading edge is termed **sonic.**

For **thin airfoil section supersonic delta wings** with **subsonic leading edges,** lift can be approximated by

$$\beta\left(\frac{C_L}{\alpha}\right) = \left(\frac{2\pi^2}{\pi + \lambda}\right)\left(\frac{\tan\varepsilon}{\tan\mu}\right)$$

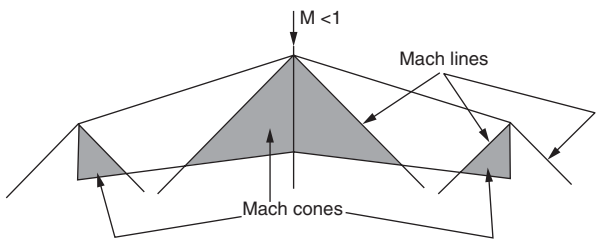

Fig. 11.4.42 Mach cones and Mach lines for wing with supersonic leading edge.

where λ is given in Fig. 11.4.44 and $\beta = (M^2 - 1)^{0.5}$, and the corresponding drag due to lift approximated by

$$C_{Di} = \left(\frac{C_L^2}{\pi A}\right)\left[2\left(1 + \frac{\lambda}{\pi}\right) - \sqrt{1 - \beta^2\tan^2\varepsilon}\right]$$

For **delta wings with supersonic leading edges,** the corresponding first approximations are

$$\left(\frac{C_L}{\alpha}\right) = \frac{4}{\sqrt{M^2 - 1}} \text{ per radian} \qquad \text{and} \qquad C_{Di} = \frac{4\alpha^2}{\sqrt{M^2 - 1}}$$

For delta wings with sharp leading edges, research at NASA (NASA TN-D 4739) established the presence of a **vortex lift** component at low

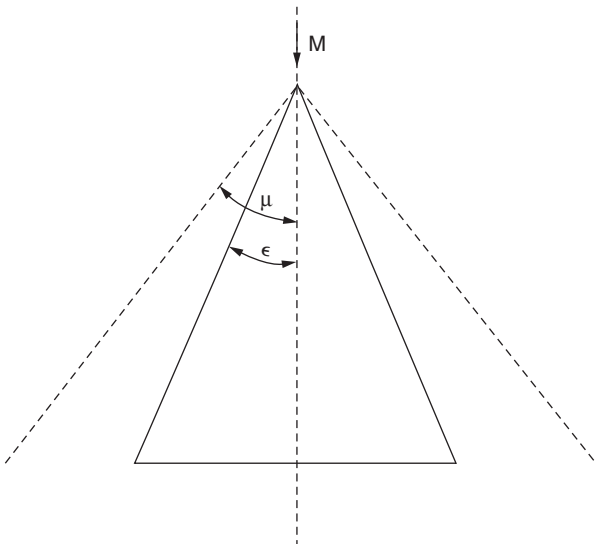

Fig. 11.4.43 Wing sweep/Mach line relationship.

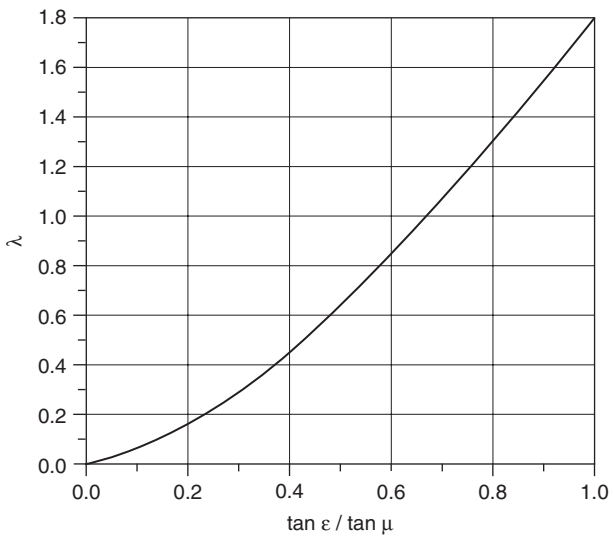

Fig. 11.4.44 Lambda (λ) variation with sweep and Mach number.

speed. Figure 11.4.45 illustrates the formation of these vortices which generates a total lift coefficient given by

$$C_L = K_p \sin\alpha \cos^2\alpha + K_v \cos\alpha \sin^2\alpha$$

Drag due to this lift is given by

$$\Delta C_{Di} = K_p \sin^2\alpha \cos\alpha + K_v \sin^3\alpha$$

where K_p and K_v are given in Fig. 11.4.46.

Rectangular wings in supersonic flight are not amenable to simple closed form solutions for either lift or drag due to lift and the reader is referred to NACA TN 2114 for lift and drag estimations.

The lift of a slender **axially symmetric body** at small angle of attack is nearly independent of Mach number and is given approximately by

$$C_L = 2\alpha \qquad (11.4.28)$$

where the lift coefficient is based on the cross-sectional area of the base. The drag for $\alpha = 0$ at subsonic speeds is made up of skin friction and

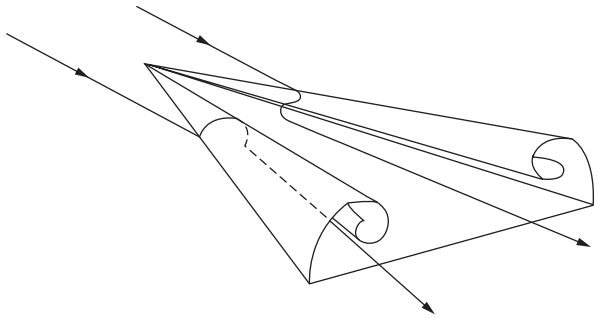

Fig. 11.4.45 Vortex-induced lift.

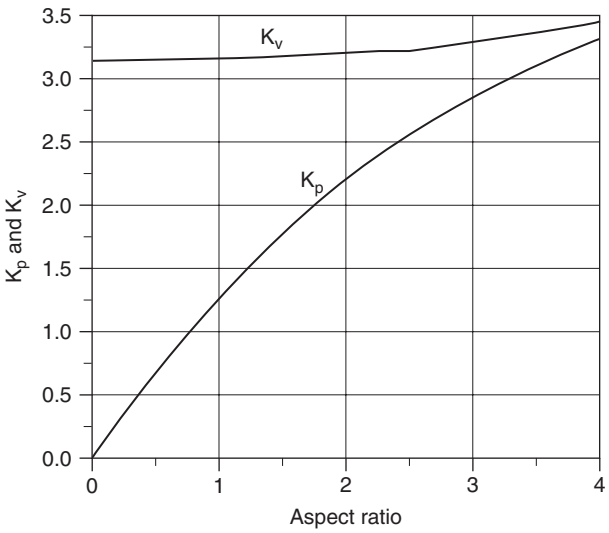

Fig. 11.4.46 Variations of K_p and K_v with wing aspect ratio.

base drag; a dead-air region exists just behind the blunt base, and the pressure here is below ambient, causing a rearward suction which is the base drag. At supersonic speeds a wave drag is added, which represents the energy dissipated in shock waves from the nose. Figure 11.4.47 shows a typical drag-coefficient curve for a body of revolution where the **fineness ratio** (ratio of length to diameter) is 12.2. The skin-friction drag coefficient based on wetted area is the same as that of a flat plate, within experimental error.

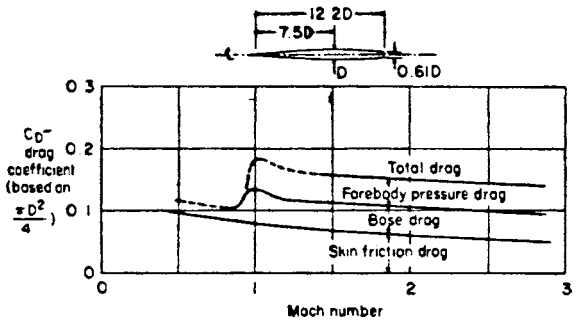

Fig. 11.4.47 Drag coefficients for parabolic-arc (*NACA-RM* 10) body (calculations from experimental data for a 30,000-ft altitude, D = 12 in, from *NACA-TR* 1160 and 1161, 1954).

At transonic and moderate supersonic speeds, the wave drag of a **wing body combination** can be effectively reduced by making the cross-sectional area distribution (including wings) a smooth curve when plotted versus fuselage station. This is the **area rule;** its application results in a decided indentation in the fuselage contour at the wing juncture. **Lift interference** effects also occur, especially when the body diameter is not small compared with the wing span. If the wing is attached to a cylindrical body, and if the wing-alone lift coefficient would have been C_L, then the lift carried on the body is $K_B C_L$, and the lift carried on the wing is $K_W C_L$. Figure 11.4.48 shows the variation of K_B and K_W with body diameter to wing-span ratio.

The **effect of compressibility on skin-friction drag** is slight at subsonic speeds, but at supersonic speeds, a significant reduction in skin-friction coefficient occurs. Figure 11.4.49 shows the turbulent-boundary-layer mean skin-friction coefficient for a cone as a function of wall temperature and Mach number. An important effect at high speed is **aerodynamic heating.**

Figure 11.4.50 illustrates the velocity profile behind the shock wave of a body traveling at hypersonic speed. The shock-wave front represents an area of high-temperature gas which radiates energy to the body, but boundary-layer convective heating is usually the major contributor. Behind this front is shown the velocity gradient in the boundary layer. The decrease in velocity in the boundary layer is brought about by the forces of interaction between fluid particles and the body (viscosity). This change in velocity is accompanied by a change in temperature and is dependent on the characteristics of the boundary layer. For example, heat transfer from a turbulent boundary layer may be of an order of magnitude greater than for laminar flow.

If the gas is brought to rest instantaneously, the total energy in the flow is converted to heat and the temperature of the air will rise. The

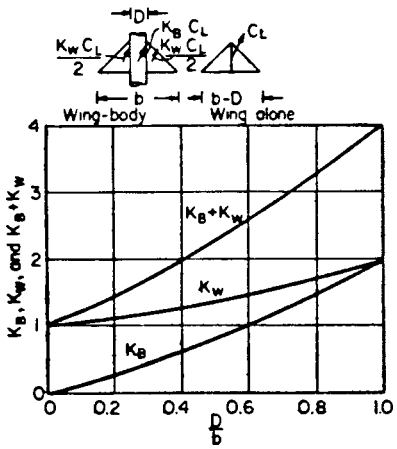

Fig. 11.4.48 Wing-body lift-interface factors.

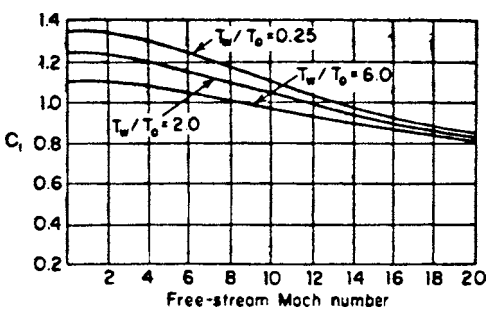

Fig. 11.4.49 Laminar-skin-friction coefficient for a cone.

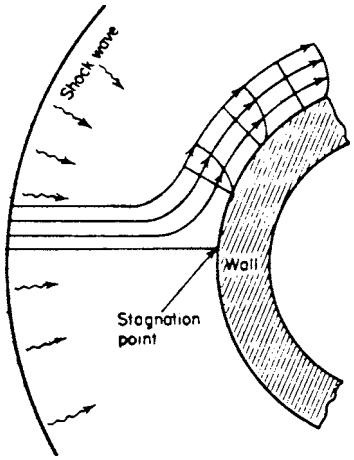

Fig. 11.4.50 Velocity profile behind a shock wave.

resulting temperature is known as the **stagnation temperature** (see stagnation point, Fig. 11.4.50).

$$T_S = T_\infty\left(1 + \frac{\gamma - 1}{2}\mathrm{M}^2\right) \tag{11.4.29}$$

T_∞ is the ambient temperature of the gas at infinity, and γ is the specific-heat ratio of the gas. For undissociated air, $\gamma = 1.4$.

In general, this simple, one-dimensional relationship between velocity and temperature does not hold for temperature in the boundary layer. The laminae of the boundary layer are not insulated from each other, and there is cross conduction. This is associated with the **Prandtl number** Pr, which is defined as

$$\mathrm{Pr} = C_p \mu / k_r \tag{11.4.30}$$

where k_r = thermal conductivity of fluid, C_p = specific heat of fluid at constant pressure, and μ = absolute viscosity of fluid.

Defining the **recovery factor** r as the ratio of the rise in the idealistic wall and stagnation temperature over the free-stream temperature,

$$r = (T_{aw} - T_\infty)/(T_s - T_\infty) = (\mathrm{Pr})^n \tag{11.4.31}$$

For laminar flow, $r = (\mathrm{Pr})^{1/2}$; and for turbulent flow, $r = (\mathrm{Pr})^{1/3}$.

Prandtl number Pr greatly complicates the thermal computations, but since it varies only over a small range of values, a recovery factor of 0.85 is generally used for laminar flow and 0.90 for turbulent flow.

For a thermally thin wall, the rate of change of the surface temperature is a function of the rate of total heat input and the surface's ability to absorb the heat.

$$dT_w/dt = q_T/wcb \tag{11.4.32}$$

where t = time, q_T = forced convective heating + radiation heating – heat radiation from the skin, w = density of skin material, c = specific heat of skin material, b = skin thickness, and T_w = skin temperature.

The heat balance may then be written

$$wcb\left(\frac{dT_w}{dt}\right) = k_c\left[T_0\left(1 + r\frac{\gamma_B - 1}{2}\mathrm{M}_0^2\right) - T_w\right] + \alpha G_s A_p - \epsilon\sigma T_w^4 \tag{11.4.33}$$

where A_p = correction factor to account for area normal to radiation source, γ_B = specific heat ratio of boundary layer, ϵ = radiative emissivity of surface, σ = Stefan-Boltzmann constant [17.3×10^{-10} Btu/(h · ft^2 · °R^4), α = surface absorptivity, G_s = solar irradiation Btu/ (h·ft^2).

For small time increments Δt,

$$\frac{dT_w}{dt} = \frac{T_{w2} - T_{w1}}{\Delta t}$$

Then

$$T_{w2} = T_{w1} + \frac{\Delta t}{wcb}\left\{h_c\left[T_0\left(1 + \frac{\gamma_B - 1}{2}\mathrm{M}_0^2\right) - T_w\right] + \alpha G_s A_p - T_w^4\right\} \quad (11.4.34)$$

The local heat-transfer coefficient h_c is defined as

$$h_c = \frac{k_r}{r^4/3} C_p C_f \rho_0 V g \quad (11.4.35)$$

where C_p = specific heat of air; C_f = local skin-friction coefficient; ρ_0 = density outside of boundary layer; V = velocity outside of boundary layer; g = acceleration of gravity.

For a cone, $k_r = 1{,}800$ (laminar Re $< 2 \times 10^6$) and $k_r = 1{,}800r^{4/3}$ (turbulent).

For a flat-plate transition, Reynolds number is 1×10^6.

Figure 11.4.49 gives laminar-skin-friction coefficient for a cone. For a flat plate, multiply C_f by $\sqrt{3}/2$. For turbulent skin-friction coefficient for a cone,

$$\frac{0.242}{\sqrt{A^2 C_f T_w/T_0}}(\sin^{-1}\psi + \sin^{-1}\theta) = 0.41 \log \frac{\mathrm{Re}}{2} C_f - 1.26 \log \frac{T_w}{T_0}$$

where

$$\psi = \frac{2A^2 - B}{\sqrt{B^2 + 4A^2}} \qquad A^2 = \frac{(\gamma_0 - \tfrac{1}{2})\mathrm{M}_0^2}{T_w/T_0}$$

$$\theta = \frac{B}{\sqrt{B^2 + 4A^2}} \qquad B = \frac{1 + (\gamma_0 - \tfrac{1}{2})\mathrm{M}_0^2}{T_w/T_0} - 1$$

For a flat plate, use Re instead of Re/2 in the above equation.

Figure 11.4.51 shows data on stagnation and adiabatic wall temperatures.

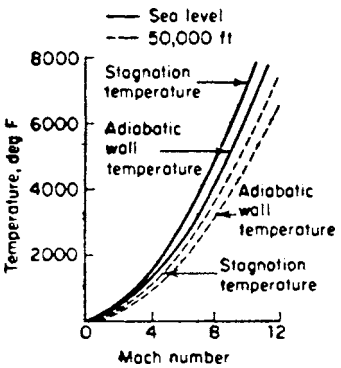

Fig. 11.4.51 Variation of stagnation and adiabatic wall temperature with Mach number.

The primary **measurements in aerodynamics** are pressure measurements. A well-aligned pitot tube with an impact-pressure hole at its nose and static-pressure holes 10 diameters or more back from the nose will accurately measure the **impact pressure** and the **static pressure** of a uniform gas stream. Up to sonic speed the impact pressure is identical with stagnation pressure, but at supersonic speeds, a detached shock wave forms ahead of the probe, through which there is drop in stagnation pressure; the portion of the shock wave just ahead of the probe is normal, so that the equation for water flow in layer form over horizontal tubes (see "Transmission of Heat by Conduction and Convection" in Sec. 4) gives the relation of the measured impact pressure to the isentropic stagnation pressure.

Force measurements of total lift, drag, side force, pitching moment, yawing moment, and rolling moment on models are made on wind-tunnel balances just as at low speed. Small internal-strain-gage balances are often used to minimize strut interference.

An open thermocouple is unreliable for determining **stagnation temperature** if it is in a stream of high velocity. Figure 11.4.52 shows a simple temperature probe in which the fluid is decelerated adiabatically before its temperature is measured. The recovery factor used in equations, for this probe, accurately aligned to the stream, is 0.98.

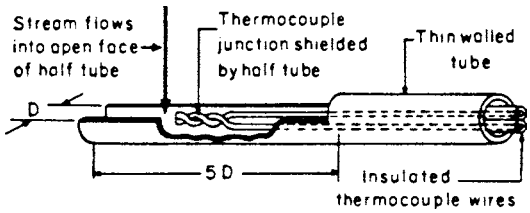

Fig. 11.4.52 Stagnation-temperature probe (recovery factor = 0.98).

Optical measurements in high-speed flow depend on the variation of index of refraction with gas density. This variation is given by

$$n = 1 + k\rho \quad (11.4.36)$$

where $k = 0.116$ ft^3/slug for air. A Mach-Zehnder **interferometer** (Fig. 11.4.53*a*), is capable of giving accurate density information for two-dimensional and axially symmetric flows. The **Schlieren** optical system (Fig. 11.4.53*b*) is sensitive to density gradients and is the most commonly used system to determine location of shock waves and regions of compression or expansion. The **shadowgraph** optical system is the simplest system (Fig. 11.4.53*c*) and is sensitive to the second space derivative of the density.

Newton's reaction principle, based on the second and third laws of motion, is the theoretical basis for all methods of propelling a body either in (or on) a fluid medium or in space. Thus, the aircraft propeller, the ships screw, and the jet propulsion of aircraft, missiles, and boats are all examples of the application of the reaction principle to the propulsion of vehicles. Furthermore, all jet engines belong to that class of power plants known as **reaction engines.**

Newton's second law states that a change in motion is proportional to the force applied; i.e. a force proportional to the rate of change of the velocity results whenever a mass is accelerated: $F = ma$. This can be expressed in a more convenient form as $F = d(mv)/dt$, which makes it clear that the application of the reaction principle involves the time rate of increase of the momentum (mv) of the body. It should be noted that the same force results from either providing a small acceleration to a large mass or a large acceleration to a small mass.

Newton's third law defines the fundamental principle underlying all means of propulsion. It states that for every force acting on a body there is an equal and opposite reaction force.

The application of this reaction principle for propulsion involves the indirect effect of increasing the momentum of a mass of fluid in one direction and then utilizing the reaction force for propulsion of the vehicle in the opposite direction. Thus, the reaction to the time rate of increase of the momentum of that fluid, called the **propulsive fluid,** creates a force, termed the **thrust,** which acts in the direction of motion desired for the propelled vehicle. The known devices for achieving the propulsion of bodies differ only in the methods and mechanisms for achieving the time rate of increase in the momentum of the propulsive fluid or matter.

The function of a propeller is to convert the power output of an engine into useful thrust. To do this it accelerates a mass of air in the direction opposite to the direction of flight, generating thrust via Newton's reaction principle. Figure 11.5.1 illustrates schematically, in the relative coordinate system for steady flow, the operating principle of the **ideal aircraft propeller**. Power is supplied to the propeller, assumed to be equivalent to an **actuator disk,** which imparts only an axial acceleration to the air flowing through it. The rotation of the actuator disk produces a **slipstream** composed of the entire mass of air flowing in the axial direction through the area of the actuator disk, i.e., the circle swept by the propeller. Atmospheric air enters the slipstream with the flight speed V_0 and mass flow rate m_a. It leaves the slipstream with the **wake velocity** w. The thrust is given in Eq. (11.5.5). Propulsion systems utilizing propellers will be termed **propeller propulsion**. (For detailed discussions of the airplane propeller, see the section "Aircraft Propellers.")

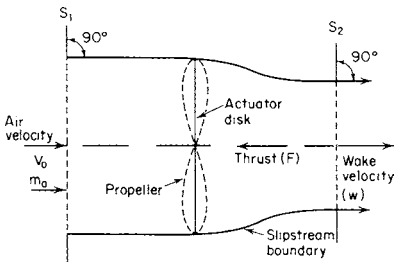

Fig. 11.5.1 Ideal propeller in the relative coordinate system.

Jet propulsion differs from propeller propulsion in that the propulsive fluid (or matter), instead of being caused to flow around the propelled body, is ejected from within the propelled body in the form of one or more high-speed jets of fluid or particles. In fact, the jet propulsion engine is basically designed to accelerate a large stream of fluid (or matter) and to expel it at a high velocity. There are a number of ways of accomplishing this, but in all instances the resultant reaction or thrust exerted on the engine is proportional to the time rate of increase of the momentum of the fluid. Thus, jet engines produce thrust in an analogous manner to the propeller and engine combination. While the propeller gives a small acceleration to a large mass of air, the jet engine gives a larger acceleration to a smaller mass of air.

Theoretically, there are no restrictions on either the type of matter, called the **propellant,** for forming a high-velocity jet or the means for producing the **propulsive jet**. The selection of the most suitable propellant and the most appropriate jet propulsion engine is dictated by the specific mission for the propelled vehicle. For example, in the case of the jet propulsion of a boat, termed **hydraulic jet propulsion,** the propulsive jet is formed from the water on which the boat moves. For the

practical propulsion of bodies through either the atmosphere or in space, however, only two types of propulsive jets are suitable:

1. For propulsion within the atmosphere, there is the jet formed by expanding a highly heated, compressed gas containing atmospheric air as either a major or a sole constituent. Such an engine is called either an **airbreathing** or a **thermal-jet engine**. If the heating is accomplished by burning a fuel in the air, the engine is a **chemical thermal-jet engine**. If the air is heated by direct or indirect heat exchange with a nuclear-energy source, the engine is termed a **nuclear thermal-jet engine.**

2. For propulsion both within and beyond the atmosphere of earth, there is the exhaust jet containing no atmospheric air. Such an exhaust jet is termed a **rocket jet,** and any matter used for creating the jet is called a **propellant**. A rocket may consist of a stream of gases, solids, liquids, ions, electrons, or a plasma. The assembly of all the equipment required for producing the rocket jet constitutes a **rocket engine**.

Modern airbreathing engines may be segregated into two principal types: (1) **ramjet engines,** and (2) **turbojet engines**. The turbojet engines are of two types: (1) the **simple turbojet engine,** and (2) the **turbofan,** or **bypass, engine**.

Rocket engines can be classified by the form of energy used for achieving the desired jet velocity. The three principal types of rocket engines are (1) **chemical rocket engines,** (2) **nuclear heat-transfer rocket engines,** and (3) **electric rocket engines**.

The propulsive element of a jet-propulsion engine, irrespective of type, is the **exhaust nozzle** or orifice. If the exhaust jet is gaseous, the assembly comprising all the other components of the jet-propulsion engine constitutes a gas generator for supplying highly heated, high-pressure gases to the exhaust nozzle.

These classifications of jet-propulsion engines apply to the basic types of engines. It is possible to have combinations of the different types of thermal-jet engines and also combinations of thermal-jet engines with rocket engines; only the principal types are discussed here.

ESSENTIAL FEATURES OF AIRBREATHING OR THERMAL-JET ENGINES

In the subsequent discussions a *relative coordinate system* is employed wherein the atmospheric air flows toward the propulsion system with the flight speed V_0, and the gases leave the propulsion system with the velocity w, *relative to the walls of the propulsion system.* Furthermore, steady-state operating conditions are assumed.

Ramjet Engine Figure 11.5.2 illustrates schematically the essential features of the simple ramjet engine. It comprises three major components: a diffusion or inlet system, (0–2); a combustion chamber (2–7); and an exhaust nozzle (7–9). In this simple ramjet engine, apart from the necessary control devices, there are no moving parts. However, for accelerating the vehicle or for operating at different Mach numbers, a variable geometry diffuser and exhaust may be required.

The operating principle of the ramjet engine is as follows. The freestream air flowing toward the engine with a velocity V_0 and Mach number M_0 is decelerated by the inlet diffuser system so that it arrives at the entrance to the combustion chamber with a low Mach number, on the order of $M_2 = 0.2$. When the inlet-flow Mach number is supersonic,

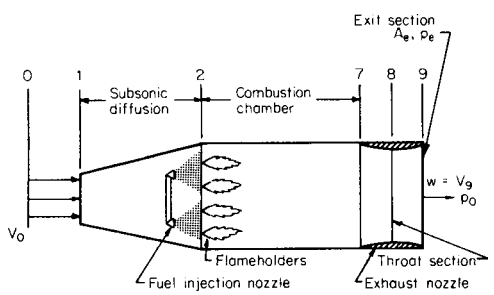

Fig. 11.5.2 Ramjet engine.

this diffuser system consists of a supersonic diffuser followed by a subsonic diffuser. The supersonic diffuser decelerates the inlet flow to approximately unity Mach number at the entrance to the subsonic diffuser; this deceleration is accompanied by the formation of shock waves and by an increase in the pressure of the air (diffusion). In the subsonic diffuser the air is further diffused so that it arrives at the entrance to the combustion chamber with the required low Mach number. If P_0 is the total pressure of the free-stream air having the Mach number M_0 and P_2 that for the air entering the combustion system with the Mach number M_2, then it is desirable that P_2/P_0 be a maximum.

In the combustion chamber a fuel is burned in the air, thereby raising the total temperature of the gases entering the exhaust nozzle (see Sec. 7) to approximately $T_7 = 4{,}260°\text{R}$ (2,366 K). Most generally a liquid hydrocarbon fuel is used, but experiments have been conducted with solid fuels, liquid hydrogen, liquid methane, and "slurries" of metallic fuels in a liquid fuel. The combustion process is not quite isobaric because of the pressure drops in the combustion chamber, because of the increase in the momentum of the working fluid due to heat addition, and because of friction. The hot gases are discharged to the atmosphere, after expanding in the exhaust nozzle, with the relative velocity $w = V_9$.

Since the ramjet engine can function only if there is a ram pressure rise at the entrance to the combustion chamber, it is not self-operating at zero flight speed. It must, therefore, be accelerated to a flight speed which permits the engine to develop sufficient thrust for accelerating the vehicle it propels to the design flight Mach number. Consequently, a ramjet-propelled missile, for example, must either be launched by dropping it from an airplane or be **boosted** to the required flight speed by means of **launching,** or **bootster,** rockets. It appears that the most appropriate flight regime for the ramjet is at low to moderate supersonic Mach numbers, between approximately $M_0 = 2$ and 5. The lower limit is associated with the necessary ram pressure rise while the upper limit is set by the problem of either cooling or protecting the outer skin of the engine body.

Scramjet Low-cost access to space is one of the major reasons for the interest in **hypersonic propulsion** (speeds above Mach 5). A vehicle to provide access to space must be capable of reaching very high Mach numbers, since orbital velocity (17,000 mi/h) is about Mach 24. The ramjet engine, which must slow the entering air to a low subsonic velocity, cannot be used much above Mach 5 or 6. The solution is to decelerate the flow in the engine to a supersonic Mach number lower than the flight Mach number but greater than the local speed of sound. This propulsion device is the **supersonic combustion ramjet,** or **scramjet,** which is capable, in principle, of operation to Mach 24. As shown schematically in Fig. 11.5.3, in contrast to the ramjet, the scramjet engine requires that fuel be added to the air, mixed, and burned, all at supersonic velocities, which is a significant technical challenge.

The advantage derived from supersonic combustion of the liquid fuel (usually liquid hydrogen) is that the diffuser of the scramjet engine is required to decelerate the air entering the engine from M_0 to only approximately $M_2 = 0.35M_0$ instead of the $M_2 = 0.2$, which is essential with subsonic combustion. This elimination of the subsonic diffusion increases the diffuser efficiency, reduces the static pressure in the combustor (and, therefore, the engine weight and heat transfer rate), and increases the velocity in the combustor (thereby decreasing engine frontal area). It is the combination of the above effects that makes ramjet propulsion at high flight Mach numbers (>7) feasible.

Pulsejets may be started and operated at considerably lower speeds than ramjets. A pulsejet is a ramjet with an air inlet which is provided with a set of shutters loaded to remain in the closed position. After the pulsejet engine is launched, ram air pressure forces the shutters to open, fuel is injected into the combustion chamber, and is burned. As soon as the pressure in the combustion chamber equals the ram air pressure, the shutters close. The gases produced by combustion are forced out the jet nozzle by the pressure that has built up within the chamber. When the pressure in the combustion chamber falls off, the shutters open again, admitting more air, and the cycle repeats at a high rate.

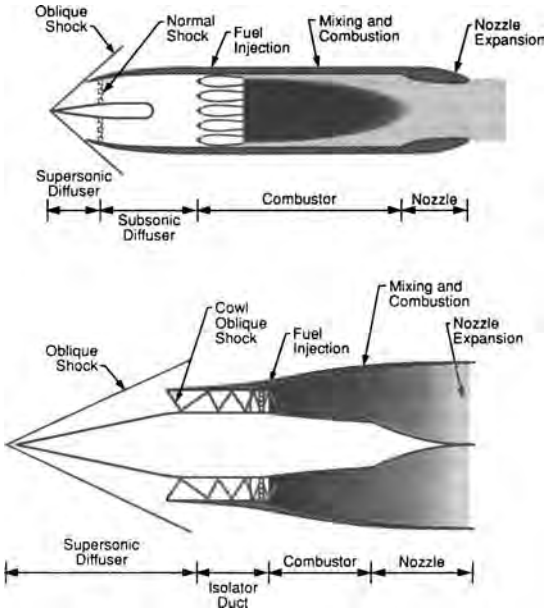

Fig. 11.5.3 Ramjet and scramjet flow configurations.

Simple Turbojet Engine Figure 11.5.4 illustrates schematically the principal features of a simple turbojet engine, which is basically a gas-turbine engine equipped with a propulsive nozzle and diffuser. Atmospheric air enters the engine and is partially compressed in the diffusion system, and further compressed to a much higher pressure by the air compressor, which may be of either the axial-flow or centrifugal type. The highly compressed air then flows to a combustion chamber wherein sufficient fuel is burned to raise the total temperature of the gases entering the turbine to approximately $T_4 = 2{,}160°\text{R}$ (1,200 K) for an uncooled turbine. The maximum allowable value for T_4 is limited by metallurgical and stress considerations; it is desirable, however, that T_4 be as high as possible. The combustion process is approximately isobaric. The highly heated air, containing approximately 25 percent of combustion products, expands in the turbine, which is directly connected to the air compressor, and in so doing furnishes the power for driving the air compressor. From the turbine the gases pass through a tailpipe which may be equipped with an **afterburner**. The gases are expanded in a suitably shaped exhaust nozzle and ejected to the atmosphere in the form of a high-speed jet.

Like the ramjet engine, the turbojet engine is a continuous-flow engine. It has an advantage over the ramjet engine in that its functioning does not depend upon the ram pressure of the entering air, although the amount of ram pressure recovered does affect its overall economy and performance. The turbojet is the only airbreathing jet engine that has been utilized as the sole propulsion means for piloted aircraft. It appears to be eminently suited for propelling aircraft at speeds above 500 mi/h (805 km/h). As the design flight speed is increased, the ram pressure increases rapidly, and the characteristics of the turbojet engine tend to change over to those of the ramjet engine. Consequently, its top speed appears to be limited to that flight speed where it becomes more advantageous to employ the ramjet engine. It appears that for speeds above approximately 2,000 mi/h (3,219 km/h) it is advantageous to use some form of a ramjet engine.

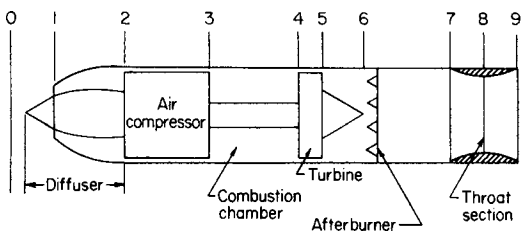

Fig. 11.5.4 Simple turbojet engine.

The thrust of the simple turbojet engine increases rapidly with T_4, because increasing T_4 increases the jet velocity V_j. Actually, V_j increases faster than the corresponding increase in T_4. It is also an inherent characteristic of the gas-turbine engine which produces shaft power, called a **turboshaft** engine, that its useful power increases proportionally faster than a corresponding increase in its turbine inlet temperature T_4. Because of the decrease in strength of turbine materials with increase in temperature, the turbine blades, stators, and disks require cooling at $T_4 > 2{,}160°\text{R}$ (1,200 K) approximately. A typical advanced turbine environment has **gas temperatures** of 3,600°R (2,000 K), with cooling provided to maintain a blade **metal temperature** of 2,250°R (1,250 K). Note that gas temperatures are being pushed toward the 4,600°R (2,556 K) stoichioemetric limit of JP4 fuel. The cooling air is bled from the compressor at the appropriate stage (or stages) and used to cool the stator blades or rotor blades by convective, film, or transpiration heat transfer. Up to 10 percent of the compressor air may be bled for turbine cooling, and this air is "lost" for turbine work for that blade row where it is used for cooling. Consequently "trade" studies must be made to "weigh" the increased complexity of the engine and the turbine work loss due to air bleed against the increased engine performance associated with increased T_4.

As in the case of any gas-turbine power plant, the efficiencies of the components of the turbojet engine have an influence on its performance characteristics, but its performance is not nearly as sensitive to changes in the efficiency of its component machines as is a gas turbine which delivers shaft power. (See Sec. 9.)

As noted previously, two types of compressors are currently employed, the axial-flow compressor and the centrifugal compressor. Irrespective of the type, the objectives are similar. The compressor must be reliable, compact, easy to manufacture, and have a small frontal area. Because of the limited air induction capacity of the centrifugal compressor, also called the radial compressor, engines for developing thrusts above 7,000 lb (31 kN) at static sea level employ axial-flow compressors (see Sec. 14).

The turbojet engine exhibits a rather flat thrust-versus-speed curve. Because the ratio of the takeoff thrust to thrust in flight is small, certain operational problems exist at takeoff. Since the exhaust gases from the turbine contain considerable excess air, the jet velocity, and consequently the thrust, can be increased by burning additional fuel in the tailpipe upstream from the exhaust nozzle. By employing **"tailpipe burning,"** or **"afterburning,"** as it is called, the thrust can be increased by 35 percent and at 500 mi/h, in a tactical emergency, by approximately 60 percent. With afterburning, the temperature of the gases entering the nozzle T_7, is of the order of 3,800°R (2,110 K).

Turbofan, or Bypass, Engine For a fixed turbine inlet temperature, the jet velocity from a simple turbojet engine propelling an airplane at subsonic speed is relatively constant. The propulsive efficiency depends on the ratio of the flight speed to the jet velocity and increases as the ratio increases. On the other hand, the thrust depends on the difference between the jet velocity and the flight speed; the larger the difference, the larger the thrust per unit mass of air induced into the engine. By reducing the jet velocity and simultaneously increasing the mass rate of airflow through the engine, the **propulsive efficiency** can be increased without decreasing the thrust. To accomplish this, a **turbofan or bypass engine** is required.

Figure 11.5.5 illustrates schematically the components of a turbofan engine. There are two turbines, a low-pressure turbine (LPT) and a high-pressure turbine (HPT); one drives the air compressor of the hot-gas generator and the other drives the fan. Air enters the fan at the rate of $\dot{m}_{aF}$ and is ejected through the nozzle of area A_{7F} with the jet velocity $V_{jF} < V_j$, where V_j is the jet velocity attained by the air flowing through the hot-gas generator with the mass flow rate $\dot{m}_{a1}$; the hot-gas generator is basically a turbojet engine.

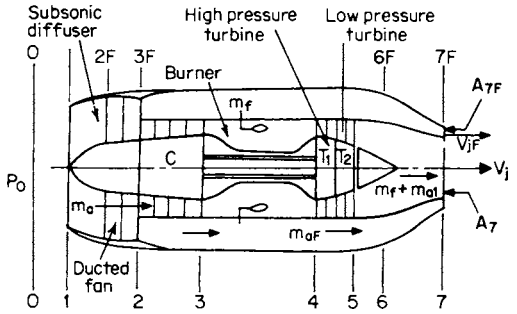

Fig. 11.5.5 Schematic arrangement of components of turbofan engines (subsonic flight).

A key parameter is the **bypass ratio,** defined as the ratio of the air mass flow rate through the fan bypass duct to that through the hot-gas generator ($\dot{m}_{aF}/\dot{m}_{a1}$). Bypass ratios of 5 to 10 are in use, with values of about 10 utilized in modern large commercial transport engines, for example, the Trent 800, the GE-90, and the PW-4000. The hot-gas generator is basically a turbojet engine. The fuel is added to $\dot{m}_{a1}$ at the rate $\dot{m}_f$. The hot-gas stream ($\dot{m}_{a1} + \dot{m}_f$) is discharged to the atmosphere through A_7 with the velocity V_j. Turbofan engines produce an "overall" jet velocity V_{jTF} which is smaller than that for a turbojet engine operating with the same P_3/P_2 and T_4. The arrangement shown in Fig. 11.5.5 is for subsonic propulsion. Fuel can, of course, be burned in the fan air m_{aF} for increasing the thrusts of the engines. Practically all the newer commercial passenger aircraft, including regional jets, are propelled by turbofan engines. The advantage of the lower effective jet velocity V_{jTF} is twofold: (1) It increases the propulsive efficiency η_p by reducing $\nu = V_{jTF}/V_0$ and, consequently, raises the value of η_0. (2) The reduced jet velocity reduces the jet noise; the latter increases with approximately the eighth power of the jet speed.

The next generation of large transport engines will be conventional high-bypass engines, but will have a larger thrust capability and will offer further improvements in specific fuel consumption, achieved by using even higher overall pressure ratios (over 50:1) and turbine inlet temperature (over 1,850 K or 2,870°F) combined with even more efficient components (Fig. 11.5.6).

A highly loaded, multiblade swept variable-pitch propeller, the **propfan** or **advanced turboprop,** could be combined with the latest

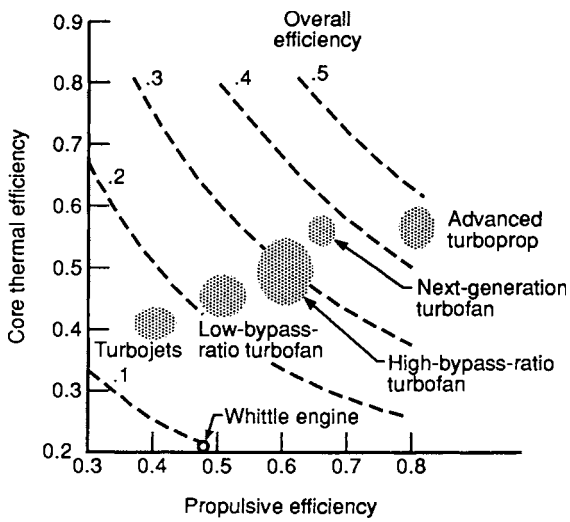

Fig. 11.5.6 Efficiency trends.

turbine engine technology. The resulting advanced turboprop would offer a potential fuel saving of 50 percent over an equivalent-technology turbofan engine operating at competitive speeds and altitudes because of the turboprop's much higher installed efficiency. To eliminate the gearbox development for a 20,000 shaft horsepower engine, the propfans of the **unducted fan (UDF)** engine were directly driven with counterrotating turbine stages, a unique concept (Fig. 11.5.7). The projected specific fuel consumption at cruise for the resulting gearless, counterrotating UDF engine was 30 percent lower than that of the most modern turbofan engines, and about 50 percent lower than that of engines presently in use on 150-passenger airplanes. The fuel-saving potential of the turboprop has already been demonstrated. If economic conditions change, this concept could replace conventional high-bypass-ratio turbofans on small aircraft and military transports.

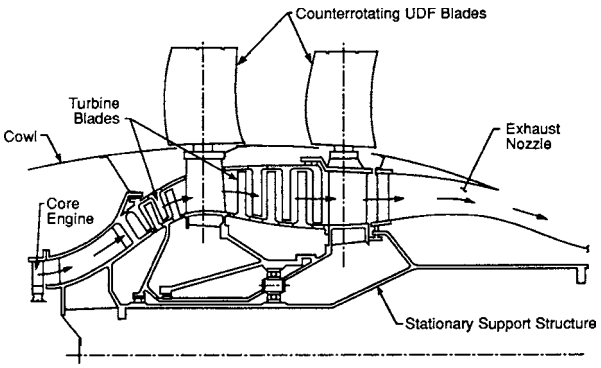

Fig. 11.5.7 UDF counterrotating turbine configuration.

The work of traditional gas turbines is based on the constant-pressure **Brayton cycle.** However, the **Humphrey cycle**'s constant-volume detonation combustion, or **pulse detonation,** has potential of increased efficiency and fuel consumption as compared to constant-pressure-combustion turbofan and turbojet engines, while having fewer moving parts and being able to operate at both subsonic and supersonic speeds. The **pulse detonation engine** (PDE) is, thus, a new engine technology currently being developed.

PDEs are essentially tubes with fuel and air admitted into one end, with **detonation combustion** occurring rather than the deflagration combustion utilized in current gas turbines. Note that there are two types of combustion: deflagration and detonation. Consider a tube containing a fuel-air mixture. The fuel is ignited by a spark at one end and the combustion reaction then propagates down the tube. With deflagration, the burning is relatively slow. Detonation combustion, in contrast, results in a high-pressure detonation or shock wave that travels down the tube at supersonic speeds, resulting in a nearly constant-volume heat addition process that produces a high pressure in the combustor and provides the thrust. This wave compresses and ignites the fuel and air in a narrow high-pressure zone, thereby resulting in burning at thousands of metres per second. Exhaust gases are expelled at the open end of the tube and, as the exhaust gases clear out, a new cycle begins. A schematic of PDE operation is shown in Fig. 11.5.8. The operation of multitube configurations at high frequencies (100+ Hz) produces near-constant thrust.

To generate the critical high-pressure combustion zone, the fuel, air, and the ignition spark must be precisely coordinated, thereby generating the **deflagration-to-detonation** transition **(DDT).** The DDT process, whereby an ordinary flame suddenly accelerates into a detonation, has four phases. In the first phase, deflagration is initiated by an electric spark. The second phase is characterized by flame acceleration and shock wave formation. This is followed by the formation and amplification of explosion centers from pockets of reactants that create small blast waves. Finally, in the last phase, a strong detonation wave is formed by coupling between the amplified blast waves and the reaction zone.

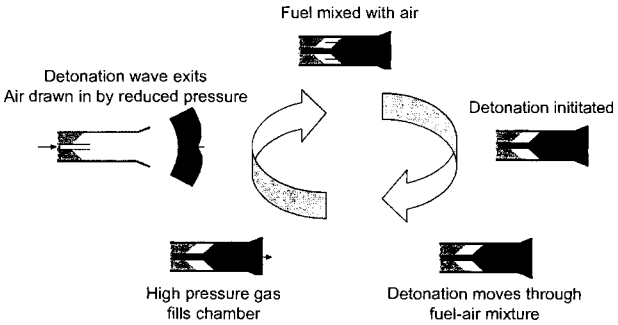

Fig. 11.5.8 Pulse detonation engine schematic.

There are three categories of pulse-detonation-based propulsion systems being considered. **Pure PDEs** are the simplest and comprise an array of detonation tubes, an inlet, and a nozzle. The upper speed limit of a pure PDE is about Mach 4 with a hydrocarbon fuel, but could be higher with hydrogen. **Combined-cycle PDEs** consist of a pure PDE combined with a ramjet/scramjet flow path or other propulsion cycle, where each cycle operates in a different speed range to optimize overall engine performance. **Hybrid PDEs** involve pure PDEs in combination with turbomachinery. For example, a hybrid turbofan-PDE would combine a turbofan with a PDE: the turbofan core engine would still power the large fan, but the bypass air would flow into a ring of PDEs, thereby producing significantly more thrust.

ESSENTIAL FEATURES OF ROCKET ENGINES

Figure 11.5.9 is a block-type diagram illustrating the essential features of a rocket engine, which comprises three main components: (A) a supply of propellant material contained in the rocket-propelled vehicle, (B) a propellant feed and metering system, and (C) a **thrust chamber,** also called a **rocket motor, thrustor,** or **accelerator.** In any rocket engine, energy must be added to the propellant as it flows through the thrustor. In Fig. 11.5.9 propellant material from the supply is metered and fed to the thrust chamber, where energy is added to it. As a consequence of the energy addition, the propellant is discharged from the thrustor with the jet velocity V_j. The thrustor F acts in the direction opposite to that for the jet velocity V_j.

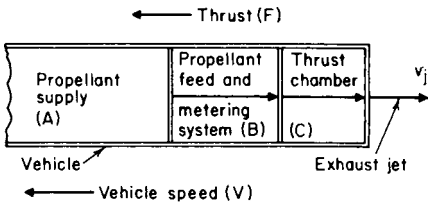

Fig. 11.5.9 Essential features of a rocket engine.

Chemical Rocket Engines

All chemical rocket engines have two common characteristics: (1) They utilize chemical reactions in a thrust chamber to produce a high-pressure, high-temperature gas at the entrance to a converging-diverging exhaust nozzle; (2) the hot propellant gas expands in flowing through the exhaust nozzle, and the expansion process converts a portion of the thermal energy, released by the chemical reaction, into the kinetic energy associated with a high-velocity gaseous-exhaust jet. Chemical rocket engines may be grouped into (1) liquid-bipropellant rocket engines, (2) liquid-monopropellant rocket engines, and (3) solid-propellant rocket engines.

Liquid-Bipropellant Rocket Engine Figure 11.5.10 illustrates the essential features of a liquid-bipropellant rocket engine employing **turbopumps** for feeding two propellants, an **oxidizer** and a **fuel,** to a rocket motor. The motor comprises (1) an injector, (2) a combustion chamber, and (3) a converging-diverging exhaust nozzle. The liquid propellants are fed under pressure, through the injector, into the combustion chamber, where they react chemically to produce large volumes of high-temperature, high-pressure gases. For a given propellant combination, the **combustion temperature** T_c depends primarily on the oxidizer-fuel ratio (by weight), termed the **mixture ratio,** and to a lesser extent upon the combustion static pressure p_c. When the mass rate of flow of the liquid propellants equals that of the exhaust gases, the combustion pressure remains constant—the mode of operation that is usually desired.

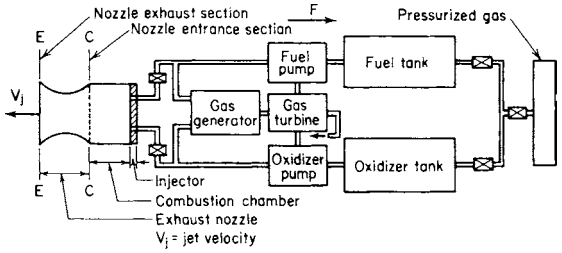

Fig. 11.5.10 Essential features of a liquid-bipropellant rocket engine.

If the bipropellants react chemically when their liquid streams come in contact with each other, they are said to be **hypergolic.** Propellants which are not hypergolic are said to be **diergolic,** and some form of ignition system is required to initiate combustion.

Except in those cases where the operating duration of the rocket motor is very short or where the combustion temperature is low, means must be provided for protecting the interior walls of the motor. The two most common methods are ablative cooling and regenerative cooling. In **ablative cooling** the inner surfaces of the thrust chamber are covered with an ablative material which vaporizes, thereby providing some cooling. Ordinarily, the material leaves a "char" which acts as a high-temperature insulating material. For high-performance engines which are to operate for relatively long periods, regenerative cooling is employed. In **regenerative cooling,** one of the propellants is circulated around the walls before injection into the motor. In some engines the regenerative cooling is combined with local liquid film cooling at critical areas of the thrust chamber. See Table 11.5.1 for bipropellant combinations.

Refer to Figure 11.5.10. By removing the oxidizer tank, the oxidizer pump, and the plumbing associated with the liquid oxidizer, one obtains the essential elements of a liquid-monopropellant rocket engine. Such an engine does not require a liquid oxidizer to cause the monopropellant to decompose and release its thermochemical energy.

There are basically three groups of monopropellants: (1) liquids which contain the fuel and oxidizer in the same molecule, e.g., hydrogen peroxide (H_2O_2) or nitromethane (CH_3NO_2); (2) liquids which contain either the oxidizer or the fuel constituent in an unstable molecular arrangement, e.g., hydrazine (N_2H_4); and (3) synthetic mixtures of liquid fuels and oxidizers. The most important liquid monopropellants are hydrazine and hydrogen peroxide (up to 98% H_2O_2). Hydrazine can be decomposed by a suitable metal catalyst, which is ordinarily packed in a portion of the thrust chamber at the injector end. The decomposition of hydrazine yields gases at a temperature of 2,260°R (1,265 K); the gases are a mixture of hydrogen and ammonia. Hydrogen peroxide can be readily decomposed either thermally, chemically, or catalytically. The most favored method is catalytically; a series of silver screens coated with samarium oxide is tightly packed in a decomposition chamber located at the injector end of the thrust chamber. At P_c = 300 psia, the

decomposition of hydrogen peroxide (98%) yields gases having a temperature of 2,260°R (1,256 K).

The specific impulse obtainable for a liquid monopropellant is considerably smaller than that obtainable from liquid-bipropellant systems. Consequently, monopropellants are used for such auxiliary purposes as thrust vernier control, attitude reaction controls for space vehicles and missiles, and for gas generation.

Solid-propellant Rocket Engine Figure 11.5.11 illustrates schematically a solid-propellant rocket engine employing an **internal-burning case-bonded grain;** the latter burns radially outward at a substantially constant rate. A solid propellant contains both its fuel and the requisite oxidizer. If the fuel and oxidizer are contained in the molecules forming the solid propellant, the propellant is termed a **double-base propellant**. Those solid propellants wherein a solid fuel and a solid oxidizer form an intimate mechanical mixture are termed either **composite or heterogeneous** solid propellants. The chemical reaction of a solid propellant is initiated by an igniter. In general, the configuration of a propellant grain can be designed so that the area of the burning surface of the propellant varies to give a prescribed thrust-versus-time curve.

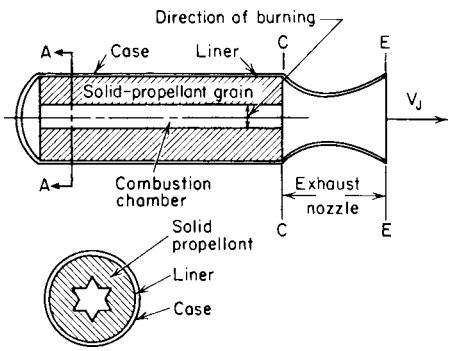

Fig. 11.5.11 Essential features of an internal-burning case-bonded solid-propellant rocket engine.

Nuclear Heat-transfer Rocket Engine

Figure 11.5.12 illustrates schematically a nuclear heat-transfer rocket engine employing a **solid-core reactor**. The heat generated by the fissions of the uranium nucleus is utilized for heating a gaseous propellant, such as hydrogen, to a high temperature of 4,000°R (2,200 K) approx at the entrance section of the exhaust nozzle. The hot gas is ejected to the surroundings after expansion in a converging-diverging exhaust nozzle. The basic difference between the operating principles of a nuclear heat-transfer and a chemical rocket engine is the substitution of nuclear fission for chemical reaction as the source of heat for the propellant gas. Since the exhaust nozzle is the propulsive element, the

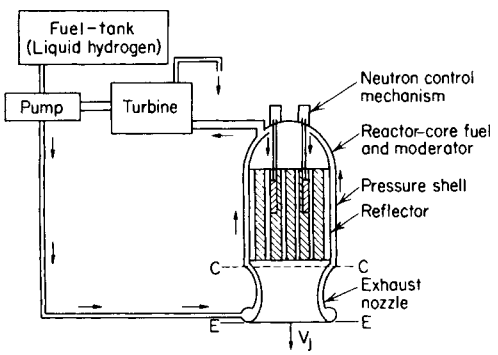

Fig. 11.5.12 Schematic arrangement of a nuclear heat-transfer rocket engine.

remaining components of the nuclear heat-transfer rocket engine constitute the hot-gas generator.

The propellant in a nuclear heat-transfer rocket engine functions basically as a fluid for cooling the solid-core nuclear reactor. Its reaction is not based on energy considerations alone, but on such properties as specific heat, latent heat, molecular weight, and liquid density and on certain practical considerations.

Electric Rocket Engines

Several different types of electric rocket engines have been conceived; the principal types are described below. All of them require some form of power plant for generating electricity. Thus the power plant may be nuclear, solar-cell batteries, thermoelectric, or other. The choice of the type of power plant depends upon the characteristics of both the electric rocket engine and the space-flight mission. Figure 11.5.13 illustrates diagrammatically an electric rocket engine, comprising (1) a **nuclear power source,** (2) an energy-conversion unit for obtaining the desired form of electric energy, (3) a propellant feed and metering system, (4) an electrically operated thrustor, and (5) the requisite control devices. Electric rocket engines may be classified as (1) electrothermal, (2) electromagnetic, and (3) electrostatic.

Electrothermal Rocket Engine Figure 11.5.14*a* illustrates the type of engine which uses electric power for heating gaseous propellant to a high temperature before ejecting it through a converging-diverging exhaust nozzle. If an electric arc is employed for heating the propellant, the engine is called a **thermal arc-jet rocket engine**.

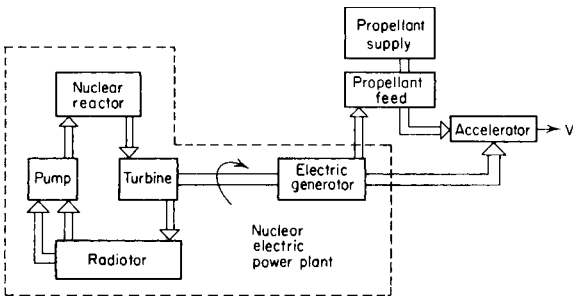

Fig. 11.5.13 Essential features of an electric rocket engine.

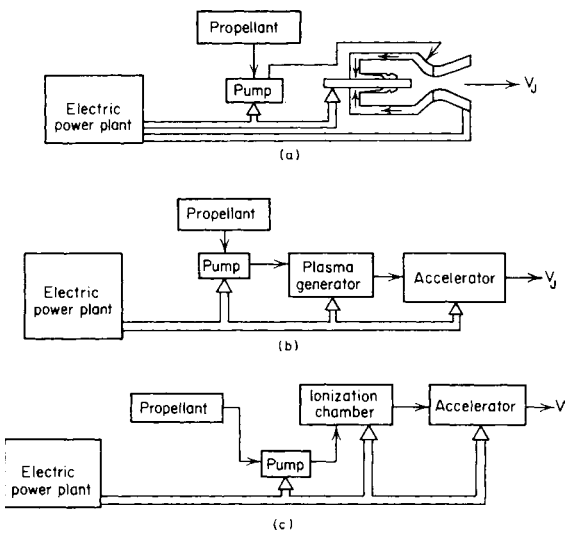

Fig. 11.5.14 Electric rocket engine. (*a*) Electrothermal rocket engine; (*b*) electromagnetic rocket engine; (*c*) electrostatic (ion) engine.

Electromagnetic Rocket Engine Figure 11.5.14*b* illustrates an electromagnetic, or plasma, rocket engine. There is a wide variety of such engines, but all of them utilize the same operating principle. A plasma (a neutral ionized conducting gas) is accelerated by means of its interaction with either a stationary or a varying magnetic field. Basically, a plasma engine differs from a conventional electric motor by the substitution of a conducting plasma for a moving armature.

Electrostatic Rocket Engine Figure 11.5.14*c* illustrates schematically the electrostatic, or ion, rocket engine, comprising (1) an electric power plant; (2) a propellant supply; (3) ionization apparatus; (4) an ion accelerator; and (5) an electron emitter for **neutralizing** the ion beam ejected from the accelerator. Its operating principle is based on utilizing electrostatic fields for accelerating and ejecting electrically charged particles with extremely large velocities. The overall objective is to transform thermal energy into the kinetic energy associated with an extremely high-velocity stream of electrically neutral particles ejected from one or more thrustors. **Mercury ion engines** are currently being tested. The engine provides thrust by a rapid, controlled discharge of ions created by the ionization of atoms of the mercury fuel supply. Solar cells convert sunlight into electricity, which is then used to bombard the mercury with free electrons. This causes one electron to be stripped from each mercury atom, resulting in ionized mercury atoms. The ions mix with other electrons to form a plasma. A magnetic field set up between two metal screens at the aft end of the engine draws the positively charged ions from the plasma and accelerates them at very high exit speeds out the back of the engine. This creates a high-velocity exit beam producing low-level but extremely long-term thrust.

All electric rocket engines are low-thrust devices. The interest in such engines stems from the fact that chemical-rocket technology, for example, the space shuttle, is now so advanced that it has become feasible to place heavy *payloads,* such as a satellite equipped with an electric rocket engine, into an earth orbit. An electric rocket engine which is virtually inoperable terrestrially can be positioned in space and can then operate effectively because of the absence of aerodynamic drag and strong gravitational fields. Consequently, if a vehicle equipped with an electric rocket engine is placed in an earth orbit, the low-thrust electric rocket engine, under the conditions in space, will accelerate it to a large vehicle velocity if the operating time for the engine is sufficiently long.

In a chemical rocket engine, the energy for propulsion, as well as the mass ejected through the exhaust nozzle, is provided by the propellants, but the energy which can be added to a unit mass of the propellant gas is a fixed quantity, limited by the nature of the chemical bonds of the reacting materials. For that reason, chemical rocket engines are said to be **energy-limited rocket engines**. Although a nuclear heat-transfer rocket engine is also energy-limited, the limitation is imposed by the amount of energy that can be added per unit mass of propellant without exceeding the maximum allowable temperature for the materials employed for the solid-core reactor.

In an electric rocket engine, on the other hand, the energy added to the propellant is furnished by an electric power plant. The power available for heating the propellant is limited by the maximum power output of the electric power plant, accordingly, electric rocket engines are **power-limited**.

NOTATION

a = acoustic speed
a_0 = acoustic speed in free-stream air
a_2 = burning rate constant for solid propellant
A_e = cross-sectional area of exit section of exhaust nozzle
A_p = area of burning surface for solid propellant
A_t = cross-sectional area of throat of exhaust nozzle
c_p = specific heat at constant pressure
c_v = specific heat at constant volume
$c^* = P_c A_t/\dot{m}$ = characteristic velocity for rocket motor
C_d = discharge coefficient for exhaust nozzle
C_F = thrust coefficient

C_{Fg} = gross-thrust coefficient for ramjet engine
C_{Fn} = net thrust coefficient
D or $\mathscr{D}$ = drag
$D_i = \dot{m}_a V_0$ = ram drag for airbreathing or thermal-jet engine
d = diameter
d_p = diameter of propeller
E_{in} = rate at which energy is supplied to propulsion system
E_f = calorific value of fuel
E_p = calorific value of rocket propellants
$f = \dot{m}_f/\dot{m}_a$ = fuel-air ratio
$f' = f/\eta_B$ = fuel-air ratio for ideal combustion chamber
F = force or thrust
$F_i = m_e w - m_i V_0 + (p_e - p_0)Ae$ = thrust due to internal flow
$F_j = m_e V_j$ = jet thrust
$F_p = (p_e - p_0)A_e$ = pressure thrust
$F_g = F_i$ = gross thrust for ramjet engine
$F_g SFC$ = gross-thrust specific-fuel consumption for ramjet engine
g_c = correction factor defined by Newton's second law of motion
h = static specific enthalpy
Δh_n = enthalpy change for exhaust nozzle
H = total (stagnation) specific enthalpy
ΔH_c = lower heating value of fuel
I = specific impulse
$I_a = F/g\dot{m}_a$ = air specific impulse
J = mechanical equivalent of heat; advance ratio, propeller
$k = c_p/c_v$ = specific heat ratio
L or $\mathscr{L}$ = lift
$\mathfrak{M}$ = mass
m = mass rate of flow
$\dot{m}_a$ = mass rate of air consumption for thermal-jet engine
$\dot{m}_e$ = mass rate of flow of gas leaving propulsion system
$\dot{m}_f$ = mass rate of fuel consumption
$\dot{m}_i$ = mass rate of flow of gas into propulsion system
$\dot{m}_o$ = mass rate of oxidizer consumption for rocket engine
$\dot{m}_p = \dot{m}_o + \dot{m}_f$ = mass rate of propellant consumption for rocket engine
$\overline{m}$ = molecular weight
M_e = momentum of gases leaving propulsion system in unit time
M_i = momentum of gases entering propulsion system in unit time
$M_0 = V_0/a_0$ = Mach number of free-stream air (flight speed)
n = revolutions per unit time
p = absolute static pressure; pitch of propeller blade
p_c = absolute static pressure of gases in combustion chamber
p_e = absolute static pressure in exit section of exhaust nozzle
p_0 = absolute static pressure of free-stream ambient air
P = absolute total (stagnation) pressure
P_c = absolute total pressure at entrance to exhaust nozzle
$P_0 = p_0\left(1 + \dfrac{k-1}{2}\mathrm{M}_0^2\right)^{k/(k-1)}$ = absolute total pressure of free-stream air
$\mathscr{P}$ = propulsion power
$\mathscr{P}_L$ = leaving loss
$\mathscr{P}_T$ = thrust power
$q = \rho V^2/2$ = dynamic pressure
$q_0 = \rho_0 V_0^2/2 = k_0 p_0 \mathrm{M}_0^2/2$ = dynamic pressure of free-stream air
Q = torque
Q_i = heat supplied to actual combustor
Q_i' = heat supplied to ideal combustor (no losses)
r_0 = linear burning rate for solid propellant
$R = R_u/\overline{m}$ = gas constant
R_u = universal gas constant $\overline{m}R$
t = absolute static temperature
t_p = temperature of solid propellant prior to ignition
T = absolute total (stagnation) temperature
T_c = absolute total temperature of gas entering exhaust nozzle of rocket motor
T_2 = absolute total temperature at entrance to air compressor (see Fig. 11.5.4)
T_3 = absolute total temperature at exit section of air compressor (see Fig. 11.5.4)
T_3' = absolute total temperature at exit section of ideal compressor (see Fig. 11.5.4) operating between same pressure limits as actual compressor
T_4 = absolute total temperature at entrance to turbine (see Fig. 11.5.4)
T_5 = absolute total temperature at exit from turbine (see Fig. 11.5.4)
T_5' = absolute total temperature at exit from ideal turbine
$u = \pi n d_p$ = propeller tip speed
V = velocity
V_F = forward speed of propeller
V_j = effective jet velocity
V_0 = velocity of free-stream air (flight speed)
w = velocity of exit gases relative to walls of exhaust nozzle or velocity of air in ultimate wake of propeller
$\dot{W}$ = weight rate of flow
$\dot{W}_o$ = weight rate of flow of oxidizer
$\dot{W}_p$ = weight rate of flow of propellants

Greek

$\alpha = T_4/t_0 = \alpha_d \alpha_1$ = cycle temperature ratio; angle of attack
$\alpha_d = T_2/t_0$ = diffusion temperature ratio
$\alpha_1 = T_4/T_2$
β = bypass ratio for turbofans; helix angle for propeller blade
$\delta = P/P_{\text{std}}$ corrected pressure
η = efficiency
$\eta_B = f'/f$ = efficiency of combustion for thermal-jet engine
$\eta_c = (T_3' - T_2)/(T_3 - T_2)$ = isentropic efficiency of compressor
η_d = isentropic efficiency of diffuser
$\eta_n = \varphi^2$ = isentropic efficiency of exhaust nozzle
$\eta_o = \mathscr{P}_T/E_{in}$ = overall efficiency of propulsion system
$\eta_p = \mathscr{P}_T/(\mathscr{P}_T + \mathscr{P}_L)$ = ideal propulsive efficiency
$\eta_t = (T_4 - T_5)/(T_4 - T_5')$ = isentropic efficiency of turbine
$\eta_{\text{th}} = \mathscr{P}_T/E_{in}$ = thermal efficiency of propulsion engine
$\lambda = gI_a/\sqrt{2gJc_p t_0}$ = thrust parameter for turbojet engine; ½ + ½ cos ϕ = divergence coefficient for exhaust nozzle for rocket engines
$\nu = V_0/w$ = speed ratio
ρ = density
$\overline{\rho}$ = mean density
$\Omega = \sqrt{k}\left(\dfrac{2}{k+1}\right)^{(k-1)(2k-1)}$
ω = angular velocity of propeller shaft
ω' = rate of rotation of slipstream at propeller
ω'' = rate of rotation of slipstream in ultimate slipstream
Φ = fan velocity coefficient $= V_F/u$
ϕ = semiangle of exhaust-nozzle divergence; effective helix angle
$\varphi = \sqrt{\eta_n}$ = velocity coefficient for exhaust nozzle
ρ = density
σ = solidity of propeller
$\Theta = (P_3/p_0)^{(k-1)/k} = \Theta_d \Theta_c$ = cycle pressure ratio parameter
$\Theta_c = (P_3/P_2)^{(k-1)/k}$ = compressor pressure-ratio parameter
$\Theta_d = (P_2/p_0)^{(k-1)/k}$ = diffuser pressure-ratio parameter
$\Theta_n = (P_7/p_0)^{(k-1)/k} = (P_7/p_9)^{(k-1)/k}$ = nozzle pressure-ratio parameter
$\Theta_t = (P_4/P_5)^{(k-1)/k}$ = turbine pressure-ratio parameter
$\theta = T/T_{\text{std}}$ = corrected temperature

Subscripts

(a) numbered
0 = free stream
1 = entrance to subsonic diffuser

2 = exit from subsonic diffuser
3 = entrance to combustion chamber
4 = entrance to turbine of turbojet engine
5 = exit from turbine of turbojet engine
6 = tail-pipe entrance
7 = entrance to exhaust nozzle
8 = throat section of exhaust nozzle
9 = exit section of exhaust nozzle

(b) lettered

a = air
B = burner or combustion chamber
b = blade
c = compressor
d = diffuser
e = exit section; effective
F = fan
f = fuel
h = hydraulic
n = nozzle
o = overall or oxidizer
p = propellant
P = propulsive
std = standard
t = turbine or throat, as specified in text

Statement on Units The dynamic equations employed in the following sections are written for *consistent sets of units,* i.e., for sets in which 1 *unit of force* = 1 *unit of mass* × 1 *unit of acceleration.* Consequently, the gravitational correction factor g_c in Newton's equation $F = (1/g_c)ma$ (see notation) has the numerical value unity and is omitted from the dynamic equations. When the equations are used for calculation purposes, g_c should be included and its appropriate value employed.

THRUST EQUATIONS FOR JET-PROPULSION ENGINES

Refer to Fig. 11.5.15, which illustrates schematically a rotationally symmetrical arbitrary propulsion engine immersed in a uniform flow field. Because of the reactions between the fluid flowing through the engine, called the **internal flow,** and the interior surfaces wetted by the internal flow a resultant **axial force** is produced, that is, a force collinear with the longitudinal axis of the engine. If an axial force acts in the **forward direction,** employing a relative coordinate system, it is called a **thrust;** if it acts in the **backward direction** it is called a **drag**. Similarly, the resultant axial force due to the **external flow,** the flow passing over the external surfaces of the propulsion system, is a thrust or drag depending upon whether it acts in the forward direction or the backward direction.

Application of the momentum equation of fluid mechanics to the generalized propulsion system illustrated in Fig. 11.5.15 gives the following equation for the thrust F_i due to the **internal flow**. Thus, if it is assumed that the external flow is frictionless, there is no change in the rate of momentum for the external flow between S_i and S_e. Hence, the thrust $F = F_i$ is due entirely to the internal flow, and

$$F = F_i = \dot{m}_e w - \dot{m}_i V_0 + (p_e - p_0)A_e \qquad (11.5.1)$$

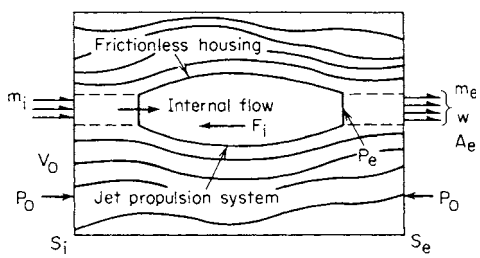

Fig. 11.5.15 Generalized jet-propulsion system.

In Eq. (11.5.1), $\dot{m}_e w = F_j =$ **jet thrust,** $\dot{m}_i V_0 = D_i =$ **ram drag,** and $(p_e - p_0)A_e = F_p =$ **pressure thrust**. Hence,

$$F_i = F_j - D_i + F_p \qquad (11.5.2)$$

It is convenient to introduce a fictitious **effective jet velocity** V_j, which is defined by

$$F = \dot{m}_e V_j - \dot{m}_i V_0 = \dot{m}_e w - \dot{m}_i V_0 + (p_e - p_0)A_e \qquad (11.5.3)$$

If the gases are expanded completely, in the exhaust nozzle, then $w = V_j$ and $F_p = 0$. No appreciable error is introduced, in general, if it is assumed that $F_p = 0$. For **thermal jet engines,** $\dot{m}_i = \dot{m}_a$ (see notation), and $\dot{m}_e = \dot{m}_a + \dot{m}_f$. Let $f = \dot{m}_f/\dot{m}_a$, $v = V_0/V_j$; then

$$F_i = \left(\frac{1+f}{v} - 1\right)\dot{m}_a V_0 + (p_e - p_0)A_e \qquad (11.5.4)$$

In the case of uncooled turbojet engines, $\dot{m}_f$ is not significantly different from the fraction of m_a utilized for cooling the bearings and turbine disk. Consequently, no significant error is introduced by assuming that $\dot{m}_e = \dot{m}_a + \dot{m}_f \approx \dot{m}_a = \dot{m}$. Hence, for a simple **turbojet engine,** one may write

$$F_e = \dot{m}_a(V_j - V_0) = \dot{m}V_0(1/v - 1) \qquad (11.5.5)$$

Equation (11.5.5) is also the thrust equation for an **ideal propeller;** in that case V_j is the **wake velocity** for the air leaving its slipstream. The thrust equation for a hydraulic jet propulsion system has the same form as Eq. (11.5.5). Let V_0 denote the speed of a boat, and $\dot{m}_w$ the mass rate of flow of the water entering the hydraulic pump and discharged by the exit nozzle with the velocity $w = V_j$ relative to the boat. Hence, for hydraulic jet propulsion

$$F = \dot{m}_s(V_j - V_0) = \dot{m}_w V_0(1/v - 1) \qquad (11.5.6)$$

where $v = V_0/V_j$.

In the case of **rocket engines,** since they do not consume atmospheric air, $\dot{m}_a = 0$, and the flow of gas out of the rocket motor, under steady-state conditions, is equal to $\dot{m}_p - \dot{m}_o + \dot{m}_f$ (see notation).

The effective jet velocity V_j is larger than $V_e =$ **exit velocity** if $p_e > p_0$; that is, if the gases are **underexpanded**. The effective jet velocity is a useful criterion because it can be determined accurately from the measured values of F_i and $\dot{m}_p$ obtained from a static firing test of the rocket motor. The ratio $F_i/\dot{m}_p$ is denoted by I and called either the **specific thrust** or the **specific impulse**. Hence

$$I = F/\dot{m}_p = V_j/g_c \qquad (11.5.7)$$

Although the dimensions of specific impulse are force/(mass)(s), it is conventional to state its units as *seconds.*

Equation (11.5.5) for the thrust of a **turbojet engine,** when expressed in terms of the effective jet velocity V_j, becomes

$$F = \dot{m}_a(V_j - V_0) \qquad (11.5.8)$$

POWER AND EFFICIENCY RELATIONSHIPS

In a jet-propulsion engine the **propulsion element** is the **exhaust nozzle,** and the rate at which energy is supplied to it is called the **propulsion power,** denoted by $\mathcal{P}$. The rate at which the propulsion system does useful work is termed the **thrust power** $\mathcal{P}_T$ and is given by

$$\mathcal{P}_T = FV_0 \qquad (11.5.9)$$

Assume that $p_e = p_0$, and that the only energy loss in a propulsion system is the **leaving loss** $\mathcal{P}_L = \dot{m}(V_j - V_0)^2/2$, that is, the kinetic energy associated with the jet gases discharged from the system; then the propulsive power is given by

$$\mathcal{P} = \mathcal{P}_L + \mathcal{P}_T \qquad (11.5.10)$$

The **ideal propulsive efficiency** is defined, in general, by

$$\eta_P = \mathcal{P}_T/(\mathcal{P}_T + \mathcal{P}_L) = \text{thrust power/propulsion power} \qquad (11.5.11)$$

For a turbojet engine and hydraulic jet propulsion,

$$\eta_P = 2v/(1 + v) \tag{11.5.12}$$

For a chemical rocket engine,

$$\eta_P = 2v/(2 + v^2) \tag{11.5.13}$$

The propulsive efficiency η_P is of more or less academic interest. Of more importance is the overall efficiency η_o, which for airbreathing and rocket engines is defined by

$$\eta_o = \eta_{\text{th}}\eta_P \tag{11.5.14}$$

where

$$\eta_{\text{th}} = \mathcal{P}/E_{in} = \text{thermal efficiency of system} \tag{11.5.15}$$

and E_{in} is the rate at which energy is supplied to the propulsion system.

The overall efficiency of a hydraulic jet-propulsion system is given by

$$\eta_o = \eta_{\text{th}}\eta_h\eta_p = \eta_h\eta_{\text{th}}[2v/(1 + v)] \tag{11.5.16}$$

where η_{th} is the thermal efficiency of the power plant which drives the water pump, and η_h is the hydraulic efficiency of the water pump. To achieve a reasonable fuel consumption rate, η_h must have a larger value. For an airbreathing jet engine, $E_{in} = \dot{m}_f(E_f + V_0^2/2)$, and

$$\eta_o = \frac{2v}{1 + v}\frac{\mathcal{P}}{\dot{m}_f(E_f + V_0^2/2)} \tag{11.5.17}$$

The ratio $\dot{m}_f/F$ is called the **thrust specific-fuel consumption** (TSFC) and is measured in mass of fuel per hour per unit of thrust. Hence,

$$\text{TSFC} = \dot{m}_f/F = f\dot{m}_a/F \tag{11.5.18}$$

For a rocket engine, $E_{in} = \dot{m}_p(E_p + V_0^2/2)$, so that

$$\eta_o = \frac{2v}{1 + v^2}\frac{\mathcal{P}}{\dot{m}_p(E_p + V_0^2/2)} \tag{11.5.19}$$

PERFORMANCE CHARACTERISTICS OF AIRBREATHING JET ENGINES

The Ramjet Engine In ramjet technology the thrust due to the internal flow F_i is called the **gross thrust** and denoted by F_g. Refer to Fig. 11.5.2 and assume $\dot{m}_0 \approx \dot{m}_9 = \dot{m}_a$. Then

$$F_g = F_i \approx \dot{m}_a(V_j - V_0) \tag{11.5.20}$$

In level unaccelerated flight F_g is equal to the external drag of the propelled vehicle and the ramjet body.

It is customary to express the thrust capabilities of the engine in terms of the **gross-thrust coefficient** C_{Fg}. *If* A_m is the maximum cross-sectional area of the ramjet engine, $q_0 = \rho_0 V_0^2/2 = k_0 p_0 \text{M}_0^2/2 =$ the **dynamic pressure** of the free-stream air, then

$$C_{Fg} = \frac{F_g}{q_0 A_m} = \frac{2F_g}{A_m k_0 p_0 \text{M}_0^2} \tag{11.5.21}$$

In terms of the Mach numbers M_0 and M_9,

$$C_{Fg} = \frac{2A_9/A_m}{k_0 \text{M}_0^2}\left(\frac{P_9}{p_0}\frac{1 + k_9\text{M}_9^2}{P_9/p_9} - 1\right) - 2\frac{A_0}{A_m} \tag{11.5.22}$$

In a fixed-geometry engine, M_9 depends upon the total temperature T_7, the total pressure P_7, the fuel-air ratio f, the nozzle area ratio A_e/A_t, and the efficiency of the nozzle η_n. For estimating purposes, $k_0 = 1.4$ and $k_9 = 1.28$, when the engine burns a liquid-hydrocarbon fuel. The manner in which C_{Fg} varies with altitude M_0 and fuel-air ratio f is shown schematically in Fig. 11.5.16.

If $\alpha = T_7/t_0 =$ cycle temperature ratio, and k_B is the mean value of k for the combustion gases, the rate at which heat is supplied to the engine is

$$Q_i = Q_i'/\eta_B = \dot{m}_a c_{pB} t_0(\alpha - T_2)/\eta_B \tag{11.5.23}$$

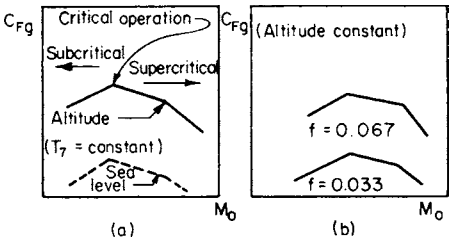

Fig. 11.5.16 Effect of altitude and fuel-air ratio on the gross-thrust coefficient of a fixed-geometry ramjet engine. (*a*) Effect of altitude; (*b*) effect of fuel-air ratio.

It is readily shown that

$$Q_i = \frac{A_0 p_0 V_0}{\eta_B J}\frac{k_B}{k_B - 1}\left[\alpha - \left(1 + \frac{k_0 - 1}{2}\text{M}_0^2\right)\right] \tag{11.5.24}$$

The **gross-thrust specific-fuel consumption** (F_gSFC) is, by definition,

$$F_g\text{SFC} = \dot{m}_f/F_g \tag{11.5.25}$$

The principal sources of loss are aerothermodynamic in nature and cause a decrease in total pressure between stations 0 and 7. For estimating purposes, assuming $\text{M}_0 = 2.0$ and $T_6 = 3{,}800°\text{R}$ (2,111 K), the total pressures across different sections of the engine may be assumed to be approximately those tabulated below.

Part of engine	Total pressure ratio
Supersonic diffuser (0–1)	$P_1/P_0 = 0.92$
Subsonic diffuser (1–2)	$P_2/P_1 = 0.90$
Flameholders (2–7)	$P_7/P_2 = 0.97$
Combustion chamber (2–7)	$P_7/P_2 = 0.92$
Exhaust nozzle (7–9)	$P_9/P_7 = 0.97$

The Simple Turbojet Engine A good insight into the design performance characteristics of the turbojet engine is obtained conveniently by making the following assumptions: (1) The mass rate of flow of working fluid is identical at all stations in the engine; (2) the thermodynamic properties of the working fluid are those for air; (3) the air is a perfect gas and its specific heats are constants; (4) there are no pressure losses due to friction or heat addition; (5) the exhaust nozzle expands the working fluid completely so that $p_9 = p_0$; and (6) the auxiliary power requirements can be neglected. Refer to Fig. 11.5.4 and let

$$\Theta = \left(\frac{P_3}{p_0}\right)^{(k-1)/k} \quad \Theta_d = \left(\frac{P_2}{p_0}\right)^{(k-1)/k} \quad \Theta_c = \left(\frac{P_3}{P_2}\right)^{(k-1)/k}$$

$$\Theta_t = \left(\frac{P_4}{P_5}\right)^{(k-1)/k} \quad \Theta_n = \left(\frac{P_7}{p_0}\right)^{(k-1)/k} = \left(\frac{P_7}{p_9}\right)^{(k-1)/k}$$

$$\alpha = T_4/t_0 \qquad \alpha_d = T_2/t_0 \qquad \alpha_1 = T_4/T_2$$

In view of the assumptions,

$$\Theta = \Theta_d\Theta_c = \Theta_t\Theta_n \tag{11.5.26}$$

and

$$\alpha = \alpha_a\alpha_1 \tag{11.5.27}$$

The diffuser pressure-ratio parameter Θ_d is given by

$$\Theta_d = 1 + \eta_d[(k - 1)/2]\text{M}_0^2 \tag{11.5.28}$$

where η_d = isentropic efficiency of diffuser (0.75 to 0.90 for well-designed systems).

The turbine pressure-ratio parameter Θ_t is given by

$$1/\Theta_t = 1 - [(\Theta_c - 1)/\alpha_1\eta_c\eta_t] \tag{11.5.29}$$

where η_t = the isentropic efficiency of the turbine (0.90 to 0.95).

Heat supplied, per unit mass of air, is

$$Q_1 = (c_p/\eta_B)(T_4 - T_3)$$

or

$$Q_i = \frac{c_p t_0}{\eta_B \eta_c} \alpha_d \left(\frac{\alpha}{\alpha_d} \eta_c - \eta_c - \Theta_c + 1 \right) \qquad (11.5.30)$$

where η_c is the isentropic efficiency of the air compressor (0.85 to 0.90), and η_B is the efficiency of the burner (0.95 to 0.99).

The enthalpy change for the exhaust nozzle Δh_n is given by

$$\frac{\Delta h_n}{c_p t_0} = \frac{\eta_n}{\eta_c} [\alpha \eta_c - \alpha_d(\Theta_c - 1)] \times \left\{ 1 - \frac{\alpha_1 \eta_c \eta_t}{\Theta_c[1 + \eta_d(\alpha_d - 1)][\alpha_1 \eta_c \eta_t - (\Theta_c - 1)]} \right\} \qquad (11.5.31)$$

The **specific thrust,** also called the **air specific impulse,** is

$$I_a = F_i/\dot{m}_a g = (\sqrt{2\Delta h_n} - V_0)/\dot{m}_a \qquad (11.5.32)$$

The overall efficiency η_o is given by

$$\eta_o = \eta_{\text{th}} \eta_p = \frac{I_a V_0}{J Q_i} = 2\eta_B \eta_c \frac{\lambda M_0 \left(\frac{k-1}{2} \right)^{1/2}}{\alpha \eta_c - \left(1 + \frac{k-1}{2} M_0^2 \right)(\eta_c + \Theta_c - 1)} \qquad (11.5.33)$$

where η_B ranges from 0.95 to 0.99 and λ is the dimensionless turbojet specific thrust parameter.

The TSFC for a turbojet engine is given by

$$\text{TSFC} = \frac{\dot{m}_f}{F} \qquad (11.5.34)$$

It can be shown by dimensional analysis, if the effects of Reynolds numbers are neglected, that the variables entering into the performance of a given turbojet engine may be grouped as indicated in Table 11.5.2.

Table 11.5.2

Nondimensional group	Uncorrected form	Corrected form
Flight speed	$V_0/\sqrt{t_0}$	$V_0/\sqrt{\theta}$
Rotational speed	$N/\sqrt{T}$	$N/\sqrt{\theta}$
Air flow rate	$\dot{W}_a\sqrt{T}/D^2P$	$\dot{W}_a\sqrt{\theta}/\delta$
Thrust	F/D^2P	F/δ
Fuel flow rate	$\dot{W}_f J \Delta H_c/D^2P\sqrt{T}$	$\dot{W}_f/\delta\sqrt{\theta}$

$\theta = T/T_{\text{std}} = T/519$ (T/288) = corrected temperature (exact value for T_{std} is 518.699°R).
$\delta = P/p_{\text{std}} = P/14.7$ (P/1.013 × 10^5) = corrected pressure.

Figure 11.5.17 is a design-point chart presenting λ and η_o as functions of α, P_3/P_2, and Θ_c for the subsonic performance of simple turbojet engines. The curves apply to propulsion at 30,000 ft (9.14 km) altitude for engines having characteristic data indicated in the figure. Curve A illustrates the effect of pressure ratio P_3/P_2 or Θ_c for engines operating with $\alpha = 5.0$. It is seen that increasing the compressor pressure ratio increases η_o but it approaches a maximum value at P_3/P_2 approximately equal to 19. Curve B applies to the design point of engines having a fixed compressor pressure ratio of 10 : 1 but having different values of α, that is, turbine inlet temperature. It shows that increasing α much above $\alpha = 5$ reduces the overall efficiency and consequently TSFC. Curve C presents the design-point characteristics for engines operating with $\alpha = 5$ but having different compressor pressure ratios. The maximum value of λ is obtained at a relatively low pressure ratio: approximately $P_3/P_2 = 5$. Curve D presents the design-point characteristics of engines having a fixed compressor pressure ratio of

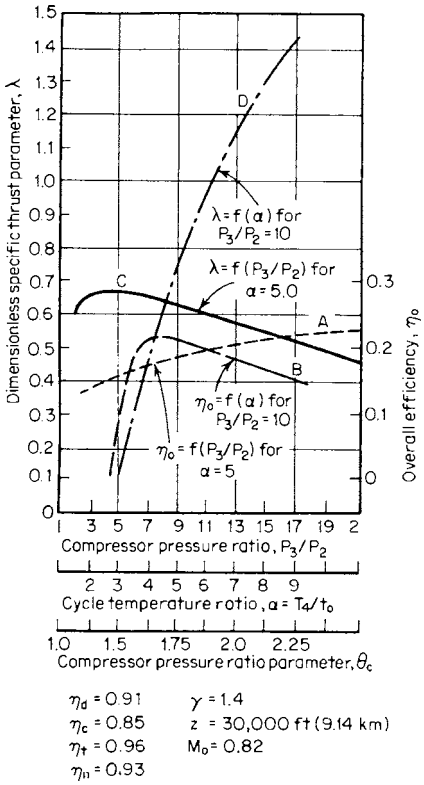

Fig. 11.5.17 Dimensionless thrust parameter λ and overall efficiency η_0 as functions of the compressor pressure ratio (simple turbojet engine).

10 : 1 but different cycle temperature ratios. Increasing α gives significant increases in λ. Hence, large values of turbine inlet temperature T_4 offer the potential for large thrusts per unit of frontal area for such turbojet engines.

Figure 11.5.18 presents the design-point characteristics for engines having $\eta_c = 0.85$, $\eta_t = 0.90$, $\eta_r = 0.93$, and $\eta_B = 0.99$. Different values of diffuser efficiency are presented for flight Mach numbers $M_0 = 0.8$ ($\eta_d = 0.91$), $M_0 = 1.60$ ($\eta_d = 0.90$), and $M_0 = 2.4$ ($\eta_d = 0.88$). Two different classes of engines are considered, those with $P_3/P_2 = 4.0$ and those with $P_3/P_2 = 12.0$. The dimensionless thrust λ is plotted as a function of α with M_0 as a parameter. It is evident that increasing λ, that is, the turbine inlet temperature T_4, offers the advantage of a large increase in thrust per unit area of the engine under all the conditions considered in Fig. 11.5.18.

Figure 11.5.19 presents the effect of flight speed on the design-point performance, at 30,000 ft (9.14 km) altitude, for engines having $\eta_c = 0.85$, $\eta_t = 0.90$, $\eta_B = 0.95$, $T_4 = 2{,}000$°R (1,111 K) and burning a fuel having a heating value $\Delta H_c = 18{,}700$ Btu/lbm (10,380 kcal/kgm). The magnitude of the compressor pressure ratio P_3/P_2 approaches unity when V_0 is approximately 1,500 mi/h, indicating that at higher speeds the compressor and turbine are superfluous; i.e., the propulsion requirements would be met more adequately by a ramjet engine. Raising T_4 tends to delay the aforementioned condition to a high value of V_0.

It is a characteristic of turbojet engines, since $\eta_o = \eta_{\text{th}}\eta_p$, that for a given M_0 increasing η_{th} causes Δh_n to increase, and hence the jet velocity V_j. As a consequence, η_p is decreased. It is this characteristic which causes $\eta_o = f(\alpha)$, curve B of Fig. 11.5.17, to be rather flat for a wide range of values of $\alpha = T_4/t_0$.

The curves of Figs. 11.5.17 to 11.5.19 are design-point performance curves; each point on a curve is the design point for a different turbojet engine. The performance curves for a specific engine are either

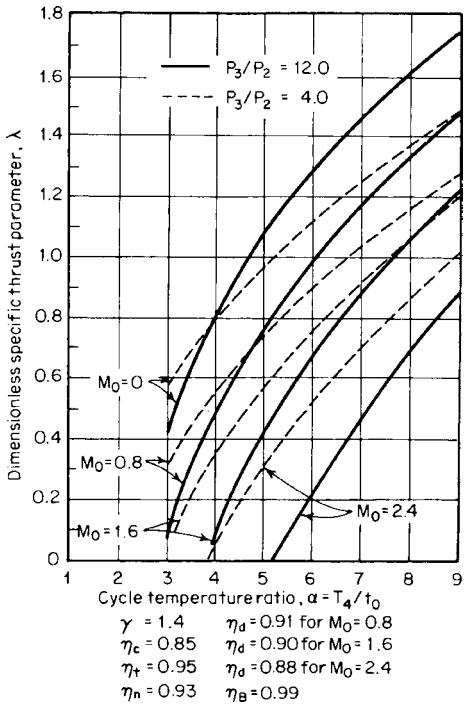

Fig. 11.5.18 Dimensionless thrust parameter λ for a simple turbojet engine and its overall efficiency η_0 as functions of the cycle temperature ratio α, with the flight Mach number as a parameter.

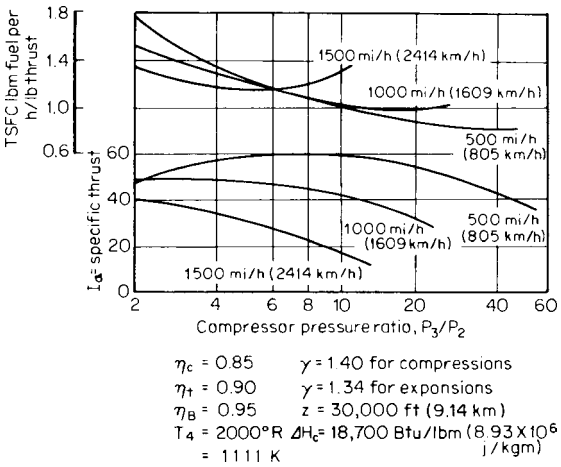

Fig. 11.5.19 *TSFC* and specific thrust I_a functions of the compressor pressure ratio, with flight speed as a parameter (simple turbojet engine).

computed from experimental data pertaining to its components operating over a wide range of conditions or obtained from testing the complete turbojet engine. It is customary to present the data in standardized form.

The Turbofan or the Ducted-Fan Engine Refer to Fig. 11.5.5*b*. Assume that the hot-gas flow $(\dot{m}_{a1} + \dot{m}_f)$ is ejected through the converging nozzle, area A_t, with the effective jet velocity V_j, and that the airflow $\dot{m}_{aF}$ is ejected through the converging annular nozzle, area A_{7F}, with the jet velocity V_{jF}. Let $\beta = \dot{m}_{aF}/\dot{m}_{a1}$ denote the bypass ratio, approximately 5 to 10 for modern transport engines.

The thrust equation for the turbofan engine is

$$F = \dot{m}_{a1}(1 + f)V_j + \beta\dot{m}_{a1}V_{jF} - \dot{m}_{a1}(1 + \beta)V_0 \quad (11.5.35)$$

where $V_{jF} < V_j$. The thrust per unit mass of airflow, or air specific impulse, is

$$I_a = F/\dot{m}_{a1}(1 + \beta) \quad (11.5.36)$$

The TSFC is given by

$$\text{TSFC} = \dot{m}_f/F \quad (11.5.37)$$

One of the most important applications of turbofans is for **high-subsonic transport aircraft** where the fuel consumption in cruise is a major consideration. In general, as the bypass ratio increases, the TSFC decreases but the engine weight and external drag increase. The **optimum bypass ratio** for any particular application is determined by a trade-off between fuel weight, which is reduced by increasing the bypass ratio, and engine weight and external drag, which increase with bypass ratio for a given thrust. In general, the optimum value of β is that which makes the difference $(F - D_e)$ a maximum, where D_e is the external drag of the engine. Up to a certain point, the more sophisticated and efficient the engine, the larger the bypass ratio.

To achieve the maximum potential for the turbofan engine, high values of turbine inlet temperature T_4 are essential; i.e., cooled turbine stator and rotor blades must be developed. There is an upper limit to T_4; above it the TSFC begins to increase. As T_4 is increased, however, the optimum value of β must also be increased to avoid excessive leaving losses in the propulsive jet.

Mechanical Design

Blades New technologies being developed to achieve higher thrust-to-weight ratios in advanced gas turbine engines also cause higher vibratory blade row responses and stresses that delay engine development and may adversely affect engine reliability. In particular, the design trend toward higher stage loadings and higher specific flow are being attained through increased tip speeds, lower radius ratios, lower aspect ratios, and fewer stages. The resultant axial-flow compressor blade designs utilize thin, low-aspect-ratio blading with corresponding high steady-state stresses. Also, the mechanical damping is considerably reduced in newer rotor designs, particularly those with integral blade-disk configurations (**blisks**) and in those without shrouds. These are similar trends in turbine blading, but they are further complicated by increased inlet and cooling temperatures that have resulted in thin-walled, complex cooling passage designs. As a result, advanced axial-flow blade designs, both compressors and turbines, feature low-aspect-ratio blading which affect the **structural integrity** of the blading. These problems can be classified into two general cateories: (1) **flutter** and (2) **forced response**. A fundamental parameter common to both categories is the **reduced frequency,** $k = \omega b/V$, where b is the blade semichord, ω the frequency of vibration, and V the relative free-stream velocity. For engine applications, the frequency corresponds generally to one of the lower-blade or coupled-blade disk **natural frequencies**.

Under certain conditions, a blade row operating in a completely uniform flow can enter into a self-excited vibrational **instability** termed **flutter.** The vibration is sustained by the extraction of energy from the uniform flow during each vibratory cycle. The outstanding feature of flutter is that **high stresses** exist in the blading, leading to short-term, high-cycle, **fatigue failures.** Its importance is evidenced by the fact that if a portion of a single blade fails due to flutter, the result may be instantaneous and total loss of engine power.

Figure 11.5.20 is a typical compressor map showing schematically the more common types of flutter. At subsonic Mach numbers, up to 0.8 to 0.9, either positive or negative **stall flutter** in the **bending** or **torsion** mode may occur. It is caused by operating beyond some critical airfoil angle of attack. A **critical reduced frequency** value of 0.8 has been cited for stall flutter; i.e., if $k < 0.8$ stall flutter is possible. **Choking flutter** usually occurs at negative incidence angles at a part-speed condition with the blade operating either subsonically or transonically. The physical mechanism of choke flutter is not fully understood; both high negative

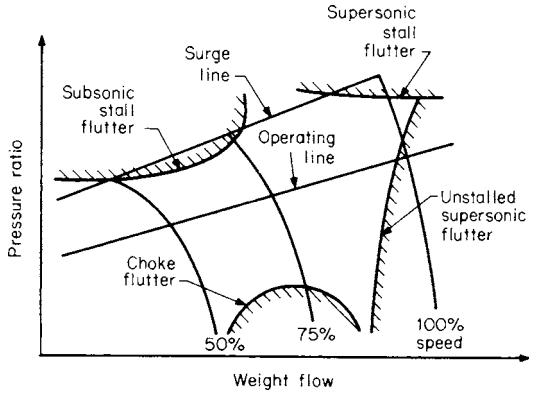

Fig. 11.5.20 Common types of compressor flutter.

incidence angles and choked flow are viable candidates. **Supersonic unstalled flutter** is largely associated with thin **fan blades** operating at supersonic relative flow velocities at the tip section. It is caused by a lagging of the unsteady aerodynamic forces relative to the blade motion and imposes a limit on the **high-speed operation** of the engine. The stress encountered during this type of flutter can be catastrophically large, decreasing rapidly as a constant speed line is traversed toward higher pressure ratios. High-speed operation near the surge line can lead to **supersonic stall flutter.** Because this flutter is associated with **high pressure ratios,** there can be strong shocks present within the blade passages, and in some circumstances, ahead of the blade row.

Destructive aerodynamic **forced responses** have been noted in all engine blading. These failure-level vibratory responses occur when a periodic forcing function, with frequency equal to a natural blade **resonant frequency,** acts on a blade row. Responses of sufficient magnitude to fail blades have been generated by a variety of sources including upstream and downstream blade rows, flow distortion, bleeds, and mechanical sources.

The importance of forced response lies in the **multiple sources** of excitation for any rotating system. The rotor speeds at which forced responses occur are predicted with **"Campbell"** or **speed-frequency** diagrams. These display the **natural frequency** of each blade mode versus rotor speed and, at the same time, the forcing function frequency (or **engine order** E lines) versus rotor speed, as indicated schematically in Fig. 11.5.21. These E lines represent the loci of available **excitation energy** at any rotational speed for 1, 2, 3, etc. excitations per revolution.

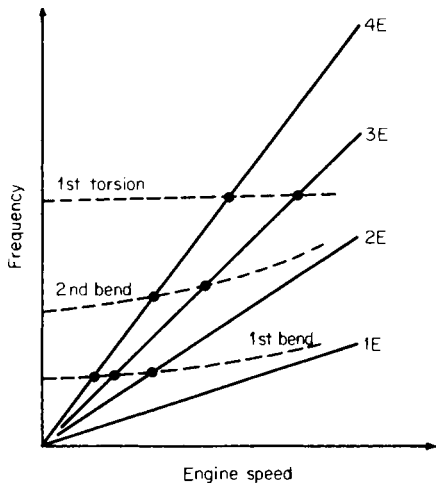

Fig. 11.5.21 Schematic speed-frequency diagram.

Wherever these curves intersect, a potential source of destructive forced response exists. Not all intersections can be avoided. Design practice is to eliminate the lower-order excitations from the operating range whenever possible. This is because the sources of most forced response energy usually result from these lower-order resonances, particularly the 2E line.

High-cycle fatigue (HCF) of turbomachine blading resulting from flow-induced vibrations is a significant problem throughout the gas turbine industry. To address this problem, various approaches have been developed. In these, the response of a tuned airfoil row, i.e., a rotor with all airfoils having the same structural properties and thus identical natural frequencies, is analyzed. In fact, there are small airfoil-to-airfoil structural property variations that result, for example, from the manufacturing process or as a consequence of in-service wear. These are collectively referred to as **mistuning** and are known to lead to significant increases in airfoil resonant response amplitudes as compared to that of the tuned airfoil row, with mistuning thus often cited as a source of HCF in gas turbine engines. Hence, the key metric that characterizes the resonant response of mistuned bladed disks is the **amplification factor,** defined as the ratio of a blade's response amplitude on a mistuned bladed disk to its response amplitude on a tuned bladed disk.

Turbomachinery rotors typically have been bladed disks, with individual airfoils inserted into a slotted disk and retained by means of a dovetail or fir-tree attachment. However, advances in manufacturing techniques have resulted in bladed-disk assemblies with increased uniformity; i.e., the blade-to-blade natural frequency variation, termed mistuning, is small. In addition, new design and manufacturing techniques have enabled the development and implementation of **integrally bladed rotors** (IBRs) wherein the blades and disk are machined from a single piece of material. IBRs have even less blade-to-blade mistuning than do bladed disks. Unfortunately, smaller mistuning does not translate into smaller amplification factors. On the contrary, as mistuning decreases, the maximum amplification factor on a disk tends to increase until some threshold is reached, at which point it decreases rapidly toward 1. Figure 11.5.22 shows this trend; it is based on studies wherein many hundreds of bladed disks are simulated for each percent mistuning, with the maximum resulting amplification factor taken. The decrease in mistuning due to new manufacturing methods is on the negative slope portion of Fig. 11.5.22, thus rendering the new manufacturing methods a strong impetus for improving models which predict mistuned bladed disk response. In contrast to the maximum amplification factor of Fig. 11.5.22, there is a **theoretical maximum amplification factor** that depends only on the number of blades N; specifically, amplification factor $= 0.5(1 + \sqrt{N})$. Taking these theoretical maxima into account during design is an important first step in building blade rows resistant to HCF failure.

Environmental Issues

The increasing worldwide concern for the environment has led to two technical issues becoming significant: (1) airport noise and (2) the Earth's ozone layer.

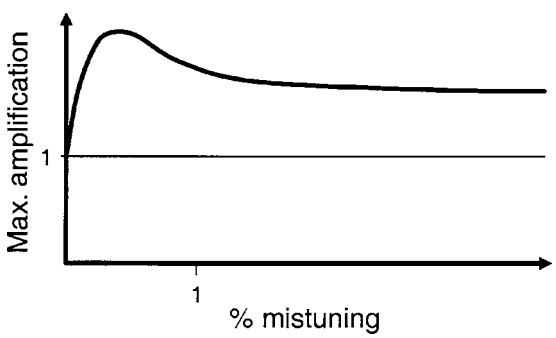

Fig. 11.5.22 Amplification factor versus mistuning level.

Aeroacoustics is an increasingly important issue in the design of advanced gas turbine engines for commercial aircraft. This is because engine certification requires meeting prevailing **International Civil Aviation Organization (ICAO) Chapter 3 noise regulations** established in 1978. Aircraft are certified to a standard that is actually a combination of three measures: the noise generated as the plane approaches the runway radiating to the community under its flight path; the noise it generates during takeoff radiating to the areas surrounding the runway; and the noise under the flight path further out in the community during takeoff (Fig. 11.5.23).

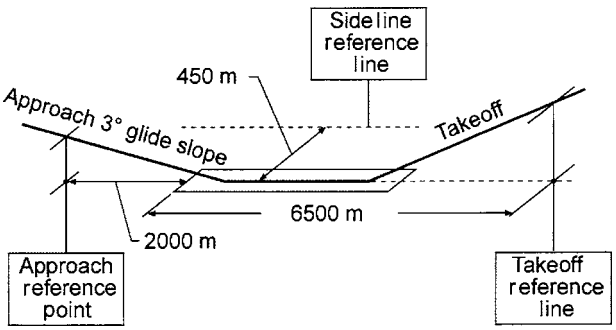

Fig. 11.5.23 Aircraft certification noise measurement locations.

The ICAO Chapter 3 regulations specify approach, sideline, and takeoff perceived noise levels (EPNL) as a function of the aircraft takeoff gross weight (Fig. 11.5.24). The total or cumulative margin for a given aircraft defined as the sum of the margin at all three conditions. Note that all current-technology aircraft meet ICAO Chapter 3 regulations.

Air travel has increased dramatically since 1978. To meet the demands of community groups for stricter aircraft noise requirements, ICAO has established a new set of limits which are to become effective in 2006—the **Chapter 4 rule**. These new limits require aircraft to be 10 dB (cumulative) quieter than current Chapter 3 levels. The use of trades to meet the new rules was also eliminated. With Chapter 3, an aircraft could exceed the limits on one measure of noise, takeoff, as long as it was lower than the limits at the other conditions by an offsetting amount. With Chapter 4, an aircraft must operate below the Chapter 3 curve at all three conditions: approach, sideline, and takeoff.

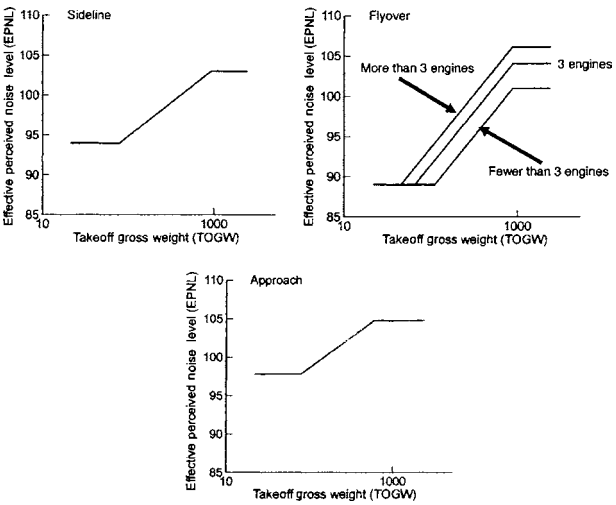

Fig. 11.5.24 Chapter 3 regulations specify EPNL at approach, sideline, and takeoff.

The high-bypass-ratio turbofans introduced in the late 1960s had a major effect on engine noise reduction. ICAO recognized this when it established the Chapter 3 regulations in 1978. Turbofans direct more air through the bypass than through the core. As a result, the maximum jet exhaust velocity is substantially reduced and the **turbomachinery noise** is more important. The fan, the low-pressure or boost compressor, and the low-pressure turbine are the primary noise sources for a high-bypass turbofan. Their noise signatures include a broadband noise level with large spikes or tones at multiples of blade passing frequencies (Fig. 11.5.25).

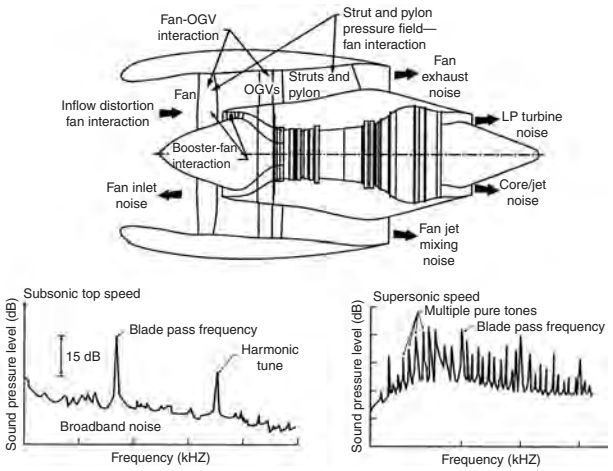

Fig. 11.5.25 High-bypass-ratio turbofan noise sources and noise spectrum.

Current noise control and reduction methods for high-bypass turbofans are a combination of turbomachinery noise source control and suppression. Source control is accomplished by increasing the axial spacing between adjacent blade rows and by selecting blade and vane number combinations to produce *cutoff*, whereby the highest-energy acoustic modes decay exponentially with distance along the ducting. Source suppression is achieved with acoustic liners in the fan inlet and exhaust ducts and the core exhaust duct. As a result, future advanced turbofans will have much lower levels of turbomachinery noise. Thus, the dominant engine sources in these future engines are the fan at takeoff and approach and the turbulent mixing in the jet exhaust stream at takeoff.

The **emissions** generated by the combustion of aviation fuel include carbon dioxide (CO_2), carbon monoxide (CO), oxides of nitrogen (NO_x), and particulates such as soot and oxides of sulfur (SO_x). The effect that each has on the atmosphere depends on the altitude at which it is emitted and its concentration. Most commercial aircraft cruise in the **troposphere**, which ranges from an altitude of 11 mi (58,000 ft) at the equator to 6 mi (33,000 ft) at the poles. In this region, the temperature decreases with increasing altitude, resulting in large air motions and mixing. Increased NO_x concentration results in increased ozone concentration through complex photochemical reactions with CO and hydroxyls (HO_x). Ozone also acts as a global warming gas in the troposphere. Methane is another global warming gas, although NO_x reduces the concentration of methane.

It has been projected that, by 2050, aircraft emissions will increase by a factor of 4 because of an increase in air traffic and that the total contribution to **global warming** by aircraft will be a factor of 2 greater than from CO_2 alone. In addition, aircraft exhaust plumes contribute to global warming. Contrails are formed by water in the exhaust freezing in cold atmospheric conditions, with their formation aided by the particulates present in exhaust plumes. These contrails may turn into cirrus clouds, which lead to a net increase in warming.

In summary, pollutants generated by aircraft engines contribute to global warming because of the altitude at which they operate and the projected growth of the aviation industry. Hence, there is a distinct need

to develop ultralow-emission combustor designs for aircraft engines. The two primary approaches to ultralow-emission combustors are rich and lean front-end designs. Each has demonstrated the potential to achieve low emissions.

The International Civil Aviation Organization (ICAO) standards limit aircraft engine emissions in the vicinity of an airport, up to 3,000 ft altitude. A standardized **landing-takeoff cycle (LTO)** is specified, which includes time at each of four engine power settings. Typical levels of engine emissions as a function of engine thrust are presented in Fig. 11.5.26. Emissions of carbon monoxide (CO) and unburned hydrocarbons (UHC) are dominant at low power conditions such as idle, and rapidly decrease to negligible levels as engine power increases. Most modern combustor designs result in very low levels of CO and UHC at all cruise power settings through efficient combustion that minimizes fuel burn. Nitrogen oxides (NO_x) and soot particle emissions or smoke both exhibit the opposite trend, increasing with engine power.

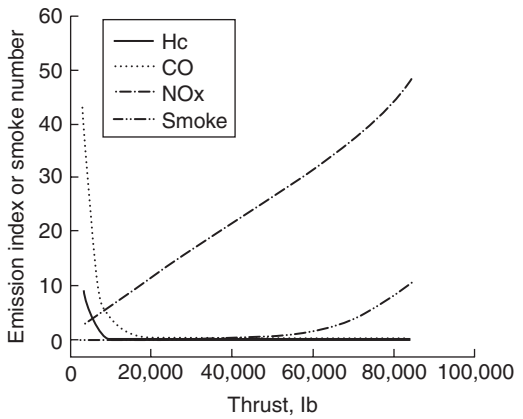

Fig. 11.5.26 Typical aircraft combustor emission characteristics.

Aircraft spend much more time at takeoff, climb, and cruise settings than at idle. Thus, NO_x is the dominant pollutant by mass in a flight. In fact, the **NO_x produced** at cruise is significantly higher than that produced during the LTO cycle. NO_x emissions are a result of the high temperatures in the combustor, with the rate of NO_x production highly nonlinear with temperature. This is shown in Fig. 11.5.27, with the NO_x production rate presented as a function of the combustion reaction **equivalence ratio,** which is the ratio of fuel to air in the actual mixture divided by the fuel-to-air ratio for stoichiometric conditions. The peak is in the region of stoichiometric combustion, i.e., an equivalence ratio of 1.0.

Rich-front-end combustors are found in most current engines. Fuel is introduced at the front and mixed with some of the total combustor airflow to create a stable rich reaction zone (Fig. 11.5.28), with the remainder of the airflow introduced in a mixing zone. The combination of rich oxygen-depleted products from the front end quicky react with the mixing air and are then diluted to exit conditions. This mixing zone

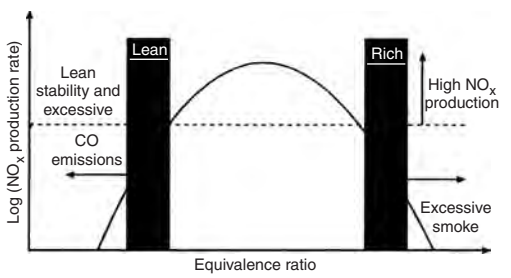

Fig. 11.5.27 NO_x production rate versus equivalence ratio.

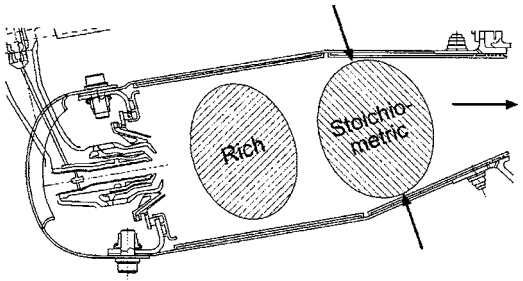

Fig. 11.5.28 Schematic of rich-front-end combustor.

can be highly nonuniform, resulting in local stoichiometric combustion with high NO_x production rates.

The **lean-front-end combustor** focuses on mixing the air and fuel in the front end of the combustor exactly to create a combustion zone that is, on average, below the peak stoichiometric equivalence ratio of 1.0. The lower flame temperature at these lean conditions significantly reduces the NO_x production rate. Lean-front-end combustors require multiple fuel stages to achieve the operability requirements for aircraft application. Typical modern engine designs require the combustor to operate with a factor of 3 higher exit fuel-air ratio at maximum power than at minimum power. A lean combustion system must be optimized to a much narrower range of fuel-air ratios to avoid high CO production, if too lean, and high NO_x production, if too rich. This issue has been addressed by combustors with many small air and fuel injectors and sequentially fueling a subset of these as engine power increases.

CRITERIA OF ROCKET-MOTOR PERFORMANCE

In most applications of rocket motors the objective is to produce a large thrust for a limited period. The criteria of rocket-motor performance are, therefore, related to thrust-producing capabilities and operating duration. If $\dot{W}_p$ denotes the rate at which the rocket motor consumes propellants, P_c the total pressure at the entrance to the exhaust nozzle, and C_w the **weight flow coefficient,** then

$$\dot{W}_p = C_w P_c A_t \tag{11.5.38}$$

Ordinarily, the values of C_w as a function of P_c and **mixture ratio** $\dot{W}_o/\dot{W}_f$ are determined experimentally. If no experimental data are available, the values of C_w can be calculated with good accuracy from the calculated thermodynamic properties of the combustion gases. If T_c is the total temperature, and P_c the total pressure of the combustion gases at the entrance section of the nozzle, then, for steady operating conditions, $\dot{W}_p = \dot{W}_g$,

$$\dot{W}_g = C_d A_t P_c \Omega \sqrt{\frac{g}{RT_c}} \tag{11.5.39}$$

where

$$\Omega = \left(\frac{2}{k+1}\right)^{(k-1)/[2(k-1)]} \sqrt{k} \tag{11.5.40}$$

An equation similar to Eq. (11.5.38) can be written for the thrust developed by the rocket motor. Thus

$$F = C_F P_c A_t \tag{11.5.41}$$

The values of the **thrust coefficient** C_F for specific propellant combinations are determined experimentally as functions of P_c and the ratio $\dot{W}_o/\dot{W}_f$. When no experimental values are available, C_F can be calculated from the following equation. Therefore

$$C_F = C_d \lambda \phi \Omega \sqrt{\frac{2k}{k-1} Z_t} + \left(\frac{p_e}{P_c} - \frac{p_0}{P_c}\right)\frac{A_e}{A_t} \tag{11.5.42}$$

where

$$Z_t = 1 - \left(\frac{p_e}{P_c}\right)^{(k-1)/k}$$

Equation (11.5.42) shows that C_F is independent of the combustion temperature T_c and the molecular weight of the combustion gases. The nozzle area ratio A_e/A_t is given by the formula

$$\frac{A_e}{A_t} = \frac{(P_c/p_e)^{1/k}}{\left(\frac{k+1}{2}\right)^{1/(k-1)} \sqrt{[(k+1)/(k-1)]Z_t}} \qquad (11.5.43)$$

Figure 11.5.29 presents C_F calculated by means of the preceding equations, as a function of the area ratio A_e/A_t, with P_c/p_0 as a parameter, for gases having $k = 1.28$; the calculations assumed $\lambda = 0.983$ and $C_d = \varphi = 1.0$). The curves do not take into account the separation phenomena which occur when A_e/A_t is larger than that required to expand the gases to p_0.

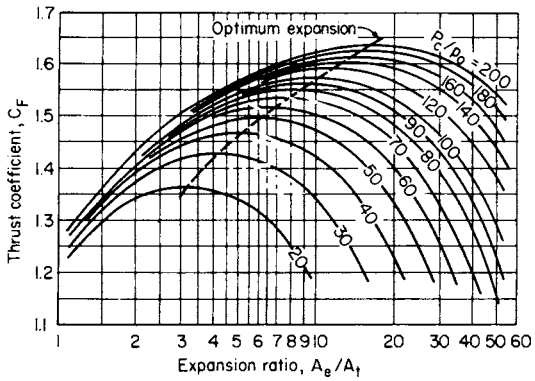

Fig. 11.5.29 Calculated thrust coefficient versus expansion ratio for different pressure ratios (based on $k = 1.28$, $\lambda = 0.9830$, $C_d = \varphi = 1.0$).

The specific impulse I is defined by Eq. (11.5.8) and can be shown to be given by

$$I = F/\dot{m}_p = C_F/C_w = V_j/g_c \qquad (11.5.44)$$

A criterion which is employed for stating the performance of rocket motor is the characteristic velocity c^*. By definition

$$c^* = V_j/C_F = P_c A_t/\dot{m} = I/C_F \qquad (11.5.45)$$

The values of c^* for a given propellant combination are determined experimentally. It should be noted that the value of c^* is independent of the thrust. Basically, c^* measures the effectiveness with which the thermochemical energy of the propellants is converted into effective jet kinetic energy. When no experimental data are available the value of c^* can be estimated quite closely from

$$c^* = \sqrt{RT_c}/\Omega \qquad (11.5.46)$$

Table 11.5.1 presents values of specific impulse for some possible rocket-propellant combinations.

Solid-propellant rocket motors may be segregated into (1) **double-base powders** and (2) **composite, or heterogeneous, propellants.** Double-base powders are gelatinized colloidal mixtures of nitroglycerin and cellulose to which certain stabilizers have been added. Heterogeneous, or composite, propellants are physical mixtures of a solid oxidizer in powder form and some form of solid fuel, such as a plastic or rubberlike material.

Solid-propellant rocket motor technology has made tremendous strides. It is possible to produce solid propellants with a wide range of linear burning rates and with good physical properties. It has been demonstrated experimentally that large thrust rocket motors with chamber diameters of approximately 22 ft (6.7 m) are feasible. As a result, the solid-propellant rocket motor has displaced the liquid rocket engine from a large number of applications, which heretofore were considered the province of the liquid rocket engine. In military applications, there is a strong tendency to supplant liquid rocket engines with solid rocket engines. Only in such areas as the large thrust launching rockets for boosting manned vehicles into space have the liquid rocket engines reigned supreme; the space shuttle is equipped with liquid-bipropellant rocket engines, but it is boosted with auxiliary solid-propellant rocket motors.

The following considerations are what make solid-propellant rocket motors attractive: (1) They are simpler in construction than liquid rocket engines; (2) they are easier to handle in the field; (3) they have instant readiness for use; (4) they have very good storage properties; (5) they have a larger average density $\bar{\rho}_P$ than most liquid-propellant combinations; (6) they have considerably fewer parts; and (7) their reliability in practice has been very good. Furthermore, once the performance characteristics and physical properties of a solid propellant have been established, it is a relatively straightforward engineering problem to design and develop solid-propellant rocket motors of widely different thrust levels and burning times t_R.

Rocket motors which burn double-base propellants find the greatest use in weaponry, e.g., artillery rockets, antitank weapons, etc.

Rocket motors burning heterogeneous, also called **composite,** solid propellants are used for propelling all kinds of military missiles and for sounding rockets. Modern composite propellants have three basic types of ingredients: (1) a fuel which is an organic polymer, called the **binder;** (2) a finely powdered oxidizer, ordinarily ammonium perchlorate (NH_4NO_3); and (3) various additives, for catalyzing the combustion process, for increasing the propellant density, for increasing the specific impulse (e.g., powdered aluminum), for improving the physical properties of the propellant, and the like. After the ingredients have been thoroughly mixed, the resulting viscous fluid is poured, usually under vacuum to prevent the formation of voids, directly into the chamber of the rocket motor which contains a suitable mandril for producing the desired configuration for the propellant grain. The propellant is cured by polymerization to form an elastomeric material. Some of the more common binders are butadiene copolymers and polyurethane.

Modern composite solid propellants have densities ranging from 1.60 to 1.70, depending upon the formulation, and specific impulse values of approximately 245 s, based on a combustion pressure of 1000 psia and expansion to 14.7 psia.

In the case of solid-propellant rockets the rate of propellant consumption $\dot{m}_p$ is related to the **linear burning rate** for the propellant r_0, that is, the rate at which the burning surface of the propellant recedes normal to itself as it burns. For practical purposes it can be assumed that the linear burning rate r_0 is given by

$$r_0 = a_2 p_c^n \qquad (11.5.47)$$

where a_2 and n are constants which are determined by experiment.

If ρ_p denotes the density of the solid propellant and A_p the area of the burning surface, then the propellant consumption rate $\dot{m}_p$ is given by

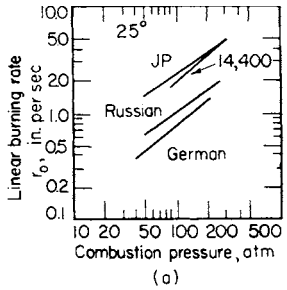
$$\dot{m}_p = A_p \rho_p r_0 = a_2 A_p \rho_p p_c^n \qquad (11.5.48)$$

Figure 11.5.30 presents the linear burning rate as a function of the combustion pressure for several propellants.

The linear burning rate r_0 is influenced by the temperature of the solid propellant t_p prior to its ignition. Low values of t_p reduce the burning rate, and vice versa. Consequently, the temperature of the propellant must be given in presenting data on linear burning rates. Figure 11.5.31 presents r_0 as a function of p_c for $t_p = -40$, 60, and 140°F for a composite propellant manufactured by the Aerojet-General Corp., Azusa, Calif.

AIRCRAFT PROPELLERS

The function of the aircraft propeller (or airscrew) is to convert the torque delivered to it by an engine into the thrust for propelling an airplane. If the airplane is in steady, level flight, the propeller thrust and



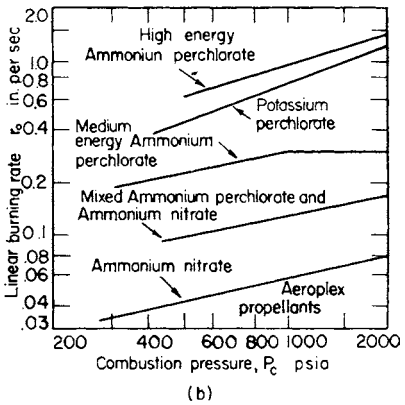


Fig. 11.5.30 (*a*) Linear burning rate as a function of combustion pressure for double-base propellants; (*b*) burning-rate characteristics of several heterogeneous propellants at 60°F (15.5°C). *(Aerojet-General Corp.)*

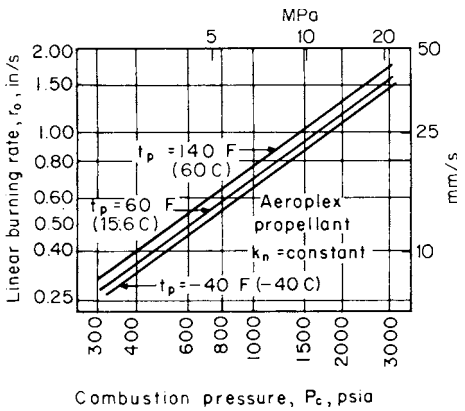

Fig. 11.5.31 Effect of propellant temperature upon the linear burning rate of a heterogeneous propellant. *(Aerojet-General Corp.)*

the airplane drag equal each other. If the airplane is climbing, the thrust must overcome the drag plus the weight component of the airplane.

The propeller may be the sole thrust-producing element, but it can also be employed in conjunction with another thrust-producing device, such as the exhaust jet of a **turboprop** or **gas-turbine engine.** It may also be employed as a **windmilling** device for producing power.

The conventional propeller consists of two or more equally spaced radial blades, which are rotated at a substantially uniform angular velocity. At any arbitrary radius, the section of a blade has the shape of an airfoil, but as the hub is approached, the sections become more nearly circular because of considerations of strength rather than aerodynamic performance. The portions of the blades in the vicinity of the hub contribute, at best, only a small portion of the thrust developed by the propeller blades.

Each section of the propeller blade experiences the aerodynamic reactions of an airfoil of like shape moving through the air in a similar manner. Furthermore, at each radius, the section of one blade forms with the corresponding sections on the other blades a series of similar airfoils, which follow one another as the propeller rotates.

The torque of the rotating propeller imparts a rotational motion to the air flowing through it and, furthermore, causes the pressure immediately behind the propeller to increase while that in front of it is reduced; i.e., the air is sucked toward the front of the propeller and pushed away behind it. A slipstream is created as illustrated in Fig. 11.5.1. The ratio of the cross-sectional area of the slipstream at any station to that of the actuator disk is termed the **slipstream contraction.**

The thrust produced by the propeller follows the relationships developed from the momentum theorem of fluid mechanics for jet engines as presented in Fig. 11.5.15 and Eq. (11.5.5). The thrust equation for the airbreathing engine (simplified) and the propeller is

$$F = \dot{m}(w - V_0) = \rho A V_0 (w - V_0) \qquad (11.5.49)$$

In the case of a propeller the mass flow m is large and the velocity rise across the propeller is small, as compared with a jet engine of the same thrust. However, the thrust of propellers falls off rapidly as air compressibility effects on the propeller become large (flight speeds of 300 to 500 mi/h).

Propeller efficiency is defined as the useful work divided by the energy supplied to the propeller:

$$\eta_p = \frac{P_T}{P} = \frac{FV_0}{P} = \frac{m(v - V_0)V_0}{m/2(w^2 - V_0^2)} = \frac{2v}{1 + v} \qquad (11.5.50)$$

where $v = V_0/w$.

Since w is only slightly larger than V_0, the ideal efficiency is of the order of 0.95, and actual efficiencies are in the range of 0.5 to 0.9.

Propeller Theory

Axial-Momentum Theory The axial-momentum theory of the propeller is basically a special case of the generalized jet-propulsion system presented in Fig. 11.5.15. It is only a first approximation of the action of the propeller and cannot be employed for design purposes. It neglects such factors as the drag of the blades, energy losses due to slipstream rotation, blade interference, and air compressibility effects. Because of those losses, an actual propeller requires power to rotate at zero thrust, and at zero thrust its propulsive efficiency is, of course, zero.

Blade-Element Theory This theory, called **strip theory**, takes into account the profile losses of the blade sections. It is the theory most commonly employed in designing a propeller blade and for assessing the off-design performance characteristics of the propeller.

Each section of the propeller is considered to be a rotating airfoil. It is assumed that the radial flow of air may be neglected, so that the flow over a blade section is two-dimensional. Figure 11.5.32 illustrates diagrammatically the velocity vectors pertinent to a blade section of length dr, located at an arbitrary radius r. The projection of the axis of rotation is OO′, the plane of rotation is OC, the blade angle is β, the angle of attack for the air flowing toward the blade (in the relative coordinate system) with the velocity V_0 is α, the tangential velocity of the blade

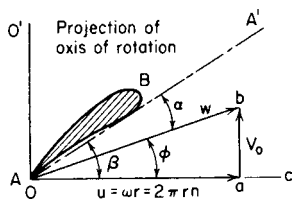

Fig. 11.5.32 Vector diagram for a blade element of a propeller.

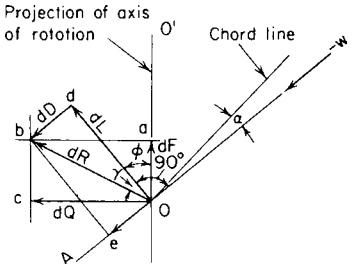

Fig. 11.5.33 Aerodynamic forces acting on a blade element.

element is $u = 2\pi nr$, and the **pitch** or **advance angle** is ϕ. From Fig. 11.5.32

$$\alpha = \beta - \phi \tag{11.5.51}$$

and

$$\phi = \tan^{-1}(V_0/\pi nd) \tag{11.5.52}$$

Figure 11.5.33 illustrates the forces acting on the blade element. If b denotes the width of the blade under consideration and C_L and C_D are the lift and drag coefficients of the blade (airfoil) section, then the thrust force dF acting on the blade element is given by

$$dF = \tfrac{1}{2}\rho V_0^2 b\, dr C_L \frac{\cos(\phi + \gamma)}{\cos\gamma \sin^2\phi} \tag{11.5.53}$$

The corresponding torque force dQ is given by

$$dQ = \tfrac{1}{2}\rho V_0^2 b\, dr C_L \frac{\sin(\phi + \gamma)}{\cos\gamma \sin^2\phi} \tag{11.5.54}$$

where

$$\tan\gamma = d\mathcal{D}/d\mathcal{L} = C_D/C_L = \mathcal{D}/\mathcal{L} \tag{11.5.55}$$

where $\mathcal{D}$ and $\mathcal{L}$ denote drag and lift, respectively.

The propulsion efficiency of the blade element, termed the **blading efficiency,** is defined by

$$\eta_b = \frac{V_0 dF}{u\, dQ} = \frac{\tan\phi}{\tan(\phi + \gamma)} = \frac{\mathcal{L}/\mathcal{D} - \tan\phi}{\mathcal{L}/\mathcal{D} + \cot\phi} \tag{11.5.56}$$

The value of ϕ which makes η_b a maximum is termed the **optimum advance angle** ϕ_{opt}. Thus

$$\phi_{\text{opt}} = \frac{\pi}{4} - \frac{\gamma}{2} = 45° - \frac{57.3}{2(\mathcal{L}/\mathcal{D})} \tag{11.5.57}$$

The maximum blade efficiency is accordingly

$$(\eta_b)_{\max} = \frac{2\gamma - 1}{2\gamma + 1} = \frac{2(\mathcal{L}/\mathcal{D}) - 1}{2(\mathcal{L}/\mathcal{D}) + 1} \tag{11.5.58}$$

A force diagram similar to Fig. 11.5.33 can be constructed for each element of the propeller blade, taking into account the variation in ϕ with the radius. The resultant forces acting on the propeller are obtained by summing (integrating) those forces acting on each blade element.

The integrated lift coefficient is

$$C_{Li} = \int_{r_i/R}^{r/R=1.0} C_{Lr} \left(\frac{r}{R}\right)^3 d\left(\frac{r}{R}\right) \tag{11.5.59}$$

where C_{Lr} = propeller-blade-section lift coefficient and r/R = fraction of propeller-tip radius.

The integrated lift coefficient is in the range 0.15 to 0.70. There is a dilemma in the design and selection of blade sections since high static thrust requires high C_{Li} which gives relatively low η_p at cruise. Cruise conditions require low C_{Li} for good η_p. Variable camber propellers permit optimization of C_{Li}, but at the expense of weight and complexity.

Vortex Theory The simple two-dimensional blade-element theory can be further improved by taking account of the actual velocity distribution in the slipstream and thus determining the actual loading on the blading by the so-called *vortex theory.* The blades are represented by bound vortex filaments sweeping out vortex sheets to infinity. The vortex sheets are distorted both by the slipstream contraction and by the profile drag of the blades. If such distortions are neglected, the induced velocity in the wake can be calculated by assuming the vortex sheets to be tubular. Thus, in Fig. 11.5.32, the induced axial velocity becomes the arithmetic mean of the axial velocities at far distances upstream and downstream of the rotor disk; and the induced rotational velocity at the disk becomes $\omega - 0.5\omega'$, where ω' is the rotation of the slipstream in the plane of the propeller. Hence, the angle of attack α for a rotor element is given by

$$\alpha = \beta - \tan^{-1}[V_F/r(\omega - 0.5\,\omega')] \tag{11.5.60}$$

where V_F is the induced axial velocity in the plane of the propeller.

The addition of the vortex effects improves the representation of the propeller by the blade sections. There are, however, three-dimensional flow effects which are not included, and the following coefficients have been suggested to include this effect (which reduces the lift coefficient).

Lift Curve Slope Correction Factors for Three-Dimensional Airfoils

Radial station (ratio r/R)	Correction factor
(0.2)(0.3)(0.45)(0.6)(0.7)	0.85
0.8	0.80
0.9	0.70
0.95	0.65

Performance Characteristics

The pitch and the angle ϕ (Fig. 11.5.32) have different values at different radii along a propeller blade. It is customary, therefore, to refer to all parameters determining the overall characteristics of a propeller to their values at either $0.7r$ or $0.75r$.

For a given blade angle β, the angle of attack α at any blade section is a function of the **velocity coefficient** V_0/u, where $u = \pi n d_p$; it is customary, however, to replace V_0/u by its equivalent, the **advance ratio** $J = V_0/nd_p$.

For given values of β and n, the angle of attack α attains its maximum value when $V_0 = 0$, with $\phi = 0$. In other words, the propeller thrust F is maximum at takeoff. As V_0 increases, α decreases and so does the thrust. Finally, a forward speed is reached for which the thrust is zero.

Increasing $J = V_0/nd_p$, for a constant blade angle, causes the propeller to operate successively as a fan, propeller, brake, and windmill. Most of the operation, however, is conducted in the propeller state. At takeoff, the propeller is in the fan state. Windmilling must be avoided because it may overspeed the engine and damage it.

The lift coefficient C_L is a linear function of α up to the stalling angle, and C_D is a quadratic function of α. Furthermore, the lift $\mathcal{L}$ is zero at a negative value for α. Figure 11.5.34 presents the $\mathcal{L}/\mathcal{D}$ ratios of typical propeller sections. Figure 11.5.35 presents the blade (section) efficiency as a function of the pitch angle ϕ for different values of $\mathcal{L}/\mathcal{D}$. Propellers normally operate at $\mathcal{L}/\mathcal{D}$ ratios of 20 or more. Supersonic propellers operate with $\mathcal{L}/\mathcal{D}$ ratios of approximately 10, and from Fig. 11.5.34 it is apparent that they must operate close to the optimum pitch angle ϕ to obtain usable blade efficiencies.

Propeller Coefficients It can be shown, neglecting the compressibility of the air, that

$$f(V_0, n, d_p, \rho, F) = 0 \tag{11.5.61}$$

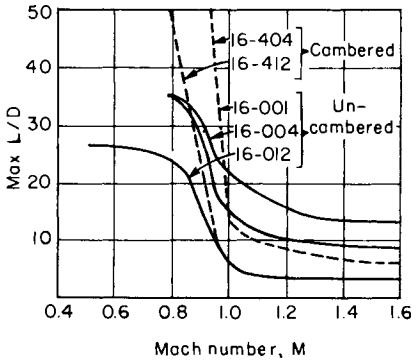

Fig. 11.5.34 Maximum lift-drag ratios for representative sections.

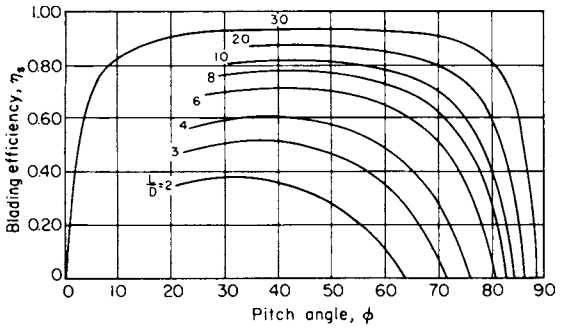

Fig. 11.5.35 Blade-element efficiency versus pitch angle.

By dimensional analysis, the following coefficients are obtained for expressing the performances of propellers having the same geometry:

$$F = \rho n^2 d_p^4 C_F \qquad Q = \rho n^2 d_p^5 C_Q \qquad \mathcal{P} = \rho n^3 d_p^5 C_p \tag{11.5.62}$$

C_F, C_Q, and C_P are termed the **thrust, torque,** and **power coefficients,** respectively. They are independent of the size of the propeller. Consequently, tests of small-scale models can be employed for obtaining the values of F, Q, and $\mathcal{P}$ for geometrically similar full-scale propellers. Hence, the ideal propulsive efficiency of a propeller is given by

$$\eta_p = \frac{FV_0}{\mathcal{P}} = \frac{C_F}{C_p}\frac{V_0}{d_p n} = J\frac{C_F}{C_P} \tag{11.5.63}$$

Other useful coefficients are the **speed-power coefficient** C_S and the **torque-speed confficient** C_{QS}. Thus,

$$C_S = V_0 5\sqrt{\rho/\mathcal{P}n^2} \qquad C_{QS} = V_0\sqrt{\rho d_p^3/Q} \tag{11.5.64}$$

A commonly employed factor related to the geometry of a propeller is the **solidity** σ. By definition,

$$\sigma = c/p \tag{11.5.65}$$

The solidity varies from radius to radius; at a given radius, σ is proportional to the power-absorption capacity of the annulus of blade elements.

The **activity factor** of a blade AF is an arbitrary measure of the blade solidity and hence of its ability to absorb power. It takes the form

$$AF = \frac{100{,}000}{16}\int_{r_h/R}^{r/R=1.0}\frac{c}{d_p}\left(\frac{r}{R}\right)^3 d\left(\frac{r}{R}\right) \tag{11.5.66}$$

where $R = d_p/2$, r = radius at any section, and r_h = spinner radius.

Performance

Static Thrust From the simple axial-momentum theory, the static thrust F_0 of an actuator disk of diameter d_p is given by

$$F_0 = (\pi\rho/2)^{1/3}(\mathcal{P}d_p)^{2/3} = 10.4\text{bhp} \times d_p^{2/3} \qquad \text{(at sea level)} \tag{11.5.67}$$

The **thrust horsepower** (thp) is accordingly

$$\text{thp} = \frac{F_0}{\text{bhp}} = (38{,}400/Nd_p)(1/C_p^{1/3}) \tag{11.5.68}$$

Equations (11.5.67) and (11.5.68) assume uniform axial velocity, no rotation of the air, and no profile losses. Consequently, they may be in error by as much as 50 percent. Hesse suggests the use of the equations

$$\eta_{p\,\text{static}} = \sqrt{\frac{2}{\pi}}\frac{C_F^{3/2}}{C_P} = 0.798\frac{C_F^{3/2}}{C_p} \tag{11.5.69}$$

and

$$F = 10.42[d_p(\eta_{p\,\text{static}})\,\text{shp}]^{2/3}(\rho/\rho_0)^{1/3} \tag{11.5.70}$$

together with data computed for a specific propeller, as illustrated in Fig. 11.5.36. The static thrust for a given power input increases with the diameter and the number of blades. Controllable pitch propellers selected for good overall performance will develop 3 to 4 lb of thrust per shp.

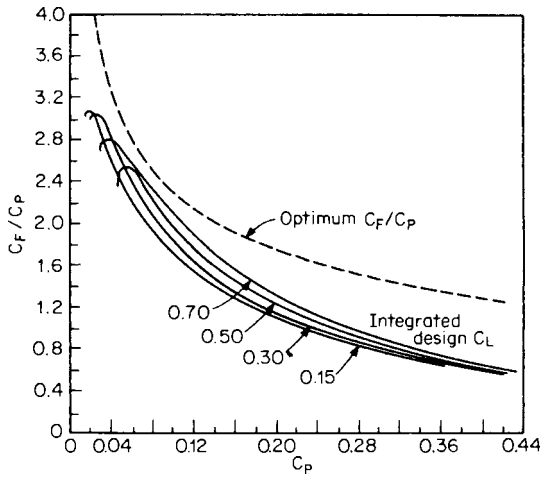

Fig. 11.5.36 Static-thrust performance of a propeller; four-bladed, 100 activity-factor propellers of various integrated design C_L's. *(From Hamilton Standard Division, United Aircraft Corporation.)*

At flight conditions the performance may be obtained from generalized charts presenting C_P as a function of the advance ratio J, with the propeller efficiency and blade pitch angle at 75 percent radius, $\theta_{3/4}$, as parameters. Figure 11.5.37 is such a chart.

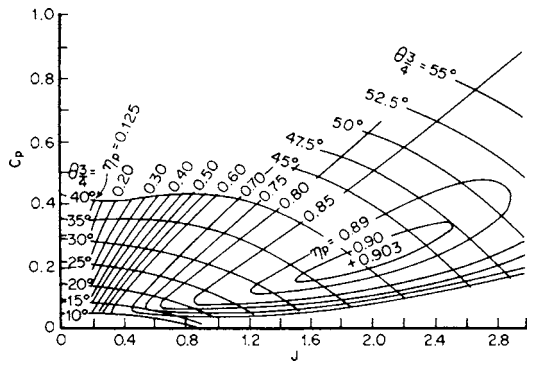

Fig. 11.5.37 Propeller performance—efficiency in forward flight; four-bladed, 100 activity factor, 0.500 integrated design C_L propeller. *(From Hamilton Standard Division, United Aircraft Corporation.)*

Reverse Thrust By operating the propeller blades at large negative angles of attack, reversed thrust can be developed. In that condition, the blades are stalled, and as in the case of static thrust, the forces acting on the blades cannot be calculated. In practice, the reverse-pitch stop is set by trial and error so that the propeller can absorb the rated power at zero speed, i.e., at $V_0 = 0$. With fixed-pitch reversing, the power absorbed when there is forward speed will be smaller than the rated value, but the reversed thrust is usually substantially larger than the static forward thrust corresponding to the rated power. The landing roll of an aircraft with reversed thrust plus brakes is approximately 45 percent of that with brakes alone.

Compressibility Effects As the relative velocity between an airfoil and the free-stream air approaches the sonic speed, the lift coefficient C_L decreases rapidly, and simultaneously there is a large increase in the drag coefficient C_D. The propeller is subject to those effects. Since the acoustic speed decreases from sea level to the isothermal altitude, the effects appear at lower tip speeds at high altitude. Furthermore, the effect is more pronounced at higher tip speeds. Shock waves are formed at the leading edge of a propeller blade when its pitch-line velocity approaches the local sonic velocity of the air. As a consequence, the coefficient C_F is reduced and C_P is increased, thereby adversely affecting the propulsive efficiency of the propeller.

Because of the high propulsive efficiency of propellers, the application of advanced technologies may provide **turboprop**-powered transports with cruise speeds and other desirable characteristics comparable to advanced turbofan-powered transports, but with a 15 to 20 percent reduction in fuel consumption.

Advanced turboprop propeller blades operate at high power loading, are extremely thin, and have swept leading edges to minimize compressibility losses. Shaping the spinner and nacelle minimizes choking and compressibility losses. Efficiencies of about 70 percent at Mach 0.8 and design power loadings have been achieved in research propellers. Such propellers may be relatively noisy because the tips may be slightly supersonic at Mach 0.8 cruise. Attenuating the noise within the cabin wall will likely add airframe weight and reduce the fuel savings.

Mechanical Design

Blades The principal blade loadings are (1) steady tensile, due to centrifugal forces; (2) steady bending, due to the aerodynamic thrust and torque forces; and (3) vibratory bending, due to cyclic variations in airloads and other excitations originating in the engine. The most serious and limiting stresses usually result from the vibratory loadings. The principal vibratory loading results from the cyclic variation in angle of attack of the blades when the axis of rotation is pitched or yawed relative to airstream. When the axis is pitched up, such as when the aircraft is in a high-angle-of-attack climb, the blades are at a higher angle of attack on the downstroke than when on the upstroke. This results in a once per revolution, $1E$, variation in aerodynamic loading on the blades, usually referred to as $1E$ **aerodynamic excitation,** and a steady **side force** and **yawing moment,** which are transmitted through the shaft to the aircraft.

The degree of pitch or yaw of the propeller axis is usually measured in terms of the **excitation factor,** defined as

$$\text{Excitation factor} = \psi(V_i/400)^2 \qquad (11.5.71)$$

where ψ = angle of pitch or yaw, deg; V_i = indicated flight velocity, mi/h. Another factor sometimes used is Aq, where $A = \psi^o$, $q = 12\rho V_i^2$, Aq = excitation factor × 410.

Because of the restoring moment of the **centrifugal loads** on the blade elements when the blade deflects in bending, centrifugal forces have the effect of apparently stiffening the blade in **bending.** In Fig. 11.5.38, the bending natural frequency increase with rpm. At some rpm, the bending natural frequency will come into resonance with the $1E$ excitation, at which point small loadings will be greatly magnified (limited only by the damping present in the blade).

Propellers are designed so that the $1E$ resonant speed is above any expected operating speed. However, there will always be some magnification of the vibratory loads (due to proximity to resonant speed),

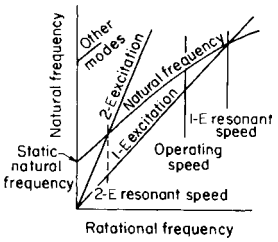

Fig. 11.5.38 Relation between blade natural frequency and major excitations.

resulting in disproportionately high vibratory stresses. As indicated in Fig. 11.5.38, blades normally pass through a $2E$ **resonance** in coming up to speed (usually not critical because it is a transient condition) and may pass through or be close to resonance with other modes.

The **natural frequencies** of the rotating propeller blade can be computed with good accuracy, but since the excitation varies from aircraft to aircraft and is usually not well defined, vibration surveys must be made of all new installations. These often result in the definition of ranges at which continuous operation should be avoided. **Allowable vibratory** stresses are limited by the fatigue strength of the material. Unlike the steady-stress limits, **fatigue strength** is not a unique function of the material but is a function of surface finish as well. A sharp notch in the surface reduces the fatigue strength to a very low value. If propellers were designed to hold vibratory stresses below the lowest possible fatigue strength, the blades would be unacceptably heavy. Thus propellers are designed on the maintenance of a reasonably smooth surface finish. Since the blade surfaces are constantly subject to **store damage,** blades must be regularly inspected to make sure that the finish does not deteriorate below design standards.

Propeller blades are stalled when operating at low forward speeds and when reversing (see Performance, above). Under these conditions torsion-mode **stall flutter** can occur.

In general, $1E$ **considerations** control the design of the **inboard** portions of a blade, and **stall flutter** the **outboard** sections.

There are five types of **blade construction** in common use today: **solid aluminum; fabricated steel; one-piece steel; monocoque, fiberglass construction,** supported on a steel shank; and a construction with a **hollow steel central spar and a lightweight fiberglass cover** that forms the aerodynamic contour of the blade. As in any beam designed on the basis of bending loads, it is desirable to concentrate the structural material at the maximum radii, as in the flanges of a simple I beam, and omit it from the center, where it carries no load. This is accomplished, with steel blades, by making them hollow. The structural material is concentrated in the outer fibers, or surface. In general, steel blades weigh about 80 to 85 percent of the equivalent solid aluminum blade. The advantage of steel increases with size. The blades normally constitute from one-third to one-half of the total propeller weight.

The **hub** retains the blades and contains the pitch-change motor. A **pitch-change mechanism** is provided so that the blades can be positioned at the proper angle of attack α to absorb the desired power at the desired rpm, regardless of flight speed. If the pitch is unchanged, as in Fig. 11.5.39, the angle of attack is excessive at low speed. This prevents the engine from reaching rated speed and delivering rated power. The centrifugal loads on the blade elements tend to rotate the blades toward flat pitch (see Fig. 11.5.40). The pitch-change motor acts against this moment by applying a pitch-increasing moment. The addition of **counterweights,** shown dotted in Fig. 11.5.40, reduces the moment and the size of the pitch-change motor. Counterweights, however, add to the radial centrifugal load of the blades, necessitating a heavier retention, and consequently do not necessarily reduce the net weight of the propeller.

Most pitch-change mechanisms employ a **hydraulic piston,** mounted on the hub, with feed through the propeller shaft and with rotation of the blades by means of gears or links. **Electric motors** and **direct mechanical drives** have been used successfully. In the past, the weight of all systems, when fully developed, has turned out to be about the same.

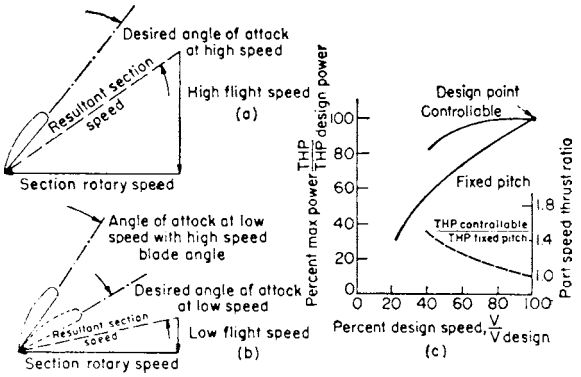

Fig. 11.5.39 Effect of flight speed on the desired blade angle.

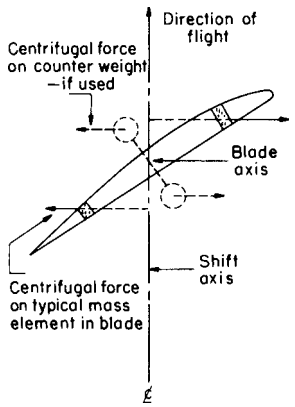

Fig. 11.5.40 Twisting effect of centrifugal loads on blades.

Action of the pitch-change motor is limited by **low-** and **high-pitch stops**. These prevent the blades from assuming negative angles with reverse thrust. On reciprocating engines, the low-pitch stop is set to allow the propeller to absorb approximately rated power at zero forward speed. A lower setting results in higher windmilling drags in gliding flight, which could be dangerous if carried too far. In reversing propellers the low-pitch stop is automatically removed when the controls are set for reverse pitch. The high-pitch stop prevents the propeller from reversing through the positive range. In feathering propellers it is set at the angle which gives zero aerodynamic moment about the shaft.

Propeller feathering is provided in order to reduce the drag of a dead engine. To accomplish it, the blade-angle range is extended to 90°, approximately. Auxiliary pitch-change power is provided to complete the feathering as the engine slows down and to unfeather when the engine is stationary.

Reversing is provided in order to give propeller braking on the landing roll. It is accomplished by removing the flight low-pitch stop and driving the blades to a high negative **reverse-pitch angle**. The principal mechanical problem is to provide a mechanism which has the least possible chance of going into reverse inadvertently.

The **propeller control** is that portion of the system which regulates the blade angle. In light aircraft, this may consist merely of a mechanism which sets a given blade angle corresponding to a given position of the cockpit control. In such cases the propeller acts as a fixed-pitch propeller except when activated by the pilot. In most cases, the propeller control regulates blade angle so as to maintain a preset rotary rpm, irrespective of flight speed or shaft power. The **basic elements** of this system

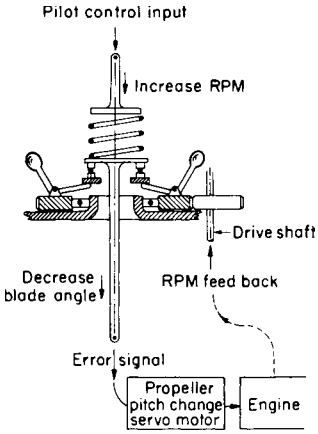

Fig. 11.5.41 Propeller-speed governor.

normally consist of a spring-balanced, engine-drive flyweight delivering an error signal which directs the servo, or pitch-change motor, to increase or decrease blade angle (Fig. 11.5.41). The control loop is closed by rpm feedback through the main engine. This basic system may be embellished with anticipating and delay devices to maintain speed in rapid throttle movements, synchronizing to coordinate two or more engines, and with overriding features to activate the reversing and feathering sequences. (See also Sec. 16.)

Propeller **controls** are fundamentally the same, with several added secondary features. First, because the engine is capable of a very rapid increase or decrease in torque and because of the high gear ratio between the propeller and engine shaft, anticipating features are necessary to prevent overspeeds in the propeller from producing large overspeeds and possible failure in the turbine. Second, because of the high idle rpm needed to maintain the pressure ratio in the compressor, the low-pitch stop of the turboprop engine propeller must be set substantially lower than for a piston engine. This is not true of a free-turbine drive and is only partially true of a split-compressor engine. In the event of an **engine failure,** the propeller, sensing the loss in rpm, will govern down to the low-pitch stop. This may lead to large, often uncontrollable, negative thrust. To avoid this possibility, an engine-shaft torque signal is put into the control, a negative torque automatically activating the feathering system. This portion of the system is known as the **ENT (emergency negative-thrust)** system. Third, because of the high idle rpm characteristic of the turboprop engine, and the resulting low blade angles at low power in the ground-taxi regime, provision must be made to cut out the governing system and substitute direct blade-angle regulation (known as **beta control**). This is required because the propeller will not govern under these conditions as the torque-to-blade-angle relationship goes to zero. The propeller control of a turboprop engine is normally mechanically coordinated directly to the engine throttle, leaving only a single control, with so-called power lever, in the aircraft.

The shaft on which the propeller is mounted is subjected to the steady-thrust load, vibratory loads due to the propeller side, and **gyroscopic forces** (the $1E$ moment, acting on the blades, is reactionless in propellers with three or more blades). In large aircraft, the shaft size is usually determined by the propeller side force. In aircraft used for aerobatics, gyroscopic loads may become limiting. The **gyroscopic moment** on the propeller shaft is given by $2\omega_1 \cdot \omega_2(I_1 - I_2)$, where ω_1 = angular velocity of maneuver, ω_2 = angular velocity of shaft, I_1 = polar moment of inertia of propeller about shaft, I_2 = moment of inertia of propeller about diameter in plane of rotation. (See also Sec. 3.)

11.6 ASTRONAUTICS

SPACE FLIGHT

by Aaron Cohen

The science of astronautics deals with the design, construction, and operation of craft capable of flight through interplanetary or interstellar space. In addition to orbits around, and trajectories between, such bodies as stars, planets, and planetoids, the ascents from and descents to the surface of such bodies are considered to be part of the field.

The purposes of such craft are numerous and include the transportation of people and cargo, the transmission or relaying of signals, and the carrying of instruments for the measurement of the characteristics of (1) the environment through which the craft flies, (2) the surface of the celestial body over which the craft flies, or (3) astronomical objects or phenomena. The commercial applications of space are now being realized. Many communication, weather, and earth-sensing satellites have been deployed. The space shuttle which provides a method to go to and from low earth orbits offers an expanded use of space.

Processing of materials in a microgravity environment is proving to be very reliable. In microgravity the effects of thermal convection and gravity are eliminated, hence purer materials can be manufactured. Containerless processing can also be accomplished which will lead to additional applications in microgravity materials technology. The space shuttle allows payloads up to 32,000 lb to be placed in earth orbit at altitudes of 150 to 200 nautical miles (nmi) and inclinations of 28.5° to 90°. A description of the space shuttle is contained in Table 11.6.1. Using expendable launch vehicles or the space shuttle and propulsion-assistance modules, satellites can be placed in various orbits. A polar orbit is one whose orbital plane includes the earth's axis and permits line-of-sight contact between the spacecraft and every point on earth on a periodic basis. Synchronous orbits have angular rates equal to the rotational rate of the earth about its axis, providing a spacecraft locus of positions at nearly constant longitude. Orbital-parameter variation provides a wide variety of other orbits, permitting the selection of characteristics most suitable for the specific flight objective, such as communication relays, meteorological observations, earth surface monitoring, or interplanetary trajectories.

SHUTTLE THERMAL PROTECTION SYSTEM TILES

by William C. Schneider

Texas A & M University

REFERENCES: "National Space Transportation System Reference Document," NASA, June 1988. Moser and Schneider, "Strength Integrity of the Space Shuttle Orbiter Tiles," AIAA First Flight Testing Conference, Nov. 11–12, 1981, Las Vegas, paper AIAA-81-2469. Schneider and G. J. Miller, "The Challenging Scales of the Bird (Shuttle Tile Structural Integrity)," Space Shuttle Technical Conference, June 28–30, Houston. O'Hearn, "Application of Probabilistic Analysis to Aerospace Structural Design," AIAA 81-0231.

The thermal protection system (TPS) consists of various materials applied externally to the outer structural skin of the shuttle orbiter to passively maintain the skin within acceptable temperatures, primarily during the entry phase of the mission. The orbiter's outer structural skin is constructed primarily of aluminum and a limited amount of graphite epoxy. During entry, the TPS materials protect the orbiter outer skin from exceeding temperatures of 350°F. In addition, they are reusable for 100 missions, with refurbishment and maintenance. These materials perform in temperature ranges from −250°F in the cold soak of space to entry temperatures that reach nearly 3,000°F. The TPS also withstands the forces induced by deflections of the orbiter airframe as it responds to the various external environments. Because the thermal protection system is installed on the outside of the orbiter skin, it establishes the aerodynamics over the vehicle. The orbiter interior temperatures also are controlled by internal insulation, heaters, and purging techniques in the various phases of the mission.

The TPS is a passive thermal insulation system consisting of materials selected for stability at high temperatures and weight efficiency. Additionally, the TPS has to be reusable flight after flight. These highly constraining requirements drove the design to the highly reliable, passive, lightweight, reusable system that, flight after flight, protects the Shuttle Orbiter. However, the TPS was never designed to withstand significant impacts of any kind any more than an automobile windshield was designed to withstand significant impacts. The region of the orbiter vehicle where each material is used is depicted in Fig. 11.6.1. These materials are as follows:

1. **Reinforced carbon-carbon** (RCC) protects areas where the surface temperatures exceed 2,300°F during entry, such as the wing leading edges and the nose cap.
2. Black **high-temperature reusable surface insulation** (HRSI) tiles protect areas where the surface temperatures are below 2,300°F but above 1,200°F. These tiles have a black surface coating, necessary for entry emittance. HRSI tiles are used in areas on the upper forward fuselage, including around the forward fuselage windows; the entire underside of the vehicle where RCC is not used; portions of the orbital maneuvering system and reaction control system pods; the leading and trailing edges of the vertical stabilizer; wing glove areas; elevon trailing edges; adjacent to the RCC on the upper wing surface; the base heat shield; the interface with wing leading edge RCC; and the upper body flap surface.
3. Black tiles, called **fibrous refractory composite insulation** (FRCI), with higher strength and weight were developed later in the thermal protection system program. FRCI tiles replace some of the HRSI tiles in selected areas of the orbiter.
4. **Low-temperature reusable surface insulation** (LRSI) tiles protect areas where surface temperatures are below 1,200°F but above 700°F and have a white surface coating to provide better thermal characteristics on orbit. These white tiles are used on the upper wing and vertical tail and in selected areas of the forward, mid-, and aft fuselages, etc.
5. After the initial delivery of Columbia to the assembly facility, an **advanced flexible reusable surface insulation** (AFRSI) was developed. This material consists of composite quilted fabric insulation batting sewn between two layers of white fabric. AFRSI was used on Discovery and Atlantis to replace the vast majority of the LRSI tiles. Following its seventh flight, Columbia also was modified to replace most of the LRSI tiles with portions on the upper wing. The AFRSI blankets provide improved producibility and durability, reduced fabrication and installation time and costs, and a weight reduction over that of the LRSI tiles.
6. White blankets made of coated Nomex **felt reusable surface insulation** (FRSI) protect areas where surface temperatures are below 700°F and are used on the upper payload bay doors, portions of the mid-fuselage and aft fuselage sides.
7. Additional materials are used in other special areas such as the thermal panes for the windows; metal for the forward reaction control system fairings and elevon seal panels on the upper wing-to-elevon interface; and a combination of white- and black-pigmented silica cloth

Table 11.6.1 Specifications of the Space Shuttle System and Its Components

Component	Characteristic	Specifications
Overall system	Length	184.2 ft (56.1 m)
	Height	76.6 ft (23.3 m)
	System weight	
	Due-east launch	4,490,800 lbm (2037.0 Mg)
	104° launch azimuth	4,449,000 lbm (2018.0 Mg)
	Payload weight	
	Due-east launch	65,000 lbm (29.5 Mg)
	104° launch azimuth	32,000 lbm (14.5 Mg)
External tank	Diameter	27.8 ft (8.5 m)*
	Length	154.4 ft (47.1 m)
	Weight	
	Launch	1,648,000 lbm (747.6 Mg)
	Inert	70,990 lbm (32.2 Mg)
Solid rocket booster (SRB)	Diameter	12.2 ft (3.7 m)
	Length	149.1 ft (45.4 m)
	Weight (each)	
	Launch	1,285,100 lbm (582.9 Mg)
	Inert	176,300 lbm (80.0 Mg)
	Launch thrust (each)	2,700,000 lbf (12.0 MN)
Separation motors (each SRB), four aft, four forward	Thrust (each)	22,000 lbf (97.9 kN)
Orbiter	Length	121.5 ft (37.0 m)
	Wingspan	78.1 ft (23.8 m)
	Taxi height	57 ft (17.4 m)
	Weight	
	Inert	161,300 lbm (73.2 Mg)
	Landing	
	With payload	203,000 lbm (92.1 Mg)
	Without payload	173,000 lbm (78.5 Mg)
	Cross range	1,100 nmi (2037.2 km)
Payload bay	Length	60 ft (18.3 m)
	Diameter	15 ft (4.6 m)
Main engine (three)	Vacuum thrust (each)	470,000 lbf (2090.7 kN)
Orbital maneuvering system engines (two)	Vacuum thrust (each)	6,000 lbf (26.7 kN)
Reaction control system engines		
38 engines	Vacuum thrust (each)	870 lbf (3870 N)
6 vernier rockets	Vacuum thrust (each)	24 lbf (111.2 N)

* Includes spray-on foam insulation.

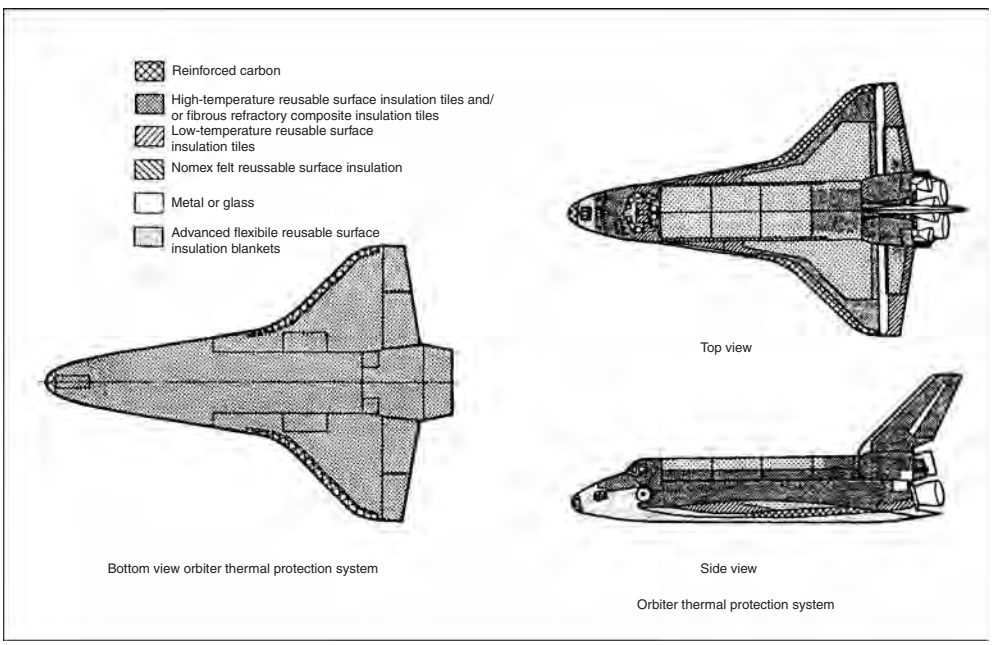

Fig. 11.6.1 Thermal protection system regions.

for thermal barriers and gap fillers around operable penetrations, such as main and nose landing gear doors, egress and ingress flight crew side hatch, umbilical doors, elevon cove, forward RCS, RCS thrusters, mid-fuselage vent doors, payload bay doors, rudder/speed brake, and gaps between TPS tiles in high differential pressure areas.

The area of the shuttle orbiter vehicle protected by the TPS tiles is shown in Fig. 11.6.1 and is designated as reusable surface insulation. As can be seen in Fig. 11.6.2, the tiles protect the vehicle from surface temperatures in the range of 700°F to 2,300°F.

The RSI tiles, shown conceptually in Fig. 11.6.3, are designed to radiate 80 to 90 percent of the reentry heat back to space before it can be conducted to the Orbiter's structure. Since the structure deforms in-plane during a mission, continuous covering for large areas would be prohibitive because of the weak RSI material, therefore the nominal 6-in-square tile with a 0.05-in gap between was used. To accommodate the flight-induced out-of-plane structural deformation, the individual tiles are individually mounted on a compliant strain isolation pad (SIP) made of Nomex felt, the same material as FRSI. This design concept of using individual tiles on SIP becomes fairly obvious with a limited amount of stress analysis using the RSI physical properties shown in Table 11.6.2.

As the LI-900 RSI 13-psi ultimate flatwise tension strength allowable was being established, the strength properties of the tile/SIP system were also being established. The effective joint allowable of this interface was approximately 50 percent that of the LI-900 material. This reduction in strength was caused by stress concentrations in the RSI because of "stiff spots" introduced into the SIP by the needling felting process. The challenge of accommodating these stiff spots for the more highly loaded tiles, as opposed to using the heavier, higher-strength LI-2200, was met by locally densifying (strengthening) the underside of the tile. A solution of colloidal silica particles is applied to the noncoated tile underside and baked in an oven at 3,500°F for 3 hours. The densified layer produced is 0.1 in thick and increases the weight of a typical 6- by 6-in tile by only 0.06 lb. For load distribution, the densified layer serves as a structural plate that distributes the concentrated SIP loads evenly into the weaker unmodified RSI material. As shown in Fig. 11.6.4, this forces the failure surface to occur above the densified layer. This enhancement in itself offers somewhat of a fail-safe feature for thermal protection, but the major enhancement is in the improved tile/SIP system strength shown in Fig. 11.6.5.

There were many tiles that had standard 6- by 6-in square planforms but the numerous special tiles created a greater structural design challenge. It was necessary to design thousands of unique tiles that had compound curves, which interfaced with thermal barriers and hatches, which had penetrations for instrumentation and structural access, etc. The overriding challenge then was to assure the strength integrity of the tiles with a confidence that there was no greater chance than 1/10,000 of losing any one of the more than 10,000 more critical tiles (i.e., a probability of tile failure of no greater than $1/10^8$). The statistical treatment of the tile strength integrity is addressed in the first reference.

To accomplish this magnitude of system reliability and still minimize the weight it was necessary to define the detail loads and environments on each tile. Each tile experienced stresses induced by the following combined sources:

- Substrate or structure out-of-plane displacement
- Aerodynamic loads on the tile
- Tile accelerations due to vibration and acoustics
- Mismatch between tile and structure at installation
- Thermal gradients in the tile
- Residual stress due to tile manufacture
- Substrate in-plane displacement

Literally years of complex structural analysis, hundreds of tile specimens on high-speed-aircraft flow tests, tens of multitile wind tunnel tests, approximately 40 full-scale structural vibroacoustic tests

The forces required to propel a space vehicle from the launch pad are tremendous. The dynamic pressures generated in the atmosphere by large rocket engines are exceeded only by nuclear blasts. Slow initial ascent from the launch pad is followed by rapid acceleration and high g loading, and acoustic and aerodynamic forces drive every point of the vehicle surface. The space-vehicle velocity quickly becomes supersonic and continues to hypersonic velocities. Gradually, as the space vehicle leaves the atmosphere, the aerodynamic forces recede. Then suddenly the rocket thrust decays and is followed by the ignition of another rocket, which quickly develops thrust and continues to accelerate the space vehicle. Finally, the space vehicle becomes weightless. In completing a mission, a space vehicle is subjected to the additional environmental extremes of planetary landings, escape, and earth reentry.

These environments represent basic criteria for space-vehicle design. For operational reliability, the most important are the shock, vibration, and acoustic environments which are present to varying magnitudes in all operational phases and which constitute major engineering problems.

It is not possible to have original environmental data prior to fabrication and testing of a particular structure. Vibration, shock, and acoustic noise adversely affect structural integrity and vehicle reliability. These environments must be considered prior to design and fabrication and then again for design verification through ground testing. Precise vibration and acoustic environmental predictions are complicated because of structural nonlinearities, random forcing functions, and multiple degree-of-freedom systems. Current environmental-prediction techniques consist mainly of extrapolating measured data obtained from existing vehicles. Acoustic environments produced during ground test are important factors in evaluating ground-facility locations and design, personnel safety, and public relations.

A source of sound common to all jet and rocket-engine propulsion systems is the turbulent exhaust flow. This high-velocity flow produces pressure fluctuations, referred to as noise, and has adverse effects on the vehicle and its operations. Also, far-field uncontrolled areas may be subjected to intense acoustic-sound-pressure levels which may require personnel protection or sound-suppression devices. (See also Sec. 12.)

The sound-generation mechanism is presented in empirical and analytical form, utilizing measured sound pressures and the known engine operational parameters. This combination of empirical terms and analytical reasoning provides a generalized relationship to predict sound-pressure levels for the vehicle structure and also for far-field areas. It has been shown by Lighthill (*Proc. Royal Soc.,* 1961) that acoustic-power generation of a subsonic jet is proportional to $\rho V^8 D^2/a_0^3$, where ρ is the density of the ambient medium, a_0 is the speed of sound in the ambient medium, V is the jet or rocket exit exhaust velocity, and D is a characteristic dimension of the engine. Attempts have been made to extend this relationship to allow supersonic-jet acoustic-power predictions to be made, but no one scheme is accepted for broad use.

From acoustic-data-gathering programs utilizing rocket engines, various trends have been noted which facilitate acoustic predictions. For rocket engines of up to 5×10^9 W mechanical power, the acoustic efficiency shows a nonlinear rate of increase. For greater mechanical power, the acoustic efficiency approaches a value slightly higher than 0.5 percent (Fig. 11.6.6).

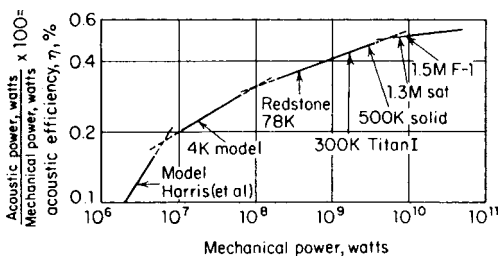

Fig. 11.6.6 Acoustic-efficiency trends.

Turbulent-exhaust-flow sound-source mechanisms also exhibit directional characteristics. Figure 11.6.7 shows data from a Saturn rocket vehicle launch with the microphone flush-mounted on the vehicle skin at approximately 100 ft above the nozzle plane.

During the period between on-pad firing and post-lifting-off or mainstage flight, the exhaust-flow direction changes. The directivity has also shifted 90° to retain its inherent relationship to the exhaust stream. The sound-pressure-level variation during a small time interval—between on-pad condition and shortly after liftoff—depends on the changes which have occurred in the directivity and the jet-exhaust-velocity vector (Fig. 11.6.7). The change in sound-pressure level is 20 dB

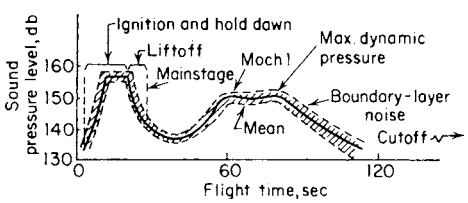

Fig. 11.6.7 Vehicle acoustic environment.

approximately in this case and is indicative of the significance of a sound source's directional properties, which depend on velocity and temperature of the jet.

The acoustic environments produced by a given conventional engine can be empirically described by that engine's flow parameters and geometry. It is difficult to predict the acoustic environments for nonconventional engines such as the plug-nozzle and expansion-deflection engines.

The turbulent-boundary-layer problem of high-velocity vehicle flights is difficult to evaluate in all but the simplest cases. Only for attached, homogeneous, subsonic flows can the boundary-layer noise be estimated with confidence.

The vibratory environment on rocket vehicles consists of total-vehicle bending vibrations, in which the vehicle is considered a nonuniform beam, with low-frequency responses (0 to 20 Hz) and localized vibrations with frequencies up to thousands of hertz. (See also Sec. 5.)

The response of a simple structure to a dynamic forcing function may be described by the universal equation of motion given as $M\ddot{x} + c\dot{x} + Kx = F(t)$ or $F(t)x(t) = (M - K\omega^2) - j(c/\omega)$ and is a complex function containing real and imaginary quantities. In the case of rocket-vehicle vibrations, $F(t)$ is a random forcing phenomenon. Thus, the motion responses must also be random. Random vibration may be described as vibration whose instantaneous magnitudes can be specified only by probability-distribution functions giving the probable fraction of the total time that the magnitude, or some sequence of magnitudes, lies within a specified range. In this type of vibration, many frequencies are present simultaneously in the waveform (Fig. 11.6.8). Power spectral density (PSD; in units of g^2/Hz) is defined as the limiting mean-square value of a random variable, in this case acceleration per unit bandwidth; i.e.,

$$\text{PSD} = \lim_{\Delta f \to 0} \bar{g}^2/\Delta f = d\bar{g}^2/df$$

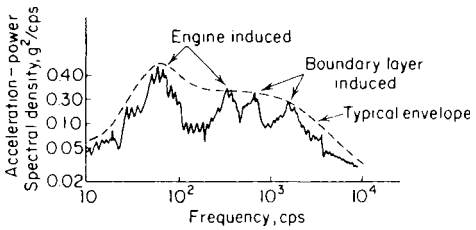

Fig. 11.6.8 Random-vibration spectrum of a space-vehicle structure.

The sources of vibration excitation are (1) acoustic pressures generated by rocket-engine operation; (2) aerodynamic pressures created by boundary-layer fluctuations; (3) mechanically induced vibration from rocket-engine pulsation, which is transmitted throughout the vehicle structure; (4) vibration transmitted from adjacent structure; and (5) localized machinery. Since the mean square acceleration is proportional to power, the total vibrational power at any point on the vehicle may be expressed as

$$Pv \doteq Pv(1) + Pv(2) + Pv(3) + Pv(4) + Pv(5)$$

This is illustrated in Fig. 11.6.9 for an arbitrary vehicle. In many instances, the structure is principally excited by only one of these sources and the remaining can be considered negligible (Fig. 11.6.10). The vibration characteristics of structure B, taken from a skin panel, closely correspond to the trends of the acoustic pressures during flight. However, structure A, taken from a rocket-engine component, exhibits stationary trends, indicating no susceptibility to the impinging acoustic field. Thus, for this structure, it can be assumed that only $Pv(3)$ is significant, whereas for structure B, only $Pv(1)$ is the principal exciting source during the on-pad phase and only $Pv(2)$ is significant during the maximum dynamic-pressure phase. This also holds true for captive firings of the vehicle, in which only $Pv(1)$ is significant for structure B and $Pv(3)$ for structure A.

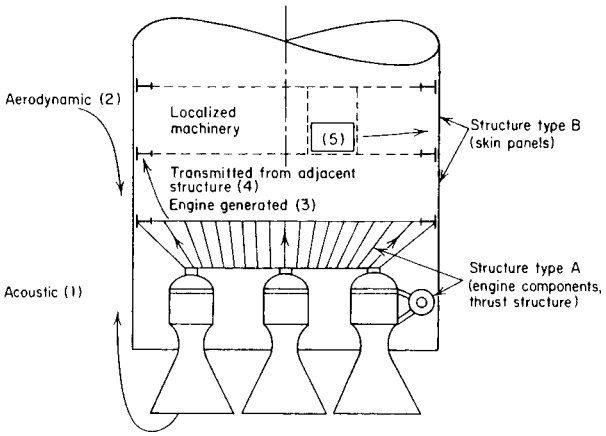

Fig. 11.6.9 Sources of vibration excitement.

Notation

A = reference area
A_z = launch azimuth
B = ballistic coefficient
C_L = lift coefficient
e = eccentricity
f = stage-mass fraction (WP/W_A)
H = total energy
H_∞ = hyperbolic excess energy

I = specific impulse
Δ_i = plane-change angle
L = lift force
m = mass
n = mean motion ($2\pi/p_{sid}$)
p = ambient atmospheric pressure
q = dynamic pressure
R = earth's equatorial radius
S = wing area
T = transfer time, time, absolute temperature
t_{pp} = time after perigee passage
V_c = injection velocity
V = velocity
V_g = velocity loss to gravity
W = weight
W_L = payload weight
W_P = propellant weight
Y = distance
α_Ω = right ascension of the ascending node
$\gamma = \theta - 90°$ = flight-path angle used in reentry analysis
v = true anomaly
ω = earth's rotational velocity
ψ = central angle
$\sigma = \rho/\rho_0$ = relative atmospheric density
Υ = vernal equinox
A_e = nozzle exit area
a = semimajor axis
C_D = drag coefficient
D = drag force
E = eccentric anomaly
F = thrust
g = acceleration due to gravity
H_{esc} = escape energy
h = altitude
i = inclination
J_2 = oblateness coefficient of the earth's potential (second-zonal harmonic)
M = molecular weight, mean anomaly
nm = nautical miles
P = period of revolution
P_e = nozzle exit pressure
q_s = stagnation-point heat-transfer rate
r = radius
s = range
t = time
V_∞ = hyperbolic excess velocity
V_{id} = ideal velocity
ΔV = impulsive velocity
W_A = stage weight ($W_O - W_L$)
W_O = gross weight
X = distance
α = angle of attack, right ascension
β = exponent of density-altitude function
λ = longitude
τ = hour angle
ω = argument of perigee
ϕ' = latitude
ρ = atmospheric density
θ = flight-path angle

Subscripts

a = apogee
e = entry
f = final
o = sea level conditions at 45° latitude
s = space fixed
vac = vacuum
circ = circular orbital condition
esc = escape
i = initial
p = perigee
M = mean
SL = sea level
sid = sidereal

ORBITAL MECHANICS

by O. Elnan and W. R. Perry
University of Cincinnati

The motion of the planets about the sun, as well as that of a satellite in its orbit about a planet, is governed by the inverse-square force law for attracting bodies. In those cases where the mass of the orbiting body is small relative to the central attracting body, it can be neglected. This simplifies the analysis of the orbital motion. The shape of the orbit is always a conic section, i.e., ellipse, parabola, or hyperbola, with the central attracting body at one of the foci. Parabolic and hyperbolic orbits are open, terminate at infinity, and represent cases where the orbiting body escapes the central force field of the attracting body.

The **laws of Kepler** for satellite orbits are (1) the radius vector to the satellite from the central body sweeps over equal areas in equal times; (2) the orbit is an ellipse, with the central attracting body at one of its foci; and (3) the square of the period of the satellite is proportional to the cube of the semimajor axis of the orbit.

Six **orbital elements** are required to describe the orbit in the orbit plane and the orientation of the plane in inertial space. The three elements that define the orbit are the semimajor axis a, eccentricity e, and period of revolution P. The orientation of the orbit (Fig. 11.6.11) is defined by the right ascension of the ascending node α_Ω, inclination of the orbit plane to the earth's equatorial plane i, and the argument of perigee ω, which is the central angle measured in the orbit plane from ascending node to perigee. The following equations compute these orbital elements and other orbital parameters.

$$a = (r_a + r_p)/2 = \mu/V_a V_p = r_a/(1 + e) = r_p/(1 - e)$$
$$e = (r_a/a) - 1 = (V_p - V_a)/(V_p + V_a) = (r_p V_p^2/\mu) - 1$$
$$r = a(1 - e^2)/(1 + e\cos v)$$
$$r_a = a(1 + e) = r_p(1 + e)/(1 - e)$$
$$r_p = a(1 - e) = r_a(1 - e)/(1 + e)$$
$$V = [\mu(2/r - 1/a)]^{0.5}$$
$$P = 2\pi(a^3\mu)^{0.5} \qquad \text{(for circular orbits, } r = a\text{)}$$
$$V_a = V_p(1 - e)/(1 + e) = [\mu(1 - e)/a(1 + e)]^{0.5}$$
$$V_p = V_a(1 + e)/(1 - e) = [\mu(1 + e)/a(1 - e)]^{0.5}$$
$$v = \cos^{-1}\{[2r_a r_p - r(r_a + r_p)]/r(r_a - r_p)\}$$
$$t_{pp} = (a^3/\mu)^{0.5}\{\cos^{-1}[(a - r)/ae] - e[1 - (a - r)^2/(ae)^2]^{0.5}\}$$
$$M = nt_{pp} = E - e\sin E$$
$$r = a(1 - e\cos E)$$
$$V_{esc} = (2\mu/r)^{0.5}$$

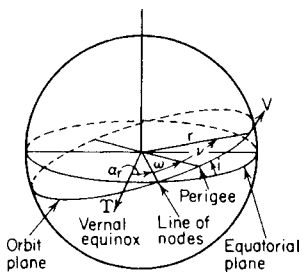

Fig. 11.6.11 Elements of satellite orbit around a planet.

The elements may be determined from known injection conditions. For example,

$$1/a = V_i^2\mu - 2/r_i$$
$$e^2 = \cos^2 V_i(r_i V_i^2/\mu - 1)^2 + \sin^2 V_i$$

General precession in longitude of vernal equinox:

$$x = 50''.2575 + 0''.0222T$$

where T is in Julian centuries of 36,525 mean solar days reckoned from 1900 Jan. 0.5 UT.

Measurement of Time

The concept of time is based on the position of celestial bodies with respect to the observer's meridian as measured along the geocentric celestial equator. The mean sun and the vernal equinox (Υ) are used to define mean solar time and sidereal time. The mean sun, rather than the apparent (true) sun, is used since the latter's irregular motion from month to month gives a variation in the length of a day. The mean sun moves with uniform speed along the equator at a rate equal to the average of the true sun's angular motion during the year.

One sidereal day is the interval between two successive transits of the vernal equinox across the observer's meridian. A mean solar day is the interval between two successive transits of the mean sun. Local civil time (LCT) is defined to be the hour angle of the mean sun plus 12 h. Local sidereal time is the hour angle of the vernal equinox plus 12 h. For an observer at the Greenwich meridian, the local civil time is Greenwich mean time (GMT) or universal time (UT). The earth is divided into 24 time zones, each 15° of longitude wide. Each zone keeps the time of the standard meridian in the middle of the zone. (See Fig. 11.6.12.)

Time $T = \tau + 12$ h
Local sidereal time LST $= \tau_\Upsilon + 12$ h
Greenwich sidereal time GST = LST + $\lambda(w)$
Local civil time LCT $= \tau_M + 12$ h = mean solar time
Equation of time ET $= \tau - \tau_M = \alpha_M - \alpha$
Greenwich mean time GMT = UT $= \tau_M$(Greenwich) + 12 h = universal time

$$\text{LCT} = \text{UT} - \lambda(w)$$
$$\text{GMT} = \text{ZT} \pm \lambda°/15$$

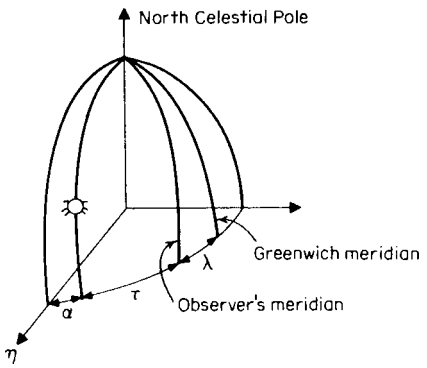

Fig. 11.6.12 Time-zone geometry.

The "American Ephemeris and Nautical Almanac" gives the equation of time for every day of the year and conversions of mean solar time to and from sidereal time.

Hohmann Transfer This is a maneuver between two coplanar orbits where the elliptical transfer orbit is tangent at its perigee to the lower orbit and tangent at its apogee to the higher orbit. To transfer from a low circular orbit to a higher one, the impulsive velocity required is the difference between the velocities in the circular orbits and the velocities in the corresponding points on the transfer orbit. Using the general velocity equation above, the transfer velocities are $\Delta V_i = \{\mu[2/r_i - 2/(r_i + r_f)]\}^{0.5} - (\mu/r_i)^{0.5}$ and $\Delta V_f = (\mu/r_f)^{0.5} - \{\mu[2/r_f - 2/(r_i + r_f)]\}^{0.5}$, where V_i is the orbiting velocity in low orbit and V_f is the orbiting velocity in the high orbit.

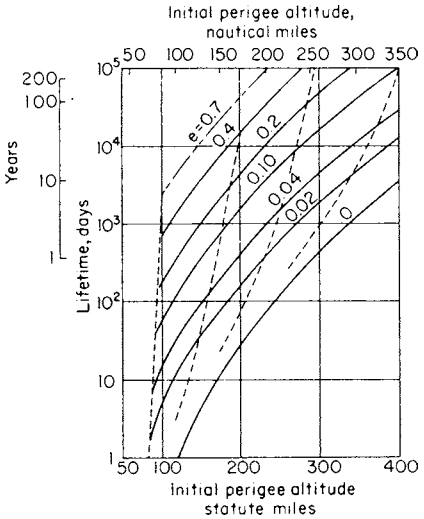

Fig. 11.6.13 Satellite lifetimes in elliptic orbits. ρ = ARDC, 1959; $B = C_D A/2m = 1.0$ ft²/slug; e = initial eccentricity; --- = decay histories.

Orbital Lifetime The satellite orbit will gradually decay to lower altitudes because of the drag effects of the atmosphere. This drag force has the form $D = \frac{1}{2} C_D A_\rho V^2$, where values of the drag coefficient C_D may range from 2.0 to 2.5. The atmospheric density, as a function of altitude, can be used for computing an estimated orbital lifetime of a satellite (Fig. 11.6.13). (See NASA, "U.S. Standard Atmosphere" and "Space Flight Handbooks.")

Perturbations of Satellite Orbits There are many secular and periodic perturbations of satellite orbits due to the effects of the sun, the moon, and some planets. The most significant perturbation on close-earth satellite orbits is caused by the oblateness of the earth. Its greatest effects are the precession of the orbit along the equator (nodal regression) and the rotation of the orbit in the orbit plane (advance of perigee). The nodal-regression rate is given to first-order approximation by

$$\dot{\alpha}_\Omega = -\tfrac{3}{2}(\mu/a^3)^{0.5} J_2[R/a(1 - e^2)]^2 \cos i$$

The mean motion of the perigee is

$$\dot{\omega} = J_2 n(2 - (\tfrac{5}{2}) \sin^2 i)/a^2(1 - e^2)^2$$

LUNAR- AND INTERPLANETARY-FLIGHT MECHANICS

by J. W. Russell
University of Cincinnati

The extension of flight mechanics to the areas of lunar and interplanetary flight must include the effects of the sun, moon, and planets on the transfer trajectories. For most preliminary performance calculations, the **"sphere-of-influence,"** or **"patched-conic,"** method—whereby the multibody force field is treated as a series of central force fields—provides sufficient accuracy. By this method, the trajectories in the central force field are calculated to the "sphere of influence" of each body as standard Keplerian mechanics, and the velocity and position of the extremals are then matched to give a continuous trajectory. After the missions have been finalized, the precision trajectories are obtained by numerically integrating the equations of motion which include all the perturbative elements. It is necessary to know the exact positions of the sun, moon, and planets in their respective orbits.

Lunar-Flight Mechanics The moon moves about the earth in an orbit having an eccentricity of 0.055 and an inclination to the ecliptic of about 5.145°. The sun causes a precession of the lunar orbit about the ecliptic, making the inclination of the lunar plane to the earth's equatorial plane oscillate between 18.5 and 28.5° over a period of 18.5 years approx. To compute precision earth-moon trajectories, it is necessary to know the precise launch time to be able to include the perturbative effects of the sun, moon, and planets. The data presented are based on the moon being at its mean distance from earth and neglect the perturbation of the sun and planets; they are therefore only to be considered as representative data. The injection velocity (see Gazley) at 100 nmi for earth-moon trajectories and the impulsive velocity for braking into a 100-nmi orbit about the moon are shown in Fig. 11.6.14 as a function of transfer time. Additional energy is required to offset losses due to gravity and aerodynamic drag as well as to provide plane-change and launch-window capabilities.

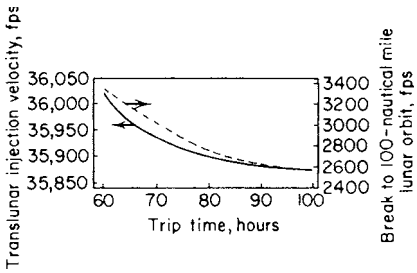

Fig. 11.6.14 Lunar-mission velocity requirements.

Interplanetary-Flight Mechanics The fact that planetary orbits about the sun are not coplanar greatly restricts the number of feasible interplanetary trajectories. The plane of the interplanetary trajectory must include the position of the departure planet at departure, the sun, and the position of the target planet at arrival. The necessary plane change can be prohibitive even though the relative inclinations of the planetary orbits are small. The impulsive velocity required to effect a plane change for a spacecraft departing earth can be approximated by $\Delta V = 195{,}350 \sin(\Delta_i/2)$, where Δ_i is the amount of plane change required and ΔV is in ft/s.

For interplanetary flight, the "ideal" total energy that must be imparted to the spacecraft is the energy required to escape the gravitational field of the departure planet plus the energy required to change path about the sun so as to arrive at the target planet at the desired position and time. The energy required to escape the gravitational attraction of a planet can be determined by Keplerian mechanics to be $H_{esc} = \mu/r$, where μ is the gaussian gravitational constant and r is the distance from the center of the planet. After escaping the departure planet, the velocity must be altered in both magnitude and direction—in order to arrive at the target planet at the chosen time—by supplying additional energy, $H_\infty = \frac{1}{2}V_\infty^2$.

For determination of vehicle size necessary to inject the spacecraft into the interplanetary trajectory, it is convenient to express the total energy $H = H_{esc} + H_\infty$ in terms of the required injection velocity

$$V_c = \sqrt{2(H_{esc} + H_\infty)} \qquad \text{or} \qquad V_c = \sqrt{(2\mu/r) + V_\infty^2}$$

Hyperbolic excess velocities V_∞ for earth-to-Mars missions are shown in Table 11.6.3 as a function of date. These velocities are near optimum for the trip time and year given but do not represent absolute-optimum trajectories. Mars has a cyclic period with respect to earth of 17 years approx; hence the energy requirements for Mars missions from earth also follow approximate 17-year cycles.

Figure 11.6.15 shows how the hyperbolic excess velocities of Table 11.6.3 can be converted to stage characteristic velocities for a vehicle leaving a 100-nmi earth parking orbit. These are simple cases.

Table 11.6.3 Hyperbolic-Excess-Velocity Requirements (ft/s) for Typical Mars Missions

Trip time, days	Opposition year				
	1982	1984	1986	1988	1990
100	27,241	23,012	18,070	15,569	19,955
150	15,940	13,088	11,437	10,520	13,792
200	12,268	10,021	11,486	9,308	12,463

In many recent planetary missions, use has been made of planetary flybys to gain velocity and aim the space probe. These "gravity assists" significantly increase the capability of interplanetary flight.

ATMOSPHERIC ENTRY

by D. W. Fellenz
University of Cincinnati

A vehicle approaching a planet possesses a considerable amount of energy. The entry vehicle must be designed to dissipate this energy without exceeding its limits with respect to maximum decelerations or heating.

The trajectory parameters of an entering vehicle are determined largely by its initial trajectory conditions (suborbital, orbital, superorbital), by the ratio of gas-dynamic forces acting upon it, and by its mass (ballistic factor, lift-drag ratio) and the type of atmosphere it is entering.

Planetary atmospheres (Table 11.6.4) can be assumed, as a first approximation, to have exponential density-altitude distributions: $\sigma = \rho/\rho_{SL} = e^{-\beta h}$, where

$$\beta = -(1/\rho)(d\rho/dh) = Mg/RT$$

For more exacting analyses, empirical atmospheric characteristics (e.g., U.S. Standard Atmosphere) have to be used.

The trajectory of the vehicle in flight-path fixed notation with the assumption of a nonrotating atmosphere is described as $dV/dt = g \sin\gamma - (C_D A/m)(\rho/2)V^2$ and $(V/\cos\gamma)(d\gamma/dt) = g - (V^2/r) - (C_L A/m)(\rho/2)(V^2/\cos\gamma)$. Solutions exist for direct ($\gamma > 5°$) ballistic entry and for equilibrium glide-lifting entry for $L/D > 1$. General solutions of the equations of motion have been obtained for shallow entry of both ballistic and lifting bodies. For a survey of analytical methods available, see Chapman, Loh, Grant, Lees, and Gervais.

The **energy of an earth satellite** at 200 mi altitude is about 13,000 Btu/lb, and a vehicle entering at escape velocity possesses twice this energy. This energy is transformed, through the mechanism of gas-dynamic drag, into thermal energy in the air around the vehicle, of which only a fraction enters the vehicle surface as heat. This fraction depends on the characteristics of the boundary-layer flow, which is determined by shape, surface condition, and Reynolds number. Figure 11.6.16 illustrates the **energy conversion** where it is necessary to manage a given

Table 11.6.4 Planetary Atmospheres

Planet	V_{esc}, ft/s	Gases	M, gmol^{-1}	T, K	β^{-1}, ft	$\beta\tau$	ρ_{SL}, lb/ft^3
Venus	34,300	2% N_2 98% CO_2	40	250–350	2×10^4	1,006	1.0
Earth	36,800	78% N_2 21% O_2	29	240	2.35×10^4	880	0.0765
Mars	16,900	95% N_2 3% CO_2	28	130–300	6×10^4	132	0.0062
Jupiter	195,000	89% H_2 11% He	2.2	100–200	6×10^4	3,600	

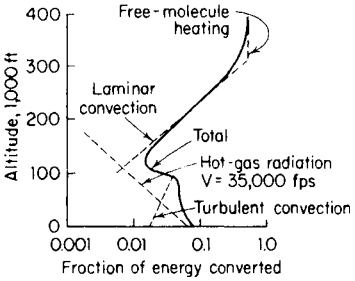

Fig. 11.6.16 Energy conversion during reentry. (*After Gazley in Knoelle, "Handbook of Astronautical Engineering."*)

amount of energy in a way that minimizes structural and heat-protection weights, operational restraints, and cost. It would be most desirable if this energy could be dissipated at a constant rate, but with constant vehicle parameters, decelerations vary proportionally to ρV^2 and heating rates proportionally to ρV^3. The selection of a heat-protection system depends on the type of entry flown. Lifting entry from orbit results in relatively long flight times (in the order of ½ h) as compared with 10 min in the case of a steep ballistic entry. **Radiative-heat-transfer systems** favor low heating rates over long time periods. **Ablative systems** favor short heat pulses. In fact, longer soaking periods may melt the ablation coating without getting the benefit of heat absorption through multiple-phase changes. A more uniform dissipation of energy can be achieved by modulation of vehicle parameters.

Determination of an **entry-vehicle configuration** is a process of iteration. The entry-flight profile and the entry and recovery procedures are mainly determined by whether experiments or passengers are carried. The external shape is determined by requirements for hypersonic glide capability and subsonic handling and landing characteristics and also by the relations between aerodynamic shape, heat input, and structural-materials characteristics. Intermediate results are fed back into the evaluation of performance and operational effectiveness of the total transportation system.

If reentry capability from any point of the ascent trajectory is desired for a manned vehicle, vehicle constraints and trajectory requirements must be compatible. **Performance-optimized trajectories** encompass combinations of relatively small velocities and large flight-path angles, which would result in considerable decelerations. In such cases, either reshaping the ascent trajectory or adding velocity at the time of abort, resulting in lower entry-flight-path angles, is effective (see Fig. 11.6.17). Lower flight-path angles during ascent depress the trajectory and increase drag losses. **Atmospheric entry is initiated** by changing the vehicle-velocity vector so that the virtual perigee of the descent ellipse comes to lie inside the atmosphere. The retrovelocity requirement for entry from low orbit is between 250 and 500 ft/s, depending on the range desired from deorbit to landing. For nonlifting entry, maximum deceleration and heat input into the vehicle are largely a function of entry angle, with the ballistic factor

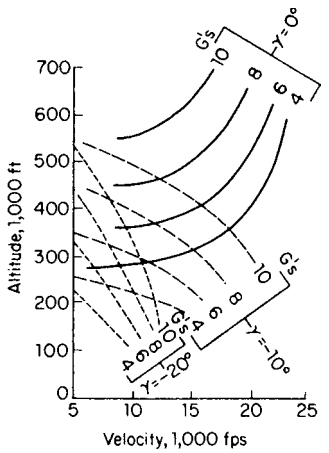

Fig. 11.6.17 Suborbital entry of a lifting vehicle. $W/C_DA = 28$ lb/ft; $L/D = 0.7$.

W/C_DA determining the altitude at which the maximum decelerations and heating rates occur. Deceleration can be readily determined through the approximate relation $-(1/g)(dv/dt) \approx q/(W/C_DA)$. Decelerations and temperatures are drastically reduced with increasing lift-drag ratio (Fig. 11.6.18) and decreasing W/C_DA (Figs. 11.6.19 and 11.6.20). This effect is particularly beneficial at steeper entry angles. The combination of longer flight times with lower heating rates, however, may actually result in a larger total heat input into the vehicle.

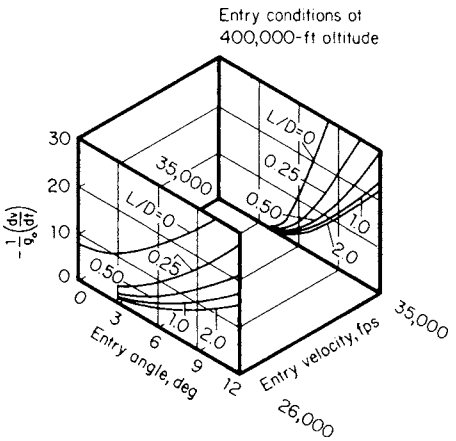

Fig. 11.6.18 Peak decelerations for entry at constant L/D.

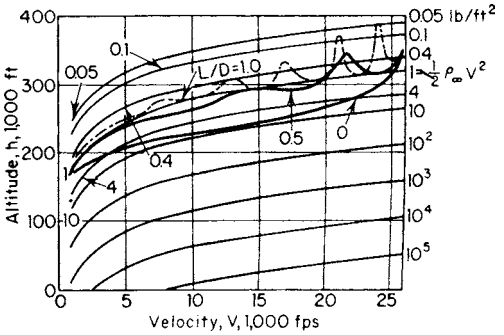

Fig. 11.6.19 Glide reentry, dynamic pressure. $W/C_DA = 1$ lb/ft^2; $\gamma = 2°$; $\frac{1}{2}\rho_\infty V = (W/C_DA)(\frac{1}{2}\rho_\infty V^2)$; $h = h_1 - 23{,}500 \ln (W/C_DA)$; $V = V_1$.

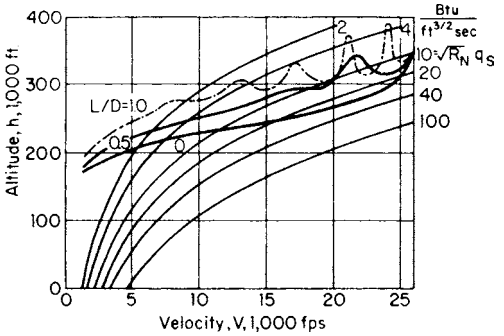

Fig. 11.6.20 Glide reentry, stagnation-heating rate. $W/C_DA = 1$ lb/ft^2; $\gamma = 2°$; $q_s = q_{s1}\, W/C_DA$; $h = h_1 - 23{,}500 \ln (W/C_DA)$; $V = V_1$.

The **influence of lift** on the reduction of decelerations is greatest for the step up to $L/D \approx 1$. The influence of W/C_DA on decelerations disappears beyond $L/D \approx 0.6$. Higher, hypersonic L/D ratios serve to improve maneuverability. For entry from low orbit, the landing area selection (footprint) can be increased (see Table 11.6.5).

Table 11.6.5

L/D	Lateral, nmi	Longitudinal, nmi
0.5	≈ 200	≈ 2,000
1	≈ 600	≈ 4,000
1.5	≈ 1,200	≈ 6,000
2	≈ 2,000	≈ 9,000

* Assumptions: $\gamma_e = 1°$; $b_e = 400{,}000$ ft; $V_e = 26{,}000$ ft/s.

For entry at parabolic or hyperbolic speeds, it is necessary to dissipate sufficient energy so that the planet can capture the vehicle. Vehicle mass and aerodynamic characteristics determine the minimum allowable entry angle, the skip limit. The vehicle must be steered between the skip limit and the angle for maximum tolerable deceleration and heating. (See Figs. 11.6.21 and 11.6.22.)

ATTITUDE DYNAMICS, STABILIZATION, AND CONTROL OF SPACECRAFT

by M. R. M. Crespo da Silva

University of Cincinnati

A spacecraft is required to maintain a certain angular orientation, or attitude, in space in order to perform its mission adequately. For example, within a certain tolerance, it may be required to point a face toward the earth for communications and observation purposes, as well as a solar panel toward the sun for power generation. A vehicle in space is subject to several external forces which produce a moment about its center of mass tending to change its attitude. The environmental moments that can act on a spacecraft can be due to solar radiation pressure, aerodynamic forces, magnetic forces, and the gravity-gradient effect. The relative importance of each of the above moments depends on the spacecraft design and on how close it is to a central attracting body. Most often, the effect on the vehicle's attitude of the first three moments mentioned above is undesirable, although they have been used occasionally for attitude control (e.g., Mariner IV, Tiros, OAO). Micrometeorite impacts can also produce a deleterious effect on the vehicle's attitude.

The most common ways to stabilize a vehicle's attitude in space are the gravity-gradient and the spin-stabilization methods. When a spacecraft is subject to the gravitational force of a central attracting body E, its mass element near the center of the gravity field will be subject to a greater force than that acting on the mass elements farther from E. This creates a moment about the center of mass, C, of the spacecraft, which depends on the inertia properties of the vehicle and also on the distance r from E to C. This gravity-gradient moment is given by

$$\mathbf{M} = (3GM_e/r^3)\hat{\mathbf{r}} \times (\mathbf{I}\cdot\hat{\mathbf{r}})$$

where $\mathbf{I}$ is the inertia dyadic of the spacecraft, referred to its mass center, and $\hat{\mathbf{r}}$ is the unit vector in the direction from E to C. As a specific example, consider the elongated orbiting spacecraft shown in Fig. 11.6.23. The body-fixed x axis (yaw) departs an angle θ_3 from the local vertical, and the body-fixed z axis (pitch) remains normal to the orbital plane. The gravitational moment about C is readily found to be as given in the equation below (it is assumed that the maximum dimension of the vehicle is much smaller than the distance r).

$$\mathbf{M} = (3GM_e/2r^3)(I_x - I_y)(\sin 2\theta_3)\hat{\mathbf{z}}$$

(I_x and I_y are the spacecraft's moments of inertia about the x and y axes, respectively.) It is seen that unless the spacecraft's x axis is vertical or horizontal, this moment is nonzero, and for $I_x < I_y$ it tends to force the x axis of the vehicle to oscillate about the local vertical. Thus, the gravity-gradient moment provides a passive, and therefore very reliable, means for stabilizing the vehicle's attitude.

The orientation of a rigid body with respect to a reference frame is described by a set of three Euler angles. Figures 11.6.24 and 11.6.25 show a rigid body in orbit around a central attracting point E and the coordinate systems used to describe its attitude. The unit vectors $\hat{\mathbf{a}}_1$, $\hat{\mathbf{a}}_2$, and $\hat{\mathbf{a}}_3$, with origin at the spacecraft's center of mass, define the orbital reference frame. The vector $\hat{\mathbf{a}}_1$ points in the direction of the vector from E to C; $\hat{\mathbf{a}}_3$ in the direction of the orbital angular velocity (whose magnitude is denoted by n); and $\hat{\mathbf{a}}_2$ is such that $\hat{\mathbf{a}}_2 = \hat{\mathbf{a}}_3 \times \hat{\mathbf{a}}_1$. The unit vectors $\hat{\mathbf{x}}, \hat{\mathbf{y}}$, and $\hat{\mathbf{z}}$ in Figs. 11.6.24 and 11.6.25 are directed along the three principal axes of inertia of the spacecraft. The attitude of the vehicle with respect to the orbiting frame is defined by the three successive rotations θ_1 (yaw), θ_2 (roll), and θ_3 (pitch) as shown in Fig. 11.6.25.

Using the above Euler angles, the gravity-gradient moment (about C) acting on the vehicle is given as

$$\mathbf{M} = \tfrac{3}{2}n^2[\hat{\mathbf{x}}(I_y - I_z)\sin 2\theta_2 \sin\theta_3 + \hat{\mathbf{y}}(I_x - I_z)\sin 2\theta_2\cos\theta_3 + \hat{\mathbf{z}}(I_x - I_y)\cos^2\theta_2 \sin 2\theta_3]$$

If the spacecraft is subject to an external (other than the gravitational attraction of E) torque $\mathbf{T} = T_x\hat{\mathbf{x}} + T_y\hat{\mathbf{y}} + T_z\hat{\mathbf{z}}$ about its center of mass C, and if its attitude deviations θ_1, θ_2, and θ_3 remain small, its linearized equations of motion are obtained as given in the following equations.

$$I_x\ddot{\theta}_1 + n\dot{\theta}_2(I_z - I_y - I_x) + n^2\theta_1(I_z - I_y) = T_x$$
$$I_y\ddot{\theta}_2 + n\dot{\theta}_1(I_x - I_z + I_y) - 4n^2\theta_2(I_x - I_z) = T_y$$
$$I_z\ddot{\theta}_3 + 3n^2(I_y - I_x)\theta_3 = T_z$$

Care must be taken in the design of a gravity-gradient stabilized satellite in order to guarantee that $I_x/I_z < I_y/I_z < 1$ for the attitude motions to be stable in the presence of the least amount of damping. For augmenting the gravity-gradient moments, booms are added to the satellite in order to make its inertia ellipsoid thinly shaped. It is interesting to note that theoretically stable motions can also be obtained when the axis of minimum moment of inertia is normal to the orbital plane. However, this orientation is unstable if damping is present, and this is what occurs in practice since all actual vehicles have parts that can move relative to each other, such as an antenna.

It is seen from the equations above that for infinitesimal oscillations the pitch motion of the satellite is uncoupled from its coupled roll-yaw motions. The natural frequency ω_p of the infinitesimal pitch oscillations is given by

$$\omega_p = n\sqrt{3(I_y - 1_x)/I_z}$$

and those of the coupled roll-yaw oscillations are given by the roots of the polynomial $\omega^4 - a_2n^2\omega^2 - a_0n^4 = 0$, where

$$a_2 = 1 - [3 + (I_z - I_y)/I_x](I_x - I_z)/I_y$$
$$a_0 = 4(I_z - I_y)(I_x - 1_z)/(I_xI_y)$$

For noninfinitesimal oscillations the pitch motion is coupled to the roll-yaw motion through nonlinear terms in the equations of motion. This coupling may give rise to an internal undesirable energy interchange between the modes of the oscillation, causing the roll-yaw motion, if uncontrolled, to oscillate slowly between two bounds. The upper bound of this nonlinear resonant roll-yaw motion may be much greater than (and independent of) the roll-yaw initial condition. For given values of I_x, I_y, and I_z, it can be decreased only by reducing the initial conditions of the pitch motion. This phenomenon can be excited if $\omega_p \approx 2\omega_1$ or $\omega_p \approx 2\omega_2$, where ω_1 and ω_2 are the two natural frequencies of the roll-yaw oscillations. The same phenomenon can also be excited if $\omega_p \approx \omega_1$ (or $\omega_p \approx \omega_2$). However, the observation of this latter

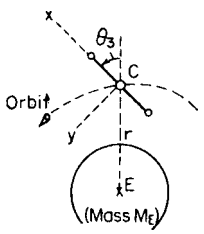

Fig. 11.6.23 Dumbell satellite.

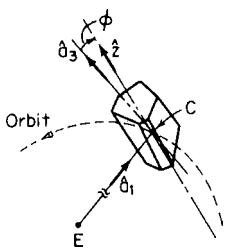

Fig. 11.6.24 Orbiting satellite.

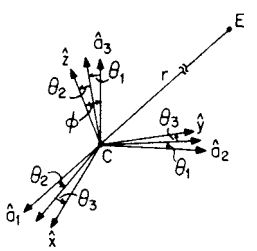

Fig. 11.6.25 Coordinate frames and Euler angles.

resonance requires a much finer "tuning" between the modes of oscillation, and therefore it is of lesser importance.

As the altitude of the orbit increases, the gravity-gradient moment decreases rapidly. For precise pointing systems, spin stabilization is used. Historically, spin stabilization was the first method used in space and is still the most commonly employed today. Simplicity and reliability are the advantages of this method when only two-axis stabilization is needed. By increasing the spin rate, the vehicle can be made very stiff in resisting disturbance moments.

A rigid body spins in a stable manner about either its axis of maximum or of minimum moment of inertia. However, in the presence of energy dissipation, even if it is infinitesimal, a spin about the axis of minimum moment of inertia leads to an unstable roll-yaw motion. Spinning satellites are built in such a way as to achieve symmetry about the spin axis which, in practice, is the axis of maximum moment of inertia. A spin of a rigid body about its intermediate axis of inertia leads to an unstable roll-yaw motion. Since damping can destroy roll-yaw stability, an individual analysis of the equations of motion must be performed to guarantee the stability of the motions when the spacecraft houses a specific damper.

For planet-orbiting spinning satellites (for which the gravitational moment can now be viewed as a disturbance) the stability of the roll-yaw motion depends not only on the magnitude of the spin rate but also on the direction of its angular velocity (relative to the orbital reference frame) due to spin. Denoting the satellite's angular velocity due to spin by $\mathbf{s} = s\hat{\mathbf{z}}$, the following inequalities must be satisfied for the roll-yaw motions of a spinning symmetric ($I_x = I_y$) satellite in a circular orbit to be stable in the presence of an infinitesimal amount of damping:

$$\left(1 + \frac{s}{n}\right)\frac{I_z}{I_x} - 1 > 0$$

$$\left(4 + \frac{s}{n}\right)\frac{I_z}{I_x} - 4 > 0$$

Very often, a spinning pitch wheel is added to a satellite to provide additional stiffness for resisting motions out of the orbital plane. Also, the inclusion of such a wheel provides more freedom to the spacecraft designer when specifying the range of the inertia ratios to guarantee that the attitude motions of the vehicle are stable.

Let us assume that a pitch wheel with axial moment of inertia I_w is connected to the spacecraft shown in Fig. 11.6.24. It is assumed that the wheel is driven by a motor at a constant angular velocity $\mathbf{s} = s\hat{\mathbf{z}}$ relative to the main body of the spacecraft. If the attitude deviations of the main body with respect to the orbiting reference frame remain small, the linearized equations for the attitude motion of the vehicle are now given as

$$I_x\ddot{\theta}_1 + n\theta_2(I_z - I_y - I_x + \beta I_z) + n^2\theta_1(I_z - I_y + \beta I_z) = T_x$$

$$I_y\ddot{\theta}_2 + n\dot{\theta}_1(I_x - I_z + I_y - \beta I_z) - n^2\theta_2[4(I_x - I_z) - \beta I_z] = T_y$$

$$I_z\ddot{\theta}_3 + 3n^2(I_y - I_x)\theta_3 = T_z$$

In these equations, the parameter β is defined as $\beta = I_w s/I_z n$, and I_x,I_y, I_z refer to the principal moments of inertia of the entire vehicle (rotor included).

Figure 11.6.26 shows a "stability chart" for this spacecraft when its center of mass, C, is describing a circular orbit around the central attracting point E. In this figure, a cut along the plane $\beta = 0$ produces the stability conditions for a gravity-gradient satellite, whereas a cut along the plane $K_1 + K_2 = 0$ (that is, $I_x = I_y$) gives rise to the inequalities for a spin-stabilized vehicle. Note that a rotor's spin rate with opposite sign to the orbital angular speed ($s < 0$) may destabilize the roll-yaw motions. Nonlinear resonances, as previously discussed, can also be excited in this vehicle. However, since the natural frequencies of the roll-yaw motions now also depend on the magnitude and sign of the internal angular momentum due to the rotor, the resonance lines are displaced in the region shown in Fig. 11.6.26 when the spin rate s of the rotor is changed to a different constant. Therefore, this phenomenon, when excited, can be avoided simply by changing the parameter β.

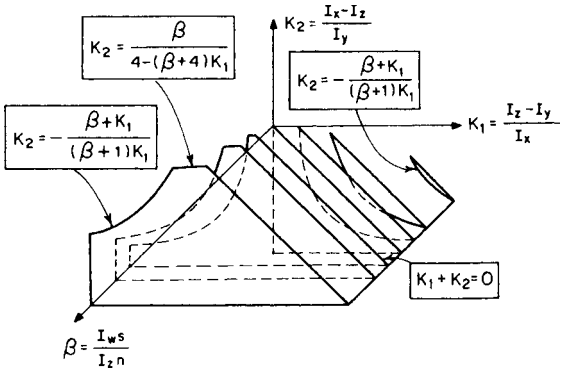

Fig. 11.6.26 Stable region of the vehicle parameter space.

For a spacecraft to perform its mission adequately during a long period of time, an attitude control system to maintain the vehicle's attitude within specified limits is necessary. Typically, this is done by means of a set of mass expulsion jets mounted on the vehicle, which are actuated by the output of a controller that receives information from the attitude sensors.

Drag-Free Satellites For scientific applications that require the use of a satellite that follows a purely gravitational orbit, a translational control system is incorporated into the vehicle. Typical applications include satellite geodesy and navigation where accurate ephemeris prediction is needed. A drag-free satellite consists of a vehicle that contains a spherical cavity which houses an unsupported spherical proof mass. Sensors in the satellite detect the relative position of the proof mass inside the cavity and activate a set of thrustors placed in the vehicle, forcing it to follow the proof mass without touching it. Since the proof mass is shielded by the satellite from nongravitational forces, it follows a purely gravitational orbit.

METALLIC MATERIALS FOR AEROSPACE APPLICATIONS

A wide variety of materials are utilized in aerospace applications where performance requirements place extreme demands on the materials.

Some of the more important engineering properties to be considered in the selection of materials are (1) strength-to-weight ratio, (2) density, (3) modulus of elasticity, (4) strength and toughness at operating temperature, (5) resistance to fatigue damage, and (6) environmental effects on strength, toughness, and fatigue properties. Factors such as weldability, formability, castability, quality control, and cost must be considered.

Although it is desirable to maximize the strength-to-weight ratio to achieve design goals, materials with high strength-to-weight ratios generally are sensitive to the presence of small cracks and may exhibit catastrophic brittle failure at stresses below the nominal design stress. The problem of premature brittle fracture is accentuated as the temperature decreases and the yield and ultimate strength increase. For these reasons it is imperative that the tendency toward brittle failure be given major consideration for low-temperature applications. For example, liquid oxygen, a common oxidizer, boils at −297°F (−183°C) whereas liquid hydrogen, an important fuel, boils at −423°F (−253°C), and the problem of brittle failure is predominant. The fracture-mechanics approach has gained wide acceptance, and nondestructive inspection (NDI) characterization of flaws allows safe operating stresses to be calculated. A considerable amount of fracture-mechanics data has been collected and evaluated ("Damage Tolerant Design Handbook"). Stress corrosion cracking and corrosion fatigue become important for repetitive-use components such as aircraft airframes, landing gear, fan shafts, fan and compressor blades, and disks, in addition to brittle fracture problems such as fatigue crack formation and propagation.

The presence of flaws must be assumed (they may occur either during processing or fabrication) and design must be based on **fatigue crack propagation** (FCP) properties (Sec. 5). FCP of many materials follows an equation of the form

$$da/dN = R(\Delta K)^n \qquad (11.6.1)$$

where a refers to crack length, N is the number of cycles, K is the fluctuation in the stress-intensity parameter, and R and n are material constants. Equation (11.6.1) can be integrated to determine the cyclic life of a component provided that the stress-intensity parameter is known (Sec. 5). Although fatigue-crack initiation is generally retarded by having smooth surfaces, shot-peening, and other surface treatments, FCP of commercial aerospace alloys is relatively insensitive to metallurgical treatment and, to a reasonable approximation, whole classes of materials (i.e., aluminum alloys, high-strength steels, etc.) can be represented within the same scatter band.

It should be noted that increases in the plane-strain fracture toughness K_{IC} result in increased stress, through its linear relationship to the stress-intensity parameter, which in turn causes an exponential increase in the FCP rate and may introduce a fatigue problem where previously there was none.

The effect of environment on materials used for aerospace problems is usually to aggravate the FCP rate. It should be emphasized that fatigue loads have a synergistic effect on the environmental component of cracking and that the crack growth rate during corrosion fatigue is rarely the sum of the FCP and stress-corrosion cracking rates. In weldments of castings or wrought material, tests are needed to simulate anticipated use conditions and to prove weld soundness.

Materials in the turbine section of jet engines are subjected to deleterious gases such as O_2 and SO_2, high temperatures and stresses, and cyclic loads. Consequently the most significant metallurgical factors to consider are microstructural stability, resistance to oxidation and sulfidization, creep resistance, and resistance to low cycle fatigue. Nickel-base superalloys are generally used in the turbine section of the engine for both disks and blades. (See "Aerospace Structural Metals Handbook," Vols. II and IIA, for specific properties.) Although the Ni-base superalloys generally exhibit excellent strength and oxidation resistance at temperatures up to 1,800°F (982.22°C), the interactive effects of sustained and cyclic loads are difficult to handle because, at high temperature, plastic deformation of these materials is time-dependent. An approach based on strain range partitioning is described in ASTM STP 520, 1973, pp. 744–782. The utility of this approach is that frequency and temperature dependence are incorporated into the analysis by the way in which the strain is partitioned and reasonable envelopes of the expected life can be calculated.

STRUCTURAL COMPOSITES

by Terry S. Creasy

Texas A & M University

REFERENCES: MIL-HDBK-17, "Plastics for Aerospace Vehicles," Sept. 1973. Advanced Composites Design Guide, Vols. I–V, 3d ed., Sept. 1976. Herakovich, "Mechanics of Fibrous Composites," 1998.

High-performance composite materials are fiber-filled matrix materials with specific strength (strength/mass) and specific stiffness (modulus/mass) greater than that found in monolithic materials such as high-performance alloys or polymers (Fig. 11.6.27). The fibers contribute high strength and stiffness to the composite. The fibers and matrix must be chemically compatible and structurally sound at the application temperature.

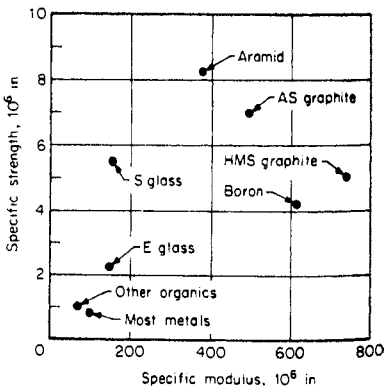

Fig. 11.6.27 Specific properties of nonmetallic reinforcement materials compared with most metals. *(Hercules Aerospace Co.)*

A first-order estimate of the composite's effective Young's modulus in the fiber (primary) direction can be found using the rule of mixtures relation:

$$E_1 = (E_f - E_m)V_f + E_m$$

where the Es indicate the Young's modulus of the composite (1), the fiber (f), and the matrix (m), and the volume fraction of the fiber in the composite is V_f. The fiber volume fraction of fiber composites can vary between 0.5 and 0.7, i.e., 50 to 70 percent. Inspection of this relation shows that the effective Young's modulus E_1 is less than the fiber's modulus but greater than the modulus of the matrix material. Fiber composites are anisotropic—their properties are strong functions of the material orientation. The composite's stiffness perpendicular to the fiber direction (transverse direction) comes from this equation:

$$E_2 = \frac{E_m}{V_f\left(\frac{E_m}{E_f} - 1\right) + 1}$$

In the range of typical fiber volume fraction, the transverse modulus E_2 is only moderately larger than that of the matrix alone. Combined layers of composite produce a laminated structural material. As the primary and secondary modulus equations suggest, the properties will vary with the orientation of the material. The fiber placement must address the state of stress in the design.

Material selection must address two issues: (1) the fibers must provide the specific strength and stiffness needed for the design and (2) the matrix must be compatible with the fibers and they must survive the maximum use temperature for the application.

Table 11.6.6 Properties of Fibers Used in Composites

Fiber	Modulus, 10^6 lb/in^2	Tensile strength, ksi	Tensile failure strain, %	Specific gravity	Density, lb/in^3
Boron (4 mil)	60	460	0.8	2.60	0.094

* With oxidation resistance.

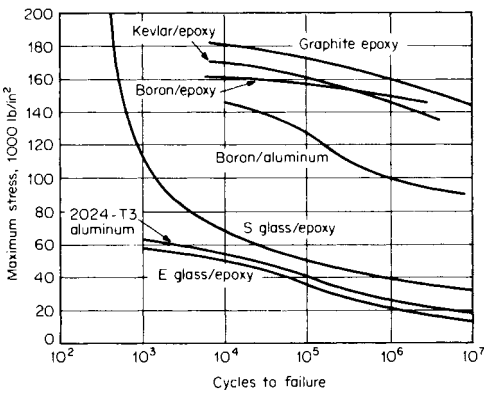

Fig. 11.6.28 Fatigue behavior of unidirectional composites and aluminum. *(Hercules Aerospace Co.)*

Finally, composite materials provide two unique capabilities for astronautic structures. Some carbon fibers have a negative coefficient of thermal expansion of approximately -0.2×10^{-6} in/in. With careful design a composite structure can compensate for expansion and contraction of other components. In addition, carbon fibers provide high thermal conductivity in the fiber direction. Thermal management of astronautic systems can take advantage of this capability.

MATERIALS FOR USE IN HIGH-PRESSURE OXYGEN SYSTEMS

by Robert L. Johnston
NASA

Oxygen is relatively reactive at ambient conditions and extremely reactive at high pressures. The design of high-pressure oxygen systems requires special consideration of materials and designs. The types of potential ignition sources that could be present in even a simple component are quite varied. Sources of ignition include electrical failures, particle impact in high-flow regions, pneumatic shock, adiabatic compression, fretting or galling, and Helmholtz resonance in blind passages. Other sources of ignition energy are also possible. A comprehensive review of potential design problems is available in NASA Reference Publication 1113, A.C. Bond et al., "Design Guide for High Pressure Oxygen Systems."

Materials currently used in high-pressure oxygen systems range from ignition-resistant materials like Monel 400 to materials of widely varying ignitability like butyl rubber and the silicones. The range of ignitability of various materials is shown in Figs. 11.6.29 and 11.6.30.

While material selection alone cannot preclude ignition, proper choices can markedly reduce the probability of ignition and limit propagation. Selecting materials with small exothermic heats of combustion will reduce the possibility of propagation. Materials with high heats of

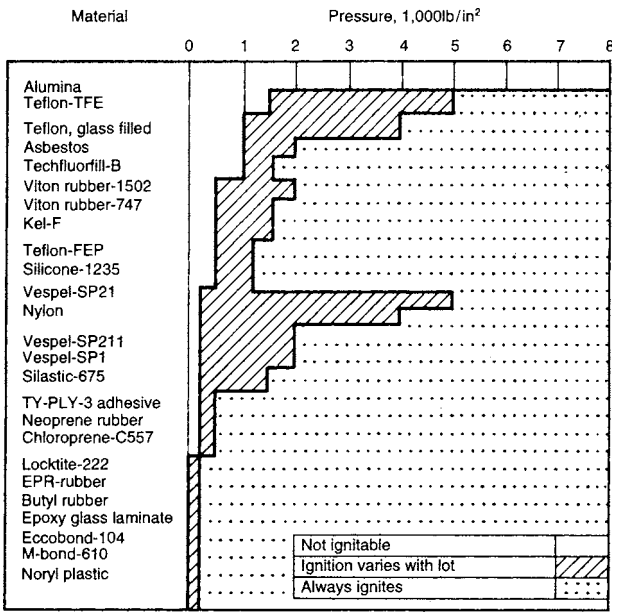

Fig. 11.6.29 Ignition variability of current oxygen-system nonmetallic materials.

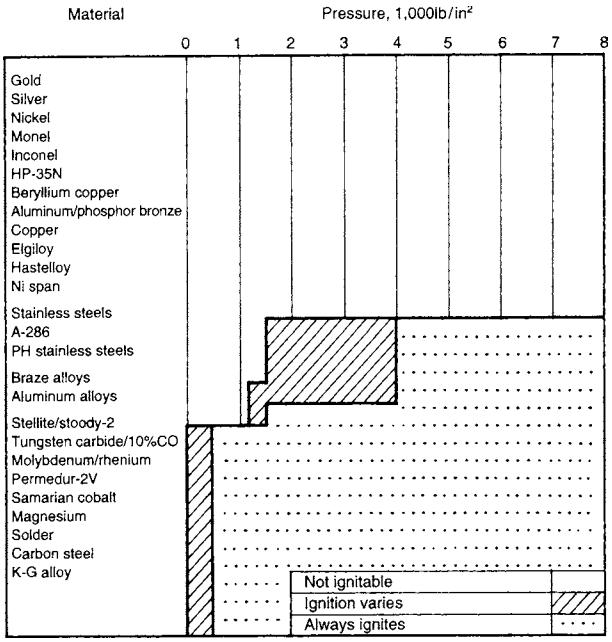

Fig. 11.6.30 Ignition variability of current oxygen-system metallic materials.

combustion (stainless steels) or very high heats of combustion (aluminum) should be avoided. A summary of heats of combustion, as well as other design properties of a few currently used materials, is shown in Table 11.6.8.

The materials listed in Table 11.6.9 have superior resistance to ignition and fire propagation in high-pressure oxygen systems. Monel alloys are available in the necessary range of hardnesses. Springs can be made of Elgiloy. Sapphire poppet balls should replace tungsten carbide or steel balls because sapphire has a lower level of reactivity (and therefore is less combustible) than either tungsten carbide or steel and is more resistant than tungsten carbide to breakup under mechanical impact in an oxygen environment.

Titanium and its alloys, normally attractive as materials for pressure vessels, cannot be used for oxygen vessels because they are impact-sensitive in oxygen. Inconel is a good choice for vessels for high-pressure oxygen.

In no case should an alloy be used at an oxygen pressure above which it can be ignited by particle impact. This criterion would limit the use of aluminum alloys and stainless steels to pressures below 800 lb/in^2 to allow some margin for error in test results and impact predictions.

METEROID/ORBITAL DEBRIS SHIELDING

Valve balls	Sapphire
Lubricants	Batch- or lot-tested Braycote 3L-38RP
	Batch- or lot-tested Everlube 812
O-seals and backup rings	Batch- or lot-tested Viton
	Batch- or lot-tested Teflon
Pressure vessels	Inconel

Spacecraft shielding is designed to prevent a majority of the meteoroid/orbital debris particles that can impact the spacecraft during its lifetime from causing serious damage that would endanger the continuing operation of the spacecraft and/or endanger crew survivability. Because of spacecraft size and mass constraints, it is not possible with current shielding technology to eliminate completely the risk from meteoroid/orbital debris (M/OD) impact. Current practice calls for designing shields to meet or exceed protection requirements, which are generally expressed in terms of a minimum acceptable reliability level or success criteria (i.e., a probability of *not* being struck by a M/OD particle that will completely penetrate through the spacecraft shielding). Shielding is an important component of the overall strategy used to reduce the risk from meteoroid/orbital debris impact, which can also include other operational means, such as collision warning and avoidance to reduce the risk from orbital debris impact.

Spacecraft M/OD Environment

NASA standard meteoroid and debris environment models are used in the risk assessments to determine the cumulative flux of particles with a diameter that exceeds the ballistic limits. The environment models indicate that there are many more smaller particles than larger particles. Thus, raising the shielding performance in terms of the M/OD particles sizes the shielding can "stop" decreases the flux of penetrating particles and improves spacecraft reliability.

Meteoroid Environment Model Meteoroids are the natural particles in orbit about the sun, which have quite high impact velocities relative to spacecraft in orbit about earth. Meteoroid velocities range from 11 km/s to 72 km/s, with an average for earth orbiting spacecraft of 19 km/s. A majority of meteoroids impacting a spacecraft are thought to originate from comets, with relatively low particle densities, ranging from 2 g/cm^3 (for particles 1 μg and less) to 0.5 g/cm^3 (particle mass 0.01 g and greater). This is contrasted with the meteorites that survive atmospheric entry and are found on earth's surface, which are higher

Table 11.6.8 Physical Properties of Typical Oxygen System Metallic Materials

Property	Aluminum alloys	Stainless steel	Inconel 718	Monel 400
Density, lb/in^3	0.10	0.28	0.30	0.31
Tensile, ultimate, lb/in^2	40,000	140,000	180,000	145,000
Maximum use temperature, °F	350	950	1,200	1,000
Heat of combustion, Btu/lb	130,000	33,500	15,100	14,200
Maximum use pressure, lb/in^2	1,250	1,250	8,000	8,000

density and thought to originate mainly from asteroids. The meteoroid environment model to be used for shielding design is defined in the NASA documentation.

Orbital Debris Environment Model Orbital debris is human-created pieces of spacecraft that are in orbit about earth (Fig. 11.6.31). Orbital debris impact velocities are lower than meteoroids, generally impacting spacecraft in low earth orbit at relative speeds of less than 1 km/s to just over 15 km/s, with an average velocity of about 9 km/s for a 400-km altitude. The debris environment threat is composed of metallic fragments, paint, aluminum oxide, and other components of spacecraft and solid-rocket motor exhaust. Typically, for debris risk assessments, orbital debris particle density is assumed to be 2.8 g/cm^3, corresponding to aluminum metal. Because the orbital debris environment is tied to human activities in space, it is much more dynamic then the meteoroid environment, and the orbital debris environment definitions are subject to periodic updates and revisions as more data is collected on the amount and evolution of orbital debris in earth orbit. The current debris environment model for purposes of shielding design is defined by NASA TP-2002-210780 and referred to as ORDEM2000.

Fig. 11.6.31 Orbital debris "snapshot."

Design Requirements

Vehicles from the early years of space exploration have used the probabilistic approach to design meteoroid shielding. Table 11.6.10 provides a listing of historical M/OD protection design requirements. Generally, each program defines "critical" penetrations as those that would endanger the survivability of the vehicle and/or crew, although requirements for mission success and functionality have been applied as well.

Space Station Design Requirements The Space Station has meteoroid/debris protection requirements consistent with past programs. As such, it carries by far the most capable meteoroid/debris shields ever flown. This is because ISS is larger and exposed longer than other space vehicles. It operates at higher altitudes in general than other spacecraft and its operation will extend into the future. These factors increase the expected number of meteoroid/debris impacts. To meet comparable protection requirements, ISS shielding must be more effective. For instance, most ISS critical hardware exposed to the M/OD flux in the velocity vector (front) or port/starboard (side) directions will be protected by shields effective at stopping 1- to 1.3-cm-diameter aluminum debris particle at typical impact velocity and angle (9 km/s, 45°). In comparison, the Mir space station is able to stop 0.3-cm particles, the space shuttle orbiter is capable of stopping 0.2- to 0.5-cm particles, and Apollo and Skylab were able to stop 0.15 to 0.2-cm particles under similar impact conditions. ISS will also have the ability to maneuver from ground-trackable debris particles (typically >10 cm diameter). By virtue of the large internal volume of ISS, its crews will have time to locate and isolate leaks, if they were to occur, by closing hatches. Hole repair kits will be available and crews will be trained to repair a leak in a module if it occurs. Crew escape vehicles will be docked to ISS in the event of a major event requiring evacuation.

Risk Assessment Process

The approach to evaluating and designing protection systems to meet requirements is illustrated in Fig. 11.6.32. By using this methodology, the analyst will be able to accurately evaluate spacecraft risks from M/OD impact, identify zones or areas of the spacecraft that are the "risk drivers" that control the M/OD risk, and evaluate options to reduce risk. Each major step in the risk assessment process is described in the following sections.

Space Geometry Spacecraft size is directly proportional to the number of impacts as given in Eq. (11.6.1). Risk of M/OD impact failure increases as the area and time exposed to the M/OD flux increases.

$$N = \sum_{i=1}^{n} N_i = \sum_{i=1}^{n} (FAt)_i \qquad (11.6.1)$$

where N is the number of impacts causing failure and is equal to the sum of the impact failures in each region (N_i) over all regions ($i = 1$ to n) of the spacecraft. N_i is found from the product of flux (F, number/m^2-year) of meteoroid and debris impacts that exceed the failure ballistic limits of a region, exposed area (A, m^2), and time (t, year). It is important to break down the spacecraft geometry into different regions, each with a

Table 11.6.10 Historical Meteoroid/Debris Shielding Requirements

Vehicle	Environments	Required probability of no penetration (PNP)
Apollo command module	Meteoroid	0.996 per 8.3-day mission
Skylab module	Meteoroid	0.995 for 8-month mission
Shuttle orbiter	Meteoroid	0.95 for 500 missions (design requirement)
	Meteoroid and debris	0.995 per mission (for critical penetration)
	Meteoroid and debris	0.984 per mission (for radiator leak—mission abort)
Spacelab module	Meteoroid	0.999 for 7-day mission
Hubble space telescope	Meteoroid and debris	0.95 for 2 years
ISS	Meteoroid and debris	0.98 to 0.998 per critical element over 10 years

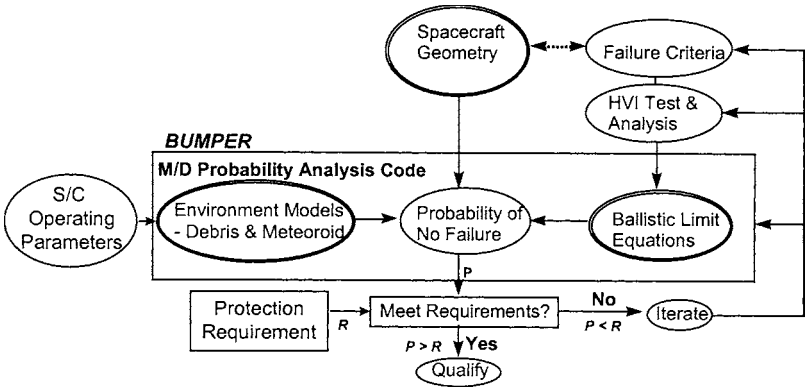

Fig. 11.6.32 Meteoroid/orbital debris risk assessment methodology.

different exposed area, materials of construction, shielding configurations, and thickness. For instance, there are over 400 different shields protecting International Space Station (ISS) habitable modules and external critical items (pressure vessels, control moment gyros) which have been optimized according to their location and exposure to the M/OD threat to provide the necessary M/OD protection.

Impact Directionality The front and sides of a spacecraft are more exposed to debris impact, while the front, sides, and top (zenith) are more exposed to meteoroid impact. The Long Duration Exposure Facility (LDEF) had 20 times more craters observed on the forward face compared to the aft, and 200 times more craters on the forward than the earth-facing side (Fig. 11.6.33). Heavier shielding is typically placed on front and sides of spacecraft with fixed orientation relative to the velocity direction to protect from higher impact rates on these surfaces.

Spacecraft Failure Criteria A key step in the risk assessment process is to precisely define what is meant by "failure," that is, to define potential damage modes from M/OD impact and, for each, to quantify the minimum amount of damage that can lead to failure of spacecraft hardware. This definition establishes the failure criterion or criteria that are assigned to each region of the spacecraft geometry model. For instance, M/OD damage modes and failure criteria for elements of the Space Station are given in Table 11.6.11.

Hypervelocity Impact Tests Hypervelocity impact (HVI) tests are an integral part of the analyses conducted to ensure adequate design of spacecraft M/OD shielding. Two-stage light-gas guns (LGGs) are used to accelerate projectiles up to 7 km/s (Fig. 11.6.34). LGGs are capable

Fig. 11.6.33 Long duration exposure facility.

of launching a variety of different and well-controlled projectile shapes. A disadvantage is that LGGs are capable of velocities that cover only a fraction of the orbital debris threat. Since average orbital debris velocity in low-earth orbit is on the order of 9 km/s, LGG can directly simulate only 40 percent of the orbital debris threat.

Other techniques exist to launch projectiles at speeds over 10 km/s. For instance, an inhibited shaped-charge launcher (ISCL) at Southwest Research Institute (SwRI) is capable of launching aluminum projectiles, 0.25 g to 2 g mass, in the shape of a cylinder to 11.5 km/s (Fig. 11.6.35). Another high-speed launcher that has provided useful information on shield capabilities in excess of 10 km/s is the three-stage hypervelocity launcher (HVL) developed at Sandia National Laboratories.

Table 11.6.11 Damage Modes and Failure Criteria for Space Station Elements
(Note: Critical failure criteria marked with*.)

Critical elements	Thermal protection system (TPS) damage	Spall/perforation of shield exterior of pressure shell	Perforation of pressure shell	Uncontrolled decompression	Catastrophic rupture	Detonation
Crew modules			X*	X	X	
Pressure vessels (liquids and gases)		X*[1]	X*[1]		X	X
Control moment gyros (rotating equipment)		X*			X	
Crew return vehicles	X		X*	X	X	

[1] Failure criterion for Russian PVs is perforation of pressure shell. Failure criterion of other designs is perforation or detached spall of shielding surrounding PV.

Functional elements	Surface degradation	Leak	Short or open circuit
Radiator panels	X	X	
Radiator flex/hard lines		X	
Thermal loop lines and exchangers		X	
Power cables			X
Batteries		X	X
Solar arrays	X		X
Data lines/cables			X
Window outer panes	X		

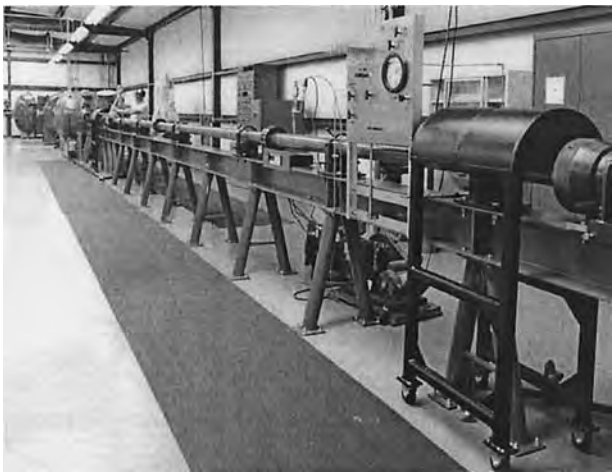

Fig. 11.6.34 NASA JSC-WSTF two-stage light-gas gun.

This launches thin disks (L/d = 0.1 to 0.2, mass = 0.2 to 1 g) of aluminum and titanium from 10 to 15 km/s with some bowing and tilting of the projectile. Hydrocode simulations are used to assess projectile shape effects on shield response.

Ballistic Limit Equations

Ballistic limit equations (BLEs) or "penetration" equations are based on the HVI test results, numerical simulations, and analytical assessments (Christiansen, 2003). BLEs describe the particle sizes that are on the failure threshold of a particular spacecraft component. The ability of a particular shield to withstand hypervelocity impact is predicted by a BLE. BLEs are a function of the target "failure criteria"; target configuration, materials, and thickness; and projectile parameters such as velocity, angle, shape, and density. M/OD risk assessments require a BLE defined for each surface of a spacecraft, for each failure criterion assessed. Shield design equations have also been developed that provide a means to estimate shielding parameters needed to defend against specific projectile threats.

Because of the complexity of spacecraft and their HVI failure modes, many different ballistic limit equations exist for a wide variety of shielding types, spacecraft components and hardware, and differing damage/failure modes. A description of ballistic limit equations for one particular type of shield, the basic Whipple shield, is provided in the following section. This example illustrates the considerations involved in developing ballistic limit equations.

Whipple Shield Ballistic Limit Equations

Fred Whipple proposed in the 1940s a meteoroid shield for spacecraft consisting of a thin "sacrificial" bumper at a distance from a rear wall.

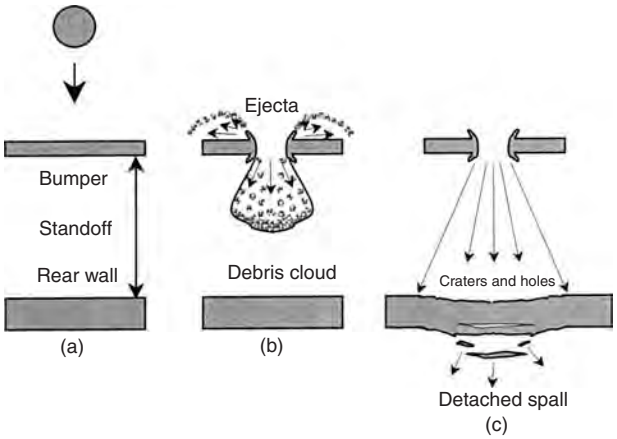

Fig. 11.6.36 Whipple shield. (*a*) Whipple shields consist of a bumper, standoff (gap or spacing), and real wall. (*b*) Hypervelocity impacts will generate a cloud of bumper and projectile debris that can contain solid fragments, liquid, and vapor particles. (*c*) The rear wall must survive the fragments and debris cloud impulsive loading. It could fail by perforation from solid fragments, spall, or tear and petal from the impulsive loading.

The Whipple shield is shown in Fig. 11.6.36. The function of the first sheet, or bumper, is to break up the projectile into a cloud of material containing both projectile and bumper debris. This cloud expands while moving across the standoff, resulting in the impactor momentum being distributed over a wide area of the rear wall (Figs. 11.6.37 to 11.6.39). The back sheet must be thick enough to withstand the blast loading from the debris cloud and any solid fragments that remain. For most conditions, a Whipple shield results in a significant weight reduction over a single plate, which must contend with deposition of the projectile kinetic energy in a very localized area.

Whipple shields were used to provide protection to the Apollo command module and lunar lander. Apollo shields were capable of stopping 0.16-cm-diameter aluminum particles at 7 km/s, normal impact angle (0°).

Whipple Shield Design Equations For design purposes, Eq. (11.6.2) to (11.6.4) provide bumper and rear wall thickness to defeat a given threat particle (assuming $V_n \geq 7$ km/s).

$$t_b = c_b m_p/\rho_b = c_b d\rho_p/\rho_b \tag{11.6.2}$$

$$t_w = c_w d^{0.5} \mathrm{M}^{1/3} (\rho_p \rho_b)^{1/6} \rho_w^{-1} (V \cos\theta) S^{-3/4} \sigma'^{-1/2}_h \tag{11.6.3}$$

where $c_b = 0.25$ when $S/d < 30$, $c_b = 0.20$ when $S/d \geq 30$, and $c_w = 0.79\ \mathrm{cm}^{-3/4} \cdot \mathrm{s} \cdot \mathrm{g}^{1/3} \cdot \mathrm{km}^{-1}$. Normalized yield stress (unitless) $\sigma'_h = (\sigma/70\,\mathrm{ksi})$.

The ballistic limit criterion is no perforation or spall of the rear wall. Bumper fragments become the primary source of rear wall damage at impact angles greater than 65°. Therefore, for oblique angles over 65°,

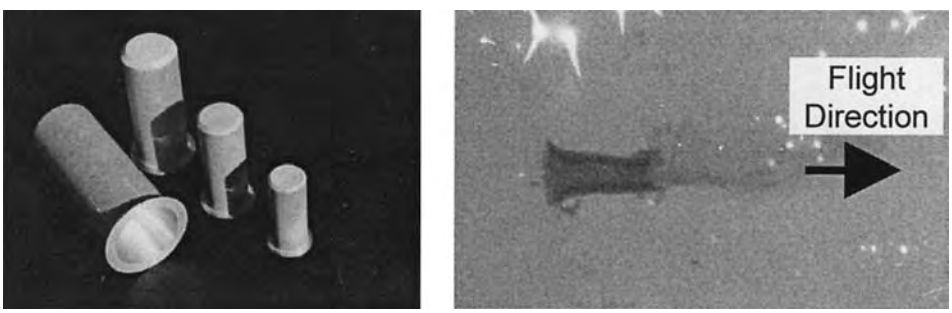

Fig. 11.6.35 SwRI's inhibited shaped-charge launcher. Various size charges are available that are capable of launching 0.25 to 2 g aluminum projectiles up to 11.5 km/s (left view). Projectiles are typically in the shape of a hollow cylinder (right view.)

Fig. 11.6.37 A 0.32-cm projectile impacts bumper at 6.8 km/s, left to right, with 1 μs between frames. [High-speed camera film *(photograph by Cordin)*.]

the calculated rear wall thickness should be constrained to 65°. Coefficient c_w should be adjusted by the factor $[(S/d)/(S/d)_0]$ where $(S/d)_0 = 15$, when $S/d < 15$, as follows.

$$c_w = 0.79\,[(S/d)/(S/d)_0]^{-0.185} \qquad (11.6.4)$$

Fig. 11.6.39 Rear wall after impact.

Whipple Shield Ballistic Limits for All Impact Velocities Typical ballistic limits for a Whipple shield at all impact velocities are illustrated in Fig. 11.6.40 for normal impact by an aluminum sphere. The Whipple shield ballistic limit is compared to a monolithic, single aluminum plate of same mass as the combined Whipple shield's bumper and rear wall. Protection capabilities are defined for three penetration regimes based on normal component velocity (V_n) for an aluminum impact on a Whipple shield: ballistic regime ($V_n < 3$ km/s), fragmentation regime (3 km/s $< V_n <$ 7 km/s), and melt/vaporization regime ($V_n > 7$ km/s). Important shield physical and material properties that influence ballistic limits of the shield vary as a function of impact velocity. Equations used to quantify ballistic limits for various types of shields are provided in the literature (Christiansen, 2003).

A key factor governing the performance of spaced shields is the "state" of the debris cloud projected from the bumper toward the rear wall. The debris cloud may contain solid, liquid, or vaporized projectile and bumper materials, or a combination of the three states, depending

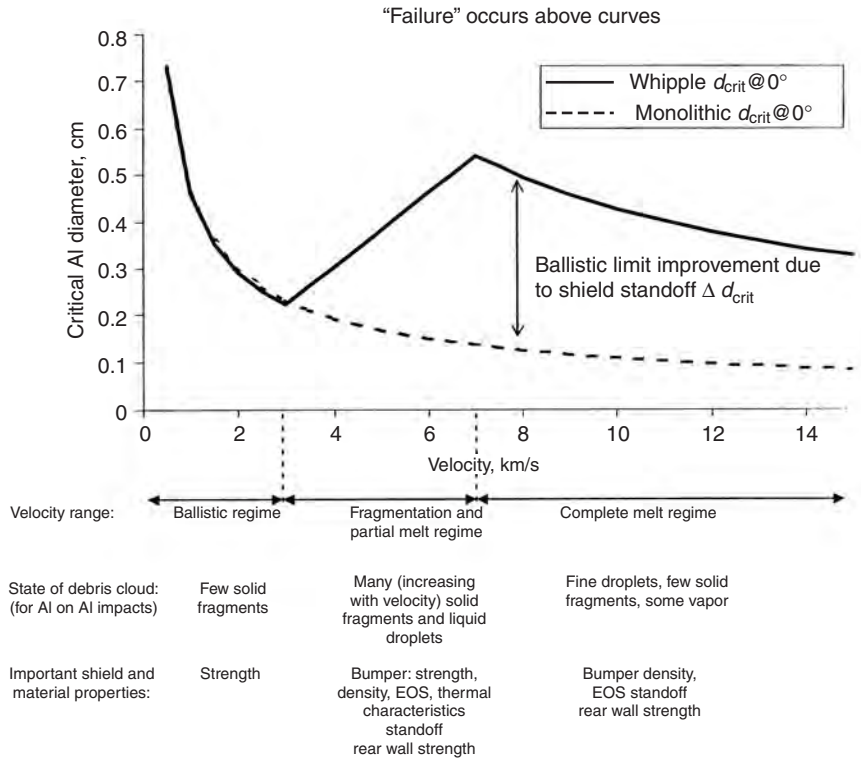

Fig. 11.6.40 Ballistic limits for equal mass monolithic target and Whipple shield. Failure criterion is threshold perforation or detached spall from rear wall. Monolithic target is 0.44-cm-thick Al 6061T6. Whipple shield consists of 0.12-cm-thick A1 6061T6 bumper followed at 10 cm by 0.32-cm-thick A1 6061T6 rear wall.

on the initial impact pressure. Solid fragments in the debris cloud are generally more penetrating when they contact the rear wall than liquid or vapor particles. Blast loading in the rear wall is a function of shield standoff, which becomes of increasing importance as impact velocity increases above about 5 km/s.

Bumper Code

The BUMPER code has been the standard in use by NASA and contractors to perform meteoroid/debris risk assessments since the early 1960s. Over that period of time, it has undergone extensive revisions and updates. NASA has applied BUMPER to risk assessments for space station, shuttle, Mir, extravehicular mobility units (i.e., "space suits"), and other satellites and spacecraft. Significant effort has been expended to validate BUMPER and "benchmark" it to other M/OD risk assessment codes used by some ISS international partners. Figure 11.6.31 illustrates where BUMPER fits in the risk assessment process. The BLEs and M/OD environment models are embedded into BUMPER. A finite-element model (FEM) that describes the spacecraft geometry is created in and input into BUMPER. BUMPER calculates the number of failures by determining the number of M/OD particles that exceed the ballistic limits for each element of the FEM, and calculates the total number of failures by summing the individual elements. BUMPER results are used to determine the risk drivers, that is, the areas on the spacecraft that control the risk. Emphasis on risk reduction is placed on lowering the risk for the drivers.

Probability of No Penetration (PNP)

Probability of no penetration (PNP) failure is assessed on the basis of Poisson statistics [Eq. (11.6.5)], where N is defined by Eq. (11.6.1). This is NASA's standard approach used to assess meteoroid shielding since Apollo. The same probabilistic approach has been extended to designing spacecraft protection systems for the combined meteoroid and debris environments, assessing risks of functional failure, or calculating risks of impact damage exceeding a user-defined size (diameter or depth). The same statistical approach is used to assess risks of any kind of damage extent that can be expressed in terms of different ballistic limit equations.

$$\text{PNP} = \exp(-N) \tag{11.6.5}$$

The risk of penetration is:

$$\text{Risk} = 1 - \text{PNP} \tag{11.6.6}$$

Analysis Iteration and Design Qualification

Assessed PNP is compared to requirements for M/OD protection. The shielding design effort is successful when the assessed PNP is greater than the required PNP. As illustrated in Fig. 11.6.31, iteration of the risk assessment and risk reduction process is often necessary to meet protection requirements and optimize the design, i.e., meet the requirements with less weight, lower volume (less standoff), less cost, etc. The last step in the process is to conduct final shield verification by analysis (supported by HVI test as appropriate), prior to final design certification and acceptance.

Risk Reduction Practices

Engineering practices to decrease risk, improve shielding performance, and decrease shielding mass are summarized below.

Find M/OD Risk Drivers Perform detailed assessment of penetration risks for the overall vehicle to determine the zones that control the risks. Selectively improve the protection capability in the areas identified as risk drivers.

Shielding Enhancement

1. Optimize the shielding weight distribution to account for the directional M/OD distribution. Shielding on each critical item is tailored for the environment and its location on station. Because M/OD impact rate is highest on forward and side surfaces, more capable shielding (heavier or with greater standoff) is applied to these surfaces and less on the earth-facing surface. Shielding is also reduced in areas where shadowing from neighboring structures will reduce impacts. The goal of this effort is to equalize the ratio of risk to area for the various vehicle zones. The risk/area ratio for each zone is assessed and optimized by repeated BUMPER code runs.
2. Incorporate enhancements such as increasing the spacing between bumper and rear wall, or using higher-performance alloys and materials for the rear wall.
3. Implement more-fundamental changes such as incorporating more efficient, multibumper shielding concepts.
4. Incorporate toughening materials, such as ceramic fabric and high-strength fabric into the multilayer insulation (MLI) thermal blanket that is often integral to the M/OD shielding.

Impact Reduction

1. *Maximize shadowing.* Take advantage of shielding/shadowing from neighboring items. Locate external critical equipment to trailing or earth-facing surfaces to reduce M/OD impact rates, or put them in areas highly shadowed by other hardware.
2. *Select low frontal area orientations*. It has been shown that the best orientation for a relatively short cylinder (length/diameter of 1.8) in terms of lowest meteoroid/debris impact risk is with cylindrical length axis oriented perpendicular to the orbital plane. A vertical (gravity-gradient) orientation (with length axis parallel to earth radial) has a 30 percent higher M/OD impact risk. An orientation with length axis parallel to velocity vector is in the middle.
3. *Flight attitude.* Selecting the best flight attitude by pointing the most vulnerable surfaces aft or toward earth is standard procedure for the shuttle. Other spacecraft can take a similar approach.

Insert Stored Energy Equipment After use, stored energy equipment should be made inert if possible. For instance, completely depressurize any storage tank after it is emptied. The risk of catastrophic rupture is eliminated when stress levels in the pressure wall are made negligible by depressurizing to a small value. This would require design modifications to implement for propellant tanks and other fluid storage tanks. Another example is to keep spare flywheels, gyros, and other momentum storage devices in an inactive state until required. A corollary idea for gaseous pressure vessels is to use them in series (not parallel) and deplete first the pressure vessels in the locations that are most exposed to M/OD impact (those in the forward or side positions), followed by less exposed positions.

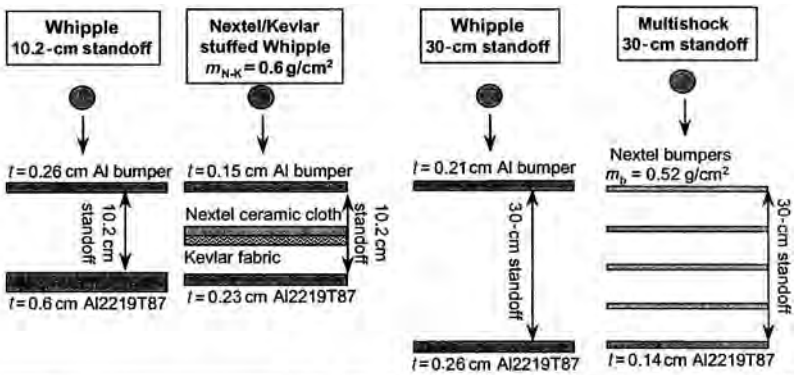
Reduce Hazards if Shield Penetration Occurs Design and operational options may exist to reduce hazards if a penetration occurs. For instance, some hatches to unoccupied modules can be kept closed to prevent a depressurization of an entire station if a penetration occurred to the module. A perforation into an unoccupied module with hatch closed would not result in loss of crew from the fragments/shrapnel, light flash, acoustic overpressure, or depressurization. Vent lines between modules could be left open to allow for some air circulation and to keep pressures equalized to facilitate hatch opening during normal operations.

Critical Damage Detection, Repair, and Replacement (R&R) Inspection and repair of impact damage to critical areas of reentry vehicles (such as the crew return vehicle attached to ISS) can be used as a supplement to M/OD shielding for maintaining flight worthiness. Some impact damage to thermal protection systems (TPS) on earth-return vehicles is not a hazard while on orbit (and may therefore be undetected) but could become hazardous later during reentry aerodynamic heating phases. Properly placed instrumentation with correct sensitivity to detect critical TPS damage can help support the inspection/detection process.

Enhanced Shielding

The primary purpose of developing improved shielding is to provide higher levels of spacecraft meteoroid/debris protection with less weight.

To illustrate the issue, consider the shielding required to stop 1-cm-diameter aluminum projectiles at 7 km/s, 0° impact angle. Four shield concepts to meet the requirement are given in Fig. 11.6.41: a conventional aluminum Whipple shield with a 10.2-cm standoff, a



Areal density (kg/m²)	Whipple S = 10 cm	Stuffed Whipple S = 10 cm	Whipple S = 30 cm	Multishock S = 30 cm
Bumper:	7.0	10.6	5.6	5.2

Total: (include support)	3800	3050	2340	1720

Fig. 11.6.41 Shielding concepts comparison. (Projectile in all cases 1-cm-diameter aluminum, 1.5 g, 7 km/s, normal impact.)

Nextel/Kevlar stuffed Whipple shield with the same standoff, a Whipple shield with a 30-cm standoff, and a Nextel multishock shield concept. The stuffed Whipple shield incorporates a blanket between the outer aluminum bumper and inner pressure wall that combines two materials: Nextel™ ceramic fabric and Kevlar™ high-strength fabric. The shielding mass estimates are made assuming the shielding encloses a cylinder, with 4.2-m inside diameter by 8.5 m long. Stuffed Whipple and multishock shields are described in more detail later in this section. But it is clear for this example that there are significant mass savings by using advanced shielding concepts (i.e., up to 50 percent reduction).

Also, it is possible to trade weight for protection capability (i.e., capability and shield PNP are related), so it can be shown that lower weight and more effective protection in terms of higher PNP are possible by using Nextel/Kevlar stuffed Whipple and multishock shields, compared to conventional Whipple shields.

SPACE-VEHICLE STRUCTURES

Space vehicles include a large variety of vehicle types, like their predecessors, earth vehicles. Airplanes were the first generation of space vehicles, and our definition of space vehicle has changed as the airplane approached the limits of the earth's atmosphere. Space, in this discussion, is the region beyond the earth's atmosphere.

Many space vehicles are hybrids since they are required to operate in the earth's atmosphere and beyond. The space shuttle orbiter is such a hybrid space vehicle. The Apollo command and service module is also a hybrid, but the Apollo lunar module, which primarily functioned outside the earth's atmosphere, was a space vehicle.

The design procedure for any vehicle structure is basically the same:

1. Establish the design requirements and criteria
2. Define the loads and environments
3. Perform the design and analysis
4. Iterate the previous two steps (as required) because of the interrelation between configuration and loads
5. Verify the design

There are conditions and requirements which are unique for hybrid and space-vehicle structures.

Minimum weight and high reliability are significant but opposing requirements for space-vehicle structures which must be balanced to achieve an efficient, reliable structure design. Depending on the mission of the particular space vehicle, the ratio between the weight of the earth launch vehicle and the payload (e.g., interplanetary probe) can be as high as 400 to 1. The large weight leverages require that the design be

as efficient as possible. Structural materials, therefore, must be stressed (or worked) as close to the capabilities as possible. Like aircraft structures, space-vehicle structures should be designed for a zero margin of safety (MS):

$$\text{MS} = \frac{\text{material ultimate allowable}}{\text{FS (limit stress)}} - 1$$

1. *Material ultimate allowable.* The stress at which the material will fail.

2. *FS (factor of safety).* This factor usually ranges between 1.25 and 1.50, for space structures, depending on the maturity of the design, the behavior of the material, the confidence in the loads, etc.

3. *Limit stress.* The maximum (reasonable) stress that the structural component would be expected to encounter.

Failure can be based on rupture, collapse, or yield as dictated by the functional requirements of the component. High reliability is necessary for most space vehicle structures since a failure is usually catastrophic or nonrepairable. Total structural reliability is composed of many of the design elements—loads, materials, allowables, load paths, factor of safety, analysis techniques, etc. If the reliability is specified and the statistical parameters are known for each design element, then the process is straightforward. A total structural reliability is seldom specified and good engineering practice is used for the solution of the reliability of each design element. Commonly used to assure structural reliability are (1) material allowables equivalent to A values from MIL-Handbook-5A for safe-life structure and B values for fail-safe structures; (2) limit loads which correspond to events and conditions which would not be exceeded more often than 3 times in 1,000 occurrences; (3) factor of safety equal to 1.4 for crew-carrying space vehicles and 1.25 for those without crews; and (4) verification of the structural design by test demonstration. A good structural design is one which has the correct balance between minimum weight and high reliability.

Space vehicles are usually manufactured and assembled on earth and transported to space. The launch environments of acceleration, vibration, aerodynamic pressure, rapid pressure change, and aerodynamic heating coupled with the space environments of extremely low pressure, wide ranges in temperature, meteroids, and radiation dictate that the design engineers accurately define the magnitudes of these environments and the correct time-compatible combinations of these environments if realistic loads are to be determined. Many natural environments have been defined and are documented in the references. The induced environments, which are a function of the system and/or structural characteristics (e.g., dynamic pressure, vibration, etc.), must be determined by analysis, test, or extrapolation from similar space vehicles. Quantifying the induced loads for the structural designers is one of the major consumers of time and money in any aerospace program and one of the most important. Load determination can be a very complex task. For further guidance the reader is directed to the references.

For a space vehicle which is not exposed to the launch loads, the load determination is greatly simplified. In the absence of an appreciable atmosphere and gravitational accelerations the predominant external force on a space-vehicle structure is that of the propulsion and attitude control systems and the resulting vibration loads. Even though not induced by an external force, thermal stresses and/or deflections can be a major design driver. Space vehicles commonly experience larger thermal gradients because of the time- or attitude-related exposure to solar radiation.

The thermal effects of stress and deflections of the structure require that temperature distributions be defined consistent with the strength and deflection requirements. From a strength integrity standpoint, temperature distribution on a space vehicle can be as important as the pressure distribution on an aircraft. The significance and sensitivity of thermal effects are greatly reduced by the use of composite materials for the structure. The materials can be layered to achieve, within limits, the desired thermal coefficient of expansion and thereby reduce the thermal effects.

Space vehicles which return to the earth must withstand the extremely high temperatures of atmospheric reentry. This produces dynamic temperature distributions which must be combined with the aerodynamic pressures and vehicle dynamic loads.

Innovative, clever, and efficient structural designs minimize the effects of loads associated with launch for a vehicle which is to remain in space. This is accomplished by attaching the space vehicle to the booster rocket to minimize scar weight and to reduce the aerodynamic loads by the use of shrouds, fairings, or controlling the attitude during atmospheric flight.

Efficiencies of weight-critical structures have been greatly improved by more accurately quantifying the loads and stress distributions in complex structural configurations. **Finite element methods** (FEM) of analysis and large capacity, high-speed digital computers have enabled the increased fidelity of analyses. In this process, the structure is modified with finite elements (beams, bars, plates, or solids) by breaking the structure into a group of nodal points and connecting the nodal points with the finite elements which best represent the actual structure. Loads are applied at the nodal points or on the elements which then distribute the loads to the nodal points. Constraints are also applied to the nodal points to support or fix the structure being analyzed. The finite element program then assembles all the data into a number of linear simultaneous equations and solves for the unknown displacements and then for internal loads and stresses, as required. Many finite element programs have been developed to perform a variety of structural analyses including static, buckling, vibration, and response.

The loads in a structure depend on the characteristics of the structure and the characteristics of the structure are largely dictated by the loads. This functional dependency between loads and structures requires an iterative design process.

Classically, when structures are worked to stresses near the capability of the materials, e.g., airplane structures, the design is verified by test demonstration. This method of verification was common before high-fidelity structural mathematical models were employed and is still used when practical to apply the design loads and environments to a dedicated test article to verify the design. Design deficiencies are then corrected depending on the importance and the manufacturing schedule.

Space-vehicle structures often do not lend themselves to the classical test approach because of the multitude of loads and environments which must be applied, because testing in earth's gravity precludes realistic loadings, and because of the size and configuration. Verification by analyses with complementary component tests and tests of selected load conditions are common.

INFLATABLE SPACE STRUCTURES FOR HUMAN HABITATION

by William C. Schneider

Texas A & M University

Inflatable space structures have been considered for many years and even some have been put into practice for applications such as large reflecting satellites, shock attenuation, and reentry vehicles. Their clear advantage over rigid structures from the standpoint of weight, compactness, and large volume potential have been recognized for years, but only recently, as a result of the development of very high strength fabrics, has serious development of inflatable structures for human application taken place. NASA, as well as some private aerospace companies, recognize the increasing demand for human-inhabited inflatable space structures in astronautics. As newer, even higher strength, fabrics are developed, the full utilization of inflatable structures for human space will be realized. In the following subsections the TransHab and the portable hyperbaric chamber are discussed, and they represent only two examples of the emerging inflatable space structure technology for human habitation.

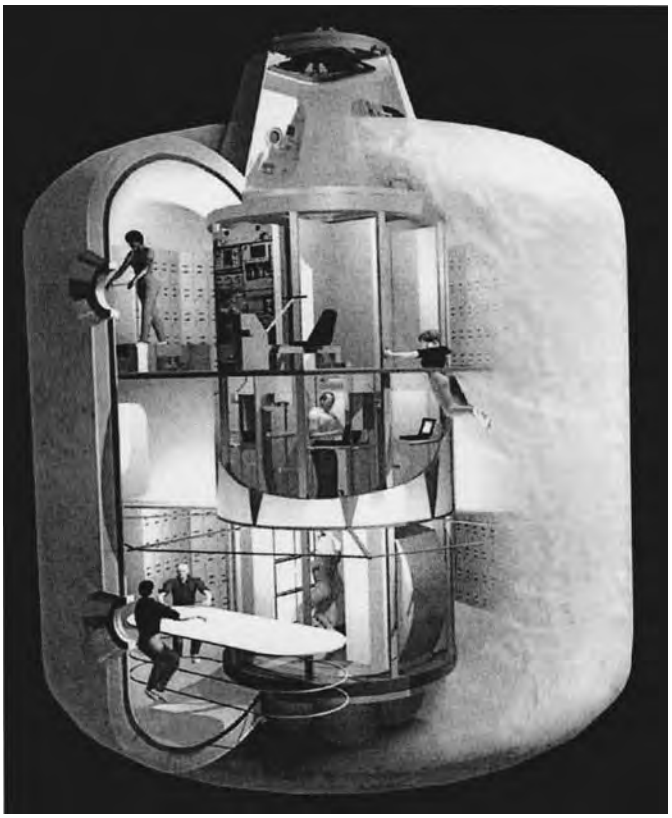

Fig. 11.6.42 TransHab inflatable habitation module.

TransHab

by Horacio de la Fuente

NASA

One example of the significant advantages derived from the use of inflatable technology for human space applications was demonstrated by the TransHab inflatable habitation module. Figure 11.6.42 shows a unit developed at the NASA Johnson Space Center. The TransHab is an inflatable human habitation module (30 ft long × 25 ft in diameter) originally conceived as an interplanetary module for use in spaceflight missions beyond low earth orbit. The long transit times required for these types of missions create several significant design challenges. Because multiple crewmembers will be living in a confined space for long periods of time, psychological health required the spacecraft to have a large-volume living space yet be lightweight. The ability of inflatable structures to be folded and packaged during the launch environment is a key feature that allows this requirement to be met. The advantages of inflatable modules, however, go beyond the obvious volumetric packing efficiency. The inflatable TransHab is folded and packaged tightly during the launch phase of the mission and is inflated only after it is in the quiescent space environment. Huge weight savings are realized when compared to a large rigid shell structure, since the rigid shell must be designed to withstand the severe steady-state, transient, and vibration launch loads as a large, rigid shell. There is, however, no requirement for the inflated TransHab to react to the launch loads. It must only withstand the differential pressure experienced in space.

The TransHab module design was later adapted to serve as a habitation module for the International Space Station. This change primarily resulted in modifications to some of the inflatable shell layers. As described later, the shell layers most affected by this change were the orbital debris protection layer, the atomic oxygen protection layer, and the restraint layer, which was strengthened to be compatible with the 14.7-lb/in^2 internal pressure of the International Space Station.

Central Structure Core Turning the large volume into a functional living environment creates additional challenges. Once inflated, the space habitation module requires several internal integrated subsystems such as environmental control and life support, power distribution, communication, and data handling, as well as crew mobility and translations aids. In addition, to maintain psychological health during the long stay times, dedicated living spaces for exercise, personal hygiene, food preparation and consumption, and sleeping are required. All of the above require internal structure as well as a significant amount of preintegration. For this reason the TransHab is designed as a preintegrated system. The integrated systems approach for TransHab used a hard central structural core, shown in Fig. 11.6.43, to provide the necessary backbone structure to allow for the preintegration and checkout of all the subsystems before launch, to support the subsystems during launch, and to provide the necessary internal structure for the module after inflation.

The inflatable shell of the TransHab is folded and wrapped around the central structural core during launch, then released and inflated on orbit, leaving a central structural core running down the central axis of the inflated module. All of the necessary structural elements needed to support the internal distributed systems, crew translation aids, and dedicated living spaces are obtained from the central structural core, which is already inside the module. Many of the structural elements of the central structural core are repositioned after inflation to provide a new function within the module. A good example is the use of removable shelf elements in the core. These shelves, which contain preintegrated subsystem components, are used to strengthen the core during launch and are

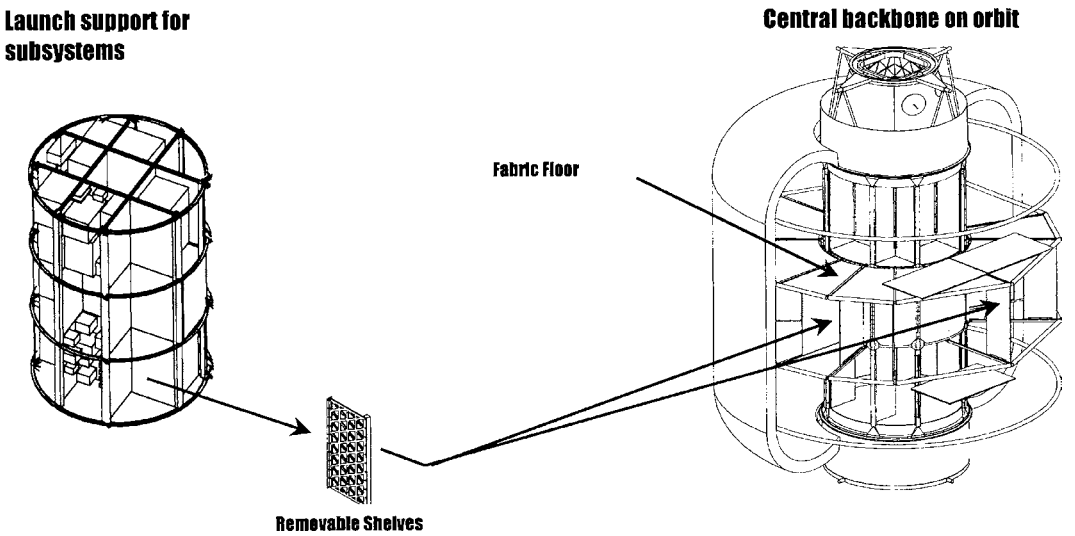

Fig. 11.6.43 Central structural core.

then repositioned adjacent to the core after inflation. Another example is a stretched fabric flooring system that partitions the internal volume into three separate "floors" after inflation. These floor system elements were also used to provide a protective barrier between the central structural core and the inflatable shell during launch.

The approach of reusing elements for multiple purposes is a common feature used throughout the TransHab design.

Inflatable Shell The design of the inflatable shell is driven by several requirements. These requirements include the need for flexure resistance, high tensile strength, low air permeability, internal puncture resistance, protection from meteoroid and orbital debris, thermal insulation, and protection against atomic oxygen. Finding a single material construction that meets all these requirements is difficult. As shown in Fig. 11.6.44, the TransHab design uses a multilayer construction to satisfy all of these requirements. This allows each layer to be optimized for its specific function. In addition, the use of separate layers loosely connected to each other allows the layers to slip relative to each other during the folding process. The different layers used in the TransHab design are an inner protective liner, a redundant bladder system, a strong restraint layer, a multilayer meteoroid and orbital debris layers, a multilayer insulation system, and an atomic oxygen protection layer. These layers are described briefly below.

Inner protective liner. The primary function of the inner liner is to protect the bladder layers from internal puncture and from flammability hazards. It uses a Nomex fabric backed by Kevlar felt. This layer is directly attached to the innermost bladder layer.

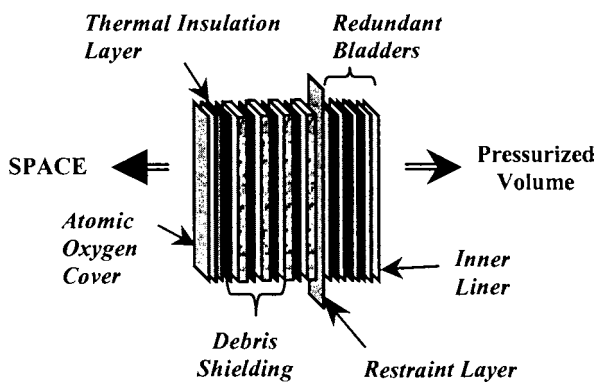

Fig. 11.6.44 Multilayer inflatable shell.

Bladder system. The primary function of the bladder system is to contain the internal gas, in this case air, from escaping. Because this layer is so critical, the TransHab design uses more than one bladder for redundancy in the event of a puncture. The bladder layers are made from a polyurethane-based laminated film, which provides extremely low permeability as well as excellent flexure characteristics at low temperature. The bladder system is oversized so that it transfers the entire pressure load to the restraint layer.

Restraint layer. The primary function of the restraint layer is to react the shell loads created by internal pressure. The restraint layer is composed of interwoven Kevlar straps running in a circumferential and a longitudinal direction.

Orbital debris protection layer. The primary function of the orbital debris protection layer is to act as a shield to protect the inboard layers from space debris impacts. To shield against hypervelocity impacts, the debris protection layer consists of multiple layers of Nextel and Kevlar™ cloth separated by foam spacers. While the spacing of the debris protection layers is needed for the shield to function, it also makes the inflatable shell difficult to fold and package. The use of open cell foam inside individual bags allows the foam spacers to be vacuum packed and collapsed for easy folding. After deployment of the inflatable shell, the lack of external atmospheric pressure allows the foam to expand back to its original state. As a result, the debris protection layer contributes approximately 16 inches to the overall thickness of the inflatable shell after deployment.

Thermal insulation layer. The primary function of the thermal insulation layer is to protect the inboard layers from the extreme on-orbit temperatures. The thermal insulation layer for TransHab uses standard multilayer insulation blankets with some modifications to account for having the shell constrained during launch and then released on orbit.

Atomic oxygen layer. The primary function of the atomic oxygen layer is to protect the inboard layers from atomic oxygen degradation in low earth orbit. The TransHab module uses a standard Beta-cloth layer for this purpose.

Integrity Tests Two of the key TransHab features, the ability to protect against space debris and the structural integrity of the TransHab restraint layer design, were verified by test. Sample cross sections of the debris protection layer were shot with a hypervelocity gun. The debris protection layer successfully stopped an approximately 2-cm-diameter aluminum projectile traveling at 7 km/s from penetrating into the bladder layers. A 1-g particle traveling at 11.5 km/s was also tested successfully. The structural integrity of the

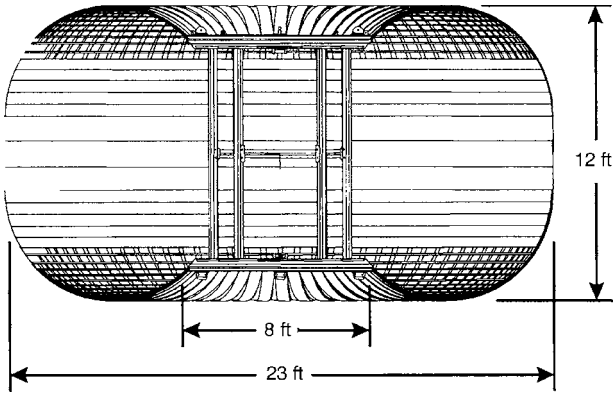

Fig. 11.6.45 Structural integrity test article.

restraint layer was test-verified through hydrostatic pressure testing. A full-scale-diameter, yet shorter length, test article, shown in Fig. 11.6.45, was fabricated and hydrostatically pressurized. While space habitation modules are designed to withstand a structural factor of safety equal to 2 (2× the operating pressure) and are typically 14 ft in diameter, the TransHab test article was 23 ft in diameter and was tested to a factor of safety equal to 4 (4× the operating pressure). Because pressure vessel stresses increase linearly with diameter, the test showed that the test article had much greater structural capability than its metallic counterpart. Since the structural weight of the TransHab module was comparable to that of existing metallic habitation modules, the test showed the significant advantages of inflatable habitation modules.

Portable Hyperbaric Chamber

by Chris Hansen and Jim Locke
NASA

The assembly and maintenance of the International Space Station requires that astronauts perform many extravehicular activities (EVAs), or spacewalks. The interior habitable compartment contains a nitrogen/oxygen atmosphere maintained at sea level atmospheric pressure (14.7 lb/in^2 or 760 mm Hg). Current spacesuit designs must be operated at significantly lower pressures, so that they are flexible enough to allow the performance of meaningful work. The NASA extravehicular mobility unit (EMU) spacesuit operates in space at a pressure of 4.3 lb/in^2 (220 mm Hg), or an earth altitude equivalent of approximately 30,000 ft. Depressurizing from sea level to 30,000 ft can cause the nitrogen gas dissolved in body tissues to leave solution and form gas bubbles, which can lead to decompression sickness (DSC), or "the bends." The risk of such altitude DCS can be mitigated by breathing pure oxygen prior to depressurization. This safely decreases tissue nitrogen content and decreases bubble formation. However, even with these procedures, the risk of serious, or even fatal, DCS remains. DCS can be effectively treated by using a hyperbaric chamber, a room containing air at high pressure (typically equivalent to a depth of 60 ft of seawater). Breathing pure oxygen under such high atmospheric pressure forces the nitrogen bubbles back into solution. In general, patients can be easily cured of even severe DCS if the hyperbaric chamber treatment is initiated quickly. Since it takes more than 24 hours to leave the space station, reenter the earth's atmosphere, land, and reach a terrestrial hyperbaric chamber, placing such a chamber on the station would be highly desirable. Unfortunately, hyperbaric chambers are typically very large and heavy, making their use on the space station impractical.

However, with the development of lightweight, high-strength inflatable construction techniques developed for the TransHab project, it was possible to design and build a portable hyperbaric chamber that was light enough to put on the space station, and could be stowed away in a relatively small space. In the late 1990s, a small NASA group was funded to develop a prototype for a portable hyperbaric chamber (PHC) that could be tested and eventually used on the space station. In the first phase of the project, the team concentrated on the structural components of the chamber, since it was considered to be the most difficult technical challenge. While TransHab had revolutionized inflatable space structures, the PHC had to be greatly scaled down from TransHab while still utilizing, as much as possible, the materials research and construction techniques previously developed. The PHC had to be just big enough to accommodate two astronauts: one (a patient) with DCS and a second to tend to the possibly incapacitated patient.

The structure of the PHC is shown in Fig. 11.6.46. It is composed of an inner, airtight polyurethane bladder surrounded by a woven Kevlar restraint layer. The restraint layer is actually composed of two sets of orthogonal interwoven Kevlar straps. One end of the chamber has a high-strength 7050 aluminum interface ring that acts as a doorway to the chamber and provides the sealing surface for the hatch and feedthroughs for air, pure oxygen, communication equipment, etc. The hatch, also high-strength aluminum, is machined in an oval shape, allowing the hatch to be internally sealing, yet allowing it to be removed by rotating it sideways and sliding it through the oval doorway. By having an internally sealing hatch, the hatch structure is greatly reduced in size and the need for numerous heavy latches is eliminated. The interface ring has series of steel brackets with Delrin rollers that connect the restraint layer to the interface ring. The Delrin rollers reduce the stress concentration in the straps at the interface ring

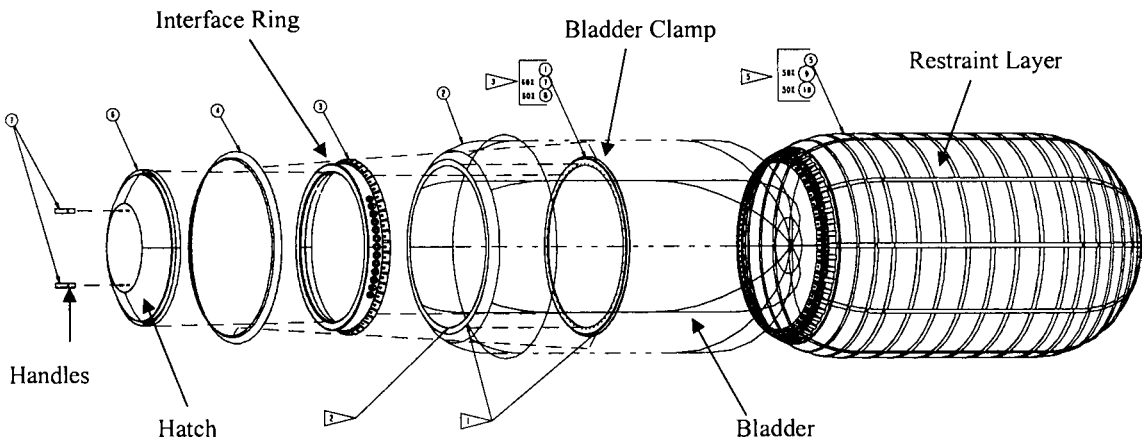

Fig. 11.6.46 Portable hyperbaric chamber structure (shown in an exploded view).

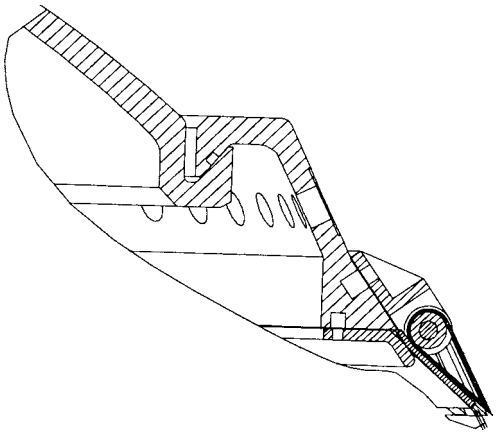

Fig. 11.6.47 Cross section of the hatch, interface ring, and restraint layer interface.

enough to allow the full pressure of the chamber to be developed without failure of the Kevlar straps. The seal between the hatch and the interface ring is formed with an O ring. The O-ring interface and the Delrin roller are shown in Fig. 11.6.47.

One of the most challenging parts of the structural design was developing a method of manufacturing the restraint layer. Made from 1-in Kevlar straps, the restraint layer had to be woven into the cylindrical shape of the chamber. Unlike TransHab, the restraint layer shape could not be formed into a flat pattern because it did not have an interface ring at each end. The second interface ring was eliminated to save weight, although it complicated the restraint layer design. However, this decision led to an estimated 30 percent reduction in weight.

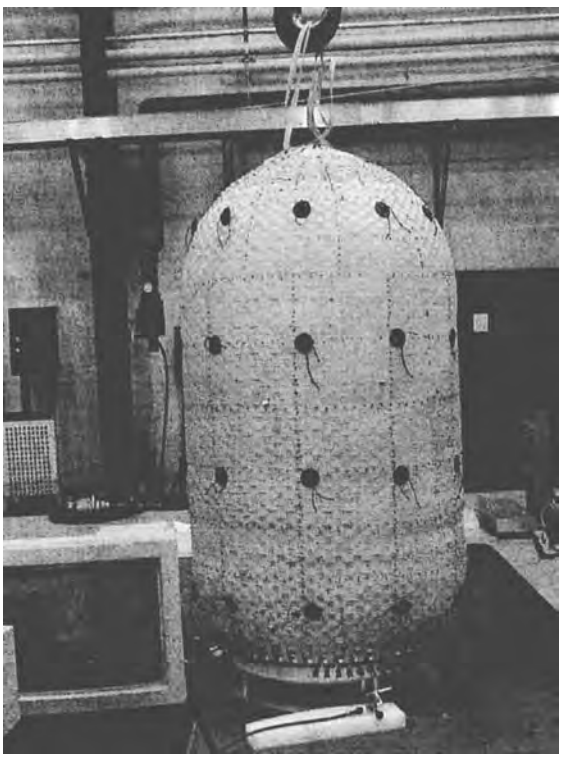

Fig. 11.6.48 Portable hyperbaric chamber structural prototype during low-pressure leak test.

After completion of the structural prototype, a pressurized hydrostatic test was performed. The working pressure of the chamber is 1.8 atm, and the chamber is designed to withstand 4.0 atm without failure. The final prototype is shown in Fig. 11.6.48 during a low-pressure leak test. All testing of the PHC was successful and demonstrated the flexibility of the inflatable structure technology developed during the TransHab project.

VIBRATION OF STRUCTURES

by Lawrence H. Sobel
University of Cincinnati

Wilkinson, "The Algebraic Eigenvalue Problem," Oxford.

As a result of the vast improvements in large-scale, high-speed digital computers, numerical methods are being used at an exponentially increasing rate to analyze complex structural vibration problems. The numerical methods most widely used in structural mechanics are the finite element method and the finite difference method. In the finite element method, the actual structure is represented by a finite collection, or assemblage, of structural components whereas, in the finite difference method, spatial derivatives in the differential equations governing the motion of the structure are approximated by finite difference quotients. With either method, the continuous structure with an infinite number of degrees of freedom is, in effect, approximated by a discrete system with a finite number of degrees of freedom (unknowns). The linear, undamped free and forced vibration analysis of such a discrete system is discussed herein. The analysis is most conveniently carried out with the aid of matrix algebra, which is well suited for theoretical and computational purposes. The following discussion will be brief, and the reader is referred to the cited references for more comprehensive treatments and examples.

Equation of Motion

Consider a conservative discrete system undergoing small motion about a state of equilibrium (neutral or stable). *Let* $q_1(t), \ldots, q_n(t)$, where t is time, be the minimum number of independent coordinates (linear or rotational) that completely define the general dynamical configuration of the system and that are compatible with any geometrical constraints imposed on the system. Then the n coordinates $q_1, \ldots, q_n$ are called generalized coordinates, and the system is said to have n degrees of freedom. Let $\{\mathbf{Q}(t)\}$ be the vector of generalized forces, and let $\{\mathbf{q}(t)\}$ be the vector of generalized displacements, $\{\mathbf{q}(t)\} = \{\mathbf{q}_1(t), \ldots, \mathbf{q}_n(t)\}$. Corresponding elements of the generalized force and displacement vectors are to be conjugate in the energy sense, which simply means that if one of the elements of $\{\mathbf{q}\}$ is a rotation (for instance), then the corresponding element of $\{\mathbf{Q}\}$ must be a moment, so that their product represents work or energy. Methods of computing $\{\mathbf{Q}\}$ are discussed in the references (e.g., Meirovitch). The matrix equation governing the small undamped motion of the system is given by

$$[M]\{\ddot{\mathbf{q}}\} + [K]\{\mathbf{q}\} = \{\mathbf{Q}\} \tag{11.6.7}$$

In this equation a dot denotes single differentiation in time, and $[M]$ and $[K]$ are the mass and stiffness matrices, respectively. $[M]$ and $[K]$ are real and constant matrices, which are assumed to be symmetric. Such symmetry will arise whenever an energy approach (e.g., Lagrange's equations) is employed to derive the equation of motion. The mass matrix is assumed always to be positive definite (and hence nonsingular, or can be made to be positive definite; see Przemieniecki).

Free-Vibration Analysis

The following equation governing the free vibration motion of the conservative system is obtained from Eq. (11.6.2) with $\{\mathbf{Q}\} = \{\mathbf{0}\}$: $[M]\{\ddot{\mathbf{q}}\} + [K]\{\mathbf{q}\} = \{\mathbf{0}\}$. To obtain a solution of this equation, we note that, for a conservative system, periodic motion may be possible. In particular, let us assume a harmonic solution for $\{\mathbf{q}\}$ in the form $\{\mathbf{q}\} = \{\mathbf{A}\} \cos(\omega t - \alpha)$. That is, we inquire whether it is possible for all coordinates to vibrate harmonically with the same angular frequency ω and the same phase angle α. This means that all points of the system will reach their extreme positions at precisely the same instant of time and pass through the equilibrium position at the same time. Substitution of this trial solution into the free vibration equation yields the eigenvector equation $[K]\{\mathbf{A}\} = \omega^2[M]\{\mathbf{A}\}$. In this equation $\{\mathbf{A}\}$ is called the eigenvector and ω^2 is the eigenvalue (the square of a natural frequency). This homogeneous equation always admits the trivial solution $\{\mathbf{A}\} = \{\mathbf{0}\}$.

Nontrivial solutions are possible provided that ω^2 takes on certain discrete values, which are obtained from the requirement that the determinant of the coefficient matrix of $\{\mathbf{A}\}$ vanishes. This yields the eigenequation (frequency equation) $\Delta(\omega^2) = |[K] - \omega^2[M]| = 0$. It is an nth-degree polynomial in ω^2, and its n roots are denoted by ω_r^2, $r = 1, \ldots, n$. The eigenvector $\{\mathbf{A}\}_r$, $r = 1, \ldots, n$, corresponding to each eigenvalue is determined from $[K]\{\mathbf{A}\}_r = \omega_r^2[M]\{\mathbf{A}\}_r$. However, the homogeneous nature of this equation precludes the possibility of obtaining the explicit values of all the elements of $\{\mathbf{A}\}_r$. It is possible to determine only their relative values or ratios in terms of one of the components. Thus, we see that for each eigenvalue ω_r^2 there is a corresponding eigenvector $\{\mathbf{A}\}_r$, which has a unique shape (based on the relative values of its components) but which is determined only to within a scalar multiplicative factor that may be regarded as being the amplitude of the shape. This unique shape is called the mode shape, and it can be thought of as being the position of the system when it is in its extreme position, and hence momentarily stationary, as in a static problem. Each frequency along with its corresponding mode shape is said to define a so-called natural mode of vibration. Methods of determining these natural modes are presented in the references (e.g., Wilkinson). If the initial conditions are prescribed in just the right way, it is possible to excite just one of the natural modes. However, for arbitrary initial conditions all modes of vibration are excited. Thus, the general solution of the free-vibration problem is given by a linear combination of the natural modes, i.e.,

$$\{\mathbf{q}\} = \sum_{r=1}^{n} C_r\{\mathbf{A}\}_r \cos(\omega_r t - \alpha_r)$$

The $2n$ arbitrary constants C_r and α_r are determined through specification of the $2n$ initial conditions $\{\mathbf{q}(0)\}$, and $\{\dot{\mathbf{q}}(0)\}$. An explicit representation for $\{\mathbf{q}\}$ in terms of $\{\mathbf{q}(0)\}$ and $\{\dot{\mathbf{q}}(0)\}$. is given later.

Some of the properties of the natural modes of vibration will now be listed. Unless stated otherwise, the following properties are all consequences of the assumptions that $[M]$ and $[K]$ are real and symmetric and that $[M]$ is positive definite: (1) the n eigenvalues and eigenvectors are real. (2) If $[K]$ is positive definite (corresponding to vibration about a stable state of equilibrium), all eigenvalues are positive. (3) If $[K]$ is positive semidefinite (corresponding to vibration about a neutral state of equilibrium), there is at least one zero eigenvalue. All zero eigenvalues correspond to rigid-body modes. (4) Eigenvectors $\{\mathbf{A}\}_r$, $\{\mathbf{A}\}_s$ corresponding to different eigenvalues $\omega_r^2, \omega_s^2 (\omega_r^2 \neq \omega_s^2; r \neq s; r, s = 1, \ldots, n)$ are orthogonal by pairs with respect to the mass and stiffness matrices (weighting matrices), that is, $\{\mathbf{A}\}_r^T[M]\{\mathbf{A}\}_s = 0$ and $\{\mathbf{A}\}_r^T[K]\{\mathbf{A}\}_s = 0$ for $r \neq s; r, s = 1, \ldots, n$. Since the eigenvectors are orthogonal, and hence independent, they form a basis of the n-dimensional vector space. Thus, any vector in the space, such as the solution vector $\{\mathbf{q}\}$, can be represented as a linear combination of the eigenvectors (base vectors). This theorem (expansion theorem) is of vital importance for the response problem to be considered next.

Response Analysis

The response of the system due to arbitrary deterministic excitations in the form of initial displacements $\{\mathbf{q}(0)\}$, initial velocities (impulses) $\{\dot{\mathbf{q}}(0)\}$, or forcing functions $\{\mathbf{Q}(t)\}$ may be obtained by means of the above expansion theorem. That is, the displacement solution of the response problem is expanded with respect to the eigenvectors of the corresponding free-vibration problem. The time-dependent coefficients in this expansion are the so-called normal coordinates of the system. The equations of motion when expressed in terms of the n normal coordinates are uncoupled, and each one of the equations is mathematically identical in form to the equation governing the motion of a simple one-degree-of-freedom spring-mass system. Hence solutions of these equations are readily obtained for the normal coordinates. The normal coordinates are then inserted into the eigenvector expansion to obtain the following explicit solution for displacement response $\{\mathbf{q}(t)\}$ (Przemieniecki) for undamped constrained or unconstrained (free) structures:

$$\begin{aligned}\{\mathbf{q}(t)\} = {} & \sum_{r=1}^{m} \frac{\{\mathbf{A}\}_{ro}\{\mathbf{A}\}_{ro}^T}{\{\mathbf{A}\}_{ro}^T[M]\{\mathbf{A}\}_{ro}} \left([M](\{\mathbf{q}(0)\} + t\{\dot{\mathbf{q}}(0)\}) \right. \\ & \left. + \int_{\tau 2=0}^{\tau 2=t} \int_{\tau 1=0}^{\tau 1=\tau 2} \{\mathbf{Q}(\tau_1)\}\, d\tau_1\, d\tau_2 \right) \\ & + \sum_{r=m+1}^{n} \frac{\{\mathbf{A}\}_{re}\{\mathbf{A}\}_{re}^T}{\{\mathbf{A}\}_{re}^T[M]\{\mathbf{A}\}_{re}} \left([M] \left(\{\mathbf{q}(0)\} \cos \omega_r t + \frac{1}{\omega_r}\{\dot{\mathbf{q}}(0)\} \sin \omega_r t \right) \right. \\ & \left. + \frac{1}{\omega_r} \int_{\tau=0}^{\tau=t} \{\mathbf{Q}(\tau)\} \sin \omega_r (t - \tau)\, d\tau \right) \end{aligned} \tag{11.6.8}$$

From this equation, it is seen that the displacement response is expressed directly in terms of the arbitrary excitations and the free-vibration frequencies and eigenvectors. The eigenvectors have been separated into two types denoted by $\{\mathbf{A}\}_{ro}$ and $\{\mathbf{A}\}_{re}$. The "rigid-body" eigenvectors $\{\mathbf{A}\}_{ro}$ correspond to the m rigid-body modes (if there are any) for which $\omega_r = 0$, $r = 1, \ldots, m$. The "elastic" eigenvectors $\{\mathbf{A}\}_{re}$ correspond to the remaining $n - m$ eigenvectors, for which $\omega_r \neq 0$, $r = m + 1, \ldots, n$. The general solution given by Eq. (11.6.8) is very useful provided that the second integral (Duhamel's integral) can be evaluated. (The first integral is easier to evaluate.) Closed-form solutions of this integral for some of the simpler types of elements of $\{\mathbf{Q}(t)\}$, such as step functions, ramps, etc., are available (see Przemieniecki). Solutions of Duhamel's integral for more complicated forcing functions can be obtained through superposition of solutions for the simpler cases or, of course, from direct numerical integration.

The displacement response obtained from Eq. (11.6.8) may be employed to obtain other response variables of interest, such as velocities, accelerations, stresses, strains, etc. Velocities and accelerations are obtained from successive time differentiations of Eq. (11.6.8). The method used to evaluate the stresses depends on the type of spatial discretization employed to approximate the structural continuum. For example, difference quotients are used in the finite difference approach. Note that the rigid-body components do not contribute to the stress or strain response and hence the first summation in Eq. (11.6.8) can be omitted for computation of these responses.

SPACE PROPULSION

by Henry O. Pohl
NASA

The propulsion system provides the maneuverability, speed, and range of a space vehicle. Modern propulsion systems have diverse forms, however, they all convert an energy source into a controlled high velocity stream of particles to produce force. Among the many possible energy sources, five are considered useful for space-vehicle propulsion:

1. Chemical reaction
2. Solar energy
3. Nuclear energy
4. Electrical energy
5. Stored energy (cold gas)

Accordingly, the various propulsion devices are categorized into chemical energy propulsion, nuclear energy propulsion, stored energy propulsion, solar energy propulsion and electrical energy propulsion.

Chemical propulsion can be further categorized into liquid propulsion or solid propulsion systems. Many combinations of fuels and oxidizers are available. Likewise, electrical energy propulsion can be subdivided into systems using resistive heating, arc heating, plasma, or ion propulsion. Nuclear energy and solar energy are external energy sources used to heat a gas (usually hydrogen).

All space propulsion systems, with the exception of ion propulsion, use nozzle expansion and acceleration of a heated gas as the mechanism for imparting momentum to a vehicle. The fundamental relationships of space propulsion systems are commonly expressed by a number of parameters as follows: The basic performance equation can be derived from the classical newtonian equation $F = MA$. It is defined as

$$F = \left(\frac{\dot{W}}{g}\right) V_e + A_e(P_e - P_a)$$

where F = thrust, lbf; $\dot{W}$ = propellant weight flow rate; g = gravitational acceleration; V_e = exhaust velocity; A_e = nozzle exit area; P_e = pressure at nozzle exit; and P_a = ambient external pressure.

The specific impulse is one of the more important parameters used in rocket design. It is defined as $I_s = F/W$, where I_s = specific impulse in seconds, F = thrust, and W = propellant weight flow rate per second of operation. I_s increases in engines using gas expansion in a nozzle as the pressure and temperature increase and/or the molecular weight of the gas decreases. The specific impulse values for representative space propulsion systems are shown in Table 11.6.12.

The total impulse $I_t = \int F(t)\,dt$ is useful to determine candidate rocket firing duration and thrust combinations required to satisfy a given change in momentum, where F = thrust and t = time.

Mass fraction is the ratio of propellant to total weight of the vehicle and is defined as $\gamma = (W_i - W_f)/W_i$, where γ = mass fraction; W_i = total weight of the vehicle including the propellant, structure, engine, etc., at the start of operation; and W_f = total weight of the vehicle less the weight of propellant consumed.

In the simplified case of a vehicle operating free of atmospheric drag and gravitational attractions, the velocity increment obtained from a propulsion system is defined as $\Delta V = I_s g \ln(W_i/W_f)$, where ΔV = velocity increment obtained; W_i = total weight of vehicle including propellant, structure, engine, etc., at start of operation; and W_f = total weight of vehicle less weight of propellant consumed during operations. This equation brings together the mission parameters, vehicle parameters, and rocket-engine parameters.

Figure 11.6.49 graphically shows the effect specific impulse and mass fraction have on the ability of a propulsion system to change the velocity of a payload in space.

Table 11.6.12 Specific Impulse for Representative Space Propulsion Systems

Engine type	Working fluid	Specific impulse
Chemical (liquid)		
Monopropellant	Hydrogen peroxide-	110–140
	hydrazine	220–245
Bipropellant	O_2-H_2	440–480
	O_2-hydrocarbon	340–380
	N_2O_4-Monomethyl hydrazine	300–340
Chemical (solid)	Fuel and oxidizer	260–300
Nuclear	H_2	600–1000
Solar heating	H_2	400–800
Arc jet	H_2	400–2000
Cold gas	N_2	50–60
Ion	Cesium	5000–25,000

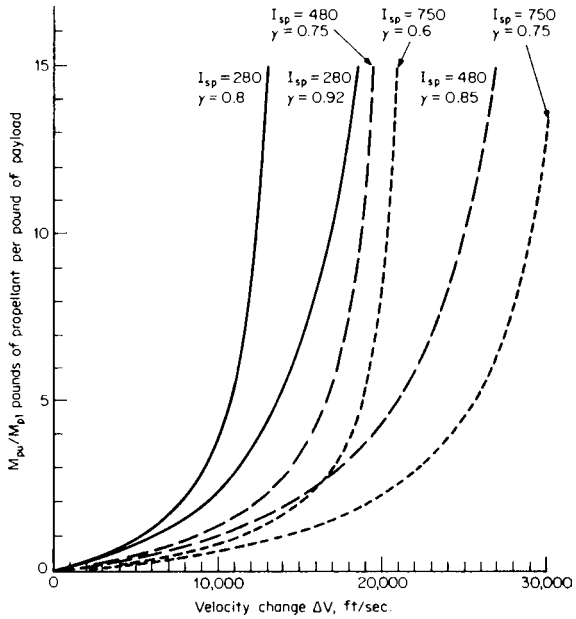

Fig. 11.6.49 Performance curves for a range of specific impulse and mass fractions.

Chemical Propulsion Only chemical energy has found wide acceptance for use in space propulsion systems. Modern materials and current technologies have made it possible to operate rockets at relatively high pressures. When these rockets are fitted with very large expansion-ratio nozzles (nozzle exits 40 to 200 times the area of the throat) the force produced per unit of propellant consumed is greatly increased when operating in the vacuum of space.

Solid-propellant rocket motors are used for moderate total impulse requirements, in spite of their low specific impulse, provided that the total impulse requirements can be precisely set before the rocket is built. The low specific impulse for these applications is largely offset by the high mass fraction (ratio of propellant weight to total propulsion system weight including propellant weight). They are simple to start, have good storage characteristics and multiple velocity requirements can be accommodated by staging, i.e., using a separate motor for each burn.

Liquid-propellant systems are generally used for moderate to high total impulse requirements, multiple burns, velocity-controlled thrust terminations, variable thrust requirements or for applications where the total impulse requirement is likely to change after the rocket is built or launched.

Bipropellant systems are the most commonly desired systems to satisfy moderate to high total impulse requirements. A fuel and oxidizer are injected into a combustion chamber where they burn, producing large volumes of high-temperature gases. Oxygen and hydrogen produce the highest specific impulse of any in-service chemical rocket (440 to 460 s). These systems also have good mass fractions (0.82 to 0.85). Oxygen and hydrogen, as stored in the rocket propellant tanks, are cryogenic, with boiling points of −296.7°F and −442°F, respectively. Storing these propellants for long periods of time requires thermally insulated propellant containers and specially designed thermodynamic vents or refrigeration systems to control boil-off losses. The low density of hydrogen (4.4 lb/ft^3) requires the use of bulky containers. Because of these characteristics, oxygen/hydrogen rocket systems can best satisfy moderate to high total-impulse requirements. Where designs are constrained by volume, very long durations of time between firings, many short burns, or precise impulse requirements, nitrogen tetroxide and monomethylhydrazine are often preferred, if the total impulse requirements are moderate.

Monopropellant systems generally use a single propellant that decomposes in the presence of a catalyst. These are usually low total-impulse

systems used to provide attitude control of a spacecraft or vernier velocity corrections. For attitude control, small thrustors are arranged in clusters around the perimeter of the vehicle. These small thrustors may, in the course of a single mission, produce over 1,000,000 impulses, to keep the vehicle oriented or pointed in the desired direction.

Solar-heating propulsion would use a solar collector to heat the working fluid which is exhausted through a conventional nozzle. The concentrated solar energy heats the rocket propellant directly through the heat exchanger. The heated propellant is then exhausted through the nozzle to produce thrust. Many design problems make the practical development of the solar-heating rocket quite difficult. For example, the solar collector must be pointed toward the sun at all times and the available solar energy varies inversely with the square of the distance from the sun. Using hydrogen as a working fluid, this type system would have a specific impulse of 400 to 800 s and could satisfy very high total impulse requirements at low thrust levels.

Nuclear propulsion is similar to solar-heating propulsion except that the energy source is replaced by a nuclear reactor. A propellant is injected into the reactor heat exchanger, where the propellant is heated under pressure and expanded through the nozzle. Liquid hydrogen is the best choice for the nuclear rocket's working fluid because its low molecular weight produces the highest exhaust velocity for a given nozzle-inlet temperature. For example, for a given entrance nozzle pressure of 43 atm and temperatures of 1650, 3300, and 4950 K the following specific impulses are obtainable: 625, 890, and 1,216 s, respectively. The nuclear rocket engine is started by adjusting the reactor neutron-control drums to increase the neutron population. Propellant flow is initiated at a low reactor-power level and is increased in proportion to the increasing neutron population until the design steady-state reactor power output is obtained.

For shutdown of the engine, control drums are adjusted to poison the core and decrease the neutron population. Steady-state reactor thermal power, in megawatts, is determined by the relation $P1 = Kw\,(h_{out} - h_{in})$, where w and h are core flow rate and enthalpy, respectively, and K is the appropriate conversion factor to megawatts.

The reactor is a high-power-density, self-energizing heat exchanger which elevates the temperature of the hydrogen propellant to the limit of component materials.

SPACECRAFT LIFE SUPPORT AND THERMAL MANAGEMENT

by Walter W. Guy

NASA

Life Support—General Considerations

To sustain human life in a spacecraft two functions must be provided. The first is to replenish those substances which humans consume and the second is to control the conditions of the environment at levels consistent with human existence. Humans consume oxygen, water, and food in the metabolism process. As a by-product of this metabolism, they generate CO_2, respired and perspired water, urine, and feces (Table 11.6.13). The provisioning of man's necessities (and the elimination of his wastes) is a primary function of life support. However, an equally important function is the maintenance of the environment in which he lives.

Table 11.6.13 Metabolic Balance for Humans

Consumed		Produced	
Oxygen	1.84	Carbon dioxide	2.20
Drinking water	5.18	Perspiration	2.00
Food (⅔ H_2O)	3.98	Respiration	2.00
		Urine	4.53
		Feces	0.27
	11.00		11.00

NOTE: Metabolic rate = 11,200 Btu/human-day and RQ = 0.87; RQ (respiratory quotient) = vol CO_2 produced/vol O_2 consumed. All values are in units of lb/human-day.

There are three aspects of environmental control—ambient pressure, atmospheric composition, and thermal condition of the environs. In a typical spacecraft design the ambient pressure is maintained generally in the range between ⅓ atm and sea-level pressure, with the oxygen partial pressure varying in accordance with Fig. 11.6.50 in order to provide the appropriate partial pressure of oxygen in the lungs for breathing.

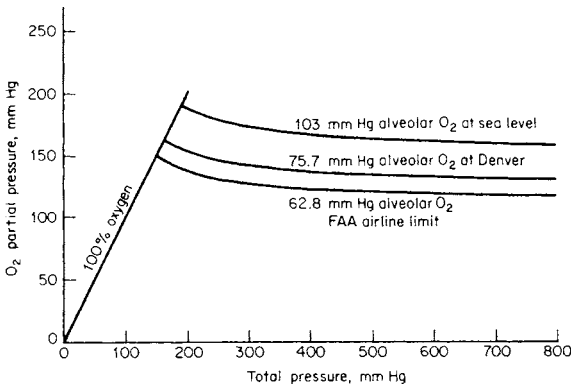

Fig. 11.6.50 Atmospheric oxygen pressure requirements for humans.

The other constituents of concern in the atmosphere are the diluent, CO_2, water vapor, and trace amounts of noxious and toxic gases. The percent of the diluent in the atmosphere (or indeed whether a diluent is present at all) is selectable after proper consideration of the design parameters. For instance, short-duration spacecraft can take advantage of human adaptability and use atmospheric pressures and compositions significantly different from those at sea level, with the attendant advantage of system design simplicity. The Mercury, Gemini, and Apollo spacecrafts utilized 5-lb/in^2 pure oxygen as the basic cabin atmosphere. Skylab used an oxygen-nitrogen mixture although at a reduced pressure, while the shuttle is designed for an essentially sea-level equivalent atmosphere. When selecting the pressure and composition, it is important to remember that although a two-gas system adds complexity, it can eliminate the concerns of (1) flammability in an oxygen-rich environment, (2) oxygen toxicity of the crew, and (3) decreased atmospheric cooling potential for electronic equipment in a reduced-pressure cabin. In the selection of a diluent, nitrogen should be considered first, since its properties and effects on humans and equipment are well understood. However, other diluents, such as helium, which have characteristics attractive for a special application, are available.

The other atmospheric constituents—CO_2, water vapor, and trace gases—must be controlled within acceptable ranges for comfort and well-being. Although the partial pressure of CO_2 is less than half a millimetre of mercury in an ambient earth environment, humans are generally insensitive to CO_2 levels up to 1 percent of the atmosphere (or 7.6 mmHg) unless mission durations increase to more than a month. As spacecraft missions are further extended, the partial pressure of CO_2 should approach the earth ambient level to ensure physiological acceptance. Atmospheric water vapor (or humidity) should be maintained high enough to prevent drying of the skin, eyes, and mucous membranes, but low enough to facilitate evaporation of body perspiration, maximizing crew comfort. The generally accepted range for design is 40 to 70 percent relative humidity. In the closed environment of the spacecraft, cabin noxious and toxic gases are of particular concern. It should be noted that 8-h/day industrial exposure limits are not appropriate for the continuous exposure which results from a sealed spacecraft cabin. Therefore, materials which can offgas should be screened and limited in the crew compartment. The small quantities which

cannot be completely eliminated, as well as certain undesirable products of metabolism, must be actively removed by the life-support system to maintain an acceptable atmosphere for the crew.

The third of the environmental control aspects—atmospheric thermal condition—is subject to several design variables, all of which must be taken into account. Thermal comfort is a function of the temperature and relative humidity of the surrounding atmosphere, the velocity of any ventilation present, and the temperature and radiant properties of the cabin walls and equipment. The interrelationship of these parameters is shown in Fig. 11.6.51 for a reasonable range of flight clothing ensembles. Because of the effective insulations available to the vehicle designers, the problem of thermal control in the spacecraft cabin is generally one of heat removal. Utilizing increased ventilation rates to enhance local film coefficients is one means of improving thermal comfort within the cabin. However, the higher power penalties associated with gas circulation blowers, as compared to liquid pumps, should suggest using the spacecraft thermal control liquid circuit in reducing the temperature of the radiant environment as potentially a lower-power alternative. However, if the walls or equipment are chilled below the dew point, condensation will occur.

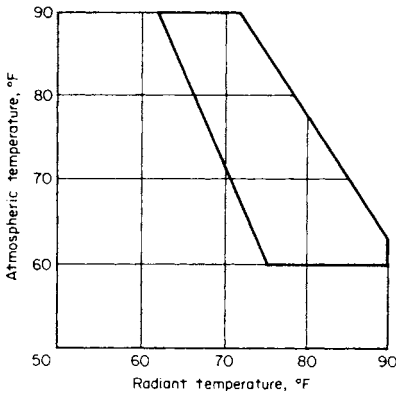

Fig. 11.6.51 Thermal comfort envelope for humans. (Note: metabolic rate 300–600 Btu/h; air velocity 15–45 ft/min; pressure 14.7 lb/in^2.)

As an additional benefit, maintaining an acceptable thermal environment through radiative means reduces the psychological annoyance of a drafty, noisy environment. Ventilation rates between 15 and 45 ft/min are generally considered comfortable, and exceeding this range should be avoided.

Life Support—Subsystems Selection

In designing the life-support system for a spacecraft, subsystems concepts must be selected to accomplish each of the required functions. This process of selection involves many design criteria. Size, weight, power consumption, reliability of operation, process efficiency, service and maintenance requirements, logistics dependency, and environmental sensitivity may each be very important or inconsequential depending on the spacecraft application. In general, for life support subsystems, the dominant selection criterion is mission duration. Various subsystem choices for accomplishing the life support functions are shown in Fig. 11.6.52.

To illustrate the relationship between mission duration and subsystem selection, the various concepts for removal of CO_2 from the atmosphere shown in Fig. 11.6.52*b* will be discussed. The simplest method of controlling the level of CO_2 in the spacecraft cabin is merely to purge a small amount of the cabin atmosphere overboard. This concept is simple and reliable and requires almost no subsystem hardware, although it does incur a fairly significant penalty for atmospheric makeup. For missions such as Alan Sheppard's first Mercury flight,

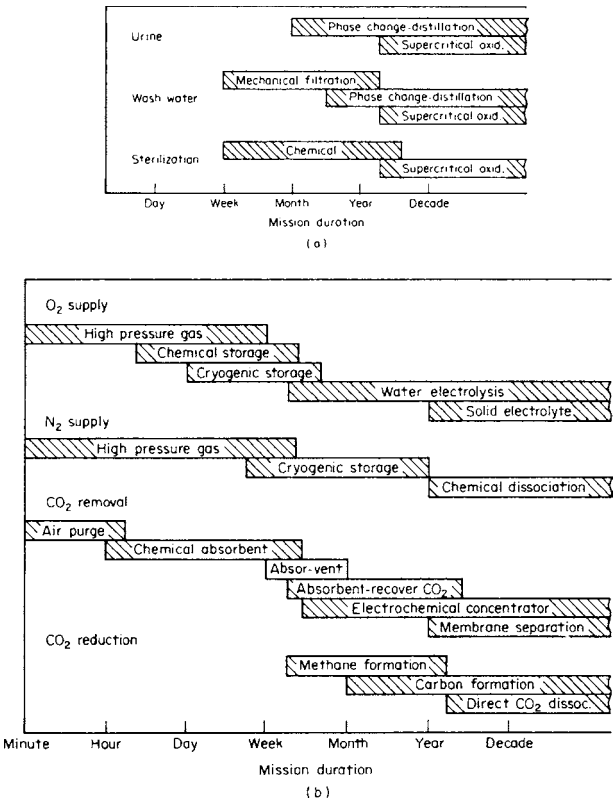

Fig. 11.6.52 Concepts to accomplish the life-support function. (*a*) Water recovery; (*b*) atmospheric revitalization.

this concept is probably optimum. However, even a minor increase in mission duration will result in a sizable weight penalty to the spacecraft. By adding a simple chemical absorption bed to the spacecraft ventilation loop (with a chemical such as lithium hydroxide as the absorbent), the expendable penalty for CO_2 removal can be reduced to the weight of the chemical canisters consumed in the absorption process. This concept was used on the Apollo spacecraft. The penalty for this type of concept also becomes prohibitive if mission durations are further extended. For missions such as Skylab, the expendable chemical absorbent can be replaced by a regenerable adsorbent. This change eliminates the lithium hydroxide weight penalty but incurs a small atmospheric ullage loss during the vacuum regeneration of the adsorbent. In addition, the regenerable system is more complex, requiring redundant beds (one for adsorption while the alternate bed desorbs), and mechanical-timing circuits and switching valves. This result is typical in that reducing expendable requirements is generally at the expense of system complexity.

The three CO_2 removal concepts discussed above all prevent the subsequent use of the collected CO_2 after removal from the atmosphere. Should the CO_2 be required for reclaiming the metabolic oxygen (such as will be the case for a space station design), the regenerable concepts can be adapted to accommodate retrieval of the CO_2 during desorption. However, this enhancement further complicates the subsystem design. There is an alternative CO_2 removal concept available which utilizes a fuel-cell-type reaction to concentrate the CO_2 in the atmosphere through electrochemical means. This process is mechanically simple (as compared to the adsorption-desorption system) but does require more electrical power. However, it has an integration advantage in that it provides the CO_2 collected from the atmosphere mixed with hydrogen, which makes its effluent a natural feedstock for either one of

several CO_2 reduction subsystems (which will be required for oxygen recovery on a space station). Although Fig. 11.6.52 identifies the various life-support subsystem choices for candidate spacecraft designs of different mission durations, this information should be used only as a guide. The crew size as well as other design parameters can skew the range of applicability for each subsystem (e.g., a large crew can render expendable dependent subsystems inappropriate even for relatively short missions).

There is another major aspect of life support system design for spacecraft (in addition to subsystem selection) and that is process integration and mass balance. For example, a space-station-class life-support system design must accommodate wastewater with a wide range of contamination levels—from humidity condensate which includes only minor airborne contamination to various wash and rinse waters (including personal hygiene, shower, clothes washing, and dish washing) and urine. The degree of contamination generally influences the reclamation process selection; therefore, multiple contaminated sources tend to result in multiple subsystem processes. For example, highly contaminated water, such as urine, is most reliably reclaimed through a distillation process since evaporation and condensation can be more effectively utilized to separate dissolved and particulate material from the water, while less contaminated wash waters can be effectively reclaimed through osmotic and mechanical filtration techniques at significantly less power penalties in watts/lb H_2O recovered. Regardless of the techniques selected, water must be made available for drinking, food preparation, and cleaning the crew and the equipment they use, as well as for generating the oxygen they breathe. In fact, the space station life-support design process can be looked upon, in one respect, as a multifaceted water balance since the dissociation of CO_2 and generation of O_2 both involve water in the respective processes. Figure 11.6.53 is a typical space station schematic depicting the interrelationship of the subsystems and the resulting mass balance.

Thermal Management—General Considerations

Although there is an aspect of life support associated with thermal comfort, the area of spacecraft thermal management encompasses a much broader scope. In the context of this section, thermal management includes the acquisition and transport of waste heat from the various sources on the spacecraft, and the disbursing of this thermal energy at vehicle locations requiring it, as well as the final rejection of the net waste heat to space. Although there are thermal implications to the design of most spacecraft hardware, the Life Support and Thermal Management section only deals with the integration of the residual thermal requirements of the various vehicle subsystems to provide an energy-efficient spacecraft design (i.e., one which utilizes waste heat to the maximum and therefore minimizes requirements for the vehicle heat rejection system).

Thermal management systems are typically divided into two parts. The first, associated with the spacecraft cabin, has design requirements associated with maintaining the crew environment and equipment located in the cabin at acceptable temperatures, and in addition has special requirements imposed on its design because of the location of the system in the pressurized compartment and its proximity to humans. These additional requirements are usually dominant. Any cooling medium which is used in the crew compartment must have acceptable toxicological and flammability characteristics in order to not impose a hazard to the crew in the event of malfunction or leakage. Although there are thermal control fluids which have low toxicity potential, reasonable flammability characteristics and adequate thermal transport properties, none are better than water.

The second aspect of the thermal management system involves those spacecraft systems located outside the cabin. The dominant design criteria in thermal control fluid selection for these systems are thermal transport efficiency and low-temperature characteristics. The thermal transport efficiency is important since the size, weight, and power requirements of the pumping and distribution system depend on this parameter. However, in the environs of deep space the potential exists for very low temperatures. Therefore, for maximum system operating flexibility, the characteristics of the thermal transport fluid must be such that operation of the system can continue even in a cold environment; thus, low-temperature properties become a fluid selection constraint. Although the range of acceptable fluids is broader here, several fluids in the Freon family meet these requirements. For single-phase, pumped-fluid systems, the temperature levels of the heat sources are

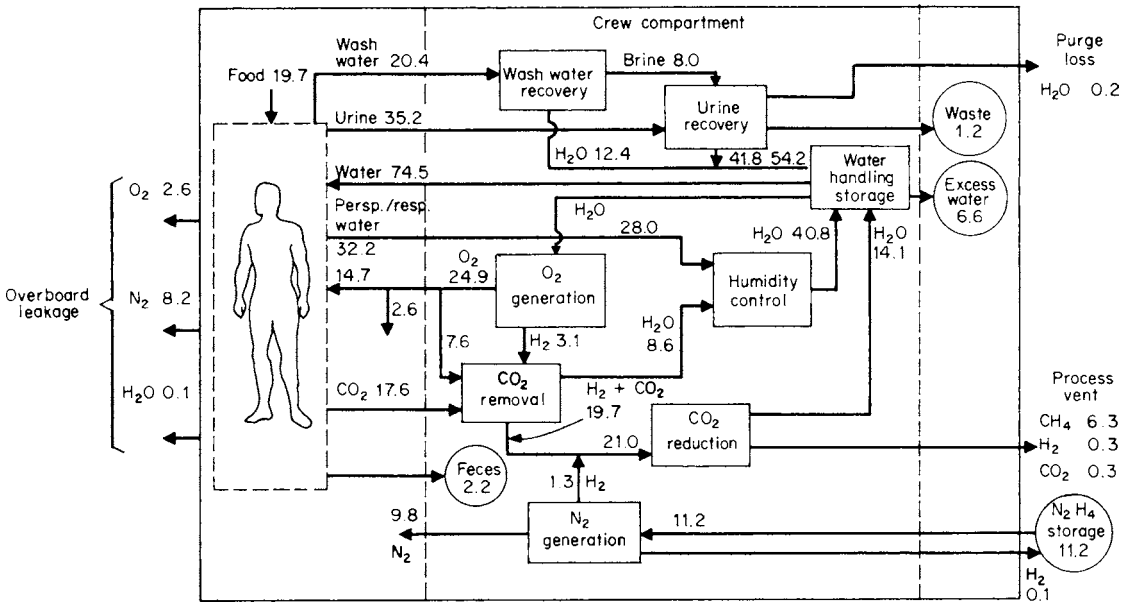

Fig. 11.6.53 Life-support systems mass balance. (All values are in pounds per day for an eight-person crew.)

important in determining the optimum sequence for locating equipment in the thermal circuit. The equipment with the lowest-temperature heat sink requirements are accommodated by placing them immediately after the heat rejection devices, while equipment which can accept a higher-temperature heat sink are located downstream. Also, those subsystems which require heating must be located at a point in the circuit which can provide the thermal energy at the required temperature level.

Typically spacecraft heat sources include cabin-atmosphere heat exchangers, the avionics system as well as other electronic black boxes, power generation and storage equipment, etc., while heat sinks include propulsion system components, various mechanical equipment requiring intermittent operation, dormant fluid systems which have freezing potential, etc. The ultimate elimination of the net thermal energy (i.e., sources minus sinks) is by rejection to space. This is accomplished through expendables or radiation.

Recent developments in thermal management technology have resulted in the consideration of a two-phase acquisition, transport, and rejection system. This concept uses the heat of evaporation and condensation of the transport fluid to acquire and reject thermal energy, reducing by several orders of magnitude the amount of fluid required to be pumped to the various heat sources and sinks within the spacecraft. This concept has the added advantage of operating nearly isothermally, permitting the idea of a thermal "bus" to be included in future spacecraft design, with indiscriminate sequencing of the heat sources and sinks within the vehicle.

Thermal Management Subsystem Selection

The subsystem selection process associated with the thermal management area depends largely on the magnitude of thermal energy being managed and the duration of the mission. Figure 11.6.54 graphically depicts the areas of applicability for various types of heat-rejection devices as a function of these parameters.

Small heat-rejection requirements can sometimes be met by direct heat sinking to the structure (or a fluid reservoir). Often, passive heat sinks need to be supplemented with fusible heat sinks (to take advantage of the latent heat of fusion) or evaporative heat sinks (to take advantage of the latent heat of evaporation). Of the three types of heat sinks, the evaporative heat sink is the only one which has been used as the primary vehicle heat-rejection device in the manned spaceflight program to date. Both the Mercury spacecraft and the lunar module utilized a water evaporative heat sink in this manner. However, the Apollo spacecraft and the shuttle have also used evaporative heat sinks and Skylab used a fusible heat sink as supplemental heat rejection devices.

Since space is the ultimate heat sink for any nonexpendable heat rejection, devices which allow the thermal energy which has been collected in spacecraft coolant circuits to be radiated to space become the mainstay of the thermal management system. These "radiators" take many forms. The simplest design involves routing the cooling circuits to the external skin of the spacecraft so that the thermal energy can be radiated to deep space. Because of spacecraft configuration restrictions, only partial use can be made of the external skin of the spacecraft, and the amount of thermal energy which can be rejected by this technique is thereby limited. Although the Gemini and Apollo spacecraft successfully used integral skin radiators, the unique characteristics of the outer surface of the orbiter required a different technique be adopted for its radiator design. Accordingly, the radiators were designed to be deployed from inside of the payload bay doors. This not only provides good exposure to space, but also, in the case of the forward panels, allows two-sided exposure of the panels, thereby doubling the active radiating area.

Heat rejected Q_{rej}, according to the Stefan-Boltzmann law, is given by the following equation:

$$Q_{rej} = \varepsilon \gamma A T^4$$

where γ = constant, 0.174×10^{-8} Btu/(h · ft^2 · °R^4); ε = emittance property of surface (termed emissivity), A = area available for radiation; and T = radiating temperature. From this equation it is obvious that a radiator with both sides exposed will reject twice as much heat to space as one of the same dimensions which is integral with the skin of the vehicle. A space radiator can absorb as well as reject thermal energy. The net heat rejected Q_{net} from a radiator is given by the following equation:

$$Q_{net} = Q_{rej} - \sum_{N}^{A=1} Q_{abs}$$

The energy absorbed by the radiator, Q_{abs}, can come from various sources (see Fig. 11.6.55).

The most common heat sources for an earth-orbiting spacecraft are direct solar impingement, reflected solar energy from the earth (i.e., albedo), direct radiation from the earth, radiation from other parts of the spacecraft, and radiation from other spacecraft in the immediate vicinity. These energy sources are absorbed on the radiator surface in direct proportion to the absorptance characteristic of the surface,

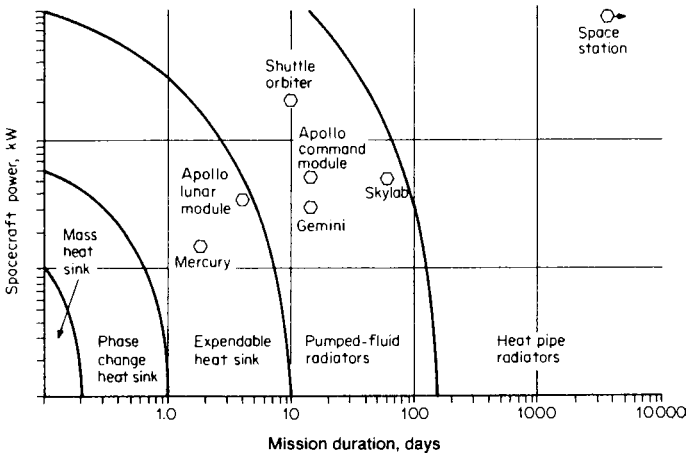

Fig. 11.6.54 Range of application of various heat-rejection methods.

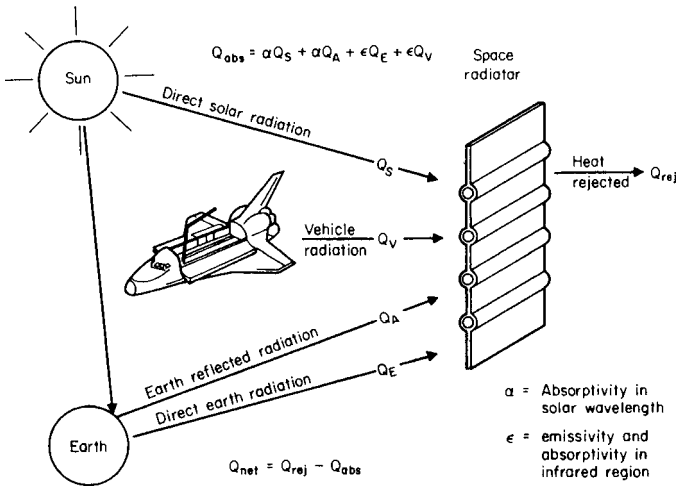

Fig. 11.6.55 Space radiator energy balance.

termed absorptivity. Emissivity and absorptivity are unique to each surface material but are variables directly linked to the temperature of the source of the radiation (i.e., wavelength of the radiation). Therefore, since absorptivity and emissivity are characteristics of the surface, the careful selection of a surface coating can significantly enhance the effectiveness of the radiator. The coating should have a high emissivity in the wavelength of the rejected energy from the radiator (for good radiation efficiency) and a low absorptivity in the wavelength of the impinging radiation (for minimal absorbed energy). Since generally the earth and the surrounding spacecraft are producing thermal energy of essentially the same wavelength as the radiator, it is necessary to restrict the view of the radiating surface to these objects since absorptivity and emissivity of a surface are equal for the same wavelength energy. Thus, radiators which can be located so that they are not obstructed from viewing deep space by elements of the spacecraft or other spacecraft in the vicinity will be much more effective in rejecting waste heat. The sun, however, emits thermal energy of a dramatically different wavelength and, therefore, coatings can be selected which absorb less than 10 percent of the solar energy while radiating nearly 90 percent of the energy at the emitting temperature of the radiator.

For applications which require large radiating surface areas as compared to the vehicle's size, integral skin radiators offer insufficient area and thus space radiators which use deployment schemes must be considered. However, as radiators become larger the mechanisms become very complicated. To circumvent the mechanical problems of deployment, a new radiator concept has been developed which allows in-orbit construction. This concept utilizes a single-tube heat pipe as the primary element (see Fig. 11.6.56).

There are two distinct advantages of heat pipe radiators. The first is that assembly of large surface areas in-orbit can be effected without breaking into the thermal control circuit. This is practical since the heat pipe radiator element is completely self-contained. The second advantage is that in-orbit damage from accidental collision or meteoroid puncture affects only that portion of the radiator actually damaged and does not drain the entire radiating surface of fluid as it would the radiators which have been used on spacecraft to date. Because of this advantage, future missions which require either of the three types of radiators (i.e., integral skin, deployable, or space constructible) will utilize the heat pipe concept to transport the thermal energy to the exposed radiating surface.

The design of space radiators can take many forms, but the basic concept is an exposed surface made of a conducting material with regularly spaced fluid tubes to distribute the heat over the surface (see Fig. 11.6.57).

The selection of the material and configuration of the radiating surface (i.e., honeycomb, box structure, thin sheet, etc.) determine its thermal conductance. This conductance, when coupled with tube spacing and the internal heat transfer characteristics within the tube and fluid system, determines the temperature gradient on the radiating surface between adjacent tubes. This so-called "fin effectiveness" represents a loss in radiating potential for any particular radiator design; therefore, these parameters should be selected carefully to optimize the radiator design within the constraints of each application. Figure 11.6.58 demonstrates the effect of the configuration parameters of the radiator on panel weight.

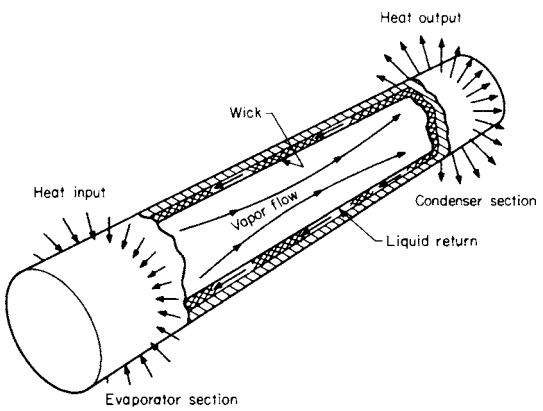

Fig. 11.6.56 Basic heat-pipe operation.

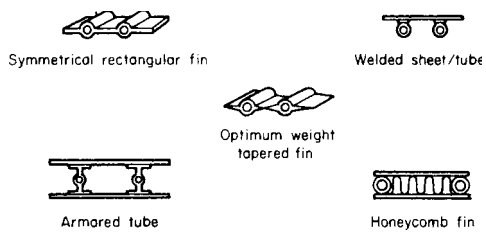

Fig. 11.6.57 Typical radiator tube/fin configurations.

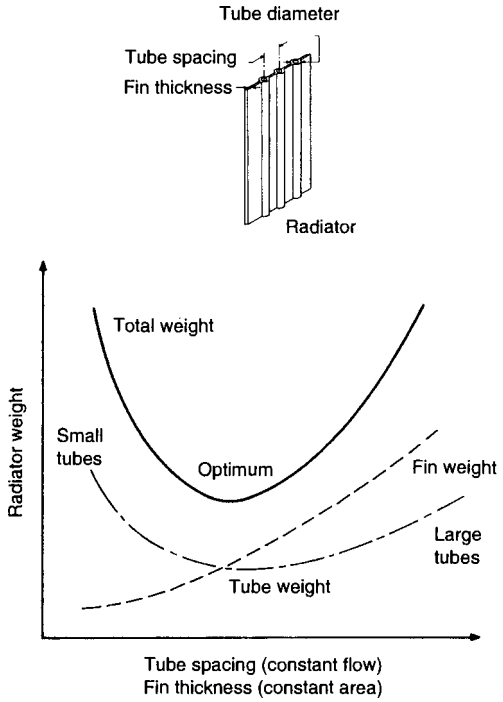

Fig. 11.6.58 Radiator configuration optimization.

DOCKING OF TWO FREE-FLYING SPACECRAFT

by Siamak Ghofranian and Matthew S. Schmidt

Rockwell Aerospace

The information in this section covers the mechanics of docking two free-flying unconstrained vehicles in space. Different methods of mating are addressed with the emphasis applied to docking. The content does not encompass all facets of the procedure, but it does bring forth the physics of the operation which make the process an engineering challenge.

Types of Mating

The understanding of mating is a precursor to preliminary design. Different techniques of mating free-flying bodies are often discussed when planning the rendezvous of two vehicles in space. The mating of two structures can be performed in three ways: docking, berthing, or a combination of both. **Docking** relies on the transfer of vehicle momentum to provide the means to force the docking ports into alignment. If a significant amount of momentum is required for capture, jet firings can be used to introduce the impulse into the system as needed. **Berthing** relies on a secondary system, such as a robotic arm to enforce the docking ports into alignment. The active vehicle grapples the other with a robot manipulator and guides the structural interfaces together. If manipulator usage is attempted, specific design factors need to be considered: arm configuration, gearbox stiffness, linkage flexibility, and controllability.

Mating of two structures in space is by every means considered a multibody dynamic event. Docking involves a significant level of momentum transfer, while berthing involves relatively little. The dynamics result from the deliberate impact of the two vehicles. As docking occurs the system responds with rigid-body motion and mechanical motion of the docking device. Depending on the relative states between the vehicles and the mode in which the maneuver is attempted, the response of the system and the physics vary considerably.

For discussion purposes the two docking vehicles can be considered as a target vehicle (passive) and a docking vehicle (active). The passive vehicle maintains attitude control as the active vehicle is navigated along an approach corridor. The active vehicle holds an attitude control mode with translational control authority. As the corridor narrows, sighting aids, range, and range-rate feedback on both vehicles are used to guide the docking ports into contact.

As the vehicles approach, a closing velocity exists. From a design standpoint the operation of a docking system involves various mechanism operational phases: mechanism deployment, interface contact and capture, attenuation of relative motion, mechanism retraction, and structural lockup. The **deployment phase** is where the mechanism is driven from its stowed position to its ready-to-dock position. Vehicle interface contact and capture are initiated when the docking ports of each vehicle are maneuvered into contact. Ideally, a positive closing velocity should be maintained from initial contact through capture. Once an opening velocity develops, the probability of a failed capture increases. As the vehicles interact the mechanism interfaces are indexed into alignment as the system responds to the impact loads. The compliance of the system occurs in two forms: mechanism movement and rigid body vehicle motion.

When the docking interfaces interact, the system responds in six degrees of freedom and the docking system is stroked as the mechanism absorbs the relative misalignments. Once the interfaces are fully aligned, capture latches lock the opposing interfaces together, and the vehicles are "soft-docked." After capture, residual energy in the system allows relative motion between the structures to continue. Depending on the location of the docking system relative to the vehicle center of masses, the motion may dissipate due to the inherent hysteresis in the docking system; otherwise, separate energy-dissipation devices may be necessary. After attenuation the vehicles are likely to be misaligned due to the new relative equilibrium position of the spacecraft. Separate procedures or devices can be used to bring the structural interfaces into alignment.

The **retraction process** is where the active mechanism is driven back to its stowed position. Once they are fully retracted, the structural interfaces are latched at hard interfaces, and the vehicles are "hard-docked."

The mass of each vehicle is an essential part of the docking system design. The momentum of the docking vehicle is the medium which provides the force required by the docking mechanism to comply with the relative misalignments between the vehicles at the docking interface. The operation can be complicated if a vehicle center of mass is offset from the longitudinal axis of the docking system. As a result, the vehicle effective mass at the docking interface is reduced. Furthermore, the center-of-mass offset induces relative rotation after contact which complicates the capture and attenuation process. Ideally two vehicles should dock such that the velocity vector and longitudinal axis of the docking system have minimum offset from the center of mass. The relative rotation of the vehicles after contact is known as *jackknifing.*

The docking mechanism center-of-mass offset and the vehicle size significantly influence the design of the docking interfaces, attenuation components, docking aids, piloting procedures, and capture-assist methods. The relative vehicle misalignments and rates at the moment the docking interfaces first come into contact (initial conditions) should be known in order to size the mechanism attenuation components, to establish piloting procedures and training criteria, and to study the mechanics of the system before, during, and after docking.

The initial conditions result from vehicle as-built tolerances, thermal and dynamic distortions, variation in piloting performance, and control system tolerances. The misalignments are composed of lateral misalignments in the plane of the docking interface and angular misalignments about three axes. The rates are composed of translational velocities along three axes and angular velocities about three axes.

The mass and motion of the system are the basic ingredients for providing the energy necessary to join the interfaces. Ideally the interfaces should capture before an opening velocity develops between the docking interfaces. Adequate momentum at the docking port is required to actuate the mechanism. The impulse introduced to the system during the impact must be less than that required to reduce the relative interface velocity to zero. If the relative interface velocity goes to zero before capture, the vehicles will separate. For low closing velocities, a small axial impulse due to initial contact can reduce the relative interface velocity to zero and cause a "no capture" condition.

A drive system along the longitudinal axis of the docking mechanism or reaction control jets increases the probability of capture. It extends the docking system toward the target vehicle once initial contact is made and thus improves capture performance for a docking vehicle with a low closing velocity. However, a drawback of a drive system is that the reaction has the tendency to push the vehicles apart. The action of jet thrusting has the opposite effect; it tends to push the vehicles together. If the momentum required to provide a low possibility of no capture becomes operationally prohibitive, thrusting can be used as a substitute and applied as necessary.

As energy introduced into the system increases, whether in the form of vehicle momentum or jets pulsing, a tradeoff exists between acceptable internal vehicle loads, allowable component stroke limits, vehicle jackknifing, and piloting capability.

Vehicle Mass and Inertia Effects

Concentrated spherical masses colliding in two dimensions can be used to describe the dynamic effects of an impact. The same class of examples are consistently used in beginning physics textbooks to describe the macroscopic concepts of impulse, momentum, and energy. The same theory should be applied to understand the requirements of mating two vehicles and perform conceptual and preliminary design studies. A single-degree-of-freedom mechanical equivalent exhibiting simple harmonic motion is a useful example for understanding the mechanics.

Consider two spacecraft in a two-dimensional plane on a planned course of docking without any misalignments and with some closing velocity. If only the docking-axis degree of freedom is considered, the effective mass of each body, M_1 and M_2, can be computed from

$$M_1(\text{or}\,M_2) = M - (ML)^2/(I + ML^2)$$

where M is the vehicle mass, I is the vehicle mass moment of inertia about the center of mass, and L is the mass center offset from the docking axis. In this case the process of capture and attenuation can be thought of as a perfectly plastic impact of two bodies. The masses dock and stick together. After impact the two bodies continue their trajectory with some final velocity. The combined effective mass of the two bodies represented as a single degree of freedom can be computed from $M_{\text{eff}} - M_1M_2/(M_1 + M_2)$. Since momentum is conserved during a perfectly plastic impact, kinetic energy loss during docking can be computed from $\frac{1}{2}M_{\text{eff}}v^2$, where v is the capture velocity. Since at capture we know the effective mass of the system and the capture velocity, the unknown parameter becomes the work required to bring the system to rest.

Design Parameters

The energy loss during docking is equal to the work done, $F \times d$, by the mechanism-attenuation components. If a hysteresis brake is used to bring the system to rest, then a trade can be performed on the force-distance relationship by using

$$\tfrac{1}{2}M_{\text{eff}}\,v^2 = Fd$$

where F represents the force necessary to bring the system to rest over distance d. Using the hysteresis brake as a starting point provides the average about which other devices would oscillate. For an underdamped spring/damper attenuation system, the relative motion and maximum force can be computed from

$$x = v/\omega_d \times e^{-\zeta\omega} \sin \omega_d t \qquad \text{and} \qquad F = Kx + C\,dx/dt$$

respectively. In this representation,

$$\omega_d = \omega(1 - \zeta^2)^{1/2} \qquad \text{and} \qquad \omega^2 = K/M_{\text{eff}}$$

where ζ represents the damping factor and K and C represent the attenuation component characteristics. As can be seen, minimal knowledge of the basic system characteristics can be used to design the type and arrangement of the attenuation components. During the design of the attenuation components the following components may prove useful: preloaded centering springs, staged springs, ON/OFF dampers, and variable-level hysteresis brakes. The material in this section is only a first look at understanding the design of a docking system. As more detail is developed, the effects of relative vehicle motion, interface contact dynamics, mechanism performance, and vehicle flexibility need to be simulated, which goes beyond the scope of this section. For a comprehensive background, the reader should refer to the cited references.

11.7 PIPELINE TRANSMISSION

by. G. David Bounds

NATURAL GAS

General According to AGA Estimates for 2003, approximately 73 percent of the U.S. natural gas reserves occur in five states (Texas, Wyoming, New Mexico, Colorado, and Oklahoma) and the Gulf of Mexico Federal Offshore. Within these areas alone, estimated production in 2003 exceeded 15 trillion ft^3 (425 billion m^3). Total exports, interstate and international, from these states in 2002 were estimated at approximately 9.1 trillion ft^3 (258 billion m^3), while imports were approximately 4.6 trillion ft^3 (130 billion m^3). Offshore production is becoming increasingly significant. According to an INGAA Foundation report referenced by PLATTS in May, 2002, the Gulf of Mexico is the strongest growth area for U.S. gas production through the year 2020.

Citing the growing interest in deepwater resources, current production, averaging 5 trillion ft^3 (142 billion m^3) per year, is predicted to increase to 7.2 trillion ft^3 (204 billion m^3) per year by 2020. In 2003, approximately 12 percent of the total proven U.S. natural gas reserves and 22 percent of natural gas production were located in the Gulf of Mexico Federal Offshore Area. U.S. natural gas reserves in the state of Wyoming are second only to those in Texas, due to the approximately 114 trillion ft^3 (3.2 trillion m^3) of recoverable gas resources in the Appalachian Basin, of which almost 20 trillion ft^3 (566 billion m^3) is from coal bed methane (CBM). Industry leaders are excited about this supply of gas but are concerned that the future of this resource will not be determined by how much is produced, but rather by how much pipeline capacity is available to carry it to market. Actual production from these CBM resources is only about 50 billion ft^3 (1.4 billion m^3) per year because of insufficient pipeline capacity, onsite power generation and water handling facilities.

Natural gas consumption in the United States increased by 17 percent in the past decade; from 19.0 trillion ft^3 (538 billion m^3) in 1991 to 22.3 trillion ft^3 (631 billion m^3) in 2000. This demand is expected to grow even more rapidly over the next 20 years. To meet this increasing demand, natural gas pipeline transmission companies have transformed the way they do business. In addition to the extensive growth in the U.S. natural gas pipeline network, the growth of natural gas market centers integrating underground storage facilities and the consolidation of corporations through acquisitions and mergers have been the key factors in this transformation.

In 2002, production in the United States declined by 750 billion ft^3 (21.2 billion m^3) compared to 2001. In the same year, consumption increased by 860 billion ft^3 (24.4 billion m^3). Hurricanes in the Gulf of Mexico played a role in the reduced production, which was partially offset by increased production of 11.4 billion ft^3 (3.2 billion m^3) in Colorado and Wyoming. The increased demand was primarily met, however, by increased withdrawals from storage. In 2002, natural gas storage capacity in the United States was approximately 8.2 trillion ft^3 (232 billion m^3). Over 40 percent of this capacity and 35 percent of all storage facilities in the nation were located in four sates: Michigan, Illinois, Pennsylvania, and Texas. Ranked by storage capacity, the common types of natural gas storage fields are: depleted fields (82 percent), acquifers (15 percent), and salt formations (3 percent). At the beginning of 2002, natural gas storage inventory was 2.9 trillion ft^3 (82 billion m^3), the largest volume since 1990. At the end of 2002, natural gas storage volume was 35 billion ft^3 (1 billion m^3) less than the previous 5-year average of 2.4 trillion ft^3 (68 billion m^3).

Implementation of FERC Order 636, issued in 1992, has had a significant impact on natural gas transmission pipelines. Order 636 mandated interstate natural gas pipeline companies to transform themselves from natural gas marketers to strictly transporters of natural gas. Pipeline companies that built and operated gathering systems to support contractual obligations are now restricted from including costs for these activities with the costs of buying, transporting, and selling gas, because of the mandate that gathering be provided as a separate service. Open-access marketing has replaced bundled sales services to meet the instantaneous needs of buyers at competitive prices. When open-access marketing was first tried in the early 1980s, competitive bidding resulted in curtailment of gas flow to approximately 18 trillion ft^3 (510 billion m^3) per year through a national pipeline grid that had moved 24 trillion ft^3 (680 billion m^3) per year in the 1970s. The swing in market demand and compliance with FERC Order 637 has magnified the need for pipeline companies to provide "parking" and "lending" type services. Under guidance from the Gas Industry Standards Board (GISB), FERC now requires all natural gas pipeline companies to have an Internet site providing information on its rates (tariffs), operational capabilities, and availability. Pipeline companies typically offer interruptible service supported by system linepack and storage facilities in both gathering and market areas to provide the flexibility required to operate efficiently in an open access market. Market centers and hubs have evolved to provide gas shippers the physical and administrative capabilities formerly provided as "bundled" services by the interstate pipelines. The two primary functions of these hubs are to provide interconnection with other pipelines and to provide short-term receipt/delivery balancing needs. Many of the hubs also developed Internet-based access to gas trading platforms and capacity release programs that have improved the efficiency of the entire gas transportation and marketing processes. In 2003, there were 37 operational market centers in the United States and Canada (see Table 11.7.1). The collapse of Enron in 2001 precipitated financial difficulties for many gas marketing companies and the shutdown of most major Internet-based energy trading platforms. However, the impact on gas market center activity was short-term. By the middle of 2003, most market centers reported business levels that matched or exceeded previous levels.

Increasing competition brought about as a consequence of open-access marketing has been accompanied by major shifts in pipeline ownership and changes in the way pipeline companies do business. In addition to a large number of mergers and acquisitions, many pipeline companies created affiliated marketing arms, or subsidiaries, and transferred merchant functions to these new divisions to comply with FERC Order 636. Many of these marketing entities engage in marketing other types of energy as well, and some are much larger now than the pipeline divisions from which they were originally developed. Corporate expansion strategies have helped pipeline companies to maintain market share and reduce overhead costs as they search to find more efficient ways to operate. A snapshot of the major gas pipeline companies in the United States, showing shifts in ownership as of the year 2001, is shown in Table 11.7.2.

The need to transport natural gas from the producing regions to consuming areas throughout the continent has generated a burgeoning network of transmission pipelines. In 1950, there were 314,000 miles (505,000 km) of gas pipelines in this country. By 2000, with natural gas continuing to supply 24 percent of the nation's energy requirements, this mileage had increased to 1,369,000 miles (2,204,000 km), an increase of 435 percent in 50 years. Approximately 250,000 miles (402,500 km) of this pipeline is devoted to transmission service. Field gathering pipelines amount to about 40,000 miles (64,400 km). The remaining 1,079,000 miles (1,737,000 km) are in distribution service. In 2002, an additional 3,571 miles (5,750 km) of pipelines was added to the pipeline grid in the United States, incorporating a record increase of 12.8 billion ft^3 (362,000 m^3) per day to the national pipeline capacity.

Modern gas pipelines in the United States consist of diameters ranging from 2 to 48 in (60 to 1,219 mm) and grades of steel with specified minimum yield strengths (SMYS) ranging from 35,000 to 80,000 lb/in^2 (2,460 to 5,625 kg/cm^2). The type of longitudinal seams available are seamless (SMLS) in sizes ranging from 2 to 20 in (60 to 508 mm) diameter, electric resistance weld (ERW) in sizes ranging from 2 to 24 in (60 to 610 mm) diameter, and double submerged arc weld (DSAW) in sizes ranging from 16 to 48 in (406 to 1,219 mm) diameter. Higher yield strengths are usually more cost-effective in sizes larger than 10 in (273 mm) diameter.

Although the trend has been toward the use of larger pipe diameters and pipe steel of greater tensile strength, the economics of pipe production and coating and the ease of handling, including transportation as well as installation, has led to greater utilization of 36-in-diameter (914-mm) pipe with a specified minimum yield strength of 70,000 lb/in^2 (4,922 kg/cm^2).

In most new construction, mainline valves are usually ball or gate valves and are of the full-opening variety to allow for the passage of cleaning pigs and inspection tools. Ball and gate valves are also used in addition to check and plug valves on piping other than mainline piping.

Pipe bends are usually made on site by a contractor; however, on short-distance pipelines, or in cases where a large degree of bend is required, shop-fabricated bends are produced by induction heating.

Repairs to a pipeline segment according to current regulations of the Department of Transportation (DOT) are to either replace the segment, or use alternative methods that have been shown by reliable testing and analysis to restore pipeline serviceability. The installation of steel repair sleeves over localized pipeline defects has been used extensively to effect permanent repairs. Repair sleeves may be installed by welding or bolting in place. A newer repair method being used by many pipeline

operators is a polymer composite reinforcement warp (Clock Spring® or equivalent) which is wrapped around the repair area. For this type of repair, welding is not required.

The rapidly growing network of large-diameter pipelines, along with increasing pressure capabilities, has brought forth a considerable rise in prime mover and compressor requirements. Natural gas pipelines in the United States have experienced an increase from about 6 million installed hp (4.5 million kW) in 1960 to 15 million hp (11.2 million kW) by the end of 2003, an increase of 250 percent. More than 1,600 compressor stations are now installed on interstate gas pipelines at a spacing of between 50 to 75 miles (80 to 120 km). Natural gas–fueled engines, natural gas–fueled combustion gas turbines, and electric motors are employed as prime movers on gas pipelines. Approximately 60 percent of the existing 15 million hp is created by 5,700 reciprocating engines driving large-bore, slow-speed reciprocating compressors. The greatest part of the remaining 6 million hp (4.5 million kW) is developed by gas turbines and electric motors driving high-speed centrifugal compressors. Gas-fueled engines range in size from 2,500 to 13,500 hp (1,865 to 10,070 kW). Combustion gas turbines range in size from 1,000 to 35,000 hp (745 to 26,110 kW), and electric-motor drivers range in size from 2,500 to 20,000 hp (1,865 to 14,920 kW). Modified aircraft-type jet engines are also employed as prime movers, driving centrifugal compressors and range in size from 800 to 45,000 hp (600 to 33,570 kW).

Much progress has been made in automated operations of all types of pipeline facilities. Valves, measuring and regulating stations, and other facilities are operated remotely or automatically. Factory-packaged compressor station assemblies, most of which are highly automated, are now commonplace. Whole compressor stations with thousands of horsepower are operated unattended by coded dispatching systems handled by high-speed communications.

Automatic supervision and operation of pipeline systems are becoming almost commonplace in today's climate of microprocessor-based remote terminal units (RTUs). These ultrahigh-speed data-gathering systems can be used to gather operational data, do calculations, provide proportional integral derivative (PID) process control, and undertake other auxiliary functions. Data may be communicated to a central dispatch office for real-time control. A system of several hundred locations may be scanned and reported out in a few seconds.

Table 11.7.2 Major Interstate Natural Gas Pipeline Companies—Mergers as of 2001

Parent Pipeline name	Marketer affiliate Prior ownership	Merger year	System mileage	System capacity, MMCFD
CMS Energy Corp.	**CMS–MST**			
Panhandle Eastern Pipeline Co.	PanEnergy Corp.	2000	6,467	2,765

Natural gas measurement stations usually consist of pressure control valves and gas measurement devices—either AGA dimensioned orifices, turbine meters, or ultrasonic meters. Flow and pressure control valves, as well as overpressure protection, may also be required. If a large temperature drop is anticipated across any of the pressure-reducing valves, then a radiant heater or indirect-fired heater may be required. A rough estimate of temperature drop is 6°F per 100 lb/in^2 (3.3°C per 690 kPa) of pressure drop. Electronic flow measurement has become commonplace, meeting the requirements of current regulations. Microprocessors calculate, remotely monitor, and control flow in real time using the latest calculation methods of the AGA and American Petroleum Institute (API) reports. The quality of the gas is also measured by one of several means. For small-volume stations, a continuous gas sampler accumulates a small volume for laboratory testing. Medium- and large-volume stations will use a gas chromatograph.

Flow From the thermodynamic energy balance equations for the flow of compressible fluids (Sec. 4), the general flow formula is derived and expressed in *BuMines Monograph 6* (1935) as

$$Q = K\frac{T_0}{P_0}\left[\frac{(P_1^2 - P_2^2)d^5}{GT_fL_f}\right]^{1/2} \qquad (11.7.1)$$

where Q is the rate of flow, ft^3/day; T_0 is the temperature base, °R; P_0 is the pressure base, psia; P_1 is the initial gas pressure, psia; P_2 is the final gas pressure, psia; d is the internal pipe diameter, in; G is the specific gravity of the gas, which is dimensionless (for air, $G = 1.0$); T_f is the gas flowing temperature, °R; and L_f is the length of the pipeline, mi. The general flow equation for constant-volume (steady-state), isothermal, horizontal flow of natural gas is given by *U.S. BuMines Monograph 9* (1956) as

$$Q = 38.7744\frac{T_b}{P_b}\left[\frac{(P_1^2 - P_2^2)D^5}{fZGTL}\right]^{0.5} \qquad (11.7.2)$$

where Q = rate of flow, ft^3/day; T_b = temperature base, °R; P_b = pressure base, psia; P_1 = inlet pressure, psia; P_2 = outlet pressure, psia; D = internal pipe diameter, in; f = friction factor, dimensionless; Z = average gas compressibility, dimensionless; G = gas gravity (for air, $G = 1.0$); T = average flowing temperature, °R; and L = length of pipe, mi. Monograph 9 also gives a good discussion of friction factors and elevation corrections.

Other flow equations may be derived from the general equation by substitution of the proper expression for the friction factor. The applies to the Panhandle A equation, which has the form

$$Q = 435.87\left(\frac{T_b}{P_b}\right)^{1.0788}\left(\frac{P_1^2 - P_2^2}{G^{0.8539}TL}\right)^{0.5394} D^{2.6182}E \qquad (11.7.3)$$

where E = pipeline flow efficiency, a dimensionless decimal fraction (design values of 0.88 to 0.96 are common). In the Panhandle A equation, the compressibility is included in the pipeline efficiency, and the other symbols are as previously defined. This formula may be solved graphically as described by C. W. Marvin, *Oil and Gas Journal,* Sept. 20, 1954.

An AGA paper, Steady Flow in Gas Pipelines (1965), gives a good general review of constant-volume gas flow equations, both with and without elevation corrections. Equations and test data are included for both the partially turbulent (Reynolds number–dependent) flow regime and the fully turbulent flow regime using effective internal pipe roughness. In this reference, the drag factor is introduced to account for pressure losses for fittings such as bends and valves and is applied in the partially turbulent flow regime.

When the volume of gas flowing varies with time and position (transient or unsteady-state flow), the simultaneous momentum and mass balance equations are usually solved by use of numerical methods and the aid of computers. An AGA computer program, **Pipetran,** is available for this purpose, as are several related texts on transient flow. A paper entitled Gas Transportation System Modeling appears in the *1972 AGA Operating Proceedings.* Gas flowing in a pipeline undergoes a number of transient, or unsteady-state, flow conditions caused by such things as prime movers starting and stopping, valves opening and closing, and flows either into or out of the pipeline. DOS-based computer programs, such as **WinFlow** (Gregg Engineering) and others, allow the engineer to model simple as well as complex pipeline situations. These programs can be used to test proposed system expansions such as loops or additional compressor stations, to perform capacity studies, and to evaluate the effects of the transients mentioned above.

Compression The theoretical horsepower requirements for a station compressing natural gas may be calculated by polytropic compression formulas (see Sec. 4). The change of state that takes place in almost all reciprocating compressors is close to polytropic. Heat of compression is taken away by the jacket cooling and by radiation, and a small amount of heat is added by piston-ring friction. Compression by centrifugal compressors is even closer to polytropic (see Sec. 14).

For general design, the horsepower requirements for a station compressing natural gas with reciprocating compressors can be calculated as follows:

$$\text{Reciprocating station horsepower} = \text{hp}\,Z_s\frac{T_s}{520} \qquad (11.7.4)$$

The value of hp can be taken from Fig. 11.7.1, typical manufacturer's curve; T_s is suction temperature, °R; and Z_s can be taken from Fig. 11.7.2.

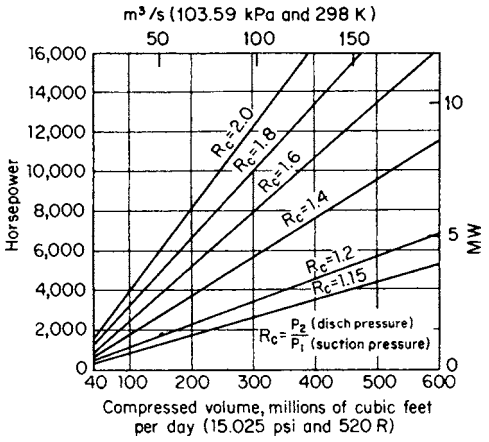

Fig. 11.7.1 Reciprocating-compressor horsepower (MW) graph. $R_c = P_2/P_1$ = discharge pressure, lb/in^2 abs ÷ suction pressure, lb/in^2 abs.

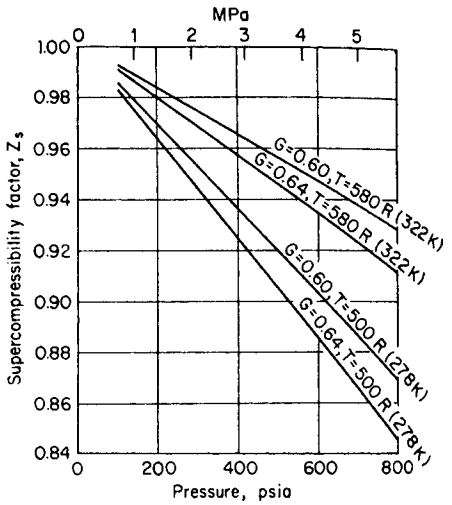

Fig. 11.7.2 Supercompressibility factor Z_s for natural gas. (Natural gas, 1 percent N_2.)

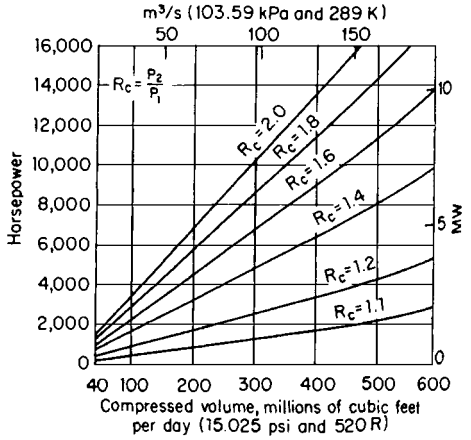

Fig. 11.7.3 Centrifugal-compressor horsepower (MW) graph. $R_c = P_2/P_1$ = discharge pressure, lb/in² abs ÷ suction pressure, lb/in² abs.

Similarly, the horsepower requirements for a station compressing natural gas with centrifugal compressors can be calculated as follows:

$$\text{Centrifugal station horsepower} = \frac{\text{hp}Z_s}{E_c}\frac{T_s}{520} \qquad (11.7.5)$$

The value for hp can be taken from Fig. 11.7.3, typical centrifugal horsepower curve; E_c is the centrifugal-compressor shaft efficiency. (Design shaft efficiencies of 80 to 85 percent are common.)

Compression ratios across a single machine normally do not exceed 3.0 because of outlet temperature limitations. For greater ratios, compressors can be arranged in series operation with an interstage gas cooler placed between the individual units. Multiple units can also be placed in parallel operation in order to increase flexibility and provide for routine maintenance.

Design The pipe and fittings for gas transmission lines are manufactured in accordance with the specifications of the API, ANSI, ASTM, and MSS (see also Sec. 8). Interstate pipelines are installed and operated in conformance with regulations of the U.S. Department of Transportation (DOT). The ANSI B31.8 Code and the *Gas Measurement Committee Report 3* (Orifice) and *Gas Measurement Committee Report 9* (Ultrasonic) of the AGA provide supplemental design guidelines. The equation for pipeline design pressure, as dictated by the DOT in Part 192 of Title 49, Code of Federal Regulations, is

$$P = \frac{2St}{D}FET \qquad (11.7.6)$$

where P = design pressure, psig; S = specified minimum yield strength, lb/in²; t = nominal wall thickness, in; D = nominal outside diameter, in; F = design factor based on population density in the area through which the line passes, dimensionless; E = longitudinal joint factor, dimensionless; and T = temperature derating factor (applies above 250°F only), dimensionless.

The selection of the diameter, steel strength, and wall thickness of a line and the determination of the optimum station spacing and sizing are based on transportation economics. Figures 11.7.4 through 11.7.6 show schematically methods of analysis commonly used to relate design factors to the cost of transportation. A perspective of various elements of the cost of transportation for a long-distance, large-diameter, fully developed pipeline system is presented in Fig. 11.7.7.

The cost of installed pipelines varies greatly with the location, the type of terrain, the design pressure, the total length to be constructed, and many other factors. In general, figures from $32,000 to $90,000 per in (per 2.54 cm) of OD represent the range of approximate costs per mile (per 1.61 km) of installed pipeline. Offshore pipeline installed costs vary with such items as length, water depth, bottom conditions,

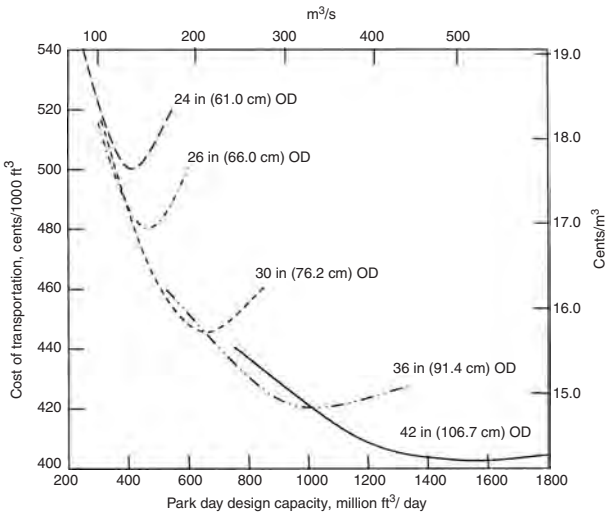

Fig. 11.7.4 Schematic relationship of cost of transportation versus design capacity for a given length of line with various pipeline diameters at equal design pressures.

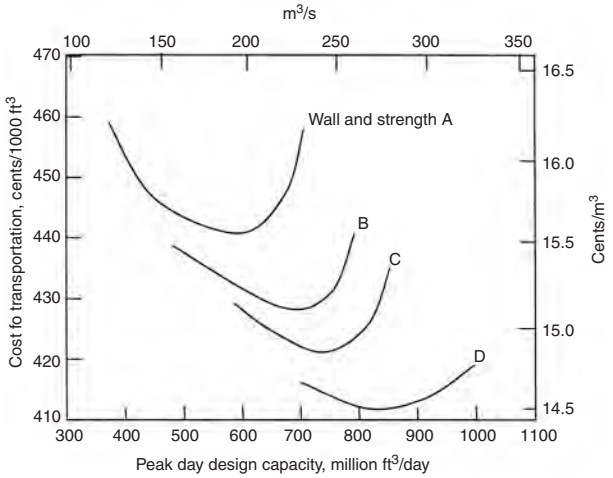

Fig. 11.7.5 Schematic relationship of cost of transportation versus pipeline steel strength and wall thickness.

- *A* = 36-in dia., 0.385-in wall thickness, 52,000-lb/in² min. yield (800-lb/in² operating pressure).
- *B* = 36-in dia., 0.385-in wall thickness, 60,000-lb/in² min. yield (924-lb/in² operating pressure).
- *C* = 36-in dia., 0.404-in wall thickness, 65,000-lb/in² min. yield (1,050-lb/in² operating pressure).
- *D* = 36-in dia., 0.438-in wall thickness, 70,000-lb/in² min. yield (1,220-lb/in² operating pressure).

pipeline crossings, depth of bury, and many other factors. These costs range from $53,000 to $76,000 per inch (per 2.54 cm) of OD per mile (per 1.61 km) for a typical offshore pipeline. Compressor-station installed costs vary widely with the amount and type of horsepower to be installed and with the location, the type of construction, and weather conditions. The installed costs of gas turbine stations range from $800 to $3,300 per installed hp ($1,070 to $4,425 per kW); gas engine stations, from $1,700 to $7,800 per hp ($2,280 to $10,455 per kW); and electric motor stations, from $1,300 to $5,000 per hp ($1,740 to $6,700 per kW).

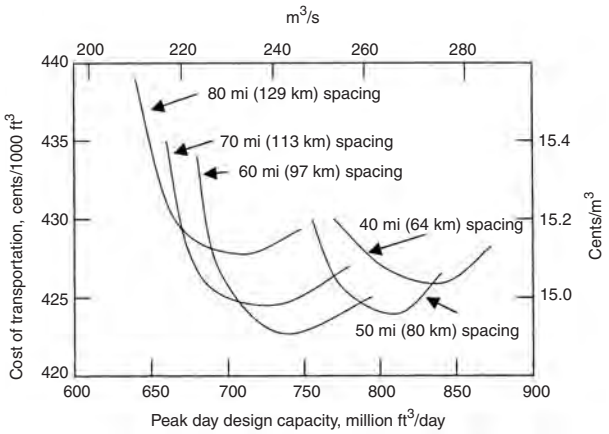

Fig. 11.7.6 Schematic relationship of cost of transportation versus design capacity for a given pipeline diameter and length, with various spacings of compressor stations.

After a pipeline system is constructed and fully utilized, expansion of delivery capacity can be accomplished by adding pipeline loops (connecting segments of line parallel to the original line), by adding additional horsepower at compressor stations, or by a combination of these two methods.

CRUDE OIL AND OIL PRODUCTS

General Approximately 91 percent of the U.S. proven liquid hydrocarbon reserves are situated in the seven states of Texas, Alaska, California, New Mexico, Oklahoma, Wyoming, and Louisiana, or in the marine areas off their coasts. Offshore production is becoming increasingly significant. The refinement of multiphase pumping systems has enhanced crude oil recovery from formerly marginal offshore fields. In 2003, approximately 23 percent of the total proven crude oil reserves were located in federal waters offshore of California, Louisiana, and Texas. The major markets in which petroleum products are consumed are remote from the proven reserves. About 61 percent of all petroleum consumed in the United States is imported and must be moved from ports to the centers of consumption. Forty percent of all movements of petroleum and petroleum products is made by pipeline. The interstate pipelines alone transport over 2 billion barrels (318 million m^3) of petroleum a year. There are about 177,000 mi (285,000 km) of operating interstate liquid-petroleum trunk lines in the United States.

Consumption of refined petroleum products in the United States has been divided into five Petroleum Administration for Defense Districts, or PADDs, based on historical, demographic, geological, and topographical characteristics, by the Energy Information Administration. The East Coast (PADD 1) is the most heavily populated and has the highest petroleum consumption. With virtually no local natural petroleum resources and limited refineries, the Northeast area must cover its deficit in refined product supply through pipeline deliveries from the Gulf Coast and imports of refined products by tanker. The Midwest (PADD II) has a better balance of supply and demand to meet the needs of its less heavily populated area. Logistics hubs as well as refining hubs in the region, such as the Chicago hub, depend on deliveries from pipelines to provide their services. The Gulf Coast (PADD III) is the nation's primary oil supply region. The design and sophistication of refineries in this region are unrivaled in the world. Production from this region alone is greater than all but two members of the Organization of Petroleum Exporting Countries (OPEC). Low regional demand enables it to provide for the needs of the other regions. The Rocky Mountain States (PADD IV) are thinly populated and more than 80 percent of the consumption within the area is low-sulfur diesel fuel for highway

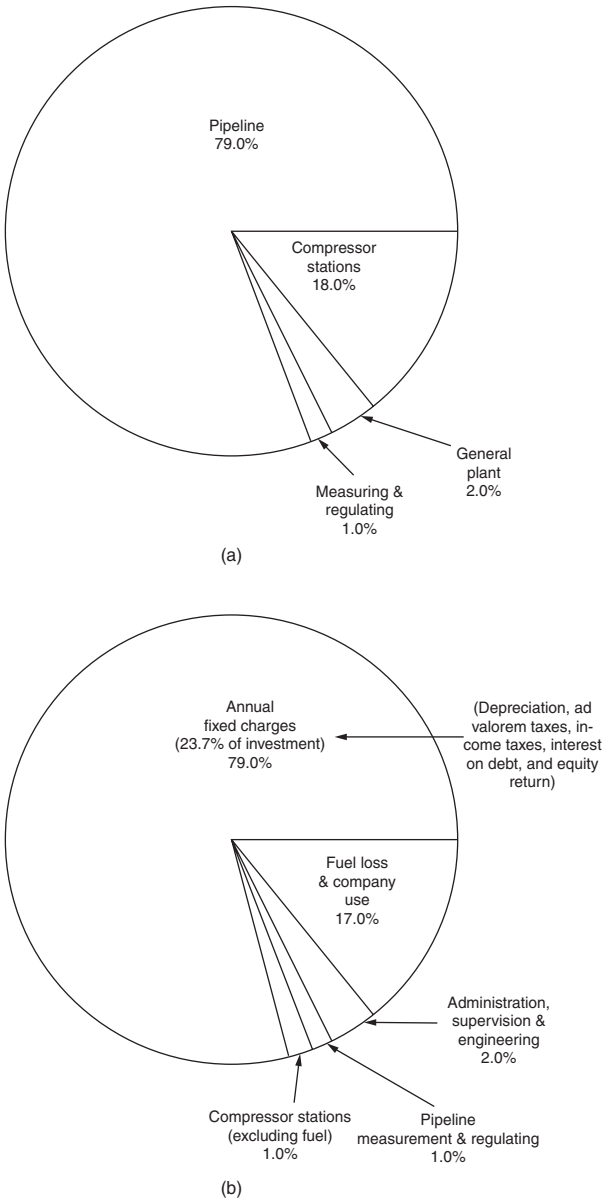

Fig. 11.7.7 Analysis of (*a*) investment and (*b*) cost of transportation.

consumption. On a per capita basis, the consumption of diesel fuel is approximately 60 percent higher than the national average, but its consumption per square mile is less than 30 percent of the national average. Pipelines serving this region distribute products from refineries in Denver, CO, Billings, MT, and Casper, WY. The West Coast (PADD V) oil market is separated from the rest of the country geographically as well as politically. For many years, the Rockies have been a challenge to the transport of oil in and out of the region. More recently, California's stringent oil product specifications have exacerbated its isolation from oil supplies. There is high demand in the region, due to the high population in California. Kinder Morgan is one of the key pipeline companies in the region, redistributing products from refineries in the northwest corner of Washington and from its own system in Arizona, which connects to supplies in PADD III.

Centrifugal pumps have been used extensively. Generally, these units are multistaged, installed in series or parallel, depending on the application. Many operators install smaller multiple units instead of larger single units to improve operating efficiency and flexibility.

Reciprocating pumps are installed in parallel; i.e., a common suction and a common discharge header are utilized by all pumps. There are instances where rotary, gear, and vane-type pumps have been employed to fulfill specific requirements.

Electrically driven centrifugal pumps are now widely employed for the liquid pipeline industry because they are environmentally friendly and because of their compactness, low initial costs, and ease of control. Centrifugal pumps driven by gas-turbine engines have also come into routine use.

Positive-displacement and turbine meters are in general use on products systems (see Sec. 16). Totalizers for multimeter installations and remote transmission of readings are an industry standard. Greater application of meters with crude-oil gathering facilities is being made as automatic-custody units are installed.

Flow The **Darcy formula,**

$$h_f = \frac{fLV^2}{D2g} \tag{11.7.7}$$

where h_f = friction loss, ft; f = friction factor (empirical values), dimensionless; L = length of pipe, ft; D = ID, ft; V = velocity flow, ft/s; and g = 32.2 ft/s^2, is in general use by engineers making crude-oil pipeline calculations. The Darcy formula, when stated in a form utilizing conventional pipeline units, is

$$P = 34.87\frac{fB^2S}{d^5} \tag{11.7.8}$$

where P = friction pressure drop, lb/(in^2 · mi); f = friction factor (empirical values), dimensionless; B = flow rate, bbl/h (42 gal/bbl); S = specific gravity of the oil, dimensionless; and d = ID, in.

The **Williams and Hazen formula,** which has wide acceptance for product pipeline calculations, can be stated in a form employing conventional pipeline terms as follows:

$$P = \frac{2340B^{1.852}S}{C^{1.852}d^{4.870}} \tag{11.7.9}$$

where P = friction pressure drop, lb/in^2 per 1,000 ft of pipe length; B = flow rate, bbl/h; S = specific gravity of the oil product; C = friction factor, dimensionless; and d = ID, in. The friction factor C includes the effect of viscosity and differs with each product (C for gasoline is 150; for No. 2 furnace oil, 130; for kerosene, 134).

The brake horsepower for pumping oil is

$$\text{hp} = \frac{RSh}{3960E} \tag{11.7.10a}$$

or

$$\text{hp} = \frac{BP}{2450E} \tag{11.7.10b}$$

where R = flow rate, gal/min; S = specific gravity of the oil; h = pump head, ft; E = pump efficiency, decimal fraction; B = flow rate, bbl/h; and P = pump differential pressure, lb/in^2.

Design The pipe and fittings for oil transmission lines are manufactured in accordance with specifications of the API and are fabricated, installed, and operated in the United States in conformance with Federal Regulations, DOT, Part 195 (see also Sec. 8). Many factors influence the working pressure of an oil line, and the ANSI B31.4 code for pressure piping is used as a guide in these matters. A study of the hydraulic gradient, land profile, and static-head conditions is made in conjunction with the selection of the mainline pipe (Sec. 3).

Oil pipelines typically carry multiple products or grades of product in the same pipeline. This is accomplished by introducing the different products sequentially at the origin of the pipeline so that a given "batch" of the product occupies a section of the pipeline during the transport. A 25,000-barrel (4,000-m^3) product will occupy nearly 50 miles (80 km) of 10-in-diameter (273-mm) pipeline. Product batches are typically transported without any special means or devices to separate them. Turbulent flow minimizes interface mixing, whereas flows that start and stop will generate greater interface contamination. In most pipelines, interface contamination is relatively minor. It is typical for 150 barrels (24 m^3) of mixed material to be generated in a 10-in (273-mm) pipeline over a shipment of 100 miles (161 km). The mixed material is not lost or wasted, as it reflects the two materials from which it is generated. The interface mix between batches of different grades of the same material is generally blended back into the lower-grade material. The interface mix between batches of different products which cannot be blended is segregated and reprocessed in a full-scale refinery or special facility built for that purpose.

Terminals receiving products typically distinguish between batches by monitoring the specific gravity of the product. The pipeline operator "swings" batches from one pipeline or storage facility to another based on this signal of the interface location. This method of separating batches of low-sulfur diesel fuel may become inadequate, however, as ultralow-sulfur diesel (ULSD) fuel specifications are mandated. The ULSD may be contaminated by the sulfur in the adjacent product by the time the shift in specific gravity is discernable. This is one of the challenges facing products pipelines as product specifications become more critical.

Oil and refined petroleum products pipelines that are referred to as *trunk* lines transport high volumes of product over long distances. Pipelines that transport smaller volumes over shorter distances are called *delivering* pipelines. Both types of pipelines deliver batches of product based on contract deliveries. These delivery contracts also fall into two modes of operation: batched service and fungible service. Under *batched service*, a specific volume of refined petroleum products tracked throughout the transportation process. The product delivered is the same material designated for the contract at the origin of the shipment. Under *fungible service*, the carrier does not deliver the same material that is designated for the contract at the origin of the shipment, but instead delivers material that has the same product specifications. Operating and economic efficiency are the bases for which mode of operation is used. In general, the fungible mode is most efficient since it tends to minimize the generation of interface contamination and permits split-stream deliveries to multiple customers from the same batch. Trunk lines in fungible service provide greater flexibility than delivering pipelines operating in batch mode. The chances for operating lockouts increase as a trunk line reaches its furthest delivery capillaries. Such a lockout could occur if a terminal does not have the capacity to accept a scheduled shipment and there are no alternative terminals available to accept it. The pipeline would be stalled until the product can be delivered.

Determining the pipe size and station spacing to transport a given oil or oil product at a specified rate of flow and to provide the lowest cost of transportation is complex matter. Usually the basic approach is to prepare (1) a series of pipeline cost estimates covering a range of pipe diameters and wall thicknesses and (2) a series of station cost estimates for evaluation of the effect of station spacing. By applying capital charges to the system cost estimates and estimating the system operating costs, a series of transportation-cost curves similar to those in Fig. 11.7.8 can be drawn.

Estimates of $30,000 to $120,000 per in (per 2.54 cm) of OD represent the cost per mile (1.61 km) of installed trunk pipeline. The tabulation of pump-station investment costs for automated electric-motor, centrifugal-type installations presented in Table 11.7.3 can be used for preliminary evaluations.

Careful design and good operating practice must be followed to minimize contamination due to interface mixing in oil-product pipelines. When the throughput capacity of an oil line becomes fully utilized, additional capacity can be obtained by installing a parallel pipeline or a partial-loop line. A partial loop is a parallel line that runs for only part of the distance between stations. In the case of product lines, careful attention must be paid to the design of the facilities where the loop line is tied into the original pipeline to prevent commingling of products.

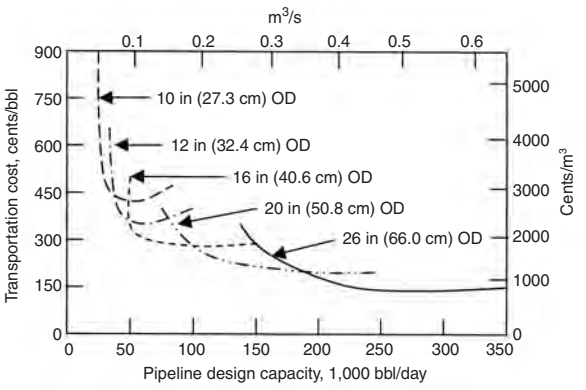

Fig. 11.7.8 Schematic relationship of pipeline capacity to cost of transportation.

Table 11.7.3 Pump-Station Investment Costs

Pump-station installed hp, total	Cost per installed hp (1 hp = 0.746 kW)
250–500	$800–1,400
500–750	$600–1,050
750–1,000	$500–850
1,000–2,000	$350–600
Above 2,000	$300

SOLIDS

General Solids may be transported by pipeline by a number of different methods. In *capsule pipelining*, dry solids are placed in a circular capsule, which is then pumped down the pipeline. This method can have economic and other advantages in many cases, especially where water is scarce, because the water is never contaminated and can be returned easily in a closed loop.

Another method being developed for the transport of coal is by *coal log pipelines* (CLPs). Pulverized coal is mixed with a binder (usually petroleum-based) to form a solid log, designed to resist water absorption, that can be transported down the pipeline intact. No dewatering is required with this method of coal transportation, and because the binder is combustible it enhances burning. Considerable research, funded by the Department of Energy (DOE), the National Science Foundation, the Missouri Department of Economic Development and the Electric Power Research Institute (EPRI) as well as numerous private companies, is being conducted at the Capsule Pipeline Research Center (CPRC), University of Missouri [both the Columbia Campus (UMC) and the Rolla Campus (UMR)]. A number of coal companies and electric utilities have proposed potential demonstration projects to refine this methodology so that it may be considered commercially viable. In addition to economic advantages, CLP offers environmental benefits that may improve the chances for state-level eminent domain legislation that restricts the development of coal slurry pipelines in the United States. These advantages include considerably less water usage (25 percent) than slurry pipelines; reduced water contamination compared to slurry pipelines; reduced air and noise pollution, due to fewer coal trucks and coal trains; reduced traffic congestion and accidents; less coal dust; and cleaner power plants. It is also predicted that commercial development of this methodology will lead to greater use of capsule pipelines for transportation of grain, agricultural products, solid wastes, and other solids.

The most prevalent method of transporting solids by pipeline is by *slurry*. A slurry is formed by mixing the solid in pulverized form with a true liquid, usually water, to a consistency that allows it to be pumped down the pipeline as a liquid. Nonvolatile gases, such as carbon dioxide, may also be used as the carrying fluid. In some instances, the carrying fluid may also be marketed after separation from the solid.

Slurry Transport Some of the solids being transported in slurry from considerable distances by pipeline are coal, coal refuse, gilsonite, phosphate rock, tin ore, nickel ore, copper ore, gold ore, kaolin, limestone, clay, borax, sand, and gravel. Solids pipelines differ from pipelines for oil, gas, and other true fluids in that the product to be transported must be designed and prepared for pipeline transportation. After much research in the field of slurry hydrotransportation, methods for predicting the energy requirements for pipeline systems have vastly improved and slurries are transported today at much higher concentrations than 20 years ago. In the early, 1980s, slurry designs ranging from 45 to 58 percent concentration, by weight, were common. Today, ultrafine coal-water mixtures with concentrations, by weight, ranging up to 75 percent, or more, are used. Dispersants and chemical additives, such as **Carbogel** and **Densecoal** are used to reduce drag and facilitate pumping. These additives significantly reduce the operating costs of slurry pipelines. Additional savings are realized by direct burning of these high-concentration coal-water mixtures through a nozzle, since dewatering is not required.

Current trends in the construction of solids pipelines and those proposed for construction indicate that future transportation of minerals and other commodities will bear more consideration. Some of the commercially successful slurry pipelines throughout the world are listed in Table 11.7.4.

Advances in slurry rheology studies and technology related to homogeneous and heterogeneous slurry transport have made the potential for slurry pipelining unlimited. Immediate advantages for slurry pipelines exist where the solids to be transported are remotely located; however, each potential slurry transport project possesses some other advantages. Materials must satisfy the following conditions to be transported by long-distance pipelines: (1) the largest particle size must be limited to that which can readily pass through commercially available pumps, pipes, and other equipment; (2) solids must mix and separate easily from the carrying fluids or be consumable in the slurry state; (3) material degradation must be negligible or beneficial to pipelining and utilization; (4) material must not react with the carrying fluid or become contaminated in the pipeline; (5) the solids-liquid mixture must not be excessively corrosive to pipe, pumps, and equipment; (6) solids must not be so abrasive as to cause excessive wear at carrying velocities.

Coal Slurry Uncleaned coal can be transported by pipeline, but a more stable and economic long-distance pipeline operation can be achieved with clean coal. The use of clean coal allows a variety of supply sources; produces a slurry with a lower, more uniform friction-head loss; reduces the pipe-wall wear, and increases the system capacity. Cleaning pipeline coal costs considerably less than cleaning coals for other forms of transportation, since drying can be eliminated after the cleaning operation.

Coal-slurry preparation normally consists of a wet grinding process for reducing clean coal to the proper particle size and size-range distribution. The final slurry-water concentration can be adjusted before it enters the pipeline with quality control of the slurry holding tanks. The cost of slurry preparation is only slightly affected by changes in concentration or size consist. The normal slurry-preparation-plant practice is to hold the concentration within 1 percent of design to provide a slurry with a uniform pressure drop. Continued research has made it possible to predict accurately the anticipated pressure drop in a pipeline by using a laboratory and computer correlation.

Optimum characteristics for a slurry are (1) maximum concentration, (2) low rate of settling, and (3) minimum friction-head loss. Variables that can be manipulated to control and optimize slurry design are particle shape, size distribution, concentration, and ash content. Established computer techniques are used to evaluate these variables.

Design Because of the many slurry variations, there is no single formula available by which the friction-head loss can be readily determined for all slurry applications. A general approach is described by Wasp, Thompson, and Snoek (The Era of Slurry Pipelines, *Chemtech*, Sept. 1971, pp. 552–562), and by Wasp, Kenny, and Gandhi in their book, "Solid-Liquid Flow Slurry Pipeline Transportation," giving calculation methods that have been developed for predicting slurry pressure drops. The described methods are quite accurate and can be used for preliminary design. Additional calculation procedures and methods for specifying slurry size consist (solid size–range distribution) and

velocity have been developed by continuing research and may be found in the following books: Shook and Roco, "Slurry Flow Principles and Practice," Butterworth Heinemann, 1991, and Wilson, Addie, and Clift, "Slurry Transport Using Centrifugal Pumps," Elsevier, 1992. Slurry hydraulics should be verified with bench-scale tests and compared with commercial operating data reference points or pilot-plant operations before constructing a full-scale long-distance pipeline.

Slurry velocities are generally limited to a minimum critical velocity to prevent solids from settling to the bottom of the pipe and a maximum velocity to prevent excessive friction-head loss and pipe-wall wear. These velocity limitations and the throughput volume determine the diameter of the mainline pipe. The relationship of volume and velocity to the pipe diameter is expressed as $\text{ID} = 0.6392 \sqrt{(\text{gal/min})/V}$, where the ID is in inches, gal/min is the volume rate of slurry flow (gallons per minute), and V is flow velocity, ft/s.

Pipe-wall thickness in inches is computed by the modified Barlow formula as $[(PD/2SF) + t_c]/t_m$, where P = maximum pressure, lb/in^2; D = pipe OD, in; S = minimum yield strength of the pipe, lb/in^2; F = safety factor; t_m = pipe mill tolerance, usually 0.875; and t_c = internal erosion/corrosion allowances, in, for the life of the system. The internal metal loss results from the erosion of corrosion products from the pipe wall and thus can be limited with chemical inhibitors and velocity control. This metal loss occurs in all pipeline steels and according to Cowper, Thompson, et al., Processing Steps: Keys to Successful Slurry-Pipeline Systems, *Chem. Eng.*, Feb. 7, 1972, pp. 58–67, must be evaluated on a case-by-case basis. A minimum pipe wall of 0.250 in (0.635 cm) is often used to provide mechanical strength for large lines, even where pressures and wear permit the use of a thinner wall. Coal pipelines employ a graduated wall thickness to meet the demands of the hydraulic gradient, which saves pipe costs.

Pump-station hydraulic horsepower is calculated as $(P_d - P_s)(Q)/1{,}716$, where $(P_d - P_s)$ = pressure across the station, lb/in^2; Q = maximum flow rate through the station in gallons per minute, and 1,716 is a constant, gal/(ft in^2). Stations usually employ positive-displacement reciprocating pumps of the type used for oil-field mud pumps, as they attain high pressures with low slurry velocities. This allows fewer stations and lower overall costs than with centrifugal pumps. Stations are located where the friction-head loss and the effects of terrain have reduced the pressure head to 100 ft (30.48 m). Centrifugal pump usage is advantageous in low-pressure, high-velocity applications such as coarse coal transportation for short distances.

The annual tonnage throughput for any diameter line can be varied within the velocity limits or by intermittent operation near the low velocity limit. The optimum mainline size for high-load-factor systems is found by comparing the relative cost of transportation for a series of pipe sizes, as in Fig. 11.7.9.

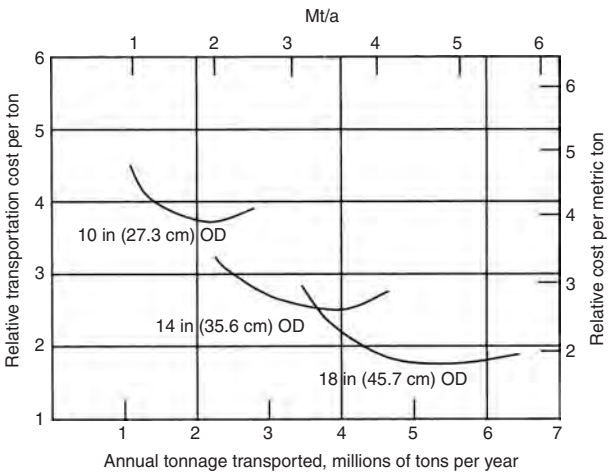

Fig. 11.7.9 System relative transportation cost for various mainline pipe sizes.

When a main-line size is selected, the cost of transportation for that line size at various rates of throughput is weighed against the projected system growth and compared with other line sizes to determine the size which gives the best overall system economics. Coal pipelines cannot be expanded by line looping because of the velocity limitations. Some expansion can be attained by oversizing the line and operating it intermittently near the minimum velocity in the earlier years of life.

11.8 CONTAINERIZATION

(Staff Contribution)

REFERENCE: Muller, "Intermodal Freight Transportation," 4th ed., Eno Foundation for Transportation. "The Container Handbuch," Web address: www.containerhandbuch.de.

Shipping of freight has always suffered from pilferage and other losses associated with the handling of cargo and its repeated exposure to weather conditions and to human access. In addition, the extremely labor-intensive loading and unloading practices of the past became more and more expensive. In the late 1920s and early 1930s the forerunners of present-day container service were offered. They varied from containers on trucks to services in which railroad cars were loaded onto rubber-tired trailers and delivered to the customer's door with no intermediate handling of the cargo. Starting in 1956, containerization as we know it today came into being.

The immense savings in shipping costs resulted in the rapid growth of containerization throughout the world in the 1960s and 1970s and in international standardization. The time savings obtainable through the use of containers is particularly noticeable in maritime service. It is estimated that a container-handling ship can achieve a 4 : 1 sea-to-port time ratio compared to 1 : 1 for a conventional break-bulk ship.

CONTAINER SPECIFICATIONS

There are many **standards** which apply to containers, among which are ISO, ANSI, the International Container Bureau (BIC), and the American Bureau of Shipping (ABS).

In order for a container to be used on a ship or a plane, a **CSC plate** is required. CSC stands for the International Convention for Safe Containers. CSC is also defined as standing for Container Safety Convention. A CSC plate is good for 5 years after construction. After that, the container must be reinspected at least every 2 years. Alternatively, a container may come under an Approved Continuous Examination Program (ACEP) under which registered owners examine, maintain, and repair their own containers.

Every conceivable aspect about containers, their construction, usage, labeling, biological-pest treatment, marking and numbering, is covered by detailed international standards. "The Container Handbuch," which is in both German and English and has Web address www.containerhandbuch.de, describes many of these.

Types Ninety percent of containers are dry, nonrefrigerated units with double doors on one end. Other types include refrigerated and/or insulated units, ventilated units, tank containers, and frames with folding ends or corner posts for carrying large items such as automobiles.

Condensation can be a problem inside a closed container. While a good unit can protect against outside elements, it cannot protect against condensation inside the container unless special steps are taken. Condensation typically arises from the moisture in the product being shipped; temperature changes during the trip; or moisture from dunnage, packing, or the container itself.

Construction materials usually consist of a steel, aluminum, or fiberglass outer cover on an internal steel frame. Containers are designed to be stacked from six to ten units high. Since containers are designed with oceangoing shipment in mind where the container, and those stacked on top of it, will be rising and falling with the movement of the ship, the additional acceleration forces have to be taken into account. This is usually done by rating the maximum stacking load using a *g* force of 1.8.

Figure 11.8.1 shows a typical 20-ft container. At each of the eight corners there are special fittings which facilitate the lifting, stacking, interconnecting, and tying down of units. These fittings have specially shaped slots and holes which enable standard crane and sling hooks and clevises to be used as well as special hooks and twist-locks.

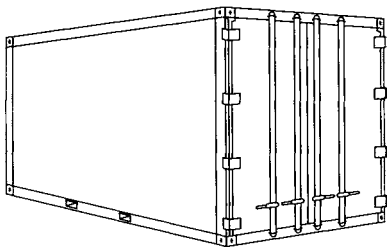

Fig. 11.8.1 Typical 20-ft container.

Sizes The most widely used containers are 20 ft (6.1 m) or 40 ft (12.2 m) long by 8 ft (2.5 m) wide by 8 ft (2.5 m) high. The usual height of 102 in (2.6 m) includes an 8-in-deep (200-mm) underframe. This frame often has two, or sometimes four, transverse slots for forklift forks. Standard lengths are: 20, 35, 40, 45, and 48 ft (6.1, 10.7, 12.2, 13.7, and 14.6 m).

Typical specifications for a 20-ft (6.1-m) container are: maximum gross weight of 52,910 lb (24,000 kg), tare of 5,070 lb (2,300 kg), payload of 47,840 lb (21,700 kg), cubic capacity of 1,171 ft^3 (33.2 m^3), and allowable stacked weight for a *g* force of 1.8 of 423,280 lb (192,000 kg).

Typical specifications for a 40-ft (12.2-m) container are: maximum gross weight of 67,200 lb (30,480 kg), tare of 8,223 lb (3,730 kg), payload of 58,977 lb (26,750 kg), allowable stacked weight for a *g* force of 1.8 of 304,170 lb (182,880 kg), cubic capacity of 2,300 ft^3 (65 m^3). Thus a 40-ft (12.2-m) container has roughly the same volume as a 40-ft (12.2-m) highway semitrailer. A typical 40-ft (12.2-m) dry-cargo container with an aluminum outer skin weighs about 6,000 lb (2,720 kg).

Specifications for a typical 40-ft (12.2-m) **refrigerated** container are: maximum gross weight of 67,200 lb (30,480 kg), tare of 8,770 lb (3,980 kg), payload of 58,430 lb (26,500 kg), allowable stacked weight for a *g* force of 1.8 of 423,307 lb (192,000 kg), cubic capacity of 2,076 ft^3 (58.8 m^3). The refrigeration system specifications are: minimum inside temperature of 0°F (–18°C), maximum outside temperature of 100°F (38°C). The refrigeration system is powered through cables connected to the loading site, the ship, or to a generator mounted in the bed of the container chassis or trailer.

Some companies have a sufficiently large volume of shipping to have containers differing from these specifications. For example, the refrigerated containers used to ship Chiquita bananas are 43 ft (13.1 m) long. Their specifications are: maximum gross weight of 67,200 lb (30,480 kg), tare of 8,270 lb (3,750 kg), payload of 58,930 lb (26,730 kg), allowable

stacked weight for a *g* force of 1.8 is 335,980 lb (152,400 kg), and a cubic capacity of 2,324 ft^3 (65.8 m^3). The height of the floor above the bottom of the underframe is 11 in (280 mm). The refrigeration rating is 16,721 Btu/h (4,214 kcal/h). Electric power supplied is three-phase at 460 V, 60 Hz (or 380 V, 50 Hz). The overall heat-transfer rate is 7,965 Btu/h (2,007 kcal/h).

ROAD WEIGHT LIMITS

The gross weight of a typical 40-ft (12.2-m) dry-cargo container is about 67,000 lb (30,000 kg). The special-purpose semitrailer for carrying containers on the highway is called a **container chassis** and weighs about 10,000 lb (4,500 kg). The towing tractor weighs about 16,000 lb (7,256 kg). Many U.S. highways do not allow such heavy loads. Typical allowable axle loads are 12,000 lb (5,442 kg) on the front wheels, 34,000 lb (15,420 kg) on the tractor rear wheels, and 34,000 lb (15,420 kg) on the chassis wheels. So if the container is to be forwarded by truck in the United States, the load must be limited to 54,000 lb (24,500 kg) and, on many secondary roads, even less. Similar constraints exist elsewhere in the world as well. As with any closed shipping space, depending on the density of the material being shipped, the weight or the volume may be the controlling factor.

CONTAINER FLEETS

As of 1988 about half of the world's containers were owned by container-leasing companies. Most of the remainder were owned by carriers. About 4 percent were owned by shippers. Container shipment figures and fleet sizes are usually given in TEUs (20-ft equivalent units). A **TEU** is the equivalent of a 20-ft (6.1-m) by 8-ft (2.5-m) by 8-ft (2.5-m) unit.

Containers are easy to make. As a result the competition among manufacturers is intense. The low-cost manufacturers are in Japan, Taiwan, the Peoples Republic of China, and South Korea. In 2004, prices for new standard 20-ft and 40-ft dry-freight containers were in the range of $1,800 to $2,200 and $2,500 to $5,200, respectively. For 20-ft and 40-ft refrigerated containers, prices were $5,000 to $9,000 and $10,000, respectively.

CONTAINER TERMINALS

A typical marine container terminal may have 50 acres (20 hectares) of yard space. It can load and unload 150 to 200 ships a year, and in so doing handle 60,000 to 80,000 containers. Under such circumstances the requirements for record keeping and fast, efficient handling are very severe. Specialized container-handling cranes and carriers have been developed to facilitate safe, fast, damage-free handling.

Handling Equipment By its design and purpose, the container is intended to go from shipper to receiver without any access to the contents. The container with its load may, however, travel by truck trailer from the shipper to the railroad, by rail to a marine terminal, by ship across the ocean, and again by rail and by truck trailer to the receiver. While the container is on the truck trailer, rail car, or ship, little or no handling needs to be done. When a container changes from one mode of transportation to another, at intermodal or transfer points, the container requires handling.

The general transfer tasks of **container-handling machinery** are: ship to/from rail, ship to/from truck, and rail to/from truck. Since a ship may have a capacity of up to 4,400 20-ft containers, extensive yard storage space has to be available. A 50-car double-stacked railroad train can handle up to 200 containers. Container-handling equipment varies from a simple crane with some slings or a large forklift truck at low-volume sites to special-purpose gantry and boom cranes and straddle carriers at high-volume sites.

Terminal designs come in two basic types: decked and wheeled systems. With a **wheeled** system, the containers are stored on their highway trailers. They are transferred to/from the loading crane by terminal tractors, which are also called *yardhorses.* In a **decked** system, the containers are removed from their highway trailers, rail cars, or ships and stacked in rows on the paved yard surface. When the containers are to be loaded, they are picked up at the stacked location, if possible by straddle carriers or mobile cranes, and loaded onto outgoing highway trailers, railcars, or ships. When the full area of the container storage yard is not accessible to the cranes, containers may be loaded onto yard trailers and transported from their stack location to the cranes. An equivalent procedure is also used for incoming containers where they must be transferred by yard trailer from the cranes to their yard storage location.

OTHER USES

As containers age and lose their CSC certification, their use as shipping containers becomes more restricted. Many businesses are finding that containers no longer acceptable for shipping service make excellent low-cost storage facilities and construction- and other-site offices. They are weather- and rodent-proof.

12.1 INDUSTRIAL PLANTS

by Vincent M. Altamuro

REFERENCES: Hodson, "Maynard's Industrial Engineering Handbook," 4th ed., McGraw-Hill. Cedarleaf, "Plant Layout and Flow Improvement," McGraw-Hill. Immer, "Materials Handling," McGraw-Hill. Rosaler, "Standard Handbook of Plant Engineering," 2d ed., McGraw-Hill. Merritt and Ricketts, "Building Design and Construction Handbook," McGraw-Hill.

PURPOSES

Industrial plants serve many **functions.** They can:

1. Protect people, products, and equipment from the weather.
2. Preserve and conserve energy.
3. Condition the inside environment to be suitable for the processes, products, and people engaged therein.
4. Protect the outside environment from any fumes, dust, noise, or other contaminants their processes produce.
5. Provide physical security for their contents.
6. Block access, visual and/or physical, of those not authorized to see inside or enter them.
7. Provide the stable, strong, and smooth platform or surface required for operations.
8. Be the frameworks for the distribution networks of the services needed—electric power, lights, fuels, compressed air, gases, steam, air conditioning, fire protection, water, drainage piping, communications.
9. Support the cranes, hoists, racks, and other lifting and holding equipment attached to their superstructures.
10. Be integral parts of equipment (such as drying ovens) by having one or more walls serve as sides of them, and the like.
11. Be safe, pleasant, and efficient places to work for employees, impress visitors, and reflect positively on the company.
12. Fit the surroundings, blend in, be aesthetically attractive, make architectural statements.

This list of design criteria can be expanded to include functions other than those cited and which may be specific to a given proposed plant.

After a plant's expected present and future activities and contents are defined, it is designed to provide the desired functions, and then built to provide spaces for operating personnel and to house equipment and services. An existing plant considered for purchase or lease must be selected so that it will provide its user a competitive advantage. Generally, the decision to own or rent a plant depends on factors such as the expected life of the project, prudent use of capital, the possible need for early occupancy, the availability of a rentable building that matches the requirements, and the possibility of either a very rapid growth or complete failure of the enterprise. Some **commercial real estate** developers will erect a building to meet the specifications of the future operators of the industrial plant and then lease it to them under a long-term contract, often with an option to buy it at the end of the lease. A new structure to be designed and built must have its specifications clearly established so that it will serve its intended use and fit its surroundings.

The creation of an **industrial plant** involves the commitment of sizable resources for many years. The plant is therefore a valuable asset, both present and future. Its design and construction must be timely and within budget, and once undertaken, the project must, at most, be subject to minor modifications only, and preferably none. Once the structure is in place, it is very difficult or not economically feasible to move or change the plant. Even if not truly irreversible, design decisions can be corrected or changed only with great difficulty and added expense. There is often little difference in the cost of designing a plant and configuring its equipment and services layout one way versus another. The difference arises in the operating expenses and efficiencies, i.e., the wrong way versus the best way.

When designing a plant, one should estimate how long it is expected to last—both economically and physically. When making this determination, one accounts for the expected lives of the products manufactured, the processes and manufacturing methods used, the machines used, and the extant technology, as well as the duration of the market, the supply of labor, and so forth. Plant life and production life should coincide to the maximum extent possible. Major difficulties arise when a plant becomes obsolete and may warrant either abandonment or, at best, major modification for conversion. Often the manufacturing methods employed in production have so far outgrown the original methods that the conversion of an existing plant cannot be justified at all.

Obsolescence can be deferred by making the factory versatile, adaptable, and flexible. Possible changes in conditions can be anticipated and the ability to alter the plant can be included in the original design. An industrial plant is said to be *versatile* if it can do more than one thing, if its equipment can switch over and make more than one variation of the product, or if its output can be raised or lowered easily to match demand. It is said to be *adaptable* if it can make other related products with only programming and tooling changes to its equipment, without the need to alter their layout. It has *flexibility* to the degree that it is easy to move its services, machines, and other equipment to change the layout and flow paths, and thereby accommodate different products and changing product mixes. Such a building will have a minimum of permanent walls, barriers, and other fixed features. A plant can be made to be general-purpose or special-purpose, or more one than the other. A general-purpose plant is more generic and can be used for a wide variety of purposes. It is usually easier and less expensive to design, build, and convert to new use and is more salable when no longer needed. A special-purpose plant is designed for a specific task. It is more efficient and can make a lower-cost product, as long as the specifications stay within narrow limits. With modular machines, quick-change tooling, and programmable automation, such as robots, it is possible to gain the advantages of both general- and special-purpose construction in one plant. It can be built with the versatility, adaptability, and flexibility to be configured one way for one set of requirements, then reconfigured when conditions change. This enables the manufacturer to produce the wide variety of products that consumers want, and still make them with the lower per unit costs of a special-purpose plant. Both economy of scale and economy of scope are possible in the same facility.

Most industrial buildings are intended to be permanent structures—or at least to last many years. In cases where a permanent building is not essential, an industrial type of tent may be an alternative. **Tent technology** has advanced markedly. The advantages are that tents can be erected more quickly, more easily, and less expensively. They can be made with aluminum arch struts which support membrane envelopes made of flame-retardant vinyl, resulting in large poleless open spaces. The stronger designs can withstand winds of up to 80 mi/h (128.7 km/h). Naturally, they are not as strong as conventional structures, and security may be a problem; vandals can cut right though the vinyl skin. They find applications as churches, schools, prisons, and other entities as well as industrial buildings. In some cases, they are used to handle expansion or additional space needs until more permanent conventional buildings can be built. Models are now available with two floors, stairs, elevators, mezzanines, windows with screens, double doors with locks, wood flooring or carpeting, chandeliers, tiled toilets, lockers, HVAC, etc.

There are trends in the design of some products which are causing plants to be constructed differently, in addition to the demand for the benefits of versatility, adaptability, and flexibility cited above. Some products are getting smaller: computers, electronic circuits, TV cameras, and the like. For other products, greater manufacturing precision and freedom from processing contamination require the establishment

of ultraclean facilities such as clean rooms. These and other trends are causing some plants to be built with the ratio of manufacturing space to administrative space different from that in the past. In some plants with large engineering, design, test, quality control, research and development, documentation, clerical, and other departments, the prior ratios have been reversed, so that manufacturing and warehousing spaces constitute a rather small percent of the total plant.

In addition to the basic building structure and its supporting services, an industrial plant comprises people, raw materials, piece parts, work in process, finished products, warehouse stock, machines and supporting equipment, systems and services, office furniture and files, computers, supplies, and a host of other things. While each is an individual entity, the plant must be designed so that all can work together in an **integrated and balanced system.** For a new facility, the best way to achieve this end is to design it in a progressive manner, going from the general to the specific, with each step based on prior decisions, until a set of detailed specifications is established. The sequence of design decisions is not linear, wherein one is finalized before the next one starts. Rather, it is more like a series of loops, with the output of one feeding back and possibly modifying prior decisions. For example, plant size could influence the site chosen, which then could influence the amount of air conditioning and other services needed, all of which, in turn, require space that could change the prior estimate of plant size. Almost all decisions have an impact on one or more interrelated plant specifications. The design of the product influences the degree of automation, which sets in motion a chain of decisions, starting with the number of employees required, down through the number of toilets, the size of the cafeteria, medical department, parking lot, personnel department, etc., and ultimately even placement of emergency exit doors.

PLANT DESIGN

An industrial plant must fulfill its intended functions efficiently and economically. Its design must consider and account for the basic operating conditions to be served. A detailed discussion along those lines follows.

Prerequisite Data, Decisions, and Documentation

The decision to build or buy an individual plant is made by the company's senior executives. It involves the commitment of large sums of money and is properly based on major considerations: need for additional production capacity; introduction of a new product; entering new markets; availability of new and/or better technology and machinery; building a new plant to replace an existing inefficient one or refurbishing and tailoring the existing plant for new production processes and cycles; relocation to a different area, especially if closer proximity to markets and availability of specialized labor are involved; making products in house which were previously bought for resale. Studies, analyses, and projections provide input data to help determine the proper site, size, shape, and specifications of a plant. Economic analyses, technological forecasts, and market surveys are used to justify the investment in a plant and to calculate the approximate amount of money required, break-even point, payback period, and profitability. Detailed product design and engineering documentation includes drawings, parts lists, test points, inspection standards, and specifications. Product variations, models, sizes, and options are defined. Sales forecast data addresses expected unit volumes, seasonality, peaks and valleys, growth projections, and other patterns. In addition to projections, constraints on the plant must also be understood at the outset. These may include location restrictions, budgetary limitations, timing deadlines, degree of mechanization, the type of building and its appearance, limits on its effluents, exhaust fumes, and noise, and other effects on the neighborhood and environment.

Activities and Contents

The determination of the activities and contents of a plant is facilitated by a series of analyses and management decisions. Make/buy decisions determine which items or component piece parts are to be made in the plant and which are to be purchased and stored until needed. Some purchased items are used as received, others need work (e.g., painting, plating, cutting to size). Parts purchased on a just-in-time basis will reduce the amount of in-process storage space required.

Processes are classified as **continuous** (e.g., refineries, distilleries, paper mills, chemical and plastic resin production); **repetitive** (e.g., automobiles, air conditioners, appliances, computers, telephones, toys); or **intermittent,** custom job shop, or to order (e.g., elevators, ships, airliners). Some plants include combinations of these processes when they make several types of products. In such mixed, or **hybrid,** situations, one product and processing method usually dominates, but there are cases where a plant set up for mass production work has a special-order shop to make small quantities of variations of the basic product, such as a vending machine that accepts only specific foreign coins. The manufacturing methods used in these processes may include casting, shearing, bending, drawing, forming, welding, machining, assembly, etc. (see Sec. 13). **Engineering documentation** used to facilitate manufacturing analysis includes operations analyses, flow process charts, precedence diagrams, "gozinto" charts, bills of materials, and exploded views of subassemblies and final assemblies. With computer-aided design (CAD) and other graphics, these documents can often be constructed, updated, and stored in a common database.

These documents help define the operations, their sequence and interrelationships, inspection points, storage points, and the points in the process where materials and parts join others to form subassemblies and the finished product. (See Hodson, "Maynard's Industrial Engineering Handbook.") Special characteristics of the operations may be noted on these documents, such as "Very noisy operation," "Piece parts can be stacked, but after assembly, they cannot," and the like. Product movement is determined. People/tools/things must move in an industrial plant. Workers and their tools go to the stationary work in process, as in shipbuilding; the worker and the work go to stationary tools, as in a general machine shop; the work in process goes to the workers and the tools, as in an assembly line. Other combinations of the relative movement of workers, tools, and work in progress are used. (See Cederleaf, "Plant Layout and Flow Improvement.")

An industrial plant should be designed to facilitate, not hamper, the **smooth movement of people, material, and information.** The efficiency of flow is also influenced by the layout of the equipment and other contents of the building. A multilevel building implies movement between the levels, which usually takes more time, energy, and expense than having the same activities on one level. Some operations are performed better in high structures, where raw material is elevated and then gravity-fed down through the lower levels as it evolves into a finished product. A plant built into the side of a hill receives material directly into an upper level without the need to elevate it. In most cases, a single-level plant affords the opportunity for the most efficient flow of materials and product. Even a single-level plant should have all its floor at the same elevation so that material moving from one area to another need not go up or down steps, ramps, or inclines. Features of the building such as toilets and utilities should be located where they will not interfere with the most efficient plant layout, and will not have to be moved in relayouts or expansions.

To the maximum extent possible, the **material flow** through an industrial plant should be smooth, straight, unidirectional, and coupled (the output of one machine should be the input to another, without a large cushion of inventory between them); require the least rehandling; be at constant speed over the shortest direct route, with the least energy and expense; and be always directed toward the shipping dock. Raw materials and piece parts should move continuously through the plant as they are converted progressively by a combination of people and equipment into finished products of the desired quantity and quality. Materials must flow with few interruptions, side excursions, or stops, so that they are in the plant for the shortest time possible and thereby facilitate expeditious product completion. Where possible, movements should be combined with operations, such as having a mobile robot or an automatic guided vehicle (AGV) work on (inspect, sort, mark, pack, etc.) the item while transporting it. An analysis of the plant's activities,

including a list of its contents and an analysis of their relative movements, results in a rational determination of how they must flow through it. This must be done for materials (raw materials, purchased parts, work in process, finished goods, scrap, and supplies), people, data, and services.

Space and Size Calculations

Annual sales forecasts plotted by the month sometimes show peaks and valleys due to **seasonal variations** in demand. A plant with the capacity to produce the highest month's demand has much of its capacity idle or underutilized in the other months. The ideal plant would have a constant output every month, with long production runs of each item to minimize tool changes and setup times. This is not always practicable, for either very high inventory buildups or shortages could result. The compromise is the calculation of a production schedule that is more level than the sales forecast, builds as little inventory as possible without risking shortages, and allows for rejects, equipment breakdowns, vacations, bad weather, and other interruptions and inefficiencies. This will result in a plant with less production equipment and space but with more inventory space (and associated material handling equipment) to accumulate finished product to meet shipping demands in response to sales. Obviously, the warehouse and other storage areas must accommodate the maximum amount of inventory expected to be stored.

The proper size of a plant is determined by **calculating the total space required** (immediate and future) by all its contents: material at all stages of production, people (employees and visitors), equipment (production, materials handling, support, and services) and the ancilliary spaces required (working room, aisles, lobbies). At first, only the **general types of equipment are specified** (spot welders, overhead chain conveyors, forklift trucks, etc.). Later, **specific items are selected** and listed by manufacturer, model number, capacity, speed, size, weight, power, and other requirements. (See Sec. 10.) Finally, one model may be substituted for another to gain a particular advantage. A simplified typical equipment selection calculation follows:

1. Define the operation: Joining.
2. Decide the method: Welding.
3. Note personnel available: Semiskilled.
4. Determine general machine type: Spot welder.
5. Calculate required production output:

Spot Welds Required

	Product			
	A	B	C	Total
Number of spots	120	60	80	
Units per year	10,000	40,000	20,000	
Spots per year, millions	1.2	2.4	1.6	5.2
Spots per day (250 days/year)				20,800
Spots per hour (8 h/day)				2,600
Spots per minute (60 min/h)				44

6. Select a particular candidate machine, considering type of metal, thickness of metal, diameter of spot. From catalog, choose manufacturer (e.g., Hobart) and model (e.g., series 1500 rocker arm SW-V).
7. Calculate capacity of one machine in minutes per spot.

Operating time	0.03
Material handling time	0.06
Setup time allocated	0.01
Minutes per spot	0.10

8. Calculate the number of machines needed.

$$N = \frac{TP}{60HU}$$

where N = number of machines required; T = standard time to perform the operation, minutes; P = production needed per day, operations; H = standard working hours per day; U = use factor—up-time of the machine, its utilization (percent of time it is producing), or its efficiency. Example:

$$N = \frac{0.10 \times 20{,}800}{60 \times 8 \times 0.80} = 5.4 \text{ machines}$$

9. Round off to next higher number: 5.4 becomes 6 machines.
10. Alternatively, return to catalog to see if there is a faster model. If so, 5.4 could become 5 of a different model machine.
11. Record specifications of selected machine on an equipment card or in a computer file. Appropriate notations should be made therein, such as:

Crane must go over this machine.
Must be near outside wall for venting.
Will require supplemental lighting.
Requires a special foundation.
Requires a drain for water.
Allow room on side for gear changes.
Allow room for largest-size sheet-metal parts.

12. Use data for all machines needed to help establish specifications for equippage of the plant:

Sum of space required (including space for workers, material, aisles, services) becomes size of that department or function.

Sum of utilities and supplies (electricity, water, steam, compressed air, oxygen, nitrogen, acetylene, coolants, lubricants, air conditioning) addresses requirements for them.

Sum of weights affects floor loading capacities and specifications. For some parameters, the extreme value is important in establishing the building specifications; i.e., the height of the tallest machine may set the required clear height inside the plant, locally or throughout. Equipment mounted on columns or roof beams will influence their size. Specific equipment may require special foundations or subfloor access pits.

Sums of the prices of the machines and the required tooling, the number of workers, their required skills, and their wages and benefits provide information regarding the investment and operating expenses for the plant.

The same procedure is used to determine the **material handling equipment,** its required space, and its influence on the plant's specifications. (See Immer, "Materials Handling.") Equipment may be capable of moving materials horizontally, vertically, or in both directions; some have a fixed path of travel, while the paths of others can be varied. The general types of equipment that move materials horizontally in a fixed path include conveyors, monorails, and carts pulled by trucks, dragged by chains in floor troughs, or that follow buried wires. Conveyors are overhead or floor-level type. Overhead conveyors clear the floors of some congestion but add to the loads carried by the building's columns and beams. Other types of conveyors are installed at floor level or at working height, and include belt conveyors and powered or unpowered roller conveyors. The general types of material handling equipment that travel in variable horizontal paths include hand trucks, powered trucks, pallet trucks, and automatic guided vehicles. Those that travel in fixed vertical paths include elevators, skip hoists, chutes, and lift tables. Those that travel in both horizontal and vertical fixed paths include traveling bridge cranes, gantry cranes, jib cranes, and pneumatic tubes. Those that travel in both horizontal and vertical variable paths include robots and forklift trucks. Forklift trucks may be powered by either battery, gasoline, or liquefied petroleum (LP) gas. Those powered by batteries will require the installation of charging facilities within the plant, and those with internal combustion engines will require safe fuel-storage space.

The installation of each of the above-listed material handling equipment types will influence the plant's specifications in some way. In computing loads on the building's structural members, all static and dynamic loads arising from material handling equipment must be factored into their design, as applicable.

With respect to **raw material,** its form, weight, size, temperature, ruggedness, and other qualities are considered, as are the expected distances to be moved, speed of transit, number of trips, and amount carried per trip. For **warehouses,** the important considerations are cubic space and density of use for various package sizes, weights, and stacking patterns.

The same basic approach is used for **support functions** and **plant services.** The space required for people can be estimated by listing them by functions, jobs, and categories (male versus female, plant versus office, department, location, shift, etc.), then allocating space to each. For example, office floor space allocation in ft^2 (m^2) per person may be: plant manager, from 150 to 300 (13.9 to 27.9) depending on size and type of plant; assistant plant manager, 125 to 250 (11.6 to 23.2); department heads, 100 to 200 (9.3 to 18.6); section heads, engineers, specialists, 100 to 150 (9.3 to 13.9); general personnel, 50 to 100 (4.6 to 9.3). When accounting for all employees in an industrial plant, the space per person can range from about 200 to 4,000 ft^2 (18.6 to 370 m^2), depending on the type of industry and the degree of automation employed. An estimate of the male/female ratio often must be made early in the planning stage, for many localities will issue a building permit only if adequate sanitary and rest facilities are included for each gender.

The space required for each department and function is compiled and added to show the approximate total plant size. See Fig. 12.1.1, which also shows the percent of the total plant floor space allotted to functional subtotals. The size of the plant should not be deemed final without including the manner in which to allow for anticipated growth and/or plant expansion. Anticipated growth, if realistic, must enter into the decisions reached as to the initial size of the plant to be built. When dealing with the initial plant size vis-à-vis any anticipated future expansion, some questions usually posed are: Should it be large enough to accommodate expected growth, knowing that it will be too big initially? Should it meet only present needs, then be expanded as and if required? Should a midsize compromise be made? A plant too big for present needs will cost more to build and operate and may place the firm in an uncompetitive position. Expenses for taxes, insurance, heating, air conditioning, etc. for a partially vacant plant are almost the same as for one fully occupied. On the other hand, a plant built just to satisfy present requirements of a growing business can quickly become cramped and inefficient and may lead to rental of external storage and warehouse space, with all the added expense and loss of control entailed thereby. Any future expansion of the original plant will not only be disruptive to operations, but also will cost significantly more than building it bigger in the first place. The correct choice is made by analyzing all options and comparing expected costs and profits and the realistic probability of growth.

Department or function	Area ft^2	Area m^2
Main receiving	5,700	530
Incoming inspection	900	84
Main stockroom	9,600	892
Large-component storage	6,000	557
Coil steel storage	1,840	171
Steel coil line	2,360	219
Sheet metal fabrication	18,000	1,672
Welding	3,000	279
Sheet-steel storage	13,800	1,282
Copper tubing storage	600	56
Tubing fabrication	1,200	111
Cleaning and painting	9,600	892
Insulating	1,200	111
Electrical subassembly	1,200	111
Final assembly	33,600	3,121
Finished goods storage	40,200	3,735
Wood storage and fabrication	2,400	222
Shipping	9,600	892
Maintenance and tool room	600	56
Print shop	600	56
Plant offices	1,200	111
Engineering laboratory	12,000	1,115
Reproduction room	420	39
Canteen/eating area	3,600	334
Medical/first aid	330	31
Offices and lobby	21,600	2,007
Toilets	1,650	154
Total	202,800	18,840

Function	% of total plant	ft^2	m^2
All receiving, incoming inspection, storage, and shipping	44.2	89,440	8,309
All production	35.3	71,360	6,629
Engineering lab and repro	6.2	12,420	1,154
Support areas: Maintenance and tool, print, first aid, canteen, toilets, plant offices	4.0	7,980	741
General offices and lobby	10.3	21,600	2,007
Total	100.0	202,800	18,840

If a building is to be expanded or upgraded easily and economically after it is built, that capability must be included at the outset. This is done by deciding in advance the direction and degree of possible future expansion, knowing that if the business grows, not all sections of the plant may have to be expanded to the same degree. After the basic form of the building shape and envelope have been addressed, attention is then directed to other matters: location of the building on the property; materials of construction for internal walls that may have to be rearranged; location of spaces and equipment that will be difficult or impossible to move in the future, such as toilets, shipping/receiving docks, transformers, heavy machinery, and bridge cranes.

Superstructure members, pipes, monorails, ducts, and so on can be terminated at the proposed expansion side of the plant, with suitable end caps or terminations which may be removed easily and activated quickly when required. Installations of major utilities are prudently sized to handle future expansion. If the initial design strategy includes anticipation of vertical expansion via mezzanines, balconies, or additional stories, foundations, footings, superstructure, and other structural elements must be designed with that expansion in mind. To accommodate that requirement at some later date will prove to be prohibitively expensive and will disrupt ongoing operations to a degree unimaginable. By the same token, if future operations require a contraction of active space in the proposed plant, space would be available, at worst, for sublease to others. Regardless of whether possible expansion or contraction is contemplated, the initial plant design should consider both possibilities and seek to have either occur with minimum disruption of production.

Plant Emplacement and Site Selection

The emplacement of a plant is defined by its geographical location, site, position, and orientation, in that order. Geographical location is determined by the country, region, area, state, county, city, and municipality in which the plant is situated. The site is that particular plot of land which can be identified by street address or block and lot numbers in that geographical location. The position and orientation speak to the exact placement and compass heading of the building on the site.

Those responsible for finding a place to build an industrial plant should be aware that places once polluted, unbuildable, and uninhabitable can sometimes be cleaned and cleared for occupancy after a time and treatments. The famous Love canal site in upstate New York had to be evacuated in 1978–1980 after more than 21,000 short tons of buried chemicals started oozing into basements and contaminating groundwater. Now, 20 years later, people are living safely in new homes there. Therefore, it might be productive to look at previously condemned places for the possible reclassification by the EPA as removed from the **Superfund** list and now decontaminated and buildable. Places cleaned

up just enough that the remaining risk is compatible with the way the land is to be used are called **brown fields,** such that one may be designated as "clean," or not, if, say, a parking lot, an industrial plant, or homes are to be built on it.

Typical considerations entering each stage of the placement decision, from broad to specific, follow.

Location: Political and economic environment. Stability of currency and government. Market potential. Raw materials supply. Availability and cost of labor. Construction or rental costs. Environmental regulations. Climate. Applicable laws within the governing jurisdiction. Port, river, rail, highway, airport quality. Utilities and their relative costs. Taxes. Incentives offered. Local commercial services. Housing, schools, hospitals, shops, libraries, museums, restaurants, parks, houses of worship, and other community attractions. Crime rate, police and fire protection. General ambiance of the locality. Also, the trends of all the above.

Site: Availability. Price. Incentives offered. Building and zoning codes. Near highway entrance/exit, on railroad spur, waterway, and major road. Public transportation for employees. Availability of water, sewer, and other utilities. Topography, elevation, soil properties, subsurface conditions, drainage, flood risk, earthquake faults. Neighbors. Visibility.

Position: Placement for possible expansion with sides of building that may be extended facing an open area or parking lot and the sides not to be extended close to the property line. Proximity to railroad tracks, road, utilities or other fixed features. Positions of buildings on neighboring property.

Orientation: Turned toward or away from winter's wind and summer's sun, as desired, considering the frequently open large shipping and receiving doors. Needs for heating, air conditioning, natural light, color matching, and the like that would be affected by compass heading.

Proximity to competitors may be desirable if the locale has developed into a well-recognized center for that industry, where are found skilled people and a wide variety of suppliers and supporting services, (e.g., testing laboratories, local centers of higher learning with faculty available for consultation on an ad hoc basis). Without these conditions, and especially if the product is heavy and expensive to ship, it is desirable to locate close to market areas and distant from competitors.

The amount of land required depends on plant size, the number of employees and their need for parking space, the probability of storing some raw materials and finished goods outdoors, the need to turn large trucks around on the property, the possibility of future expansion of the plant, zoning, and the possible desire to create an open park-like ambiance. Total land area of from 4 to 8 times the plant size is usually adequate; the lower end of the range applies in built-up areas, and the higher end applies in suburban areas. In some locations the land can cost more than the plant.

Before placement of a plant becomes final, all conditions and extremes should be simulated, including winter storms, rainy seasons, floods, several consecutive days of 100°F heat, power outages, labor disruptions, and the like. It is unlikely that the perfect site will be found, thus sought-after attributes must be ranked in order of importance. As an incentive to get new industry, some governments will build roads and schools and reroute buses if necessary. Test borings are often taken at a candidate site before a commitment is made to buy or lease it to ensure that it is suitable. A plot plan (see Fig. 12.1.2) can be made with an approximation of the planned plant on the candidate site indicating land size, topography, drainage, position on the plot, anticipated expansion, compass orientation, location of power lines, railroad tracks, roads, rivers, open fields, neighbors, etc.

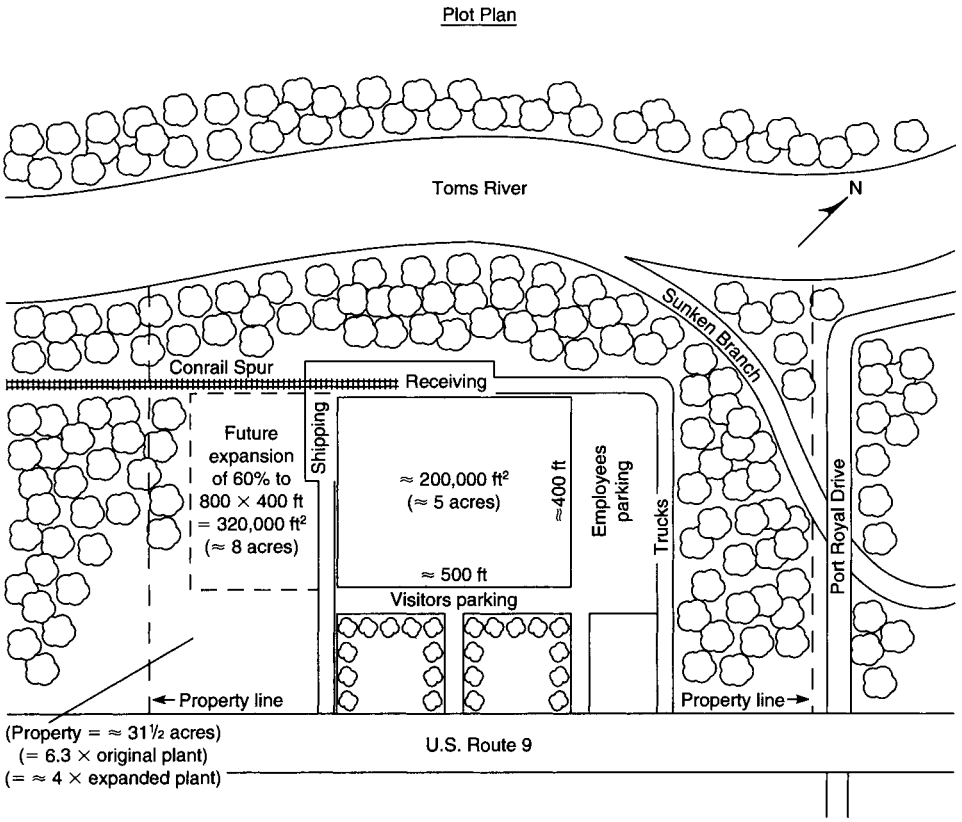

Fig. 12.1.2 Plot plan of an industrial plant. *(Source: VMA, Inc.)*

Configuration

The configuration of a plant is determined ideally by the optimum layout of its contents. Compromises are usually made, however, often resulting in a conventionally shaped building. A building with several extended branches is very expensive. For a given floor area, a square building requires less total wall length than other quadrilateral shapes, but rectangular buildings are the most common compromise between cost and efficiency. For the lease or purchase of an existing building, the best approach is to design the best layout and then seek an existing building within the desired area in which that layout may be accommodated. For a new building, the layout is set down before the location is selected and then adjusted for the particular features of the site. A layout prepared after the site has been selected can be tailored to fit the site, all the while maintaining the desired features of that layout.

Before the configuration and layout become final, certain broad and tentative choices about the type of building should be made. These include general-purpose versus special-purpose, multilevel versus single level, use of mezzanines and balconies, with windows or windowless, etc. Setting aside considerations of material flow, a multilevel building enjoys the advantages, on a unit floor area basis, of using less land and costing less to build. The columns, however, will generally be spaced closer together, thereby presenting an impediment to desired flow paths and a reduction in options for overall layout. A single-level building, on the other hand, can more easily support heavier floor loads by virtue of its concrete slab on grade floor construction.

The matter of the shipping/receiving floor level vis-à-vis the truck bed level must be resolved satisfactorily, keeping in mind that loading and unloading ought to be effected with small hoists or forklifts for maximum efficiency. To that end the loading floor level can be built to be flush with the bed height of most of the anticipated truck traffic, or the truck parking apron can be inclined downward to align the two. If those cases when trucks with other bed heights have to be accommodated, small demountable ramps can be employed, the same being built sufficiently rigid to permit forklift traverse.

Balconies and mezzanines may be added to gain more storage space, to locate offices with a view of the production areas below, for raw materials or subassembly work that can be gravity-fed and drop-delivered to the operations below, and for the placement of service equipment (hot-water tanks, compressors, air conditioners, and the like). Basements may be included for the placement of heavy equipment, pumps, compressors, furnaces, the lower portion of very tall machines, supplies, and employee parking.

Windows in an industrial plant lower lighting bills, permit truer color matching in natural light, aid cooling and ventilation when opened, may provide a means of egress in case of fire, and may lower fire insurance rates. The advantages of a windowless plant are easy control of the intensity and direction of light (elimination of glare, contrasts, shadows, diffusion, and changing direction); (sometimes) less expensive construction; and less heat transfer, dust and dirt infiltration, maintenance expense to wash and repair glass, and worker distraction; better security; lower theft insurance rates. It is generally easier and more economical to design a windowless building. The absence of fenestration allows more flexibility in interior layouts by virtue of uninterrupted wall space. The absence of low windows, in particular, obviates the need for blinds or drapes to keep the interior private from the passing viewer. Elimination of an enticing target to vandals and terrorists is not to be dismissed lightly; often damage to machinery and equipment, as well as injury to personnel, results from flying missiles launched at and through windows.

The relative positions and detailed layouts of each department's machines, support equipment, services, and offices are based on analyses of their functions, contents, activities, operations, flow, relationships, and frequency of contacts. The layouts may be product- or process-oriented, or a combination of the two. In a product-oriented layout, machines are arranged in the sequence that the production process requires. This permits the product to advance in a direct path, such as on an assembly line, and with smooth material flow. In a process-oriented layout, the machines are grouped by type, such as a welding or drilling area. This requires that the products requiring those operations be brought to that area. It is used where products vary and the output of each is low, such as in a job shop, and allows production to continue even when a machine breaks down.

Another early decision involves the preferred placement of the receiving and shipping departments and the related basic pattern of material flow through the plant. If it is preferred to have the material enter at one end of the plant and exit at the other (Fig. 12.1.3*a* and *b*), then separate receiving and shipping facilities, equipment, and personnel will be required. Capital investment and operating economies ensue from combining these functions, with shared personnel, equipment, supervision, and space, but then the basic material flow will loop back to allow the finished product to exit from the same location where raw materials entered (Fig. 12.1.3*c*).

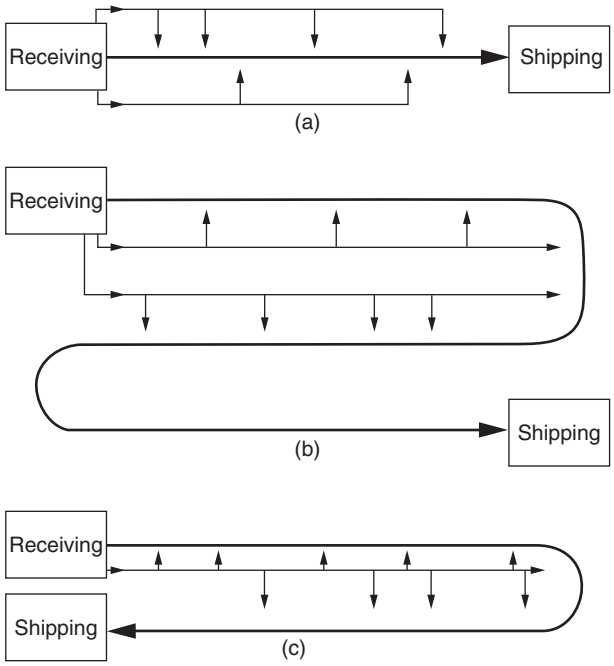

Fig. 12.1.3 Three different relative positions of a plant's receiving and shipping areas. *(Source: VMA, Inc.)*

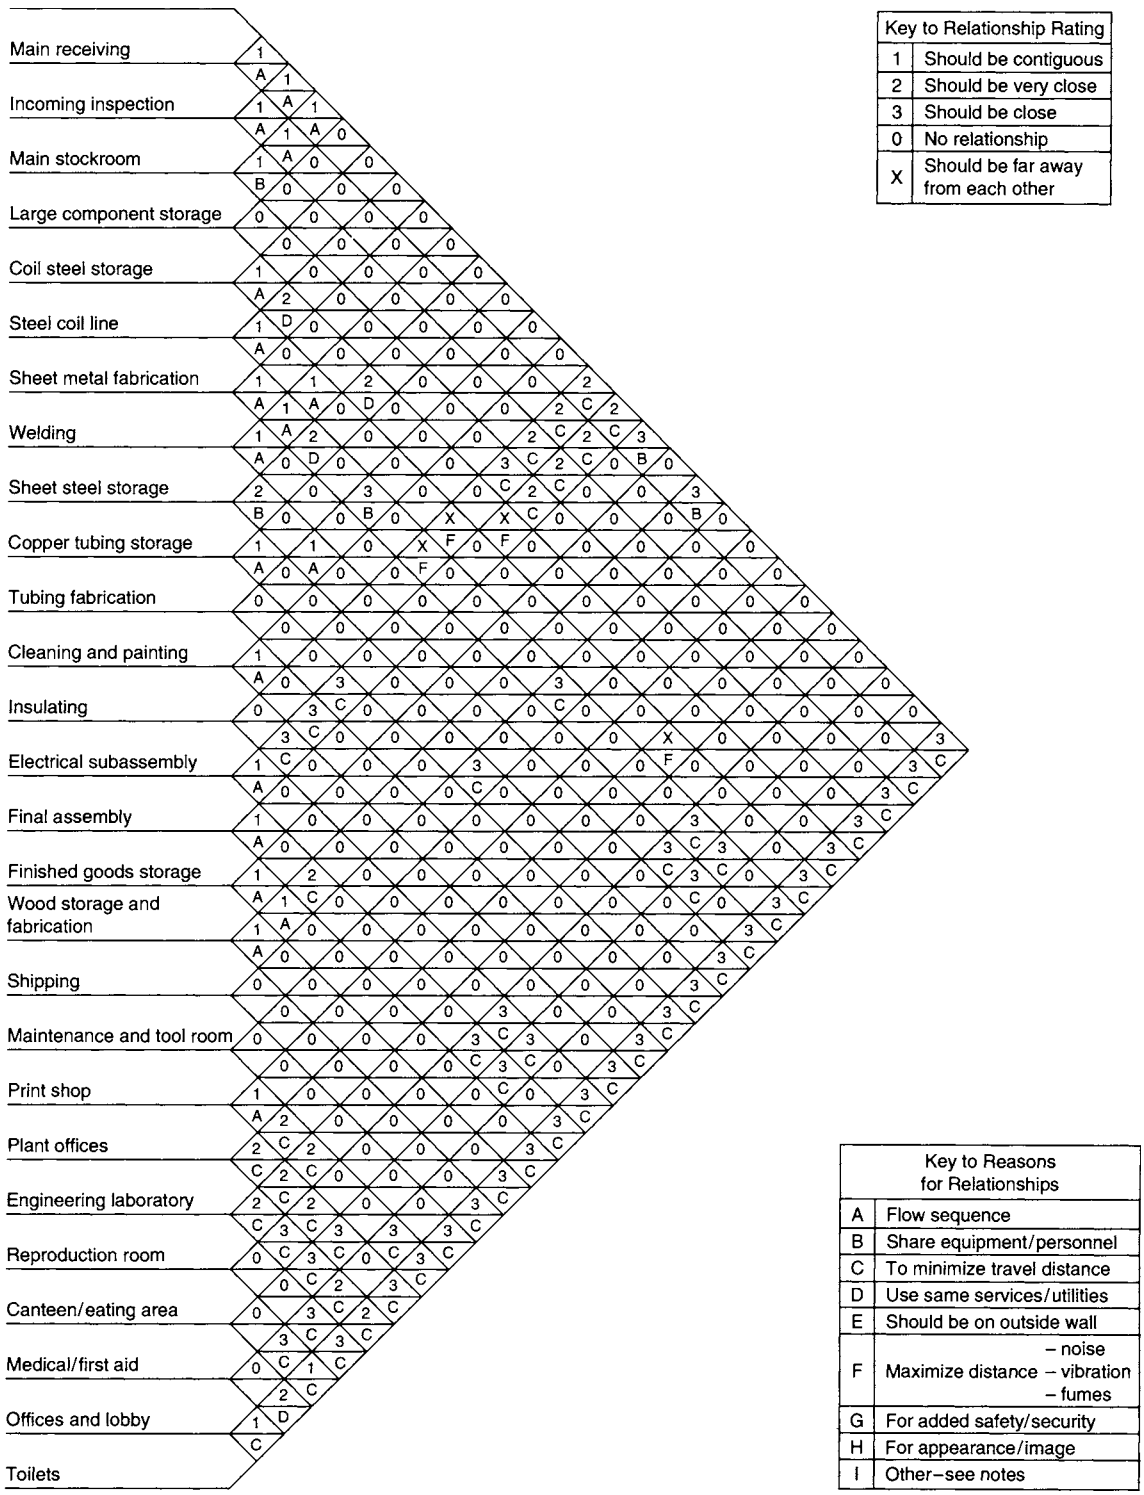
The drawing showing the size, shape, and position of each department or area of an industrial plant is called a **block diagram.** It is developed by constructing a series of **analysis documents.** These include the frequency of relationship chart, proximity preference matrix, relative position block arrangement, sized block arrangement, initial block diagram, refined block diagram, and final block diagram (or simply block diagram). The **frequency of relationship chart** (also called a **from/to chart**) is constructed from an analysis of the engineering and manufacturing documentation and the activities of the plant. It shows the frequency and magnitude of movement, flow, and contacts between the entries. It may be weighted to include the importance of high-priority factors. The **proximity preference matrix** (also called a **relationship chart**) is constructed the same way. It shows (Fig. 12.1.4) which functions, departments, equipment, and people should be close to each other, how close, and why, and which should be away from which other and why. It is constructed with a diamond-shaped box at the intersection of every two entries. The notations made in each box show the importance of their need to be either close or separated by a number or code. The reasons can also be shown by entering a code in the lower half of the box, as shown in Fig. 12.1.4. The matrix may be made at the function



Key to Relationship Rating	
1	Should be contiguous
2	Should be very close
3	Should be close
0	No relationship
X	Should be far away from each other

Key to Reasons for Relationships	
A	Flow sequence
B	Share equipment/personnel
C	To minimize travel distance
D	Use same services/utilities
E	Should be on outside wall
F	Maximize distance – noise – vibration – fumes
G	For added safety/security
H	For appearance/image
I	Other–see notes

Fig. 12.1.4 A proximity preference matrix listing the departments, functions, and areas, and ranking how near or far each should be relative to the others, and why. *(Source: VMA, Inc.)*

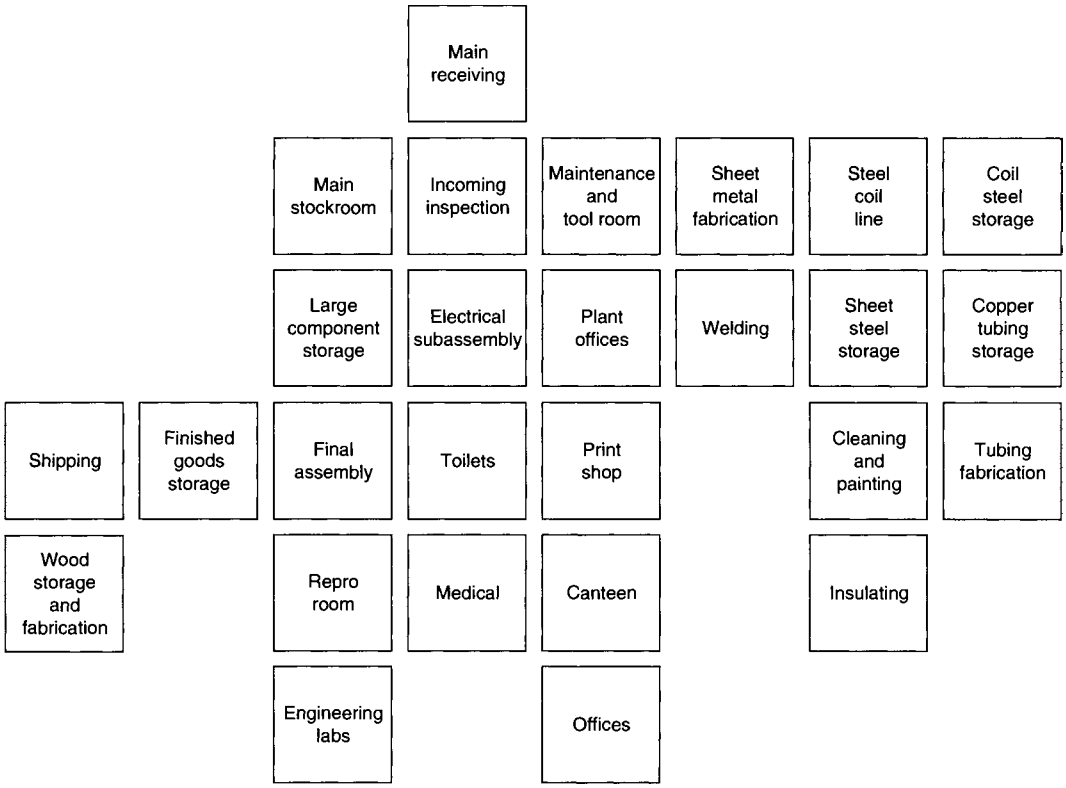


Fig. 12.1.5 A relative position block arrangement that attempts to satisfy and optimize the dictates of the prior proximity preference matrix. *(Source: VMA, Inc.)*

or department level and, later, at the individual machine or person level. The objective of the matrix and chart is to lay out the plant so that things are as close to (or as far from) other things to satisfy the criteria established, and ensure that those with the highest number of contacts are so located to minimize the time, distance, and energy required.

When this is done, a **relative position block arrangement** (Fig. 12.1.5) may be made; this shows the various arrangements possible by shifting around pieces representing the departments. The arrangement selected is the one that best satisfies the relationships (in decreasing order of importance) and degrees of contacts, as previously determined. The size of each model (or computer graphic representation) is the same because only the relative positions of the departments or areas is of interest at this stage of the design. Assigning a different color or background pattern to each adds to clarity and, when carried through to final and detailed drawings, helps visualize quickly the totals of separated areas; e.g., the total of inventory storage areas spread throughout the plant can be understood quickly if all are shaded the same color on the drawings. The **sized block arrangement diagram** (Fig. 12.1.6) is the relative position block arrangement with the size of each area scaled (but still square) to represent its square footage as determined by its expected contents and room for expansion (unless the expansion is to be handled by extending the building, in which case the department should be placed where expansion is proposed. The **initial block diagram** converts the square representation of each department into a shape that is more suitable for its contents and activities, but of the same square footage. The **refined block diagram** (Fig. 12.1.7) adjusts the initial shapes to effect a compromise between the advantages of having them be the best operational shape and those of fitting them in an economical rectangular building. L-, T-, U-, H-, and E-shaped buildings are often the result of such configuration compromises.

After the main aisles are drawn, as straight as possible, to serve as dividers between departments, the size and shape of each area can be fine-tuned, and a **final block diagram,** or simply **block diagram,** is drawn, keeping the same color code scheme used throughout. Detailed layouts are constructed for each department and function to fit within the spaces allocated in the block diagram. When assembled onto one drawing, the block diagrams become the detailed layout for the entire plant.

There are several aids to constructing both block diagrams and detailed layouts. These range from scaled templates to three-dimensional models of machines and equipment. They are available as plain blocks and as highly detailed plastic or cast-metal models. Computer-based optimization programs are also available. Some computer-aided design packages contain libraries of plant components and equipment that can be selected, positioned, rotated, and moved on the screen until a satisfactory layout is achieved. See Figs. 12.1.8 and 12.1.9 for two- and three-dimensional, respectively, computer-generated detailed layout drawings. Arrows are added to these diagrams to show flow paths. Copies of these drawings can be annotated with dimensions and machinery and furniture descriptors and given to vendors and contractors for them to submit bids to supply and install the items. They are also kept on file for use in future maintenance and/or revisions.

Features not expected to be moved in the future or that will become permanent parts of the building should be located first, e.g., stairways, doors, toilets, transformers, steam boilers, fuel tanks, pumps, compressors, piping, and permanent walls. Accurately dimensioned definitive drawings must be made to guide installers of equipment and services.

In addition to the layouts of the production areas, the support functions must also be planned. Support groups assist the production departments; they include research and development, testing laboratories, engineering, production planning and control, quality control,

machine shop, sales and advertising, technical literature, purchasing, data processing, accounting and finance, files storage, personnel, medical, administration and management, general office, supply storage, reception lobby, conference rooms, training rooms, library, mail room, copying and reproduction, cafeteria, vending machines, water fountains, washrooms, toilets, lockers, custodial and maintenance, security, and so on. Adequate space must be provided for the people working in these areas and their workstations must be designed with ergonomics, lighting, air quality, comfort, and safety in mind.

Many industrial plants have the supervisors' offices situated on the factory floor for better contact with and control of their people. Likewise, offices for quality control inspectors, industrial engineers, and manufacturing or process engineers often are located in the production areas. Such offices may be built with the building or may be purchased and installed as preengineered, prefabricated units. General and administrative offices usually are distant from the plant's machinery and equipment, whose noise and vibrations would otherwise affect the performance of the occupants therein and their ancillary equipment (computers, for example).

Office furniture may be arranged in military style (orderly straight rows), the open plan method (fewer and movable partitions), landscaped (free form with plants and curved dividers), individual offices (glass, wallboard, steel, or masonry walls), or any combination of these. In those arrangements wherein the partitions and dividers are classified as furniture instead of parts of the building, they may be depreciated over a much shorter period of time than the permanent structure. Space is allocated on the basis of position in the organization chart, with the senior executives getting windows (if any) and the most senior getting a large corner office. Floor coverings, ranging from tile to carpeting, again depends on position, as do the amount and type of furniture.

The plant's reception lobby should measure approximately 160 ft^2 (14.9 m^2) if seating for four persons is required, and at least 200 ft^2 (18.6 m^2) for 10 visitors. Add 60 to 100 ft^2 (5.6 to 9.3 m^2) if a receptionist is to be seated there. Cloak rooms require 6 ft^2 (0.6 m^2) per 10 garments.

If a cafeteria is included, 20 ft^2 (1.9 m^2) per person of expected occupancy should be provided if it is equipped with tables and chairs, plus space required by any vending machines. Conference and meeting rooms should provide about 20 ft^2 (1.9 m^2) per person of expected attendance, and training rooms with theater-type seating should be 400 ft^2 (37.2 m^2) for groups of 20, 600 (55.8) for 40, and 1,000 (92.9) for 80. A plant library will range from 400 to 1,000 ft^2 (37.2 to 92.9 m^2), depending on its contents. Record storage requires 6 ft^2 (0.6 m^2) per file cabinet. Storage space must be provided for stationery and supplies. Slop sink and mop closets should be 12 to 15 ft^2 (1.1 to 1.4 m^2). Facilities should be placed as close as possible to those who will use them; those for universal use must be located conveniently. In very large plants, spaces and facilities for universal use must be supplied in

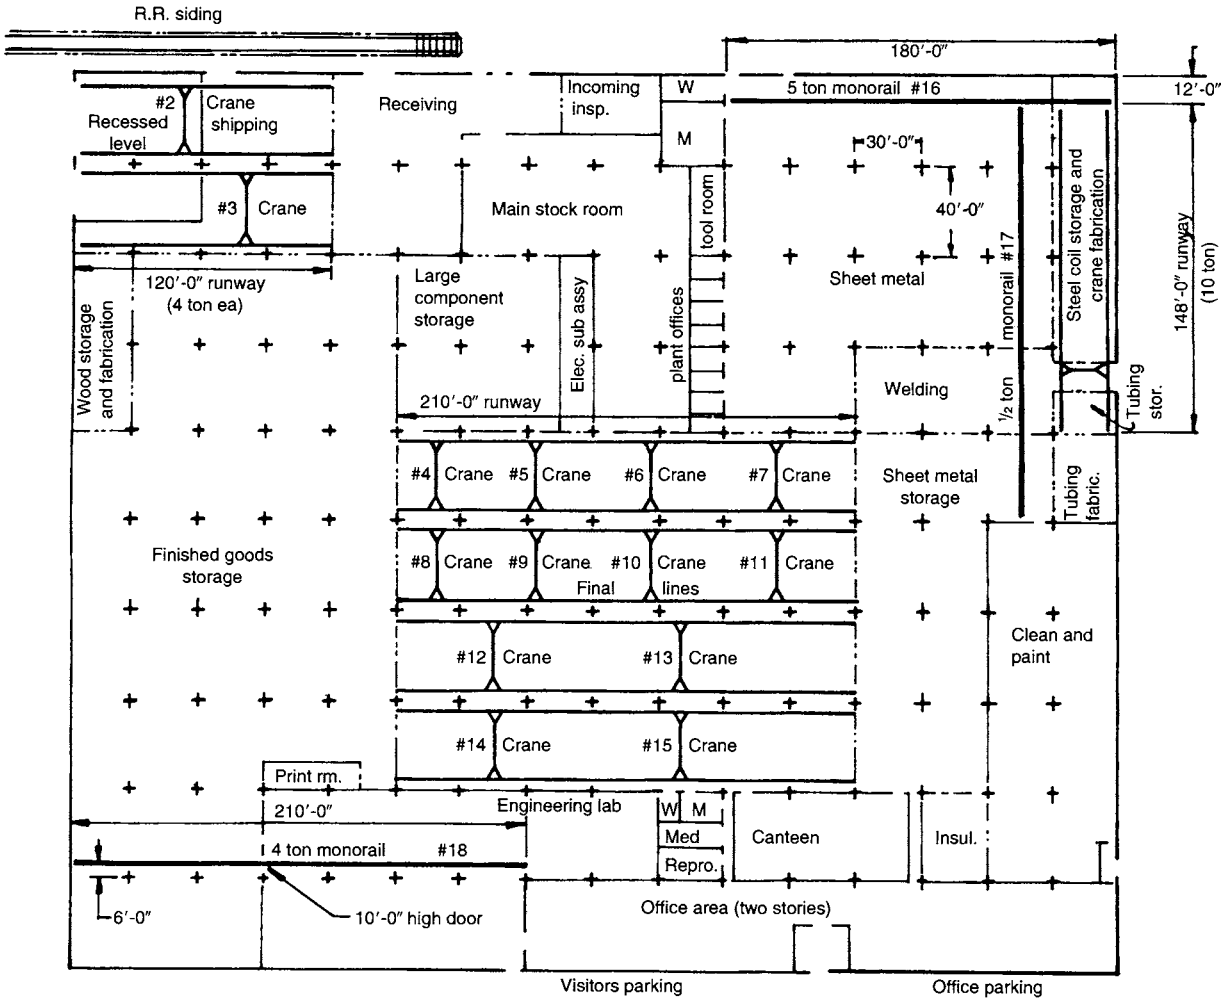

Fig. 12.1.7 A refined block diagram that converts the prior sized block arrangement onto one that makes the shape of each department, function, and area be such that, together, they fit into a building of a more conventional shape, while maintaining the size and relative position of each. *(Source: VMA, Inc.)*

multiples, and include toilets, clothes closets, lockers, time clocks, emergency exit doors, copy machines, vending machines, and drinking fountains. Aisle locations and widths are critical elements in the management of internal traffic, and are based on: use only for pedestrians or by material handling vehicles as well, in which case load widths must also be included as a design parameter; whether traffic is one-way or two-way, with loaded vehicles passing each other; traversing vehicular traffic only or with dropoff and/or pickup points along the route; and provision of turnaround space for vehicles (forklifts and the like) or restrictions on maneuvering within aisles. For efficient traffic flow, the configuration that will work best most often is one with one main aisle and a number of smaller feeder aisles, with straight, well-marked aisles intersecting at right angles. Aisles located at exterior walls will result in loss of storage space, and generally will be remote from the central area meant to be served. While necessary and functional, aisle space can occupy from 15 to 30 percent of the plant's total floor space. Planning for aisle space and the location of exits must defer to any applicable labor laws or local ordinances.

Services

An industrial plant's services are those utilities that power and supply the production and support functions. They include electric power and backup emergency power; heating, ventilating, and air conditioning (HVAC); water for processes, drinking, toilets, and cleaning; smoke, fume, and fire detection and fire fighting; natural gas and/or fuel oil, process liquids and gases, compressed air, steam; battery chargers for electric forklift trucks, AGVs, and mobile robots; communication networks and links for telephone, facsimile, computers, and other database nodes; surveillance and security systems; and waste, scrap, and effluent disposal drains and piping. The design of these requires not only the specification of the equipment, but also the layout of the distribution networks, with drops to where needed and points of interface to the apparatus served.

Flexibility is increased and unsightly and dangerous wires are eliminated by installing buried electric raceways in the floor before concrete is poured. Wires channeled thus are connected to floor-mounted equipment through access caps; changes in machine layout or additions to the complement of machinery are facilitated via connections into the raceways. Definitive, current records of buried raceways document exact locations of raceways and any modifications made thereto over periods of time, and while they are archival in nature, they serve to prevent confusion and guesswork. Other raceways and wire conduits are dispersed through the plant to accommodate electric convenience outlets, communication equipment, and similar services.

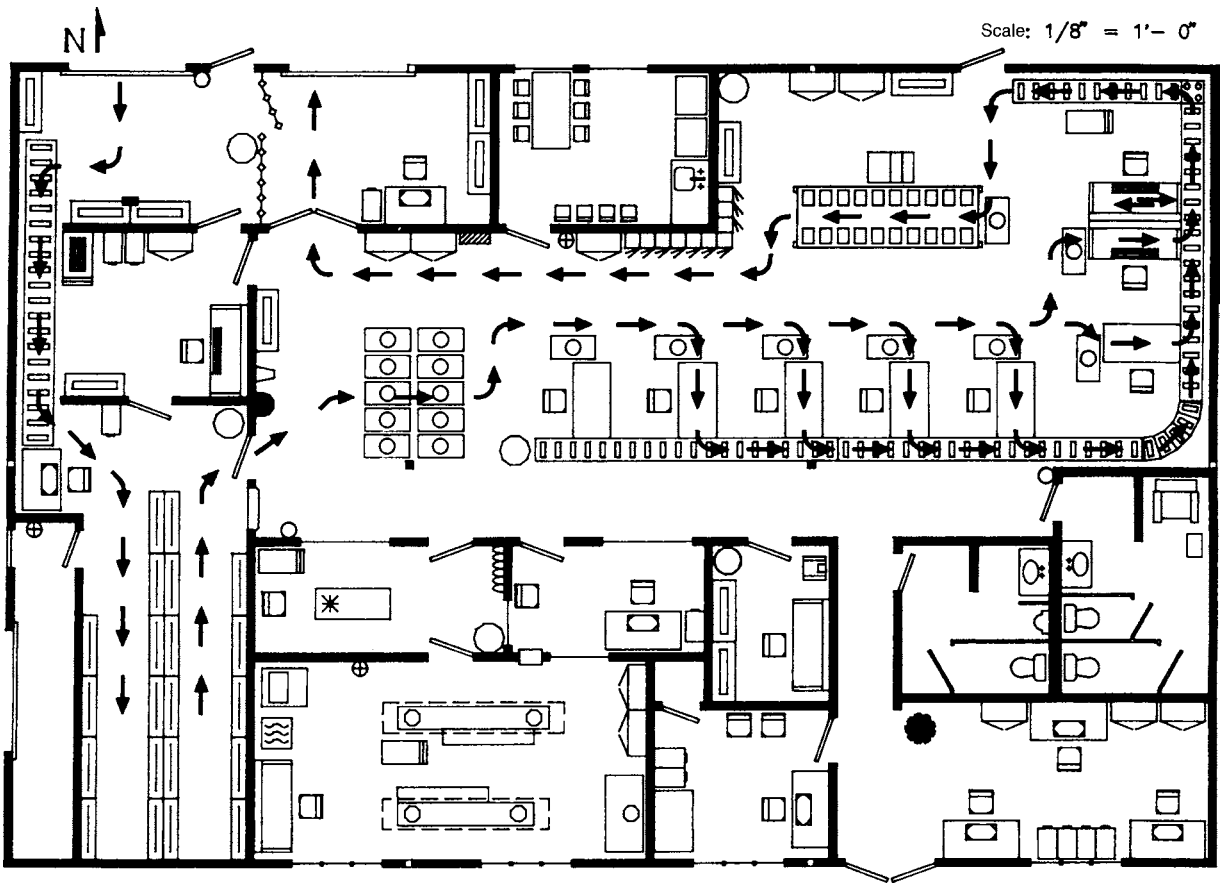

Fig. 12.1.8 A two-dimensional computer-generated detailed layout of one area of an industrial plant, showing furniture, fixtures, and flow path. *(Source: Cederleaf, "Plant Layout and Flow Improvement," McGraw-Hill.)*

Electric power is usually transmitted over the utility's lines at between 22,000 and 115,000 V. The plant usually includes transformers to reduce voltage to 2,300–13,000 V. Most building codes require that these transformers be installed outside the building. The next level of voltage reduction, down to 120–480 V, is provided by transformers usually located inside the building and dispersed to strategic locations to provide balanced service with minimum-length runs of service connections. Alternatively, the plant may arrange for the local utility to supply electric power already stepped down to the levels needed; 240/120-V single phase, three-wire; 208/120-V three-phase, four-wire; 480/277-V three-phase, four wire. The last is more economical for motors and industrial lighting.

Natural light entering the plant through windows and skylights is erratic and difficult to control. All areas of the plant must be illuminated adequately for the activities conducted therein. Section 12.5 lists typical illumination levels. Density of light, illuminance, is designated in footcandles, fc (lumens per square foot) or lux, lx (lumens per square meter). One fc = 10.76 lx. In most cases, tasks requiring illuminance more than 100 to 150 fc (1,080 to 1,600 lx) also require directed supplemental illumination. No area should be illuminated at a level less than 20 percent of nor more than 5 times that of adjacent areas because eyes have trouble adjusting rapidly to drastic differences in illuminance. Proper illumination is also a function of the type and form of the lighting fixtures. Luminaires are selected to shed direct, indirect, or diffused light. Lamp types include incandescent, fluorescent, mercury vapor, metal halide (multivapor), and high-pressure sodium vapor. The number and type of lamps per luminaire, height, spacing, and percent reflectance of the floor, walls, and ceiling are contributing factors. The plant should have a portion of its lights attached to an emergency power source that switches on when the regular power fails. (See Rosaler, "Standard Handbook of Plant Engineering.") A stationary diesel-, gas-, or gasoline-powered electric generator is usually installed to provide emergency electric power. The available fault current at all points in the electric distribution system should be determined so that protective devices can be installed to interrupt it. Selected circuits should have uninterruptible power supplies (UPSs), isolators, and regulators to protect against outages, voltage surges, sags, spikes, frequency drifts, and electrical noise. Exit signs and a clear path to the exits should be capable of being energized by emergency power, from either a standby generator or batteries.

Water, water distribution, and fixtures are essential for many plant processes, including paint booth "waterfalls"; for cooling machines, welders, and the like; for adding water as an ingredient in some products; in toilets, showers, cafeterias, and drinking fountains; for sprinkler systems and fire fighting; and for custodial work and landscaping maintenance. If large amounts of hot and/or cold water are required by the process, boilers and/or chillers are provided, along with associated piping and pumps for fuel and water distribution. The number of toilet fixtures as required by building codes is based on the number and gender of expected building occupants. Dispensers that chill and/or heat water are useful to prepare beverages and soups. Water consumption per person per 8-hr shift in personnel facilities ranges from 30 to 80 gal (114 to 303 L).

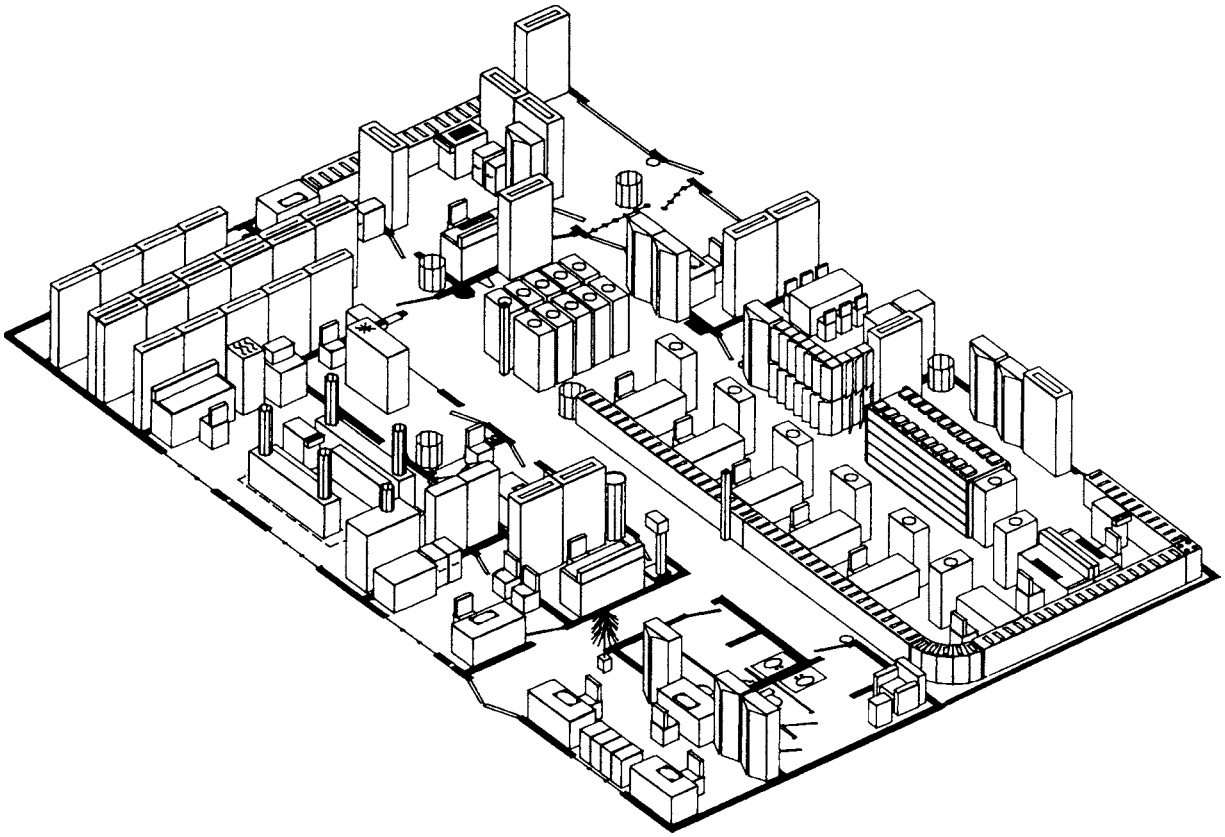

Fig. 12.1.9 A three-dimensional computer-generated detailed layout of the same area shown in Fig. 12.1.8. *(Source: Cederleaf, "Plant Layout & Flow Improvement," McGraw-Hill.)*

Fire protection In cases of large fires, fireproofing materials can prevent, lessen, or slow down the heating of a building's steel structural components, lest they lose strength, weaken, deform, and possibly collapse. Further studies of the collapse of the World Trade Center suggest that gaps in the sprayed-on insulation could act as gateways to actually direct heat onto the steel, rather than keep it away. Lightweight, fluffy fireproofing material is popular because it is relatively inexpensive and easy to spray onto the steel. But it is also easily damaged during the maintenance work on ducts, cabling, wiring, sprinkler piping, etc.; and it becomes friable over time such that the slightest touch causes it to fall off, creating the above-mentioned gaps.

Sprinklers are installed according to the recommendations of the National Fire Protection Association (NFPA). Automatic sprinklers can be the wet type, wherein water is always in the pipes up to each head, or the dry type, wherein the pipes are filled with air under pressure to restrain water until the fusible link in the head melts and releases the air pressure, allowing water to flow.

The dry type is used outdoors and in unheated areas where water could freeze. Sprinkler heads are either standard or deluge type. Standard heads have a fusible element in each head that is melted by the heat of a fire, thereby opening the head and releasing water. Deluge heads do not have fusible elements, but a deluge valve which is opened in response to a signal from any of several heat sensors situated in the protected area. In the standard type, only the heads whose elements are melted release water, whereas deluge heads act simultaneously. A deluge system is more likely to extinguish sparks at the periphery of a fire, but it also may ruin materials that are doused unnecessarily with water. A preaction system includes sensors and an alarm which gives plant personnel a chance to deal with the fire before sprinklers actuate and douse valuable merchandise. The alarm may also be wired to signal the local fire department. The sprinkler heads must be spaced in accordance with the prevailing code: generally one head per 200 ft^2 (18.6 m^2) for low-hazard areas, 90 ft^2 (8.4 m^2) for high-hazard areas, and about 120 ft^2 (11.2 m^2) for general manufacturing; about 8 to 12 ft (2.44 to 3.66 m) between heads and height of the highest head not over 15 ft (4.57 m) are typical. (See also Sec. 18.3). Drains should be installed to carry away sprinkler water. The supply of water for all of the above listed needs must be adequate and reliable. For fire fighting, the greatest fire hazard and the size of the water supply required to deal with it must be estimated. The expected flow from all hoses and sprinklers, the static pressure, and the minimum flow available at a given residual pressure must be considered. Again, codes and insurance company requirements control. Sources of water include city mains, gravity tanks on towers, reservoirs on roofs or in decorative ponds that are part of the landscaping, wells, nearby lakes, and rivers.

Heat The **heat** required for personnel comfort depends on the plant's location, which in turn, influences the types and capacities of heaters selected. Generally, factory areas can be kept a little cooler, about 65°F than the 72°F recommended for office areas. Heating systems include warm air, hot water, steam, electric, and radiant. Warm air requires a furnace to heat the air and ducts and blowers to distribute it. Circulating hot water and steam heat also require boilers and furnaces and a network of distribution pipes and radiators. Electric space heaters require fixed wiring and local outlets. Unit radiant heats may be fueled by gas, steam, hot water, or electricity and are placed above doors and work areas, oriented to direct heat where it is required. Piping can be

embedded in the concrete slab on grade, and in other floors, walls, and ceilings to provide radiant heat from circulating hot water.

Ventilation, the introduction of fresh outside air, the exhaust of stale inside air, or merely the movement of otherwise still inside air, can be effected naturally or mechanically. Natural ventilation requires windows, skylights, louvers, or other openings. Mechanical ventilation requires fans and blowers (and sometimes ducts) to draw air in, circulate it, and exhaust it. The number of cubic feet per minute (cubic metres per minute) of air per person required by people working in an office is about 10 (0.3), and between 25 and 50 (0.7 to 1.4) for those working on the factory floor. The total amount of air needed and the number of air changes per hour determine the number and sizes of fans, motors, and ducts. One change per hour is too little, with no discernible difference in air quality; 50 to 60 changes of air per hour are too many, and the resulting high-velocity drafts cause sensations of chilling and accompanying discomfort. Minimally, 5 changes of air per hour are required.

Whether a building is air conditioned or not, large high-mounted slow-speed **fans** can aid in expelling hot air in the summer when vents are opened. When vents are closed in the winter, they redirect risen warm air to the occupied spaces below.

Air conditioning adds to employee comfort, increases their productivity, and is essential for the manufacture of certain products. The calculation of the expected heat gains required to specify an **air-conditioning** installation is similar to the procedure for calculating heat loss in the design of a heating system. For air conditioning, the required cooling load is calculated in Btu per hour and converted to required tons of refrigeration by dividing by 12,000. (See Sec. 12.4.) The tonnage required would be one basis for the selection of the type of water-cooled or evaporative condensers, compressors, air handling units, motors, pumps, ducts, registers, circuitry, panels, and controls to be installed. Packaged air-conditioning units mounted on window sills, floors, ceilings, or roofs are often used. (See Merritt and Ricketts, "Building Design and Construction Handbook.")

The design and installation of a **compressed-air system** includes the summation of the volume and pressure of air required at all plant locations. The pipe diameters and total pressure drops between compressor and the most remote point of delivery must be determined. Pressure drop is a function of pipe and hose friction and the requirements of air-powered devices. Piping may be fixed, by and large, but the number and types of air-powered devices will change from time to time as production processes are changed or rearranged. Thus, there is some variability to be expected in the calculations to determine compressor discharge volume and pressure. Suitable allowances for unknown quantities are usually factored into the final design selection.

Internal and external communications systems must be installed. With autofacturing (see Sec. 17), the design, manufacture, production control, inventory control, storekeeping, warehousing, sales, and shipping records are all integrated and tied to the same information database. An internal local-area network (LAN), with computers, terminals, displays, and printers distributed throughout the plant and offices, will be required to plan, analyze, order, receive and accept material, record, feed back data, update files, and control and correct operating conditions. AGVs and mobile robots can be programmed to navigate off beacons installed throughout the plant.

Parking for employees and visitors must include spaces for handicapped persons. Parking lots are usually paved with 3 in (7.6 cm) of asphaltic cover over 6 in (15.2 cm) of gravel base. Lines are painted to designate spaces, which may be "straight in" (at a 90° angle to the curb), or at a smaller angle, typically 45° to 60°. The angle used influences the width of the aisles, depth (distance from the edge of the aisle to the curb) of each space, and the amount of curb length required for each car. For example, parking at a 45° angle requires an aisle width of about 13 to 15 ft (4.0 to 4.6 m), a space depth of about 20 to 21 ft (6.1 to 6.4 m) and uses about 13 ft (4.0 m) of curb per space (because of the overlaps); a 90° layout requires an aisle width of about 24 to 27 ft (7.3 to 8.2 m) and a space depth of about 19 to 20 ft (5.8 to 6.1 m) and uses about 9 to 10 ft (2.7 to 3.1 m) of curb per space. The width of each space (except those for the handicapped, which are wider) ranges from 9 to 10 ft (2.7 to 3.1 m) and their lengths from 19 to 20 ft (5.8 to 6.1 m). The number of parking spaces to be provided depends on the number of people expected and the extent to which public transportation is available and used. It is expected that there will be more than one employee per vehicle. Factors ranging from 1.2 to 2.5 persons per car can be used, depending on the firm's best estimate of the practices of its employees. For multiple-shift operations, it must be recognized that those working the second shift will arrive and need parking spaces before those on the first shift leave and vacate them. For those using public transportation, a shelter against the weather may be erected; often it is provided by the bus company.

In addition to parking space for automobiles, **space must be provided for trucks** that bring material to the plant and carry products away. Sizes of trucks, truck tractors, and their trailers vary widely, as do their turning radii. Many trucks will drive in frontward, maneuver to turn around, and back into the loading docks and platforms. Space must be provided for them to do this, even when there are other trucks present. The minimum size apron (measured by the distance from the outermost obstruction, whether it be a part of the building, the front of another truck already in the loading dock, or anything else that is in the way), required to maneuver a tractor-trailer into or out of a loading position, in one maneuver and with no driver error, varies with the length of the tractor-trailer expected and the width of the position to be provided. For example:

Tractor-trailer length	Position width	Minimum apron size
35 ft (10.7 m)	10 ft (3.1 m)	46 ft (14.0 m)
	12 ft (3.7 m)	43 ft (13.1 m)
	14 ft (4.3 m)	39 ft (11.9 m)
40 ft (12.2 m)	10 ft (3.1 m)	48 ft (14.7 m)
	12 ft (3.7 m)	44 ft (13.4 m)
	14 ft (4.3 m)	42 ft (12.8 m)
45 ft (13.7 m)	10 ft (3.1 m)	57 ft (17.4 m)
	12 ft (3.7 m)	49 ft (15.0 m)
	14 ft (4.3 m)	48 ft (14.6 m)

Truck heights range from about 8 ft (2.4 m) for a panel truck to around 13.5 ft (4.1 m) for double-axle semis and others. Doorways must be sized accordingly. Seals and pads may be added around the doors to fill the gap between the back of trucks and the building. Besides conventional rollup doors, plastic strips and air curtains may be used to provide a partial barrier between the plant's environment and the weather.

The **plant's security** measures should include structural protection against wind, rain, flood, lightning, earthquakes, and fire. Security against intruders, breakins, and vandalism can include fencing, gates, perimeter lights, surveillance cameras, and sensors. Security guard booths may be purchased as prefabricated units, complete with lights, heat, and air conditioners.

Emergency **egress** should provide for more than one route to safety, minimal distances to doors, doors that are locked from the outside but can be opened with a push from the inside (by panic bars), all to be accessible and usable by the handicapped. When designing a plant for ease of use by handicapped employees and visitors, all physical barriers must be eliminated and aids installed, such as ramps, braille signs, wheelchair-width doors and toilet booths, wheelchair-height sinks and drinking fountains, and the like. Applicable local building codes and federal regulations will guide and control the final designs.

Most of the above services and systems are built into the structure or influence its design and, therefore, must be determined before the specifications of the building become final.

Building Structure

The specifications for an industrial plant's **structure** depend on its contents, intended use, general location, and specific site. In the usual order in which they are constructed are foundation and footings, columns (and bay sizes), beams and roof trusses, exterior walls, floor slab, roof decking and covering, exterior doors and fenestration, interior partitions,

walls, doorways, services (electric power, compressed air, etc.), interior decor, and other special features.

Firm foundations and footings are required to support the columns, peripheral and some interior walls, machinery, and other equipment. Especially heavy machines, or those subject to large dynamic loads (often repetitive), may require special design that incorporates measures to isolate vibrations. Depth, size, and foundation reinforcement depends on the subsurface conditions. Installation of piles may be dictated by unsuitable load-bearing soil. Almost all foundations consist of cast-in-place concrete; in rare instances, load-bearing concrete blocks are set onto a previously poured concrete base. Site topography and location of the building may require the construction of retaining walls; these may be cast concrete or assembled with precast concrete sections which may serve also to provide a decorative treatment. The subgrade on which the concrete floor slabs will be poured must be well-compacted and made level. Often, the floor slab is not cast until heavy equipment (used to erect superstructure) is removed from the site.

Steel superstructure members are designed to provide the clear spans delineated by the selected **bay sizes.** They also support intermediate floors (if any); roof-mounted equipment; material handling equipment such as monorails; and lighting fixtures, piping, ductwork, and other utilities. The design must account for all dead and live loads, usually in accordance with applicable local building codes and other accepted structural codes. (See Secs. 5, 6, and 12.)

The sizes and locations of **columns and beams** establish the bay sizes. The longer the span, the larger the bay size, but this reflects back into construction with heavier columns, deeper beams and trusses, and concomitant higher costs. Inasmuch as larger bay sizes permit greater freedom in plant layouts and ease material handling, the added expense of large bay sizes is often worth it. Accordingly, the trend in plant design is to incorporate large bays. While any bay size is feasible, a cost/benefit tradeoff may set reasonable limits. Typical bay sizes are 30 × 40 ft (9 × 12 m), 40 × 60 (12 × 18), and 40 × 80 (12 × 24). There are warehouses whose bay size is dictated by the requirement to accommodate stacks of standard pallets with minimum waste space. Aircraft manufacturing plants and commercial hangars enclose enormous column-free cavernous spaces; lengths of 300 to 400 ft (91 to 122 m) are the norm in those applications.

When columns must support heavy traveling bridge cranes, a second row of columns is incorporated into the main columns to provide support for rails and to effect a stiffer structural configuration.

Beams are set at the top of columns and establish the clear height of the building interior; 15, 20, and 25 ft (4.5, 6.1, and 7.6 m) are typical in manufacturing areas, and 30 to 40 ft and more (9.1 to 12.2 m) are employed in warehouse space. When a two-story office is part of a single-level plant (Fig. 12.1.7) the overall height of the building is often set to the second-story height to permit a simple flat roof. Factory clear heights should be at least the height of the highest machine, with a generous margin added; for large products, the clear height is often designed to be twice the height of the largest product. Anything suspended from the beams or girders reduces the clear height. Deeper open roof trusses permit some piping, wiring, and other services to be woven through them and light fixtures placed between them, thereby not reducing clear working space. Roof decking and roofing is affixed to roof trusses or beams.

Exterior walls can be load bearing (support one end of a beam) or nonbearing. If nonbearing, all beam loads are transferred to columns spaced at intervals along the building perimeter. Walls are constructed of masonry [brick or concrete block masonry units (CMUs), sometimes incorporating glass block]; metal panels, usually integrally stiffened; wood for special applications (storage of highway deicing salts); natural stone or stone veneer/precast-concrete panels; or stone veneer on masonry backup walls. Where conditions allow, poured concrete walls are cast on the flat (at grade), then tilted up and secured into place; this technique is attractive especially for warehouses with repetitive wall construction devoid of windows and other openings. Metal panels are usually galvanized steel, with or without paint, or painted aluminum.

Factory floors may be required to sustain live loads from less than 100 pounds per square foot (psf) (0.5 kPa) to over 2,000 psf (96 kPa). A general-purpose light-assembly floor ordinarily will have no less than 100 psf (0.5 kPa) floor load capacity. A special purpose plant floor may be built with floor load capacities which vary from place to place in accordance with the requirements for different load-carrying capacity. Certainly, in the extreme, to build in a maximum floor loading capacity of, say, 2,000 psf (96 kPa) throughout a plant when there is minimal likelihood for that requirement other than in discrete areas, would not be cost-effective. Concentrated live loads (most often from wheeled material handling vehicles) are accounted for in the design of the floor slabs as required. The final design of the plant floor will meld the above factors with other requirements so that the sum of all dead and live loads can be safely sustained in the several areas of the floor.

Virtually all slab on-grade concrete floors are cast in place; in rare cases, precast concrete sections are used. Wooden plank flooring is rarely used on new construction. Upper floors are most often constructed with precast concrete planks overlaid with a cement mortar topping coat, or employ ribbed decking. When upper-floor loading capacities require it, those floors can also be cast in place; in those instances, concrete is cast into ribbed metal decking which acts as wet form work and remains in place. End grain wood blocks may be set atop a concrete floor to mitigate against unavoidable spillage of liquids. (See Sec. 12.2.)

The load-carrying capacity of concrete slabs on grade is ultimately limited not only by the strength of the concrete itself, but also by the ability of the subgrade material to resist deformation. The proper design of the floor, especially at grade, will account for all the parameters and result in a floor which will safely sustain design floor loading. Automatic guided vehicle systems and mobile robots (see Sec. 10) require level and smooth floors. The floor surface may be roughened slightly with a float to reduce slipping hazards, or have a steel trowel finish to accommodate AGV and mobile robot navigation. If it is contemplated that products or equipment will be moved by raising and floating them on films of air, the floor must be crack-free. If a slight floor slope can be tolerated from an operational point of view, that will ease cleaning by allowing water to flow to drains. The slab's surface may be coated, treated, or tiled for protection, comfort, ease of maintenance, and/or aesthetics. Expansion joints around column bases will inhibit propagation of small cracks resulting from differential settlement between column footings and floor slabs.

At this stage, the building looks like the one shown in Fig. 12.1.10.

A flat roof is always slightly pitched to drain water toward scuppers, gutters, and downspouts. It is constructed with ribbed metal decking or precast concrete planks, topped with a vapor barrier, insulation, a topping surface, flashing, sealants or caulking, and roof drains. The covering of a **built-up roof (BUR)** comprises three to five layers of roofing felt (fiberglass, polyester fabric, or other organic base material), each layer mopped with hot bitumen (asphalt or coal tar pitch). The wearing surface of roofing may include a cap sheet with fine mineral aggregate, reflective coating, or stone aggregate. When extensive roof traffic is anticipated, pavers or wood walkways are installed. A recent successful roof surface is composed of a synthetic rubber sheet, seamless except at lapped, adhesively bonded joints. It has proved to be a superior product, providing long, carefree life.

The seal between roofing and parapet walls or curbed openings is effected with **flashing** bent and cemented in place with bituminous cement. The flashing material may be galvanized steel aluminum, copper, stainless steel, or a membrane material.

Flat roofs lend themselves to ponding water to help cool the plant. Roof ponds (and water sprays) can reduce interior temperatures by 10 to 15°F (6 to 9°C) in the summer. Roof ponds can serve as a backup source of water for fire fighting. If water is ponded on a roof, roof construction must be handled expressly for that purpose. There are structural implications which must be considered as well.

Doors and ramps should be made 2 ft (0.6 m) larger than the largest equipment or material expected and large enough to allow ingress of fire fighting apparatus. It is often convenient to place very large pieces of equipment such as molding machines and presses inside the building

Fig. 12.1.10 A view of a plant during construction. Shown are its columns, roof trusses, and exterior masonry walls. The reinforced-concrete floor slab is being poured over compacted soil. *(Source: VMA, Inc.)*

envelope before the walls are completed. After exterior walls and roof are in place, the building interior is sufficiently secure for assembling materials for the remaining construction and to receiving smaller equipment.

Interior walls and **partitions** (masonry, wood, wallboard, and metal) follow, after which office flooring and framing are installed (Fig. 12.1.11). **Steel framing** (called *steel for stick* by some) is sometimes an alternative to using wood studs. Walls framed with steel studs look the same as those made of wood when they are finished with any material externally, and with regular drywall inside. Metal is longer-lasting, stronger, and able to have larger spans, creating clearer spaces with fewer interior supports, which offers greater design and architectural flexibility and styling options. The studs are bolted and screwed together, versus the nails used with wood. The sizes and gage of the members can range from lighter and thinner galvanized steel to thicker, heavier "red iron" members. They come with prepunched access holes for ease of installing wire and cable and of adding cross supports to make their assemblage more rigid. **Metal framing** requires fewer wall studs, thus creating fewer uninsulated thermal bridges. Metal frames can also be more energy-efficient when dimensioned to provide deeper wall cavities to hold thicker insulation. They are impervious to insects, mold, rot, splits, shrinkage, and warpage. Many are made from recycled metal. The price of sheet metal studs may be higher or lower than for wood studs; but for a true cost comparison, the total cost (e.g., material, time, labor) of building with metal versus wood must be considered. The remainder of the construction involves completion of wiring, lighting, and other services; application of paint or wall coverings, floor coverings, and decor; and so on.

Other Considerations

Industrial plants must be built in conformance with all state and local codes. The International Code Council has issued—and periodically updates—an "International Building Code (affixed with the year of the latest version)." It applies to the design and construction of all buildings except one- and two-family houses, which are covered by other codes. It also has subcodes, such as for plumbing, electrical, HVAC, fire protection, and most recently energy conservation. Each individual state in the United States can and does select parts of or all the International Building Code to create its own pertinent code.

The **applicable standards, regulations, and procedures** of the 1971 Williams-Steiger Occupational Safety and Health Act (OSHA), as amended, must be followed in the construction and operation of the building and the design and use of the plant's equipment; likewise, the regulations of the Environmental Protection Agency (EPA), as amended, and the design standards of the Americans With Disabilities Act (ADA), as amended, must be followed.

Color can serve several purposes in an industrial plant. As an aid to safety, it can be used to identify contents of pipes, dangerous areas, aisles, moving parts of equipment, emergency switches, and fire fighting and first aid equipment. It also can be used to improve illumination, conserve energy, reduce employee fatigue and influence on morale positively.

OSHA, American National Standards Institute (ANSI) specification Z53.1, and specific safety regulations require the use of specific **identity colors** in certain applications. As a general guide, yellow or wide yellow-and-black bands are used to indicate the need for caution and to

Fig. 12.1.11 A view of framing for the first- and second-story offices of a plant, with a roof beam and the steelwork supporting the second floor visible. *(Source: VMA, Inc.)*

highlight physical hazards that persons might trip on, strike against, or fall into, such as edges of platforms, low beams, stairways, and trafficked aisles along which equipment moves. Orange designates dangerous parts of machines or energized equipment that may cut, crush, shock, or otherwise injure, such as the inside of gear boxes, gear covers, and exposed edges of gears, cutting devices, and power jaws. Red is the basic color for the identification of fire protection equipment and apparatus, danger and stop signs, fire alarm boxes, fire exit signs, and sprinkler piping. Green designates safety items, such as first aid kits, gas masks, and safety deluge showers, or their locations. Blue designates caution and is limited to warning against starting, use of, or movement of equipment under repair, and utilizes tags, flags, or painted barriers. Purple designates radiation hazards. Black, white, or a combination of both designates traffic control and housekeeping markings, such as aisleways, drinking fountains, and directional signs.

There are also color conventions for the identification of fluids conducted in pipes. Instead of being painted their entire length, pipes are painted with colored bands and labels at intervals along the lines, at valves, or where pipes pass through walls. ANSI Standard A 13.1-1975 specifies the following colors for pipe identification: red for fire protection; yellow for dangerous materials; blue for protective materials; green and white, black, gray, or aluminum for safe materials.

The **noises** created during the operation of a plant can be dealt with at their **sources, along their paths,** and at their **receivers.** At the sources, noise is minimized or eliminated by: changing the process; replacing (with quieter) equipment; modifying equipment by redesign or component changes; moving to another location; installing mufflers and shock mounts; using isolation pads; and shielding and enclosing equipment with material having a high sound transmission loss (STL) value. STL is a measure of the reduction in sound pressure as it passes through a material. Along the paths, attenuation of noise is enhanced by increasing the distance between sources and receivers; introducing discontinuities in the transmission path, such as barriers and baffles which interrupt direct transmission; installing acoustical barriers with an STL of at least 24 dB and with sufficient absorption to prevent reflection of the noise back to its source; and by placing sound-absorbent material on surfaces along its path, such as acoustical ceilings and floor and wall coverings. At the receivers, enclosures, workstation partitions of sound-absorbing material, earplugs, and "white-noise" generators can be used. (See Secs. 12.6 and 18.2.)

Provisions must be made for **waste disposal,** including: disposal of refuse and garbage, treatment of process fluids and solids, and waste and recyclables recovery, all in accordance with applicable EPA and other regulations.

Among many other things, the plant design process must address matters such as fuel storage, storm and surface drainage, snow removal facilities and procedures (if the local climate warrants), design for ease of maintenance of the building as well as the grounds and associated landscaping, the articulation of the architect's idiom, energy efficiency in the materials of construction and the equipment installed to service the plant, and diligence in compliance with environmental impact studies (if required). Buildings, like other designed and made products, can—to varying degrees—help or hurt the environment. Once pristine sites can become air-, soil-, and water-fouled by sewerage, animal waste, toxic materials dumping, lawn chemicals, etc. Governments, attempting to preserve the environment, tend to make it more and more difficult for prospective builders to get permits. A **green** industrial building is one whose design, construction, and operation have a positive—or at least a minimal negative—impact on the environment. The builders might have selected an "environmentally friendly" site; used salvaged and recycled materials in their construction and operations; minimized consumption of water, energy, and other resources; provided for good indoor air quality; treated their effluents; and done all other things possible to maintain a healthier ("greener") presence. Builders that do such things to a required degree may be awarded an **LEED** (Leadership in Energy and Environment) rating by the U.S. Green Building Council, There are comparable organizations in some other countries.

After the plant is designed, but before a commitment is made to build it, its operations should be simulated to bring forth and correct any errors or omissions. In addition to testing its specifications for normal conditions, extremes (severe storms, power outages, truckers' strikes, etc.) should also be evaluated. This simulation is similar to that done before the plant's site is made final, but comes after the structure and layout have been designed. A sensitivity analysis should be made to see the effect on operations of changes in inputs and operating conditions. Depending on these analyses and best guesses as to the future, adjustments may have to be made to ensure that the plant will operate effectively and economically under all reasonable conditions, and that it has no features that will harm people or do damage to the products or the environment.

CONTRACT PROCEDURES

Cost Estimates

Cost estimates fall into three general classes:

1. Preliminary estimates made usually from sketch drawings and brief outline specifications to determine the approximate total cost of a project.
2. Comparative estimates made usually during the progress of design to determine the relative cost of two or more alternative arrangements of equipment, type of building, type of floor framing, and the like.
3. Detail estimates made from final plans and specifications and based on a careful quantity survey of each component part of the work.

Primary quantity estimates are usually more accurate when comparison with comparable projects is lacking or not feasible. The procedure entails

computations based on quantity takeoffs from preliminary plans and specifications, and can include the gross area of exterior walls, interior partitions, floors, and roof. Each is multiplied by known (or estimated) unit cost factors. Other items, such as number of electrical outlets and number of plumbing fixtures and sprinklers, are estimated, and their cost computed. Equipment costs can be based on preliminary quotations from manufacturers.

The following items should be included in preliminary estimates (or in other more detailed estimates which may follow as plans develop to the final stage): land cost; fees to real estate brokers, lawyers, architects, engineers, and contractors; interest during construction; building permits; taxes, including local sales or use taxes; demolition of existing structures including removal of old foundations; yard work including leveling, drainage, fencing, roads, walks, landscaping, yard lighting, and parking spaces; transportation facilities including railroad tracks, wharves, and docks; power supply and source; water supply and source; sewer and industrial waste disposal. A judicious **contingency factor** is included to provide for unforeseen conditions that may arise during the development of the project. It may amount to 5 to 15 percent (or more) depending on the character and accuracy of the estimate, whether the proposed design and construction will follow established procedures or incorporate new state-of-the-art features, and the exact purpose for which the estimate is made.

Especially for complex new or altered construction, estimates may be updated continually as a matter of course. This will serve to monitor the evolving cost of the project and the time constraints placed on construction.

Working Drawings, Specifications, and Contracts

The technical staff of a given industry has special knowledge of trade practices, process requirements, operating conditions, and other fundamentals affecting successful operation in that field and is best fitted to determine the basic factors of process design and plant expansion. Unless the company is extremely large, it is unlikely that they will have the specialized staff or that their own staff will have the time available to undertake the complete layout. The efficient transformation of these requirements into completed construction usually requires experience of a different nature. Therefore, it is generally advisable and economical to employ engineers or architects who specialize in this particular field.

Three general procedures are in common use. First, the employment on a percentage or fixed-fee basis of an engineering and construction organization skilled in the industrial field to prepare the necessary working drawings and specifications, purchase equipment and materials, and execute the work. This has become known as **design/build.** For the duration of the project, such an organization becomes a part of the owner's organization, working under the latter's direction and cooperating closely with the owner's technical staff in the development of the design and in the purchase and installation of equipment and materials. This procedure permits construction work to start as soon as basic arrangements and costs have been determined, but before the time required to complete all working drawings and specifications. This is often termed **fast tracking.** Such a program will result in the earliest possible completion consistent with economical construction.

A second procedure is to employ engineers or architects with wide experience in the industrial field to prepare working drawings and specifications and then to obtain **competitive lump-sum bids** and award separate contracts for each or a combination of several subdivisions of the work, such as foundations, structural steel, and brickwork. This method provides direct competition restricted to units of like character and permits intelligent consideration of the bids received. Provision must be made for proper coordination of these separate contracts by experienced and skilled field supervision. In recent years, a **construction manager** has been hired for this purpose. This procedure requires more time than that first described, since all work of a given class should be completely designed before bids for that subdivision are sought. Where construction conditions are uncertain or hazardous, the first method is likely to be more economical. A combination of the first method for uncertain conditions and the second method for the balance may prove most advantageous at times.

A third procedure is to employ engineers or architects to complete all plans and specifications and then **award a lump-sum contract** for the entire work, or one for all building work, and one or more supplementary major contracts to furnish and install equipment. This method is particularly useful where there are no serious complications or hazards affecting construction operations, but it requires considerably more time, since most of the working drawings and specifications must be complete before construction is started. It has the significant advantage, however, of fixing the total cost within narrow limits before the work starts, provided the contracts cover the complete scope of work intended and no major changes ensue.

CONSTRUCTION

The design, construction, occupancy, and operation of an industrial plant is a complex endeavor involving many people and organizations. **Project control tools and techniques** such as the critical path method (CPM), the program evaluation and review technique (PERT), bar charts, dated start/stop schedules, and daily "do lists" and "hot lists" of late items are all helpful in keeping construction on time and within budget.

Checkpoints and milestones, with appropriate feedback as the project progresses, are established to monitor progress. Bailout points are established in the event the project must be aborted sometime after the beginning of construction. On the other hand, contingency plans should be in hand and include planned reassignment of equipment, materials, and financial and personnel resources to keep the project on schedule. Figure 12.1.12 shows the scheduled and actual dates of completion of the phases noted for a small plant depicted in several of the previous figures.

Some portion of the organization (often the construction manager's office), is charged with the delicate task of coordinating contractors and the multiplicity of trades at the job site, and as part of its function, it will generate "punch lists" of deficient and/or incomplete work which must be completed to the owner's satisfaction before payment therefore is approved.

	Scheduled	Actual
Project planning	March	March

LOADS AND FORCES

Buildings and other structures should be designed and constructed to support safely all loads of both permanent and transient nature, without exceeding the allowable stresses for the specified materials of construction. Usually, there are governing local codes, either unique to the jurisdiction or incorporating accepted codes (International Building Code, Building Code Requirements for Structural Concrete, Uniform Building Code, etc.,—sometimes amended locally), that will guide the selection of appropriate loads. In general, the following will enter into the design considerations: **dead loads,** generally agreed to include the weight of all permanent construction; **live loads,** produced by the use or occupancy of the building; **external** (or **environmental**) **loads** resulting from wind, snow, rain, ice, and earthquakes. The individual types of loading may be used singly or in combination, depending upon the use and location of the building and its inherent design features. For instance, the building may be designed to impound water on the roof for the purpose of keeping the roof deck (and the building below) cooler. In that case the collected and retained water has a major impact on the design of the roof structure. The governing code will address the matter of loading per se, or the use of combined loads by reference to other definitive sources whose information has standing. Absent specific guidance in the local governing code, for areas not so regulated, the data cited in the paragraphs below have been culled from many years of successful application.

Live loads on floors are generally regulated by the building codes in cities or states. For areas not regulated, the following values will serve as a guide for live loads in lb/ft^2 (kPa): rooms for habitation, 40 (1.92); offices, 50 (2.39); halls with fixed seats, 60 (2.87); corridors, halls, and other spaces where a crowd may assemble, 100 (4.76); light manufacturing or storage, 125 (5.98); heavy manufacturing or storage, 250 (11.95); foundries, warehouses 200 to 300 (9.58 to 14.37). Floor decks and beams that support only a small floor area must also be designed for any local concentrations of load that may be placed upon them. Girders, columns, and members that support large floor areas, except in buildings such as warehouses where the full load may extend over the whole area, may often be designed for live loads progressively reduced as the supported area becomes greater. Where live loads, such as cranes and machinery, produce **impact** or **vibration,** static loads should be increased as follows: elevator machinery, 100 percent; reciprocating machinery, 50 percent; others, 25 percent.

Roof live loads should be taken as a minimum of 20 lb per horizontal ft^2 (957.6 kPa) for essentially flat roofs (rise less than 4 in/ft), varying linearly with increasing slope to 12 lb/ft^2 for steep slopes (rise greater than 12 inches per foot). Reductions may also be made on the basis of tributary area greater than 200 ft^2 (18.58 m^2) of the member under consideration, to a maximum of 40 percent for tributary areas greater than 600 ft^2. The minimum roof live load shall be 12 lb/ft^2 after all reduction factors have been applied. Where **snow loads** occur, appropriate design values should be based on the local building codes.

Dead loads are due to the weight of the structure, partitions, finishes, and all permanent equipment not included in the live load. The weights of common building materials used in floors and roofs are given below (see also Sec. 6).

Material	Weight, lb/ft^2
Asphalt and felt, 4-ply	3
Corrugated asbestos board	5
Glass, corrugated wire	5–6
Glass, sheet, ⅛ in thick	2
Lead, ⅛ in thick	8
Plaster ceiling (suspended)	10
Acoustical tile	1–2
Sheet metal	1–2
Shingles, wood	3
Light-weight concrete over metal deck	30–45
Sheathing, 1 in wood	3
Skylight, 3/16 to ¼ in, glass and frame	6–8
Slate, 3/16 to ½ in thick	8–20
Tar and gravel, 5-ply	6
Tar and slag, 5-ply	5
Roof tiles, plain, ⅝ in thick	20

NOTE: lb/ft^2 × 0.04788 = kPa.

Earthquake Effects Two distinct methods of designing structures for seismic loads are currently accepted. The more familiar method, employed by the Uniform Building Code (UBC), yields equivalent loading for use with the allowable stress design approach. The National Earthquake Hazard Reduction Program (NEHRP) has developed Recommended Provisions for the Development of Seismic Regulations for New Buildings, which is based on the ultimate strength design approach. The NEHRP approach is the basis for model codes, such as the IBC. SEI/ASCE 7-05 has an extended and detailed presentation applicable to determination of rational earthquake loads.

Wind Pressures on Structures Every building and component of buildings should be designed to resist wind effects, determined by taking into consideration the geographic location, exposure, and both the shape and height of the structure. For structures sensitive to dynamic effects, such as buildings with a high height-to-width ratio, structures sensitive to wind-excited oscillations, such as vortex shedding or icing, and very tall buildings, special consideration should be given to design for wind effects and procedures used should be in accordance with approved national standards. Wind loads should not be reduced for the shading effects of adjacent buildings.

Wind pressure on walls of buildings should be assumed to be a minimum of 15 lb/ft^2 (0.72 kPa) on surfaces less than 50 ft above the ground. For buildings in exposed locations and in locations with high wind velocity, pressures should be calculated based on the procedures outlined in SEI/ASCE 7-05, or as dictated by the governing code. Boundary-layer wind tunnels, which simulate the variation of wind speed with height and gusting, are used to better estimate the design wind loading.

The effect of the sudden application of **gust loads** has sometimes been blamed for peculiar failures due to wind. In most cases, these failures can be explained from the pressure distributions in a steady wind. If a relatively flexible structure such as a radio tower, chimney, or skyscraper with a natural period of 1 to 5 s is set into vibration, the stresses in

the structure may be increased over those calculated from a static-load analysis. Provision should be made for this effect by increasing the static design wind. A rational analysis should be performed to calculate the magnitude of this increase, which will depend on the flexibility of the structure.

Even a steady wind may give rise to periodic forces which may build up into large vibrations and lead to failure of the structure when the frequency of the exciting force coincides with one of the natural frequencies of vibration of the structure. The periodic exciting force may be due to the separation of a system of **Kármán vortices** (Fig. 12.2.1) in the wake of the body. The exciting frequency n in cycles per second is related to d, the dimension of the body normal to the wind velocity V. Dangerous vibrations related to the "flutter" of airplane wings may arise on bridges and similar flat bodies. These self-induced vibrations may be caused (1) by a negative slope of the curve of lift against angle of attack (Den Hartog, op. cit.) or (2) by a dynamic instability which arises when a body having two or more degrees of freedom (such as bending and torsion) moves in such a manner as to extract energy out of the air stream. The first of these vibrations will occur at one of the natural frequencies of the structure. The second type of vibration will occur at a frequency intermediate between the natural frequencies of the structure.

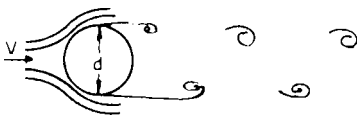

Fig. 12.2.1 Von Kármán vortices.

The wind forces and the **pressure distribution** over a structure corresponding to a design wind V can be determined by **model testing** in a wind tunnel. Extrapolation from model to full scale is based on the fact that at every other point on the body, the pressure p is proportional to the stagnation pressure q (see Sec. 11) and thus the ratio p/q = constant for a fixed point on the body, as the scale of the model or the velocity of the wind is changed. Since the principal component of the wind force is due to the pressures, the force F acting on the surface S is

$$F \approx p_{\text{avg}} S = (p/q)_{\text{avg}} qS$$

and denoting $(p/q)_{\text{avg}}$ by a normal force coefficient or **shape factor** C_N

$$F = C_N \tfrac{1}{2} \rho V^2 S = C_N qS$$

The shape factors so obtained apply to full scale for structures with sharp edges whose principal resistance is due to the pressure forces. For bodies that do not have any sharp edges perpendicular to the flow, such as spheres or streamlined bodies, the factor C_N is not constant. It depends upon the Reynolds number (see Sec. 3). For such bodies, the law for variation of the shape factor C_N must be determined experimentally before safe predictions of full-scale forces can be made from model measurements.

Radio Towers and Other Framed Structures For open frame towers, by using round structural members instead of flat and angular sections, a substantial reduction in wind force can be effected.

Load Combinations Methods of combining types of loading vary with the governing local codes. Dead loads are usually considered to act all the time in combination with either full or reduced live, wind, earthquake, and temperature loads. The reductions in live loads are based on the improbability of fully loaded tributary areas, generally when the tributary area exceeds 150 ft^2. Most codes consider that wind and earthquake loads need not be taken to act simultaneously. There are two basic design methods in use: allowable stress or working stress design and limit states or ultimate strength design. Whereas allowable stress design compares the actual working stresses with an allowable value, the limit states approach determines the adequacy of each element by comparing the ultimate strength of the element with the factored design loads. For load combinations see SEI/ASCE 7-05, or as dictated by the governing code.

DESIGN OF STRUCTURAL MEMBERS

Members are usually proportioned so that stresses do not exceed allowable **working stresses** which are based on the strength of the material and, in the case of compressive stresses, on the stiffness of the element under compression. Internal forces and moments in **simple beams,** columns, and pin-connected truss bars are obtained by means of the equations of static equilibrium. **Continuous beams,** rigid frames, and other members characterized by practically rigid joints require for analysis additional equations derived from consideration of deflections and rotations.

Design may also be on the basis of the **ultimate strength** of members, the factor of safety being embodied in stipulated increases in the design loads. In steel-frame construction, the procedures of **plastic design** determine points where the material may be allowed to yield, forming *plastic hinges,* and the resulting redistribution of internal forces permits a more efficient use of the material.

Floors and Roofs

Except in reinforced-concrete flat-slab construction, floors and roofs generally consist of flat decks supported upon beams, girders, or trusses. The decks may usually be considered a series of beamlike strips spanning between beams and themselves designed as beams. The design of a beam consists chiefly in proportioning its cross section to resist the maximum bending and shear and providing adequate connections at its supports, without exceeding the unit stresses allowed in the materials (see Sec. 5) and limiting maximum live load deflection at midspan to $\frac{1}{360}$ of the span.

Up to spans of 20 to 30 ft (6.1 to 9.1 m), either wood or steel beams of uniform section are generally more economical than trusses, while for spans above 50 to 70 ft (15.2 to 21.3 m), trusses are usually more economical. Between these limits, the line of economy is not well-defined. Conditions that favor the use of trusses are as follows: (1) identical trusses are repeated many times, (2) the height of the building need not be increased for the greater depth of the truss, and (3) fire protection of wood or metal is not required.

Roof trusses often have their top chords sloped with the roof. Common trusses for steeply pitched roofs are shown in Figs. 12.2.2 to 12.2.6, the top chord panels equal in each truss. The members shown by heavy lines are in compression under ordinary loads, those in light lines in tension. The trusses of Figs. 12.2.6 to 12.2.9 are adapted for either steel or wood. In wooden trusses, the tensile web members may be steel rods with plates, nuts, and threaded ends. The truss of Fig. 12.2.6 is usually made of steel.

The forces in any member of these trusses under a vertical load uniformly distributed may be found by multiplying the coefficients in Tables 12.2.1 to 12.2.5 by the panel load P on the truss. For other slopes, types of trusses, or loads, see "General Procedure" below. Trusses for flat roofs are commonly of one of the types shown in Figs. 12.2.7 to 12.2.13 except that the top chords conform to the slope of the roof.

Floor trusses normally have parallel chords. Common types are shown in Figs. 12.2.7 to 12.2.13 in which heavy lines indicate members in compression, light lines in tension, and dash lines members with only nominal stress, under equal vertical panel loads. The panel lengths l in each truss are equal. The stress in each member is written next to the member in the figure, in terms of the panel load and the lengths of members. For a truss like one of the figures turned upside down, the stresses in the chords and diagonals remain the same in magnitude but reversed in sign. Forces in verticals must be computed (compare Figs. 12.2.7 and 12.2.8). For other loads and other types of trusses see "General Procedure" below.

Weights of Trusses The approximate weight in pounds of a wooden roof truss may be taken as $W = LS(L/25 + L^2/6{,}000)$, where L is the span and S the spacing of trusses in feet. The approximate weight in pounds of a steel roof truss may be taken as $W = \frac{1}{3} LS(\sqrt{L} + \frac{1}{8} L)$.

Choice of Roof Trusses

WOODEN TRUSSES. For pitched roofs with spans up to 20 ft (6.1 m) the simple king-post truss (Fig. 12.2.2) may be used. For spans up to 40 ft (12.2 m) the trusses of Fig. 12.2.2 and Fig. 12.2.4 are good. For spans up to 60 ft (18.3 m) the trusses of Figs. 12.2.3 and 12.2.5 are good. The number of panels rarely exceeds eight or the panel length, 10 ft (3m). For flat roofs, the Howe truss (Figs. 12.2.7, 12.2.10, and 12.2.12) is built of wood with steel rods for verticals; the depth is one-eighth to one-twelfth the span. Wooden trusses are usually spaced 10

to 15 ft (3.0 to 4.6 m) on centers. Wood is rarely used in roof trusses with span over 60 ft (18.3 m) long. Steel trusses for pitched roofs may well take the form shown in Figs. 12.2.3 to 12.2.6 for spans up to 100 ft (30.5 m). For flat roofs, the Warren truss (Figs. 12.2.9, 12.2.11, and 12.2.13) is usually constructed in steel; the depth of the trusses ranges from one-eighth to one-twelfth the span, with trusses spaced from 15 to 25 ft (4.6 to 7.6 m) on centers.

Stresses in Trusses

An ideal truss is a framework consisting of straight bars or members connected at their ends by frictionless ball-and-socket joints. The external forces are applied only at these ball-and-socket joints. Internal forces and

stresses in such straight bars are axial, either tension or compression, without bending. Since frictionless ball-and-socket joints are impossible, and the ends of bars are often bolted or welded, the ideal truss is never realized. For purposes of analysis, the primary stresses, which are always axial, are determined on the assumption that the truss under consideration conforms to the ideal. Secondary stresses are additional stresses, generally flexural or bending, brought about by all the factors that make the actual truss different from the ideal. In the following discussion, only primary forces and stresses will be considered.

Analytical Solution of Trusses

General Procedure After all external forces (loads and reactions) have been determined, the internal force or stress in any member is found (1) by taking a section, making an imaginary cut through the members of the truss, including the one whose stress is to be found, so as to separate the truss into two parts; (2) by isolating either of these parts; (3) by replacing each bar cut by a force, representing the force in the bar; and (4) by applying the equations of statics to the part isolated.

The various ways in which sections can be taken and the equations used to determine the forces are illustrated by a solution of the truss in Fig. 12.2.14.

A section 1–1 (Fig. 12.2.14) may be taken around a joint, L_0. Isolate the forces inside the section (Fig. 12.2.15*a*). Assume the unknown forces to be tension. Since the forces are concurrent and coplanar, two independent equations of statics will establish equilibrium. These may be either $\Sigma x = 0$ and $\Sigma y = 0$ or $\Sigma M = 0$ taken about two axes perpendicular to the plane of the forces and passing through two points selected so that neither point is the intersection of the forces, or so that the line joining the two points is not coincident with either of the unknown forces.

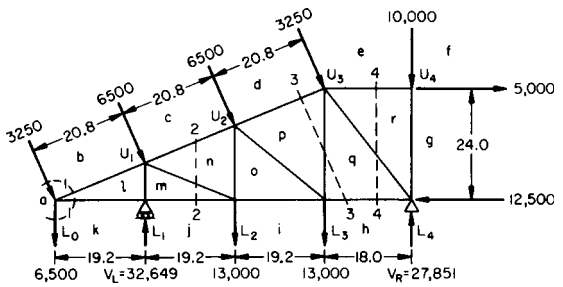

Fig. 12.2.14

Using the first set of equations and taking components of all forces along horizontal and vertical axes; e.g., the horizontal component of the 3,250-lb force is 1,250 and the vertical component is 3,000 lb.

$$\Sigma x = 0 = s_{lk} + s_{bl}(19.2/20.8) + 1{,}250$$
$$\Sigma y = 0 = s_{bl}(8/20.8) - 9{,}500$$

From these equations, $s_{lk} = -24{,}050$ and $s_{bl} = 24{,}700$.

The minus sign indicates that the force acts opposite to the assumed direction. If all the unknown forces are assumed to be in tension, then a plus sign in the result indicates that the force is tension and a minus sign indicates compression.

Hence, s_{lk} is 24,050 lb compression and s_{bl} is 24,700 lb tension.

Using the $\Sigma M = 0$ twice,

$$\Sigma M \text{ about } U_1 = 0 = -s_{lk} \times 8 - 1{,}250 \times 8 - 9{,}500 \times 19.2$$

from which $S_{lk} = 24{,}050$ lb compression.

$$\Sigma M \text{ about } L_1 = 0 = s_{bl}(8/20.8)19.2 - 9{,}500 \times 19.2$$

from which $s_{bl} = 24{,}700$ tension.

Instead of taking a section around a joint, a cut may be made vertically or inclined, cutting a number of bars such as Fig. 12.2.15*b* or Fig. 12.2.15*c*. If only three members are cut, and they are neither concurrent nor parallel, the forces can be found by taking moments of all forces on either side of the section about axes passing through the intersections of any two members.

Considering the part to the left of section 2–2, the forces in the three members (Fig. 12.2.15*b*) may be determined by taking moments about L_0, U_1, and L_2 of all forces acting on the part on either side of the section, e.g., on the left of the section because it has the fewer forces:

$$\Sigma M \text{ about } L_0 = s_{mn}(8/20.8)38.4 + 2{,}500 \times 8 - (32{,}649 - 6{,}000)19.2$$
$$\Sigma M \text{ about } U_1 = 0 = -s_{mj} \times 8 - 1{,}250 \times 8 - 9{,}500 \times 19.2$$
$$\Sigma M \text{ about } L_2 = 0 = s_{cn}(19.2/20.8)16 + 2{,}500 \times 8 - 9{,}500 \times 38.4 + 26{,}649 \times 19.2$$

from which $s_{mn} = 33{,}290$ tension, $s_{mj} = 24{,}050$ compression, and $s_{cn} = 11{,}298$ compression.

This method is sometimes called the "method of moments."

Considering the part to the right of section 3–3, the forces in the three members (Fig. 12.2.15*c*) may be determined by taking moments about L_0, U_3, L_3 of all the forces acting on part or either side of the section, e.g., on the right of the section because it has the fewer forces:

$$\Sigma M \text{ about } L_0 = 0 = s_{pq} \times 57.6 + 6{,}250 \times 24 + 3{,}000 \times 57.6 - (27{,}851 - 10{,}000) \times 75.6$$
$$\Sigma M \text{ about } L_3 = 0 = -s_{dp}(19.2/20.8)24 + 6{,}250 \times 24 - 17{,}851 \times 18$$
$$\Sigma M \text{ about } U_3 = 0 = s_{qh} \times 24 + 12{,}500 \times 24 - 17{,}851 \times 18$$

from which $s_{pq} = 17{,}825$ tension, $s_{dp} = 7{,}733$ compression, and $s_{qh} = 888$ tension.

Considering the part to the right of section 4–4, the forces in the three members (Fig. 12.2.15*d*) may be found by taking moments about axes where two unknowns intersect, e.g., about U_3 and L_4. Since two unknown forces are parallel, their lines of action do not intersect. However, the equation $\Sigma y = 0$ will enable one to find the force in the member which is not parallel to the other two:

$$\Sigma M \text{ about } U_3 = 0 = s_{qh} \times 24 - (27{,}851 - 10{,}000)18 + 12{,}500 \times 24$$
$$\Sigma M \text{ about } L_4 = 0 = -s_{er} \times 24 + 5{,}000 \times 24$$
$$\Sigma y = 0 = s_{rq}(24/30) + 27{,}851 - 10{,}000$$

from which $s_{qh} = 888$ tension, $s_{er} = 5{,}000$ tension, and $s_{rq} = 22{,}314$ compression.

Columns and Walls

Vertical elements in building construction consist of columns, posts, or partitions that transmit concentrated loads; walls or partitions that transmit linearly distributed loads (and may, if so designed, transmit lateral loads from story to story); rigid frames that transmit lateral as well as vertical loads; and braced frames that, ideally, transmit only lateral loads from story to story.

Columns may be of timber, steel, or reinforced concrete and should be proportioned for the allowable stresses permitted for the material used and for the flexibility of the column. Care must be taken in the framing of beams and girders to avoid or to provide for the additional stresses due to connections which transfer loads to columns with large eccentricities. For instance, a beam framing to a flange of a steel column, with a seat or web connection, will produce an eccentric moment in the column equal to $Rd/2$, where R is the beam reaction and d the depth of the column section. Columns not adequately restrained against deflection of the top may be subject to considerable additional moment because of the resulting eccentricity of otherwise axial loads.

Rigid frames consist of columns and beams welded, bolted, or otherwise connected so as to produce continuity at the joints and permit the

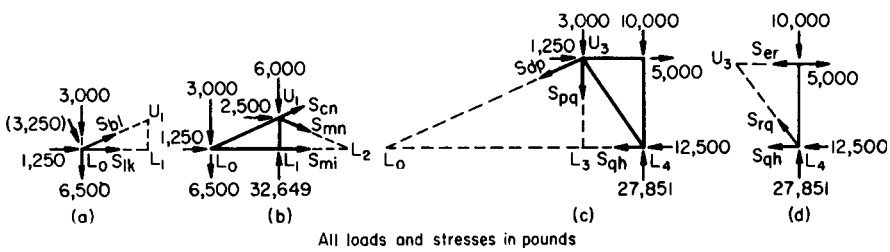

Fig. 12.2.15 Resolution of forces for truss shown in Fig. 12.2.14.

entire frame to behave as a unit, capable of resisting both vertical and lateral loads. Advantages of rigid frames are the ease and simplicity of erection, increased headroom, and more open floor plans free of braced frames. Rigid frames composed of rolled sections are commonly used for spans up to 100 ft (30.5 m) in length. Built-up members have been utilized on spans to 250 ft (76.2 m). Welded fabrication offers particular advantages for frames utilizing variable-depth members and on parabolic-shape roofs. The distribution of moments in the statically indeterminate rigid frame is effected by the relationship of the column height to span and roof rise to column height, as well as the relative stiffness of the various members. The solution for the moments in the frame is obtained from the usual equations of statics plus one or more additional equations pertaining to the elastic deformations of the frame under load.

Bearing walls, which are intended to transmit gravity loads from story to story, are designed as vertical elements of unit width such that the combined effects of axial and/or bending stresses do not exceed their allowable values according to the formula $fa/Fa + fb/Fb \leq 1.0$, where f is the actual stress in the axial or bending mode, and F is the allowable stress in the appropriate mode.

Shear walls, either concrete or masonry, which are intended to transmit earthquake, wind, or other lateral loads from story to story parallel to the plane of the wall, are designed as cantilevered vertical shear beams. Loads are distributed among the various wall elements, created by door and window openings, on the basis of their relative rigidities. Unless special conditions indicate otherwise, the assumption is made, in calculating individual stiffnesses, that the wall is fixed against rotation, in the plane of the wall, at the bottom. The individual wall elements are then designed to resist both their share of the wall shear and the moments it induces as well as any vertical loads due to bearing wall action and/or overall wall overturning. Individual wall elements, then, will have special vertical reinforcing at each side (trim reinforcement) to resist bending moments. Diagonal trim reinforcements, 96 bar diameters in total length, where possible, are placed at corners of openings in concrete walls to inhibit cracking. Trim reinforcing should consist of a minimum of two ⅝-in-diameter (1.6-cm) bars (No. 5 bars).

Uplift and downward forces at opposite ends of the shear walls, due to the tendency of the wall to overturn in its own plane when acted upon by lateral forces, must be resisted by vertical reinforcement at those locations. Special boundary elements are required for shear walls in areas of high seismicity (UBC Zones 3 and 4). Only minimum tributary dead loads may be counted upon to help resist uplift while maximum dead plus live loads should be assumed acting simultaneously with downward overturning loads. **Load reversal,** due to wind or seismic loads, must be considered.

Shear walls should be positioned throughout the plan area of the building in such a manner as to distribute the forces uniformly among the individual walls with approximately one-half of the wall area oriented in each of the two major directions of the building. At least one major wall should be positioned, if possible, near each exterior face of the building. Shear walls should be continuous, where possible, from top to bottom of the building; avoid offsetting walls from floor to floor, and particularly avoid discontinuing walls from one level to the level below. Positioning shear walls near major floor openings that would preclude proper anchorage of floor (or roof) to wall should be avoided so that diaphragm forces in the plane of the floor may have an adequate force path into the wall.

Where **rigid diaphragms** (such as concrete slabs or metal deck with concrete fill) exist, shears are distributed to the individual walls on the basis of their relative rigidity taking into account the additional forces due to the larger of either accidental or actual horizontal torsion resulting from the eccentricity of the building seismic shear (located at the center of mass) or eccentricity of applied wind load with respect to the center of rigidity of the walls. Where **flexible diaphragms** (such as metal deck with nonstructural fill or plywood) exist, shears are distributed to walls on the basis of tributary area. When diaphragms are semirigid, based on type, construction, or spacing between supporting elements, shears could be distributed by both methods (relative rigidity and tributary area) with individual walls designed to resist the larger of the two shears.

Braced frames, which are intended to transmit lateral loads from floor to floor, are designed as trusses that are loaded horizontally instead of vertically and are principally used in steel construction. Lateral loads are distributed to them on the same basis as to shear walls; therefore, the same general rules apply to their ideal placement. Bracing of individual bays may take the form of X-bracing, single diagonal bracing, or K-bracing. Where K-braces are used, the additional bracing forces associated with vertical floor loads to the braced beam must be considered. Alternative floor framing to avoid large beam loads to the braced beam should be considered where possible.

X-bracing may be designed so that either the tension diagonal takes all the lateral load or so that the tension and compression diagonals share the load. When the tension diagonal resists all the lateral load, the minimum slenderness ratio (kl/r) of the member should not exceed 300; the additional axial load in the column to which the top of the brace is connected, the connection load at each end of the brace and the horizontal footing load at the bottom of the brace, is double that obtained when braces share the load. In X-bracing systems where the tension and compression members share the lateral load, maximum slenderness ratios should be limited to 200 (the members may be considered to brace each other about axes that are normal to the plane of the bay), but connection and individual horizontal foundation loads are decreased. With either method of design, it is important to follow the path of the force from its origin through the structure until it is transferred to the ground. With any bracing system, it is wise to sketch to scale the major connection details prior to finalization of calculations; the desirable intersection of member axes is often more difficult to achieve than a single line drawing would indicate. Connection of braces to columns at intermediate points between floors should be avoided because plastic hinges in columns lead to structural instability.

Stud walls consist of wood or steel sheet metal studs with one or more lines of horizontal bridging. The allowable vertical load on the wall is a function of the maximum permissible load on each stud as a column and the spacing of the studs.

Corrugated or flat sheet steel or aluminum, are commonly employed for walls of industrial or mill buildings. These sheets are usually supported on steel girts framing horizontally between columns and supported from heavier eave struts by one or more lines of vertical steel sag rods.

Reinforced-concrete or masonry walls should be designed so that the allowable bending and/or axial stresses are not exceeded, but the minimum thicknesses of such walls should not be less than the following:

Material	Max ratio, unsupported height or length to thickness	Nominal min thickness, in*
Reinforced concrete	25	6
Plain concrete	22	7
Reinforced brick masonry	25	6
Grouted brick masonry	20	6
Plain solid masonry	20	8
Hollow-unit masonry	18	8
Stone masonry (ashlar)	14	16
Interior nonbearing concrete or masonry (reinforced)	48	2
Interior nonbearing concrete or masonry (unreinforced)	36	2

* × 25.4 = mm.

Foundations

Bearing Pressure of Soils The bearing pressure which may be allowed on soil may vary over a large range. For important structures, the nature of the underlying soil should be ascertained by borings or test pits. If the soil consists of medium or soft clay, a settlement analysis based on consolidation tests of undisturbed soil samples from the

foundation strata is necessary. Structures founded upon mud, soft clay, silt, peat, or artificial filling will almost certainly settle, and no foundation for a permanent structure should rest on or above such material without adequate provision for the resulting settlement. Table 12.2.6 gives a general classification of soils and typical safe pressures which they may support.

These values approximate the pressures allowed by the building law in most cities. Actual allowable bearing pressures should be based on the quality and engineering characteristics of the material obtained from analysis of borings, standard penetration tests, and rock cores. Other laboratory tests, when the cost thereof is warranted by the magnitude of the project, may show higher values to be safe. The foundation for a building housing heavy vibrating machinery such as power hammers, heavy punches, and shears should receive some allowance for possible compression and rearrangement of soil due to the vibrations transmitted through it. The foundation for a tall chimney should be designed with a comparatively low pressure upon the soil, because of the disastrous results which might occur from local settlement.

Footings The purpose of footings is to spread the concentrated loads of building walls and columns over an area of soil so that the unit pressure will come within allowable limits. Footings are usually constructed of concrete, placed in open excavations with or without sheeting and bracing. In the past, stone, where available in quantity and the proper quality, has been used economically for residential building footings.

Table 12.2.6 Safe Bearing of Soils

Nature of soil	Safe bearing capacity tons/ft^2	Safe bearing capacity MPa
Solid ledge of hard rock, such as granite, trap, etc.	25–100	2.40–9.56
Sound shale and other medium rock, requiring blasting for removal	10–15	0.96–1.43
Hardpan, cemented sand, and gravel, difficult to remove by picking	8–10	0.76–0.96
Soft rock, disintegrated ledge; in natural ledge, difficult to remove by picking	5–10	0.48–0.96
Compact sand and gravel, requiring picking for removal	4–6	0.38–0.58
Hard clay, requiring picking for removal	4–5	0.38–0.48
Gravel, coarse sand, in natural thick beds	4–5	0.38–0.48
Loose, medium, and coarse sand; fine compact sand	1.5–4	0.15–0.38
Medium clay, stiff but capable of being spaded	2–4	0.20–0.38
Fine loose sand	1–2	0.10–0.20

Allowable bearing pressures for granular materials are typically determined as 10 percent of the standard penetration resistances (N values) obtained in the field from standard penetration tests (SPTs) and are in tons/ft^2.

Concrete footings may be either plain or reinforced. Plain concrete footings are generally limited to one- or two-story residential buildings. The center of pressure in the wall or column should always pass through the center of the footing. Where columns, because of fixity, impose a bending moment on the footing, the maximum soil pressures, due to the combined axial and moment components, shall be positive throughout the area of the footing (i.e., no net uplift) and shall be less than the allowable values. Footings in ground exposed to freezing should be carried below the possible penetration of frost.

Deep foundations are required when a suitable bearing soil is deep below the surface, typically more than 10 to 15 ft. (3.0 to 4.6 m). Sometimes deep foundations are necessary even if the suitable bearing materials are shallower, but groundwater conditions make excavation for footings difficult. The most common types of deep foundations include caissons or drilled piers and piles. Where the bearing soil is clay stiff enough to stand with undercutting, and the material immediately above it is peat or silt, the **open-caisson method** may be economical. In this method, cylindrical steel casings 3 ft and more in diameter are sunk as excavation proceeds, the casings having successively smaller diameters. At the bottom of the shaft thus formed, the soil is undercut to obtain sufficient bearing area. The shaft and the enlargement at the base are then filled with concrete, the cylinders sometimes being withdrawn as the concrete is placed. The open-caisson method cannot be used where groundwater flows too freely into the excavation. Where large foundations under very heavy buildings must be carried to great depth to reach rock or hardpan, particularly where groundwater flows freely, the **pneumatic-caisson method** is used.

Drilled-in piers are formed by drilling with special power augers up to 5 ft (1.5 m) diameter or greater. The holes are drilled to the desired bearing level with or without metal casings, depending on the soil conditions. Belling of the bottom may also be performed mechanically from the surface. In poor soils, or where groundwater is present, the hole may be retained with bentonite clay slurry which is displaced as concrete is placed in the caisson by the **tremie method.**

Pile Foundations Piles for foundations may be of wood, concrete, steel, or combinations thereof. Wood piles are generally dressed and, if required, treated offsite; concrete piles may be prepared offsite or cast in place; steel piles are mill-rolled to section. They can be driven, jacked, jetted, screwed, bored, or excavated. Wood piles are best suited for loads in the range of 15 to 30 tons (133.4 to 177.9 kN) per pile and lengths of 20 to 45 ft (6.6 to 15 m). They are difficult to splice and may be driven untreated when located entirely below the permanent water table; otherwise piles treated with creosote should be used to prevent decay. Wood piles should be straight and not less than 6 in in diameter under the bark at the tip. Concrete piles are less destructible, and hence are adaptable to many conditions, including driving in dense gravels, and can be up to approximately 120 ft (40 m) long. Concrete piles are divided into two classes: those poured in place and those precast, cured, and driven. Cast-in-place piles are made by driving a mandrel into the ground and filling the resulting hole with concrete. In one well-known pile of this type (Raymond), a thin sheet-steel corrugated shell is fitted over a tapered mandrel before driving. This shell, which is left in the ground when the mandrel is removed, is filled with concrete. Prestressing of precast-concrete piles provides greater resistance to handling and driving stresses. With a concrete pile, 25 to 60 tons (222.4 to 533.8 kN) or more per pile are carried. Structural steel H columns and steel pipe with capacities of 40 to 300 tons (350 to 1,800 kN) per pile have been driven. Experience has shown that corrosion is seldom a practical problem in natural soils, but if otherwise, increasing the steel section to allow for corrosion is a common solution.

Methods of Driving Piles The drop hammer and the steam or pneumatic hammer are usually employed in driving piles. The steam or pneumatic hammer, with its comparatively light blows delivered in rapid succession, is of advantage in a plastic soil, the speed with which the blows are delivered preventing the readjustment of the soil. It is also of advantage in soft soils where the driving is easy, but a light hammer may fail to drive a heavy pile satisfactorily. The water jet is sometimes used in sandy soils. Water supplied under pressure at the point of the pile through a pipe or hose run alongside it erodes the soil, allowing the pile to settle into place. To have full capacity, jetted piles should be driven after jetting is terminated particularly if the pile is to resist uplift loads. Diesel hammers are sometimes used if the equipment is available. They do not require a steam boiler or an auxiliary engine for pneumatic power and thus generally render more economical service. When driving piles (or sheet piling) into relatively sandy soils, vibratory hammers have proved successful; the vibrations imparted to the hammer by an engine-driven unbalanced eccentric serve to set up dilatory action in the pile, making penetration faster and much simpler.

In applications where piles must be pulled, or extracted, the reverse operation is performed by the hammer; i.e., the pile is subjected to a tensile force for removal. Vibratory hammers offer exemplary performance in such applications.

Determination of Safe Loads for Piles Piles may obtain their supporting capacity from friction on the sides or from bearing at the point. In the latter case, the bearing capacity may be limited by the strength of

the pile, considered as a column, to which, however, the surrounding soil affords some lateral support. In the former case, no precise determination of the bearing capacity can be made. Many formulas have been developed for determining the safe bearing capacity in terms of the weight of the hammer, the fall, and the penetration of the pile per blow, the most generally accepted of which is that known as the ***Engineering News* formula:** $R = 2wh/(s + 1.0)$ for drop hammers, $R = 2wh/(s + 0.1)$ for single-acting steam or pneumatic hammers, $R = 2E/(s + 0.1)$ for double-acting steam or pneumatic hammers, where R = safe load, lb; w = weight of hammer, lb; h = fall of hammer, ft; s = penetration of last blow, in; E = rated energy, ft · lb per blow. This formula and similar ones are based on the determination of the energy in the falling hammer, and from this the pressure which it must exert on the top of the pile. The *Engineering News* formula is currently used typically for timber piles with capacities not exceeding 30 tons. It assumes a factor of safety of 6. It is a wise practice to drive index piles and determine their bearing capacity through pile load tests typically carried to twice the service load of the pile before proceeding with the final design of important structures to be supported on piles. The design then is based on the safe service load capacity so determined, and the piles are driven to the same penetration resistance to which the successfully tested index piles where driven by the same driving hammer.

Spacing of Piles Wood piles are preferably spaced not closer than 2½ ft (0.76 m), and concrete piles 3 ft (0.91 m) on centers. If driven closer than this, one pile is liable to force another up. Piles in a group must not cause excessive pressure in soil below their tips. The efficiency, or supporting value of friction piles when driven in groups, by the Converse-Labarre method, is

$$\frac{1 - d/s[(n - 1)m + (m - 1)n]}{90mn}$$

where d = pile diameter, in (cm); s = spacing center to center of piles, in (cm); m = number of rows; n = number of piles in a row.

Capping of Piles Piles are usually capped with concrete; wood piles sometimes with pressure-treated timber. Concrete is the most usual material and the most satisfactory for the reason that it gets a full bearing on all piles. The piles should be embedded 4 to 6 in (10 to 15 cm) in the concrete. In the event some pile(s) may be subjected to tension, a means of anchoring the pile top(s) into the concrete must be used.

Retaining Walls A wall used to sustain the pressure of earth behind it is called a retaining wall. Retaining walls which depend for their stability upon the weight of the masonry are classed as gravity walls. Such walls built on firm soil will usually be stable when they have the following proportions: top of fill level, back vertical, base, 0.4 height; top of fill level, back battered, base, 0.5 height; top of fill steeply inclined, back vertical, base, 0.5 height; top of fill steeply inclined, back battered, base, 0.6 height. An additional factor of safety is obtained by building the face on a batter. Care should be taken in the design of a wall that the allowable soil pressure is not exceeded and that drainage is provided for the back of the wall. The foundations of retaining walls should be placed below the level of frost penetration. Retaining walls of reinforced concrete are made thin, with a broad base, and the wall either cantilevered from the base or braced with buttresses or counterforts.

It is impossible to derive formulas for the earth pressure on the back of the wall which will take account of all the actual conditions. Assuming the earth to be a loose, homogeneous, granular mass, and the coefficient of friction to be independent of the pressure, Rankine deduced the following formula for a wall with vertical back:

$$P = \left(\frac{1}{2}wh^2 + vh\right)\cos d\left[\frac{\cos d - \sqrt{\cos^2 d - \cos^2 a}}{\cos d + \sqrt{\cos^2 d - \cos^2 a}}\right]$$

the center of pressure being at a height $\frac{1}{3}H(wh + 3v)/(wh + 2v)$ above the base, where P = earth pressure per lin ft (m) of the wall, lb (kg); h = height of the wall, ft (m); w = weight of earth per ft^3 (m^3), lb (kg); v = weight of superposed load per ft^2 (m^2) of surface, lb (kg); d = the angle with the horizontal of the earth surface behind the wall; and a = angle of internal friction of the earth, deg. (For sands, a = 30 to 38°.) The direction of the pressure is parallel to the earth's surface. The retaining wall should have sufficient thickness at the base so that the resultant of the earth pressure P combined with the weight of the wall falls well within the base. If this resultant falls at the outside edge of the middle third, the maximum vertical pressure on the foundation (at the outer edge of the base) will be equal to $2W/T$ lb/ft^2 (Pa), where W is the total vertical pressure on the base of 1 ft (m) length of wall and T the thickness of the wall at the base, ft (m).

In the design of walls of buildings which must withstand earth pressure and low independent walls, where refinement is not necessary, the earth pressure is frequently assumed to be that of a fluid weighing 40 to 45 lb/ft^3 (641 to 721 kg/m^3).

MASONRY CONSTRUCTION

The term **masonry** applies to assemblages consisting of fired-clay, concrete, or stone units, mortar, grout, and steel reinforcement (if required). The choice of materials and their proportions is based on the required strength (compressive, flexural, and shear), fire rating, acoustics, durability, and aesthetics. The strength and durability of masonry depends on the size, shape, and quality of the unit, the type of mortar, and the workmanship. Resulting bond strength is affected by the initial rate of absorption, texture, and cleanliness of the masonry units.

Brick Common red bricks are made of clay burned in a kiln. Quality characteristics are hardness and density. Light-colored brick is apt to be soft and porous. Brick for masonry exposed to the weather or where strength is desired should have a crushing strength of not less than 2,500 lb/in^2 (17.3 MPa) and should absorb not over 20 percent of water by weight, after 5-h immersion in boiling water (see Sec. 6).

Mortar Mortar is the bonding agent that holds the individual units together as an assembly. All mortars contain cement, sand, lime, and water in varying proportions. Mortars are classified as portland-cement-lime mortar or masonry cement mortar. (See Sec. 6.9.)

Laying and Bonding Brick should be laid in a full bed of mortar and shoved laterally into place to secure solid bearing and a bed of even thickness and to fill the vertical joints. Clay brick should be thoroughly wet before laying, except in freezing weather. Concrete bricks/blocks should not be wetted before placement. Brick laid with long dimension parallel to the face of the work are called stretchers, perpendicular to the face, headers. Bats (half-brick) should not be used except where necessary to make corners or to form patterns on the face of the wall. Each continuous vertical section of a wall one masonry unit thick is called a **wythe.** Multiwythe walls, of brick or block faced with brick, are now commonly tied together with ties or anchors between each wythe of brick and block. Such ties are typically provided every other course. When the wythes are adequately bonded or tied; the wall may be considered as a composite wall for strength purposes. Walls may also be tied together longitudinally by overlapping stretchers in successive courses. Transverse bond is obtained by making every sixth course headers, the headers themselves overlapping in successive courses in the interior of thick walls. Variations in the arrangement of headers are often used in the face of walls for appearance. The area of cross section of full-length headers should not be less than one-twelfth the face of the wall, in bonding each pair of transverse courses of brick. Three examples of bond are shown in Fig. 12.2.16.

Arches over windows and doorways are laid in concentric rings of headers on edge, with radial joints. The radius of the arch should be 1 to 1¼ times the width of the opening.

Lateral Support Brick walls should be supported laterally by bonding to transverse walls or buttresses, or by anchoring to floors, at intervals not exceeding 20 times the thickness. Floors and anchors must be capable of transmitting wind pressure and earthquake forces, acting outward, to transverse walls or other adequate supports, and thus to the ground. The height of piers between lateral supports should not exceed 12 times their least dimension.

Concrete Masonry Units (CMUs) Hollow or solid concrete blocks are used in building walls, often faced with brick or stone on the exterior walls. Standard block sizes are based on a brick module, nominally 4 in high.

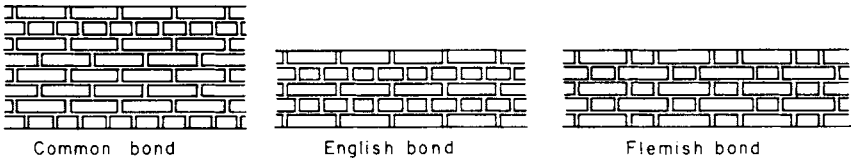

Fig. 12.2.16 Bonds used in bricklaying.

Allowable compressive stresses in masonry are related to the masonry unit strength and the type of mortar as follows:

Kind of masonry	Type M or S mortar lb/in²	Type M or S mortar MPa	Type N mortar lb/in²	Type N mortar MPa
Stone ashlar	360	2.48	320	2.20
Rubble	120	0.83	100	0.69
Clay brick (2500 lb/in²)	160	1.10	140	0.97
Hollow CMU (1000 lb/in²)	75	0.52	70	0.48
Solid CMU (2000 lb/in²)	160	1.10	140	0.97

Minimum thickness of load-bearing masonry walls shall be 6 in for up to one story and 8 in for more than one story.

Reinforced Masonry The design of masonry with vertical reinforcing bars placed and fully grouted in some of the cells provides increased capacity to resist flexure and axial loads. In addition, in areas where seismic design is required, due to the brittle nature of unreinforced masonry, all masonry must be reinforced to prevent a brittle failure mode. The design principles for reinforced masonry are similar to the design for reinforced concrete.

Reinforced Concrete See Sec. 12.3.

TIMBER CONSTRUCTION

Floors The framing of wooden floors may be divided into two general types: joist construction and solid, or mill, construction. The first consists of **joists** 2 to 6 in wide, of the necessary depth, and spaced about 12 to 16 in (30 to 40 cm) on centers. The wall ends should rest on and be anchored to walls and the interior ends carried by a line of girders on columns. These joists should be securely cross-bridged not over 8 ft (2.4 m) apart in each span to prevent twisting and to assist in distributing concentrated loads. Solid blocking should be provided at ends and at each point of support. The floor is formed of a thickness of rough boarding on which the finish flooring is laid. **Solid** or **mill-construction floors** are designed to do away with the small pockets which exist in joist construction and thus reduce the fire hazard. They are generally framed with beams spaced 8 to 12 ft (2.4 to 3.6 m) on centers and spanning 18 to 25 ft (5.5 to 7.6 m). The wall ends of beams rest on and are anchored to the wall, and the interior ends are carried on columns and tied together to form a continuous tie across the building. Ends of timbers in masonry walls should have metal bearing plates and ½ in space at sides and end for ventilation, to prevent rot. The ends should be beveled and the anchors placed low to avoid overturning the wall if the beams drop in a fire. In all cases, care should be taken to provide sufficient bearing at the points of support so that the allowable intensity of compression across the grain is not exceeded. In case it is desirable to omit columns, or the floor load requires a closer spacing of beams, girders are run lengthwise of the building over the columns to take the beams, the ends of which are hung in hangers or stirrup irons and tied together, over or through the girders. This is called **intermediate framing.** Steel beams are sometimes used in place of wooden beams in this type of construction, in which case a wooden strip is bolted to the top flange of the beam to take the nailing of the plank, or the plank is laid directly on top of the beam and secured by spikes driven from below and clinched over the flange. The floor is formed of 3 or 4 in (7.5 or 10 cm) plank grooved in each edge, put together with splines and securely spiked to beams. On top of the plank is laid flooring, with a layer of sheathing paper between. In case the floor loads require an excessive thickness of plank, or in localities where heavy plank is not easily obtainable, the floor is built up of 3 × 6 in (7.5 × 15 cm), or other sized pieces, placed on edge, and securely nailed together. (See Table 12.2.7.)

The roofs of buildings of joist and mill construction are framed in a manner similar to the floors of each type and should be securely anchored to the walls and columns. In case columns are not desired in the top story, steel beams or trusses of either steel or wood are used. For spans up to 35 ft (10.7 m), trussed beams can often be used to advantage.

* Divide tabular value by square of span in feet.
† For other fiber stress f, multiply tabular value by f/1,000.
‡ For deflection in, multiply coefficient by load, lb/ft², and by fourth power of span in ft, and divide by 1,000,000. For other modulus of elasticity E, multiply coefficient of col. 8 by 1,000,000, and divide by E.
NOTE: 1 in = 2.54 cm; 1 lb = 4.45 N; 1 lb/in² = 6.89 kPa.

For **unit stresses in timber,** see Sec. 6.7. For unit stresses in wooden columns, see Table 12.2.9. Table 12.2.7 gives the properties of mill floors made of dressed plank, and of laminated floors made of planks of edge, laid close.

Timber Beams

Properties of Timber Beams Table 12.2.8 presents those properties of wooden timbers most useful in computing their strength and deflection as beams. (The "nominal size" of a timber is indicated by the breadth and depth of the section in inches. The "actual size" indicates the size of the dressed timber, according to National Lumber Manufacturers Assoc. The moment of inertia and section modulus are with the neutral axis perpendicular to the depth at the center. The **safe bending moment** in inch-pounds for a given beam is determined from the section modulus S by multiplying the tabular value by the allowable fiber stress. To select a beam to withstand safely a given bending moment, divide the

* For total safe uniform load, pounds, on beam of span L, feet, divide tabular value by L. For fiber stress f other than 1,000 lb/in^2 multiply by f and divide by 1,000.
† For shearing stress other than 100 lb/in^2, multiply by stress and divide by 100.
‡ For deflection, inches, multiply coefficient by total load, pounds, and by cube of span, feet, and divide by 1,000,000. For other modulus of elasticity E, multiply coefficient by 1,000,000 and divide by E.
NOTE: 1 in = 2.54 cm; 1 ft = 0.305 m; 1 lb = 4.45 N; 1 lb/in^2 = 6.89 kPa.

bending moment in inch-pounds by the allowable fiber stress, and choose a beam whose section modulus S is equal to or larger than the quotient thus obtained. For formulas for computing bending moments, see Sec. 5.2. Note that the allowable fiber stress must be modified by adjustment factors: C_D, load duration factor; C_M, wet-service factor; C_t, temperature factor; C_F, size factor; and other factors which apply to laminated, curved, round, and/or flat use. (See also Sec. 6.7, "Properties of Lumber Products.")

Maximum loads in Table 12.2.8, cols. 7 and 8, are for uniform loading. Use half the values of col. 7 for a single load concentrated at midspan; for other loadings compute the bending moment and use the section modulus, col. 6. The values of col. 8 apply to all symmetrical loadings. For unsymmetrical loading, compute the maximum shear, which must not exceed one-half the tabular value.

The **coefficients of deflection** listed in Table 12.2.8 can be used to deduce deflection as indicated in the footnotes to the table. Coefficients of deflection under concentrated loads applied at the middle of the span may be obtained by multiplying the values in the table by 1.6. The results are only approximate, as the modulus of elasticity varies with the moisture content of the wood.

The deflection due to live load of beams intended to carry plastered ceilings should not exceed $\frac{1}{360}$ of the span (span in inches).

A convenient rule may be derived by assuming that the modulus of elasticity is 1,000 times the allowable fiber stress, which applies to all woods with sufficient accuracy for the purpose. Beams loaded uniformly to capacity in bending will then deflect $\frac{1}{360}$ of the span when the depth in inches is 0.90 times the span in feet; and beams with central concentration, when the depth is 0.72 times the span in the same units. For such beams, the deflection in inches is, for uniform load, $0.03L^2/d$; for central concentration, $0.024L^2/d$, where L is the span, ft, and d the depth, in. Variation in type of loading affects this result comparatively little.

Timber Columns

Timber columns may be either square or round and should have metal bases, usually galvanized steel, to cut off moisture and prevent lateral displacement. For supporting beams, they should have caps which, at roofs, may be of steel, or wood designed for bearing across the grain. At intermediate floors, caps should be of steel, although in some cases hardwood bolsters may be used. Except when caps or beams are of steel, columns should run down and rest directly on the baseplate. Table 12.2.9 gives **working unit stresses for wood columns** recommended where the building laws do not prescribe lower stresses. Use actual, not nominal, dimension of timbers. The column capacity $P_{col} = F'_c A_{net}$, where F'_c is interpolated from Table 12.2.9, and A_{net} is the net cross-sectional area of the column. The values for F'_c in Table 12.2.9 are generally conservative and are based on the factors cited in the table footnotes. In the event $E < 1{,}000F_c$, the value of F'_c must be computed to include the value of C_P as follows:

$$F'_c = F_c C_D C_M C_t C_F C_P$$

(Note that actual design stress $f_c \le F'_c$.)

$$C_p = \text{column stability factor} = \frac{1 + F_{cE}/F^*_c}{2c} - \sqrt{\left(\frac{1 + F_{cE}/F^*_c}{2c}\right)^2 - \frac{F_{cE}/F^*_c}{c}}$$

$$F^*_c = F_c C_D C_M C_t C_F$$

$$F_{cE} = \frac{K_{cE}E}{(l_e/d)^2} = \text{critical buckling design stress in compression parallel to the grain for a given wood species and geometrical configuration of column}$$

where F_c = tabulated allowable design value for compression parallel to the grain for the species (Sec. 6.7); K_{cE} = 0.3 for visually and mechanically graded lumber and 0.418 for glulam members; l_e = effective length of column; d = least dimension of the column cross section; E = modulus of elasticity for the species (Sec. 6.7); c = constant for the type member: 0.8 for sawn lumber, 0.85 for timber piles, 0.9 for glulam members; for factors C_D, etc., see Sec. 6.7.

Glued Laminated Timber Structural glued laminated timber, commonly called glulam, refers to members which are fabricated by pressure gluing selected wood laminations of either ¾ or 1½ in (19 or 38 mm) surfaced thickness. The grain of all the laminations is approximately parallel longitudinally, with exterior laminations being of generally higher-quality wood since bending stresses are greater at the outer fibers. Curved and tapered structural members are available with the recommended minimum radii of curvature being 9 ft 4 in (2.84 m) for ¾-in laminations and 27 ft 6 in (8.4 m) for 1½-in lamination thickness. Laminations should be parallel to the tension face of members; sawn tapered cuts are permitted on the compression face.

Available net (surfaced) widths of members in inches are 2¼, 3⅛, 5⅛, 8¾, 10¾, 12¼, and 14¼; depths are determined by stress requirements. Economical spans (see "Timber Construction Manual," American Institute of Timber Construction) for roof framing range from 10 to 100 ft (3 to 30 m) for simple spans. Floor framing, which is designed for much heavier live loads, economically spans from 6 to 40 ft (1.8 to 12 m) for simple beams and from 25 to 40 ft (7.5 to 12 m) for continuous beams.

Glued laminated members are generally fabricated from either Douglas fir and larch, Douglas fir (coast region), southern pine, or California redwood, depending on availability. Allowable design stresses depend on whether the condition of use is to be wet (moisture content in service of 16 percent or more) or dry (as in most covered structures), the species and grade of wood to be used, the manner of loading, and the number of laminations as well as the usual factors for duration of loading. The cumulative reduction factors described above also apply to glulam beams. Additional factors including C_v, volume factor; C_{fu}, flat use factor; and C_c, curvature factor, also must be applied to glued laminated beams. Refer to the National Design Specification for Wood Construction for further information on glued laminated timber design. (See Sec. 6.7.)

* Values of F'_c in the table are based on C_D = 0.9 (long-duration, permanent, 50-year loading); C_M = 0.8 (moisture content > 16%); C_t = 1.0 (operating temperature < 100°F); C_F = 1.0 (cross section up to 5 in wide × 12 in deep); K_{cE} = 0.3; $E \ge 1{,}000\ F_c$. If $E < 1{,}000\ F_c$, see text for procedure to compute F'_c; c = 0.8.
† Columns should be limited to l_e/d = 50, except for individual members in stud walls, which should be limited to l_e/d = 80.

A summary of allowable unit stresses may be found in Sec. 6.7 for glued laminated timber.

Connections

Bolted Joints Compression may be transmitted by merely butting the timbers, with splice pieces bolted to the sides to keep alignment and resist incidental bending and shear. The same detail (Fig. 12.2.17)

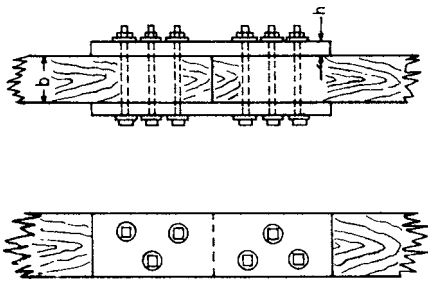

Fig. 12.2.17 Bolted splices for timber framing.

serves in tension, but the entire stress must then be transmitted through the bolts and splice pieces. If of wood, these should have a thickness h equal to $\frac{1}{2}b$. In light, unimportant work, splice pieces may be spiked. Table 12.2.10 gives the allowable load in pounds for one bolt loaded at both ends (double shear) when h is at least equal to $\frac{1}{2}b$. When steel side plates are used for side members, the tabulated loads may be increased 25 percent for parallel-to-grain loading, but no increase should be made for perpendicular-to-grain loads. When a joint consists of two members (single shear), one-half the tabulated load for a piece twice the thickness of the thinner member applies. The safe load for bolts loaded at an angle θ with the grain of the wood is given by the formula $N = PQ/(P \sin^2 \theta + Q \cos^2 \theta)$, where N = allowable load per bolt in a direction at inclination θ with the direction of the grain, lb; P = allowable load per bolt in compression parallel to the grain, lb; and Q = allowable load per bolt in compression perpendicular to the grain, lb.

The size, arrangement, and **spacing of bolts** must be such that tension on the net section of the timber through the bolt holes and shear along the grain do not exceed allowable values. Bolts should be at least 7 diameters from the end of the timber for softwoods and 5 diameters for hardwoods and spaced at least 4 diameters on center parallel to the grain. Crossbolting, to prevent splitting the timber end, is sometimes desirable.

The efficiency of bolted timber connections may be greatly increased by the use of **ring connectors.** Split rings and shear plates are fitted into circular grooves, concentric with the bolt, in the contact surfaces, and transmit shear stresses across the joint. Grooves for split rings and shear plates are cut with a special tool, while toothed rings are usually seated by drawing together the timbers with high-strength bolts. Allowable loads for these various connectors are given in the "Design Values for Wood Construction," published by the National Lumber Manufacturers Assoc. Selected values are given in Table 12.2.11.

The **holding power of wire nails** is as follows ("Design Values for Wood Construction"): The resistance to withdrawal is proportional to the length of embedment, to the diameter of the nail (where the wood does not split), and to $G^{2.5}$, where G is the ovendry specific gravity of the wood (see Sec. 6 for G values of various species). The safe resistance to withdrawal of common wire nails driven into the side grain of seasoned wood is given by Table 12.2.12. Nails withdrawn from green wood have generally slightly higher resistance, but nails driven into green wood may lose much of their resistance when the wood seasons; the allowable withdrawal load should be one-fourth of that given in Table 12.2.12. Cement and other coatings on nails may add materially to their resistance in softwoods. Drilling lead holes slightly smaller than the nail adds somewhat to the resistance and reduces danger of splitting. The structural design should be such that nails are not loaded in withdrawal from end grain.

The safe **lateral resistance** of common wire nails driven in side grain to the specified penetrations is given in Table 12.2.12 and is proportional to $D^{1.5}$ where D is the diameter, in. These values are for seasoned wood and should be reduced 25 percent for woods which will remain wet or will be loaded before seasoning. For nails driven into end grain, values should be reduced one-third.

Common wire **spikes** are larger for their lengths than nails. Their resistance to withdrawal and lateral resistance are given by the same formulas as for nails, but greater precautions need to be taken to avoid splitting.

The **resistance of wood screws to withdrawal** from side grain of seasoned wood is given by the formula $P = 2{,}850G^2D$, where P = the allowable load on the screw, lb/in penetration of the threaded portion; G = specific gravity of ovendry wood; D = diameter of screw, in. Wood screws should not be designed to be loaded in withdrawal from end grain.

The **allowable safe lateral resistance** of wood screws embedded 7 diameters in the side grain of seasoned wood is given by the formula $P = KD^2$, where P is the lateral resistance per screw, lb; D is the diameter, in; and K is 4,800 for oak (red and white), 3,960 for Douglas fir (coast region) and southern pine, and 3,240 for cypress (southern) and Douglas fir (inland region).

	0.67		57	66	75	75	82	97	105	114	124	133
Lateral load*†	0.60–0.75		78	97	116	116	132	171	191	218	249	276
	0.50–0.55		63	78	94	94	107	139	154	176	202	223
	0.42–0.50		51	64	77	77	88	113	126	144	165	182
	0.31–0.41		41	51	62	62	70	91	101	116	132	146

* The allowable lateral load for nails driven in end grain is two-thirds the values shown above.
† The minimum penetration for full lateral resistance for the four groups listed is 10, 11, 13, and 14 diam from higher to lower specific gravities, respectively. Reduce by interpolation for lesser penetration; minimum penetration is one-third the above.
NOTE: 1 in = 2.54 cm; 1 lb = 4.45 N.

The following rules should be observed: (1) the size of the lead hole in soft (hard) woods should be about 70 (90) percent of the core or root diameter of the screw; (2) lubricants such as soap may be used without great loss in holding power; (3) long, slender screws are preferable generally, but in hardwood too slender screws may reach the limit of their tensile strength; (4) in the screws themselves, holding power is favored by thin sharp threads, rough unpolished surface, full diameter under the head, and shallow slots.

The allowable **withdrawal load of lag screws** in side grain is given by the formula $p = 1{,}800D^{3/4}G^{3/2}$, allowable load per inch of penetration of threaded portion of lag screw into member receiving the point, lb; D = shank diameter of lag screw, in; G = specific gravity of ovendry wood. Use of lag screws loaded in withdrawal from end grain should be avoided. The allowable load in such cases should not exceed 75 percent of that for side grain (see also Sec. 8).

The allowable **lateral resistance of lag screws** for parallel-to-grain loading with screws in side grain is proportional to D^2 and is dependent on species and type of side member. Selected values are given in Table 12.2.13 for one lag screw in single shear in a two-member joint.

Lead holes for lag screws (approximately 75 percent of shank diameter) should be prebored for the threaded portion. Lead holes for the shank should be of the same diameter and length as that of the

Table 12.2.13 Allowable Lateral Loads in Pounds on Lag Bolts or Lag Screws

Side member	Length of bolt, in	Diam of bolt at shank, in	Overndry specific gravity of species

	16	1¼	7,120	2,850	6,150	2,460	5,500	2,200	4,520	1,810

NOTE: 1 in = 2.54 cm; 1 lb = 4.45 N.

unthreaded shank. Soap or other lubricant should be used to facilitate insertion and to prevent damage to the screw. Where steel-plate side pieces are used, the allowable loads given by the formula for parallel-to-grain loading may be increased by 25 percent.

The ultimate **withdrawal load per linear inch of penetration of a round drift bolt or pin** from side grain when driven into a prebored hole having a diameter ⅛ in less than that of the bolt diameter may be determined from the formula $p = 6{,}000G^2D$, where p = ultimate withdrawal load of penetration, lb/lin in; G = specific gravity of ovendry wood; D = diameter of drift bolt, in. A safety factor of about 5 is suggested for general use. The allowable load in lateral resistance for a drift bolt should ordinarily be taken as less than that for a common bolt.

STEEL CONSTRUCTION

(Note: In the design of steel structures, 1,000 lb is frequently designated as a kilopound or "kip," and a stress of 1 kip per square inch is designated as 1 ksi.)

Structural steel design was based only on the allowable stress design (ASD) approach until the introduction of the load and resistance factor design (LRFD) technique in the mid-1980s. The LRFD approach is an ultimate strength design approach, similar to that adopted by the American Concrete Institute for concrete design. Both ASD and LRFD are accepted in current codes. The ASD method is still the most commonly used for design.

Specifications The following are in part condensed excerpts from the Specifications of the American Institute of Steel Construction.

Material Ordinary steel for rolled shapes, plates, and bars is typically specified by ASTM A36, with a yield stress of 36,000 lb/in^2 (248.2 MPa). However, advances in mill production methods have resulted in most steels satisfying the higher strength requirements of ASTM A572, Grade 50, leading to increased use of higher-strength steel at little or no cost premium. Other higher-strength steels used in structures are A440, A441, A588, and A242. Steel materials for pipe and tube, specified by ASTM A53 (welded-seam pipe) and A500 (cold-formed), have yield strengths of 33,000 to 50,000 lb/in^2 (227.5 to 344.7 MPa).

Ordinary unfinished machine bolts are specified by A307. Bolts used for structural steel connections are typically high-strength bolts specified by A325 or A490. Riveting is now rarely used, but may often be encountered in older structures. The most common rivets are A502, Grade 1.

Allowable Stresses in A36 Steel

	lb/in^2	MPa
Tension F_t:		
On gross section	22,000	151.6
On net section, except at pinholes	29,000	200
On net section, at pinholes	16,000	110.2
Compression F_c: See Table 12.2.14		
Bending tension and compression on extreme fibers F_b:		
Basic stress, reduced in certain cases	22,000	151.6
Compact, adequately braced beams	24,000	165.3
Rectangular bearing plates	27,000	186.0
Shear F_v: Web of beams, gross section	14,500	99.9

NOTE: 1 ksi = 6.89 MPa.

Allowable Stresses* in Riveted and Bolted Connections

	lb/in^2	MPa
Bearing: A36 steel		
Pins in reamed, drilled, or bored holes	32,400	223.3
Bolts and rivets	69,000	475.7
Roller, lb/lin in (N/lin cm)	760 × diam (in)	1,131 × diam (cm)
Shear: bearing-type connections†		
A502, grade 1 hot-driven rivets	17,500	120.6
A307 bolts	10,000	68.9
A325 bolts when threading is excluded from shear planes (std. holes)	30,000	206.8
A325 bolts when threading is not excluded from shear planes (std. holes)	21,000	144.7
Shear: friction-type connections† (with threads included or excluded from shear plane)		
A325 bolts in standard holes	17,500	120.6
A325 bolts in oversized or short slotted holes	15,000	103.4
A325 bolts in long slotted holes	12,000	82.6
Tension:		
A502, grade 1, hot-driven rivets	23,000	158.5
A307 bolts	20,000	137.9
A325 bolts	44,000	303.3
Bending in pins of A36 steel	27,000	186.1

* Allowable stresses are based on nominal body area of fasteners unless indicated.
† Rivets or bolts may not share loads with welds on bearing-type connections but may do so in friction-type connections.

Proportion of Parts

Most simple beams, columns, and truss members are proportioned to limit the actual stresses to the allowable stresses stipulated above. Other stability or serviceability criteria may control the design. **Deflection** may govern in such members as cantilevers and lightly loaded roof beams. **Buckling,** rather than strength, may govern the design of compression members. The slenderness ratio Kl/r, where Kl is the effective length of the member and r is its radius of gyration, should be limited to 200 in compression members, and L/r limited to 300 in tension members. Kl should not be less than the actual unbraced length l in columns of a frame which depends on its bending stiffness for lateral stiffness. **Width-thickness ratios** are specified for projecting elements under compression. Repeated fluctuations in stress leading to fatigue may be a controlling factor. Rules are given for **combined stresses** of tension, compression, bending, and shear.

Tension members should be proportioned for the gross and net section, deducting for bolt or rivet holes ⅛ in (0.3 cm) larger than the nominal diameter of the fastener.

Columns and other **compression members** subject to eccentric load or to axial load and bending are governed by special rules. A long-established rule is that $f_a/F_a + f_b/F_b$ should be equal to or less than unity, where f_a is the axial stress, f_b the bending stress, and F_a and F_b are the corresponding allowable stresses if axial or bending stress alone exist. This is still considered valid when f_a/F_a is less than 0.15. Joints shall be fully spliced, except that where reversal of stress is not expected and the joint is laterally supported, the ends of the members may be milled to plane parallel surfaces normal to the stresses and abutted with sufficient splicing to hold the connected members accurately in place. Column bases should be milled on top for the column bearing, except for rolled-steel bearing plates 4 in (10 cm) or less in thickness.

Beams and girders, of rolled section or built-up, should in general be sized such that the bending moment M divided by the section modulus S is less than the allowable bending stress F_b. For built-up sections a rule of thumb is, for A36 steel, flanges in compression should have a thickness of 1/16 the projecting half width, and webs should have a thickness of 1/320 the maximum clear distance between flanges. Web stiffeners should be provided at points of high concentrated loads; additional web stiffeners are required in plate girders. Splices in the webs of plate girders should be made by plates on both sides of the web. When two or more rolled beams or channels are used side by side to form a beam, they should be connected at separators spaced no more than 5 ft (1.52 m); beams deeper than 12 in (30 cm) are to have at least two bolts to each separator.

The **lateral force on crane runways** due to the effect of moving crane trolleys may be assumed as 20 percent of the sum of the weights of the lifted loads and of the crane trolley (but exclusive of the other parts of the crane) applied at the top of the rail, one-half on each side of the runway, and shall be considered as acting in either direction normal to the runway rail. The **longitudinal force** may be assumed as 10 percent of the maximum wheel reactions of the crane applied at the top of the rail.

Bolted or riveted connections carrying calculated stress, except lacing and sag bars, should be designed to support not less than 6,000 lb (27.0 kN). Rivets or high-strength bolts are preferred in all places, and both are implied in these paragraphs wherever "bolting" is mentioned; unfinished bolts, A307, may be used in the shop or in field connections of lightly loaded structures, or for secondary members, bracing, and the like.

Members in tension or compression, meeting at a joint, shall have their lines of center of gravity pass through a point, if practicable; if not, provision shall be made for the eccentricity. A group of bolts transmitting stress to a member shall have its center of gravity in the line of the stress, if practicable; if not, the group shall be designed for the resulting eccentricity. Where stress is transmitted from one member to another by bolts through a loose filler greater than ¼ in in thickness, except in slip critical connections using high-strength bolts, the filler shall be extended beyond the connected member and the extension secured by enough bolts or sufficient welding to distribute the total stress in the member uniformly over the combined sections of the member and the filler.

Most bolted connections transmit shearing forces by developing the shearing or bearing values of the bolts, but bolts in certain connections, such as shelf angles and brackets, are required to transmit tension forces.

Bolts shall be proportioned by the nominal diameter. Rivets and A307 bolts whose grip exceeds 5 diam shall be allowed 1 percent less safe stress for each 1/16 in (0.16 cm) excess length. The minimum distance between centers of bolt holes shall be 2⅔ diam of the bolt; but preferably not less than 3 diam.

The minimum distance from the center of any bolt hole to a sheared edge shall be 2¼ in (5.7 cm) for 1¼-in (32-mm) bolts, 2 in (5.1 cm) for 1⅛-in (28-mm) bolts, 1¾ in (4.4 cm) for 1-in (25-mm) bolts, 1½ in (3.8 cm) for ⅞-in (22-mm) bolts, 1¼ in (3.2 cm) for ¾-in (19-mm) bolts, 1⅛ in (2.8 cm) for ⅝-in (16-mm) bolts, and ⅞ (2.22 cm) for ½-in (13-mm) bolts. The distance from any edge shall not exceed 12 times the thickness of the plate and shall not exceed 6 in (15 cm).

Design of Members

Properties of Standard Structural Shapes Detailed dimensions, geometric properties, and other data for standard rolled sections are listed in the AISC Manual of Steel Construction. This reference is usually the starting point when one is embarking on a design utilizing steel shapes. For sizes not standard, or for *unusual* (*generally much higher*) geometric properties required for special applications, an endless variety of beam and column shapes can be fabricated by welding the desired sections from plate stock.

A great variety of tees is produced by shearing or gas-cutting standard beams (S shapes) or wide-flange sections (W shapes) lengthwise at midheight of the web, making two T sections.

Welding The main advantage of assembling and connecting steel frames by welding is the reduction in the amount of metal used. The saving in metal is achieved by (1) elimination of bolt holes which reduce the net section of tension members, (2) simplification of details, and (3) elimination of splice plate and gusset plate material. (See also Sec. 13.3.)

Allowable stresses in welds depend on the type of weld, the manner of loading, and the relative strengths of the weld metal and the base metal. For **complete-penetration groove welds** in which the full edge thickness of

the thinner part to be joined is beveled in preparation for welding, allowable stresses due to tension or compression normal to the effective area or parallel to the axis of the weld are the same as the base metal, and the allowable shear stress on the effective area is 0.3 times the nominal tensile strength of the weld metal (limited by 0.4 times yield stress in the base metal). The effective area for a complete-penetration groove weld is the width of the part joined times the thickness of the thinner part.

For **partial-penetration groove welds,** allowable stresses due to compression normal to the effective area and tension or compression parallel to the axis of the weld are the same as the base metal. For tension normal to the effective area, the allowable stress is 0.3 times the nominal tensile strength of the weld metal (limited by 0.6 times the yield stress of the base metal); for shear parallel to the axis of the weld, the allowable stress on the effective area is 0.3 times the nominal tensile strength of weld metal (limited by 0.4 times yield stress of the base metal). The effective thickness of partial-penetration groove welds depends on the welding process, welding position, and the included angle of the groove but may be safely taken as the depth of the chamfer less ⅛ in.

For **fillet welds,** allowable shear stresses on the effective area are taken as 0.3 times nominal tensile strength of the weld (limited by 0.4 times yield stress of the base metal), and for tension or compression parallel to the axis of the weld, allowable stresses are the same as the base metal. Fillet welds are not to be loaded in tension or compression normal to the effective area; they transfer loads between members in shear only. The effective area of a fillet weld is the overall length of the full-size weld times the shortest distance from the root to the face (normally leg size × sin 45°). Allowable shear in a fillet weld is taken as 930 lb/in of length (163 N/mm) for each 1/16 in (1.59 mm) of leg size. (See Sec. 13.) Typical details of welded connections are indicated in Fig. 12.2.18.

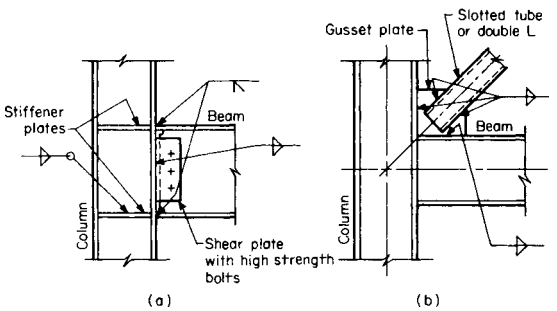

Fig. 12.2.18 Welded connections. (*a*) Moment connection; (*b*) bracing connection.

Safe Loads for Steel Beams To determine the safe load uniformly distributed, as limited by bending, for a structural steel beam on a given span, apply the formula $W = 8F_b s/l$, where W is the total load, lb.; F_b is the allowable fiber stress (24,000 lb/in^2 or any other); S is the section modulus for the beam in question, and l is the span, in. (This formula may also be used with equivalent metric units.) The safe load concentrated at midspan is one-half this amount. For other safe loads, note that F_bS is the safe resistance to bending in inch-pounds (or newton-metres) afforded by the beam. Compute the load, of whatever type or distribution, which will produce a maximum bending moment equal to safe moment of resistance (see Sec. 5 for bending-moment formulas).

To select a beam to support a given load, compute the maximum bending moment in inch-pounds, divide by the allowable fiber stress F_b, and refer to the table for a beam having a section modulus which is not smaller than the quotient.

Formulas for the safe loads and deflections of beams with various methods of support and of loading are given in Sec. 5.

Short beams should be investigated for crippling of the web. In the tables are given the safe end reactions for beams of A36 steel resting on a seat 3½ in (9 cm) long along the axis of the beam. Short beams should also be investigated for shear, by dividing the maximum shear, in pounds, by the area of the web, excluding the flanges.

Single angles used as beams and loaded in the plane of axis *X-X* or *Y-Y* tend to deflect laterally as well as in the plane of the loads. Unless this is prevented, as by pairing the angles back to back and securing them together, the unit fiber stress due to bending may be as much as 40 percent above that computed by dividing the bending moment by S for the axis perpendicular to the plane of the loads. The relation $f = M/S$ does not hold for single angles and for Z bars, which are unsymmetrical about both axes.

Deflection of Beams Table 12.2.15 gives **coefficients of deflection** for steel shapes under uniformly distributed loads, and is based on the formula; deflection in inches $= 30fL^2/Ed$, the table giving the values of $30fL^2/E$. (f = fiber stress, lb/in^2; L = span, ft; d = depth of section, in; E = modulus of elasticity = 29,000,000 lb/in^2.)

To find the deflection in inches of a section symmetrical about the neutral axis, such as a beam, channel, etc., divide the coefficient in the table corresponding to given span and fiber stress by the depth of the section in inches.

To find the deflection in inches of a section which is not symmetrical about the neutral axis but which is symmetrical about an axis at right angles thereto, such as a tee or pair of angles, divide the coefficient corresponding to given span and fiber stress by twice the distance of extreme fiber from neutral axis obtained from table of elements of sections.

To find the deflection in inches of a section for any other fiber stress than that given, multiply this fiber stress by either of the coefficients in the table for the given span and divide by the fiber stress corresponding to the coefficients used.

I beams and channels loaded to a fiber stress of 24,000 lb/in^2 (165.5 MPa) will not deflect in excess of 1/360 of the span (allowed for plastered ceilings) if the depth in inches (cm) is not less than 0.74 (6.21) times the span in feet (m) for uniform loads and 0.60 (5.00) times the span for central concentration.

Beam Supports Steel beams are supported at the ends generally (1) by means of web connections to girders and columns, (2) by resting on structural-steel seats, or (3) by resting on masonry. Limiting values of end reactions of the second type, for seats 3½ in (9 cm) long, are listed in the AISC Manual of Steel Construction. Standard AISC web connections of the first type are called **framed beam** connections and are designated by the number of rows of bolts. Examples of connections are given in Fig. 12.2.19. These connections may be specified as "Standard 3 row, 4 row, etc., connections." Connections must always be designated and detailed for the calculated design reaction.

The capacity of web connections is governed by the shearing of the fastener, or the bearing of the fastener on the web or on the material to which the beam is connected, or by the strength of the connecting angles. For example, the supporting values of standard framed beam connections, using ⅞ in fasteners in members of A36 material, are given in Table 12.2.16. For fasteners in webs thicker than 0.34 in use the values in the column headed Double Shear; for thinner webs, bearing limits the value, and the coefficients for web bearing are to be used. For ¾-in fasteners, multiply tabular bearing values by 6/7 and shear values by 36/49. Fasteners connecting the outstanding legs to the supporting metal are in double shear if two beams are framed opposite or in single shear if a beam is connected on one side only. If the supporting material of A36 steel is thinner than 0.34 in in double-shear connections or thinner than 0.17 in in single-shear connections, the capacity is limited by bearing. The value of any ⅞-in fastener in bearing on A36 material is 60,900t, where t is the thickness of the plate. The value of ⅞ in A502, grade 1 rivets or A325 HS bolts (slip-critical connections) is 9,020 lb in single shear and 20,400 lb in double shear. The corresponding values for A307 unfinished bolts are 6,000 lb and 12,000 lb, respectively.

Cast-iron columns were often used in the past instead of wood, to save space, in the lower stories of heavy buildings, but are obsolete. Occasionally they are encountered in repair and alteration work in older buildings. The ratio of length to least radius of gyration l/r should not exceed 70, and the average unit stress under axial compression should not exceed 9,000 – 40l/r lb/in^2.

Table 12.2.15 Coefficients of Deflection for Simply Supported Steel Beams under Uniformly Distributed Loads

Span, ft	Fiber stress of 24,000 lb/in²	Span, ft	Fiber stress of 24,000 lb/in²	Span, ft	Fiber stress of 24,000 lb/in²	Span, ft	Fiber stress of 24,000 lb/in²
1	0.026	14	4.87	27	18.1	39	37.7
2	0.098	15	5.59	28	19.5	40	39.8
3	0.223	16	6.36	29	20.9	41	41.8
4	0.398	17	7.18	30	22.4	42	43.9
5	0.621	18	8.04	31	23.9	43	45.8
6	0.892	19	8.97	32	25.4	44	48.0
7	1.23	20	9.93	33	27.0	45	50.4
8	1.59	21	10.9	34	28.7	46	52.6
9	2.01	22	12.1	35	30.5	47	54.7
10	2.48	23	13.1	36	32.2	48	57.1
11	3.00	24	14.3	37	34.1	49	59.5
12	3.58	25	15.6	38	35.8	50	62.2
13	4.20	26	16.8				

NOTE: For a load concentrated at midspan, use ⅘ of the coefficient given. 1 ft = 0.305 m; 1 lb/in² = 6.89 kPa.

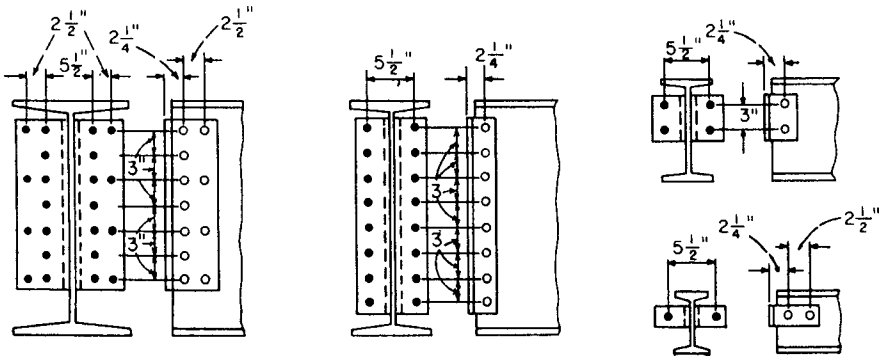

Fig. 12.2.19 Framed beam connections.

Steel joists consisting of lightweight rolled sections, thin for their height, or open-web trussed members fabricated by welding or otherwise, are used with economy in buildings where spans are long and loads are light, and where a plaster ceiling affords sufficient fire protection. They are rarely used in industrial buildings, except to support roof loads.

Steel pipe is often used for columns under light loads. Table 12.2.17 gives the safe loads on standard size pipes (ASTM A501 or A53, grade B) used as columns. For extra-strong and double extra-strong pipe used as columns, the safe loads will increase approximately in the same proportion as the weight per foot. (See Sec. 8.7.)

Structural steel tubing (ASTM A500, grade B), in square or rectangular cross section with F_y = 46 ksi (317.1 MPa), is also used for columns, bracing members, and unbraced members subjected to large torsional loads. The closed box shape makes tube sections especially suited for resisting torsional loads.

Corrugated metal deck and siding is used for roofs and walls, respectively, to span between purlins for roof loads or between girts for wind loads. The decking is sized to resist the bending caused by these loads. Roof decking is often also used as a diaphragm to transfer wind or seismic loads to the lateral bracing system below. Load tables specifying safe loads for different spans are available from metal deck manufacturers.

Lightweight, cold-rolled, galvanized steel sheet metal structural sections are used when the design will allow. A popular use is as a substitute for wood framing (wall studs and light beams). Assembly is commonly through use of self-drilling, self-tapping screws with corrosion-resistant plating, although the thicker product is amenable to welding. The most common cross sections rolled are shown in Fig. 12.2.20. Wall stud sections are manufactured with punch-outs along their length to facilitate easy installation of electric wiring, piping, etc. The sections are fabricated per ASTM 653 specifications and come in minimum yield strengths of 33 and 50 ksi. Some of the larger sections are used as beams and columns when used as-rolled or when assembled into stiffer cross sections. (See Steel Stud Manufacturers Association literature.)

Fire Resistance The resistance to fire of building materials has been tested extensively by various agencies. Table 12.2.18 gives the fire-resistance rating of a few of the common building materials and methods of construction as established by the Uniform Building Code from standard fire tests.

Table 12.2.16 Values of Standard Framed-Beam Connections
(⅞-in A325 HS bolts in standard holes,* A36 members)

AISC designation	Two angles thickness × length	Shear 1,000 lb	Bearing on beam web (*t*), 1,000 lb
10 rows	5/16 × 2′5½″	204	609*t*
9 rows	5/16 × 2′2½″	184	548*t*
8 rows	5/16 × 1′11½″	164	487*t*
7 rows	5/16 × 1′8½″	143	426*t*
6 rows	5/16 × 1′5½″	123	365*t*
5 rows	5/16 × 1′2½″	102	304*t*
4 rows	5/16 × 0′11½″	81.8	243*t*
3 rows	5/16 × 0′8½″	61.3	182*t*
2 rows	5/16 × 0′5½″	40.9	121*t*

* Values indicated are for slip-critical connections or bearing type where threads are not excluded from the shear plane. For bearing-type connections where threads are excluded from the shear plane, shear values may be increased by 1.47.

† If the web of the supporting beam is thinner than 0.17 in (0.42 in if beams frame on both sides), bearing must also be investigated.

NOTE: 1 in = 2.54 cm; 1 lb = 4.45 N.

Table 12.2.17 Safe Axial Loads for Standard (Schedule 40) Steel Pipe Columns, kips
(Stress according to AISC specification for A501 pipe*)

Nominal pipe size, in	Outside diam, in	Wall thickness, in	Effective length of column K1, ft										
			6	7	8	9	10	11	12	14	16	18	20
3	3.500	0.216	38	36	34	31	28	25	22	16	12	10	
3½	4.000	0.226	48	46	44	41	38	35	32	25	19	15	12
4	4.500	0.237	59	57	54	52	49	46	43	36	29	23	19
5	5.563	0.258	83	81	78	76	73	71	68	61	55	47	39
6	6.625	0.280	110	108	106	103	101	98	95	89	82	75	67
8	8.625	0.322	171	168	166	163	161	158	155	149	142	135	127
10	10.750	0.365	246	243	241	238	235	232	229	223	216	209	201
12	12.750	0.375	303	301	299	296	293	291	288	282	275	268	261

* Yield stress is 36 ksi (248.2 MPa). Pipe ordered to ASTM A53, type E or S grade B, or to API standard 5L grade B will have a yield point of 35 ksi (241.3 MPa) and may be designed at stresses allowed for A501 pipe.

NOTE: 1 in = 2.54 cm; 1 ft = 0.305 m. For dimensions of standard pipe see Sec. 8. Safe loads above underscore lines are for values of Kl/*r* more than 120 but not over 200.

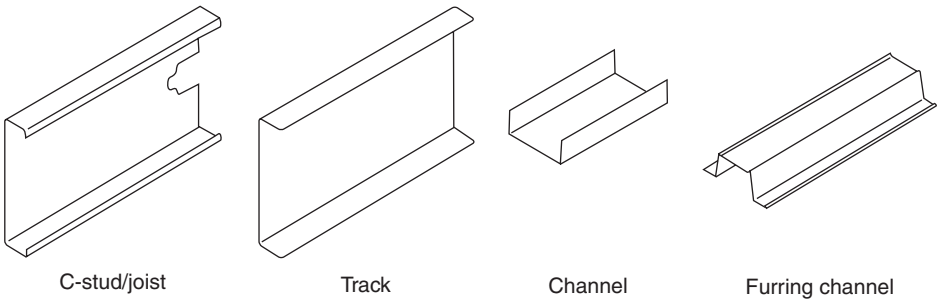

Fig. 12.2.20 Light-gage sheet metal cross sections.

Table 12.2.18 Selected Fire-Resistance Ratings

Type	Details of construction	Rating
Reinforced-concrete beams and girders	Grade A concrete, 1½ in clear to reinforcement	4 h
	Grade B concrete, 1½ in clear to reinforcement	3 h
Steel beams, girders, and trusses	2½ in cover to steel	4 h
	1 in gypsum-perlite plaster on metal lath, 1¼ in clear of steel	3 h
	Ceiling of 1⅛ in gypsum-perlite plaster on metal lath with 2½ in min air space between lath and structural members	4 h
Reinforced concrete columns	Grade A concrete 1½ in clear to reinforcement; 12-in columns or larger	4 h
	Grade B concrete 2 in clear to reinforcement; 12-in columns or larger	4 h
Steel columns, 8 × 8 in or larger	Concrete (siliceous gravel):	
	2½ in clear to steel	4 h
	2 in clear to steel	3 h
	1 in clear to steel	2 h
	1⅛ in gypsum-perlite plaster on metal lath spaced from flanges with 1¼-in steel furring channels	4 h
	⅞ in portland-cement plaster on metal lath over ¾-in channels	1 h
Reinforced concrete slabs	5 in concrete (expanded clay, shale, slate, or slag) 1 in clear to reinforcement	4 h
	6½ in concrete (all other aggregate) 1 in clear to reinforcement	4 h
Heavy-timber floors	3 in tongue-and-groove plank floor with 1 in finish flooring	1 h
Wood joists	Wood floor; 1 in tongue-and-groove subfloor and 1 in finish floor with asbestos paper between. Ceiling of ⅝ in Underwriters' Laboratories listed wallboard	1 h
Brick walls	Solid walls, unplastered, with no combustible members framed in wall:	
	8 in nominal	4 h
	4 in nominal	1 h
Concrete masonry units	8 in Underwriters' Laboratories listed concrete blocks, laid as specified in Underwriters' Laboratories listing	4h
	4 in Underwriters' Laboratories listed concrete blocks; laid as specified in Underwriters' Laboratories listing	3 h
Steel-stud partitions	¾ in gypsum-perlite plaster both sides on metal lath	2 h
	⅝ in gypsum wallboard on 3⅝-in steel studs; attached with 6 d nails; joints taped and cemented	2 h
Wooden-stud partitions	Exterior walls: one side covered with ½ in gypsum sheathing and wood siding; other side faced with ½ in gypsum-perlite plaster on ⅜-in perforated gypsum lath	1 h
	Interior Walls: 2 × 4 in studs with ⅝ in gypsum wallboard on each side	1 h
Plain or reinforced concrete walls	Solid, unplastered:	
	7 in thick	4 h
	6½ in thick	3 h
	5 in thick Grade B Grade A	2 h
	3½ in thick	1 h

Grade A concrete is made with aggregates such as limestone, calcareous gravel, trap rock, slag, expanded clay, shale, or slate or any other aggregates possessing equivalent fire-resistance properties.

Grade B concrete is all concrete other than Grade A concrete and includes concrete made with aggregates conaining more than 40 percent quartz, cherts, or flint.

NOTE: 1 in = 2.54 cm.

The design, theory, and notation of this chapter are in general accord with the 2005 Building Code Requirements for Structural Concrete of the American Concrete Institute, although many detailed provisions have been omitted.

Standard Notation

Load Factors

D = dead load of structure or force caused by dead load
E = earthquake load or force
L = live load of structure or force caused by live load
W = wind load or force
U = required strength of structure to resist design ultimate loads
ϕ = understrength or capacity reduction factor

Beams and General Notation

a = depth of compression zone, using approximate method
A_b = area of individual reinforcing bar, in^2
A_{ps} = area of prestressing steel
A_s = area of tension reinforcement
A'_s = area of compression reinforcement
A_v = area of steel in one stirrup
b = width of compression face of beam
b_w = width of stem of T beam
$c = k_u d$ = depth to neutral axis at ultimate, from compression face
d = effective depth of beam, compression face to centroid of tension steel
d' = depth of compression steel, from compression face
d_b = diam of individual reinforcing bar, in
E_c = Young's modulus of concrete
E_s = Young's modulus of steel
f'_c = compressive strength of concrete from tests of 6 × 12 in cylinders, lb/in^2
$\sqrt{f'_c}$ = measure of shear and tensile strength of concrete, lb/in^2, i.e., if f'_c = 4,900 lb/in^2, then $\sqrt{f'_c}$ = 70 lb/in^2
f_{pu} = ultimate stress of prestressing steel, lb/in^2
f_y = yield stress of reinforcing steel, lb/in^2
h = overall height or thickness of member
k_u = ratio of ultimate neutral axis depth to effective depth
l_d = development length of reinforcing bar, in
s = spacing of shear reinforcement
M_n = nominal moment capacity of ideal section
M_u = ultimate moment of section = ϕM_n or required ultimate moment
v_c = shear stress in concrete
V_c = shear force resisted by concrete
V_s = shear force resisted by web reinforcement
V_u = shear strength of section or required ultimate shear
β_1 = factor relating neutral axis position to depth of equivalent approximate stress block (see Fig. 12.3.2)
ε_{su} = reinforcement strain at time of failure of member
ε_y = yield strain of reinforcement
ρ = tension reinforcement ratio = A_s/bd
ρ' = compression reinforcement ratio = A'_s/bd
ρ_{bal} = balanced reinforcement ratio

Columns

$A_c = A_g - A_s$ = net area of concrete in cross section
A_{core} = area within spiral
A_g = gross area of column
A_s = area of steel in column
e = eccentricity of axial load on column
$M = Pe$ = applied bending moment
P = axial thrust
P_0 = failure load of short column under concentric load
ρ_g = gross steel ratio = A_s/A_g
ρ_s = spiral steel ratio = volume of spiral steel/volume of core
ε_t = strain, extreme steel layer at nominal strength

Floor Systems

b_0 = effective shear perimeter around column in flat plate, flat slab, or footing
c_1 = width of supporting column or capital, in direction of span being considered
c_2 = width of supporting column, in transverse direction
I_b = moment of inertia of beam
K_b = flexural stiffness of beam, moment per unit rotation
K_c = flexural stiffness of columns at joint, moment per unit rotation
K_s = flexural stiffness of slab of width l_2, moment per unit rotation
l_1 = span, center to center of supports, in direction considered
l_2 = span, center to center of supports, in transverse direction
$l_n = l_1 - c_1$ = clear span in direction considered
M_0 = static moment
q = distributed design load, including load factors
α_1 = EI of beam in direction 1/EI of slab of width l_2

Footings

A_1 = loaded area
A_2 = area of same shape and concentric with A_1
f_b = ultimate bearing stress on concrete
β = ratio of long side/short side of footing

Walls

l_c = unbraced height of wall

Prestressed Concrete

A_{ps} = area of prestressed reinforcement
A_t = area of anchorage-zone reinforcement
f'_{ci} = compressive strength of concrete at time of prestressing
f_{ps} = stress in reinforcement at time of failure of member
f_{pu} = ultimate stress of prestressing reinforcement
$f_{se} = f_{si} - \Delta f_s$ = stress in reinforcement at service load
f_{si} = reinforcement stress at time of tensioning steel
Δf_s = loss of prestress from initial tensioning value
$\rho_p = A_{ps}/bd$

MATERIALS

Reinforced concrete is a combination of concrete and steel acting as a unit because of bond between the two materials. Concrete has a high compressive strength but a relatively low tensile strength. Beams of plain concrete fail by tension at very low stresses, but if properly reinforced by embedment of steel in their tensile regions, they may be loaded to utilize the much higher compressive strength of the concrete. Reinforced concrete structures are practically monolithic, are more rigid than steel structures of the same strength, and are inherently fire-resistant. Reinforcement in the concrete also controls cracking caused by temperature changes and shrinkage.

Prestressed concrete is a form of reinforced concrete in which initial stresses opposite those caused by the applied loads are induced by tensioning high-strength steel embedded in the concrete. Members may be *pretensioned,* in which the steel is tensioned and the concrete then cast around it, or *posttensioned,* in which the concrete is cast and cured, after which steel placed in ducts through the concrete is tensioned.

Concrete For reinforced concrete work, only high-quality portland cement concrete may be used, and the aggregates must be carefully selected. The proportions are governed by the required strength, durability, economy, and the quality of the aggregates. Concretes for building construction normally have compressive strengths of 3,000 to 5,000 lb/in^2 (20 to 35 MPa), except that concrete for columns may be considerably stronger, with 12,000 to 14,000 lb/in^2 common in some geographic areas. Most concrete for prestressed members will have 5,000 lb/in^2 or higher compressive strength. The higher-strength concretes require thorough quality control if the strengths are to be consistently obtained. Generally, lean, harsh mixes should be avoided because the bond with the steel will be poor, permeability will be high, and durability of the concrete may be poor. A consistency of concrete that will flow sluggishly but not so wet as to produce segregation of the materials when transported must be used for all reinforced concrete work in order to embed the steel and completely fill the molds or forms. The use of vibration is almost mandatory, and enables the use of stiffer, more economical, concretes than would otherwise be possible (see also Sec. 6.9).

Steel Reinforcing steel may be deformed or plain bars, welded-wire fabric, or high-strength wire and strand for prestressed concrete. Bars with deformations on their surfaces are designed to produce mechanical bond and greater adhesion between the concrete and steel, and are used almost universally in the United States. Welded-wire fabric is suitable in many cases for slabs and walls, and may result in cost savings through labor savings. Fabric is made with both smooth and deformed wires, and the deformed fabric may have some advantage in terms of better crack control. Deformed reinforcing bars having minimum yield stresses from 40,000 to 75,000 lb/in^2 (275 to 517 MPa) are currently manufactured. The higher-strength steels have the advantage of allowing higher working stresses, but their ductility may be less and it may be difficult to cold-bend them successfully, especially in the larger sizes. The chemical makeup of most reinforcing steels is such that it is not readily weldable without special techniques, including careful preheating and controlled cooling. Furthermore, the variation of the material from batch to batch is so great that separate procedures must be devised for each batch. Tack welding in assembling bar cages can be particularly troublesome because of the stress raisers introduced. A weldable steel is produced with the specification ASTM A-706, but it is not widely available. Prestressing steel is heat-treated high-carbon steel, and 7-wire strand will have a breaking stress of 250,000 or 270,000 lb/in^2 (1,720 or 1,860 MPa). The usual steel is Grade 270, low-relaxation strand. The strength of solid wire for prestressing is slightly less. ASTM specifications cover the various steels, and all steel used as reinforcement should comply with the appropriate specification.

Reinforcing Steel Sizes The sizes of reinforcing bars have been standardized, and the designation numbers are approximately the bar diameter, in 1/8-in units. Table 12.3.1 gives the nominal diameter, cross-sectional area, and perimeter for each bar size. Bars are now marked in nominal millimeter diameters. Other marks on the bars identify the type of steel, the yield stress (grade), and the manufacturer. The areas of the four most common 7-wire prestressing strands are given below:

	Area, in^2	
Diam, in	Grade 250	Grade 270
½	0.144	0.153
0.6	0.216	0.217

Table 12.3.1 Dimensions of Deformed Bars

	Diam			
No.	in	mm	Area, in^2	Perimeter, in
3	0.375	10	0.11	1.178
4	0.500	13	0.20	1.571
5	0.625	16	0.31	1.963
6	0.750	19	0.44	2.356
7	0.875	22	0.60	2.749
8	1.000	25	0.79	3.142
9	1.128	29	1.00	3.544
10	1.270	32	1.27	3.990
11	1.410	36	1.56	4.430
14	1.693	43	2.25	5.32
18	2.257	57	4.00	7.09

Plain and deformed wires are used as reinforcement, usually in the form of welded mats. Plain wires are made in sizes W0.5 through W45, where the number designates the cross-sectional area of the wire in hundredths of square inches. Deformed wires are made in sizes D1 through D45, and the number has the same meaning. Not all sizes are made by all manufacturers, and local suppliers should be consulted about availabilities of sizes. The formerly used wire gage numbers are no longer used for size specifications.

Moduli of Elasticity For concrete the modulus of elasticity E_c may be taken as $w^{1.5}33\sqrt{f'_c}$ in lb/in^2, where w is the weight of the concrete between 90 and 155 lb/ft^3. Normal weight concrete may be assumed to weigh 145 lb/ft^3. For steel the modulus of elasticity may be taken as 29,000,000 lb/in^2 (200 GPa), except for prestressing steel for which the modulus shall be determined by tests or supplied by the manufacturer, but is usually about 28,000,000 lb/in^2.

The **modular ratio** $n = E_s/E_c$ is of importance in designing reinforced concrete. It may be taken as the nearest whole number but not less than six. The value of n for lightweight concrete may be taken as the same for normal weight concrete of the same strength, except in calculations for deflections.

Protection of Reinforcement Reinforcement, for both regular and prestressed concrete, must be protected by the concrete so as to prevent corrosion. The amount of cover needed for various degrees of exposure is as follows:

Member and exposure	*Cover, in*
Concrete surface deposited against the ground	3
Concrete surface to come in contact with the ground after casting:	
Reinforcement larger than No. 5	2
Reinforcement smaller than No. 5	1½
Beams and columns not exposed to weather:	
Main steel, stirrups, and ties	1½
Joists, slabs, and walls not exposed to weather	¾
Column spirals and ties	1½

The clear cover and clear bar spacings should ordinarily exceed ⅓ times the maximum sized aggregate used in the concrete.

The amount of protection recommended is a minimum, and when corrosive environments or other severe exposure occurs, the cover

should be increased. The concrete in the cover should be made as impermeable as possible. Fire-resistance requirements may also control the cover requirements.

LOADS

The dead and live loads are combined in determining the cross sections of the members. The dead load includes the weight of the structure, all finishing materials, and usually the installed equipment. The live load includes the contents and ordinarily refers to the movable items.

The **live load** (pounds per square foot) to be used for design depends upon the loadings that will occur in the particular structure as well as on the requirements of the local building code. The Boston Building Code illustrates good practice and is as follows for floor loads:

Heavy manufacturing, sidewalks, heavy storage, truck garages, 250; public garages, intermediate manufacturing, and hangars, 150; stores, heavy merchandise, light storage, 125; armories, assembly halls, gymnasiums, grandstands, public portions of hotels, theaters, and public buildings, corridors and fire escapes from public assembly buildings, light merchandising stores, stairs, first and basement floors of office buildings, theater stages, 100; upper floors of public buildings, office portions of public buildings, stairs, corridors and fire escapes except from public assembly buildings, theater and assembly halls with fixed seats, light manufacturing, locker rooms, stables, 75; church auditoriums, 60; office buildings above first floor including corridors, classrooms with fixed seats, 50; residence buildings and residence portions of hotels, apartment houses, clubs, hospitals, educational and religious institutions, 40. [Note: 100 lb/ft^2 = 4.79 kPa.]

Live loads affecting structural members supporting considerable tributary floor areas are sometimes reduced in recognition of the low probability that the entire area will be loaded to the full design load at the same time. Roofs are commonly designed to support live loads of 20 to 30 lb/ft^2, with many special provisions for snow loads in SEI/ASCE 7. Wind loads are commonly from 15 to 30 lb/ft^2 (higher in areas subject to hurricanes) of vertical projection. In the case of heavy moving loads, allowance should be made for impact by increasing the live load by 25 to 100 percent.

Dead loads include the weight of both structure and finishing materials, and the weights of some typical wall, floor, and ceiling materials are as follows:

Description	*Weight, lb/ft^2*
Granolithic finish, per in of thickness	12
7/8-in hardwood, 1 1/8-in plank intermediate floor, and tar base	16
3-in wood block in coal-tar pitch	10
Lightweight concrete fill, 2 in thick	14
Plaster on concrete, tile, or concrete block, two coats	5
Plaster on lath	10
6-in concrete block wall	25
Suspended ceiling	12

SEISMIC LOADINGS

Earthquakes induce forces in structures because of inertial forces which resist the ground motions. These forces have damaged or destroyed large numbers of structures throughout the world. The art and science of designing to resist seismic effects are still evolving, and may be thought of in several steps.

1. Determine the ground motion to be expected at the site of interest. This usually requires consulting a map in ASCE-7 or the prevailing local building code, such as the Uniform Building Code (UBC). Several steps may be required, including finding the expected acceleration of the bedrock, followed by an accounting for the soil types between the bedrock and the structure. There is an implicit or explicit assumption of a probability that this ground motion will not be exceeded in some particular time interval, such as 50 or 100 years.

2. Determine the effects of the ground accelerations on the structure which is being analyzed. This will require consideration of the natural period of vibration of the structure and of structural characteristics such as damping and ductility, and more elaborate analyses will be required for large and important structures than for smaller, less crucial cases. Member forces, moment, shear, thrust, torsion, and deformations such as story drift and member end rotations will result from this analysis. The major building codes all have specific requirements and provisions for this analysis, and the UBC is the most widely used in seismically active regions. In most cases, an equivalent static horizontal load will be applied to the structure, with the force in the range of 10 percent or less to as much as 30 percent of the mass of the structure.

3. Design and detail members and connections for the imposed forces. Chapter 21 of the ACI Code has many requirements for the detailing of the reinforcement in the members and joints. When compared with designs for static loadings which include only dead, live, and wind loads, seismic designs will have much more lateral reinforcement in columns, and often much heavier shear reinforcement (especially near the joints), and will usually have extra reinforcement within the joint regions. Much of this added reinforcement is referred to as **confinement reinforcement,** and the intent is to utilize the fact that triaxially confined concrete may be able to sustain much greater strains before failure than unconfined concrete. Obviously, steps 2 and 3 are parts of an iterative process which converges to an acceptable structural design solution.

The current seismic design philosophy includes the assumption that it is not economically possible to design structures to resist extremely large earthquakes without damage. It is expected that structures will resist smaller earthquakes, such as might be expected several times during the life of a structure, with minimal damage, while a very large earthquake which might be expected to occur once during a structure's design life would cause significant damage but would leave the structure still standing. The assignment of an importance factor for buildings is one consequence of this design philosophy. Hospitals, school buildings, and fire stations, for example, would be designed to a higher seismic standard than would a three-story apartment building.

LOAD FACTORS FOR REINFORCED CONCRETE

The current ACI Building Code for Reinforced Concrete is based on a **strength design** concept, in which the strength of a member or cross section is the basis of design. This approach has been adopted because of the difficulty in assigning reasonable and consistent allowable stresses to the concrete and steel. Factors of safety are expressed in terms of *overload* and *understrength* factors. Overload factors reflect the uncertainty of the applied loads. The ACI Building Code and SEI/ASCE 7 have many loading combinations. The most common, omitting some of the lesser loads (snow, rain, roof live load), are as follows:
With no wind or earthquake loads:

$$U = 1.2D + 1.6L \qquad (12.3.1)$$

With wind acting, use the larger of Eq. (12.3.2) or (12.3.3):

$$U = 1.2D + 0.8W \qquad (12.3.2)$$

$$U = 1.2D + 1.6W + 1.0L \quad \text{or} \quad U = 0.9D + 1.6W \qquad (12.3.3)$$

No section may be weaker than required by Eq. (12.3.1). Other load combinations include seismic (earthquake) forces, liquids, and earth pressure loadings. The understrength factors reflect the ductility of failure in the mode considered, and the consequences of a failure on the rest of the structure. These are expressed as ϕ factors with the following values:

Bending and tension	$\phi = 0.90$
Shear and torsion	$\phi = 0.75$
Spiral columns	$\phi = 0.70$
Tied columns and bearing	$\phi = 0.65$

These factors are used to reduce the computed ideal strengths of members, reflecting possible weaknesses related to materials, dimensions, and workmanship.

In addition to strength requirements, serviceability checks must be made to ensure freedom from excessive cracking, deflections, vibrations,

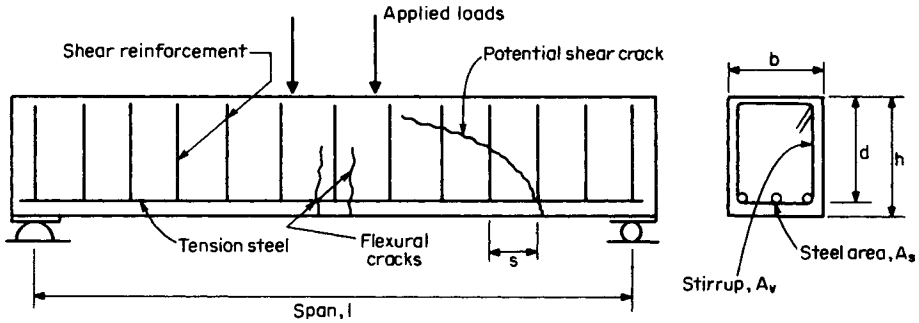

Fig. 12.3.1 Typical arrangement of reinforcement in beams.

etc., at working loads. Prestressed-concrete members must also satisfy a set of allowable stresses at this load level.

Deflections are usually controlled by specifying minimum member depths. The values of *l*/16 and *l*/21, for beams which are simply supported and continuous at both ends, respectively, are typical, unless an investigation is conducted to show that shallower members will result in acceptable deflections. Crack control is obtained by careful distribution of the steel through the tensile zone. In this regard, several small bars are superior to one large bar.

The approach to design is not a "limit design" or "plastic design" concept, as the ultimate forces are derived from elastic analyses of structures, using maximums for each critical section. The plastic collapse loads and mechanisms currently used in the "plastic design" of some steel structures in the United States are not considered.

Bridges may be designed using the same general concepts, but different overload and understrength factors are used, and the serviceability requirements include checks on the fatigue strength.

REINFORCED CONCRETE BEAMS

Concrete beams are reinforced to resist both flexural and shear forces. A typical reinforcement scheme for a simply supported beam is shown in Fig. 12.3.1.

As the load on a reinforced concrete beam is increased, vertical tension cracks appear in the maximum moment regions, and gradually grow in length, width, and number. By the time the working load is reached, some of the cracks extend to the neutral axis and the contribution of the tensile strength of the concrete to the flexural capacity of the beam has become very small. As the load is increased further, the reinforcement eventually yields. This load is nearly the maximum the member can sustain. Further attempts at loading produce large increases in deflection and crack widths with very small increases in load and a gradual reduction in the remaining concrete compression area. When a limiting concrete strain of about 0.003 is reached at the compression face of the beam, the concrete starts crushing and the capacity of the beam starts dropping. For static design purposes, the achievement of the 0.003 strain is usually regarded as the end of the useful life of the beam.

Within limits to be checked later, at the time of flexural failure of a beam the stress in the steel is equal to the yield stress, which greatly simplifies the analysis of the member. The strain and stress distributions in a beam are shown in Fig. 12.3.2, at failure.

It is assumed that plane sections remain plane, that adequate bond exists, that the stress-strain relationships for concrete and steel are known, and that tension in the concrete has a negligible influence.

The **flexural strength** of a cross section may be written as, including the understrength factor and rounding the terms in the parentheses to one significant figure:

$$\begin{aligned} M_u &= \phi A_s f_y d(1 - 0.4k_u) \\ &= \phi A_s f_y d(1 - 0.6\rho f_y/f'_c) \end{aligned} \tag{12.3.4}$$

where $\rho = A_s/bd$ = reinforcement ratio. The reinforcement ratio will ordinarily be between 0.005 and 0.02.

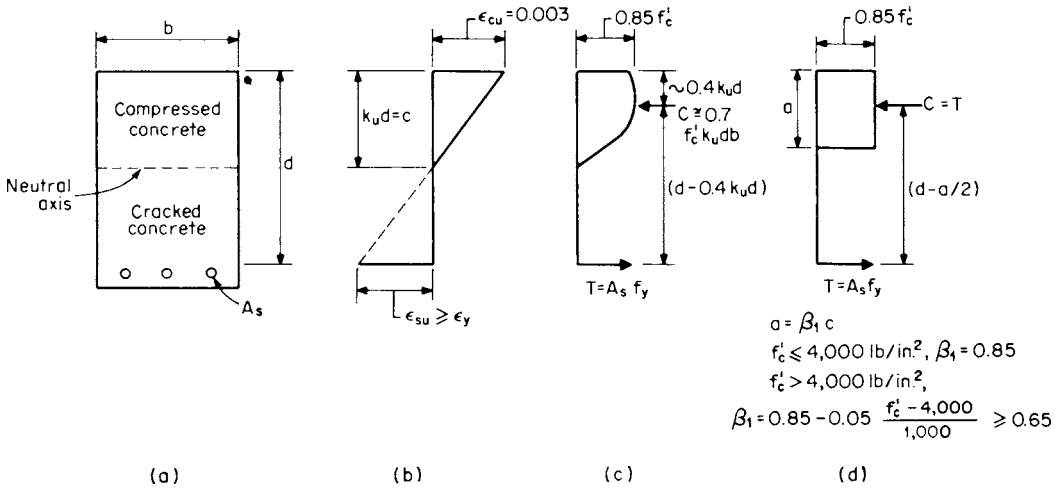

Fig. 12.3.2 Stress and strain distribution in reinforced concrete beam at failure. (*a*) Section; (*b*) strains; (*c*) stresses; (*d*) approximate stresses.

A satisfactory approximate stress distribution is shown in Fig. 12.3.2*d*. Since $T = C = 0.85f'_c ba$, then $a = A_s f_y/0.85f'_c b$ and the flexural capacity is

$$M_u = \phi A_s f_y(d - a/2) \tag{12.3.5}$$

It must be demonstrated for each case that the stress in the reinforcement has reached f_y, and the simplest approach is to show that $\varepsilon_{su} \geq \varepsilon_y$. From Fig. 12.3.2*b*, $\varepsilon_{su} = 0.003(1 - k_u)/k_u = 0.003(d - c)/c$. The ACI Code requires that $\varepsilon_{su} \geq 0.004$ to ensure that at least some yielding, with resultant large deflections, occurs before a member fails.

Beams may contain both compression and tension reinforcement, especially when the beam must be kept as small as possible or when the long-term deflections must be minimized. The forces at ultimate are shown in Fig. 12.3.3, and the moment may be calculated as

$$M_u = \phi[A'_s f_y(d - d') + (A_s - A'_s)f_y(d - a/2)] \tag{12.3.6}$$

where $a = (A_s - A'_s)f_y/0.85f'_c b$. These equations assume that the compression steel yields. If it does not, the computed a value will be wrong, but the computed M_u value will be close to the correct value. Again, $\varepsilon_{su} \geq 0.004$ is required. The compression steel strain is $\varepsilon'_{su} = 0.003(k_u d - d')/k_u d$, and the generalized steel stress is $f_s = \varepsilon_s E_s \leq f_y$. A general solution requires adjusting $k_u d$ so that $T = C_c + C_s$ and then summing moments of forces about some convenient axis.

Many reinforced concrete beams are flanged sections, or T beams, by virtue of having a slab cast monolithically with the beam, and such a cross section is shown in Fig. 12.3.4. It will be found that the neutral axis lies within the flange in most instances, and if $k_u d \leq t$, then the beam is treated as a rectangular beam of width b. This is checked using $k_u d = A_s f_y/0.85\beta_1 f'_c b$, developed from equilibrium (Fig. 12.3.2). If $k_u d > t$, the flexural capacity is computed by

$$M_u = \phi[(A_s - A_{sw})f_y(d - a/2) + A_{sw} f_y(d - t/2)] \tag{12.3.7}$$

where $A_{sw} = (b - b_w)t0.85f'_c/f_y$; and $a = (A_s - A_{sw})f_y/0.85f'_c b_w$.

Continuous T beams are treated as rectangular beams of width b_w in the negative moment regions where the lower surface of the beam is in compression. Most continuous beams will have compression steel in the negative moment regions, as some bottom steel is always continued into the support regions.

Both T beams and beams with compression steel may be thought of in terms of dividing the beam into two components—one a rectangular beam containing part of the tension steel and the other a couple with the rest of the tension steel at the bottom and either the compression steel or the T-beam flanges at the top. Both components of the beam must satisfy horizontal equilibrium.

The reinforcement ratio should not be less than $\rho_{\min} = 3\sqrt{f'_c}/f_y \geq 200/f_y$. This is to ensure that the ultimate moment is somewhat greater than the initial cracking moment. For T beams, $\rho = A_s/b_w d$ for purposes of the minimum steel requirement. This minimum steel ratio applies for concrete strengths up to about 4,000 lb/in^2. Stronger concretes require slightly larger steel quantities.

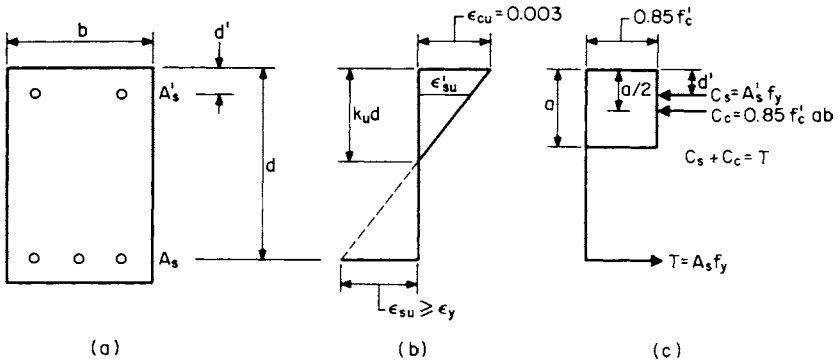

Fig. 12.3.3 Stress and strain distributions in a doubly reinforced concrete beam. (*a*) Section; (*b*) strains (*c*) approximate stresses.

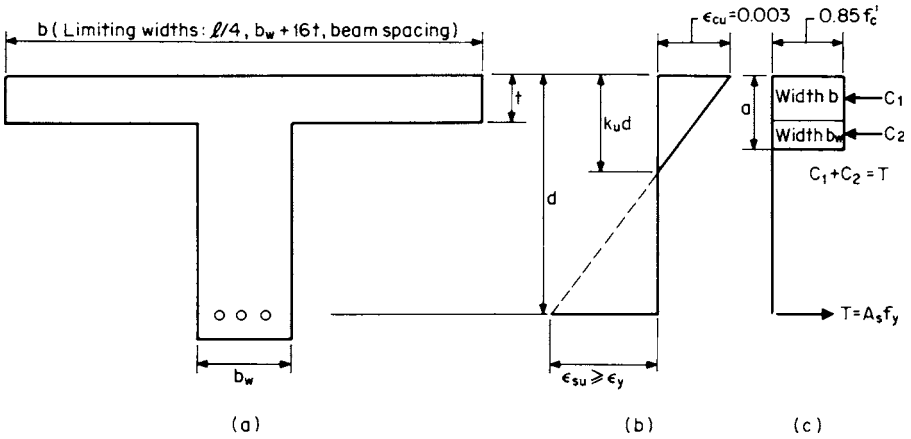

Fig. 12.3.4 Strain and stress distribution in a T beam. (*a*) Section; (*b*) strains; (*c*) approximate stresses.

In the selection of a cross section, it is convenient to transform Eq. (12.3.4) by substituting pbd for A_s and rearranging to obtain

$$M_u/\phi bd^2 = \rho f_y(1 - 0.6\rho f_y/f'_c) \tag{12.3.8}$$

With given materials f_y and f'_c selection of a ρ value enables calculation of the required bd^2, from which a cross section may be selected. For convenience, values of $M_u/\phi bd^2$, are plotted against ρf_y in Fig. 12.3.5, for several values f'_c.

The strengths of prestressed-concrete beams are treated much the same as reinforced concrete beams, and the differences will be noted later.

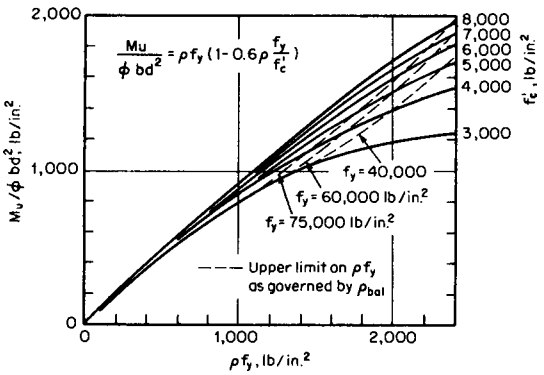

Fig. 12.3.5 Design factors for single reinforced concrete beams.

In addition to the tension stresses caused by bending forces, **shear forces** cause inclined tension stresses which may lead to inclined cracking such as is sketched in Fig. 12.3.1. Unless web reinforcement is present, the formation of such a crack usually leads directly to the complete collapse of the member at the load which caused the crack, or only slightly higher.

As a result of this undesirable behavior, shear reinforcement is required in all major beams, and the normal design procedure is to proportion the beam for the flexural requirements and then add shear steel, usually in the form of stirrups, to make the shear strength adequate.

The concrete can be assumed to resist a shear stress of $v_c = \phi 2\sqrt{f'_c}$, or a shear force of

$$V_c = \phi 2\sqrt{f'_c}\, bd \tag{12.3.9}$$

(or $V_c = \phi 2\sqrt{f'_c}\, b_w d$ for T beams). The shear reinforcement must resist the force in excess of V_c, so that

$$V_u - V_c = V_s \tag{12.3.10}$$

The area of shear reinforcement is then selected to satisfy

$$V_s = \phi A_v f_y d/s \tag{12.3.11}$$

Shear reinforcement to satisfy this requirement is provided at every section of the beam, except that the region between the support and the section at the distance d from the support is supplied with the steel required at d from the support.

The stirrup spacing should not exceed $d/2$, and is reduced to a maximum of $d/4$ if $V_u > \phi 6\sqrt{f'_c}\, bd$. V_u must not exceed $\phi 10\sqrt{f'_c}\, bd$. The minimum area of shear reinforcement allowed is $A_v = 50 b_w s/f_y$. Closed stirrups of the form shown in Fig. 12.3.1 are recommended, and are essential in areas subjected to earthquake loadings.

Shear in prestressed-concrete members is handled in a similar manner, and the designer is referred to the ACI Code for details. However, it will be found that most prestressed members designed for buildings and which do not support major concentrated loads will have adequate shear strength if the minimum steel given by the following expression is supplied:

$$A_v = \frac{A_{ps}}{80}\frac{f_{pu}}{f_y}\frac{s}{d}\sqrt{\frac{d}{b_w}} \qquad \text{in}^2 \tag{12.3.12}$$

The maximum stirrup spacing is 0.75 of the member depth, or 24 in, and for constant-depth members, d is measured at the section of maximum moment.

At least the minimum area of shear reinforcement must be supplied over the full length of most reinforced and prestressed members unless it can be shown, by a test acceptable to the building official, that the members can sustain the required ultimate loads without the steel.

Recent ACI Codes have undergone major revisions to reflect the effects of bar spacing and bar cover on development length, l_d, and on splice lengths. In some common cases the current development lengths will be much greater than in ACI Codes from 1983 and earlier. The current development lengths for straight bars are given in Code Sec. 12.2.2, and a more complex, less conservative, set of requirements are in Sec. 12.2.3. When the available anchorage lengths are less than l_d, hooks are often used. The conservative Sec. 12.2.2 requirements may be summarized as

$$l_d = K d_b \frac{f_y \psi_t \psi_e \lambda}{\sqrt{f'_c}} \tag{12.3.13}$$

in which K is as follows:

	No. 6 and smaller bars and deformed wire	*No. 7 and larger bars*
1. Clear spacing of bars being developed or spliced $\geq d_b$ and clear cover $\geq d_b$ with minimum ties or stirrups or	$1/25$	$1/20$
2. Clear spacing $\geq 2d_b$ and clear cover $\geq d_b$	$1/25$	$1/20$
3. Other cases	$3/50$	$3/40$

The other terms are defined as

d_b = diameter of bar or wire, in
ψ_t = bar location factor
= 1.3 for top bars (horizontal with more than 12 in of concrete cast below)
= 1.0 for other bars
ψ_e = coating factor
= 1.5 for epoxy-coated bars or wires with cover $\leq 3d_b$, or clear spacing $\leq 6d_b$
= 1.2 for all other epoxy-coated bars or wires
= 1.0 for uncoated reinforcement
λ = lightweight concrete factor
= 1.3 when light-weight aggregate concrete is used
= 1.0 when normal weight aggregate is used

The product $\psi_t \psi_e$ need not be taken greater than 1.7.

Bars No. 11 and smaller are commonly spliced by simply lapping them for a distance. These splices should be avoided in regions of high computed stress, and should be spread out so that not many bars are spliced near the same section. If the computed tensile stress is less than $0.5f_y$ at the design ultimate load and not more than half the bars are spliced at one section, the lap length is $1.0l_d$. For other cases the minimum lap length is $1.3l_d$. For lower stress levels, a lap of l_d is sufficient.

Development lengths in compression, important in columns and compression reinforcement, are somewhat shorter.

Requirements for reinforcement of beams subjected to torsional moments are contained in the ACI Code. The requirements are too complex for discussion here, but the basic reinforcement scheme consists of closed stirrups with longitudinal bars in each corner of the stirrup. The most efficient method of dealing with torsion in many instances will be to rearrange the structure so as to reduce or eliminate the torsional moments.

REINFORCED CONCRETE COLUMNS

Reinforced concrete compression members are proportioned taking into account the applied thrust, the bending moments, and the relationship between length and thickness for the member. The strength of a cross section or a short column can conveniently be shown with the aid of a *moment-thrust interaction diagram* such as is shown in Fig. 12.3.6*a*, which is drawn without considering the ϕ factor. The variation in ϕ with thrust is shown in Fig. 12.3.6*b* for the same column. The ϕ factor is a function of the tensile strain in the steel layer farthest from the neutral axis at nominal strength ε_t. The value of $\phi = 0.65$ (for a tied column, 0.7 for a spiral column) when $\varepsilon_t \leq 0.002$ tension, and $\phi = 0.9$ when $\varepsilon_t \geq 0.005$. Linear interpolation is used for intermediate strains.

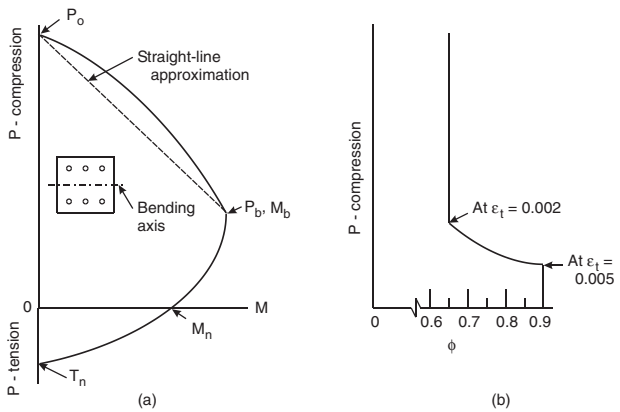

Fig. 12.3.6 Column capacity diagrams. (*a*) Typical moment-thrust interaction diagram; (*b*) variation of ϕ with *P*.

The load P_0 is the strength of a short column under a concentric load, and is expressed as

$$P_0 = 0.85A_c f'_c + A_s f_y \qquad (12.3.14)$$

The contribution of the concrete is slightly less than the cylinder strength because of differences in workmanship, curing, and position of casting. M_n is simply the strength in flexure, as was discussed for beams. The $M_b - P_b$ point is the "balance point," at which simultaneous crushing of the concrete and yielding of the reinforcement occur. Failure is initiated by crushing of the concrete at loads higher than P_b, and by yielding of the reinforcement in tension at lower loads. Only the reinforcement contributes to the tensile capacity of $T_n = A_s f_y$

The balance-point moment and thrust are found using the strain and stress distributions shown in Fig. 12.3.7, for a symmetrical section with steel in two faces. From equilibrium,

$$P_b = C_s + C_c - T \qquad (12.3.15)$$

Summing moments about the centroidal axis gives

$$M_b = A_s f_y(d - d')/2 + 0.85\beta_1 f'_c k_u db(h/2 - \beta_1 k_u d/2) \qquad (12.3.16)$$

This assumes that the compression steel has yielded, and this will be true except for very small members or members with exceptionally large cover over the steel. The compression steel strain and stress can be evaluated as noted below Eq. (12.3.6).

The portion of the interaction diagram below P_b may be constructed in a point-by-point manner. For any value of $\varepsilon_s > \varepsilon_y$, or for any value of $k_u d < k_u d_{bal}$, the strain and stress distributions are defined. Once the forces are defined, the moments and thrusts are computed using the same formulas as for the balance point. A modification will have to be made when the compression-steel stress is less than f_y. Likewise, points above the balance point can be found by assuming several values of $\varepsilon_s < \varepsilon_y$ or $k_u d > k_u d_{bal}$; finding the strains, stresses, and forces; and then summing forces and moments of forces. The straight-line approximation is always conservative.

Care must be used in the selection of the axis about which moments are to be summed, especially if the section is not symmetrical or symmetrically reinforced, since the force system is not a pure couple. The most important thing is to remain consistent, and to be certain that the internal and external moments are summed about the same axis.

In practice, either the moment-thrust curve can be reduced by the appropriate ϕ factor, or the computed ultimate *M* and *P* increased by dividing by ϕ. If the required $M - P$ point lies on or slightly inside the interaction curve, the design is acceptable. The maximum permitted factored thrust is $0.80\phi P_0$, which limits the applied thrust capacity in cases where the computed moments are relatively small. This limitation is intended to provide resistance to accidental eccentricities. Column reinforcement consists of longitudinal bars and lateral ties or spiral bars. The ratio of longitudinal steel ρ_g should be between 0.01 and 0.08. Ties are usually No. 3 or No. 4 bars which are bent to enclose the longitudinal bars, and are spaced at not more than 16 longitudinal bar diam, 48 tie diam, or the least thickness of the column. Ties are arranged to bind each corner bar and alternate intermediate bars.

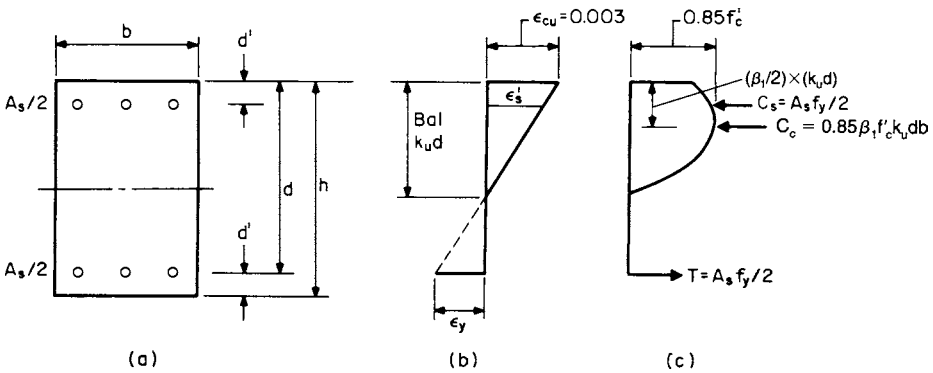

Fig. 12.3.7 Stress and strain distribution in a column at balanced moment and thrust. (*a*) Section; (*b*) strains; (*c*) stresses.

Several typical arrangements are shown in Fig. 12.3.8. Ties hold the longitudinal bars in place during construction, and may provide some shear resistance and improve the behavior of the column at loads near failure.

Spiral bars serve to confine the concrete core of the section as well as holding the longitudinal bars. The minimum amount of spiral steel, if advantage is to be taken of the higher ϕ factor for spiral columns, is

$$\rho_s = 0.45(A_g/A_{\text{core}} - 1)f'_c/f_y \qquad (12.3.17)$$

where f_y is the yield stress of the spiral, but not more than 60,000 lb/in^2. The clear spacing of the turns of the spiral must be between 1 and 3 in.

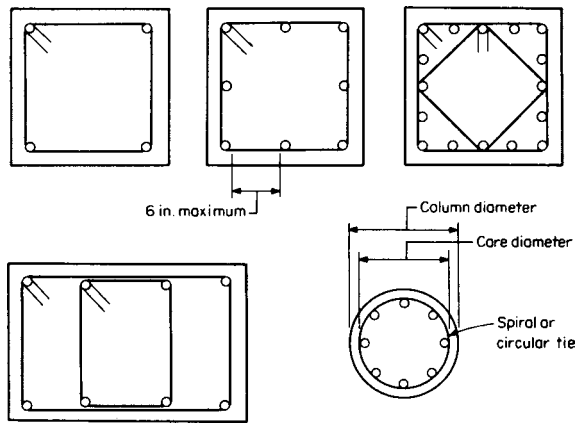

Fig. 12.3.8 Typical arrangement of steel in columns.

The strengths of compression members may be reduced below the cross-sectional strengths by length effects. Most columns in unbraced frames (frames in which the columns resist all horizontal forces) will have some strength reduction because of length effects, and most columns in braced frames will not, but this depends on the precise details of the length, width, restraint by other frame members, reinforcement, and amount of creep expected. A comprehensive method of taking column length into account is contained in the ACI Code.

Columns are also made by encasing structural steel sections in concrete, in which case the covering concrete must contain at least some steel in order to control cracks and maintain the integrity of the concrete in case of fire. Heavy steel pipes filled with concrete may also be used as columns. These are also used as piling, in which case the pipe is filled with concrete, usually after being driven to the final location.

REINFORCED CONCRETE FLOOR SYSTEMS

Several types of reinforced concrete floors are used, with the choice depending on a number of factors such as span, live load, deflection limits, cost, story-height limitations, local custom, the nature of the rest of the structural frame or system, and the probability of future alterations.

The floor systems may be divided, somewhat arbitrarily, into one-way and two-way systems. One-way systems include solid and hollow slabs and joists spanning between parallel supporting beams or walls. Floors in which panels are subdivided into a grid by subbeams spanning between main girders have usually been designed as one-way slabs when the grid length is several times the width.

Two-way systems include slabs supported on all four sides on beams or walls, traditionally called *two-way slabs.* Slabs supported only on columns located at the corners of the panels also carry loads by developing stresses in the two major directions, and are usually termed *flat plates* if the slab is supported directly on the columns and *flat slabs* if there are capitals on the columns to increase the effective support size. A waffle slab is usually designed as a flat plate or flat slab, with pockets of concrete omitted from the lower surface, and the slab appears as a series of crossing joists.

One-way slabs and joists are designed as beams. A 12-in or other convenient width of slab is selected, analyzed as an isolated beam, and a depth and steel are picked. The main steel is perpendicular to the supports. Additional steel, parallel to the supports, is placed to control cracking and help distribute minor concentrated loads. This steel is usually one-fourth to one-third of the main steel, but not less than a gross steel ratio of 0.0018 for grade 60 and 0.002 for lower-grade steels. These minimums govern in both directions, and in two-way systems as well.

One-way joists, such as that shown in Fig. 12.3.9, are usually cast with reusable sheet metal or fiberglass forms owned or rented by the contractor. Standard form sizes range from about 20 to 36 in wide and 8 to 20 in deep. The web thicknesses are made to suit the shear and fireproofing requirements, and special tapered end sections may be available to increase the web widths in the regions of high shear near the supports. Joists are exempted from the requirement that web steel be supplied regardless of the concrete shear stress. The allowable shear stress for the concrete is 1.1 times that for beams. The top slabs usually range from 2.5 to 4.5 in thick, and are reinforced to span from rib to rib. The joists are essentially designed as isolated T beams, and may be supported on girders or walls. Joist systems are suitable for reasonably long spans and heavy loads, and have low dead weights for the effective depths attainable.

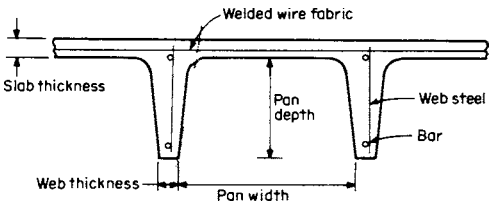

Fig. 12.3.9 Cross section of concrete floor joist.

Slabs spanning in two directions are all designed taking into account the shape of the panel and the relative stiffnesses of the supporting beams, if any. The choice of types is a matter of loadings and economics. For residential and light office loadings, the flat plate is frequently the choice, as the very simple formwork may lead to substantial economy and the story height is minimized. For heavier loads or longer spans, punching shear around the columns becomes a limiting factor, and the flat slab, with its column capitals, may be the most suitable.

In case of extremely heavy floor loads or very stringent limits on deflections, slabs with beams on all four sides of each panel will be most satisfactory. The formwork is more complex than for the other slabs, but there will be some compensating savings in the amounts of steel because of the greater depths of the beams. In addition, the two-way slab may be much more efficient if the building is to resist major lateral loads by frame action alone, because of the difficulties in transferring large moments between columns and flat plates or slabs. The design procedure is the same for slabs with and without beams. The basic steps, for each direction of span in each panel, are:

1. Compute static moment M_0.
2. Distribute M_0 to positive and negative moment sections.
3. Distribute section moments to column and middle strips and beams.

Most building slabs are designed for uniformly distributed loads, and the *static moment,* defined as the absolute sum of the midspan positive plus average negative moments, is

$$M_0 = ql_2(l_n)^2/8 \qquad (12.3.18)$$

The dimensions are illustrated in Fig. 12.3.10.

Relatively simple rules for the distribution of the static moment to various parts of the panel exist as long as the structure meets several simple limits:

1. Minimum of three spans in each direction.
2. Panel length no more than twice panel width.
3. Successive spans differ by not more than one-third the longer span.
4. Columns on a rectangular grid, or offset no more than 10 percent of the span.
5. Live load not more than two times the dead load.
6. If beams are used, they are used on all four sides of each panel and are approximately the same size, except that spandrel beams only are acceptable.

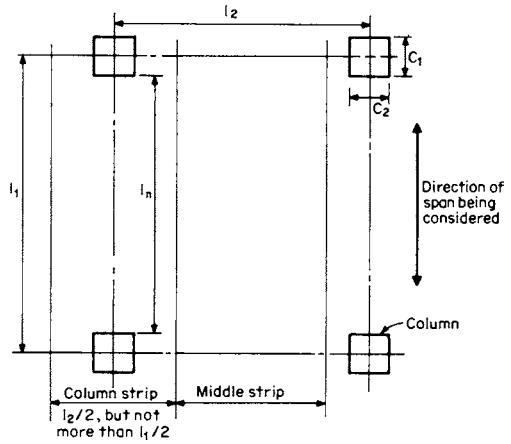

Fig. 12.3.10 Arrangement of typical slab panel.

The following is for slabs meeting these restrictions. Information on other cases is contained in the ACI Code.

The positive-negative moment distribution for interior spans is

$$+M = 0.35M_0 \qquad (12.3.19)$$

$$-M = 0.65M_0 \qquad (12.3.20)$$

For end spans, the stiffness of the exterior support must be taken into account. Table 12.3.2 gives the fractions of M_0 to be assigned to the three critical sections for five common cases.

Once the section moments have been determined, they are distributed to the column and middle strips and beams, taking into account the panel shape and the beam stiffness. The beam relative stiffness coefficient α_1 is calculated using an effective beam cross section as shown in Fig. 12.3.11, and the full width of the slab panel l_2. The locations of the column and middle strips are shown in Fig. 12.3.10.

The interior negative and positive moments are distributed to the column strips in the proportions shown in Fig. 12.3.12, with the remainder of the moment going to the middle strip. Linear interpolations are made for intermediate beam stiffnesses, but in most instances where there are beams, they will be found to have

$$\alpha_1 l_2/l_1 \geq 1.0$$

At the exterior supports, the distribution of the negative moments is a complex function of the flexural and torsional stiffnesses of the beams and of the panel shape, but satisfactory designs can usually be achieved by assigning all the negative moment to the column strip and detailing the edge beam or edge strip of the slab for torsion, by using closed stirrups at relatively small spacings, and by placing bars parallel to the edge of the structure in each corner of the stirrups. At fully restrained edges, use the distribution for an interior negative moment section.

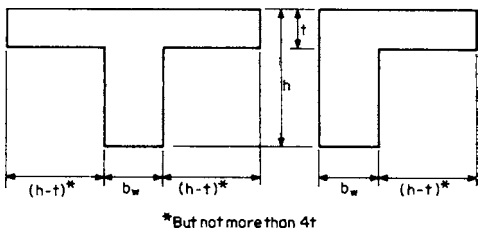

Fig. 12.3.11 Beam sections for calculation of I_b and α_1.

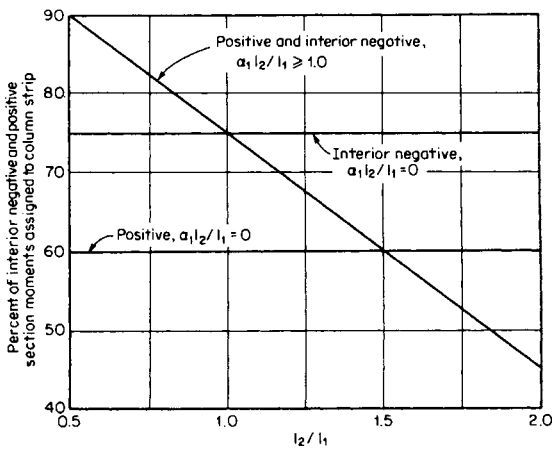

Fig. 12.3.12 Percentage of interior negative and positive moments assigned to a column strip.

Beam moments are found by dividing the column strip moment between beam and slab. If $\alpha_2 l_2/l_1 \geq 1.0$, the beam moment is 85 percent of the column strip moment. This moment is reduced linearly to zero as $\alpha_1 l_2/l_1$ approaches zero.

This design method assumes that all panels are loaded with the same uniformly distributed load at all times. This is obviously a gross simplification, and the requirement that the live load be no greater than twice the dead load limits the potential overstress caused by partial loadings.

Table 12.3.2 Moments in End Spans

	Exterior edge unrestrained (1)	Slab with beams between all supports (2)	Slab without beams between interior supports		Exterior edge fully restrained (5)
			Without edge beam (3)	With edge beam (4)	
Interior negative factored moment	0.75	0.70	0.70	0.70	0.65
Positive factored moment	0.63	0.57	0.52	0.50	0.35
Exterior negative factored moment	0	0.16	0.26	0.30	0.65

In addition, there is a requirement for column design moments, and unless a more complete analysis is made, the following moment, divided between the columns above and below the slab in proportion to their stiffnesses, must be provided for:

$$M = 0.07[(q_d + 0.5q_l)l_2l_n^2 - q'_d l'_2(l'_n)^2] \qquad (12.3.21)$$

The loads q_d and q_l are the distributed dead and live loads including the overload factors. The terms q'_d, l'_2, and l'_n are for the shorter of the two spans meeting at the column considered.

The shear strength of slab structures must always be checked, and shear stresses often govern the thickness of beamless slabs, especially flat plates.

If there are beams with $\alpha_1 l_2/l_1 \geq 1.0$, all shear is assigned to the beams, and stirrups are provided to make the shear capacity adequate, as was described in earlier coverage on beams. The beam shear is linearly reduced to zero as $\alpha_1 l_2/l_1$ is reduced to zero.

For the case of no beams, punching shear around the columns becomes a controlling factor. In this case the average shear stress, calculated as

$$v_v = V_u/b_0 d \qquad (12.3.22)$$

must not exceed the smaller of $\phi 4\sqrt{f'_c}$, $\phi(2 + 4/\beta_c)\sqrt{f'_c}$, or $\phi(\alpha_s d/b_0 + 2)\sqrt{f'_c}$, where β_c = ratio of long side of critical shear perimeter to short side and α_s = 40 for interior columns, 30 for edge columns, and 20 for corner columns.

The critical shear perimeter b_0 is defined by a section located $d/2$ away from and extending all around the column, as shown in Fig. 12.3.13. It is very important that holes in the slab in the vicinity of the column be taken into account in reducing the value of b_0, and that no unauthorized holes, such as for piping, be made either during or after construction.

It is possible to increase the shear resistance by the use of properly designed shear reinforcement, but this is not often done and is not recommended as a standard practice.

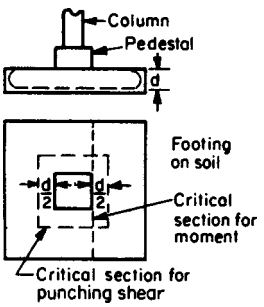

Fig. 12.3.13 Two-way reinforced concrete footing.

Transfer of moments between columns and slabs sets up shear and torsional stresses which must also be considered in the analysis of the shear strength.

FOOTINGS

Footings (Fig. 12.3.13) may be classified as wall footings, isolated column footings, and combined column footings. The bending moments, shears, and bond stresses in such footings should be determined by the principles of statics on the basis of assumed or known soil-pressure distribution over the area of the footing. The bending moment on any projecting portion of a footing may be computed as the moment of the forces acting on the area to one side of a vertical plane through the critical section.

The critical section for bending in a concrete footing supporting a concrete column, pedestal, or wall should be taken at the face of the column, pedestal, or wall. For footings under metallic column bases or under masonry walls where bond with the footings is reduced to the friction value, the critical section is assumed midway between the middle and edge of the base or wall.

Shear stresses must be considered on two sections. The footing may act as a wide beam, for which the critical section is a vertical plane located d away from the critical section for moment, and the stresses must satisfy those for a beam. Punching shear will often govern, and the critical section lies at a distance $d/2$ from the face of the column or other critical section for moment, as shown in Fig. 12.3.13, and as was the case for flat plates and slabs. Footings supported on a small number of high-capacity piles present special shear problems since the conventional critical sections for shear may not be meaningful.

The critical section for bond should be taken at the same plane as for bending. Other vertical planes where abrupt changes of section occur should also be investigated for bond and shear stresses.

In sloped or stepped footings, sections other than the critical ones may require consideration. A square footing, reinforced in two directions, should have the reinforcement uniformly distributed across the entire width. Rectangular footings, reinforced in two directions, should have the reinforcement in the long direction uniformly distributed; in the short direction a portion, Eq. (12.3.23), should be uniformly distributed across a strip equal in width to the short side and centered on the structural element supported and the remainder distributed uniformly in the outer portions. The amount included in the center strip may be computed as follows:

Reinforcement in center strip

$$= \frac{2(\text{total reinforcement in short direction})}{\beta + 1} \qquad (12.3.23)$$

where β is the ratio of the long side to the short side.

Combined Footings Footings supporting two or more columns may be designed with sufficient accuracy by assuming uniform soil pressure and applying the laws of statics. The footing shape must be such that the center of gravity coincides with the center of gravity of the superimposed loads; otherwise unequal settlement may occur. The longitudinal and diagonal tension reinforcement should be designed by the ordinary rules of beam design. Lateral reinforcement should be designed as for isolated footings and should preferably be concentrated in bands under and near the columns proportionate in area to the column loads. The lateral reinforcement at each column should be uniformly distributed within a width centered on the column and should not be greater than the width of the column plus twice the effective depth of the footing.

Spread or raft foundation, consisting of a slab extending over the entire area under the columns or of a slab supported by beams, may be considered as loaded by a uniform upward reaction of the ground. The principle of design is exactly the same as that applied to a floor system, except that the load acts upward instead of downward.

Concrete piles of various types are widely used for foundations as they have larger carrying capacity and greater durability under many conditions of exposure than wooden piles. Precast piles are designed as columns with allowance for driving and handling stresses. Cast-in-place piles are constructed either by driving a steel shell and filling it with concrete or by filling the hole formed by a shell as it is withdrawn. Another method forms a bulb at the bottom by means of a ram which forces the concrete into the ground. The design load or capacity of cast-in-place concrete piles is largely empirical, being based on load-test data. The concrete for precast piles is usually over 5,000 lb/in^2 strength and for cast-in-place piles, over 3,000 lb/in^2 strength.

Dowels and Bearing Plates The stress in the longitudinal reinforcement of concrete columns should be transferred to the footing by means of dowels, equal in number and area to the column rods and of sufficient length to transfer the stress as in a lap splice in the column.

Bearing stresses in concrete, under design ultimate loads, should not exceed the following values:

Entire surface loaded: $f_b = 0.85\phi f'_c$ (12.3.24)

Part of surface loaded: $f_b = 0.85\phi f'_c\sqrt{A_2/A_1}$ (12.3.25)

where A_1 = loaded area; and A_2 = surface area of same shape and concentric with A_1. $\sqrt{A_2/A_1}$ should not exceed 2.0.

WALLS AND PARTITIONS

Reinforced concrete is well suited to the construction of walls, especially where they have to withstand heavy pressures, such as the retaining walls of a cellar or basement, walls for coal pockets, silos, reservoirs, or grain elevators. Such walls must be designed for flexural shear and bond stresses as well as stability against overturning, sliding, and soil pressure. Drainage should be provided for by weep holes or drains. Partitions may be built of solid concrete 4 to 6 in thick, reinforced to control temperature and shrinkage cracks. Reinforced concrete walls need to be anchored by reinforcement to adjacent structural members. All walls must be reinforced for temperature with steel placed horizontally and vertically.

The horizontal reinforcement shall not be less than 0.25 percent and the vertical reinforcement not less than 0.15 percent of the area of the wall when bars are used and three-fourths of these amounts when welded fabric is used. Adequate reinforcement must be provided around all openings for windows and doors.

Retaining walls of reinforced concrete are used to resist the pressures of earth, water, and other retained materials and are usually of T or L shape. The base must be so proportioned that there is sufficient resistance to sliding and overturning and that the safe bearing strength of the soil is not exceeded. The dimensions of the concrete section and the position and amount of steel reinforcement are determined by the moments and shears at critical vertical and horizontal sections at the junction of the wall and the base. Particular attention should be given to drainage to prevent excessive water pressure behind walls retaining earth or other materials. Walls retaining water, such as tanks, should have steel tensile stresses limited to 12,000 lb/in^2 unless special consideration is given to controlling cracks and should have ample reinforcement to provide for effects caused by shrinkage of the concrete and temperature change.

Bearing Walls The allowable compressive force for a reinforced concrete wall that is restrained against lateral motion at both top and bottom and is restrained against rotation at one or both ends is given by Eq. (12.3.26). If neither end is restrained against rotation, the 40 is replaced with 32.

$$P_u = 0.55\phi f'_c A_g[1 - (l_c/40h)^2] \qquad (12.3.26)$$

For the case of concentrated loads, the effective width for computational purposes can be considered as the width of the bearing plus four times the wall thickness but not greater than the distance between loads. The wall thickness should be at least 1/25 of the unsupported height or width, whichever is smaller. For the upper 15 ft, bearing walls must be at least 6 in thick and increase at least 1 in in thickness for each successive 25 ft downward, except that walls of a two-story dwelling need to be only 6 in thick over the entire height, provided that the strength is adequate.

PRESTRESSED CONCRETE

Prestressed concrete members have initial internal stresses, set up by highly stressed steel tendons embedded in the concrete, which are generally opposite those caused by applied loads. Prestressed members are constructed in one of two ways: (1) *Pretensioned* members are factory precast products, made by tensioning steel tendons between abutments and then casting concrete directly around the steel. After the concrete has reached sufficient strength, the steel is cut and the force transferred to the concrete by bond. (2) *Posttensioned* members, either factory or site cast, contain steel in ducts cast in the concrete. After the concrete has cured, the steel is tensioned and mechanically anchored against the concrete. The ducts are preferably pumped full of grout after tensioning to provide bond and corrosion protection, or the tendons may be coated with corrosion inhibitors.

Very high strength steel is used for prestressing in order to overcome the losses of steel stress due to creep and shrinkage of concrete, and as a result of the strength, relatively small amounts of steel are required. The concrete for pretensioned members will usually be at least 5,000 lb/in^2 compressive strength, and at least 4,000 lb/in^2 for posttensioned members.

Because of the initial stress conditions, prestressed concrete members are generally crack-free at working loads and consequently are quite suitable for water-containing structures. Circular tanks and pipes are posttensioned by wrapping them with highly stressed wires, using specialized equipment.

Losses of prestress occur with time owing to creep and shrinkage of concrete and relaxation of steel stress. Pretensioned members also have an initial elastic shortening loss accompanying transfer of force to the concrete, and posttensioned members have losses due to friction between ducts and tendons and anchor set. These losses must be taken into account in the design of members.

Prestressed concrete members are checked for both strength and stresses at working loads. Because of the built-in stresses, the condition of dead load only may also govern. The flexural strength is computed using the same equations as for reinforced concrete which were developed earlier. The steel does not have a well-defined yield stress, and the steel stress at failure can be predicted from the following expressions:

Bonded tendons, low relaxation steel and no compression steel:

$$f_{ps} = f_{pu}\left(1 - \frac{0.28}{\beta_1}\rho_p\frac{f_{pu}}{f'_c}\right) \qquad (12.3.27)$$

Unbonded, $l/h \le 35$:

$$f_{ps} = f_{se} + 10{,}000 + f'_c/100\rho_p \qquad (12.3.28)$$

but not more than f_{py} or $f_{se} + 60{,}000$.

The stresses are used directly in Eq. (12.3.4), (12.3.6), or (12.3.7), as appropriate, substituting f_{ps} for f_y and A_{ps} for A_s.

Allowable Stresses at Working Load

Steel:	
Maximum jacking stress, but not to exceed recommendation by steel or anchorage manufacturer	$0.8f_{pu}$
Immediately after transfer or posttensioning	$0.7f_{pu}$
Concrete:	
Temporary stresses immediately after prestressing	
Compression	$0.6f'_{ci}$
Tension in areas without reinforcement	$3\sqrt{f'_{ci}}$
Design load stresses (after losses)	
Compression	$0.45f'_c$
Tension in precompressed tensile zones	$7.5\sqrt{f'_c}$

The allowable tension is limited to $6\sqrt{f'_c}$ in two-way slabs. Larger stresses, to $12\sqrt{f'_c}$ or more, are permitted, but with increasing checks on deflections, corrosion protection, and fatigue as the stresses increase. Details are given in the ACI Code.

The final steel stress, at working loads, will usually be 30,000 to 45,000 lb/in^2 less than the initial stress for pretensioned members. Posttensioned members will have slightly lower losses. Losses, from initial tensioning values, for pretensioned members may be predicted satisfactorily using the following expressions from the AASHTO, Bridge Specifications, Sec. 9.16.2;

$$\Delta f_s = SH + ES + CR_c + CR_s = \text{prestress loss} \quad \text{lb/in}^2 \qquad (12.3.29)$$

where SH = shrinkage loss = $17{,}000 - 150RH$; ES = elastic shortening loss = $(E_s/E_c)f_{cir}$; CR_c = creep loss = $12f_{cir} - 7f_{cds}$; CR_s = relaxation loss = $5{,}000 - 0.1ES - 0.05(SH + CR_c)$, for low relaxation strands; f_{cir} = concrete stress at level of center of gravity of steel (cgs) at section considered, due to initial prestressing force and dead load; f_{cds} = change in concrete stress at cgs due to superimposed composite or noncomposite dead load; and RH = relative humidity, percent. The loss calculations are carried out for each critical moment section. The average annual relative humidity of the service environment should be used in the SH calculation.

The shear reinforcement requirements for simple cases are covered in an earlier section. In addition to the shear steel, a few stirrups or ties should be placed transverse to the member axis as close to the ends as possible, to control potential splitting cracking. The area of steel, from the AASHTO Bridge Specification, should be $A_t = 0.04 f_{si} A_{ps}/20{,}000$. In posttensioned beams, end blocks will often have to be used to provide space for anchorage bearing plates.

The minimum clear spacing between strands in pretensioned members is three times the strand diameter near the ends of the beam, but many plants are set up to handle only 2-in spacings. Strands may be closer together in central positions of members, which will help in maximizing member effective depths and steel eccentricity.

Few precast, pretensioned members are solid rectangular sections, and double T beams and hollow floor slab units are used extensively in buildings. Hollow box beams and I-section beams are used extensively in bridges and in buildings with heavy design loads. Square piling with the prestressing strands arranged in a circular pattern is widely used. Because of the large number of possible sections, it is necessary to check availability of any particular section with local producers before designing any precast structure.

PRECAST CONCRETE

Precast slabs, beams, walls, and partitions as well as piles, retaining wall units, light standards, railroad crossings, and bridge slabs are being increasingly used because of the saving in time and labor cost. Such units vary in size from small slabs for use in floors of residences to large frames for industrial buildings. The small units, such as roof slabs, are cast in steel forms at central plants. Some of the larger units, such as bridge or highway slabs and wall units, are cast in wood forms at or near the place of use. A method by which wall or partition slabs are cast so that they are simply tilted into position has found wide use in housing and industrial construction. Another special adaptation is the method of casting complete floors on top of each other, then lifting into position vertically at the columns.

Particular attention must be given in the design of precast units to reduction in weight and to details to minimize the cost of erection and installation. Reduction in weight is obtained by the use of lightweight aggregates, high-strength concrete, and hollow units. Precast reinforced concrete units are seldom designed for concrete strengths of less than 4,000 lb/in^2. They are often combined with cast-in-place concrete so as to obtain the advantages of continuity. The combination of precast beams with cast-in-place slabs gives the advantage of T-beam action. Wall units are tied together by interlocking joints or by bolts. Care must be taken in shipping and handling to avoid damage to the precast units, and the design must take care of the stresses that come from such causes. All lifting devices built into the units should be designed for 100 percent impact. All units must be identified as to proper location and orientation in the structure.

Because precast units are made under conditions which allow good control of dimensions, certain restrictions can be relaxed that must be observed for cast-in-place concrete. Cover over the reinforcement for members not exposed to freezing need not be more than the nominal diameter of the steel but not less than ⅝ in. The maximum size of the coarse aggregate can be as large as one-third of the smaller dimension of the member. Precast wall panels are not limited to the minimum thickness requirements for cast-in-place walls.

To reduce the number of connections, precast units should generally be cast as large as can be properly handled. However, some joints will be needed to transfer moments, torsion, shear, and axial loads from one member to another. The integrity of the structure depends on the adequacy of the design of the various joints and connections. They may be made by use of bolts and pins or clips and keys, by welding the reinforcement or steel insert, or by a number of other methods limited only by the ingenuity of the designer. The connections should not be the weak links in the structure. Thought as to their location will avoid many problems. The PCI Handbook shows many proven connection details.

JOINTS

Contraction and expansion joints may be needed at intervals in a structure to help care for movement due to temperature changes and shrinkage. Joints at 20- to 30-ft intervals provide good crack control. A weakened plane, formed in the tension side of the member by a slot ¼ in wide and ½ in deep, will induce the formation of contraction cracks at selected points. Structures over 200 ft in length should have special consideration given to contraction provisions.

Construction joints are necessary in most structures because all sections cannot be cast continuously. They should be made at points of minimum shearing stress and reinforced across the joint with a steel area of not less than 0.5 percent of the area of the section cut. Provision must be made for the transfer of shear and other forces through the construction joint. Joints in columns should be made at the underside of the floor members, haunches, T beams, and column capitals.

The hardened concrete at a joint should be properly prepared for bonding with the new concrete by being cleaned, roughened, and wetted. On this surface, a coat of neat cement grout or other bonding agent should be applied just before depositing the new concrete.

FORMS

Forms are usually built of wood or metal but in special cases may be made of plastic or fiberglass reinforced plastic. Wooden forms may be the most economical unless the construction allows for the repeated use of the same forms. Plywood and compressed wood fiber sheets, specially treated to make them waterproof, are frequently used for form faces where good surfaces are required. Forms must be designed so that they can be easily erected, removed, and reerected. The usual order of removing forms is (1) column sides, (2) joists, (3) girder and beam sides, (4) slab bottoms, and (5) girder and beam bottoms. Column forms are held together by clamps made of wood or steel, the spacing of which is smallest at the bottom and increases with the decrease in pressure. Beam forms consist of the bottom and two sides held together by clamps or cleats and supported by posts. Slab forms consist of boards or other form material supported by joists spaced 2 or 3 ft apart or other means. The joists either rest on a horizontal joist bearer fastened to the clamps of the beam or girder form or are supported by stringers, or posts, or both.

Special consideration must be given to forms for prestressed concrete members. For pretensioned members the form must be constructed such that it will permit movement of the member during release of the prestressing force. For posttensioned members, the form should provide a minimum of resistance to shortening of the member. It is also necessary to consider the deflection of the members due to the stressing force.

Design in Formwork The formwork is an appreciable portion of the cost of most concrete structures. Any efforts, however, to reduce the cost of the forms must not go beyond the point of safe design to prevent failures which would in themselves raise the cost of construction.

All forms must conform to the dimensions and shape of the members and must be sufficiently tight to prevent leakage of the mortar. They must be properly braced and tied together to maintain their position and shape during the construction procedure.

The formwork must support all the vertical and lateral loads that may be applied until these loads can be carried by the concrete structure. Loads on the form include the weight of the forms, reinforcing steel, fresh concrete, and various construction live loads. The construction live load varies with conditions but is often assumed to be 75 lb/ft^2 of floor area. The formwork should also be designed to resist lateral loads produced by wind and movement of construction equipment. Most frequently the steel and concrete will not be placed in a symmetrical pattern and frequently large impact loads will occur. Because of the many varied conditions, it is frequently impossible to determine with any great precision the loads which the form must carry. The designer must therefore make safe assumptions by which the forms can be designed such that failure will not result.

Lateral pressures in forms for walls and columns are influenced by a number of factors: weight of concrete, height of placing, vibration,

temperature, size and shape of form, amount and distribution of reinforcing steel, and several other variables. Formulas have been suggested for computing safe lateral pressures to be used in form design. However, because of limited test data, they are not generally accepted by all engineers.

Form Liners Absorbent form liners are occasionally applied to the surface of forms to extract the water from the surface of the concrete, eliminate air and water voids, and produce a concrete of uniform appearance with surfaces which are superior in durability and resistance to abrasion.

The vacuum process, whereby water is absorbed from the concrete through a special form liner made of two layers of screen or wire mesh covered by a layer of cloth, has a similar effect and if properly used reduces the water content of the concrete to a depth of several inches.

Neoprene and other types of rubber have been successfully used as liners in precasting work in which a number of units are made from one form. Rubber is particularly suited for patterned work.

Plastic form liners make it easy to obtain a textured surface or a glossy smooth surface. Generally speaking, plastic liners are easily cleaned and if not too thin are suitable for a number of reuses.

Removal of Forms The time that forms should remain in place depends on the character of the members and weather conditions. The strength of concrete must be ascertained before removing the forms. Unless special precautions are taken, concrete should not be placed below 40°F. Fresh concrete should never be subjected to temperatures below freezing. As an approximate guide for the minimum time for form removal, the following rules, which assume moist curing at not less than 70°F for the first 24 h, may be observed.

Walls in Mass Work. In summer, 1 day; in cold weather, 3 days.

Thin Walls. In summer, 1 day; in cold weather, 5 days.

Columns. In summer, 1 day; in cold weather, 4 days, provided girders are shored to prevent appreciable weight reaching the columns.

Slabs up to 7-Ft Span. In summer, 4 days; in cold weather, 2 weeks.

Beams and Girder Sides. In summer, 1 day; in cold weather, 5 days.

Beams and Girders and Long-Span Slabs. In summer, 7 days; in cold weather, 2 weeks.

Conduits. 2 or 3 days, provided there is not a heavy fill upon them.

Arches. If a small size, 1 week; large arches with a heavy dead load, 3 weeks.

Forms for prestressed members may be removed when sufficient prestressing has been applied to enable them to carry their dead loads and the expected construction loads.

EVALUATION OF EXISTING CONCRETE STRUCTURES

This section is intended to give some guidance to the persons responsible for inspections of structures, whether these are done routinely, or before changing a loading or use, or during remodeling, or when something suspicious is found. Serious problems clearly need to be evaluated by a structural engineer experienced in such evaluations, testing, and renovation; such problems should not be evaluated by one who is primarily a structural designer.

The following are some signs of distress. Any cracks wider than about 0.02 in (0.5 mm) are potentially serious, particularly if there are more than a few. If the cracks are inclined like the shear crack shown in Fig. 12.3.1, they are an additional warning sign and should be investigated promptly. At interior supports and other locations where the beams are continuous with the columns, these cracks may also start at the top surface. Any cracking parallel to the member axis is potentially serious.

Rust stains and streaks from cracks indicate corrosion problems. Corrosion, especially from salt, disrupts the concrete surrounding the steel long before the bar areas are significantly reduced, because rust occupies much more volume than the steel it replaces. This rusting causes internal cracking, which can often be detected by tapping on the concrete surface with a hammer (1-lb size), which produces a distinctive "hollow" sound. "Stalactites" growing from the bottoms of members may be either salt or lime, but both indicate water-penetration problems and the need for waterproofing work.

Concrete exposed to freezing and thawing or to attack by some chemicals may crumble and disintegrate, leading to loss of section area and protective cover on the reinforcement. Large deflections and/or slopes in members may be indicative of impending distress or disaster, but sometimes members were not built very straight, and in such cases the warning sign is actually a *change* in the conditions.

Any reinforced concrete building designed before about 1956 has a potential weakness in the shear strength of the beams and girders because of a deficiency in the codes of that era, and major changes in loading and seemingly minor signs of distress should be investigated carefully. This problem may also exist in highway bridges designed before 1974. Prestressed members should not have this problem.

Repairs are made by injecting epoxy into cracks, by surface patching, by chipping away significant volumes of concrete and replacing it, and by other means. The repair materials range from normal concretes to highly modified concrete and polymer materials.

12.4 AIR CONDITIONING, HEATING, AND VENTILATING

By Norman Goldberg

References: ASHRAE Handbooks "Fundamentals," "Systems and Equipment," and "Applications." Stamper and Koral, "Handbook of Air Conditioning, Heating and Ventilating," Industrial Press. Carrier, "Handbook of Air Conditioning Design," McGraw-Hill.

Air conditioning is the process of treating air to meet the requirements of a conditioned space by controlling its temperature, humidity, cleanliness, and distribution. This section presents standards, basic data, and physical laws for use in the design of air conditioning and related heating and ventilating systems.

COMFORT INDEXES

The human body generates heat and disipates that heat to the surrounding air by sensible flow and the evaporationg of moisture.

Effective Temperature Effective temperature (ET) combines the effect of ambient temperature and humidity into a single index.

ASHRAE Comfort Chart The American Society of Heating, Refrigeration, and Air Conditioning Engineers (ASHRAE) comfort envelope shown in Fig. 12.4.1 is based on clothing and activity. Comfort varies with skin temperature and skin wettedness.

Temperature-Humidity Index

The term **temperature-humidity index (THI)** is used to describe the combined effects of temperature and humidity on comfort experienced by people. Since individual reactions can vary considerably from person to person, this quantity should be considered as a guide rather than as an absolute. However, relatively few people will feel discomfort when the THI is 70 or below. By the time it reaches 75, about half the people will be uncomfortable. An index of 80 in a work area may cause a decrease in

workers' efficiency. To compute THI, any one of the following formulas may be used:

$$\begin{aligned} \text{THI} &= 0.4(t_d + t_w) + 15 \\ &= 0.55t_d + 0.2t_{\text{dp}} + 17.5 \\ &= t_d - (0.55 - 0.55\,\text{RH})(t_d - 58) \end{aligned} \qquad (12.4.1)$$

where t_d = dry-bulb temperature, °F; t_w = wet-bulb temperature, °F; t_{dp} = dew-point temperature, °F; and RH = relative humidity, expressed as a decimal. To convert to degrees Celsius, $t_c = \frac{5}{9}(t_f - 32)$.

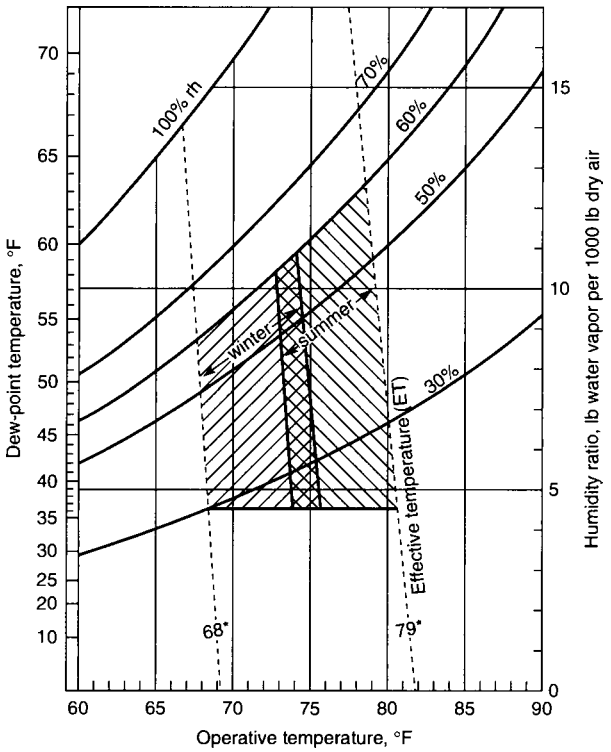

Fig. 12.4.1 Standard effective temperatures and ASHRAE comfort zones. *(ASHRAE "Handbook of Fundamentals," 1993.)*

Wind-Chill Index

The **wind-chill index (WCI)** attempts to describe how much heat the body will lose under certain conditions of wind and temperature. It is determined empirically by an equation which is used to describe the rate of heat loss from a litre cylinder of water at 33°C (91.4°F) as a function of ambient temperature and wind velocity. The formulas for the wind-chill index are

$$\text{WCI} = (10.45 - V + 10\sqrt{V})(33 - t_a) \qquad \text{kcal/(m}^2 \cdot \text{h)} \quad (12.4.2)$$

where V = metres per second, t_a = °C.

$$\text{WCI} = (10.45 - 0.447V + 6.6854\sqrt{V})(91.4 - t_a) \qquad (12.4.3)$$

where V = miles per hour, t_a = °F.

Instead of using the WCI to express the severity of a cold environment, meteorologists use an index derived from the WCI called the *equivalent wind-chill temperature.* This is the ambient temperature that would produce, in a calm wind (defined for this application as 4 mi/h), the same WCI as the actual combination of air temperature and wind velocity. Equivalent wind-chill temperature $t_{eq,wc}$ can be calculated by

$$t_{eq,wc} = -0.0818(\text{WCI}) + 91.4 \qquad (12.4.4)$$

where $t_{eq,we}$ is expressed as a temperature, °F. (See Table 12.4.1.)

INDOOR DESIGN CONDITIONS

Indoor design conditions are determined by the application, usually either the comfort of the people occupying the space or the control of conditions within that space to facilitate a process.

Comfort Conditions Typical indoor design conditions for summer and winter comfort are shown in Table 12.4.2.

Conditions for Process Design These vary widely, depending on the process. See the manufacturer's requirements and/or the ASHRAE Handbook "Applications."

OUTDOOR DESIGN CONDITIONS

Outdoor design conditions are based primarily on the geographical location but they are affected to some extent by the criticality of the application and by the economics of maintaining indoor conditions at specified design levels during unusual outdoor weather conditions.

Outdoor design conditions for comfort applications are usually not the most severe conditions that have been experienced in a locality, and recommended levels may be exceeded for an average of 5 percent of the hours during the cooling season.

Table 12.4.1 Equivalent Wind-Chill Temperature of Cold Environments*

Wind speed, mi/h	Actual thermometer reading, °F											
	50	40	30	20	10	0	−10	−20	−30	−40	−50	−60
	Equivalent chill temperature, °F											
0	50	40	30	20	10	0	−10	−20	−30	−40	−50	−60
5	48	37	27	16	6	−5	−15	−26	−36	−47	−57	−68
10	40	28	16	3	−9	−21	−34	−46	−58	−71	−83	−95
15	36	22	9	−5	−18	−32	−45	−59	−72	−86	−99	−113
20	32	18	4	−11	−25	−39	−53	−68	−82	−96	−110	−125
25	30	15	0	−15	−30	−44	−59	−74	−89	−104	−119	−134
30	28	13	−3	−18	−33	−48	−64	−79	−94	−110	−125	−140
35	27	11	−4	−20	−36	−51	−67	−83	−98	−114	−129	−145
40†	26	10	−6	−22	−38	−53	−69	−85	−101	−117	−133	−148

Little danger: In less than 5 h, with dry skin, Maximum danger from false sense of security. (WCI less than 1,400)

Increasing danger: Danger of freezing exposed flesh within one minute. (WCI between 1,400 and 2,000)

Great danger: Flesh may freeze within 30 s. (WCI greater than 2,000)

* Cooling power of environment expressed as an equivalent temperature under calm conditions.
† Winds greater than 43 mi/h have little added chilling effect.

Table 12.4.2 Recommended Inside Design Conditions

Type of application	Summer			Winter				
				With humidification			Without humidification	
	Dry bulb, °F (°C)	Rel. hum., %	Temp. swing, °F (°C)*	Dry bulb, °F (°C)	Rel. hum., %	Temp. swing, °F (°C)‡	Dry bulb, °F	Temp. swing, °F (°C)‡
General comfort (apartment, house, hotel, office, hospital, school, etc.)	74–76 (23–24)	50–45	2 (1.1)	68–72 (20–22)	35–30	3 to 4 (1.6–2.2)	70–74	4 (2.2)
Retail shops (short-term occupancy) (bank, barber or beauty shop, department store, supermarket, etc.)	74–76 (23–24)	50–45	2 (1.1)	68–72 (20–22)	35–30†	3 to 4 (1.6–2.2)	70–74	4 (2.2)
Low-sensible-heat-factor applications (high latent load) (auditorium, church, bar, restaurant, kitchen, etc.)	74–76 (23–24)	55–50	2 (1.1)	68–72 (20–22)	40–35	2 to 3 (1.1–1.7)	70–74	4 (2.2)
Factor comfort (assembly areas, machining rooms, etc.)	76–78 (24–26)	55–45	2 (1.1)	68–70 (18–21)	35–30	4 to 6 (2.2–3.3)	65–70	6 (3.3)

* Temperature swing is above the thermostat setting at peak summer load conditions.
† Winter humidification in retail clothing stores is recommended to maintain the quality texture of goods.
‡ Temperature swing is below the thermostat setting at peak winter load conditions (no lights, people, or sun).
°C = 5/9(°F − 32)
SOURCE: Adapted from Carrier Corp. "System Design Manual," with permission.

Frequently used winter outside dry-bulb design temperature are shown in Fig. 12.4.2. Summer outdoor design dry-bulb, wet-bulb, and dew-point temperatures for comfort applications are shown in Figs. 12.4.3 to 12.4.5, respectively.

Design of critical air-conditioning systems and selection of atmospheric evaporative cooling equipment are normally based on more severe outdoor conditions than for comfort applications. Figure 12.4.6 shows wet-bulb temperatures in the United States that are exceeded 1 percent of the time during the cooling season.

Ventilation and Infiltration

Ventilation Ventilation rates must be adequate to control levels of indoor contaminants and provide makeup air for exhaust systems. It must be recognized that the introduction of outdoor air into a conditioned

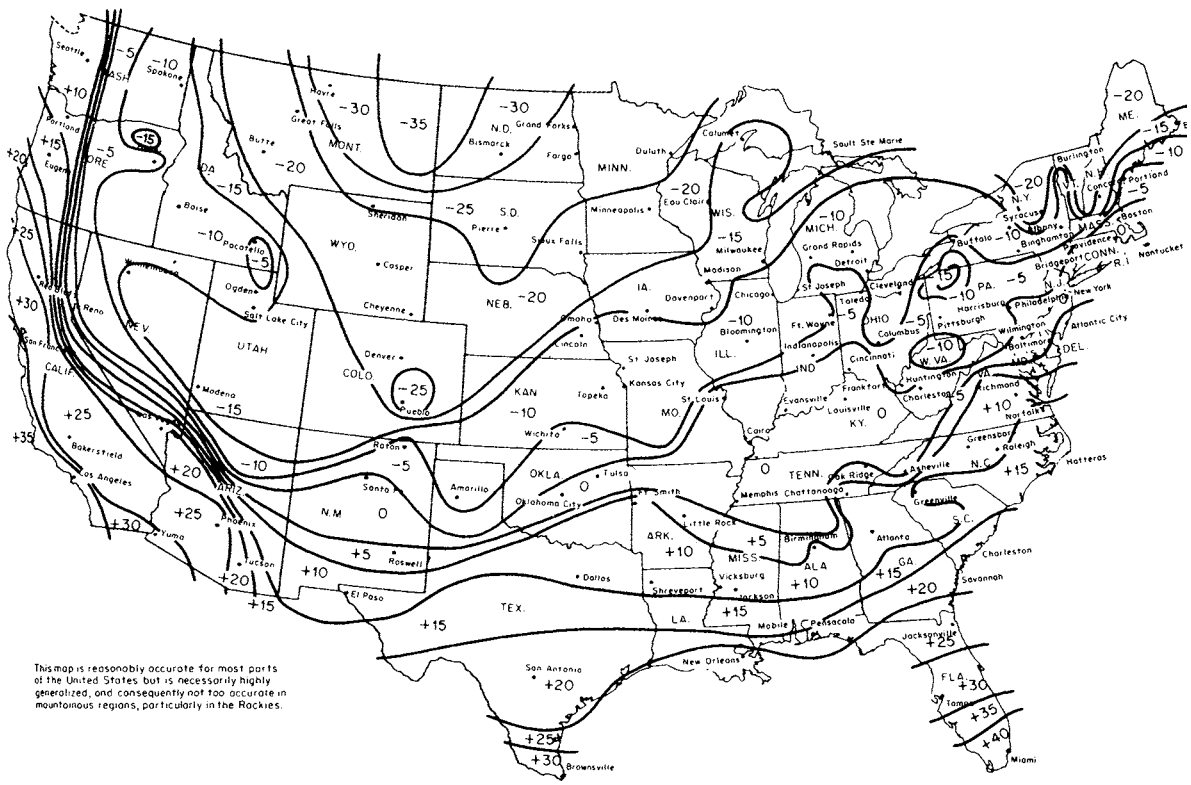

Fig. 12.4.2 Isotherms of winter outdoor temperatures, °F. *[E. Stamper and L. Koral (eds.), "Handbook of Air Conditioning, Heating and Ventilating," 3d ed., 1979, Industrial Press.]*

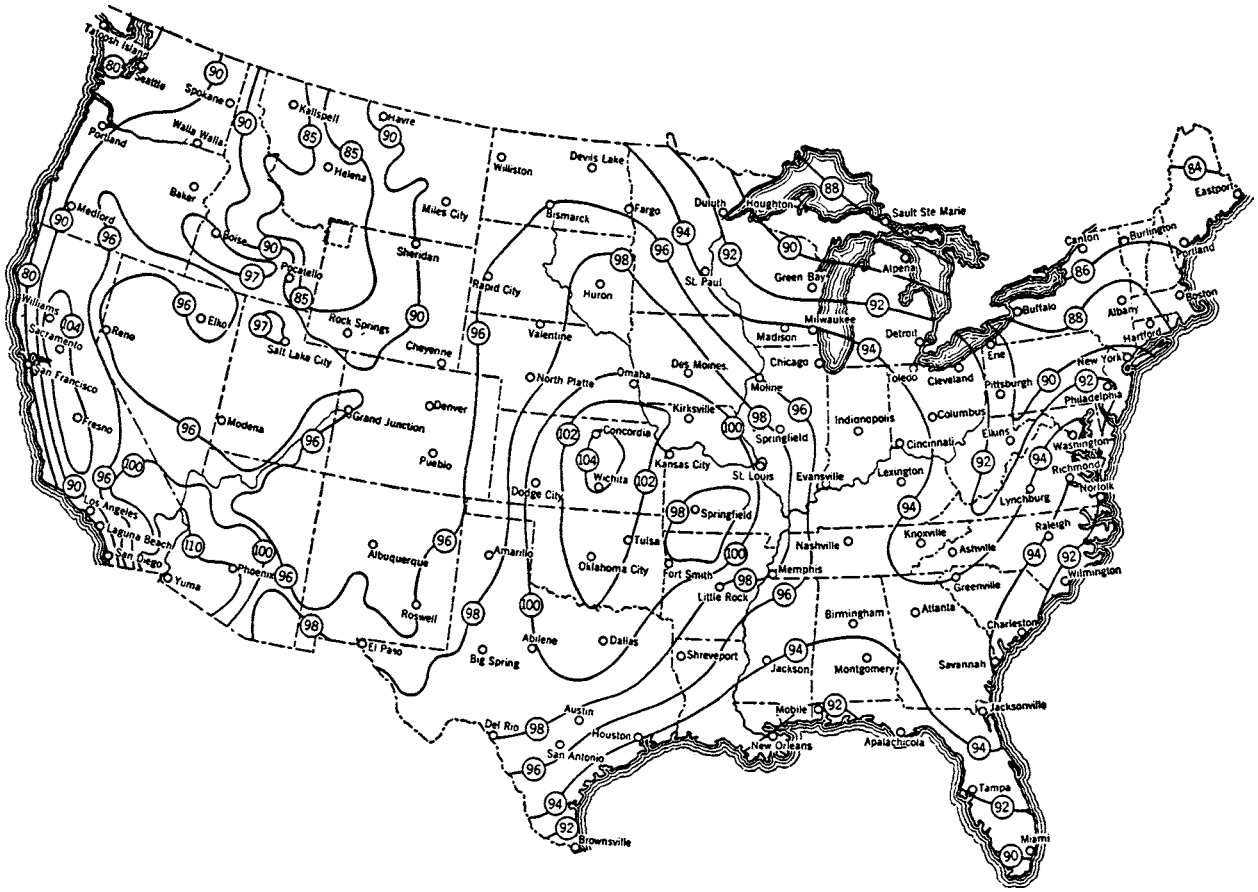

Fig. 12.4.3 Summer dry-bulb temperature data. *(Marley Co.)*

space represents a significant load on the system since it affects both temperature and moisture levels.

Mechanical ventilation is controllable and is the desirable way to introduce outdoor air into a space. Infiltration is uncontrolled airflow through cracks and other openings and, where feasible, it should be limited. ASHRAE Standard 62-1989, "Ventilation for Indoor Air Quality," presents recommendations for outdoor air rates to maintain acceptable indoor air quality for a wide variety of applications. Requirements of local building codes may differ and may require more, or accept less, ventilation air. An extract from the ASHRAE Standard 62-1989, "Table of Air Requirements," is shown in Table 12.4.3.

Infiltration Infiltration during the summer is due primarily to wind velocity creating a positive pressure on the windward side of a building. During the winter, when the density of indoor and outdoor air differ significantly, stack effect adds substantially to the wind effect. Completely offsetting infiltration by the introduction of sufficient outdoor air through the air-conditioning system is costly. Consequently, outdoor air infiltration should be curtailed by the use of vestibules and, if feasible, revolving doors at frequently used entrances, and tightly fitting windows and/or storm sash throughout. See Tables 12.4.4 and 12.4.5.

Flow of Water Vapor through Building Construction Components Water vapor flow through building construction adds to the latent load, and although it is usually a minor load factor in comfort applications, it can affect the integrity of insulation and other building components.

Vapor transmission is determined by the differences in vapor pressure and the permeability of the construction, but can be reduced by the use of vapor barriers on the high-vapor-pressure side of the construction. In applications where interior design dew points are either high or low, the vapor transmission should be calculated.

The permeance of some materials that will affect the transmission of water vapor is shown in Table 12.4.6.

Infiltration of Moisture

Infiltration of air, and particularly moisture, into a conditioned space is frequently a source of sizable heat gain or loss.

The moisture entering a building as water vapor may be expressed as

$$W_t = W_{\text{trans}} + W_{\text{inf}} + W_{\text{vent}} \tag{12.4.5}$$

where W_t = total weight of vapor, grains (grams). Assuming that W_{trans} is negligible as a load factor,

$$W_l = W_{\text{inf}} + W_{\text{vent}} \tag{12.4.6}$$

$$W_{\text{inf}} = \text{air-infiltrated vapor} = W(M_o - M_i) \quad \text{gr(g)}$$

$$= W(M_o - M_i)\,\Delta p \quad \text{gr(g)} \tag{12.4.7}$$

$$W_{\text{vent}} = \text{ventilation air vapor}$$

$$= W(M_o - M_i) \quad \text{gr(g)} \tag{12.4.8}$$

where Δp = vapor-pressure difference through flow path, inHg (N/m^2); W = weight of air, lb (kg); M_o = moisture content of outside air, g/lb (g/kg); M_i = moisture content of inside air, g/lb (g/kg).

For a given locality, the moisture content of the outdoor air may be determined from Fig. 12.4.5 (summer dew-point temperature data) and the appropriate psychrometric chart.

Conductance Coefficients Tables 12.4.7 to 12.4.9 list conductance heat-transfer coefficients U for various building components. Table 12.4.10 shows conductance heat transfer coefficients for reflective and

Dining halls	100	15	8			
Guard stations	40	15	8			

* This table prescribes supply rates of acceptable outdoor air required for acceptable indoor air quality. These values have been chosen to control CO_2 and other contaminants with an adequate margin of safety and to account for health variations among people, varied activity levels, and a moderate amount of smoking. Rationale for CO_2 control is presented in Appendix D of Standard 62-1989.

† Net occupable space.

SOURCE: Abstracted from ASHRAE Standard 62-1989, with permission.

Table 12.4.4 Infiltration through Doors—Winter*

15 mi/h (24 km/h) wind velocity†; doors on one or adjacent windward sides‡

	ft³/min per ft² area (m³/min per m²)§									
			Average use							
	Infrequent use		1 and 2 story buildings		Tall buildings, ft (m)					
	ft³/min per ft²	m³/min per m²	ft³/min per ft²	m³/min per m²	50	(15.25 m)	100	(30.5 m)	200	(61 m)
Revolving door	1.6	0.48	10.5	3.15	12.6	3.78	14.2	4.26	17.3	5.19
Glass door [3/16 in (5 mm) crack]	9.0	2.70	30.0	9.00	36.0	10.80	40.5	12.15	49.5	14.85
Wood door 3 × 7 ft (0.9 × 2 m)	2.0	0.60	13.0	3.90	15.5	4.65	17.5	5.25	21.5	6.45
Garage and shipping-room door	4.0	1.2	9.0	2.70						

* All values are based on the wind blowing directly at the window or door. When the prevailing wind direction is oblique to the window or doors, multiply the values by 0.60 and use the total window and door areas on the windward side(s).

† Based on a wind velocity of 15 mi/h (24 km.p.a). For design wind velocities different from the base, multiply the table values by the ratio of velocities.

‡ Stack effect in tall buildings may also cause infiltration on the leeward side. To evaluate this, determine the equivalent velocity V_i and subtract the design velocity V. The equivalent velocity is

$$V_i = \sqrt{V^2 - 1.75a} \text{ (upper section)}$$
$$= \sqrt{V^2 - 1.75b} \text{ (lower section)}$$

where a and b are the distances above and below the midheight of the building, respectively, in feet.

Multiple the table values by the ratio $(V_i - V)/15$ for one-half of the windows and doors on the leeward side of the building. (Use values under one- and two-story building for doors on leeward side of tall buildings.)

§ Doors on opposite sides increase values 25%.

Table 12.4.6 Water Vapor Transmission through Various Materials

Description of material or construction	Permeance, Btu/(h · 100 ft^2) (gr/lb diff) latent heat
Packaging materials	
Cellophane, moisture-proof	0.01–0.25
Glassine (1 ply waxed or 3 ply plain)	0.0015–0.006
Kraft paper soaked with paraffin wax, 4.5 lb per 100 ft^2	1.4–3.1
Pliofilm	0.01–0.025
Paint films	
2 coats aluminum paint, estimated	0.05–0.2
2 coats asphalt paint, estimated	0.05–0.1
2 coats lead and oil paint, estimated	0.1–0.6
2 coats water emulsion, estimated	5.0–8.0
Papers	
Duplex or asphalt laminae (untreated)	
30-30-30, 3.1 lb per 100 ft^2	0.15–0.27
30-60-30, 4.2 lb per 100 ft^2	0.051–0.091
Kraft paper	
1 sheet	8.1
2 sheets	5.1
Aluminum foil on one side of sheet	0.016
Aluminum foil on both sides of sheet	0.012
Sheathing paper	
Asphalt impregnated and coated, 7 lb per 100 ft^2	0.02–0.10
Slaters felt, 6 lb per 100 ft^2, 50% saturated with tar	1.4
Roofing felt, saturated and coated with asphalt	
25 lb/ft^2	0.015
50 lb/ft^2	0.011
Tin sheet with 4 holes 1/16-in diameter	0.17
Crack 12 in long by 1/32 in wide (approximate from above)	5.2

Painted surfaces: Two coats of a good vapor seal paint on a smooth surface give a fair vapor barrier. More surface treatment is required on a rough surface than on a smooth surface. Data indicates that either asphalt or aluminum paint is good for vapor seals.

Aluminum foil on paper: This material should also be applied over a smooth surface and joints lapped and sealed with asphalt. The vapor barrier should always be placed on the side of the wall having the higher vapor pressure if condemnation of moisture in wall is possible.

Application: The heat gain due to water vapor transmission through walls may be neglected for the normal air-conditioning or refrigeration job. This latent gain should be considered for air-conditioning jobs where there is a great vapor pressure difference between the room and the outside, particularly when the dew point inside must be low. Note that moisture gain due to infiltration usually is of much greater magnitude than moisture transmission through building structures.

Conversion factors: To convert above table values to:
grain/(hr) (sq ft) (inch mercury vapor pressure difference), multiply by 9.8. grain/(hr) (sq ft) (pounds per sq inch vapor pressure difference), multiply by 20.0.
To convert Btu latent heat to grains, multiply by 7000/1060 = 6.6.

Heat Transmission

Heat gain through exterior walls and roofs is highly variable and is caused by a combination of solar heat and the temperature difference between indoor and outdoor air. Total heat flow is affected by the type and weight of the construction, exposure, sun time, latitude, and design conditions. The equivalent temperature difference from Tables 12.4.13 and 12.4.14 combined with the appropriate heat-transfer coefficients U for the construction, Tables 12.4.15 and 12.4.16, permits estimating the total heat flow through walls and roofs.

Heat flow through interior construction is essentially constant and may be determined by using the actual temperatures on either side of the construction and the appropriate U values.

Solar Heat Gain

Heat gain through glass is a combination of the heat gains by conduction and solar radiation. Both factors are highly variable and one or both are affected by the type of glass, shading, day of the year, time of day, location and orientation angle to the sun, and outside and inside temperatures.

For glass:

$$Q_{\text{glass}} = Q_u + Q_{\text{solar}} \tag{12.4.12}$$

$$= A_1 U(t_o - t_i) + A_2(\text{MSHGF})(\text{CLF})(\text{SC}) \tag{12.4.13}$$

where A_1 = area of total glass, ft^2 (m^2); A_2 = area of sunlit glass, ft^2 (m^2); U = heat-transfer coefficient (Table 12.4.16); t_0 = outside design temperature, °F (°C) (Fig. 12.4.4); t_i = inside design temperature, °F (°C) (Table 12.4.2); MSHGF = maximum solar heat gain factor (Table 12.4.17); CLF = cooling load factor (Tables 12.4.18, 12.4.19, and 12.4.20); SC = shading coefficient (Tables 12.4.21, 12.4.22, 12.4.23, and 12.4.24).

Note that the data in Table 12.4.17 is for vertical and horizontal glass; the data in Tables 12.4.18 to 12.4.24 addresses the effect of heat storage within the space.

Internal Heat Gains

Internal heat gains are primarily from lighting, equipment, and occupants. They are independent of outdoor temperature and solar effect and include both sensible and latent heat.

$$Q_{\text{int}} = \text{internal heat gains} = Q_{\text{people}} + Q_{\text{lighting}} + Q_{\text{equipment}} \tag{12.4.14}$$

In some applications such as general office space, internal heat gains are relatively constant; in others where equipment cycles and/or occupancy is not constant, these loads will vary widely.

Heat gains from people vary with the activity and the proportion of men and women. The proportion of sensible latent heat varies with the temperature of the space. Table 12.4.25 lists adjusted heat gains from people for different activities and typical applications.

Lighting heat gains are based on the total electrical wattage of the operating lights, including ballasts, converted to Btu/h. Note that under some circumstances the entire electrical input to the lights may not immediately become part of the cooling load. This depends on the type and arrangement of the lights, type of air supply and return, space furnishings, the thermal characteristics of the space, and length of time the lights will be on. Unless all of these can be forseen with a high degree of certainty, and lighting represents a significant portion of the cooling load, most designers will use the full electrical input of the operating lights as the lighting load.

Representative heat gains at various lighting levels for the most common lighting fixtures are shown in Fig. 12.4.7. Curves A, B, and C are drawn for fixtures with newer electronic ballasts and high-efficiency lamps. For a given footcandle level of illumination, they use about 40 percent of the energy of earlier fixtures with magnetic ballasts and standard 40-W lamps; see curves AA, BB, and CC. Curves D and E show heat gains from recessed incandescent fixtures.

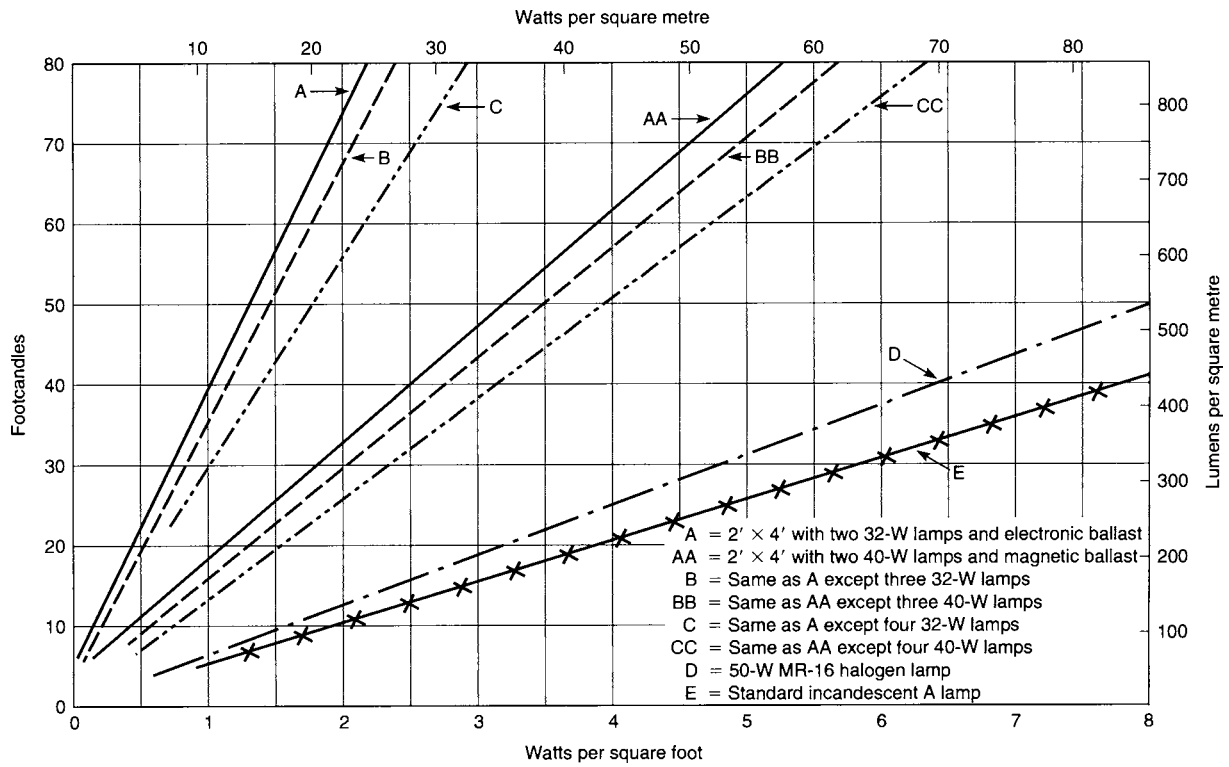

Fig. 12.4.7 Heat gain from typical lighting fixtures. *(Courtesy: S. Ricketts.)*

Table 12.4.14 Total Equivalent Temperature Differentials for Calculating Heat Gain through Flat Roofs

Description of roof construction*, †	Wt., lb/ft²	kg/m²	*U* value Btu/(h · ft² · °F)	*U* value W/(m² · K)

4 in (100 mm) l.w. concrete	17.8	86.86	0.213	1.209
2 in (50 mm) insulation + 4 in (100 mm) h.w. concrete	52.1	254.25	0.120	0.681
2 in (50 mm) insulation + 6 in (150 mm) h.w. concrete	75.4	367.95	0.117	0.664

Explanation: Total heat transmission from solar radiation and temperature difference between outdoor and room air, Btu/(h)(ft²)(W/m²) of roof area = equivalent temperature differential from above table × heat-transmission coefficient for summer, Btu/(h · ft² · °F) [W/(m² · K)].

Application. These values may be used for all normal air conditioning estimated; usually without correction (except as noted below in latitude 0 to 50° north or south when the load is calculated for the hottest weather.

Corrections. The values in the table were calculated for an inside temperature of 75°F (24°C) and an outdoor maximum temperature of 95°F (35°C) with an outdoor daily range of 21°F (12°C). The table remains approximately correct for other outdoor maximum (93 to 102°F) (34 to 39°C) and other outdoor daily ranges (16 to 34°F) (9 to 19°C) provided the outdoor daily average temperature remains approximately 85°F (30°C). If the room air temperature is different from 75°F (24°C) and/or the outdoor daily average temperature is different from 85°F (30°C), the following rules can be applied:

1. For room air temperature less than 75°F (24°C) add the difference between 75°F (24°C) and room air temperature; if greater than 75°F (24°C), subtract the difference.
2. For outdoor daily average temperature less than 85°F (30°C) subtract the difference between 85°F (30°C) and the daily average temperature, if greater than 85°F (30°C), add the difference.

Attics or other spaces between the roof and ceiling. If the ceiling is insulated and a fan is used for positive ventilation in the space between the ceiling and roof, the total temperature differential for calculating the room load may be decreased by 25 percent. If the attic space contains a return duct or other air plenum, care should be taken in determining the portion of the heat gain that reaches the ceiling.

Light color. Credit should not be taken for light-colored roofs except where the permanence of light color is established by experience as in rural areas or where there is little smoke.

For solar transmission in other months. The table values of temperature differentials that were calculated for July 21 will be approximately correct for a roof in the following months.

North latitude		South latitude	
Latitude, deg	Months	Latitude, deg	Months
0	All months	0	All months
10	All months	10	All months
20	All months except Nov., Dec., Jan.	20	All months except May, June, July
30	Mar., Apr., May, June, July, Aug., Sept.	30	Sept., Oct., Nov., Dec., Jan., Feb., March
40	April, May, June, July, Aug.	40	Oct., Nov., Dec., Jan., Feb.
50	May, June, July	50	Nov., Dec., Jan.

* Includes outside surface resistance, ½ in (12.5 mm) membrane and ⅜ in (9 mm) felt on the top and inside surface resistance on the bottom.
† Dark roof (D) = 0.30; light roof (L) = 0.15.
‡ Nominal thickness of wood.

Heat gain from equipment located within the conditioned space is often a significant portion of the air-conditioning load. Lists of equipment that will be installed, manufacturers' heat release (or wattage) data, and anticipated use and load factors should be obtained from the user early in the design process. Tables 12.4.26, 12.4.27, and 12.4.28 show anticipated gains from a variety of office equipment, restaurant appliances and electric motors. For restaurant cooking equipment, a properly designed, mechanically exhausted hood will reduce the total load of the hooded equipment by about 50 percent.

Miscellaneous Heat Gains Additional heat gains that add to the system load are the heat added at the supply and return fans and heat transferred from unconditioned areas to the distribution ductwork. An additional load on a chilled-water system is the heat equivalent of the chilled-water pump motor work.

Fan heat is the heat added by the fan motor, and manifests itself as the total power input to the fan motor when the motor is located within the airstream or conditioned space, or the net output of the fan motor when it is located out of the airstream or conditioned space. Since air can be considered to be a perfect gas, all the fan heat is added at the fan and the conditioned air temperature will increase as it flows through the fan. If the motor is in the airstream, its inefficiency will add to fan heat.

The contribution of fan heat to temperature rise Δt (°F) is computed as follows:

$$\Delta t = Q_{motor}/1.08 \qquad \text{ft}^3/\text{min} \qquad (12.4.15)$$

where Q_{motor} is obtained from data in Table 12.4.28.

Table 12.4.16 Coefficients of Transmission *U* of Windows, Skylights, and Light Transmitting Partitions
These values are for heat transfer from air to air, Btu/(h · ft² · °F).

Part A—Vertical panels (exterior windows, sliding patio doors, and partitions) —flat glass, glass block, and plastic sheet

Description	Exterior[a] Winter	Exterior[a] Summer	Interior
Flat glass[b]			
Single glass	1.10	1.04	0.73
Insulating glass—double[c]			
0.1875-in airspace[d]	0.62	0.65	0.51
0.25-in airspace[d]	0.58	0.61	0.49
0.5-in airspace[e]	0.49	0.56	0.46
0.5-in airspace, low-emittance coating[f]			
e = 0.20	0.32	0.38	0.32
e = 0.40	0.38	0.45	0.38
e = 0.60	0.43	0.51	0.42
Insulating glass—triple[c]			
0.25-in airspaces[d]	0.39	0.44	0.38
0.5-in airspaces[g]	0.31	0.39	0.30
Storm windows			
1-in to 4-in airspace[d]	0.50	0.50	0.44
Plastic sheet			
Single glazed			
0.125 in thick	1.06	0.98	—
0.25 in thick	0.96	0.89	—
0.5 in thick	0.81	0.76	—
Insulating unit—double[c]			
0.25-in airspace[d]	0.55	0.56	—
0.5-in airspace[c]	0.43	0.45	—
Glass block[h]			
6 × 6 × 4 in thick	0.60	0.57	0.46
8 × 8 × 4 in thick	0.56	0.54	0.44
—with cavity divider	0.48	0.46	0.38
12 × 12 × 4 in thick	0.52	0.50	0.41
—with cavity divider	0.44	0.42	0.36
12 × 12 × 2 in thick	0.60	0.57	0.46

Part B—Horizontal panels (skylights)—flat glass, glass block, and plastic domes

Description	Exterior[a] Winter[i]	Exterior[a] Summer[j]	Interior[l]
Flat glass[e]			
Single glass	1.23	0.83	0.96
Insulating glass—doubles[c]			
0.1875-in airspace[d]	0.70	0.57	0.62
0.25-in airspace[d]	0.65	0.54	0.59
0.5-in airspace[c]	0.59	0.49	0.56
0.5-in airspace, low-emittance coating[f]			
e = 0.20	0.48	0.36	0.39
e = 0.40	0.52	0.42	0.45
e = 0.60	0.56	0.46	0.50
Glass block[h]			
11 × 11 × 3 in thick with cavity divider	0.53	0.35	0.44
12 × 12 × 4 in thick with cavity divider	0.51	0.34	0.42
Plastic domes[k]			
Single-walled	1.15	0.80	—
Double-walled	0.70	0.46	—

Part C—adjustment factors for various window and sliding patio door types (multiply *U* values in parts A and B by these factors)

Description	Single glass	Double or triple glass	storm windows
Windows			
All Glass[l]	1.00	1.00	1.00
Wood sash—80% glass	0.90	0.95	0.90
Wood sash—60% glass	0.80	0.85	0.80
Metal sash—80% glass	1.00	1.20[m]	1.20[m]
Sliding patio doors			
Wood frame	0.95	1.00	—
Metal frame	1.00	1.10[m]	—

[a] See Part C for adjustment for various window and sliding patio door types.
[b] Emittance of uncooled glass surface = 0.84.
[c] Double and triple refer to the number of lights of glass.
[d] 0.125-in glass.
[e] 0.25-in glass.
[f] Coating on either glass surface facing airspace; all other glass surfaces uncoated.
[g] Window design: 0.25-in glass–0.125-in glass–0.25-in glass.
[h] Dimensions are nominal.
[i] For heat flow up.
[j] For heat flow down.
[k] Based on area of opening, not total surface area.
[l] Refers to windows with negligible opaque area.
[m] Values will be less than these when metal sash and frame incorporate thermal breaks. In some thermal break designs, *U* values will be equal to or less than those for the glass. Window manufacturers should be consulted for specific data.

Table 12.4.25 Rates of Heat Gain from Occupants of Conditioned Spaces*†

Degree of activity	Typical application	Total heat adult male, Btu/h	Total heat adjusted,‡ Btu/h	Sensible heat, Btu/h	Latent heat, Btu/h
Seated at theater	Theater—Matinee	390	330	225	105
Seated at theater	Theater—Evening	390	350	245	105
Seated, very light work	Offices, hotels, apartments	450	400	245	155
Moderately active office work	Offices, hotels, apartments	475	450	250	200
Standing, light work; walking	Department store, retail store	550	450	250	200
Walking; standing	Drug store, bank	550	500	250	250
Sedentary work	Restaurant§	490	550	275	275
Light bench work	Factory	800	750	275	475
Moderate dancing	Dance hall	900	850	305	545
Walking 3 mi/h; light machine work	Factory	1,000	1,000	375	625
Bowling¶	Bowling alley	1,500	1,450	580	870
Heavy work	Factory	1,500	1,450	580	870
Heavy machine work; lifting	Factory	1,600	1,600	635	965
Athletics	Gymnasium	2,000	1,800	710	1,090

* Tabulated values are based on 75°F room dry-bulb temperature. For 80°F room dry-bulb, the total heat remains the same, but the sensible heat values should be decreased by approximately 20%, and the latent heat values increased accordingly.
† All values are rounded to nearest 5 Btu/h.
‡ *Adjusted heat gain* is based on normal percentage of men, women, and children for the application listed, with the postulate that the gain from an adult female is 85% of that for an adult male, and that the gain from a child is 75% of that for an adult male.
§ Adjusted total heat gain for *Sedentary work, Restaurant,* includes 60 Btu/h for food per individual (30 Btu/h sensible and 30 Btu/h latent).
¶ For *Bowling,* figure one person per alley actually bowling, and all others as sitting (400 Btu/h) or standing and walking slowly (550 Btu/h).
SOURCE: Abstracted from ASHRAE "Handbook of Fundamentals," 1989, with permission.

Table 12.4.26 Rate of Heat Gain from Selected Office Equipment

Appliance	Size	Maximum input rating, Btu/h	Standby input rating, Btu/h	Recommended rate of heat gain, Btu/h
Cheek processing workstation	12 pockets	16,400	8,410	8,410
Computer devices

Heat transfer to the distribution duct depends on the duct area exposed, the amount of insulation on the duct, and the temperature differential between the air in the duct and the surroundings.

Outside Air

Outside air loads depend on the amount of outside air intake and its condition. Table 12.4.3 shows recommended outdoor air ventilation rates for different occupancies. Tables 12.4.4 and 12.4.5 can be used to determine the quantity of outside air that will infiltrate because of wind effects. In all cases, sufficient outside air should be provided to balance mechanical exhaust systems.

$$\begin{aligned} Q_{\text{outside air}} &= q_{\text{sensible}} + q_{\text{latent}} \quad \text{Btu/h (W)} \\ &= AU(t_o - t_i)\ \text{ft}^3/\text{min} \\ &\quad + 0.68(M_o - M_i)\ \text{ft}^3/\text{min} \quad \text{Btu/h} \end{aligned} \tag{12.4.16a}$$

where M_o = outside moisture content at design wet bulb, °F, gr/lb; and M_i = inside moisture content at design relative humidity, gr/lb. A comparable equation in SI units is

$$\begin{aligned} Q_{\text{outside air}} &= 1.2(t'_o - t'_i)\ \text{m}^3/s \\ &\quad + 42.6(M'_o - M'_i)\ \text{m}^3/\text{s} \quad \text{kW} \end{aligned} \tag{12.4.16b}$$

Table 12.4.27 Heat Gain from Restaurant Appliances
Not hooded,* gas burning and steam heated.

Appliance	Type of control	Miscellaneous data	Manufacturer's max. rating, Btu/h	Maintaining rate, Btu/h	Recommended heat gain from average use		
					Sensible heat, Btu/h	Latent heat, Btu/h	Total heat, Btu/h

where M'_o = outside moisture content at design wet bulb, °C, g/kg; and M'_i = inside moisture content at design relative humidity, g/kg. t'_o, t'_i are expressed in °C.

Moisture Load

Moisture as a cooling load is a latent heat gain expressed in Btu per hour and is computed with the following equations:

$$Q_t = Q_{\text{inf}} + Q_{\text{vent}} \tag{12.4.17}$$

$$Q_{\text{inf}} = 0.68 \times \text{ft}^3/\text{min} \times (M_o - M_i) \quad \text{Btu/h} \tag{12.4.18a}$$

$$Q_{\text{vent}} = 0.68 \times \text{ft}^3/\text{min} \times (M_o - M_i) \quad \text{Btu/h} \tag{12.4.19a}$$

where 0.68 = 60/13.5 × 1,076/7,000; 60 = min/h; 13.5 = specific volume of moist air at 70°F dB and 50 percent RH; 1,076 = average heat removal required to condense 1 lb of water vapor from the room air; and 7,000 = grains per pound.

Comparable equations in SI units are:

$$Q_{\text{inf}} = 42.6\ \text{m}^3/\text{s}\,(M'_o - M'_i) \quad \text{kW} \tag{12.4.18b}$$

$$Q_{\text{vent}} = 42.6\ \text{m}^3/\text{s}\,(M'_o - M'_i) \quad \text{kW} \tag{12.4.19b}$$

M'_o = moisture content of outside air, g/kg; and M'_i = moisture content of inside air, g/kg.

HEATING

Heating Load

$$Q_t = Q_{\text{tr}} + Q_{\text{inf}} + Q_{\text{vent}} \tag{12.4.20a}$$

where Q_t = total heating load, Btu/h; Q_{tr} = transmission load = $AU(t_i - t_o)$, Btu/h; Q_{inf} = infiltration load = 1.08 (ft³/min), $(t_i - t_o)$, Btu/h; Q_{vent} = ventilation load = 1.08 (ft³/min)$(t_i - t_o)$, Btu/h; A = area through which heat flow occurs, ft²; U = overall heat-transfer coefficient = $1/R_t$ Btu/(h)(ft²)(°F); t_o = outside-air design dry-bulb temperature, °F (Fig. 12.4.1); t_i = inside design dry-bulb temperature, °F (Table 12.4.1); R_t = thermal resistance, °F/(Btu · h · ft²) = $R_1 + R_2 + R_3 + \cdots + R_n$; and R_1, R_2, . . . = resistances to heat flow to the individual components of a composite construction. See Fig. 12.4.2 and Table 12.4.2.

A comparable equation in SI units is

$$Q_1 = Q_{\text{tr}} + Q_{\text{inf}} + Q_{\text{vent}} \tag{12.4.20b}$$

where Q_t = total heating load, kW; $Q_{\text{tr}} = AU(t_i - t_o)$, kW; Q_{inf} = 1.2 (m³/s)$(t_i - t_o)$, kW; Q_{vent} = 1.2 (m³/s)$(t_i - t_o)$, kW; A = area through which heat flow occurs, m²; U = overall heat-transfer coefficient = $1/R_t$, W/(m² · K); t_o = outside-air design dry-bulb temperature, °C; t_i = inside design dry-bulb temperature, °C; m³/s = cubic meters per second, air; and R_t = thermal resistance, K/(W · m²).

PSYCHROMETRICS

The psychrometric chart can be used to simplify the analysis of air-conditioning processes. The processes can be shown simply and visualized clearly, and the chart lends itself to quick graphical computations. In addition, the state of any air–water vapor mixture can be fixed on the psychrometric chart with reasonable accuracy by means of any two psychrometric characteristics. Usually dry-bulb temperature and wet-bulb temperature are used because they are the simplest to measure.

Figures 12.4.8 and 12.4.9 are psychrometric charts for normal temperatures in inch-pound and SI units, respectively.

Psychrometric charts at different temperatures and barometric pressures are useful for problems falling outside the ranges shown in Figs. 12.4.8 and 12.4.9. A collection of different psychrometric charts, in both USCS and SI units, for low, normal, and high temperatures, at sea level and at

four elevations above sea level, are available from ASHRAE, the Carrier Corp. of Syracuse, NY, and from other equipment manufacturers.

Figure 12.4.10 shows a psychrometric chart simplified in skeleton form.

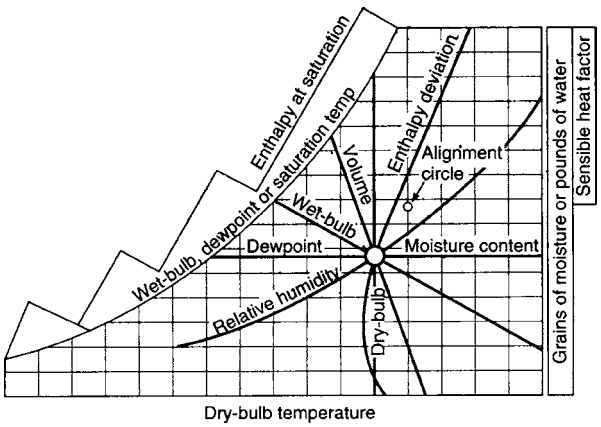

Fig. 12.4.10 Skeleton psychrometric chart.

Terminology

Dry-bulb temperature: The temperature of air as registered by an ordinary thermometer.

Wet-bulb temperature: The temperature registered by a thermometer whose bulb is covered by a wetted wick and exposed to a current of rapidly moving air.

Dew-point temperature: The temperature at which condensation of moisture begins when the air is cooled.

Relative humidity: Ratio of the actual water vapor pressure of the air to the saturated water vapor pressure of the air at the same temperature.

Specific humidity or moisture content: The weight of water vapor in grains (or pounds) of moisture per pound of dry air.

Enthalpy: A thermal property indicating the quantity of heat in the air above an arbitrary datum, in Btu per pound of dry air. The datum for dry air is 0°F and, for the moisture content, 32°F water.

Enthalpy deviation: Enthalpy should be corrected by the enthalpy deviation due to the air not being in the saturated state. On normal air-conditioning estimates it is omitted.

Specific volume: The cubic feet of the mixture per pound of dry air.

Sensible heat factor: The ratio of sensible to total heat.

Alignment circle: Used in conjunction with the sensible heat factor to plot the various air-conditioning process lines.

Pounds of dry air: The basis for all psychrometric calculations. Remains constant during all psychrometric processes.

The dry-bulb, wet-bulb, and dew-point temperatures and the relative humidity are so related that, if two properties are known, all other properties shown may then be determined. When **air is saturated,** dry-bulb, wet-bulb, and dew-point temperatures are all equal.

Room sensible heat factor is the ratio of room sensible heat to the total of room sensible and room latent heat.

A line drawn between the room design condition at the slope of the sensible heat factor is the **condition line** and it will intersect the saturation line at the apparatus dew point. See Fig. 12.4.11. In order to maintain design conditions, supply air must be provided to the space at a temperature and moisture level that, when plotted, must fall on the condition line. If air is provided at conditions of apparatus dew point, the minimum quantity of conditioned air would be required to obtain design conditions.

Supply Air Temperature The room cooling load is the sum of external and internal sensible and latent heat gains plus the difference in enthalpy between outside and room air for that portion of outside air

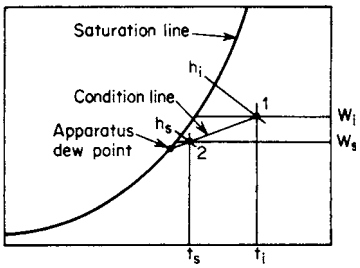

Fig. 12.4.11 Apparatus dew point and condition line.

which does not contact the cooling-coil surfaces. The percentage of air that passes through a cooling coil untreated is the numerical value of the *coil bypass factor;* e.g., a bypass factor of 20 percent represents a cooling-coil saturation efficiency of 80 percent.

The ratio of room sensible heat gains to total room sensible and latent heat gains is the **room sensible heat ratio (RSHR)**.

$$\text{RSHR} = \frac{Q_{rs}}{Q_{rs} + Q_{rl}} \qquad (12.4.21)$$

It represents the ratio of sensible cooling capacity to the total cooling capacity required of the supply air to satisfy room conditions. It is used to plot the slope of the *room-condition line* on a psychometric chart for the determination of the *apparatus dew point* (ADP). See Fig. 12.4.11.

The actual supply air temperature and off coil wet-bulb temperature will depend on the bypass characteristic of the selected cooling coil (Fig. 12.4.11).

Supply Air Rate The rate of supply air required is expressed by

$$Q_{sa} = Q_{rs}/1.08(t_r - t_s) \qquad \text{ft}^3/\text{min} \qquad (12.4.22a)$$

In SI units:

$$Q'_{sa} = Q'_{rs}/1.2(t_r - t_s) \qquad \text{m}^3/\text{s} \qquad (12.4.22b)$$

where Q_{sa} = supply air, ft³/min (m³/s); Q'_{rs} = room sensible heat, kW; t_r = room design temperature, °F (K); t_s = supply air temperature, °F (K).

The bypass factor is used to express the effectiveness of a cooling coil. It is based on the artificial premise that a portion of the air that enters a cooling coil is cooled completely to saturation, that is, to the apparatus dew point, and the remaining air is not cooled at all. The actual condition of the air that leaves the coil is then represented to be a mixture of the fully conditioned and completely unconditioned air. The ratio of unconditioned air to total air is the **bypass factor.**

The bypass factor is a function of the type and amount of coil surface and the time available for contact as the air passes over the coil. Table 12.4.29 gives approximate bypass factors for various finned coil surfaces and air velocities. A larger bypass factor requires the circulation of more conditioned air; where outside air is introduced, the bypassed air increases the room air load.

Table 12.4.29 Typical Bypass Factors for Unsprayed Coils

	5-in spacing	
	8 fins/in	14 fins/in
Depth of coils (rows)	Face velocity, ft/min	
	300–700	300–700
2	0.42–0.55	0.22–0.38
3	0.27–0.40	0.10–0.23
4	0.19–0.30	0.05–0.14
5	0.12–0.25	0.02–0.09
6	0.08–0.18	0.01–0.06
8	0.03–0.08	

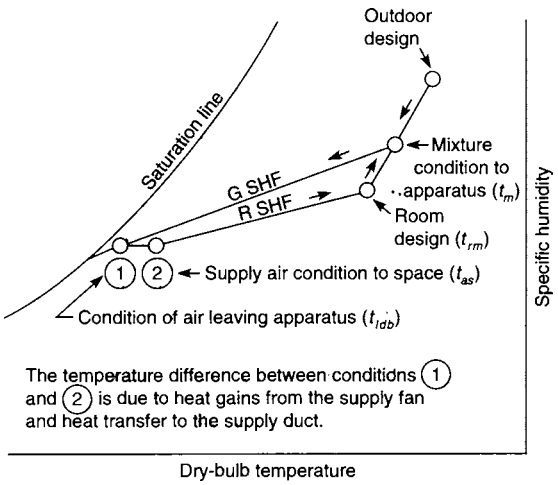

Fig. 12.4.12 Typical cooling process.

Typical Air-Conditioning Cooling Process Figure 12.4.12 depicts a typical cooling process adjusted for fan heating and duct losses.

DUCT DESIGN

Air Velocity Supply and return air ducts and apparatus are sized on the basis of air quantity and are kept within the limitations of allowable friction losses, velocity, and noise. Conveying air at low velocity will be quieter and require less pressure, less fan power, and less carefully constructed ductwork than conveying air at medium or high velocity. Lower velocities are preferred where space is available.

Pressure Loss in Duct Systems Pressure losses in duct systems are due to friction of the air in contact with the sides of the duct and dynamic losses caused by changes of duct shape or direction and by obstructions to flow.

$$\text{Friction } H_f = f\frac{L}{D}\left(\frac{V}{4{,}005}\right)^2 \qquad (12.4.23a)$$

where H_f = head loss due to friction, in H_2O: L = length of duct, ft; D = diameter of duct, ft; V = velocity of air, ft/min; and f = nondimensional friction coefficient. A comparable equation in SI units is

$$H_f = f\frac{L}{d}\frac{(V)^2}{2}\rho \qquad (12.4.23b)$$

where H_f = head loss due to friction, N/m^2; L = length of duct, m; D = diameter of duct, m; V = velocity of air, m/s; f = nondimensional friction coefficient; and ρ = density of air, kg/m^3.

$$\text{Dynamic losses } H_v = C\left(\frac{V}{4{,}005}\right)^2 \qquad (12.4.24a)$$

where H_v = velocity-head loss, in H_2O; C = experimentally determined constant; $V = Q/A$ = air velocity, ft/min; Q = airflow rate, ft^3/min; and A = cross-sectional area of duct, ft^2. A comparable equation in SI units is

$$H'_v = C'\frac{(V')^2}{2} \qquad (12.4.24b)$$

where H'_v = velocity-head loss, N/m^2; and V' = air velocity, m/s. When the equation for H'_v is written in the form above, $C' = C$.

Duct Design Methods Two methods are frequently used: **equal friction** and **static regain.**

Equal Friction The equal friction method is applicable primarily to systems using low or moderate velocities, where the velocity head is not an important factor. A friction drop per 100 ft of length is chosen, and the duct mains and branches are all sized on the basis of this friction drop. This will invariably result in higher velocities in the mains, where they can be tolerated, and low velocities in the branches, where they are desirable. Limitations are established for friction loss per 100 ft and for velocities in the mains and branches.

Static Regain The static regain method is used for both conventional and high velocity systems. It is especially applicable in the latter, where the velocity head may be appreciable. In the static regain method, the static pressure required to give proper airflow through the system outlets is determined, and this pressure is maintained by reducing the velocity at each branch or takeoff, so that the recovery in pressure due to reduction of velocity balances the friction loss in the preceding section of duct. This is possible because of the convertibility of static and velocity pressures. For practical applications it is usually assumed that 50 percent of the velocity pressure available will be converted to static pressure.

$$H_R = 0.5\left(\frac{V_1}{4{,}005}\right)^2 - \left(\frac{V_2}{4{,}005}\right)^2 \qquad (12.4.25a)$$

where H_R = head recovered, inH_2O; V_1 = system inlet velocity, ft/min; and V_2 = system outlet velocity, ft/min. A comparable equation in SI units is

$$H'_R = \frac{0.5(V'_1)^2}{2} - \frac{(V'_2)^2}{2} \qquad (12.4.25b)$$

where H'_R = head recovered, N/m^2; V'_1 = system inlet velocity, m/s; and V'_2 = system outlet velocity, m/s.

Figure 12.4.13 may be used to determine directly the friction loss per 100 ft for round ducts. Figure 12.4.14 provides a conversion from

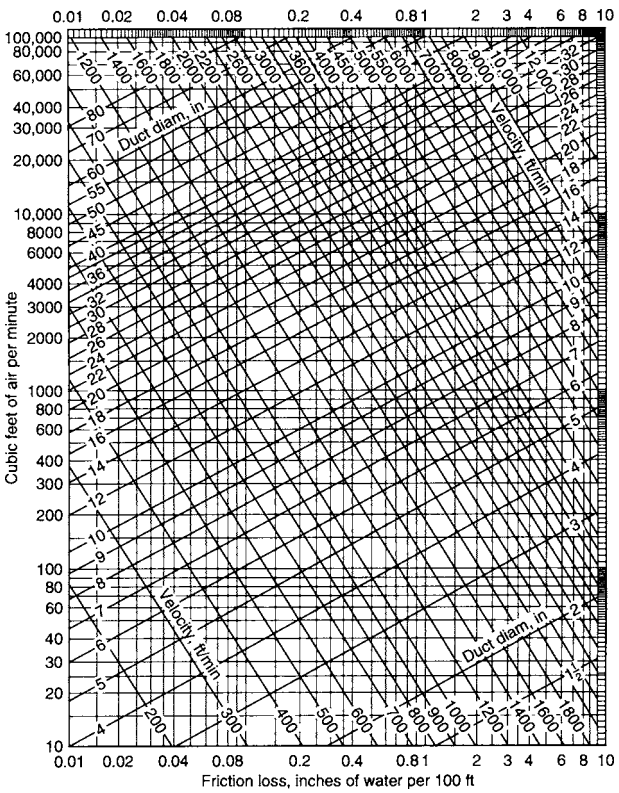

Fig. 12.4.13 Friction loss for usual conditions in round ducts. (This chart applies to smooth, round, galvanized steel ducts, and is based on air at 70°F and 29.96 inHg absolute pressure. For air of different density, the friction may be assumed to vary directly with the density.)

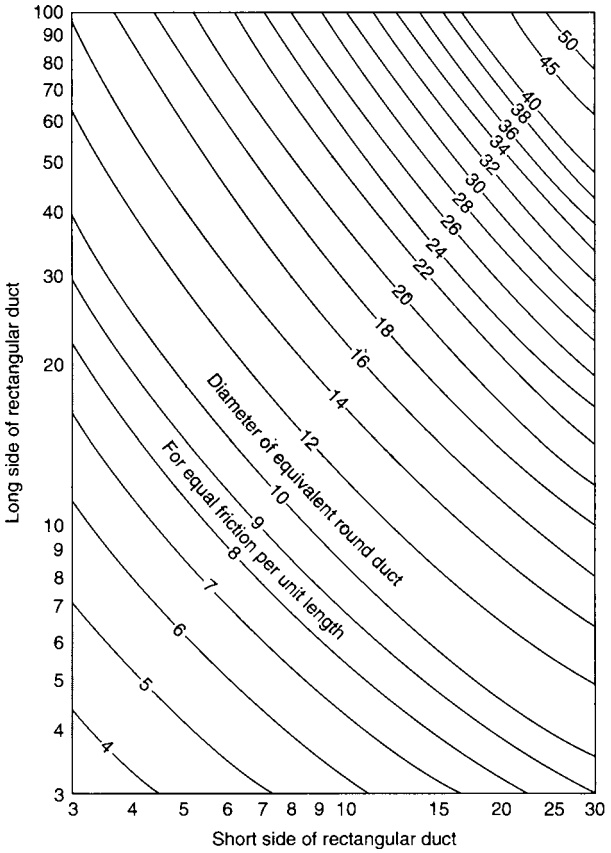

Fig. 12.4.14 Equivalent diameters of round ducts. Use with rectangular ducts, with capacity constant. *(Buffalo Forge.)*

round to rectangular ductwork with the same air capacity. Table 12.4.30 presents a range of friction loss per 100 ft and velocity limits for low- and high-velocity air systems. Typical velocities through some air system components are shown in Table 12.4.31.

Table 12.4.30 Duct System Pressure Losses and Design Velocities

	Pressure loss, in H_2O, gage, per 100 ft	Maximum velocity, ft/min
Low-velocity systems		
Noise critical	0.05–0.07	1,400
Usual design	0.08–0.1	1,800
Straight runs without takeoffs	0.08–0.12	2,400
High-velocity systems		
Usual design	0.4–0.6	2,600
Straight runs without takeoffs	0.6	3,400

Air Distribution

Air outlets are designed to control air motion, noise level, and temperature gradients caused by the introduction of air into a conditioned space and the removal of air from that space.

Supply Outlets Supply outlets (and diffusers) are usually located at near ceiling height with grilles or registers high on the sidewall. Supply outlets may be located below windows or in the floor as long as they satisfy the criteria for the space and are unobstructed. Factors which

Table 12.4.31 Typical Velocities through Air System Components

	Residences		Nonresidential buildings	
Designation	ft/min	m/min	ft/min	m/min
Outdoor-air intakes*	300	80	500	150
Filters*	250	75	300	90
Heating coils*	450	140	500	150
Cooling coils*	450	140	500	150
Air washers	500	150	500	150

* These velocities are for total face area, not the net free area; other velocities in the table are for net free area.

SOURCE: Adapted from ASHRAE "Handbook of Fundamentals," 1993, with permission.

usually affect the selection of supply outlets are noise, location of outlet, temperature of supply air, and area of diffusion. Manufacturers' performance data for supply outlets should be used as the basis for selection.

Return Outlets Selection of return outlets (and registers or grilles) is usually governed by face velocity to limit discomfort to occupants from drafts and/or noise. See Table 12.4.32.

Table 12.4.32 Recommended Return Face Velocities

	Velocity over gross area	
Intake location	ft/min	m/min
Above occupied zone	800 up	245 up
Within occupied zone, not near seats	600–800	185–245
Within occupied zone, near seats	400–600	120–185
Door or wall louvers	200–300	60–90
Undercutting of doors (through undercut area)	200–300	60–90

FANS

Supply and **return fans** must convey the conditioned air through the system efficiently and with a minimum of disturbing noise and vibrations.

Fans produce pressure by increasing airflow velocity. Velocity change is the result of tangential and radial velocity components in the case of centrifugal fans, and of axial and tangential velocity components in the case of axial-flow fans.

Centrifugal fans are most frequently used, but **axial-flow fans** have been applied successfully. Figures 12.4.15 to 12.4.17 show typical performance curves for forward-curved and backward-curved centrifugal

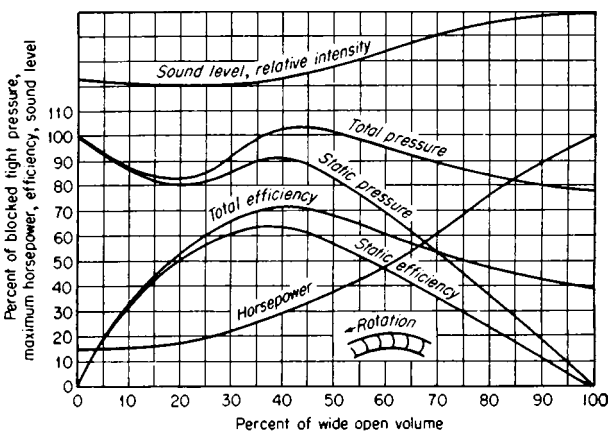

Fig. 12.4.15 Percentage performance curves for a forward-curved blade centrifugal fan.

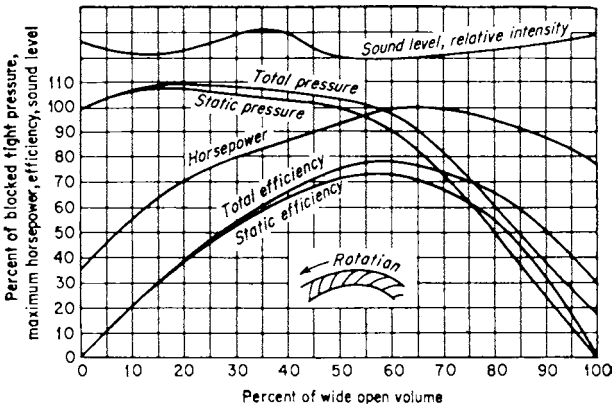

Fig. 12.4.16 Percentage performance curves for a backward-curved blade centrifugal fan.

fans and axial-flow fans. Table 12.4.33 summarizes the relative characteristics of centrifugal fans. Figure 12.4.18 shows the zone of optimum performance for a backward-curved-blade centrifugal fan.

FAN LAWS

Fan laws in Table 12.4.34 relate the performance variables for any dynamically similar series of fans. (See also Sec. 14.5.) They can be

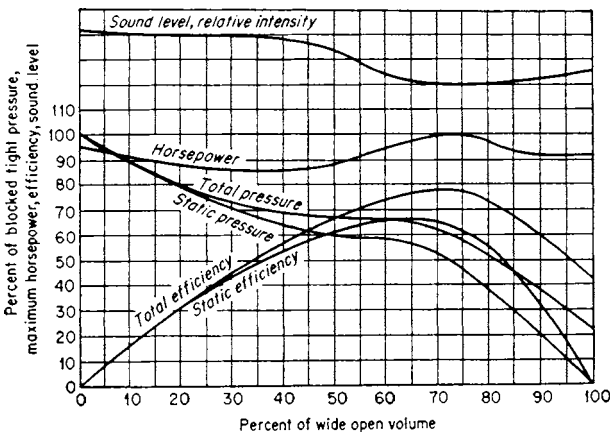

Fig. 12.4.17 Percentage performance curves for an axial fan.

used to predict the performance of any fan in a series when test data are available for a given fan in the series. Fan laws may also be used with a particular fan to determine the effect of speed change. Unless otherwise identified, fan performance data are based on dry air at standard conditions: 14.696 lb/in^2 abs and 70°F (0.075 lb/ft^3). In applications where the fan may be required to handle air or gas at some other density, because of temperature or altitude, fan performance will be affected. Table 12.4.35 shows correction factors to air volume for altitude and temperature.

Table 12.4.33 Relative Characteristics of Centrifugal Fans

Characteristic	Backward curved	Forward curved
First cost	High	Low
Efficiency	High	Low
Stability of operation	Good	Poor
Space required	Medium	Small
Tip speed	High	Low

Testing and Balancing Each fan and air duct system component should be tested, adjusted, and balanced to assure that it conforms to the design requirements.

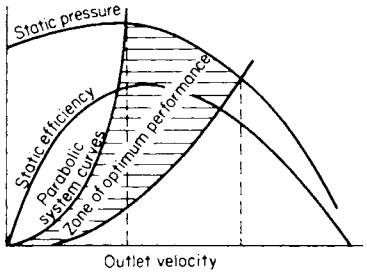

Fig. 12.4.18 Zone of optimum performance for backward-curved blade centrifugal fans.

System and Duct Noise The major sources of noise from air-conditioning systems are fans, diffusers, grilles, ducts, fittings, and vibration. **Sound control** for components consists of selecting devices that meet the design goal under all operating conditions and installing them properly so that no additional sound is generated. The sound power output of a fan is determined by the type of fan, airflow, and pressure. Sound control in the duct system requires proper duct layout, sizing, and provision

Table 12.4.34 Fan Laws*†

for installing duct noise attenuators, if required. The noise generated in a system increases with both duct velocity and system pressure. The ASHRAE Handbook "Applications" and other related sources present methods for sound control in air-conditioning systems.

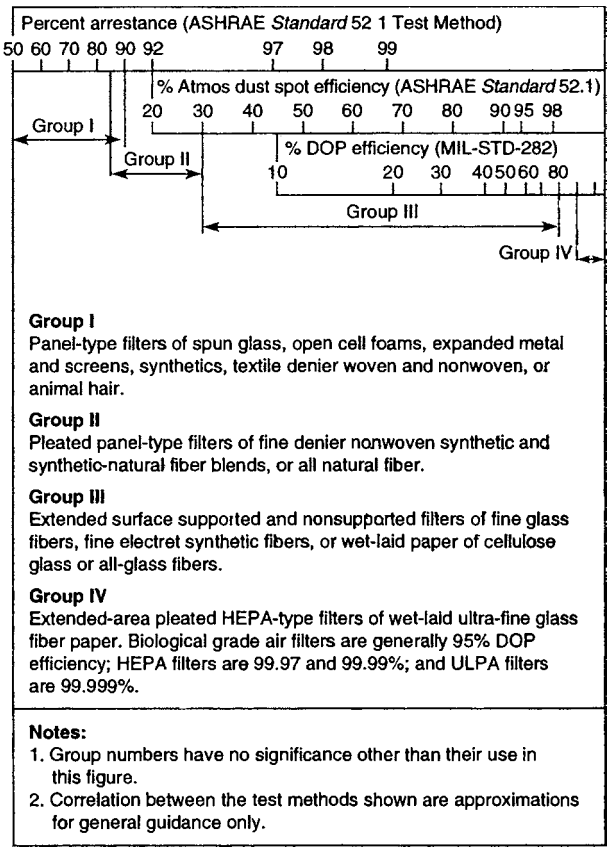

Fig. 12.4.19*a* Comparative performance of viscous impingement and dry media filters. *(ASHRAE "Handbook of Fundamentals," 1993.)*

FILTRATION

Filters are provided in air-conditioning systems to assure that the conditioned air will satisfy space cleanliness criteria and to protect air treatment equipment from fouling due to dirt accumulation. Figure 12.4.19*a* describes types of dry media filters and shows their range of performance. In addition, it shows an approximate comparison of the filtration efficiencies obtained by the use of three different testing methods.

The filters designated as Group I are usually used in least critical applications and as a prefilter to extend the operating life of more costly, higher-efficiency filters. Filters designated as Groups II and III are used in good-quality comfort and process air-conditioning applications. The very high efficiency HEPA and ULPA filters are costly and result in high pressure losses. They are applied in clean rooms and for nuclear and toxic particulate filtration.

AIR TREATMENT CRITERIA

The purpose of an air-conditioning system is to control the indoor environment to provide comfortable conditions for occupants of a space or to facilitate a process to be carried on within the space.

To satisfy these criteria, the system should control temperature, humidity, air cleanliness, and air distribution in the space within established limits and accomplish this without excessive noise. The system should maintain indoor design conditions through the full range of outdoor temperature and humidity and indoor cooling or heating loads and accomplish this reliably and economically.

Performance criteria are often demanding for process systems, but many comfort systems operate for summer cooling and convenience only. They utilize filters that remove only coarse atmospheric dust and have no provision for adding moisture during the winter; during the summer, humidity is reduced, although not controlled, as part of the cooling process. These systems often serve a single room or a small area and may operate in conjunction with a separate building heating system.

Cooling Configurations Figure 12.4.19*b* illustrates some of the configurations of the cooling portion of air-conditioning systems. These can be provided in conjunction with a variety of air filtration, heating, humidification, air distribution, and automatic control components to make a complete system.

In most air-conditioning systems, peak summer loads are cooled by utilizing some form of compression or absorption cooling system, but there are systems that obtain cooling or precooling from other sources. Some examples are installations located where ample quantities of cold,

good-quality well water are available and can be circulated through a cooling coil and areas whose summer wet-bulb temperatures are sufficiently low that substantial cooling can be achieved by evaporation of water into the supply airstream.

Direct Expansion Cooling The most widely used method of air conditioning for cooling a single room or a small area utilizes mechanical compression and the direct expansion of the refrigerant in a cooling coil in the supply airstream. This usually involves a matched compressor and cooling coil in a factory-built, self-contained package. The high-pressure refrigerant leaves the condenser and expands into the cooling coil where it absorbs heat directly from the airstream. For small-capacity applications, the arrangement provides simplified, relatively quick installations and low first costs. Larger, more complex direct expansion systems utilize the same principles.

Chilled Water Cooling Chilled water systems are the most widely used indirect systems. In these systems, the refrigerant cools a pumped closed water circuit which, in turn, is used to condition air from one or more air handlers.

The chilled water system permits serving widely separated, individually controlled air handlers from a central refrigeration system while limiting the extent of the refrigerant circulation.

Sprayed Coil Dehumidifiers Sprayed coil systems utilize chilled water coils and a recirculating water spray. The system is similar to the chilled water system in that all the mechanical cooling is provided through the closed chilled water piping and coils. The spray circuit neither adds nor removes heat, but it improves controllability by maintaining the supply air near saturation. During the winter, in conjunction with a preheat coil, the spray system can be used to control relative humidity, and during all seasons it will remove some of the water-soluble contaminants from the airstream.

Open Spray Systems Open spray systems utilizing cooled or heated spray water to cool, heat, and humidify supply air are now used primarily in industrial applications and in climates which are sufficiently dry that evaporative cooling alone can remove all or much of the sensible heat.

Nontoxic Water Treatment For sprayed coil and open spray systems, nontoxic chemical water treatment is used to inhibit corrosion, control the growth of bacteria and slime, and limit the concentration of solids.

Winter Water-Side Economizers An application that combines spray cooling with chilled water circulation is a water-side economizer system for air-conditioning applications where (1) cooling is required during cold outdoor weather, (2) the use of large quantities of outside air is not economical or otherwise unfeasible, and (3) continuous operation of the refrigeration system during cold weather is expensive.

In the example that is illustrated, with the refrigeration shut down, the building's central cooling tower is operated during the winter to provide water at temperatures approximating those of the chilled water system during normal cooling. A high-efficiency heat exchanger then permits the cooling tower water to cool the chilled water which continues to be circulated through the cooling coils.

The system reduces energy consumption and can substantially reduce the cost of winter cooling. Some of the factors that affect applicability of the system are the cold-weather capacity of the cooling tower; the hours of cold-weather cooling that are required compared with the cold-weather wet-bulb hours that can be anticipated; and how warm the chilled water can be and still satisfy the requirements of the winter cooling loads.

HEAT REJECTION APPARATUS

All the heat removed from a conditioned space and the heat equivalent of the work performed by the refrigeration equipment must be removed through the cooling system and dissipated via the refrigeration condenser. Table 12.4.36 lists approximate refrigeration equipment energy consumption values.

In most systems the heat is rejected to the atmosphere, but in some cases, water-cooled refrigeration condensers are used to transfer the rejected heat to surface water or to well water. Some examples of the most common systems used to transfer rejected heat to the atmosphere are shown in Fig. 12.4.20. The **air-cooled condenser and evaporative condenser** are arranged with the refrigeration condenser in the outdoor airstream. Refrigerant is piped directly with no intervening heat transfer. The **air-cooled condenser** is the simplest arrangement, but the condenser must operate at temperatures sufficiently high so that condensing takes place well above the outdoor ambient dry-bulb temperature. The **evaporative condenser** adds a spray system to permit condensing above the outdoor ambient wet-bulb temperature.

Closed-Circuit Coolers For larger systems and where extensive piping of refrigerant is either not desired or otherwise precluded, a water-cooled condenser is utilized. The rejected heat is transferred to water piped to an outdoor radiator—a closed-circuit dry cooler or evaporatively cooled device. The **closed-circuit dry cooler,** or **radiator,** is a simple indirect cooling arrangement, but can operate at temperatures higher than the air-cooled condenser because of the additional heat-transfer process involved.

Table 12.4.36 Refrigeration Energy Consumption per 12,000 Btu/h Cooling Capacity

Electric consumption, kW/ton cooling capacity		
	Type of heat rejection, kW/ton	
Item	Mechanical-draft cooling tower	Air-cooled condensers
Room-air conditioners		1.2–2.45*
Refrigeration compressors (motor-driven):		
Reciprocating (20 to 100 tons)	1.03–0.86	1.27–1.09
Centrifugal-hermetic	0.94–0.74	
Centrifugal-external drive (350 to 1,250 tons)	1.02–0.81	
Auxiliary equipment:		
Pump, cooling water	0.15	
Blower for air conditioner	0.10	0.10
Blower for rejection air	0.15	0.15
Steam-consumption rate lb/h/ton (kg/h/ton) cooling capacity		
	Steam rate	
Item	lb/h/ton	kg/h/ton
Centrifugal compressors (steam-driven):		
Condensing (27 in vacuum)	14.5	6.6
Noncondensing (14.7 psig)	30–35	13.6–15.9
Absorption chillers (100 to 1,200 ton) (low-pressure steam)	18–18.5	8.2–8.4
Absorption chillers (high-pressure steam)	11–11.5	5–5.2
Gas-consumption rate, Btu/ton (J/ton) cooling capacity		
	Gate rate	
Item	Btu/ton	kJ/ton
Refrigeration compressors (natural-gas-engine-driven)	8,500	8,970

* Depending on the EER (energy efficiency ratio) rating for the different manufacturers.

The dry cooler water circuit operating with antifreeze permits year-round operation.

The **closed-circuit evaporative cooler** has an indirect condenser water circuit, but uses a spray system and evaporative cooling to reduce the head pressure. In both the dry cooler and closed-circuit cooler there is no contact of either condenser water or antifreeze with the outdoor atmosphere; often this proves highly desirable.

Cooling Towers In large systems and systems where maximum overall efficiency is important, a portion of the condenser water is evaporated into the atmosphere to cool the remaining condenser water. The water lost by evaporation must be made up, usually from a domestic water source. Figure 12.4.20 shows two cooling tower configurations. The **counterflow** arrangement requires a spray system and is usually taller than the crossflow type. **Crossflow** towers have simpler gravity distribution systems.

Fig. 12.4.20 Heat rejection equipment. *(Courtesy of E. Revzina.)*

All cooling towers and all evaporative spray systems that operate during subfreezing weather must be protected against freezing. A number of methods are available to add heat to the piping circuits and the basins or sumps.

Condenser Water System For electrically driven refrigeration compressors a temperature differential of 10°F (5.5°C) may be assumed, and for steam-driven equipment a temperature differential of 20°F (11°C) is usual. In the latter case the refrigeration and steam condensers are piped in series with a temperature rise of approximately 10°F (5.5°C) each.

Condenser water, gal/min

$$= \frac{\text{total heat rejected, Btu/h}}{500 \times \text{temperature differential, °F}} \qquad (12.4.26a)$$

In SI units,

Condenser flow, m^3/s

$$= \frac{\text{total heat rejected, kW}}{4{,}190 \times \text{temperature differential, °C}} \qquad (12.4.26b)$$

Atmospheric Evaporative Cooling Equipment The lowest temperature to which water can be cooled in atmospheric cooling equipment is the wet-bulb temperature of the ambient air.

Water-Cooling Effectiveness in Percent

$$E = \frac{\text{(hot-water temp.} - \text{cold-water temp.)} \times 100}{\text{hot-water temp.} - \text{wet-bulb temp. entering}} \qquad (12.4.27)$$

The cold-water temperature must be chosen to place the requirement within the effectiveness range of the equipment used.

Makeup Water for Atmospheric Cooling Equipment Makeup water is introduced to replace losses due to evaporation, drift, and blowdown. If all water were cooled by evaporation, the loss by evaporation for the usual 10°F (5.5°C) cooling range would be:

$$\text{Evaporation, \%} = \frac{Q \times 100}{8.3 \times \text{gal/min} \times \text{hfg}} \qquad (12.4.28a)$$

where Q = total heat rejected. Btu/h; gal/min = total condenser water circulated; and hfg = evaporation heat of water, Btu/lb, at ambient design temperature. In SI units:

$$\text{Evaporation, \%} = \frac{Q' \times 100}{1{,}000 \times m^3/s \times \text{hfg}} \qquad (12.4.28b)$$

where Q' = total heat rejected, kJ/min; m^3/s = total condenser water circulated; and hfg = evaporation heat of water, kJ/kg, at ambient design temperature.

Drift losses depend on the tower design, but generally, from the cooling tower, they are limited to 0.2 percent of the circulated rate.

The makeup water replacing losses due to evaporation, drift, and blowdown introduces dissolved solids into the system.

To prevent excessive concentration, a portion of the circulating water is wasted. The quantity of blowdown depends on the original quantity of dissolved solids in the makeup water and the permissible concentration.

For most open systems, chemical water treatment is used to inhibit corrosion and minimize blowdown.

Water Distribution, Chilled-Water Systems' Temperature Differential Design temperature differentials for chilled-water systems are determined by the need to supply chilled water at an average temperature sufficiently low to provide adequate cooling and dehumidification and the desire to minimize the costs of piping, pumping energy, and refrigeration. These differentials normally range from 10°F (5.6°C) for average systems to as much as 15°F (8.3°C) or more for very large systems with widely separated loads.

Volume flow rate, gal/min

$$= \frac{\text{(total load + piping heat gains + pump heat), Btu/h}}{500 \times \text{temperature differential, °F}} \qquad (12.4.29a)$$

A comparable equation in SI units is

Volume flow rate, m^3/s

$$= \frac{\text{(total load + piping heat gains + pump heat), kW}}{4{,}190 \times \text{temperature differential, °C}} \qquad (12.4.29b)$$

Water Distribution, Chilled-Water Systems Temperature Differential

Application	Temp rise °C	Temp rise °F
Close-coupled system on one floor	5–8	3–4.5
Two- or three-story building	8–11	4.5–6
Multistory building	12–20	6.5–11

Water Piping Design

There is a **friction loss** in any pipe through which water is flowing. This loss depends on the following factors:

1. Water velocity
2. Pipe diameter
3. Interior surface roughness
4. Pipe length

System pressure has no effect on the head loss of the equipment in the system. However, higher than normal system pressures may dictate the use of heavier pipe, fittings, and valves along with specially designed equipment.

To properly design a water piping system, the engineer must evaluate not only the pipe friction loss but the loss through valves, fittings, and other equipment. In addition to these friction losses, the use of diversity in reducing the water quantity and pipe size should be considered in designing the water piping system.

Most air-conditioning applications use either steel pipe or copper tubing in the piping system. For friction loss values in steel pipe or copper tubing, refer to Figs. 12.4.21 to 12.4.23.

Pipe size determination, especially for very long systems and/or unusual construction or operating cost considerations, is based on an economic analysis, but smaller systems with less critical economic factors are often based on average conditions. In a typical system pipe sizes are selected for a pressure loss of from 3 to 6 ft per 100 ft of pipe.

Pipe Length The total friction loss in a water piping system is the sum of losses in:

1. The total straight lengths of pipe
2. The equivalent lengths of pipe due to fittings, valves, and other elements in the piping system.

Figure 12.4.24 shows the resistance of some valves and fittings in terms of equivalent length of straight pipe.

Steam System Piping

Steam systems which operate below 15 psig are classified as low-pressure systems. Tables 12.4.37 and 12.4.38 may be used to determine the size of piping for low-pressure steam and condensate systems pitched in the direction of flow and for risers in which steam and condensate flow in opposite directions.

Table 12.4.39 lists total pressure drop limitations for long-length piping systems. In such systems, pipe sizes may have to be increased to keep total pressure loss in supply and return piping within the system limits. For systems in which pressure may vary, i.e., when steam is supplied by a boiler, the distribution pressure must be based on the minimum pressure that will be available.

Tables 12.4.40 and 12.4.41 are used to size piping for use in medium- and high-pressure systems, respectively, and assume piping is installed with proper pitch and adequate provisions to remove condensate.

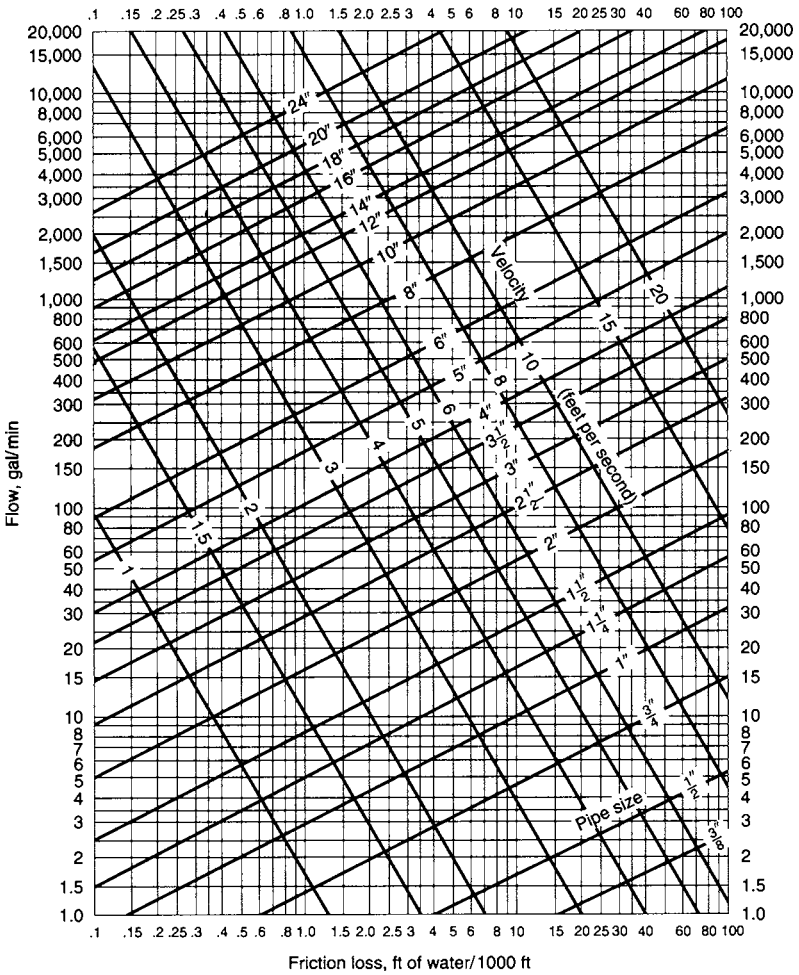

Fig. 12.4.21 Friction loss for open piping systems using schedule 40 pipe.

12.5 ILLUMINATION

by Abraham Abramowitz, Revised by Staff

REFERENCES: Amick, "Fluorescent Lighting Manual," McGraw-Hill. "IESNA Lighting Handbook." Design publications of General Electric Co., North American Philips Co. (successor to Westinghouse Electric Co. Lamp Division), and GTE-Sylvania, and others.

Ordinarily, the term **illumination** encompasses the application of the science (and sometimes the art) of lighting. Electromagnetic radiation in the wavelength range of 380 to 760 nm elicits response in the normal human eye and thereby defines what we know as the visible spectrum. Illumination engineering deals with harnessing sources of lighting into the design of a system to distribute lighting, which will produce an environment enabling us to see.

BASIC UNITS

Candela, cd, is the unit of luminous intensity of a light source. One candela is defined as the luminous intensity in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} Hz (approximately 555 nm) and of which the radiant intensity in that direction is $\frac{1}{683}$ W per steradian (W/sr) (Fig. 12.5.1).

Lumen, lm, is the unit of luminous flux ϕ. It is equal to the flux on a unit surface all points of which are one unit distant from a uniform point source of one candela. Such a point source emits 4π lumens.

Illuminance E is the density of luminous flux on a surface. If the foot is taken as the unit of length and the flux is uniformly distributed over the surface, the density in **lumens per square foot** is called **footcandles, fc;** in SI units **lumens per square metre, lux (lx)**, is used.

Luminance is the luminance intensity of any surface in a given direction per unit of projected area of the surface as viewed from that direction. The unit of luminance is cd/in^2; in SI units cd/m^2 is used.

Absorption, Reflection, and Transmission Incident light flux interacts with a medium by **absorption,** whereby incident light flux is dissipated; by **reflection,** in which the incident light flux leaves a surface or medium from the incident side; by **transmission,** in which incident light flux leaves a surface or medium on a side other than the incident side.

Reflection may occur as from a mirror (specular reflection), or it may be reflected at angles different from that of the incident flux to incident plane (diffuse reflection), or it may be a combination of the two types of reflection.

In transmission, if the light ray is reduced only in intensity, the transmission is called regular; if the light ray emerges in all directions, transmission is called diffuse. Both modes may exist simultaneously.

The incident flux ϕ_i equals the flux absorbed ϕ_a, reflected ϕ_r, and transmitted ϕ_t. That is,

$$\phi_i = \phi_a + \phi_r + \phi_t$$

Dividing this equation by ϕ_i, we obtain

$$1 = \phi_a/\phi_i + \phi_r/\phi_i + \phi_t/\phi_i$$

or

$$1 = \alpha + \rho + \tau$$

α is the *absorptance,* ρ is the *reflectance,* and τ is the *transmittance.* In each case, the incident flux may be restricted to a single wavelength, a particular direction, and a given solid angle. These must be specified.

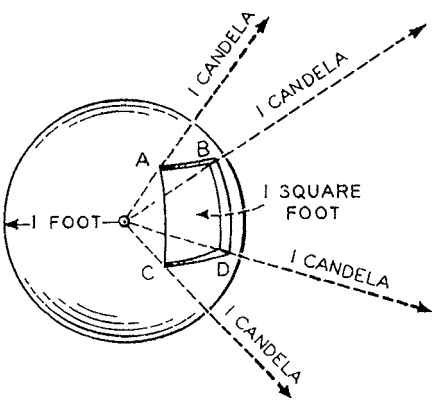

Fig. 12.5.1 Relationship between candela, lumen, and footcandle. [A uniform point source (luminous intensity or candlepower = 1 candela) is shown at the center of a sphere of 1-ft radius. It is assumed that the sphere is perfectly transparent (i.e., has 0 reflectance). The illumination at any point on the sphere is 1 ft · c (1 lumen per square foot). The solid angle subtended by the area *A B C D* is 1 steradian. The flux density is, therefore, 1 lm/sr, which corresponds to a luminous intensity of 1 cd. The sphere has a total area of 12.57 (4π) ft^2, and there is a luminous flux of 1 lm falling on each square foot. Thus the source provides a total of 12.57 lm.]

The **wavelength** of electromagnetic radiation is measured in metres. For the frequencies involved in illumination, the wavelength is given in nanometres, nm, equal to 10^{-9} m.

VISION

Most engineering designs (bridges, structures, roads etc.) are based on strength and are not concerned with the way the human organism reacts. The **response of the eye** is central to illuminating engineering. The **lens** of the **eye** focuses an image on the **retina.** Here a photochemical process takes place which sends nerve impulses to the brain via the optic nerve. The amount of light entering the eye is controlled by the **pupil.** The normal eye automatically accommodates itself to focus on an object, while the pupil adjusts itself to allow for a high or low level of object luminance. The sensors in the eye are known as **rods** and **cones.** The cones are clustered in a small central part of the retina called the **fovea.** They transmit a sharp image to the brain and give color response. Outside the fovea the rods predominate. They give neither a sharp image nor a color response. When the luminance of the visual field is low, as at night, seeing is due to the rods only and is called **scotopic vision.** At higher levels, with the cones primarily involved, seeing is called **photopic vision.** There is an intermediate region called **mesopic vision.**

The response of the eye to colors of different wavelengths is given in Fig. 12.5.2. The **luminous efficacy** (lumen output per radiated watt) is 683 lm/W at the wavelength of maximum photopic response, 555 nm. For white light, radiation which has the characteristic of an equal energy spectrum with all the energy in the visual region, it is approximately 220 lm/W.

Spectral Lumen If the response curve of the eye for photopic vision, versus λ in nanometres, is expressed as $k(\lambda)$, and the spectral power function of the source in watts per nanometre is taken to be $Q_e(\lambda)$, then the luminous flux is given by the equation

$$\phi_{\text{lumens}} = 683 \int_{380}^{780} k(\lambda) Q_e(\lambda)\, d(\lambda) \qquad (12.5.1)$$

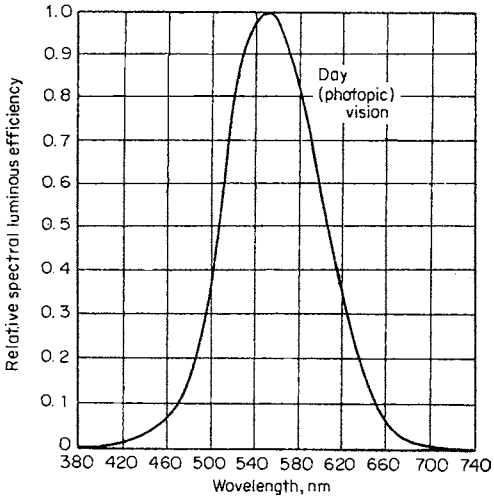

Fig. 12.5.2 Luminous efficiency versus wavelength for photoptic (day) vision.

LIGHT METERS

Early light meters compared the luminance of a diffuse highly reflecting surface with that obtained from a calibrated standard. The most common light meter in use today is similar to a photographic exposure meter. A photovoltaic cell is directly connected to a sensitive microammeter calibrated in footcandles (or dekalux). The best meters (called color-corrected) have a response similar to that of the eye in photopic vision. Special shapes are used on the cover to avoid total reflection of light from the glass surface of the cell. Such meters are said to be cosine law corrected. The microammeter is frequently replaced with an electronic amplifier using an analog or digital readout.

LIGHT SOURCES

The original and still major source of light is the sun. Next came fire, derived from candles, oil, and gas lamps. With the discovery of electricity came arc lamps, gas-discharge lamps, and hot-filament lamps. "Flame" or hot sources give a continuous spectrum. Gas-discharge devices such as sealed neon tubing and mercury-arc lamps give discrete, or line, spectra. The lines may be modified in various ways: by pressure broadening, use of phosphor coatings (to convert ultraviolet radiation into visible light), and using a mixture of gases. The continuous spectra of phosphors have colors which depend upon the mixture used. A light-emitting diode (LED) is a rectifying semiconductor device which can convert electric energy to electromagnetic radiation ranging from the near-ultraviolet to the near-infrared, i.e., from 400 to over 1,500 nm. They are extremely attractive because they are very energy-efficient, produce negligible heat, and contain no filament—and are thus highly resistant to breaking from shock, vibration, and temperature extremes. They can be inserted in standard sockets, including incandescent-type screw bases. For special applications, they can be configured as required. A major use is in display lighting or in indicators (traffic signals, panel backlighting, etc.), but they have begun to find favor as long-life energy-efficient substitutions for incandescent lighting. At this time (2005) the initial cost is quite high, but prices will probably decline as their use becomes more widespread.

Color Temperature and Luminance

In general, three quantities are required to specify the color of a light and its luminous level. However, an approximate designation is used by specifying the temperature of a hot (black-body) emitter whose color almost matches that of the light. The **color temperature** of daylight is about 6,000 K and that of tungsten lamps about 2,300 to 3,300 K.

Lamps

Electric lamps are the principal source of artificial light in common use. They convert electrical energy into light or radiant energy.

An **incandescent-filament lamp** contains a filament which is heated by the current passing through it. The filament is enclosed in a glass bulb which has a base suitable to connect the lamp to an electrical socket. To prevent oxidation of the filament at elevated temperature, the bulb is evacuated of air or filled with an inert gas. The bulb also serves to control the light from the incandescent filament, which is essentially a point source. High luminance of the source is typically reduced by acid etching to frost the inside surface of the bulb. Silica coating will also provide additional diffusion and can alter the color of the light emitted. Portions of the bulb's interior can be covered with reflecting material to give a predetermined direction to the emitted light. Chemical tinting of clear glass bulbs provides a variety of colors. Whenever the color that is normally produced by an incandescent filament is changed, the filtering process removes from the radiated light the energy of all wavelengths except those necessary to produce the desired color. This subtractive method of color alteration is less efficacious than the generation of light of varying colors by gaseous discharge.

Sizes and **shapes** of lamp bulbs are designated by a letter code followed by a numeral; the letter indicates the shape (Fig. 12.5.3), and the number indicates the diameter of the bulb in eighths of an inch. Thus a T-12 lamp has a tubular shape and is 1⅛ or 1½ in in diameter.

Fig. 12.5.3 Typical filament lamp shapes: S, straight; F, flame; G, globe; A, general service; T, tubular; PS, pear shape; PAR, parabolic; R, reflector.

Incandescent lamps are available with several **types of bases** (Fig. 12.5.4). Most general-service lamps have medium screw bases; larger or smaller screw bases are used depending on lamp wattage. Bipost and prefocus bases accurately position the filament, as in optical projection systems. Bipost lamps also serve where ruggedness and greater heat dissipation are required.

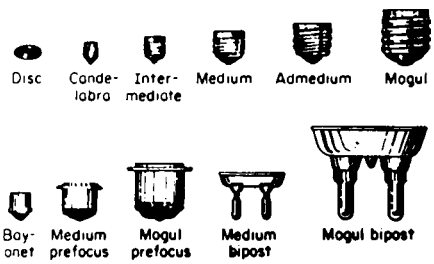

Fig. 12.5.4 Typical incandescent lamp bases.

Incandescent-lamp filaments are generally constructed of tungsten. Tungsten has a high melting point and a low vapor pressure, which permits high operating temperatures without evaporation: the higher the operating temperature, the higher the efficacy (lumens per watt) and the shorter the life. Filament evaporation throughout the life of the lamp causes blackening of the bulb and thinning of the filament with consequent lower light output. Argon-nitrogen gas filling reduces the rate of evaporation.

Tungsten filaments are also placed in compact quartz tubes filled with a halogen atmosphere where the tungsten halide lighting source continuously returns evaporated tungsten particles to the filament. The inside walls do not blacken, and light output remains fairly constant throughout the life of the lamp.

For exposed illuminated outdoor lamp signs, **gas-filled incandescent lamps** are often used, especially when high-speed animation is to be depicted by the on-off sequencing of the lamps. The lamp envelope is filled with a gas which enhances the speed with which the filament is heated and cooled. The very fast quenching of the filament without the usual decay trail of light permits a sharply defined illusion of motion.

A **fluorescent lamp** consists of a glass tube coated on the inside with phosphor powders which fluoresce when excited by ultraviolet light; filament electrodes are mounted in end seals connected to base pins (Fig. 12.5.5). The tube is filled with rare gases (such as argon, neon, or krypton) and a drop of mercury (Fig. 12.5.6), and operates at a relatively

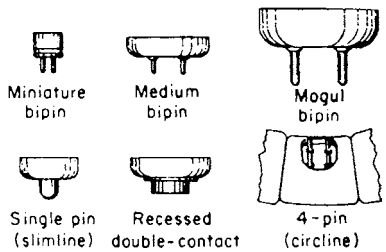

Fig. 12.5.5 Fluorescent lamp bases.

low pressure. In operation, electrons are emitted from the hot electrodes. These electrons are accelerated by the voltage across the tube until they collide with mercury atoms, causing them to be ionized and excited. When the mercury atom returns to its normal state, mercury spectral lines in both the visible and the ultraviolet region are generated. The low pressure enhances ultraviolet radiation. The ultraviolet radiation excites the phosphor coating to luminance. The resulting light output is not only much higher than that obtained from the mercury lines alone but also results in a continuous spectrum with colors dependent upon the phosphors used.

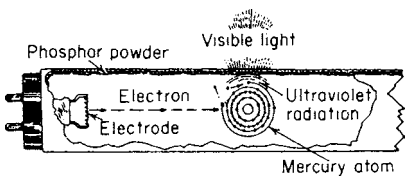

Fig. 12.5.6 Fluorescent lamp operation. *(Westinghouse.)*

As with all gas-discharge devices, these lamps have negative voltampere characteristics. Unless the voltage difference between the applied voltage and the lamp operating voltage is absorbed in some way, damaging currents will result. A reactor is used in series with the lamp. It may be capacitive or inductive. The supply voltage should be at least twice the lamp operating voltage. Where this is not the case, the supply voltage (up to 277 V is used) is stepped up by an autotransformer. The necessary reactance is frequently part of the transformer leakage inductance.

For starting purposes, voltages higher than twice lamp operating voltages may be used. For minimum line current a power-factor-correcting capacitor is used and assembled with the autotransformer. A capacitor is put across the lamp to reduce radio-frequency interference with nearby radio receivers. All these elements are placed inside a case filled with a potting compound. The assembly is called a **ballast.** The object of the compound is to reduce noise from the core lamination vibrations and to

improve heat dissipation. Built-in thermal protectors, which deenergize the ballast when dangerous temperatures are reached, are now required in the United States. Ballast manufacturers rate their units by noise levels. Some ballasts use solid-state, high-frequency generators.

To start a fluorescent lamp, electron emission from the electrodes must be induced. Two methods are generally employed: (1) the filament electrodes are heated by passing current through them; (2) a high voltage, sufficient to start an electric discharge in the lamp, is applied across it. Once a discharge starts, mercury-ion bombardment keeps the filaments at a hot electron-emitting temperature. Lamps are designed for either type of operation. The first group is further divided into preheat lamps and rapid-start lamps. Some lamps can be used for both types of circuits. The lamp current is carried primarily by electrons emitted from the filaments. The end or weakening of electron emission is an important cause of the end of lamp life.

Preheat circuits contain starters which are really switches, closed when power is first applied, permitting current to flow and preheat the electrodes. After a predetermined period of time, the starter switch opens, throwing a potential across the lamp which starts the discharge. Lamps used for preheat circuits have bipin bases (Fig. 12.5.5).

Instant-start circuits have ballasts which apply sufficient voltage across the lamp to induce current flow without preheating the electrodes. **Slimline lamps** are the principal instant-start type. They have single-pin bases because no preheating is required, are available in sizes up to 8 ft in length, and can have varying lumen outputs depending upon the ballast current rating and wattage. Because of their high starting voltage, they generally employ spring-loaded push-pull lampholders which disconnect the ballast circuit unless the lamps are properly seated in position.

Instant-start lamps are sometimes available with bipin bases similar to those used in preheat lamps. In these instances the lead wires from the pins are connected together inside the lamp. These lamps, marked "instant start," are not interchangeable with rapid-start equipment. Cold-cathode lamps employ the instant-start principle, have cylindrical iron electrodes, and tend to be less efficacious at shorter lengths because of high wattage losses at the electrodes. They are limited to low current densities because the electrodes operate at temperatures below that necessary for thermionic emission. Cold-cathode lamps, whose operation is not affected by dimming or flashing, have long life and are generally used for custom-built shapes and patterns that require bending, such as for electric signs.

Rapid-start circuit ballasts have separate windings for the electrodes which are immediately and continuously heated when the circuit is energized. This rapid heating causes sufficient ionization in the lamp for a discharge to start from the voltage of the main ballast windings. Two-lamp rapid-start ballasts are of the series sequence type, in which the lamps start in sequence and, when fully lighted, operate in series.

A new type **screw-in fluorescent lamp** with built-in ballast can be used in a standard medium-screw socket. These lamps consume less power than incandescent lamps for the same luminance; accordingly, albeit their first cost is significantly higher, they are expected to prove to be more economical by virtue of their reduced power consumption and much longer life. A significant number of them have made way into household and commercial use.

Fluorescent lamps used in low-ambient-temperature applications, as in outdoor signs, are of the **high-output (HO)** type, and require special high-output ballasts to permit the lamps to maintain their luminance at lower operating temperatures.

High-intensity-discharge lamps consist of tubes in which electric arcs in a variety of materials are produced. Outer glass jackets provide thermal insulation in order to maintain the arc tube temperature. The temperature and amount of material is controlled so that the discharge operates in a vapor pressure of several atmospheres. This results in enhancing the radiation in the visible region.

Mercury-vapor lamps consist of mercury-argon-filled quartz tubes surrounded by a nitrogen-filled glass jacket. Clear lamps radiate the visible mercury lines (bluish green). Ultraviolet radiation is absorbed to some extent by the outer jackets. The color of the light and the lumen output is improved by coating the inside of the outer jackets with a phosphor. When excited by the ultraviolet radiation of the arc, the phosphors add light in the red part of the spectrum to the output. The resulting lamps are called white, color improved, or deluxe white. The lamps start by a discharge in argon between an electrode and a starting electrode (see Fig. 12.5.7). As the mercury vaporizes, the pressure builds up and the discharge transfers to a mercury discharge. This takes several minutes. After shutdown, the lamps cannot be restarted until the inner tube pressure drops so that an argon discharge can start.

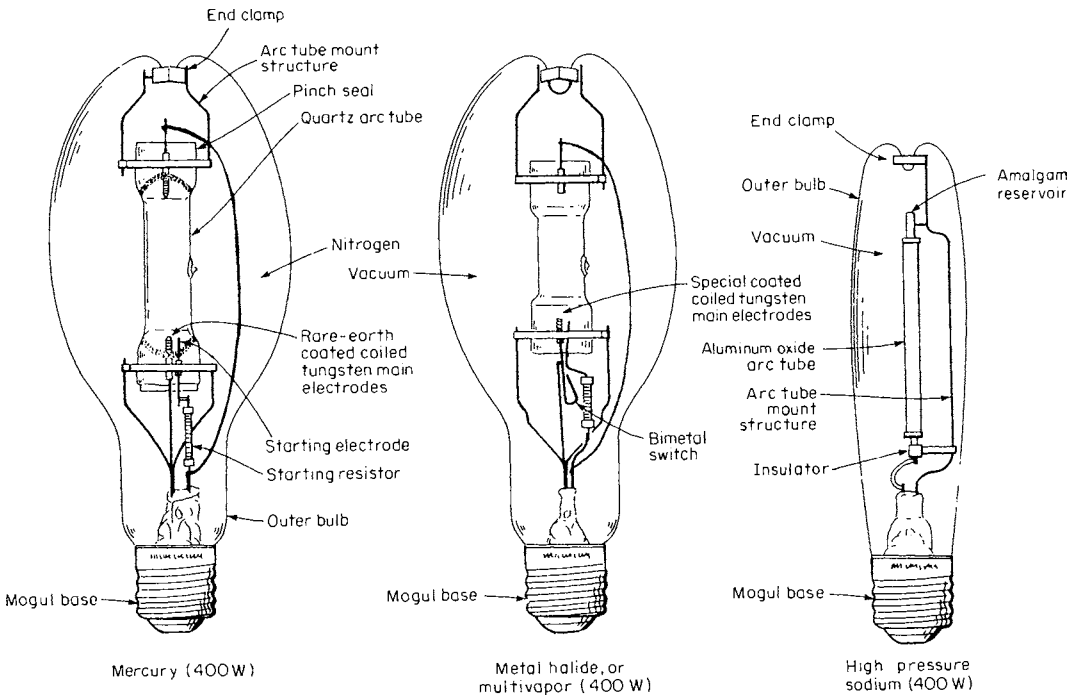

Fig. 12.5.7 High-output lamps. *(GE.)*

Metal halide (multivapor) lamps use small quantities of sodium, thallium, scandium, dysprosium, and indium iodides in addition to the usual mercury-argon mix. Color is improved and output substantially increased over high-intensity-discharge lamps using mercury alone. While the construction is similar to mercury lamps, a bimetal switch is built into the lamp to short out the starting resistor after the lamps start. A vacuum jacket is used around the quartz discharge tube (see Fig. 12.5.7).

High-pressure sodium-vapor lamps use metallic sodium sealed in translucent aluminum oxide tubes. This material is used to withstand the corrosive effect of hot sodium vapor. For starting purposes a xenon fill gas and a sodium-mercury amalgam is used. Arc temperatures are maintained by an outer vacuum jacket. The lamp is started by generating a high-voltage pulse for about a microsecond (see Fig. 12.5.7).

High-pressure discharge lamps, like fluorescent lamps, require ballasts. These provide the necessary voltage, reactances, and power-factor-correcting capacitors.

Comparative lamp efficacies (lm/w) range from about 8 for tungsten incandescent to about 140 for high-pressure sodium.

Luminaires

Luminaires are generally categorized as **industrial, commercial,** or **residential.** Use within these categories usually determines the quality and ruggedness of materials of construction. Generally speaking, style, ornament, and in most cases low cost are prime considerations for residential fixtures. Industrial fixtures require low maintenance, low operating cost, efficiency, and durability. Commercial fixtures combine the elements of all of these and place heavy emphasis on visual comfort.

Luminaires are classified by the International Commission on Illumination (ICI) in accordance with the percentages of total luminaire output emitted above and below the horizontal (Fig. 12.5.8). Industrial fixtures usually are direct or semidirect.

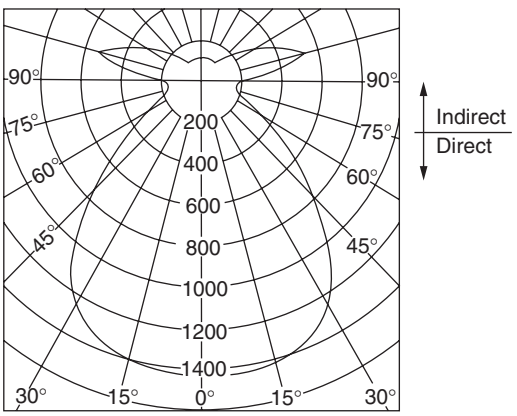

Fig. 12.5.8 Hypothetical light distribution curve for a luminaire providing both direct (below horizontal) and indirect (above horizontal) lighting. Manufacturers' literature provides such data in great detail for their lines of luminaires.

Luminaires control the source of light so that it can be better used for a given seeing task. Materials used in luminaires are designed to reflect, refract, diffuse, or obscure light.

Reflectors are commonly made of specular alzak aluminum, glass, baked-enamel steel, and porcelain-enamel steel.

Lenses with prismatic patterns refract light sources to disperse the rays or to direct them most effectively. Lenses are of glass, acrylic plastic (Plexiglas), or polystyrene. **Glass** is generally superior for incandescent fixtures because of its heat resistance. Fluorescent lamps with **acrylic** lenses have a life at least twice that of **polystyrene** because of their color stability. **Translucent** glass and plastic are used in bottom lenses, louvers, and side panels to diffuse light and to obscure light sources. Baked-enamel steel **louvers,** in egg-crate, concentric ring, or cellular configurations are widely used to shield light sources from normal viewing angles.

Fixture bodies, trims, and lens frames are commonly constructed of steel, electrogalvanized, and/or treated with a rust-inhibiting coating, and painted with several coats of baked enamel. Stamped, spun, cast, and die cast aluminum are also used.

Figure 12.5.9 shows two typical luminaires. Manufacturers' literature will provide complete details and light distribution curves for lighting design. The variety of luminaires available is large and quite diverse, offering the designer a large range of options.

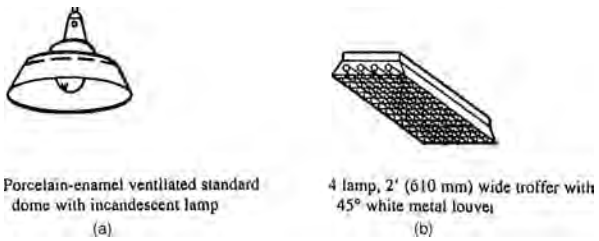

Fig. 12.5.9 Two typical luminaires. (*a*) With incandescent lamp; (*b*) with fluorescent lamps and metal louver.

PRESCRIBING ILLUMINATION

The object of a **lighting design** is to provide sufficient illuminance for a given seeing task without introducing discomfort. Sufficient light is not difficult to obtain with modern light sources, but unless properly placed and controlled, uncomfortable, glaring light will result.

A given task has a size, luminance contrast, luminance, and color. The luminance of a perfectly diffusing reflecting surface is given by

$$L = E\rho \tag{12.5.2}$$

where E is illuminance in footcandles, ρ its reflectance (ratio of reflected light flux to incident flux), and luminance L is in footlamberts. The contrast C between two adjacent areas is given by

$$C = (L_b - L_o)/L_b \tag{12.5.3}$$

where L_b is the luminance of the larger or background area and L_o is the object or task luminance for a given illuminance E. Substituting Eq. (12.5.2) into Eq. (12.5.3),

$$C = \frac{E\rho_b - E\rho_o}{E\rho_b} = \frac{\rho_b - \rho_o}{\rho_b} \tag{12.5.4}$$

Thus, contrast is basically a function of the task-to-background reflectance. Most surfaces are not perfectly diffuse and require the use of the luminance factor β (ratio of actual luminance for a given viewing angle to the illumination under actual conditions) instead of ρ. The contrast which can just be seen or detected (minimum perceptible contrast) is a function of background luminance for a given task.

Unfortunately most visual tasks are performed on mirrorlike (specular) or semimirrorlike surfaces. This results in reducing the work contrast. Where a highly luminous object such as an incandescent-lamp filament is reflected from a polished surface, "reflected glare" results. Reflections of a large luminous area by matte or semimatte material results in "veiling glare." For work on a horizontal surface, the line of sight from the eye for most people is from 0 to 40° from the vertical, with a peak angle of about 25°. If light from the source is directly reflected into the eyes, contrast and resulting visibility are greatly reduced. When a highly luminous source is directly reflected into the eye, it is possible to completely obliterate a task. Veiling reflections are controlled by proper luminaire design and placement of fixtures. Some designs keep flux out of the 0 to 40° zone. As far as possible the work area should have a matte surface without shining details, and light should come from the side or behind the worker.

In addition to veiling reflectance, there is a reduction in contrast due to light directly entering the eye from the source. This is called the disability glare effect. It produces a light veil over the image of the task on the retina. It is not a serious problem in interior lighting, but it is important in roadway lighting and similar situations.

Visual-Comfort Criteria High luminances directly or reflected in the field of view can cause discomfort without necessarily interfering with seeing even though visual performance may be impaired. This discomfort glare can be caused by direct glare from sources which have too high a luminance, are inadequately shielded, or have too great an area. Lighting systems are rated by a **visual-comfort probability (VCP),** expressed as a percentage of people who, if seated in the most undesirable location, will be expected to find it acceptable. (For a complete description of VCP, see the IESNA Handbook.) If the following conditions are met, direct glare will not be a problem in lighting installations:

1. The VCP is 70 or more.
2. The ratio of maximum-to-average luminaire luminance does not exceed 5 : 1 (preferably 3 : 1) at 45, 55, 65, 75, and 85° from the nadir crosswise and lengthwise.
3. Maximum luminaire luminances crosswise and lengthwise do not exceed the following values:

Angle above nadir, deg	*Maximum luminance*	
	cd/m²	*fL*
45	7,710	2,250
55	5,500	1,605
65	3,860	1,125
75	2,570	750
85	1,695	495

Design of Interior Lighting Systems

Lighting is as much an art as a science. While many studies have been made on what constitutes adequate lighting along with proper quality, the effect to be achieved depends upon the designer. In this section emphasis will be primarily on achieving adequate illumination.

The design approach is to consider the space to be lighted and the task to be performed. An illuminance is then selected. A suitable luminaire is picked, and calculations are made in order to determine the number and layout of the fixtures. The overall quality is then checked. If unsatisfactory, a new layout is made. An economic study is made to check costs. If these are too high, new layouts are studied until all design restraints are met.

Selection of Illuminance Levels

An illuminance level guide for selected tasks is given in Table 12.5.1. The data are based on an assumption of average conditions for people, tasks, and visual performance requirements. (For other conditions see the "IESNA Lighting Handbook.")

Room, Furniture, and Equipment Finishes

The color and finish of rooms, furniture, and equipment are important in the overall lighting design. Best results are obtained when the lighting designer coordinates his or her work with the architect, interior decorator, or plant designer.

A color scheme should be selected to give light reflectance values as follows:

Area or unit	Percent reflectance
Ceilings	70–90
Floors	20–40*
Walls, draperies	40–60†
Bench top, desks, machine, and equipment	25–45

* In storage areas, keep reflectance of aisle floors as high as possible in order to reflect light onto the lower shelves. This should also be done where the underside of objects has to be seen.

† These values should be 30 to 40 where video display terminals (VDTs) are used to avoid veiling reflections in the VDT faces.

The color and finish of a space and equipment therein set the psychological feel of the space. For example, the trend is away from drab finishes on machinery and dark gray filing cabinets. Colors such as yellow, orange, red, and light gray seem to advance toward the eye. They tend to make large spaces feel smaller. Receding colors such as violet, blue, blue green, and dark grays make small spaces feel larger. Some colors are

used for safety purposes. Various areas are painted to designate safe or hazardous locations in a fashion similar to piping identification discussed in Sec. 8. These colors have been carefully standardized in ANSI Z53.1.

Designating Color

In order to be able to obtain designed values of a lighting system, it is necessary to be able to specify the exact color wanted. Many methods have been devised for so doing. One method uses carefully controlled sets of colored chips, each one of which has a particular designation. The desired color is matched against these chips. The **Munsell system** uses *scales of hue* (the actual basic color such as red), *value* (a 10-step scale ranging from black through grays to white), and *chroma* (the amount of gray mixed in with the color). This system is used by many manufacturers to designate their colors. The **Ostwald system** describes color in terms of *color content, white content,* and *black content.* The **Inter-Society Color Council-National Bureau of Standards** (now NIST) (ISCC-NBS) **method** designates one-inch square samples with names. For color designation by the **ICI method,** a spectroradiometric curve of the source is determined together with a spectrophotometric curve of the reflecting or transmitting surface. By mathematical manipulation using spectral tristimulus values, chromaticity coordinates are obtained. See the IESNA Handbook for details. Chromaticity coordinates are extensively used for fluorescent lamp colors. These coordinates can be measured directly by photoelectric colorimeters. They are designed with filter photocell responses to be close to each of the ICI tristimulus values. Built-in logic circuitry results in direct reading of the chromaticity. Incandescent and vapor-type lamp colors are specified by color temperature.

LIGHTING DESIGN

Interior lighting is designed by the **lumen** method. This takes into account the interreflections of light inside a room. The average illuminance on the work plane equals the incident luminous flux ϕ divided by the area, or $E = \phi/A$. Lumens reaching the work plane is equal to lamp lumens multiplied by the **coefficient of utilization** CU. This factor is a function of room size, shape, and finish, mounting height of fixture, and type of luminaire used. The lumens ϕ_L initially available from the lamps may be reduced by ambient temperature, lower voltage, and the ballast used. As time goes by the room surfaces and luminaires become dirty, which further reduces the illuminance. In addition, lamp output falls, and some of them burn out. The total effect of all these factors is expressed by the *light-loss factor* LLF. The maintained illuminance E_m is the initial illumination times the LLF, or

$$E_m = (\phi_L \times \text{CU} \times \text{LLF})/A \qquad (12.5.5)$$

The required maintained illuminance is selected from Table 12.5.1 or from the more extensive data in the IESNA Handbook. A fixture and lamp is selected, and Eq. (12.5.5) is solved for the necessary lamp flux ϕ_L. The number of luminaires N is found by dividing the total lamp lumens ϕ_L by the lumens per fixture ϕ_F. A trial layout is then made. A simple layout keeps spacing between units equal to twice the distance between fixtures and wall. Spacing is checked against the maximum allowable luminaire spacing from manufacturers' data to ensure uniform illumination. However, this criterion results in inadequate lighting near the walls. In order to light desks and benches along the walls, a spacing of 2½ ft from the luminaire center to the wall is used. The ends of fluorescent luminaire rows should be 6 to 12 in from the walls with a maximum distance of 2 ft.

Wall and ceiling cavity luminances can be obtained by using luminance coefficients (LC) for the fixtures (see manufacturers' literature). For interior areas, maximum luminance ratios should be 3 : 1 or 1 : 3 between tasks and immediate surround, and 10 : 1 or 1 : 10 between tasks and remote surfaces. To ensure eye comfort, the visual-comfort probability is investigated.

The **coefficient of utilization** is found by using the **zonal-cavity** method. In this method effects of the room proportion, luminaire suspension lengths, and work-plane height on the CU are found by dividing the room into three cavities as shown in Fig. 12.5.10. For each cavity a cavity ratio is calculated:

$$\text{Cavity ratio} = \frac{5h(\text{room length} + \text{room width})}{(\text{room length}) \times (\text{room width})} \qquad (12.5.6)$$

where $h = h_{RC}$ for the room cavity ratio RCR; $= h_{CC}$ for the ceiling cavity ratio CCR; and $= h_{FC}$ for the floor cavity ratio FCR.

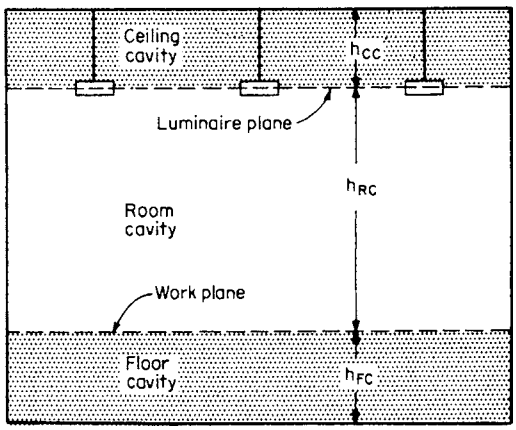

Fig. 12.5.10 The three cavities used in the zonal cavity method.

Supplemental tables for use of RCR, CCR, and FCR, together with a detailed description of the procedure to follow when applying the lumen method, are found in the IESNA Handbook.

While the lumen method is the accepted procedure for calculating interior lighting levels, it is often necessary to have a quick approximation of the quantity of lighting equipment needed to satisfy an illumination-level specification. There are several rules of thumb which serve that purpose.

Spacing Method Table 12.5.2 indicates approximate *base*-maintained footcandle levels according to fixture spacing. For levels other than the base quantity, the level is changed inversely and proportionally to a change in spacing—i.e., doubling the spacing (in one direction) halves the level; halving the spacing doubles the level. Doubling the spacing in both directions reduces the level to one-fourth.

Lumens-per-Square-Foot Method See footnote for Table 12.5.3.

Less accurate than the previous method, this one permits a fairly reasonable calculation by using the lamp lumens as given in the GE Lamp Catalog and substituting in the formula:

$$\text{Footcandle} = \frac{\text{total lamp lumens per fixture}}{2 \times \text{area per fixture}}$$

Or, for a given footcandle level, transposing the formula to determine area per fixture:

$$\text{Area per fixture} = \frac{\text{total lamp lumens per fixture}}{2 \times \text{footcandles}}$$

The 2 in the denominator assumes loss of half the lumens in fixture utilization, lamp depreciation and dirt accumulation. *(Source: General Electric.)*

Watts-per-Square-Foot Method Table 12.5.3 shows another way to arrive at a quick approximation.

Point Method of Design

If uniformity of lighting is to be investigated, or if outdoor lighting is to be designed, the point method is used. Manufacturers furnish candlepower distribution curves for their fixtures. An average curve is given for symmetrical fixtures while curves in various planes are given for asymmetrical ones. The basic equation for calculating the illumination from such curves is

$$E_h = (I_\theta \cos \theta)/D^2 = I_\theta H/D^3 \qquad (12.5.7)$$

Table 12.5.2 Approximate Footcandle Levels According to Fixture Spacing*

Lighting system		Spacings†				
Lamp	Watts	10 × 10 ft	15 × 15 ft	20 × 20 ft	25 × 25 ft	30 × 30 ft
Lucalox	70	35	15	10	—	—
	100	55	25	15	10	—
	150	95	45	25	15	10
	250	180	80	45	30	20

Table 12.5.3 Watts-per-Square-Foot Method*
A convenient, popular, quick approximation

Lamp	Per 100 fc
Lucalox	1.6 W/ft^2
Multivapor	2.5 W/ft^2
Fluorescent	3.0 W/ft^2
Mercury-vapor	3.5 W/ft^2
Incandescent (reflector lamp)	8.5 W/ft^2

* Both Table 12.5.2 and lumen-per-square-foot method are based upon *large* industrial areas, where room width (W) is six times the fixture mounting height (MH). For medium-sized areas (where W = 3MH), reduce footcandles and increase wattage 15 percent. For small areas (where W = MH), reduce footcandles and increase wattage 50 percent. Lucalox fixtures and incandescent reflector lamps tend to be more efficient and have higher lumen-maintenance characteristics; thus, for these sources increase the footcandle value about 25 percent.

where E_h is the illumination on the horizontal plane, I_θ the candlepower in the given direction, and D the distance of the luminaire to the point P. See Fig. 12.5.11.

$$E_v = (I_\theta \sin \theta)D^2 = I_\theta R/D^3$$

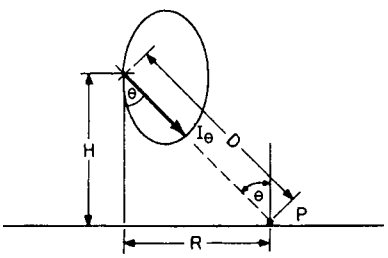

Fig. 12.5.11 Footcandle calculation diagram.

For vertical surfaces

$$E_v = (I_\theta \sin \theta)D^2 = I_\theta R/D^3 \qquad (12.5.8)$$

Nomograms and graphical solutions are available for Eqs. (12.5.7) and (12.5.8).

THE ECONOMICS OF LIGHTING INSTALLATIONS

The cost of lighting is computed by summing the annual cost of energy; relamping; cost of labor for cleaning, relamping, and servicing; interest; and depreciation.

Different lighting systems can be evaluated by comparing the costs per million lumen hours per luminaire. This is given by Eq. (12.5.9),

$$U = \frac{10}{Q \times D}\left(\frac{P + h}{L} + W \times R + \frac{F + M}{H}\right) \qquad (12.5.9)$$

where U = unit cost of light in dollars per million lumen-hours; Q = mean lamp lumens; D = luminaire dirt depreciation (average between cleanings); P = price of lamp in cents; h = cost (in cents) to replace one lamp; L = average rated lamp life in thousands of hours; W = mean luminaire input watts (lamps plus ballast); R = energy cost in cents per kilowatthour; F = fixed or owning costs in cents per luminaire-year; M = cleaning costs in cents per luminaire-year; and H = annual hours of operation in thousands of hours.

In the above equations the area can be expressed in square metres. These equations are general and basic. With the advent of energy conservation, it has become important to use electric power effectively and efficiently. The IES, in its 1981 Handbook, established a watts per square foot (square metre) for various occupancies, called a *base unit power density* (UPD). These values are used to establish a power limit for a facility. For this purpose approximate values are used for CU, lamp plus ballast, lumens per watt, and LLF. For LLF, 0.7 is used.

Another way to compare installations is to compute the watts per square foot for each proposed installation. This is computed by either method:

$$\text{Watts/ft}^2 = \frac{\text{total lamp lumens}}{\text{area, ft}^2} \times \frac{1}{\text{lumens/watt of lamp and ballast}} \qquad (12.5.10)$$

$$\text{Watts/ft}^2 = \frac{\text{designed illuminance}}{\text{CU} \times \text{LLF}} \times \frac{1}{\text{lumens/watt of lamp and ballast}} \qquad (12.5.11)$$

Typical values are shown in Table 12.5.3.

DIMMING SYSTEMS

Dimming systems are used in theaters, auditoriums, ballrooms, etc. Originally, power-consuming rheostats were used. These have been replaced by continuously variable autotransformers, variable reactors,

silicon controlled rectifiers (SCRs) and triacs. The development of controlled solid-state devices has resulted in small, reliable dimmers which can be readily programmed. Only incandescent and cold-cathode lamps can be dimmed easily. Fluorescent lamps require special ballasts which keep the electrodes hot at all times. Dimmers have been developed for high-intensity discharge (H.I.D.) lamps.

HEAT FROM LIGHTING

Lighting installations are a substantial source of heat, have long been a factor in the design of air-conditioning (cooling) systems, and are increasingly significant in the design of heating systems. The heating effect for 1 W is 3.413 Btu/h. Approximate wattage data for lighting systems at various lighting levels can be calculated by using watts per-square foot calculated from Eq. (12.5.10) or (12.5.11). Heat generated is delivered to surrounding areas in several ways, with energy distribution for fluorescent and incandescent lamps as illustrated in Fig. 12.5.12.

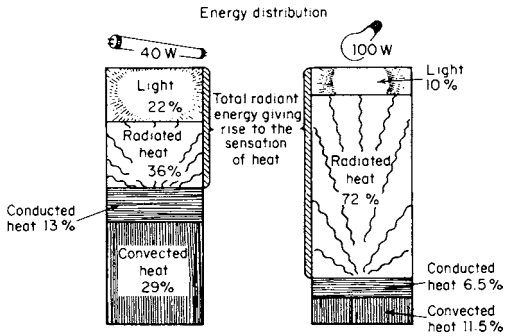

Fig. 12.5.12 Energy distribution of lamps.

With the prevalent high lighting intensities of modern buildings, it is essential to control the heat generated by a lighting system. Substantial portions of the energy which is not radiated into the room may be conducted away from the luminaire by an air stream or by water flowing through a coil attached to the luminaire. In the heating season, this heat energy is delivered to the perimeter of the building for effective space warming. In the cooling season, the heat is rejected to the exterior, thus reducing the load on the cooling system. Air-handling luminaires (Fig. 12.5.13) have been used for this purpose.

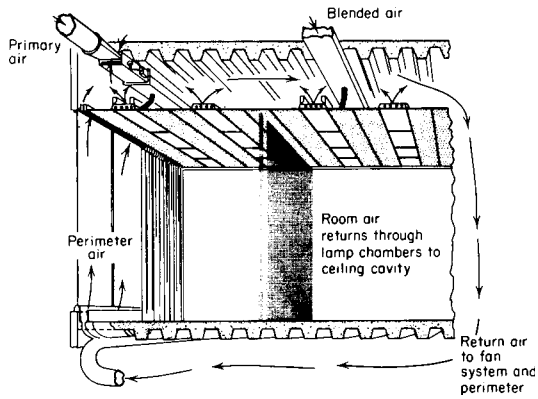

Fig. 12.5.13 Typical air handling system. *(Barber-Colman.)*

12.6 SOUND, NOISE, AND ULTRASONICS

by Robin O. Cleveland, Benjamin C. Davenny, and Jonathan D. Kemp

REFERENCES: Kinsler, et al., "Fundamentals of Acoustics," Wiley, 1982. Harris, "Noise Control in Buildings," INCE, 1997. Beranek and Ver, "Noise and Vibration Control Engineering," 1992. "2003 ASHRAE Handbook—HVAC Application," Chap. 47, Sound and Vibration Control, 2003.

SOUND

An **acoustic wave,** or a **sound wave,** is a mechanical disturbance of particles in a fluid from an equilibrium state which propagates as a wave through the medium with a speed of sound that depends on the properties of the fluid. In fluids the waves are longitudinal; i.e., the motion of the disturbed particles is in the direction of the wave propagation. Typical acoustic sources, such as audio speakers, vibrate backward and forward, generating sound waves consisting of compressional phases and rarefractional phases. The pressure, density, and particle velocity of the fluid are all affected by the passage of the wave. Similar waves exist in elastic solids, but in this case, two types of waves can propagate: **longitudinal waves** and **shear** (or **transverse**) **waves** in which the particle motion is transverse to the direction of propagation. Here, acoustic waves will refer to waves in fluids (liquids or gases) and elastic waves to those in elastic solids.

The **sound speed** c_0 is a material property, and for gases it is given by $c_0 = \sqrt{\gamma RT}$, where γ is the ratio of specific heats (1.4 for diatomic gases such as air), R is the gas constant [287 J/(kg · K) for air], and T is the absolute temperature. For air at 20°C (293 K) it is about 343 m/s (1,125 ft/s). For liquids the expressions are more involved (see, e.g., Lovett, *Jour. Acoust. Soc. Am.*, **45;** 1969, pp. 1051–1053), and an approximate value for water at room temperature is 1,500 m/s (4,920 ft/s). (See Table 12.6.1.)

Acoustic waves vary in space and time, and the relationship between the temporal separation of points on an acoustic wave (Δt) and the spatial separation of the points (Δx) is the sound speed: $\Delta x = \Delta t\, c_0$. For a sinusoidal wave the spatial extent of one cycle of the wave is called the **wavelength** λ and the concomitant temporal extent the **period** T.

Table 12.6.1 Density and Sound Speed in Selected Materials

	Density		Velocity	
Material	SI unit, kg/m^3	USCS unit, lbf/ft^3	SI unit, m/s	USCS unit, ft/s
Steel	7,700	481	6,100	20,013
Aluminum	2,700	169	6,300	20,669
Concrete	2,600	162	3,100	10,171
Glass	2,300	144	5,600	18,373
Brick	2,000	125	3,650	11,975
Lucite	1,200	75	2,650	8,694
Water	1,000	62	1,500	4,921
Pine	450	28	3,500	11,483
Cork	240	15	500	1,640
Air	1.21	0.0755	343	1,125

The frequency of the sound is $f = 1/T = c_0/\lambda$ and is measured in hertz (Hz). In older texts the units may be stated as cycles per second (cps). Acoustic waveforms may be sinusoidal in shape, but most often are not. However, the use of Fourier analysis allows any acoustic wave to be represented by a combination of different frequencies. The **audible frequency range** is normally said to extend from 20 Hz to 20 kHz, although for frequencies above 10 kHz the sensitivity of the ear decreases dramatically. As an individual gets older, the upper frequency limit becomes progressively lower. Sound with frequencies less than 20 Hz is referred to as **infrasound,** and sound with frequencies above 20 kHz is referred to as **ultrasound.** (See Table 12.6.2.)

Table 12.6.2 Acoustic Spectrum

Lower range of elephant hearing	5 Hz
Infrasound/sound transition	20 Hz
Lowest note on a piano	27 Hz
E string on a bass guitar	41.3 Hz
Dominant frequency of thunder	100 Hz
Middle C	261.63 Hz
Upper limit of telephone bandwidth	3,400 Hz
Highest note on a piano	4,096 Hz
Sound/ultrasound transition	20 kHz
Upper range of bat sonar	100 kHz
Upper range of dolphin sonar	200 kHz

The density and sound speed of a material determine its **specific acoustic impedance** $Z_0 = \rho_0 c_0$. This term is often shortened to **acoustic impedance** or just **impedance.** The impedance of air is about 415 kg/(m^2 · s) [85 lbf/(ft^2 · s)] and of water is about 1.5×10^6 kg/(m^2 · s) [0.31×10^6 lbf/(ft^2 · s)]. The unit kg/(m^2 · s) is often referred to as MKS Rayls—although this is not an SI unit. For a plane wave moving in one direction (referred to as a progressive wave) the impedance relates the pressure p to the particle velocity u through $p = uZ_0$; i.e., acoustic impedance plays a role similar to electrical impedance in circuit theory. For waves that are not plane (such as focused waves) or not moving in one direction (such as standing waves), there is normally not a simple relation between the pressure and particle velocity.

A propagating acoustic wave carries energy, and this is most commonly described by the **intensity** I, the power per unit area. The intensity can be calculated by the following integral:

$$I = \frac{1}{T_{\text{av}}} \int_{t_0}^{t_0 + T_{\text{av}}} (p \cdot u)\, dt \tag{12.6.1}$$

where the integration is done over a period for a periodic wave, over the duration of the pulse for a pulse, or over an appropriately long time for a noise signal. The units for I are watts per square metre (W/m^2). For a progressive wave the particle velocity is related to the acoustic pressure, and the intensity can be determined from measurements of the root mean square (rms) pressure and the impedance:

$$I = p_{\text{rms}}^2 / Z_0 \tag{12.6.2}$$

When an acoustic wave encounters an interface, the wave is partially reflected and partially transmitted. In the case of **normal incidence,** the intensity transmission and reflection coefficients are given by

$$R_I = \frac{(Z_2 - Z_1)^2}{(Z_2 + Z_1)^2} \tag{12.6.3}$$

$$T_I = \frac{4Z_1 Z_2}{(Z_2 + Z_1)^2} \tag{12.6.4}$$

that is, they depend predominantly on the difference in impedance. The coefficients sum to unity, and individually they must range between 0 and 1. In noise control applications, interfaces are often employed to reduce the transmission of sound, and it is common to use transmission loss TL, which is related to the intensity transmission coefficient by

$$\text{TL} = -10 \log T_I \tag{12.6.5}$$

A large transmission loss is normally desired.

For sound that is incident at oblique angles, or where there are multiple interfaces, the expressions for reflection and transmission coefficients become more complicated, and it often becomes more practical to measure the coefficients.

Attenuation of Sound When sound propagates through a medium, most of the energy remains in the sound wave, but a small amount of it is absorbed by the medium. The amplitude of an acoustic wave will therefore decay or **attenuate** as it propagates through a medium. The attenuation can be due to geometric spreading effects, scattering by inhomogeneities in the medium, and direct absorption of the energy by the medium. For a plane wave the intensity will decay exponentially with distance

$$I = I_0 \exp(-2\alpha x) \tag{12.6.6}$$

where α is the attenuation coefficient and x is the distance. The attenuation coefficient has units of nepers per metre (Np/m). Often when attenuation is reported to dB/m, it can be converted to Np/m by making use of the conversion 1 Np = 8.686 dB.

Absorption in air is dominated by the vibration of nitrogen and oxygen molecules. It varies with frequency (absorption increases with frequency) and is very sensitive to changes in temperature and humidity. Propagation distances typically need to be on the order of hundreds of metres for the attenuation to be significant. International Standard ISO 9613-1:1993 describes how to determine the attenuation of sound in air.

Absorption in pure water is very weak and normally negligible; however, it increases with the square of the frequency and can be important for frequencies above 10 MHz. In saltwater, absorption is much stronger and is dominated by chemical dissociation of salts (see Francois and Garrison, *Jour. Acoust. Soc. Am.* **72;** 1982, pp. 896–907 and 1879–1890).

In solids there are few quantitative formulas for determining attenuation, and most data are determined empirically. The attenuation in most solids typically follows a power law of the form $\alpha = \alpha_0 f^n$, where α_0 and n are material properties and n typically varies between 1 and 2. A comprehensive list of acoustic properties can be found at http://www.ondacorp.com/tecref_acoustictable.html.

Transducers

A **transducer** is a device that converts energy between two forms. In acoustics, transducers are used to measure sound (convert sound to an electric signal) and to generate sound (convert electric signals to acoustic waves).

Generating Sound Sound is generated by an object or a surface vibrating in a fluid. For a sound source to be efficient, it is necessary that the dimensions of the vibrating surface of the source be much larger than the wavelength of sound. This is often not practical; e.g., at 300 Hz the wavelength in air is about 1 m (3 ft). Efficiency is also improved if the source is mounted in a wall (baffle) or a chamber so that there is no direct path from the front and back surfaces of the vibrating surface. The presence of a path between the front and back surfaces of the source allows some of the energy to "slosh" back and forth and not radiate as a sound wave.

Moving coil loudspeakers are perhaps the most common transducer for sound generation. The heart of the transduction is a cylindrical coil of wire (voice coil) and a magnet. When a current is passed through the coil, the interaction with the magnetic field results in a force on the voice coil. The voice coil is connected to a large diaphragm which is vibrated back and forth as the coil oscillates, and this results in the generation of an acoustic wave. The diaphragm is provided with some mechanical stiffness to produce a restoring force.

The attachment of a horn to the loudspeaker improves the impedance match between the speaker and the air since it is essentially an acoustic transformer. The dimensions and flare of the horn contribute to its matching ability. The operation of the speaker may be influenced by its enclosure, the baffle which separates the front from the back radiation, or its resonances.

Whistles and sirens may also be used to produce intense sound fields in gases and liquids. In a whistle a flow of air is passed over a sharp

edge; turbulent vortices are produced which result in oscillation of the air. If a resonant chamber is placed behind the edge, then the vortices will excite the resonance and produce a tone. These oscillations can often result in high-amplitude signals. An example is flow over a car with an open sunroof, which will result in turbulence that can excite a resonance in the air in the car. The frequency of the resonance is typically less than 10 Hz (infrasound) and can be disturbing to passengers in the car. Sirens are devices in which a revolving disk or drum is perforated such that the holes alternately block and unblock a steam of air. Early sirens employed a series of holes on the outer edge of a disc with a jet of air impinging thereon. Modern sirens use a centrifugal fan inside a drum. The fan is rotated and forces air through the holes in the drum, to generate a sound.

In underwater applications, most sound sources employ piezoelectric materials. A piezoelectric material is one which generates a strain when a voltage is applied across the material. The change in thickness of the material launches an acoustic wave in the water. Typically the impedance of piezoelectric materials is much higher than that of water, and to ensure efficient sound transmission, quarter-wavelength impedance matching layers are used on the face of the transducer. Impulsive noise sources used underwater include explosions and implosions of hollow spheres.

Measuring Sound The acoustic field is typically measured in air by using a microphone and in water by using a hydrophone. Most microphones are either condensor microphones or electret microphones. The active element of a condensor microphone consists of a capacitor where one plate is free to move with the particle motion of the acoustic wave, which results in a change in bias voltage on the capacitor. An electret uses a similar concept except that the dielectric is a permanently electrically charged material so that no biasing voltage need be employed. Electret microphones are becoming the dominant transducer for measuring audible sound even for quality measurement microphones. Micro-Electro-Mechanical-Systems (MEMS) based microphones, which typically employ micrometre-sized capacitors and may have an advantage in terms of mass production and direct integration with electronic circuits, have the potential to become competitive with electrets in the near future.

Other microphones use piezoelectric materials, where the strain or stress associated with the acoustic wave induces a voltage in the material. The majority of hydrophones employ piezoelectric transducers.

Sound Pressure Level Most measurements report the acoustic disturbance in terms of pressure which has units of N/m^2 or Pa. The threshold of hearing in people with acute hearing is an rms pressure of approximately 20 μPa (2.9×10^{-9} psi) at around 4 kHz. The threshold of pain is an rms pressure of 63 Pa (9.3×10^{-3} psi). In comparison the atmospheric pressure at sea level is approximately 100,000 Pa (15 psi).

Although sound is measured as a pressure, it is normally reported in decibels as either a **sound pressure level (SPL)** or an **intensity level (IL)** which are given by

$$\begin{aligned} \text{SPL} &= 20 \log 10 (p_{\text{rms}}/p_{\text{ref}}) \\ \text{IL} &= 10 \log 10 (I/I_{\text{ref}}) \end{aligned} \qquad (12.6.7)$$

where in air $p_{\text{ref}} = 20$ μPa and $I_{\text{ref}} = 10^{-12}$ W/m^2 and are chosen so that the two levels are almost identical (less than 0.4-dB discrepancy). In terms of SPL, the threshold of hearing is 0 dB, and the threshold of pain is 130 dB. Table 12.6.3 gives typical SPLs for sound in the audible range.

Table 12.6.3 Examples of Representative SPLs for Various Environments

Rustling of leaves	15 dB
Whisper	30 dB
Normal conversation	60 dB
Average street noise	70 dB
Vacuum cleaner	80 dB
Heavy truck at 15 m (45 ft)	90 dB
Home stereo at full volume	100 dB
Rock concert (threshold of feeling)	120 dB
Jet engine at 25 m (75 ft)	140 dB

Note in underwater acoustics the **reference level** for an SPL is 1 μPa, and in older underwater acoustics literature a value of 0.1 Pa was used. It is good practice to report the reference pressure level when reporting SPL in dB to avoid confusion.

Perception of Sound

Although human hearing can extend from 20 Hz to 20 kHz, the auditory system is most sensitive to sounds in the range of 1 to 5 kHz. Due to the frequency dependence of human hearing, the SPL used for determining human response to sound is normally weighted so that sounds in the 1- to 5-kHz range are given stronger weighting. A number of algorithms have been developed that apply different weighting to sound in specific frequency bands that are either one octave or one-third-octave apart. An octave refers to a doubling of frequency; that is, 1,000 Hz is one octave above 500 Hz and two octaves above 250 Hz. An octave band centered at f_0 covers the range of frequencies from $f_0/\sqrt{2}$ to $f_0\sqrt{2}$; e.g., for 1,000 Hz it covers the range of 707 to 1,414 Hz. The most common is the A weighting (dBA) which applies 0-dB weighting at 1,000 Hz, reduces signals at 63 Hz by 26.2 dB, and adds 1.0 dB at 4,000 Hz. The A weighting is appropriate for determining the perceived sound level for relatively quiet sounds, as it accounts for the strong frequency-dependent sensitivity of the ear. For more intense sounds the ear does not display such a strong frequency sensitivity, and in this case for C weighting (dBC) is more appropriate, which is effectively a flat bandpass filter with −3-dB frequencies at 31.5 Hz and 8 kHz. The C weighting is also often appropriate for impulsive sounds. Table 12.6.4 lists the octave band corrections for the A and C weightings.

Table 12.6.4 Correction, dB, to Be Applied to an SPL Measured in Octave Bands Centered at the Specified Frequencies.

Frequency, Hz	dBA	dBC
31.5	−39.4	−3.0
63	−26.2	−0.8
125	−16.1	−0.2
250	−8.6	0
500	−3.2	0
1,000	0	0
2,000	+1.2	−0.2
4,000	+1.0	−0.8
8,000	−1.1	−3.0

OSHA regulations (Standard 1910.95) require that when workers are exposed to an average weighted sound level of 85 dBA or more in an 8-h day, then monitoring and hearing conservation practices must be implemented. These practices include regular measurement of sound levels and regular auditory testing of employess. A SPL of 90 dBA is the maximum permissible for an 8-h workday, and the exposure time goes down by 50 percent for each 5-dB increase in noise levels; i.e., workers can only be exposed to an SPL of 95 dBA for 4 h, and a level of 100 dBA reduces exposure time to 2 h. Acoustic engineering can be employed to reduce noise levels and allow for longer exposure times.

NOISE

Noise measurements are usually made with a sound level meter, comprised of a microphone, an attenuator, an amplifier, a frequency-weighting network, and an indicator. See ANSI S1.4, "Specification for Sound Level Meters," and ANSI S1.42, "Design Response of Weighting Networks for Acoustical Measurements." A sound analyzer indicates sound pressure as a function of frequency by using a filter set designed in accordance with ANSI S1.11, "Specification for Octave-Band and Fractional-Octave-Band Analog and Digital Filters." Octave band filters are typically included with sound analyzers with additional one-third octave band filter sets available on some analyzers. Modern sound analyzers permit simultaneous real-time measurement across many frequency bands. In addition, narrowband analysis with fast Fourier

transform (FFT) is available on some sound level meters. By using these instruments the components of the heterogeneous noise may be identified, and correlated with the noise sources. Once the noise source is located, techniques for noise control can be used.

Contact transducers (vibration pickups) may be used to locate sources of noise, such as in partitions and machine parts. They may be piezoelectric or magnetic and may be used to supplement information from the microphone and sound level meter.

Where the frequency distribution of the noise is significant, an analyzer may be used since the overall level meter tells nothing about frequency distribution. For most noise control applications, one-third octave band filters provide sufficient frequency resolution. However, narrowband FFT analyzers are helpful when finer frequency resolution is required.

Transmission Isolation

If the vibrations of noisy machinery cannot be suppressed at the source, their transmission to the listener should be impeded. The most effective vibration isolation method is the introduction of elastic discontinuities in the structure transmitting the noise. The discontinuities may be obtained by the use of rubber, neoprene, or springs in machinery mountings, or by the introduction of neoprene isolation sheets in expansion joints of concrete slabs. The isolation treatment should be applied as close to the source as possible, to eliminate sound radiation from the structures transmitting the vibrations. Where this is not possible, the listening space itself may be isolated. Thus quiet rooms, constructed especially for noisy measurements, are usually built as separate structures isolated from the main building.

Filtration

Some problems of noise transmission through air lend themselves to solution by methods of filtration. Typical examples are the transmission of sound in ventilating ducts and the noise production at engine exhaust pipes. In each of these cases, the steady flow of gas must not be impeded, but the alternating flow, representing sound transmission, must be effectively suppressed.

Noise in ventilating ducts is typically broadband and consists of fan noise (low and middle frequency) and turbulence noise (middle and high frequency) generated by airflow. Fans are capable of generating tones at a blade passage frequency determined by their rotational speed and number of blades. However, most fans used in HVAC are large centrifugal fans, which do not generate a tremendous amount of tonal noise. Some of this sound energy can be converted to heat by using dissipative glass or cotton fiber elements such as duct silencers or internal duct lining. Both approaches tend to give the most attenuation at middle frequencies around 1 kHz. Duct silencers, consisting of parallel baffles, are used to reduce low- and middle-frequency noise. For ventilating ducts, noise suppression may be obtained by lining the ducts with 1-in-thick glass fiber or cotton fiber sheets. Low-frequency propagation along a duct can be reduced by means of complaint duct walls that radiate noise away from the duct, or by discontinuities such as plenums and outlets. High-frequency noise can be reduced with elbows. Reactive (also known as no-fill, or no-media) silencers are commercially available and are commonly used where no fibrous fill is allowed. These silencers work on the same principle as the muffler on a car. They consist of a few pipe segments that interconnect a number of large chambers. The change in acoustic properties of the pipes (masslike) and the chambers (springlike) produce resonance effects which result in reflection of the noise back to the source.

For noise with strong tonal components, resonators can be fitted to the duct to filter specific tones. The filters are normally placed as close to the source as possible. However, a difficulty with using resonators in duct systems is that a separate resonator is needed for each tone, and tuning the resonator to the correct frequency can be difficult. Other problems include excess pressure drop and flow noise generation from duct discontinuities. Most noise control approaches incorporate broadband attenuation to reduce the entire noise spectrum below a target **noise criteria (NC)** level.

Ducts should be sized to limit airflow noise and duct drumming to acceptable levels in the spaces they serve. The volumetric flow rate is determined by the amount of air changes per hour required for the space of interest. Duct sizing and volumetric flow rate determine the average airflow velocity in the duct, which in turn affects the amount of turbulence noise that can be generated. Rules of thumb are typically used for setting appropriate airflow velocities. Main system ductwork that is usually located in building shafts away from noise-sensitive spaces is typically sized for medium-pressure standards with airflow velocities from 6 to 10 m/s [1,200 to 2,000 feet per minute (fpm)]. The main ductwork connects to branches that are sized for low-pressure standards. In general, velocity ventilation branches serving noise-sensitive rooms such as music performance spaces should be on the order of 0.5 to 1.5 m/s (100 to 300 fpm). For regular occupied spaces, such as offices, airflow velocities in duct branches should be on the order of 2 to 3 m/s (400 to 600 fpm). Spaces that have high airflow requirements such as laboratories permit higher noise levels, and airflow velocities in duct branches are on the order of 4.5 to 6 m/s (900 to 1,200 fpm).

Shielding

Noise can be reduced by the placement of sound-opaque partitions between the source and the receivers. In most buildings the panels are thin in comparison to a wavelength, and the transmission loss for normally incident sound through a thin panel is given by

$$\mathrm{TL}_0 = 20 \log (\pi f \rho l / Z_1) \qquad (12.6.8)$$

where f is frequency, ρ is the mass density of the wall material, l is the thickness of the wall, and Z_1 is the impedance of air [415 Rayls or 85 lb/(ft^2 · s)]. There is a 6 dB/octave increase in transmission loss as frequency increases. The transmission loss of sound can be increased by increasing the mass per unit area of the partition, either a denser material or a thicker panel. For sound that is not normally incident the TL is reduced, and for sound incident over a range of angles, typical transmission loss is approximately derated by 5 dB, that is, $\mathrm{TL} = \mathrm{TL}_0 - 5$ dB.

The sound transmission loss of single panels in the audible frequency range is often further reduced by coincidence effects associated with bending (or flexural) waves in the panel. This occurs when the frequency of obliquely incident sounds equals the bending wave frequency of the panel, which is determined by the thickness and stiffness of the panel. If the panel had no damping, then the sound transmission loss would be reduced to zero at this coincidence frequency; but the damping inherent in most panels reduces this degradation of transmission loss. Single panels can also have low-frequency resonances due to their mass and stiffness. However, this resonance is determined by the size of the panel, is mitigated by natural panel damping, and is usually not a concern in most noise control applications.

Typically mass-based insulation is too large and heavy to be practical. Thin panels separated by an airspace can achieve similar transmission loss to massive monolithic constructions. The sound transmission loss of double-panel constructions can be reduced by mass-air-mass resonance. Adding sound-absorptive material such as glass or mineral fiber batt insulation reduces this resonance effect and improves the general sound transmission loss of the partition. The deeper the airspace, the lower the mass-air-mass resonance frequency. Coincidence phenomena affecting each of the panels can also affect the total transmission loss of the assembly.

Double walls must be constructed carefully to avoid loss of vibration isolation through mechanical bridging between the opposite surfaces. Higher-density sound-absorbing fillers such as mineral fiber batt insulation can reduce sound insulation if they are in contact with both interior surfaces; but lower-density fill such as glass fiber batt insulation can touch both sides without degrading the isolation. A single bridging nail may alter significantly the insulating efficiency. For maximum effectiveness, one of the wall surfaces should be hung structurally free at all four edges, with the boundary cracks sealed against sound leakage with an elastometric sealant such as silicone or acrylic latex.

Given the factors that make the performance of partitions deviate from the mass law, it is advisable to use one of the many tabulations of measured sound transmission loss when selecting a construction. Sound transmission loss of partitions is measured by comparing the average sound level on each side of the partition under standardized conditions per ASTM E90, "Standard Test Method for Laboratory Measurement of Airborne Sound Transmission Loss of Building Partitions and Elements." The frequency-dependent transmission loss data from this test procedure can be reduced to a single-number **sound transmission class (STC)** by means of ASTM E413, "Classification for Rating Sound Insulation." The STC most heavily weights the transmission loss data in the 500- to 2,000-Hz frequency band, and ratings for typical partitions are shown in Table 12.6.5. Additional data on transmission loss for a wide variety of building materials and structures are available in several publications (see References).

Transmission through composite walls can be approximated as an average intensity transmission coefficient

$$T_{av} = \frac{1}{S_{tot}} \sum_n T_n S_n \qquad (12.6.9)$$

where the sum is over all the different materials in the wall, T_n is the intensity transmission coefficient, and S_n is the surface area of the nth

Table 12.6.5 Transmission Loss Data for Various Building Constructions
Data are provided at 7 different octave bands. The final column gives the STC rating.

Material	Transmission loss, dB						STC rating
	125 Hz	250 Hz	500 Hz	1,000 Hz	2,000 Hz	4,000 Hz	
Walls							
Monolithic:							
⅜-in plywood (1 lb/ft²)	14	18	22	20	21	26	22
26-gage sheet metal (1.5 lb/ft²)	12	14	15	21	21	26	20
½-in gypsum board (2 lb/ft²)	15	20	25	31	33	27	28
2 layers ½-in gypsum board, laminated with joint compound (4 lb/ft²)	19	26	30	32	29	37	31
Interior:							
2 by 4 wood studs 16 in oc with ½-in gypsum board both sides (5 lb/ft²)	17	31	33	40	38	36	33
2 by 4 staggered wood studs 16 in oc each side with ½-in gypsum board both sides (8 lb/ft²)	23	28	39	46	54	44	39
6-in dense concrete block, 3 cells, painted (34 lb/ft²)	37	36	42	49	55	58	45
3⅝-in steel channel studs 16 in oc with ½₀-in gypsum board both sides (5 lb/ft²)	26	36	43	51	48	43	43
Construction no. 19 with 3-in mineral-fiber insulation in cavity	28	45	54	55	47	54	48
Exterior:							
4½-in face brick (50 lb/ft²)	32	34	40	47	55	61	45
Two wythes of 4½-in face brick, 2-in airspace with metal ties (100 lb/ft²)	37	37	47	55	62	67	50
Two wythes of plastered 4½-in brick, 2-in airspace with glass-fiber insulation in cavity	43	50	52	61	73	78	59
6-in solid concrete with ½-in plaster both sides (80 lb/ft²)	39	42	50	58	64	67	53
Floor-Ceilings							
2 by 10 word joints 16 in oc with ½-in on floor side and ⅝-in gypsum board nailed to joists on celing side (10 lb/ft²)	23	32	36	45	49	56	37
4-in reinforced concrete slab (54 lb/ft²)	38	42	45	56	57	66	44
6-in reinforced concrete slab (75 lb/ft²)	38	43	52	59	67	72	55
6-in reinforced concrete slab with ¾-in T&G wood flooring on 1½ by 2 wooden battens floated on 1-in glass fiber (83 lb/ft²)	38	44	52	55	60	65	55
Roofs							
3 by 8 wood beams 32 in oc with 2 by 6 T&G planks, asphalt felt build-up roofing, and gravel topping	29	33	37	44	55	63	43
As above with 2 by 4s 16 in oc between beams, ½-in gypsum board supported by metal channels on ceiling side with 4-in glass-fiber insulation in cavity	35	42	49	62	67	79	53
Doors							
1¾-in hollow-core wood door, no gaskets, ¼-in air gap at sill (1.5 lb/ft²)	14	19	23	18	17	21	19
Construction no. 43 with gaskets and drop seal	19	22	25	19	20	29	21
1¾-in hollow-core 16 gage steel door, glass-fiber filled, with gaskets and drop seal (7 lb/ft²)	23	28	36	41	39	44	38
Glass							
⅛-in monolithic glass (1.4 lb/ft²)	18	21	26	31	33	22	26
¼-in monolithic float glass (2.9 lb/ft²)	25	28	31	34	30	37	31
¼-in laminated glass. 30-mil plastic interlayer (3.6 lb/ft²)	25	28	32	35	36	43	35
Double glass: ¼-in laminated + ³⁄₁₆-in monolithic glass with 2-in airspace (5.9 lb/ft²)	25	34	44	47	48	55	45

SOURCE: Adapted from data published in M. David Egan, "Architectural Acoustics," McGraw-Hill, 1988, pp. 204–206.

material. For air gaps $T_n = 1$ (perfect transmission), and so the presence of air gaps in walls should be removed as much as possible. For example, a 3-mm (⅛-in)-thick glass window offers 41 dB of transmission loss at 2,000 Hz. If the window is opened by 2.5 mm (0.1 in), the transmission loss is reduced to 26 dB.

Holes for piping penetrations should be slightly oversized to allow the penetration to be filled with fibrous insulation and to be sealed on both sides with an elastomeric sealant, to ensure that the transmission loss is not degraded by the presence of air gaps.

The benefit of shielding can be reduced by the presence of flanking paths, which are alternative ways for sound to travel from source to receiver other than the partition between them. Flanking transmission can occur when gaps are left around the perimeter of the partition. These gaps should be sealed with an elastometric sealant. Flanking transmission can also occur when lightweight partitions perpendicular to the separating partition are continuous across both rooms. The flanking noise issue can be addressed by cutting a joint in the flanking partition or by increasing the mass of the flanking partition so that its sound transmission loss approaches that of the separating partition.

Quieting

When a noise source is in a room, reflections of the noise from the wall (reverberation) can result in a higher sound level than would occur if the sound source were in free space. Placing sound-absorbing material on the interior walls will reduce the reverberation in the room and hence reduce noise levels. Sound absorption coefficients are the commonly used measurement of these panels. The sound absorption coefficient is the fraction of the total energy that reflects from a panel. The coefficient varies from 0 (for an open window where no energy returns to the room) to 1 (for a rigid wall where all the energy is reflected).

Absorbing panels typically employ highly porous materials which are very effective at converting sound vibrations to heat by friction and viscous resistance. The effectiveness of sound absorbents varies with frequency, usually being greater for high and intermediate than for low frequencies. Sound absorption coefficients are typically measured in accordance with ASTM C423, "Standard Test Method for Sound Absorption and Sound Absorption Coefficients by the Reverberant Room Method," and specific normal acoustic impedance is measured in accordance with ASTM C384, "Standard Test Method for Impedance and Absorption of Acoustical Materials by Impedance Tube Method," or ASTM E1050, "Standard Test Method for Impedance and Absorption of Acoustical Materials by Impedance Tube Method." The absorption coefficient will depend on the impedance of the panel and the attenuation of the sound within the panel material. However, it is not a property of the material alone, but depends on the mounting of the test sample per ASTM E795, "Standard Practices for Mounting Test Specimens During Sound Absorption Tests." For example, a sound-absorptive material is typically measured with higher sound absorption coefficients when backed by a deep airspace than when tested lying against a rigid surface.

The principal material employed is acoustic tile, which can be obtained as prefabricated units for use on walls and ceilings. The tile typically has an outer layer that has been mechanically perforated and conceals a porous absorbing material underneath. Note that painting or sealing of acoustic panels can have a dramatic deleterious effect on the performance of the panels, as the holes that allow the sound to permeate into the absorbing fill are blocked. This can be of particular concern in environments such as hospitals where sealing of pores and holes is desired for sterilization reasons. An alternative to tile is to hang acoustic blankets, e.g., hanging heavy drape curtains, on walls. Data on sound absorption coefficients for a wide variety of building materials are shown in Table 12.6.6.

Floors can also be considered in terms of quieting. A carpeted floor will provide improved absorption over concrete or linoleum. Carpeting will also have a positive effect on improving acoustic isolation of impact-generated noise to rooms below. Underlays made of felt, cork, or rubber can further improve the acoustic performance of the floor. Finally, absorption can be enhanced by the presence of furniture in the room; e.g., upholstered chairs can absorb a nontrivial amount of sound.

Active Noise Control (ANC)

Recent advancements in computational technology have allowed many practical applications of active noise control. Human interaction with transportation and equipment noise thus far has been the focus of this technology. As of today, successful global ("whole room") active control of **tonal disturbances** has been accomplished in aircraft, submarines, and automobiles. Civilian examples of this technology are currently limited, but include the Saab 340B aircraft and Honda hybrid-powered vehicles. Military examples abound. For nontonal, steady-state noise, such as that heard in an aircraft cabin at cruising speed, active noise control has been accomplished only for "local" or small regions near the ears of passengers, and is typically limited to less than 1 kHz in frequency. Examples include the ubiquitous ANC headsets. No published ANC system to date is capable of readily controlling transient, unpredictable noise. Transient noise would include human conversation, music, and impulsive noises. All existing control algorithms require a feed-forward sensor capable of predicting noise at the receiver and/or a feedback sensor capable of monitoring a steady-state noise.

Active noise control for low-frequency noise in ducts is possible, but operating conditions of active duct silencers are generally limited to flow velocities of 7.5 m/s (1,500 fpm) or less (2003 ASHRAE Applications Handbook, p. 47.18). To the best of the author's knowledge, there are currently no large-scale commercially available, off-the-shelf lines of active duct silencers. Any active noise control approach to ductborne noise control is likely to be a custom-made endeavor, more expensive than commercially available passive silencers.

ULTRASONICS

REFERENCES: Ultrasonic Cleaning, in "ASM Handbook," vol. 5, "Surface Engineering," 1994, pp. 44–47. "Nondestructive Testing Handbook," 2d ed., vol. 7, "Ultrasonic Testing," Birks and Green (eds.), American Society for Nondestructive Testing, Columbia, Ohio, 1991. Johnson, The New Wave in Acoustic Testing, *Materials World*, *Jour. Inst. Materials* **7,** 1999, pp. 544–546.

Sound waves in the frequency range from 10 kHz to hundreds of megahertz have numerous industrial applications. The majority of the devices operate above 20 kHz and are therefore ultrasonic. One motivation in the choice of ultrasonic frequencies is to avoid impact on human hearing. High-intensity waves are used to mechanically alter materials, such as ultrasonic cleaners or welders. Low-intensity waves are used for nondestructive evaluation or testing. The list of applications is large, and just a small subset will be described here. The Ultrasonics Industry Association (UIA) provides a referral website which lists the majority of the industrial applications of ultrasound: http://ultrasonics.org/referral.html.

High-Intensity Applications

Ultrasonic cleaners employ a water bath that is agitated with sound waves with frequencies normally around 40 kHz (the majority of devices employ frequencies in the range of 20 to 80 kHz). The agitation is generated by bonding piezoelectric or magnetostrictive transducers to the outer surface of the tank. Ultrasonic cleaners work through acoustic cavitation. Acoustic cavitation occurs when the negative pressure of the tensile phase of the wave is greater than 1 atm (100 kPa or 15 psi), a pressure relatively easily obtained in water, at which level the fluid will tear apart, creating a cavity or bubble. The cavity will grow during the tensile phase of the sound wave, but during the compressive phase of the wave it will be driven to collapse. The collapse is extraordinarily violent with pressures inside the bubble reaching hundreds of atmospheres and temperatures reaching 5,000 K (9,000°R). These phenomena are localized to a small volume around the collapse but result in sonochemistry (e.g., free-radial production) and sonoluminescence (production of light). When the cavity collapses near a surface, the bubble collapses asymmetrically and a microjet of fluid pierces the cavity and strikes the surface at velocities in excess of 100 m/s (330 ft/s). These microjets act as intense microscopic scrubbers to remove particles from the surface.

Typically a detergent will be added to the water bath of an ultrasonic cleaner. The detergent allows the water to fully wet surfaces of the component that may be hydrophobic. For cavitation to be effective, it is important that the entire surface of the component be fully wetted. Sometimes solvents may be added to the water to chemically enhance the cleaning process. Most companies that produce ultrasonic cleaners also market proprietary ultrasonic cleaning solutions. Ultrasonic cleaners are particularly useful for cleaning objects with odd shapes and hidden structure. Types of objects that can be cleaned include metal parts (e.g., castings, valves, injectors), electronic components (particularly connector pins), printed-circuit boards, lenses, optical fibers, television tubes, and filters. This list is far from exhaustive.

For typical sized tanks (a few gallons) standing waves can be excited which can result in hot and cold spots in the tank. This is so because the speed of sound in water 1,500 m/s, and so the wavelength at 40 kHz is 150 mm (5.9 in)—on the order of the tank. Modern ultrasonic cleaners will normally employ a swept frequency signal which, even for variations of just a few kilohertz, will ensure even distribution of cavitation throughout the tank.

Ultrasonic welders are employed to bond materials together. They are most commonly used on plastics, but metal, textiles, films, and other materials can also be successfully welded. Ultrasonic welding is accomplished by placing the two pieces to be welded in direct mechanical contact. One piece is held stationary, and then an ultrasonic probe is brought into contact with the second piece. When the probe is excited, it vibrates the piece that it is in contact with, which produces frictional heat at the contact point between the two pieces. This, in turn, results in a temperature rise that softens or melts the plastic on both surfaces. The heated plastic interface melts, and when the probe is removed, the plastic cools and a homogeneous solid weld results.

The ultrasonic probe consists of a stack of piezoelectric discs which are operated at frequencies varying from 20 to 40 kHz, although research devices operating above 100 kHz have be reported. The stack

is mounted to a tapered horn (or sonotrode), and as the sound energy propagates down the horn, the vibration amplitude is amplified because of the reduction in cross-sectional area of the horn. Vibrations at the tip are on the order of 100 μm. With ultrasonic welding it is possible to achieve spot welds, lap welds, butt welds, and steam welds.

Ultrasonic Atomization When ultrasound in air is incident on the surface of water, it will excite capillary waves on the surface of the water. When the amplitude of the capillary waves reaches the critical value, the waves become unstable and droplets of water are ejected into the air. The droplets are typically tens of micrometres in diameter and appear as a mist above the surface. Under the right conditions an acoustic fountain can be generated. This type of ultrasonic atomization is commonly employed in dehumidifiers. Nozzles have been created by using this principle to produce an atomized jet.

Low-Intensity Applications

Nondestructive Evaluation or Testing of Materials This application is perhaps the most widespread use of ultrasound in an industrial setting, and the most common manifestation is a pulse-echo configuration. An ultrasonic transducer is used to launch a short pulse into a sample, and whenever the pulse interacts with an interface, it is partially reflected and the echoes can be detected by the same transducer that generated the pulse. If the sound speed in the sample is known, then the distance to the interface can be determined from the time of flight. Common applications employ piezoelectric transducers with center frequencies that range from 1 to 30 MHz. The transducers are typically wideband, and so when excited with a short electrical pulse (with an amplitude on the order of 100 V), they generate an acoustic pulse that is about 1.5 cycles long. The spatial length of the pulse governs the spatial resolution of the system. At 1 MHz the pulse length is about 11 mm (0.45 in) in steel and 4 mm (0.16 in) in Lucite. At 30 MHz it is 0.4 mm (0.016 in) in steel and 0.13 mm (0.005 in) in Lucite. High frequencies therefore give better spatial resolution but typically are absorbed more strongly by the sample and so cannot "see" deeply into the material. Frequencies of hundreds of megahertz have been employed for specialized high-resolution applications.

If the transducer is focused, it will generate a pencil beam of sound, and from the received echo signal (known as an A-line) it is possible to identify the position of interfaces to within the resolution of the system. The transducer can be scanned in a line to produce two-dimensional images (a B-scan) or in a two-dimensional raster pattern to produce a three-dimensional image (a C-scan). The position of interfaces can be used to size an object or to detect the presence of flaws or inclusions. Array transducers can be used to electronically scan the beam rather than relying on mechanical translation. The same principles described here for materials testing are used in diagnostic ultrasound imaging of the body.

Other modes of ultrasonic testing include through transmission and resonant ultrasound. In through transmission, two transducers are used in a pitch and catch configuration. The amplitude of the received signal will depend on the number of interfaces and flaws in the intervening material. Through transmission can also be used to ascertain flow velocities through the Doppler effect. In this case a short tone burst (approximately 10 cycles) is transmitted through the flow. If there is a net flow from the transmitter to the receiver, then the frequency of the tone will be shifted higher; if there is flow in the opposite direction, the frequency will be shifted down. Based on the frequency shift the flow velocity can be calculated. In **resonance ultrasound spectroscopy (RUS)** a transducer is used to excite a resonance in the component to be investigated, and the frequency and Q of specific resonances can be used to extract information about the structure and flaws in the components. A new and promising development for flaw detection in components is **nonlinear resonant ultrasound spectroscopy (NRUS)** and variations thereof. In this case, the ultrasonic excitation is of large enough amplitude that the material exhibits nonlinear response, e.g., the production of harmonic overtones of the driving signal. The nonlinear response is critically dependent on flaws in the material and can be used to evaluate damage in most construction materials.

BASIC STEPS IN MAKING SAND CASTINGS

The basic steps involved in making sand castings are:

1. **Patternmaking.** Patterns are required to make molds. The mold is made by packing molding sand around the pattern. The mold is usually made in two parts so that the pattern can be withdrawn. In horizontal molding, the top half is called the **cope,** and the bottom half is called the **drag.** In vertical molding, the leading half of the mold is called the **swing,** and the back half is called the **ram.** When the pattern is withdrawn from the molding material (sand or other), the imprint of the pattern provides the cavity when the mold parts are brought together. The mold cavity, together with any internal cores (see below) as required, is ultimately filled with molten metal to form the casting.

2. If the casting is to be hollow, additional patterns, referred to as **core boxes,** are needed to shape the sand forms, or **cores**, that are placed in the mold cavity to form the interior surfaces and sometimes the external surfaces as well of the casting. Thus the void between the mold and core eventually becomes the casting.

3. **Molding** is the operation necessary to prepare a mold for receiving the metal. It consists of ramming sand around the pattern placed in a support, or **flask,** removing the pattern, setting cores in place, and creating the gating/feeding system to direct the metal into the mold cavity created by the pattern, either by cutting it into the mold by hand or by including it on the pattern, which is most commonly used.

4. **Melting** and **pouring** are the processes of preparing molten metal of the proper composition and temperature and pouring this into the mold from transfer **ladles.**

5. **Cleaning** includes all the operations required to remove the **gates** and **risers** that constitute the gating/feeding system and to remove the adhering sand, scale, parting fins, and other foreign material that must be removed before the casting is ready for shipment or other processing. Inspection follows, to check for defects in the casting as well as to ensure that the casting has the dimensions specified on the drawing and/or specifications. Inspection for internal defects may be quite involved, depending on the quality specified for the casting (see Sec. 5.4). The inspected and accepted casting sometimes is used as is, but often it is subject to further processing which may include heat treatment, painting, rust preventive oils, other surface treatment (e.g., hot-dip galvanizing), and machining. Final operations may include electrodeposited plated metals for either cosmetic or operational requirements.

PATTERNS

Since patterns are the forms for the castings, the casting can be no better than the patterns from which it is made. Where close tolerances or smooth casting finishes are desired, it is particularly important that patterns be carefully designed, constructed, and finished.

Patterns serve a variety of functions, the more important being (1) to shape the mold cavity to produce castings, (2) to accommodate the characteristics of the metal cast, (3) to provide accurate dimensions, (4) to provide a means of getting liquid metal into the mold (gating system), and (5) to provide a means to support cores by using core prints outside of the casting.

Usual allowances built into the pattern to ensure dimensional accuracy include the following: (1) **Draft,** the taper on the vertical walls of the casting which is necessary to extract the pattern from the mold without disturbing the mold walls and is also required when making the core. (2) **Shrinkage allowance,** a correction to compensate for the solidification shrinkage of the metal and its contraction during cooling. These allowances vary with the type of metal and size of casting. Typical allowances for cast iron are 1/10 to 5/32 in/ft; for steel, 1/8 to 1/4 in/ft; and for aluminum, 1/16 to 5/32 in/ft. A designer should consult appropriate references (AFS, "Cast Metals Handbook"; ASM, "Casting Design Handbook"; "Design of Ferrous Castings") or the foundry. These allowances also include a size tolerance for the process so that the casting is dimensionally correct. (See also Secs. 6.1, 6.3, and 6.4.) Table 13.1.1 lists additional data for some commonly cast metals. (3) **Machine finish allowance** is necessary if machining operations are to be used so that stock is provided for machining. Tabulated data are available in the references cited for shrinkage allowances. (4) If a casting is prone to distortion, a pattern may be intentionally distorted to compensate. This is a **distortion allowance.**

Patterns vary in complexity, depending on the size and number of castings required. **Loose patterns** are single prototypes of the casting and are used only when a few castings are needed. They are usually constructed of wood, but metal, plaster, plastics, urethanes, or other suitable material may be used. With advancements in solids modeling utilizing computers, CAD/CAM systems, and laser technology, rapid prototyping is possible and lends itself to the manufacture of protype patterns from a number of materials, including dense wax paper, or via stereolithographic processes wherein a laser-actuated polymerized plastic becomes the actual pattern or a prototype for a pattern or a series of patterns. The gating system for feeding the casting is cut into the sand by hand. Some loose patterns may be split into two parts to facilitate molding.

Gated patterns incorporate a gating system along with the pattern to eliminate hand cutting.

Match-plate patterns have the cope and drag portions of the pattern mounted on opposite sides of a wooden or metal plate, and are designed to speed up the molding process. Gating systems are also usually attached. These patterns are generally used with some type of molding machine and are recommended where a large number of castings are required.

Table 13.1.1 Average Linear Shrinkage of Castings

Bar iron, rolled	1 : 55	Cast iron	1 : 96	Steel, puddled	1 : 72
Bell metal	1 : 65	Gun metal	1 : 134	Steel, wrought	1 : 64
Bismuth	1: 265	Iron, fine grained	1 : 72	Tin	1 : 128
Brass	1: 65	Lead	1 : 92	Zinc, cast	1 : 624
Bronze	1: 63	Steel castings	1 : 50	8 Cu + 1 Sn (by weight)	1 : 13

For fairly large castings or where an increase in production rate is desired, the patterns can be mounted on separate pattern plates, which are referred to as **cope- and drag-pattern** plates. They are utilized in horizontal or vertical machines. In horizontal molding machines, the pattern plates may be used on separate machines by different workers, and then combined into completed molds on the molding floor prior to pouring. In vertical machines, the pattern plates are used on the same machine, with the flaskless mold portions pushed out one behind the other. Vertical machines result in faster production rates and provide an economic edge in overall casting costs.

Special Patterns and Devices For extremely large castings, **skeleton** patterns may be employed. Large molds of a symmetric nature may be made for forming the sand mold by **sweeps,** which provide the contour of the casting through the movement of a template around an axis.

Follow boards are used to support irregularly shaped, loose patterns which require an irregular parting line between cope and drag. A **master pattern** is used as an original to make up a number of similar patterns that will be used directly in the foundry.

MOLDING PROCESSES AND MATERIALS

(See Table 13.1.2.)

Molding Processes

Green Sand Most castings are made in **green sand,** i.e., sand bonded with clay or bentonite and properly tempered with water to give it **green strength.** Miscellaneous additions may be used for special properties. This method is adaptable to high production of small- or medium-sized castings because the mold can be poured immediately after forming, and the sand can be reused and reprocessed after the casting has solidified.

Dry Sand Molds These molds are made with green sand but are baked prior to use. The surface is usually given a refractory wash before baking to prevent erosion and to produce a better surface finish. Somewhat the same effects are obtained if the mold is allowed to **air-dry** by leaving it open for a period of time before pouring, or it is **skin-dried** by using a torch, infrared lamps, or heating elements directed at the mold cavity surface.

Core molding makes use of assembled cores to construct the mold. The sand is prepared by mixing with oil, or cereal, forming in core boxes, and baking. This process is used where the intricacy of the casting requires it.

Carbon Dioxide Process Molds These molds are made in a manner similar to the green sand process but use sand bonded with sodium silicate. When the mold is finished, carbon dioxide gas is passed through the sand to produce a very hard mold with many of the advantages of dry sand and core molds but requiring no baking.

Floor and Pit Molding When large castings are to be produced, these may be cast either directly on the floor of the foundry or in pits in the floor which serve as the flask. **Loam molding** is a variation of floor molding in which molding material composed of 50 percent sand and 50 percent clay (approx) is troweled onto a brickwork surface and brought to dimension by use of patterns, sweeps, or templates.

Shell Molding Sand castings having close dimensional tolerances and smooth finish can be produced by a process using a synthetic resin binder. The sand and resin mixture is dumped onto a preheated metal pattern, which causes the resin in the mixture to set as a thin shell over the pattern. When the shell has reached the proper thickness, the excess sand is removed by rotating the pattern to dump out the sand. The remaining shell is then cured on the pattern and subsequently removed by stripping it off, using mold release pins which have been properly spaced and that are mechanically or hydraulically made to protrude through the pattern. Mating shell halves are bonded, suitably backed by loose sand or other material, and then ready for metal to be poured. Current practice using shell molds has produced castings in excess of 1,000 lb, but often the castings weigh much less.

Plaster Molds Plaster or plaster-bonded molds are used for casting certain aluminum or copper base alloys. Dimensional accuracy and excellent surface finish make this a useful process for making rubber tire molds, match plates, etc.

A variation of this method of molding is the **Antioch process,** using mixtures of 50 percent silica sand, 40 percent gypsum cement, 8 percent talc, and small amounts of sodium silicate, portland cement, and magnesium oxide. These dry ingredients are mixed with water and poured over the pattern. After the mixture is poured, the mold is steam-treated in an autoclave and then allowed to set in air before drying in an oven. When the mold has cooled it is ready for pouring. Tolerances of ± 0.005 in (± 0.13 mm) on small castings and ± 0.015 in (± 0.38 mm) on large castings are obtained by this process.

A problem presented by plaster molds lies in inadequate permeability in the mold material consistent with the desired smooth mold cavity surface. A closely related process, the **Shaw process,** provides a solution.

Table 13.1.2 Design and Cost Features of Basic Casting Methods

Design and cost features	Process					
	Sand casting	Shell-mold casting	Permanent-mold casting	Plaster-mold casting	Investment casting	Die casting
Choice of materials	Wide—ferrous and nonferrous	Wide—except for low-carbon steels	Restricted—brass, bronze, aluminum, some gray iron	Narrow—brass, bronze, aluminum	Wide—includes hard-to-forge and machine materials	Narrow—zinc, aluminum, brass, magnesium
Complexity	Considerable	Moderate	Moderate	Considerable	Greatest	Considerable
Size range	Great	Limited	Moderate	Moderate	Moderate	Moderate
Minimum section, in	3/32	1/16	0.100	0.010	0.010	0.025
Tolerances, in ft*	1/16–1/8	1/32–3/32	1/32–7/64	1/32–5/64	0.003–0.006	1/32–1/16
Surface smoothness, μin, rms	250–300	150–200	90–125	90–125	90–125	60–125
Design feature remarks	Basic casting method of industry	Considered to be good low-cost casting method	Production economics with substantial quantities	Little finishing required	Best for parts too complicated for other casting methods	Most economical where applicable
Tool and die costs	Low	Low to moderate	Medium	Medium	Low to moderate	High
Optimum lot size	Wide—range from few pieces to huge quantities	More required than sand castings	Best when requirements are in thousands	From one to several hundred	Wide—but best for small quantities	Substantial quantities requird
Direct labor costs	High	Moderate	Moderate	High	Very high	Low to medium
Finishing costs	High	Low	Low to moderate	Low	Low	Low
Scrap costs	Moderate	Low	Low	Low	Low	Low

* Closer at extra cost.
SOURCE: Cook, "Engineered Castings," McGraw-Hill.

In this process, a refractory aggregate is mixed with a gelling agent and then poured over the pattern. Initial set of the mixture results in a rubbery consistency which allows it to be stripped from the pattern but which is sufficiently strong to return to the shape it had when on the pattern. The mold is then ignited to burn off the volatile content in the set gel and baked at very high heat. This last step results in a hard, rigid mold containing microscopic cracks. The permeability of the completed mold is enhanced by the presence of the so-called microcrazes, while the mold retains the high-quality definition of the mold surface.

Two facts are inherent in the nature of sand molds: First, there may be one or few castings required of a given piece, yet even then an expensive wood pattern is required. Second, the requirement of removal of the pattern from the mold may involve some very intricate pattern construction. These conditions may be alleviated entirely by the use of the **full mold process,** wherein a foamed polystyrene pattern is used. Indeed, the foamed pattern may be made complete with a gating and runner system, and it can incorporate the elimination of draft allowance. In actual practice, the pattern is left in place in the mold and is instantly vaporized when hot metal is poured. The hot metal which vaporized the foam fills the mold cavity to the shape occupied previously by the foam pattern. This process is ideal for casting runs of one or a few pieces, but it can be applied to production quantities by mass-producing the foam patterns. There is extra expense for the equipment to make the destructible foam patterns, but often the economics of the total casting process is quite favorable when compared with resorting to a reusable pattern. There are particular instances when the extreme complexity of a casting can make a hand-carved foam pattern financially attractive.

The **lost-wax, investment, or precision-casting, process** permits the accurate casting of highly alloyed steels and of nonferrous alloys which are impossible to forge and difficult to machine. The procedure consists of making an accurate metal die into which the wax or plastic patterns are cast. The patterns are assembled on a sprue and the assembly sprayed, brushed, or dipped in a slurry of a fine-grained, highly refractory aggregate, and a proprietary bonding agent composed chiefly of ethyl silicate. This mixture is then allowed to set. The pattern is coated repeatedly with coarser slurries until a shell of the aggregate is produced around the pattern. The molds are allowed to stand until the aggregate has set, after which they are heated in an oven in an inverted position so that the wax will run out. After the wax is removed, the molds are baked in a preheat furnace. The molds may then be supported with loose sand and poured in any conventional manner.

There have been attempts in the past to use frozen mercury as a pattern. While mercury is a viable pattern material and can be salvaged totally for reuse, the inherent hazards of handling raw mercury have mitigated against its continued use to make patterns for investment castings.

All dimensions can be held to a tolerance of ± 0.005 in (± 0.13 mm) with some critical dimensions held to 0.002 in (0.05 mm). Most castings produced by this process are relatively small.

Faithful reproduction and accurate tolerances can also be attained by the **Shaw process;** see above. It combines advantages of dimensional control of precision molds with the ease of production of conventional molding. The process makes use of wood or metal patterns and a refractory mold bonded with an ethyl silicate base material. Since the mold is rubbery when stripped from the pattern, some back draft is permissible.

In the **cement-sand process** portland cement is used as the sand binder. A typical mixture has 11 percent portland cement, 89 percent silica sand, and water 4½ to 7 percent of the total sand and cement. New sand is used for facing the mold and is backed with ground-up sand which has been rebonded. Cores are made of the same material. The molds and cores must airdry 24 to 72 h before pouring. The process can be used for either ferrous or nonferrous castings. This molding mixture practically eliminates the generation of gases, forms a hard surface which resists the erosive action of the metal, and produces castings with good surfaces and accurate dimensions. This process is seldom used, and then only for specific castings wherein the preparation of this type of mold outweighs many of its disadvantages.

Permanent-Mold Casting Methods

In the **permanent-mold casting method,** fluid metal is poured by hand into metal molds and around metal cores without external pressure. The molds are mechanically clamped together. Of necessity, the complexity of the cores must be minimal, inasmuch as they must be withdrawn for reuse from the finished casting. Likewise, the shape of the molds must be relatively simple, free of reentrant sections and the like, or else the mold itself will have to be made in sections, with attendant complexity.

Metals suitable for this type of casting are lead, zinc, aluminum and magnesium alloys, certain bronzes, and cast iron.

For making iron castings of this type, a number of metal-mold units are usually mounted on a turntable. The individual operations, such as coating the mold, placing the cores, closing the mold, pouring, opening the mold, and ejection of the casting, are performed as each mold passes certain stations. The molds are preheated before the first casting is poured. The process produces castings having a dense, fine-grained structure, free from shrink holes or blowholes. The tool changes are relatively low, and better surface and closer tolerances are obtained than with the sand-cast method. It does not maintain tolerances as close or sections as thin as the die-casting or the plaster-casting methods.

Yellow brasses, which are high in zinc, should not be cast by the permanent-mold process because the zinc oxide fouls the molds or dies.

The **semipermanent mold casting method** differs from the permanent mold casting in that sand cores are used, in some places, instead of metal cores. The same metals may be cast by this method. This process is used where cored openings are so irregular in shape, or so undercut, that metal cores would be too costly or too difficult to handle. The structure of the metal cast around the sand cores is like that of a sand casting. The advantages of permanent mold casting in tolerances, density, appearance, etc., exist only in the section cast against the metal mold.

Graphite molds may be used as short-run permanent molds since they are easier to machine to shape and can be used for higher-melting point alloys, e.g., steel. The molds are softer, however, and more susceptible to erosive damage. Steel railroad wheels may be made in these molds and can be cast by filling the mold by **low-pressure casting** methods.

In the **slush casting** process, the cast metal is allowed partially to solidify next to the mold walls to produce a thin section, after which the excess liquid metal is poured out of the permanent mold.

In **centrifugal casting** the metal is under centrifugal force, developed by rotating the mold at high speed. This process, used in the manufacture of bronze, steel, and iron castings, has the advantage of producing sound castings with a minimum of risers. In **true centrifugal castings** the metal is poured directly into a mold which is rotated on its own axis. Obviously, the shapes cast by this method must have external and internal geometries which are surfaces of revolution. The external cast surface is defined by the internal surface of the water-cooled mold; the internal surface of the casting results from the effective core of air which exists while the mold is spun and until the metal solidifies sufficiently to retain its cast shape. Currently, all cast-iron pipe intended for service under pressure (e.g., water mains) is centrifugally cast. The process is extended to other metals falling under the rubric of **tubular goods.**

In **pressure casting,** for asymmetrical castings which cannot be spun around their own axes, the mold cavities are arranged around a common sprue located on the neutral axis of the mold. The molds used in the centrifugal-casting process may be metal cores or dry sand, depending on the type of casting and the metal cast.

Die casting machines consist of a basin holding molten metal, a metallic mold or die, and a metal transferring device which automatically withdraws molten metal from the basin and forces it under pressure into the die. Two forms of die casting machines are in general use. Lead, tin, and zinc alloys containing aluminum are handled in **piston machines.** Aluminum alloys and pure zinc, or zinc alloys free from aluminum, rapidly attack the iron in the piston and cylinder and require a different type of casting machine. The pressures in a piston machine range from a few hundred to thousands of lb/in^2.

The **gooseneck machine** has a cast-iron gooseneck which dips the molten metal out of the melting pot and transfers it to the die. The pressure is applied to the molten metal by compressed air after the gooseneck is brought in contact with the die. This machine, developed primarily for

aluminum alloys, is sometimes used for zinc-aluminum alloys, especially for large castings, but, owing to the lower pressure, the casting is likely to be less dense than when made in the piston machine. It is seldom used for magnesium alloys.

In **cold chamber machines** the molten-metal reservoir is separated from the casting machine, and just enough metal for one casting is ladled by hand into a small chamber, from which it is forced into the die under high pressure. The pressures, quite high, ranging from the low thousands to in excess of 10,000 lb/in^2, are produced by a hydraulic system connected to the piston in the hot metal chamber. The alloy is kept so close to its melting temperature that it is in a slushlike condition. The process is applicable to aluminum alloys, magnesium alloys, zinc alloys, and even higher-melting-point alloys like brasses and bronzes, since the pouring well, cylinder, and piston are exposed to the high temperature for only a short time.

All metal mold external pressure castings have close tolerances, sharp outlines and contours, fine smooth surface, and high rate of production, with low labor cost. They have a hard skin and a soft core, resulting from the rapid chilling effect of the cold metal mold.

The dies usually consist of two blocks of steel, each containing a part of the cavity, which are locked together while the casting is being made and drawn apart when it is ready for ejection. One-half of the die (next to the ejector nozzle) is stationary; the other half moves on a carriage. The dies are preheated before using and are either air- or water-cooled to maintain the desired operating temperature. Die life varies with the alloy and dimensional tolerances required. Retractable and removable metal cores are used to form internal surfaces. Inserts can be cast into the piece by placing them on locating pins in the die.

A wide range of sizes and shapes can be made by these processes, including threaded pieces and gears. Holes can be accurately located. The process is best suited to large-quantity production.

A historic application of the process was for typesetting machines such as the linotype. Although now they are obsolescent and rarely found in service, for a long time the end products of typesetting machines were a prime example of a high-quality die-cast metal product.

MOLDING EQUIPMENT AND MECHANIZATION

Flasks may be filled with sand by hand shoveling, gravity feed from overhead hoppers, continuous belt feeding from a bin, sand slingers, and, for large molds, by an overhead crane equipped with a grab bucket.

Hand ramming is the simplest method of compacting sand. To increase the rate, pneumatic rammers are used. The method is slow, the sand is rammed in layers, and it is difficult to gain uniform density.

More uniform results and higher production rates are obtained by **squeezing machines.** Hand-operated squeezers were limited to small molds and are obsolete; **air-operated machines** permit an increase in the allowable size of molds as well as in the production rate. These machines are suitable for shallow molds. Squeezer molding machines produce greatest sand density at the top of the flask and softest near the parting line of pattern. Air-operated machines are also applied in vertical molding processes using flaskless molds. Horizontal impact molding sends shock waves through the sand to pack the grains tightly.

In **jolt molding machines** the pattern is placed on a platen attached to the top of an air cylinder. After the table is raised, a quick-release port opens, and the piston, platen, and mold drop free against the top of the cylinder or striking pads. The impact packs the sand. The densities produced by this machine are greatest next to the parting line of the pattern and softest near the top of the flask. This procedure can be used for any flask that can be rammed on a molding machine. As a separate unit, it is used primarily for medium and large work. Where plain jolt machines are used on large work, it is usual to ram the top of the flask manually with an air hammer.

Jolt squeeze machines use both the jolt and the squeeze procedures. The platen is mounted on two air cylinders: a small cylinder to jolt and a large one to squeeze the mold. They are widely used for small and medium work, and with match-plate or gated patterns. Pattern-stripping devices can be incorporated with jolt or squeezer machines to permit mechanical removal of the pattern. Pattern removal can also be accomplished by using jolt-rockover-draw or jolt-squeeze-rollover-draw machines.

The **sand slinger** is the most widely applicable type of ramming machine. It consists of an impeller mounted on the end of a double-jointed arm which is fed with sand by belt conveyors mounted on the arm. The impeller rotating at high speed gives sufficient velocity to the sand to ram it in the mold by impact. The head may be directed to all parts of the flask manually on the larger machines and may be automatically controlled on smaller units used for the high-speed production of small molds.

Vibrators are used on all pattern-drawing machines to free the pattern from the grip of the sand before drawing. Their use reduces mold damage to a minimum when the pattern is removed, and has the additional advantage of producing castings of more uniform size than can be secured by hand rapping the pattern. Pattern damage is also kept to a minimum. Vibrators are usually air-operated, but some electrically operated types are in use.

Flasks generally consist of two parts: the upper section, called the **cope,** and the bottom section, the **drag.** When more than two parts are used, the intermediate sections are called **cheeks.** Flasks are classified as tight, snap, and slip. **Tight flasks** are those in which the flask remains until the metal is poured. Snap flasks are hinged on one corner and have a locking device on the diagonally opposite corner. In use, these flasks are removed as soon as the mold is closed. **Slip flasks** are of solid construction tapered from top to bottom on all four sides so that they can be removed as soon as the mold is closed. Snap or slip flasks permit the molder to make any number of molds with one flask. Before pouring snap- or slip-flask molds, a wood or metal pouring jacket is placed around the mold and a weight set on the top to keep the cope from lifting. The cope and drag sections on all flasks are maintained in proper alignment by flask pins and guides.

Tight flasks can be made in any size and are fabricated of wood, rolled steel, cast steel, cast iron, magnesium, or aluminum. Wood, aluminum, and magnesium are used only for small- and medium-sized flasks. Snap and slip flasks are made of wood, aluminum, or magnesium, and are generally used for molds not over 20 by 20 in (500 mm by 500 mm).

Mechanization of Sand Preparation

In addition to the various types of molding machines, the modern foundry makes use of a variety of equipment to handle the sand and castings.

Sand Preparation and Handling Sand is prepared in **mullers,** which serve to mix the sand, bonding agent, and water. **Aerators** are used in conjunction to loosen the sand to make it more amenable to molding. **Sand cutters** that operate over a heap on the foundry floor may be used instead of mullers. Delivery of the sand to the molding floor may be by means of dump or scoop trucks or by belt conveyors. At the molding floor the molds may be placed on the floor or delivered by conveyors to a pouring station. After pouring, the castings are removed from the flasks and adhering sand at a **shakeout** station. This may be a mechanically operated jolting device that shakes the loose sand from flask and casting. The used sand, in turn, is returned to the storage bins by belt conveyor or other means. Small castings may be poured by using **stackmolding** methods. In this case, each flask has a drag cavity molded in its upper surface and a cope cavity in its lower surface. These are stacked one on the other to a suitable height and poured from a common sprue.

There is an almost infinite variety of equipment and methods available to the foundry, ranging from simple, work-saving devices to completely mechanized units, including completely automatic molding machines. Because of this wide selection available, the degree to which a foundry can be mechanized depends almost entirely on the economics of the operations, rather than the availability or lack of availability of a particular piece of equipment.

MOLDING SAND

Molding sand consists of silica grains held together by some bonding material, usually clay or bentonite.

Grain size greatly influences the surface finish of a casting. The proper grain size is determined by the size of the casting, the quality of surface required, and the surface tension of the molten metal. The grain size should be approximately uniform when maximum permeability is desired.

Naturally bonded sands are mixtures of silica and clay as taken from the pits. Modification may be necessary to produce a satisfactory mixture. This type of sand is used in gray iron, ductile iron, malleable iron, and nonferrous foundries (except magnesium).

Synthetically bonded sands are produced by combining clay-free silica sand with clay or bentonite. These sands can be compounded to suit foundry requirements. They are more uniform than naturally bonded sands but require more careful mixing and control. Steel foundries, gray iron and malleable iron foundries, and magnesium foundries use this type of sand.

Special additives may be used in addition to the basic sand, clay, and water. These include cereals, ground pitch, sea coal, gilsonite, fuel oil, wood flour, silica flour, iron oxide, pearlite, molasses, dextrin, and proprietary materials. These all serve the purpose of altering specific properties of the sand to give desired results.

The properties of the sand that are of major interest to the foundry worker are **permeability,** or the venting power, of the sand; **green compressive strength; green shear strength; deformation,** or the sand movement under a given load; **dry compressive strength;** and **hot strength,** i.e., strength at elevated temperatures. Several auxiliary tests are often made, including moisture content, clay content, and grain-size determination.

The foundry engineer or metallurgist who usually is entrusted with the control of the sand properties makes the adjustments required to keep it in good condition.

Facing sands, for giving better surface to the casting, are used for gray iron, malleable iron, steel, and magnesium castings. The iron sands usually contain **sea coal,** a finely ground coal which keeps the sand from adhering to the casting by generating a gas film when in contact with the hot metal. Steel facings contain silica flour or other very fine highly refractory material to form a dense surface which the metal cannot readily penetrate.

Mold washes are coatings applied to the mold or core surface to improve the finish of the casting. They are applied either wet or dry. The usual practice is to brush or spray the wet mold washes and to brush or rub on the dry ones. Graphite or silica flour mixed with clay and molasses water is frequently used. The washes are mixed usually with waterbase or alcohol-base solvent solutions that require oven drying time, during which not only does the wash set, but also the excess moisture is removed from the washed coating.

Core Sands and Core Binders

Green sand cores are made from standard molding-sand mixtures, sometimes strengthened by adding a binder, such as dextrin, which hardens the surface. Cores of this type are very fragile and are usually made with an arbor or wires on the inside to facilitate handling. Their collapsibility is useful to prevent hot tearing of the casting.

Dry sand cores are made from silica sand and a binder (usually oil) which hardens under the action of heat. The amount of oil used should be the minimum which will produce the necessary core strength.

Core binders are either organic, such as core oil, which are destroyed under heat, or inorganic, which are not destroyed.

Organic Binders The main organic binder is **core oil.** Pure linseed oil is used extensively as one of the basic ingredients in blended-oil core binders. These consist primarily of linseed oil, resin, and a thinner, such as high-grade kerosene. They have good wetting properties, good workability, and better oxidation characteristics than straight linseed oil.

Corn flour produces good green strength and dry strength when used in conjunction with oil. Cores made with this binder are quick drying in the oven and burn out rapidly and completely in the mold.

Dextrin produces a hard surface and weak center because of the migration of dextrin and water to the surface. Used with oil, it produces a hard smooth surface but does not produce a green bond as good as that with corn flour.

Commercial **protein binders,** such as gelatin, casein, and glues, improve flowability of the sand, have high binding power, rapid drying, fair resistance to moisture, and low burning-out point, with only a small volume of gas evolved on burning. They are used where high collapsibility of the core is essential.

Other binders include paper-mill by-products, which absorb moisture readily, have high dry strength, low green strength, high gas ratio, and high binding power for clay materials.

Coal tar pitch and **petroleum pitch** flow with heat and freeze around the grains on cooling. These compounds have low moisture absorption rates and are used extensively for large iron cores. They can be used effectively with impure sands.

Wood and **gum rosin, plastic resins,** and rosin by-products are used to produce collapsibility in cores. They must be well ground. They tend to cake in hot weather, and large amounts are required to get desired strength.

Plastics of the **urea-** and **phenol-formaldehyde** groups and **furan resins** are being used for core binders. They have the advantage of low-temperature baking, collapse readily, and produce only small amounts of gas. These can be used in **dielectric baking ovens** or in the **shell molding, hot box, or air setting** processes for making cores.

Inorganic binders include fire clay, southern bentonite, western bentonite, and iron oxide.

Cores can also be made by mixing sand with sodium silicate. When this mixture is in the core box, it is infiltrated with CO_2, which causes the core to harden. This is called the **CO_2 process.**

Core-Making Methods

Cores are made by the methods employed for sand molds. In addition, **core blowers** and **extrusion machines** are used.

Core blowers force sand into the core box by compressed air at about 100 lb/in^2. They can be used for making all types of small- and medium-sized cores. The cores produced are very uniform, and high production rates are achieved.

Screw feed machines are used largely for plain cylindrical cores of uniform cross section. The core sand is extruded through a die onto a core plate. The use of these machines is limited to the production of stock cores, which are cut to the desired length after baking.

Core Ovens Core oven walls are constructed of inner and outer layers of sheet metal separated by rock wool or Fiberglas insulation and with interlocked joints. Combustion chambers are refractory-lined, and the hot gases are circulated by fans. They are designed for operating at temperatures suitable for the constituents in the core body. Time at baking temperatures will, likewise, vary with the composition of the core.

Core driers are light skeleton cast iron or aluminum boxes, the internal shape of which conforms closely to the cope portion of the core. They are used to support, during baking, cores which cannot be placed on a flat plate.

Chaplets are metallic pieces inserted into the mold cavity which support the core. Long unsupported cores will be subject to flotation force as the molten metal fills the mold and may break if the resulting flexural stresses are excessive. Likewise, the liquid forces imposed on cores as metal flows through the mold cavity may cause cores to shift. The chaplets interposed within the mold cavity are placed to alleviate these conditions. They are generally made of the same material as that being cast; they melt and blend with the metal as cast, and they remain solid long enough for the liquid forces to equilibrate through the mold cavity.

CASTING ALLOYS

In general, the types of alloys that can be produced as wrought metals can also be prepared as castings. Certain alloys, however, cannot be forged or rolled and can only be used as cast.

Ferrous Alloys

Steel Castings (See Sec. 6.3.) Steel castings may be classified as:

1. Low carbon ($C < 0.20$ percent). These are relatively soft and not readily heat-treatable.
2. Medium carbon (0.20 percent $< C < 0.50$ percent). These castings are somewhat harder and amenable to strengthening by heat treatment.

3. High carbon (C > 0.50 percent). These steels are used where maximum hardness and wear resistance are desired.

In addition to the classification based on carbon content, which determines the maximum hardness obtainable in steel, the castings can be also classified as **low alloy** content (≤ 8 percent) or **high alloy** content (> 8 percent).

Low-alloy steels behave essentially as plain carbon steels but have a higher **hardenability,** which is a measure of ability to be hardened by heat treatment. High-alloy steels are designed to produce some specific property, like corrosion resistance, heat resistance, wear resistance, or some other special property.

Malleable Iron Castings The carbon content of malleable iron ranges from about 2.00 to 2.80 percent and may reach as high as 3.30 percent if the iron is melted in a cupola. Silicon ranging from 0.90 to 1.80 percent is an additional alloying element required to aid the annealing of the iron. As cast, this iron is hard and brittle and is rendered soft and malleable by a long heat-treating or annealing cycle. (See also Sec. 6.3.)

Gray Iron Castings Gray iron is an alloy of iron, carbon, and silicon, containing a higher percentage of these last two elements than found in malleable iron. Much of the carbon is present in the elemental form as graphite. Other elements present include manganese, phosphorus, and sulfur. Because the properties are controlled by proper proportioning of the carbon and silicon and by the cooling rate of the casting, it is usually sold on the basis of specified properties rather than composition. The carbon content will usually range between 3.00 and 4.00 percent and the silicon will be between 1.00 and 3.00 percent, the higher values of carbon being used with the lower silicon values (usually), and vice versa. As evidence of the fact that gray iron should not be considered as a material having a single set of properties, the ASTM and AFS codify gray cast iron in several classes, with accompanying ranges of tensile strengths available. The high strengths are obtained by proper adjustment of the carbon and silicon contents or by alloying. (See also Sec. 6.3.)

An important variation of gray iron is **nodular iron,** or **ductile iron,** in which the graphite appears as nodules rather than as flakes. This iron is prepared by treating the metal in the ladle with additives that usually include magnesium in alloy form. Nodular iron can exceed 100,000 lb/in^2 (690 MN/m^2) as cast and is much more ductile than gray iron, measuring about 2 to 5 percent elongation at these higher strengths, and even higher percentages if the strength is lower. (See Sec. 6.3.)

Nonferrous Alloys

Aluminum-Base Castings Aluminum is alloyed with copper, silicon, magnesium, zinc, nickel, and other elements to produce a wide variety of casting alloys having specific characteristics of foundry properties, mechanical properties, machinability, and/or corrosion resistance. Alloys are produced for use in sand casting, permanent mold casting, or die casting. Some alloys are heat-treatable using **solution** and **age-hardening** treatments. (See also Sec. 6.4.)

Copper-Base Alloys The alloying elements used with copper include zinc (brasses), tin (bronzes), nickel (nickel bronze), aluminum (aluminum bronze), silicon (silicon bronze), and beryllium (beryllium bronze). The brasses and tin bronzes may contain lead for machinability. Various combinations of zinc and tin, or of tin or zinc with other elements, are also available. With the exception of some of the aluminum bronzes and beryllium bronze, most of the copper-base alloys cannot be hardened by heat treatment. (See also Sec. 6.4.)

Special Casting Alloys Other metals cast in the foundry include **magnesium-base alloys** for light weight, **nickel-base alloys** for high-temperature applications, **titanium-base alloys** for strength-to-weight ratio, etc. The magnesium-base alloys require special precautions during melting and pouring to avoid burning. (See Sec. 6.4.)

MELTING AND HEAT TREATING FURNACES

There are several types of **melting furnaces** used in conjunction with metal casting. Foundry furnaces used in melting practice for ferrous castings are predominantly **electric arc** (direct and indirect), **induction,** and **crucible** for small operations. For cast iron, **cupolas** are still employed, although in ever-decreasing quantities. The previous widespread use of open-hearth furnaces is now relegated to isolated foundries and is essentially obsolete. In general, ferrous foundries' melting practice has become based largely on electric-powered furnaces. **Duplexing** operations are still employed, usually in the form of cupola/induction furnace, or cupola/electric arc furnace.

In nonferrous foundries, electric arc, induction, and crucible furnaces predominate. There are some residual installations which use air furnaces, but they are obsolete and found only in some of the older, small foundries which cater to unique clients.

Vacuum melting and metal refining were fostered by the need for extremely pure metals for high-temperature, high-strength applications (e.g., gas-turbine blades). Vacuum melting is accomplished in a furnace located in an evacuated chamber; the source of heat is most often an electric arc and sometimes induction coils. Gases entrained in the melt are removed, the absence of air prevents oxidation of the base metals, and a high degree of metal purity is retained in the molten metal and in the casting ultimately made from that vacuum-melted metal. The mold is also enclosed in the same evacuated chamber.

The vacuum melting and casting process is very expensive because of the nature of the equipment required, and quantities of metal handled are relatively small. The economics of the overall process are justified by the design requirements for highest-quality castings for ultimately very demanding service.

Annealing and **heat-treating furnaces** used to process castings are the type usually found in industrial practice. (See Secs. 7.3. and 7.5.)

CLEANING AND INSPECTION

Tumbling barrels consist of a power-driven drum in which the castings are tumbled in contact with hard iron stars or balls. Their impact removes the sand and scale.

In **air-blast cleaning units,** compressed air forces silica sand or chilled iron shot into violent contact with the castings, which are tumbled in a barrel, rotated on a table, or passed between multiple orifices on a conveyor. Large rooms are sometimes utilized, with an operator directing the nozzle. These machines are equipped with hoppers and elevators to return the sand or shot to the magazine. Dust-collecting systems are required.

In **centrifugal-blast cleaning units,** a rotating impeller is used to impart the necessary velocity to the chilled iron shot or abrasive grit. The velocities are not so high as with air, but the volume of abrasive is much greater. The construction is otherwise similar to the air blast machine.

Water in large volume at pressures of 250 to 600 lb/in^2 is used to remove sand and cores from medium and large castings.

High-pressure water and sand cleaning (Hydroblast) employs high pressure water mixed with molding sand which has been washed off the casting. A sand classifier is incorporated in the sand reclamation system.

Pneumatic chipping hammers may be used to clean large castings where the sand is badly burned on and for deep pockets.

Removal of Gates and Risers and Finishing Castings The following tabulation shows the most generally used methods for removing gates and risers (marked R) and for finishing (marked F).

Steel Oxyacetylene (R) hand hammer or sledge (R), grinders (F), chipping hammer, (F), and machining (F).

Cast iron Chipping hammer (R, F), hand hammer or sledge (R), abrasive cutoff (R), power saw (R), and grinders (F).

Malleable iron Hand hammer or sledge (R), grinders (F), shear (F), and machining (F).

Brass and bronze Chipping hammer (R, F), shear (R, F), hand hammer or sledge (R), abrasive cutoff (R), power saw (R), belt sanders (F), grinders (F), and machining (F).

Aluminum Chipping hammer (R), shear (R), hand hammer or sledge (R), power saw (R), grinders (F), and belt sander (F).

Magnesium Band saw (R), machining (F), and flexible-shaft machines with steel burr cutters (F).

Casting Inspection

(See Sec. 5.4.)

Castings are inspected for dimensional accuracy, hardness, surface finish, physical properties, internal soundness, and cracks. For **hardness** and for **physical properties,** see Sec. 6.

Internal soundness is checked by cutting or breaking up pilot castings or by nondestructive testing using X-ray, gamma ray, etc.

Destructive testing tells only the condition of the piece tested and does not ensure that other pieces not tested will be sound. It is the most commonly used procedure at the present time.

X-ray, gamma ray, and other methods have made possible the nondestructive checking of castings to determine internal soundness on all castings produced. Shrinks, cracks, tears, and gas holes can be determined and repairs made before the castings are shipped.

Magnetic powder tests (Magnaflux) are used to locate structural discontinuities in iron and steel except austenitic steels, but they are not applicable to most nonferrous metals or their alloys. The method is most useful for the location of surface discontinuities, but it may indicate subsurface defects if the magnetizing force is sufficient to produce a leakage field at the surface.

In this test a magnetic flux is induced in ferromagnetic material. Any abrupt discontinuity in its path results in a local flux leakage field. If finely divided particles of ferromagnetic material are brought into the vicinity, they offer a low reluctance path to the leakage field and take a position that outlines approximately its effective boundaries. The casting to be inspected is magnetized and its surface dusted with the magnetic powder. A low velocity air stream blows the excess powder off and leaves the defect outlined by the powder particles. The powder may be applied while the magnetizing current is flowing **(continuous method)** or after the current is off (**residual method**). It may be applied dry or suspended in a light petroleum distillate similar to kerosene. Expert interpretation of the tests is necessary.

CASTING DESIGN

Design for the best utilization of metal in the cast form requires a knowledge of metal solidification characteristics, foundry practices, and the metallurgy of the metal being used. Metals exhibit certain peculiarities in the formation of solid metal during freezing and also undergo shrinkage in the liquid state during the freezing process and after freezing, and the casting must be designed to take these factors into consideration. Knowledge concerning the freezing process will also be of assistance in determining the fluidity of the metal, its resistance to **hot tearing,** and its tendency to evolve dissolved gases. For economy in production, casting design should take into consideration those factors in molding and coring that will lead to the simplest procedures. Elimination of expensive cores, irregular parting lines, and deep drafts in the casting can often be accomplished with a slight modification of the original design. Combination of the foregoing factors with the selection of the right metal for the job is important in casting design. Consultation between the design engineer and personnel at the foundry will result in well-designed castings and cost-effective foundry procedures. Initial guidance may be had from the several references cited and from updated professional literature, which abounds in the technical journals. Trade literature, as represented by the publications issued by the various generic associations, will be useful in assessing potential problems with specific casting designs. Generally, time is well spent in these endeavors before an actual design concept is reduced to a set of dimensional drawings and/or specifications.

13.2 PLASTIC WORKING OF METALS

by Rajiv Shivpuri

(See also Secs. 5 and 6.)

STRUCTURE

Yieldable structural forces between the particles composing a material to be worked are the key to its behavior. Simple internal structures contain only a single element, as pure copper, silver, or iron. Relatively more difficult to work are the solid solutions in which one element tends to distribute uniformly in the structural pattern of another. Thus silver and gold form a continuous series of solid-solution alloys as their proportions vary. Next are alloys in which strongly bonded molecular groups dispersed through or along the grain boundaries of softer metals offer increasing resistance to working, as does iron carbide (Fe_3C) in solution in iron.

Bonding forces are supplied by electric fields characteristic of individual atoms. These forces in turn are subject to modification by temperature as energy is added, increasing electron activity.

The **particles** which constitute an atom are so small that most of its volume is empty space. For a similar energy state, there is some rough uniformity in the outside size of atoms. In general, therefore, the more complex elements have their larger number of particles more densely packed and so are heavier. For each element, the energy pattern of its electric charges in motion determines the field characteristics of that atom and which of the orderly arrangements it will seek to assume with relation to others like it in the orderly crystalline form.

Space lattice is the term used to describe the orderly arrangement of rows and layers of atoms in the crystalline form. This orderly state is also described as balanced, unstrained, or **annealed.** The working or deforming of materials distorts the orderly arrangement, unbalancing the forces between atoms. Cubic patterns or space lattices characterize the more ductile or workable materials. Hexagonal and more complex patterns tend to be more brittle or more rigid. Flaws, irregularities, or distortions, with corresponding unbalanced strains among adjacent atoms, may occur in the pattern or along grain boundaries. **Slip-plane** movements in working to new shapes tend to slide the once orderly layers of atoms within the grain-boundary limitations of individual crystals. Such sliding movement tends to take place at 45° to the direction of the applied load because much higher stresses are required to pull atoms directly apart or to push them straight together.

Chemical combinations, in liquid or solid solutions, or molecular compounds depend upon relative field patterns of elements or upon actual displacement of one or more electrons from the outer orbit of a donor element to the outer orbit of a receptor element. Thus the molecules of hard iron carbide, Fe_3C, may be held in solid solution in soft pure iron (ferrite) in increasing proportions up to 0.83 percent of carbon in iron, which is described as **pearlite.** Zinc may occupy solid-solution positions in the copper space lattice up to about 45 percent, the range of the ductile red and yellow brasses.

Thermal Changes Adding heat (energy) increases electron activity and therefore also the mobility of the atom. Probability of brittle failure at low temperatures usually becomes less as temperature increases. Transition temperatures from one state to another differ for different

elements. Thermal transitions therefore become more complex as such differing elements are combined in alloys and compounds. As temperatures rise, a **stress-relieving** range is reached at which the most severely strained atoms are able to ease themselves around into less strained positions. At somewhat higher temperatures, **annealing** or **recrystallization** of worked or distorted structure takes place. Old grain boundaries disappear and small new grains begin to grow, aligning nearby atoms into their orderly lattice pattern. The more severely the material has been worked, the lower is the temperature at which recrystallization begins. Grain growth is more rapid at higher temperatures. In working materials above their recrystallization range, as in forging, the relief of interatomic strains becomes more nearly spontaneous as the temperature is increased. **Creep** takes place when materials are under some stress above the recrystallization range, and the thermal mobility permits individual atoms to ease around to relieve that stress with an accompanying gradual change of shape. Thus a wax candle droops due to gravity on a hot day. Lead, which recrystallizes below room temperature, will creep when used for roofing or spouting. Steels in rockets and jet engines begin to creep around 1,300 to 1,500°F (704 to 815°C). Creep is more rapid as the temperature rises farther above the recrystallization range.

PLASTICITY

Plasticity is that property of materials which commends them to the mass-production techniques of pressure-forming desired shapes. It is understood more easily if several types of plasticity are considered.

Crystoplastic describes materials, notably metals, which can be worked in the stable crystalling state, below the recrystallization range. Metals which crystallize in the cubic patterns have a wider plastic range than those of hexagonal pattern. Alloying narrows the range and increases the resistance to working. Tensile or compressive testing of an annealed specimen can be used to show the plastic range which lies between the initial yield point and the point of ultimate tensile or compressive failure.

The **plastic range,** as of an annealed metal, is illustrated in Fig. 13.2.1. Changing values of **true stress** are determined by dividing the applied load at any instant by the cross-section area at that instant. As material is worked, a progressive increase in elastic limit and yield point registers the slip-plane movement or work hardening which has taken place and the consequent reduction in residual plasticity. This changing yield point or resistance, shown in Fig. 13.2.1, is divided roughly into three characteristic ranges. The contour of the lower range can be varied by nonuniformity of grain sizes or by small displacements resulting from prior direction of working. Random large, soft grains yield locally under slight displacement, with resulting **surface markings,** described as *orange peel, alligator skin,* or *stretcher strain markings.* These can be prevented by preparatory roller leveling, which gives protection in the case of steel for perhaps a day, or by a 3 to 5 percent temper pass of cold-rolling, which may stress relieve in perhaps 3 months, permitting recurrent trouble. The middle range covers most drawing and forming operations. Its upper limit is the point of normal tensile failure. The upper range requires that metal be worked primarily in compression to inhibit the start of tensile fracture. Severe extrusion, spring-temper rolling, and music-wire drawing use this range.

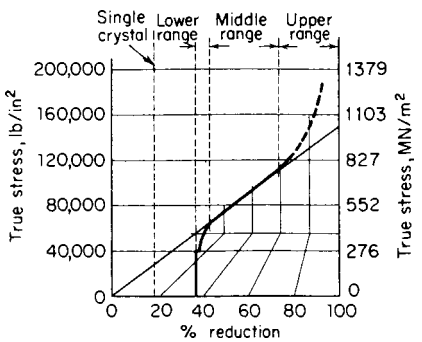

Fig. 13.2.1 Three ranges of crystoplastic work hardening of a low-carbon steel. *(ASME, 1954, W. S. Wagner, E. W. Bliss Co.)*

Dispersion hardening of metal alloys by heat treatment (see Fig. 13.2.2) reduces the plastic range and increases the resistance to work hardening. Figure 13.2.2 also shows the common methods of plotting change of true stress against **percentage of reduction**—e.g., reduction of thickness in rolling or compressive working, of area in wire drawing, ironing, or tensile testing, or of diameter in cup drawing or reducing operations—and against **true strain,** which is the natural logarithm of change of area, for convenience in higher mathematics.

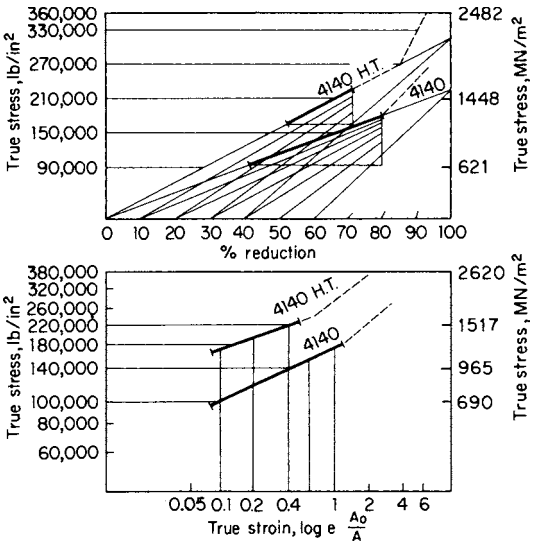

Fig. 13.2.2 High-range plasticity (dotted) of an SAE 4140 steel, showing the effect of dispersion hardening. Two plotting methods. *(ASME, 1958, Crane and Wagner, E. W. Bliss Co.)*

For metals, thermoplastic working is usually described as **hot working**, except for tin and lead, which recrystallize below room temperature. Hot-worked samples may be etched to show **flow lines,** which are usually made up of old-grain boundaries. Where these show, recrystallization has not yet taken place, and some work hardening is retained to improve physical properties. Zinc and magnesium, which are typical of the hexagonal-structure metals, take only small amounts of cold working but can be drawn or otherwise worked severely at rather moderate temperatures [Zn, 200 to 400°F (90 to 200°C); Mg, 500 to 700°F (260 to 400°C)]. Note that, although hexagonal-pattern metals are less easily worked than cubic-pattern metals, they are for that same reason structurally more rigid for a similar relative weight. Advantageous forging temperatures change with alloy composition: copper, 1,800 to 1,900°F (980 to 1,040°C); red brass, Cu 70, Zn 30, 1,600 to 1,700°F (870 to 930°C); yellow brass, Cu 60, Zn 40, 1,200 to 1,500°F (650 to 815°C). See Sec. 6 for general physical properties of metals.

Substantially pure iron shows an increasing elastic limit and decreasing plasticity with increasing amounts of work hardening by cold-rolling. The rate at which such work hardening takes place is greatly increased, and the remaining plasticity reduced, as alloying becomes more complex.

In **steels**, the mechanical working range is conventionally divided into cold, warm, and hot working. Figure 13.2.3 is a plot of flow stress, limit strain, scale factor, and dimensional error for different values of forging temperature and for two different strain rates. The **flow stress** is the resistance to deformation. As the temperature rises from room temperature to 2,072°F (1,100°C), the flow stress decreases first gradually and then rapidly to about 25 percent of its value [cold working 114 ksi (786 MPa) and hot working 28 ksi (193 MPa) at a strain of 0.5 and strain rate of 40 per second].

One measure of workability is the **strain limit.** As the temperature rises, the strain limit for the 70-in (in·s) strain rate (typical of mechanical

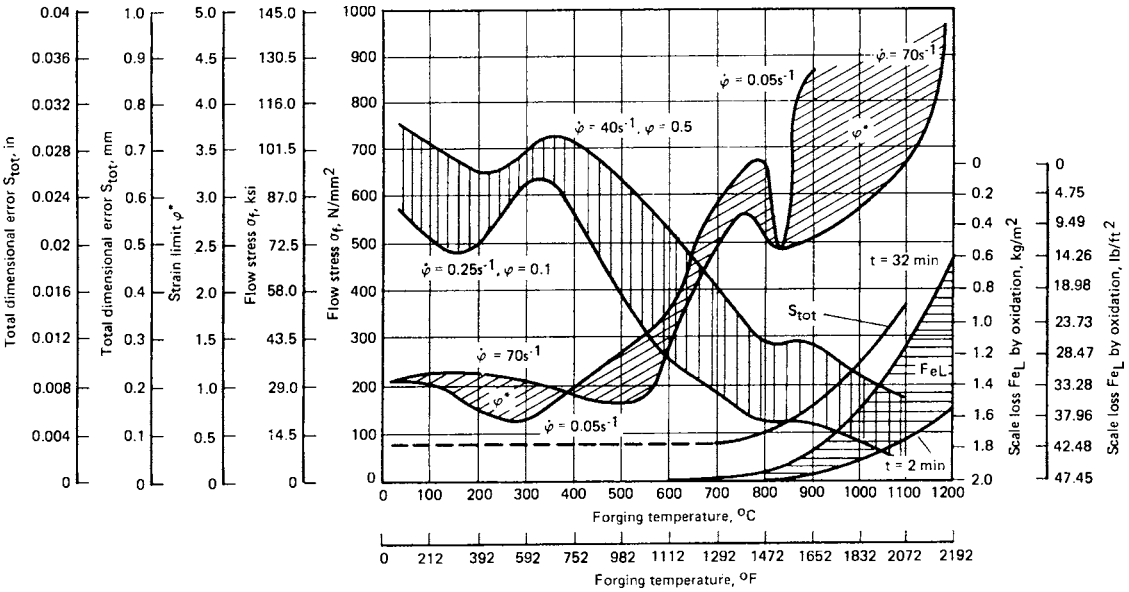

Fig. 13.2.3 Effect of forging temperature on forgeability and material properties. Material: AISI 1015 steel. ϕ = strain rate; ϕ^* = limiting strain; σ_f = flow stress; S_{tot} = dimensional error; Fe_L = scale loss. *(K. Lange, "Handbook of Metal Forming," McGraw-Hill, 1985.)*

press forging) decreases slightly up to 500°C (932°F), rises until 750°C (1,382°F), drops rapidly at 800°C (1,472°F) (often called *blue brittleness*), and beyond 850°C (1,562°F) increases rapidly to hot forging temperature of 1,100°C (2,012°F). Therefore, substantial advantages of low material resistance (low tool pressures and press loads) and excellent workability (large flow without material failure) can be realized in the hot-working range. Hot-working temperatures, however, also mean poor dimensional tolerance (total dimensional error), poor surface finish, and material loss due to scale buildup. Forging temperatures above 1,300°C (2,372°F) can lead to **hot shortness** manifested by melting at the grain boundaries.

MATERIAL RESPONSE IN METAL FORMING

The deformation conditions in metalworking processes span a range of deformation parameters, including strain and strain rates (Fig. 13.2.4) that are much higher than those encountered in conventional testing methods (Fig. 13.2.5). In machining, the strains are high and the strain rates can reach 10^5/s, while in explosive forming, strains are small at high strain rates providing extremely small response times. Forging and extrusion cover a wide range of strains and strain rates. Sheet forming carried out as small strains and strain rates differs from superplastic forming at extremely low strain rates but high strains. Consequently, different methods have been developed to test material response for different ranges of deformation parameters, i.e., strain and strain rate (Fig. 13.2.5).

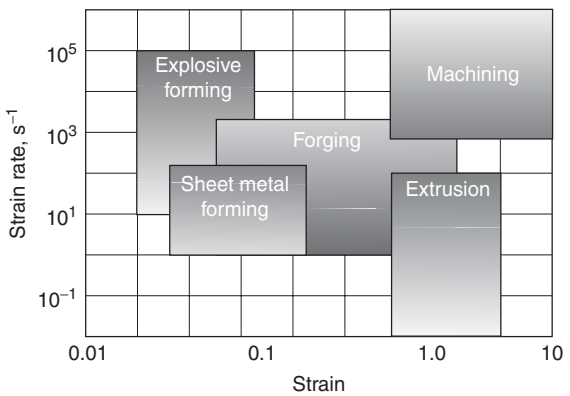

Fig. 13.2.4 Range of deformation parameters for various metalworking processes. (*Source: P. F. Bariani, S. Bruschi, and T. Dal Negro, Enhancing Performances of SHPB for Determination of Flow Curves, Annals of the CIRP,* **50,** no. 1, pp. 153–156.)

PLASTIC WORKING TECHNIQUES

In the **metalworking** operations, as distinguished from metal cutting, material is forced to move into new shapes by plastic flow. **Hot-working** is carried on above the recovery temperature, and spontaneous recovery, or annealing, occurs about as fast as the properties of the material are altered by the deformation. This process is limited by the chilling of the material in the tools, scaling of the material, and the life of the tools at the required temperatures. **Cold-working** is carried on at room temperature and may be applied to most of the common metals. Since, in most cases, no recovery occurs at this temperature, the properties of the metal are altered in the direction of increasing strength and brittleness throughout the working process, and there is consequently a limit to which cold-working may be carried without danger of fracture.

A convenient way of representing the action of the common metals when cold-worked consists of plotting the actual stress in the material against the percentage reduction in thickness. Within the accuracy required for shop use, the relationship is linear, as in Fig. 13.2.6. The lower limit of stress shown is the yield point at the softest temper, or anneal, commercially available, and the upper limit is the limit of tensile action, or the stress at which fracture, rather than flow, occurs. This latter value does not correspond to the commercially quoted "tensile strength" of the metal, but rather to the "true tensile strength," which is the stress that exists at the reduced section of a tensile specimen at fracture and which is higher than the nominal value in inverse proportion to the reduction of area of the material.

As an example of the construction and use of the cold-working plots shown in Fig. 13.2.6, the action of a very-low-carbon deep-drawing steel has been shown in Fig. 13.2.7. Starting with the annealed material with a yield point of 35,000 lb/in^2 (240 MN/m^2), the steel was drawn to successive reductions of thickness up to about 58 percent, and the

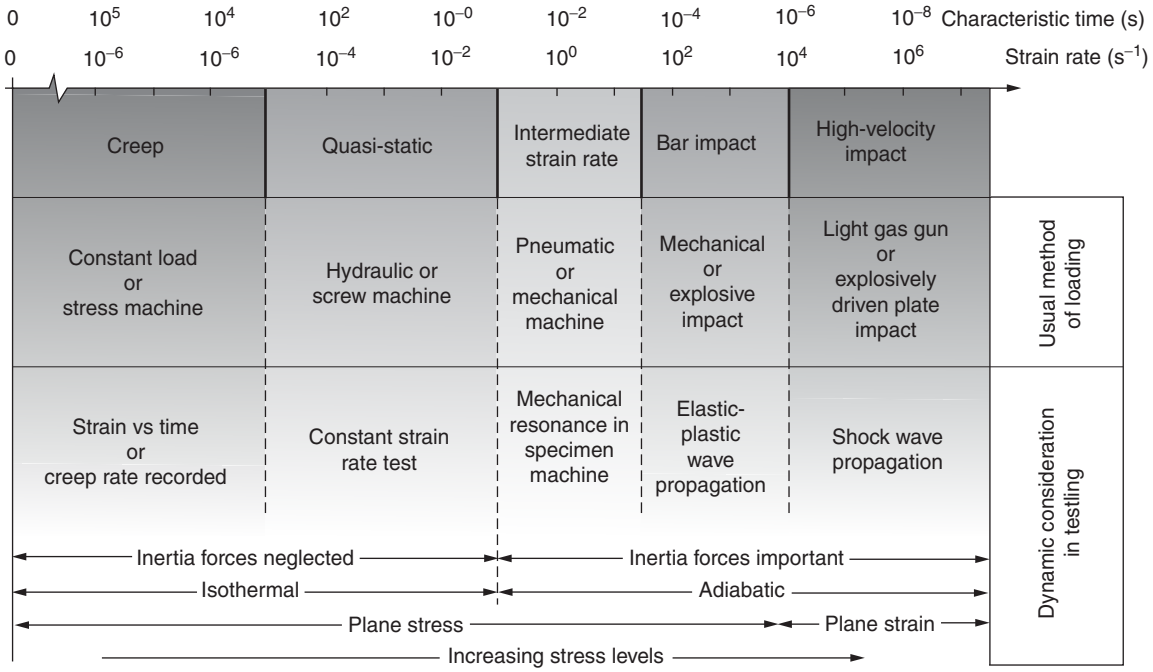

Fig. 13.2.5 Testing methods used to determine mechanical behavior of materials under various deformation regimes. *(Source: J. E. Field, W. G. Proud, S. M. Walley, and H. T. Goldrein, Review of Experimental Techniques for High Rate Deformation and Shock Studies, in "New Experimental Methods in Material Dynamics and Impact," AMAS, Warsaw, 2001.)*

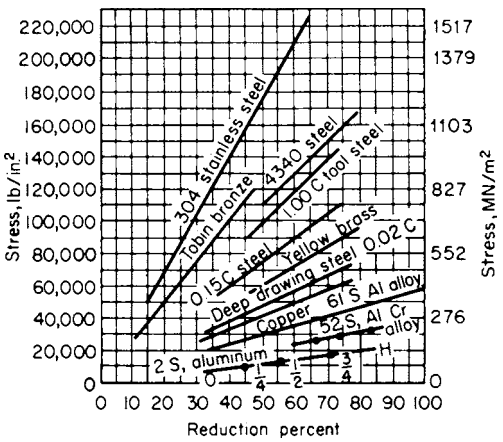

Fig. 13.2.6 Plastic range chart of commonly worked metals.

corresponding stresses plotted as the heavy straight line. The entire graph was then extrapolated to 100 percent reduction, giving the **modulus of strain hardening** as indicated, and to zero stress so that all materials might be plotted on the same graph. Lines of equal reduction are slanting lines through the point marking the modulus of strain hardening at theoretical 100 percent reduction. Starting at any initial condition of previous cold work on the heavy line, a percentage reduction from this condition will be indicated by a horizontal traverse to the slanting reduction line of corresponding magnitude and the resulting increase in stress by the vertical traverse from this point to the heavy line.

The traverse shown involved three draws from the annealed condition of 30, 25, and 15 percent each, and resulting stresses of 53,000, 63,000, and 68,000 lb/in^2 (365, 434, and 469 MN/m^2). After the initial 30 percent reduction, the next 25 percent uses (1.00 − 0.30) × 0.25, or 17.5 percent more of the cold-working range; the next 15 percent reduction uses (1.00 − 0.30 − 0.175) × 0.15, or about 8 percent of the original range, totaling 30 + 17.5 + 8 = 55.5 percent. This may be compared with the test value percent reduction in area for the particular material. The same result might have been obtained, die operation permitting, by a single reduction of 55 percent, as shown. Any appreciable reduction beyond this point would come dangerously close to the limit of plastic flow, and consequently an anneal is called for before any further work is done on the piece.

Figure 13.2.8 shows the approximate **true stress** vs. **true strain** plot of common plastic range values, for comparison with Fig. 13.2.6. In metal forming, a convenient way of representing the resistance of metal to

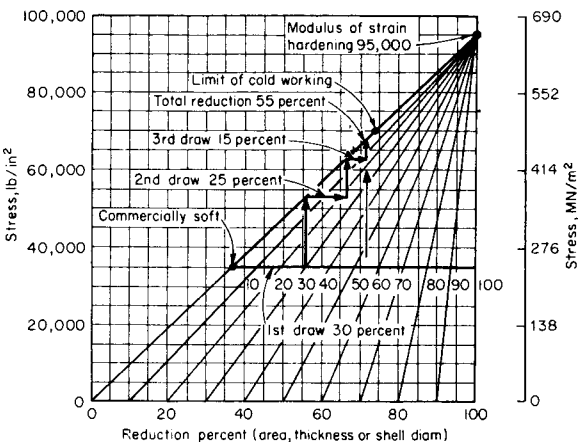

Fig. 13.2.7 Graphical solution of a metalworking problem.

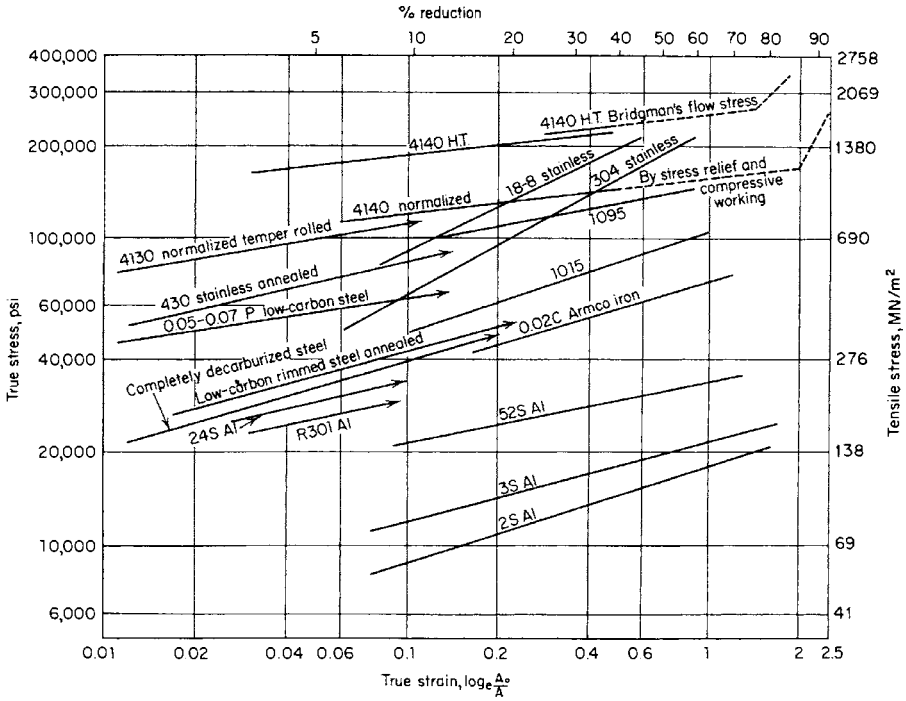

Fig. 13.2.8 True stress vs. true strain curves for typical metals. *(Crane and Hauf, E. W. Bliss. Co.)*

deformation and flow is the **flow stress** σ, also known as the **logarithmic stress** or **true stress.** For most metals, flow stress is a function of the amount of deformation at cold-working temperatures (strain $\bar{\varepsilon}$) and the deformation rate at hot-working temperatures (strain rate $\dot{\bar{\varepsilon}}$) This relationship is often given as a power-law curve; $\sigma = K\bar{\varepsilon}^n$ for cold forming and $\sigma = C\dot{\bar{\varepsilon}}^m$ for hot forming. For commonly used materials, the values of the strength coefficients K and C and hardening coefficients n and m are given in Tables 13.2.1*a* and *b*.

A practical manufacturing method of judging relative plasticity is to compute the ratio of initial yield point to the ultimate tensile strength as developed in the tensile test. Thus a General Motors research memo listed steel with a 0.51 **yield/tensile ratio** [22,000 lb/in^2 (152 MN/m^2) yp/ 43,000 lb/in^2 (296 MN/m^2) ultimate tensile strength] as being suitable for really severe draws of exposed parts. When the ratio reaches about 0.75, the steel should be used only for flat parts or possibly those with a bend of not more than 90°. The higher ratios obviously represent a narrowing range of workability or residual plasticity.

Advanced High-Strength Sheet Steels With greater emphasis being placed on weight reduction, many new grades of steel sheets for automotive bodies have been developed. Interstitial free (IF) steels were developed for applications requiring high ductility, BH bake hardening (BH) steels for dent resistance, dual phase (DP), transformation-induced plasticity (TRIP), complex phase (CP), and ferritic-bainitic (FB) steels for high-strength applications such as body panels and pillars (Fig. 13.2.9). There is a tradeoff between formability and strength in these steels. The steel industry is trying to develop steel grades that would improve both these properties simultaneously. For example, DP500, DP600, DP750, and TRIP800 grades have maximum strengths of 600, 650, 825, and 1,000 MPa, respectively. This is much higher than the 500 MPa expected from HSLA360, the most common sheet steel for automotive bodies.

ROLLING OPERATIONS

Rolling of sheets, coils, bars, and shapes is a primary process using plastic ranges both above and below recrystallization to prepare metals for further working or for fabrication. Metal squeezed in the bite area of

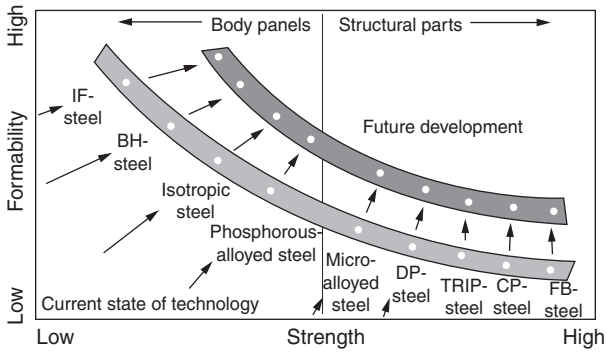

Fig. 13.2.9 New high-strength sheet steels for automotive bodies. (*Source: Ultra Light Steel Autobody Consortium, USA.)*

the rolls moves out lengthwise with very little spreading in width. This compressive working above the yield point of the metal may be aided in some cases by maintaining a substantial tensile strain in the direction of rolling.

A cast or forged billet or slab is preheated for the preliminary breakdown stage of rolling, although considerable progress has been made in continuous casting, in which the molten metal is poured continuously into a mold in which the metal is cooled progressively until it solidifies (albeit still at high temperature), whence it is drawn off as a quasi-continuous billet and fed directly into the first roll pass of the rolling mill. The increased speed of operation and production and the increased efficiency of energy consumption are obvious. Most new mills, especially minimills, have incorporated continuous casting as the normal method of operation. A reversing hot mill may achieve 5,000 percent elongation of an original billet in a series of manual or automatic passes. Alternatively, the billet may pass progressively through, say, 10 hot mills in rapid succession. Such a production setup requires precise control so that each mill stand will run enough faster than the previous one to

make up for the elongation of the metal that has taken place. Hot-rolled steel may be sold for many purposes with the black mill scale on it. Alternatively, it may be acid-pickled to remove the scale and treated with oil or lime for corrosion protection. To prevent scale from forming in hot-rolling, a nonoxidizing atmosphere may be maintained in the mill area, a highly special plant design.

Pack rolling of a number of sheets stacked together provides means of retaining enough heat to hot-roll thin sheets, as for high-silicon electric steels.

Cold-rolling is practical in production of thin coil stock with the more ductile metals. The number of passes or amount of reduction between anneals is determined by the rate of work hardening of the metal. Successive stands of cold-rolling help to retain heat generated in working. Tension provided by mill reels and between stands helps to increase the practical reduction per step. Bright annealing in a controlled atmosphere avoids surface pockmarks, which are difficult to get out. For high-finish stock, the rolls must be maintained with equal finish.

Cold Rolling of Threads and Gears Threaded parts, mostly fasteners, are cold-rolled with special tooling to impart a typical helical thread geometry to the part. The thread profile is most often a standard 60° vee, although thread profiles (i.e., Acme) for power threads are possible and have been produced. In one form, the tooling consists of two tapered reciprocating dies with the desired thread profile cut thereon. A blank of diameter smaller than the OD of the screw is positioned between the dies when they are at maximum separation. Then, as the dies reciprocate and decrease the gap between them, the blank is gripped, rolled, and plastically deformed to the desired screw profile. The indenting dies displace metal upward to form the upper part of the thread profile. There is no waste metal, and the fastener suffers no tears at the root. The resulting cold work and plastic displacement of metal results in a superior product. Subsequent heat treatment of the fastener may follow, depending on the strength properties desired for a particular application.

Thread rolling is also accomplished by using a nest of three profiled rotating rollers. In that case, the blank is fed axially when the rollers are at maximum gap and then is plastically deformed as the roll gap closes during rotation.

Gear profiles also can be rolled. The action is similar to that described for rolling threads, except that the dies or rollers are profiled to impart the desired involute gear profile. The gear blank is caught between the rollers or dies, and conjugate action ensues between the blank and tooling as the blank progresses through the operating cycle. In some applications, the rolled gear is produced slightly oversize to permit a finer finish by subsequent hobbing. The advantage lies in the reduction of metal cut by the hob, thereby increasing the production rate as well as maintaining the beneficial cold-worked properties imparted to the metal by cold rolling.

Thread and gear rolling enables high production rates; most threaded fasteners in production are of this type.

Protective coating is best exemplified by high-speed tinplate mills in which coil stock passes continuously through the necessary series of cleaning, plating, and heating steps. Zinc and other metals are also applied by plating but not on the same scale. **Clad** sheets (high-strength aluminum alloys with pure aluminum surface for protection against electrolytic oxidation) are produced by rolling together; an aluminum alloy billet is hot-rolled together with plates of pure aluminum above and below it through a series of reducing passes, with precautions to ensure clean adhesion.

On the other hand, prevention of adhesion, as by a separating film, is essential in the final stages of **foil rolling,** where two coils may have to be rolled together. Such foil may then be **laminated** with suitable adhesive to paper backing materials for wrapping purposes. (See also Sec. 6.)

Shape-rolling of structural shapes and rails is usually a hot operation with roll-pass contours designed to distribute the displacement of metal in a series of steps dictated largely by experience. **Contour rolling** of relatively thin stock into tubular, channel, interlocking, or varied special cross sections is usually done cold in a series of roll stands for lengthwise bending and setting operations. There is also a wide range of simple bead-rolling, flange-rolling, and seam-rolling operations in relatively thin materials, especially in connection with the production of barrels, drums, and other containers.

Oscillating or **segmental rolling** probably developed first in the manually fed contour rolling of agricultural implements. In some cases, the suitably contoured pair of roll inserts or roll dies oscillates before the operator, to form hot or cold metal. In other cases, the rolls rotate constantly, toward the operator. The working contour takes only a portion of the circumference, so that a substantial clearance angle leaves a space between the rolls. This permits the operator to insert the blank to the tong grip between the rolls and against a fixed gage at the back. Then, as rotation continues, the roll dies grip and form the blank, moving it back to the operator. This process is sometimes automated; such units as **tube-reducing mills** oscillate an entire rolling-mill assembly and feed the work over a mandrel and into the contoured rolls, advancing it and possibly turning it between reciprocating strokes of the roll stands for cold reduction, improved concentricity, and, if desired, the tapering or forming of special sections.

Spinning operations (Fig. 13.2.10) apply a rolling-point pressure to relatively limited-lot production of cup, cone, and disk shapes, from floor lamps and TV tube housings to car wheels and large tank ends. Where substantial metal thickness is required, powerful machines and hydraulic servo controls may be used. Some of the large, heavy sections and difficult metals are spun hot.

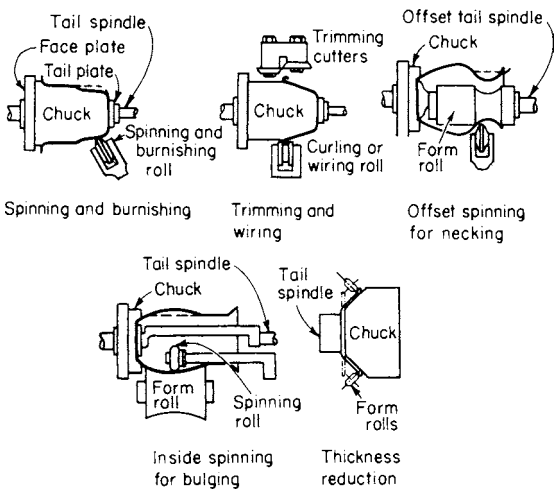

Fig. 13.2.10 Spinning operations.

Rolling operations are distinguished by the relatively rapid and continuous application of working pressure along a limited line of contact. In determining the working area, consider the lineal dimension (width of coil), the bite (reduction in thickness), and the roll-face deflection, which tends to increase the contact area. Approximations of rolling-mill load and power requirements have been worked out in literature of the AISE and ASME.

SHEARING

The shearing group of operations includes such **power press operations** as blanking, piercing, perforating, shaving, broaching, trimming, slitting, and parting. Shearing operations traverse the entire plastic range of metals to the point of failure.

The maximum pressure P, in pounds, required in shearing operations is given by the equation $P = \pi DtS = Lts$, where s is the resistance of the material to shearing, lb/in^2; t is the thickness of the material, in; L is the length of cut, in, which is the circumference of a round blank πD or the periphery of a rectangular or irregular blank. Approximate values of s are given in Table 13.2.2.

Shear (Fig. 13.2.11) is the advance of that portion of the shearing edge which first comes in contact with the material to be sheared over the last portion to establish contact, measured in the direction of motion. It should be a function of the thickness t. Shear reduces the maximum pressure because, instead of shearing the whole length of cut

Table 13.2.2 Approximate Resistance to Shearing in Dies

*1,000 lb/in² = 6.895 MN/m².

NOTE: Available test data do not agree closely. The above table is subject to verification with closer control of metal analysis, rolling and annealing conditions, and die clearances. In dinking dies, steel-rule dies, hollow cutters, etc., cutting-edge resistance is substantially independent of thickness: cotton glove cloth (stack, 2 or 3 in thick), 240 lb/in; kraft paper (stack tested, 0.20 in thick), 385 lb/in, celluloid [1½₂ in thick, warmed in water to 120 to 150°F (49 to 66°C)], 300 lb/in.

at once, the shearing action takes place progressively, shearing at only a portion of the length at any instant. The maximum pressure for any case where the shear is equal to or greater than t is given by $P_{max} = P_{av}\ t$/shear, where P_{av} is the average value of the pressure on a punch, with shear = t, from the time it strikes the metal to the time it leaves.

Distortion results from shearing at an angle (Fig. 13.2.11) and accordingly, in blanking, where the blank should be flat, the punch should be flat, and the shear should be on the die. Conversely, in hole punching, where the scrap is punched out, the die should be flat and the shear should be on the punch. Where there are a number of punches, the effect of shear may be obtained by stepping the punches.

Crowding results during the plastic deformation period, before the fracture occurs, in any shearing operation. Accordingly, when small delicate punches are close to a large punch, they should be stepped shorter than the large punch by at least a third of the metal thickness.

Clearance between the punch and die is required for a clean cut and durability. An old rule of thumb places the clearance all around the punch at 8 to 10 percent of the metal thickness for soft metal and up to 12 percent for hard metal. Actually, hard metal requires less clearance for a clean fracture than soft, but it will stand more. In some cases, with delicate punches, clearance is as high as 25 percent. Where the hole diameter is important, the punch should be the desired diameter and the clearance should be added to the die diameter. Conversely, where the blank size is important, the die and blank dimensions are the same and clearance is deducted from the punch dimensions.

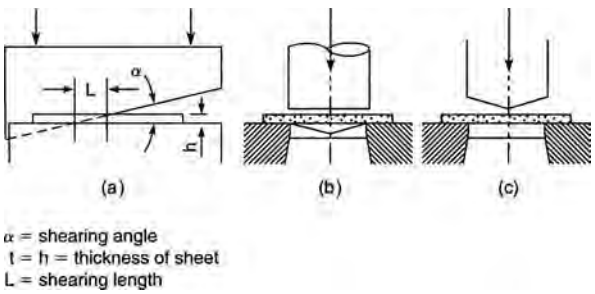

Fig. 13.2.11 Shearing forces can be reduced by providing a rake or shear on (*a*) the blades in a guillotine, (*b*) the die in blanking, (*c*) the punch in piercing. *(J. Schey, "Introduction to Manufacturing Processes," McGraw-Hill, 1987.)*

The **work per stroke** may be approximated as the product of the maximum pressure and the metal thickness, although it is only about 20 to 80 percent of that product, depending upon the clearance and ductility of the metal. Reducing the clearance causes secondary fractures and increases the work done. With sufficient clearance for a clean fracture, the work is a little less than the product of the maximum pressure, the metal thickness, and the percentage reduction in thickness at which the fracture occurs. Approximate values for this are given in Table 13.2.2. The **power required** may be obtained from the work per stroke plus a 10 to 20 percent friction allowance.

Shaving A sheared edge may be squared up roughly by shaving once, allowing for the shaving of mild sheet steel about 10 percent of the metal thickness. This allowance may be increased somewhat for thinner material and should be decreased for thicker and softer material. In making several cuts, the amount removed is reduced each time. For extremely fine finish a round-edged burnishing die or punch, say 0.001 or 0.0015 in tight, may be used. Aluminum parts may be blanked (as for impact extrusion) with a fine finish by putting a 30° bevel, approx one-third the metal thickness on the die opening, with a near metal-to-metal fit on the punch and die, and pushing the blank through the highly polished die.

Squaring shears for sheet or plate may have their blades arranged in either of the ways shown in Fig. 13.2.12. The square-edged blades in Fig. 13.2.12*a* may be reversed to give four cutting edges before they are reground. Single-edged blades, as shown in Fig. 13.2.12*b*, may have a clearance angle on the side where the blades pass, to reduce the working friction. They may also be ground at an angle or rake, on the face which comes in contact with the metal. This reduces the bending and consequent distortion at the edge. Either type of blade distorts also in the other direction owing to the angle of shear on the length of the blades (see Fig. 13.2.11).

Circular cutters for slitters and circle shears may also be square-edged (on most slitters) or knife-edged (on circle shears). According to one rule, their diameter should be not less than 70 times the metal thickness.

Knife-edge hollow cutters working against end-grain maple blocks represent an old practice in cutting leather, rubber, and cloth in multiple thicknesses. **Steel-rule dies,** made up of knife-edge hard-steel strip economically mounted against a steel plate in a wood matrix with rubber

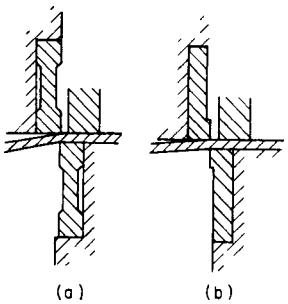

Fig. 13.2.12 Squaring shears.

strippers and cutting against hard saw-steel plates, extend the practice to corrugated-carton production and even some limited-lot metal cutting.

Higher precision is often required in **finish shearing** operations on sheet material. For ease of subsequent operations and assembly, the cut edges should be clean (acceptable burr heights and good surface finish) and perpendicular to the sheet surface. The processes include precision or fine blanking, negative clearance blanking, counterblanking, and shaving, as shown in Fig. 13.2.13. By these methods either the plastic behavior of material is suppressed or the plastically deformed material is removed.

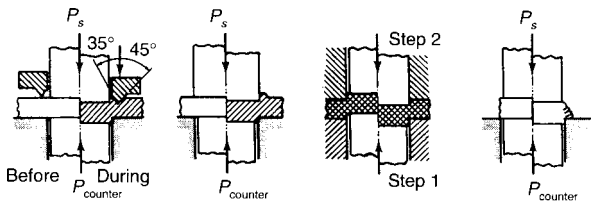

Fig. 13.2.13 Parts with finished edges can be produced by (*a*) precision blanking, (*b*) negative-clearance blanking, (*c*) counterblanking, (*d*) shaving a previously sheared part. *(J. Schey, "Introduction to Manufacturing Processes," McGraw-Hill, 1987.)*

BENDING

The bending group of operations is performed in **presses** (variety), **brakes** (metal furniture, cornices, roofing), **bulldozers** (heavy rolled sections), **multiple-roll forming machines** (molding, etc.), **draw benches** (door trim, molding, etc.), **forming rolls** (cylinders), and **roll straighteners** (strips, sheets, plates).

Spring back, due to the elasticity of the metal and amount of the bend, may be compensated for by overbending or largely prevented by striking the metal at the radius with a **coining** (i.e., squeezing, as in production of coins) pressure sufficient to set up compressive stresses to counterbalance surface tensile stresses. A very narrow bead may be used to localize the pinch where needed and minimize danger to the press in squeezing on a large area. Under such conditions, good sharp bends in V dies have been obtained with two to four times the pressure required to shear the metal across the same section.

These are illustrated in Fig. 13.2.14, where P_b is the **bending load** on the press brake, W_b is the width of the die support, and $P_{counter}$ is the counterload. The bending load can be obtained from

$$P_b = wt^2(\text{UTS})/W_b$$

where t and w are the sheet thickness and width, respectively, and UTS is the ultimate tensile strength of the sheet material.

Bending Allowance The thickness of the metal over a small radius or a sharp corner is 10 or 15 percent less than before bending because the metal moves more easily in tension than in compression. For the same reason the neutral axis of the metal moves in toward the center of the corner radius. Therefore, in figuring the length of blank L to be allowed for the bend up to an inside radius r of two or three times the

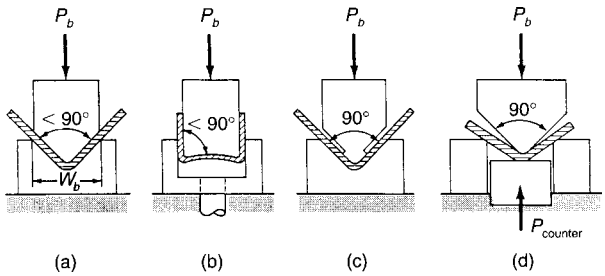

Fig. 13.2.14 Springback may be neutralized or eliminated by (*a*), (*b*) overbending; (*c*) plastic deformation at the end of the stroke; (*d*) subjecting the bend zone to compression during bending. *[Part (d) after V. Kupka, T. Nakagawa, and H. Tyamoto, CIRP 22:73–74 (1973).] (Source: J. Schey, "Introduction to Manufacturing Processes," McGraw-Hill, 1987.)*

metal thickness t, the length may be figured closely as along a neutral line at $0.4t$ out from the inside radius. Thus, with reference to Fig. 13.2.15, for any angle a in deg and other dimensions in inches, $L = (r + 0.4t)2\pi a/360 = (r + 0.4t)a/57.3$.

The factor $0.4t$, which locates the neutral axis, is subject to some variation (say 0.35 to $0.45t$) according to radius, condition of metal, and angle. In figuring allowances for sharp bends, note that the metal builds up on the compression side of the corner. Therefore, in locating the neutral axis, consider an inside radius r of about $0.05t$ as a minimum.

Roll straighteners work on the principle of bending the metal beyond its elastic limit in one direction over rolls small enough in diameter, in proportion to the metal thickness, to give a permanent set, and then taking that bend out by repeatedly reversing it in direction and reducing it in amount. Metal is also straightened by gripping and stretching it beyond its elastic limit and by hammering; the results of the latter operation depend entirely upon the skill of the operator.

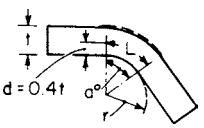

Fig. 13.2.15 Bending allowance.

For approximating **bending loads,** the beam formula may be used but must be very materially increased because of the short spans. Thus, for a span of about 4 times the depth of section, the bending load is about 50 percent more than that indicated by the beam formula. It increases from this to nearly the shearing resistance of the section where some **ironing** (i.e., the thinning of the metal when clearance between punch and die is less than the metal thickness) occurs. Where hit-home dies do a little coining to "set" the bend, the pressure may range from two or three times the shearing resistance, and with striking beads and proper care, up to very much higher figures.

The work to roll-bend a sheet or plate t in thick with a volume of V in^3, into curved shape of radius r in, is given as $W = CS(t/r)V/48$ ft·lb, in which S is the tensile strength and C is an experience factor between 1.4 and 2.

The **equipment for bending** consists of mechanical presses for short bends, press brakes (mechanical and hydraulic) for long bends, and roll formers for continuous production of profiles. The bends are achieved by bending between tools, wiping motion around a die corner, or bending between a set of rolls. These bending actions are illustrated in Fig. 13.2.16. Complex shapes are formed by repeated bending in simple tooling or by passing the sheet through a series of rolls which progressively bend it into the desired profile. Roll forming is economical for continuous forming for large volume production. Press brakes can be computer-controlled with synchronized feeding and bending as well as spring-back compression.

DRAWING

Drawing includes operations in which metal is pulled or drawn, in suitable containing tools, from flat sheets or blanks into cylindrical cups or rectangular or irregular shapes, deep or shallow. It also includes reducing

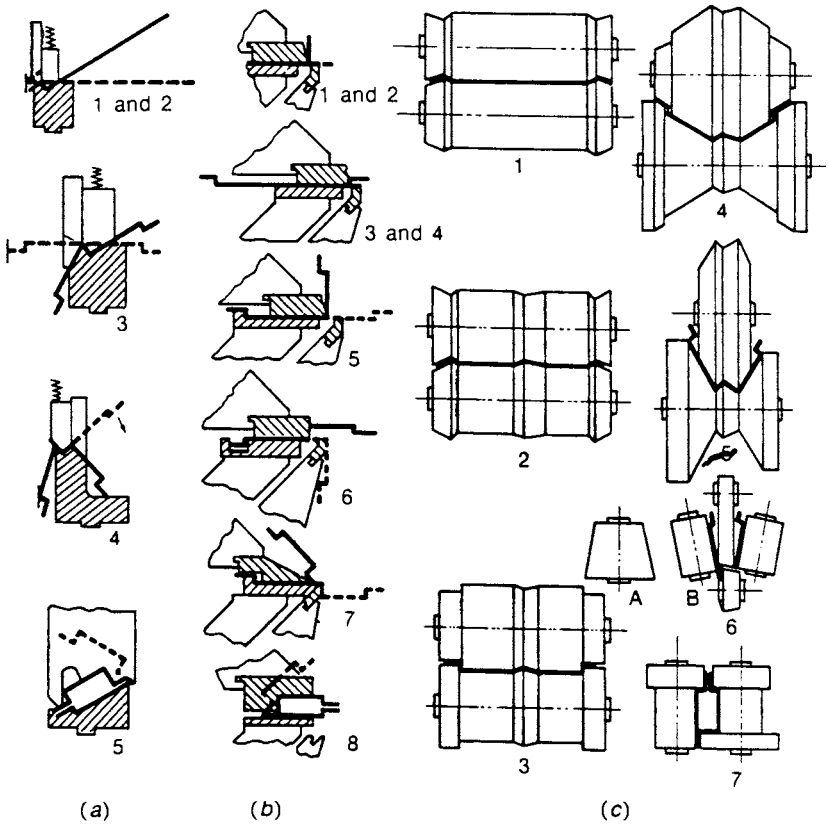

Fig. 13.2.16 Complex profiles formed by a sequence of operations on (*a*) press brakes, (*b*) wiping dies, (*c*) profile rolling. *(After Oehler; Biegen, Hanser Verlag, Munich, 1963.) (Source: J. Schey, "Introduction to Manufacturing Processes," McGraw-Hill, 1987.)*

operations on shells, tube, wire, etc., in which the metal being drawn is pulled through dies to reduce the diameter or size of the shape. All drawing and reducing operations, by an applied tensile stress in the material, set up circumferential compressive stresses which crowd the metal into the desired shape. The relation of the shape or diameter before drawing to the shape or diameter after drawing determines the magnitude of the stresses. Excessive draws or reductions cause thinning or tearing out near the bottom of a shell. Severe cold-drawing operations require very ductile material and, in consequence of the amount of plastic deformation, harden the metal rapidly and necessitate annealing to restore the ductility for further working.

The **pressure used in drawing** is limited to the load to shear the bottom of the shell out, except in cases where the side wall is ironed thinner, when wall friction makes somewhat higher loads possible. It is less than this limit for round shells which are shorter than the limiting height and also for rectangular shells. Drawing occurs only around the corner radii of rectangular shells, the straight sides being merely free bending.

A holding pressure is required in most initial drawing and some redrawing, to prevent the formation of wrinkles due to the circumferential compressive stresses. Where the blank is relatively thin compared with its diameter, the blank-holding pressure for round work is likely to vary up to about one-third of the drawing pressure. For material heavy enough to provide sufficient internal resistance to wrinkling, no pressure is required. Where a drawn shape is very shallow, the metal must be stretched beyond its elastic limit in order to hold its shape, making it necessary to use higher blank-holding loads, often in excess of the drawing pressure. To grip the edges sufficiently to do this, it is often advisable to use **draw beads** on the blank-holding surfaces if sufficient pressure is available to form these beads.

In sheet/deep-drawing practice, the punch force P can be approximated by

$$P = \pi D_p t_0 (\text{UTS})(D_0/D_p - 0.7)$$

where t_0 is the blank thickness and D_0 and D_p are the diameters of the blank and the punch.

The blank holder pressure for avoiding defects such as wrinkling of bottom/wall tear-out is kept at 0.7 to 1.0 percent of the sum of the yield and the UTS of the material. Punch/die clearances are chosen to be 7 to 14 percent greater than the sheet blank thickness t_0. The die corner radii are chosen to avoid fracture at the die corner from puckering or wrinkling. Recommended values of D_0/t_0 for deep-drawn cups are 6 to 15 for cups without flange and 12 to 30 for cups with flange. These values will be smaller for relatively thick sheets and larger for very thin blank thickness. For deeper-drawn cups, they may be redrawn or reverse-drawn, the latter process taking advantage of strain softening on reverse drawing. When the material has marked strain-hardening propensities, it may be necessary to subject it to an intermediate annealing process to restore some of its ductility and to allow progression of the draws to proceed.

Some shells, which are very thick or very shallow compared with their diameter, do not require a blank holder. Blank-holding pressure may be obtained through toggle, crank, or cam mechanisms built into the machine or by means of air cylinders, spring-pressure attachments, or rubber bumpers under the bolster plate. The length of car springs should be about 18 in/in (18 cm/cm) of draw to give a fairly uniform drawing pressure and long life. The use of car springs has been largely superseded by hydraulic and pneumatic cushions. Rubber bumpers may be figured on a basis of about 7.5 lb/in^2 (50 kN/m^2) of cross-sectional area per 1 percent

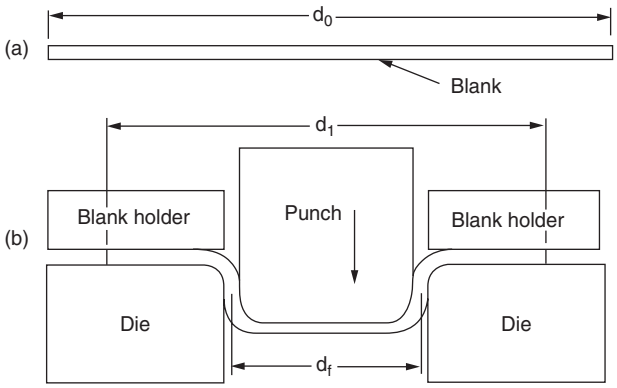

Fig. 13.2.17 Schematic of the conventional deep drawing process for sheet metal parts. (*a*) Initial blank, (*b*) drawing in process.

of compression. In practice they should never be loaded beyond 20 percent compression, and as with springs, the greater the length relative to the working stroke, the more uniform is the pressure.

Deep Drawing and Hydroforming of Sheet Metal Parts Sheet metal parts are conventionally deep drawn using rigid steel punches and dies (Fig. 13.2.17). An alternative approach is to use flexible media (Fig. 13.2.18) such as water, gas, or rubber as either the male or female die, and to perform the hydroforming process in a closed die. In hydromechanical deep drawing, the die is replaced by a fluid (Fig. 13.2.18) while in high-pressure sheet metal hydroforming the punch is replaced by the fluid medium. The use of flexible media often permits greater drawability and the possibility of combining many steps in one operation, such as permitting joining and trimming simultaneously with forming (Fig. 13.2.19). Complex parts can be made in a single step by using thin sheets, thus reducing the cost and weight of the shell structure.

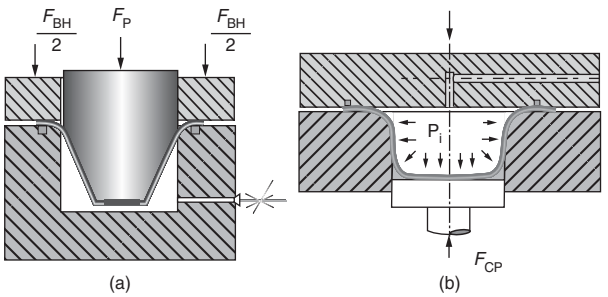

Fig. 13.2.18 Forming by flexible media. (*a*) Hydromechanical deep drawing (*Source: K. Seigert and M. Aust, Hydromechanical Deep-Drawing, Production Engineering,* VII/2, *Annals of the German Academic Society for Production Engineering, pp. 7–12.)* (*b*) High-pressure hydroforming. *M. Kliener, W. Homberg, and A. Brosius, Processes and Control of Sheet Metal Hydroforming. International Conference on Advanced Technology of Plasticity, Germany,* **2,** *1999, pp. 1243–1252.)*

Dimensions of Drawn Shells The smallest and deepest round shell that can be drawn from any given blank has a diameter d of 65 to 50 percent of the blank diameter D. The height of these shells is $h = 0.35d$ to $0.75d$, approximately. Higher shells have occasionally been drawn with ductile material and large punch and die radii. Greater thickness of material relative to the diameter also favors deeper drawing.

The area of the bottom and of the side walls added together may be considered as equal to the area of the blank for approximations. If the punch radius is appreciable, the area of a neutral surface about $0.4t$ out

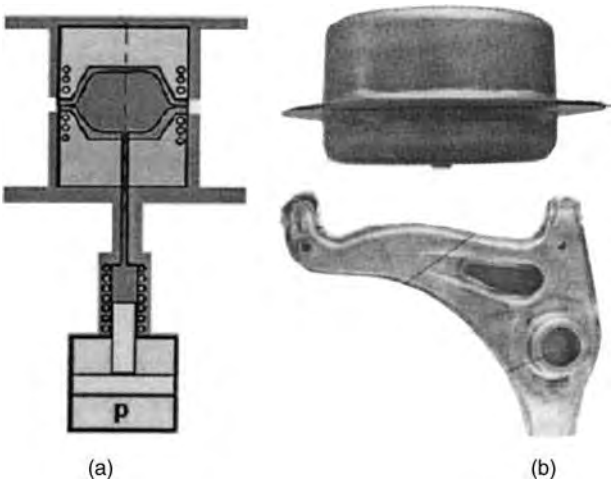

Fig. 13.2.19 Combined hydroforming, joining, and trimming of sheet metal parts. (*a*) In process; (*b*) typical parts. (*Source: P. Hein and M. Geiger, Advanced Process Control Strategies for the Hydroforming of Sheet Metal Pairs, Int. Conf. Adv. Techn. Plasticity, Germany,* **2,** 1999, pp. 1267–1272.)

from the inside of the shell may be taken for approximations. Accurate blank sizes may be obtained only by trial, as the metal tends to thicken toward the top edge and to get thinner toward the bottom of the shell wall in drawing.

Approximate diameters of blanks for shells are given by the expression $\sqrt{d^2 + 4dh}$, where d is the diameter and h the height of the shell.

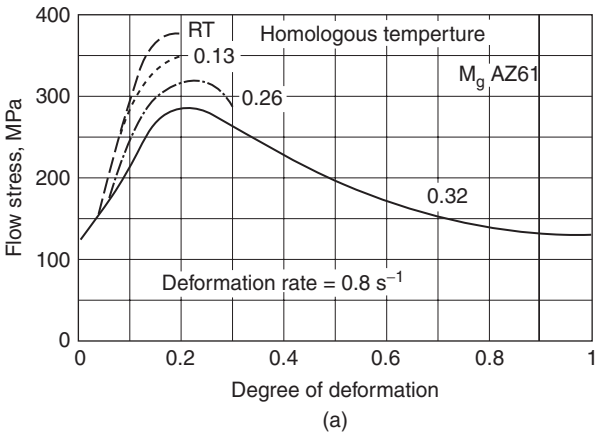
In **redrawing** to smaller diameters and greater depths the amount of reduction is usually decreased in each step. Thus in double-action redrawing with a blank holder, the successive reductions may be 25, 20, 16, 13, 10 percent, etc. This progression is modified by the relative thickness and ductility of the metal. Single-action redrawing without a blank holder necessitates smaller steps and depends upon the shape of the dies and punches. The steps may be 19, 15, 12, 10 percent, etc. Smaller reductions per operation seem to make possible greater total reductions between annealings.

Rectangular shells may be drawn to a depth of 4 to 6 times their corner radius. It is sometimes desirable, where the sheet is relatively thin, to use draw beads at the corners of the shell or near reverse bends in irregular shapes to hold back the metal and assist in the prevention of wrinkles.

Work in drawing is approximately the product of the length of the draw, and the maximum punch pressure, as the load rises quickly to the peak, remains fairly constant, and drops off sharply at the end of the draw unless there is stamping or wall friction. To this, add the work of blank holding which, in the case of cam and toggle pressure, is the product of the blank-holding pressure and the spring of the press at the pressure (which is small). For single-action presses with spring, rubber, or air-drawing attachments it is the product of the average blank-holding pressure and the length of draw.

Rubber-die forming, especially of the softer metals and for limited-lot production, uses one relatively hard member of metal, plaster, or plastic with a hard powder filler to control contour. The mating member may be a rubber or neoprene mattress or a hydraulically inflatable bag, confined and at 3,000 to 7,000 lb/in^2 (20 to 48 MN/m^2). Babbitt, oil, and water have also been used directly as the mobile member. A large hydraulic press is used, often with a sliding table or tables, and even static containers with adequate pumping systems.

Warm Forming of Aluminum and Magnesium Sheets Aluminum and magnesium are used to decrease the weight of automotive and aerospace parts. Aluminum and magnesium exhibit increased ductility at elevated temperatures (Fig. 13.2.20). Magnesium does have many limitations, but its use for structural parts is growing.



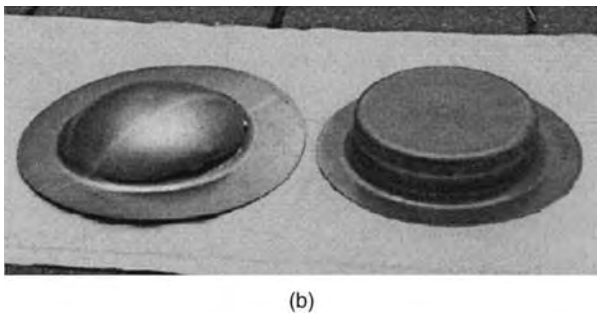


Fig. 13.2.20 Drawing of magnesium sheets at elevated temperatures. (*a*) Flow stress of magnesium AZ61. *[Chabbi, et al., 2000, Hot and Cold Forming Behavior of Magnesium Alloys AZ31 and AZ61, in K. U. Kainer (ed.), "Magnesium Alloys and Their Applications," Wiley-VCH, D, pp. 621–627.]* (*b*) Drawn AZ31B cups at room temperature (left) and at 230°C (right). (*S. Tailor Welded Blanks (TWB) in Forming With the demand for reducing both automotive structure weight and manufacturing costs many new processes are being employed:

1. Different parts are formed separately and then joined by laser. Part forming is independently optimized, followed by trimming and weld assembly. Forming is easier but welding along curved lines is more complex (Fig. 13.2.21*a*).
2. The blanks are welded, and then the panel is formed in one die. Welding is simpler, but forming is considerably more complex. Dimensional tolerances are better controlled (Fig. 13.2.21*b*).
3. Blanks of varying thickness are tailor-welded using laser techniques to create a single blank that subsequently is formed into the required geometry (Fig. 13.2.22). The forming process of TWBs is very complex as the blank areas with different thicknesses flow differently during the drawing operation.
4. Friction stir welding is used to create a single blank made of different materials or different sheet thickness. This composite blank is then drawn to final geometry (Fig. 13.2.23).

Hot drawing above the recrystallization range applies single- and double-action drawing principles. For light gages of plastics, paper, and hexagonal-lattice metals such as magnesium, dies and punches may be heated by gas or electricity. For thick steel plate and heat-treatable alloys, the mass of the blank may be sufficient to hold the heat required.

High-Pressure Hydroforming of Tubes Tubes formed to various cross sections and bent to various shapes are widely used in automotive frames. There are a number of variants of this process (Fig. 13.2.24), including forming under (1) tensile and compressive conditions,

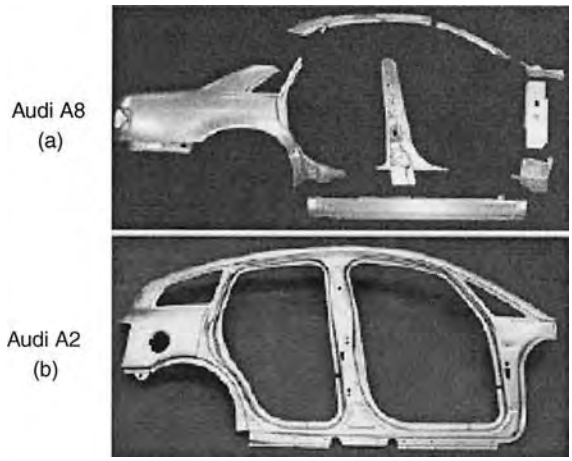

Fig. 13.2.21 (*a*) Many parts are formed separately and joined to form side panels and pillars; (*b*) single blank is trimmed and then formed. *(Source: Ruch et al., Grobserienfertigung von Aluminumkarosserien, in K. Siegert, "Neuere Entwicklungen inder Blechumformung," MATINFO, Frankfurt, D, 2000).*

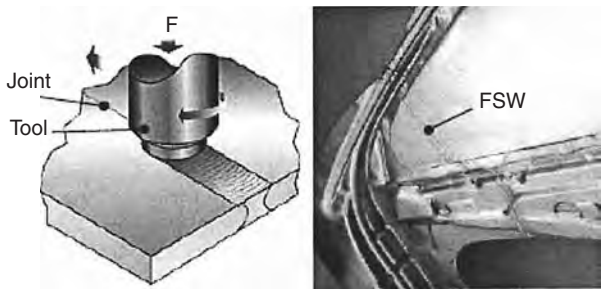

Fig. 13.2.23 Use of friction stir welding to create a blank. *(Source: The Welding Institute.)*

(2) bending conditions, and (3) shear conditions. Each variant is intended to impart a particular deformation to the tube by a predetermined motion of the tools. Motions include axial compression due to tool motion and circumferential expansion due to internal pressure. In high-pressure forming, pressurized force can reach 35,000 tons. Lead times can be very high due to the slow pressurization and depressurization required for each forming cycle. These high pressures lead to metal

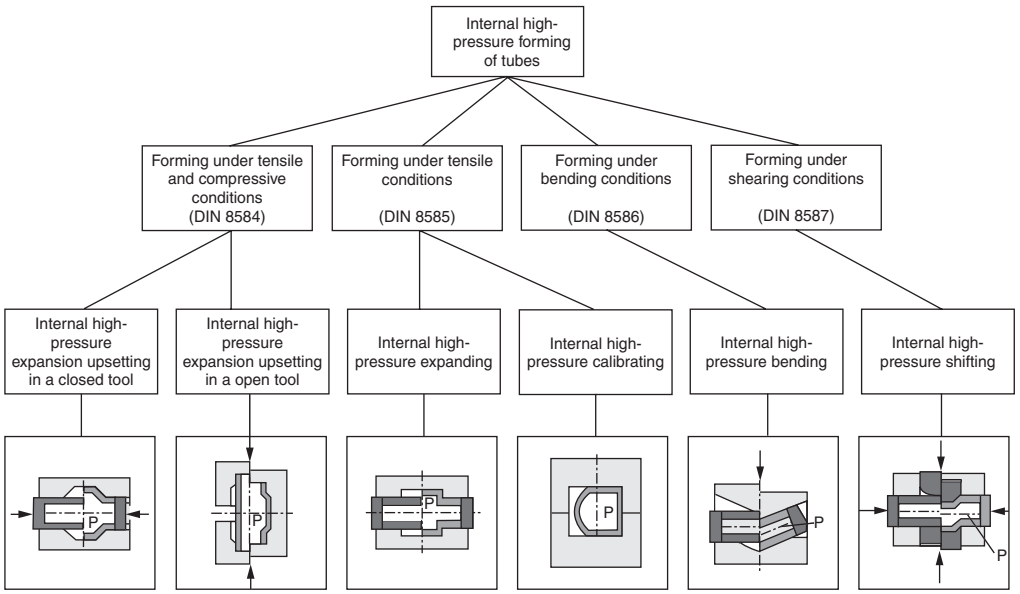

Fig. 13.2.24 Process and tooling variations in the hydroforming of tubes with high-pressure media. *(Source: D. Schmoeckel, C. Hielscher, and R. Huber, Metal Forming of Tubes and Sheets with Liquid and Other Flexible Media, CIRP Annals*, **48,** *no. 2, 1999, pp. 497–513.)*

flow-related defects, such as buckling, wrinkling, and bursting, and a safe working window has to be determined for success (Fig. 13.2.25).

Incremental Forming The incremental forming process employs local forming of the workpiece and then rotating the workpiece or the tools to form the entire surface. Since the contact area between the tools and the workpiece is small, the force required is small and the friction conditions are favorable. Consequently, high deformation levels are achieved that are not possible by conventional means. These processes include flow forming, radial forming, rotary forming, orbital forming, spinning, shear forming, and incremental sheet forming (single-point or two-point contact). Incremental sheet forming uses sheet blanks held in a fixture while rotating tools incrementally stretch the blank to the required shape (Fig. 13.2.26). In the flow forming process for thin axisymmetric parts, a roller deforms the metal and changes the thickness of the formed piece (Fig. 13.2.27).

Lubricants for Presswork Many jobs may be done dry, but better results and longer life of dies are obtained by the use of a lubricant. Lard or sperm oil is used when punching iron, steel, or copper. Petroleum jelly is used for drawing aluminum. A soap solution is commonly used for drawing brass, copper, or steel. One manufacturer uses 90 percent mineral oil, 5 percent rosin, and 5 percent oleic acid for light work and

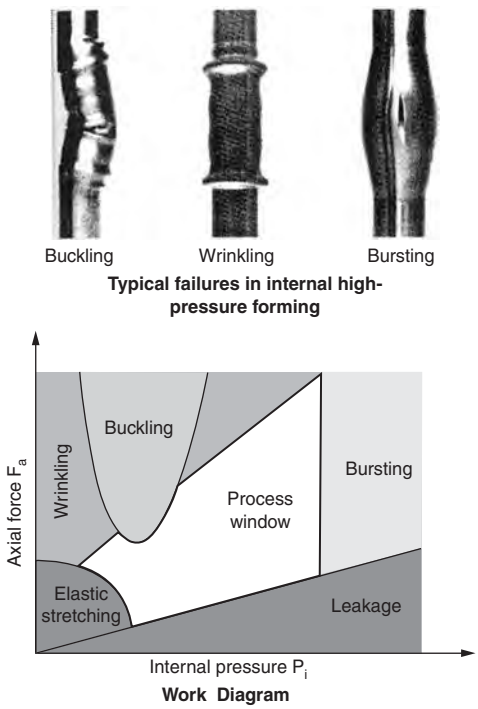

Fig. 13.2.25 Typical failures in tube hydroforming and the safe working window for the process. *(Source: D. Schmoeckel, C. Hielscher, and R. Huber, Metal Forming of Tubes and Sheets with Liquid and Other Flexible Media, CIRP Annals*, **48,** *no. 2, 1999, pp. 497–513.)*

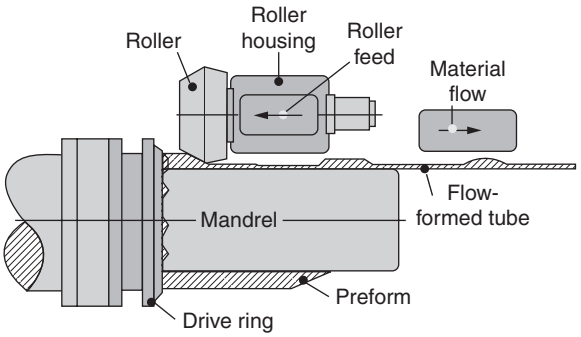

Fig. 13.2.27 Flow forming a rim for an automotive wheel.

an emulsion of a mineral oil, degras, and a pigment consisting of chalk, sulfur, or lithopone for heavy work. (See also Sec. 6.)

For heavy drawing operations and extrusion, steels may have a zinc phosphate coating bonded on, and a zinc or sodium stearate bonded to that, to withstand pressures over 300,000 lb/in^2 (2,070 MN/m^2). An anodized coating for aluminum may be used as a host for the lubricant. It is reported that such a chemical treatment plus a lacquer or plastic coating and a lubricant is effective for severe ironing operations.

The problem is to prevent local pressure welding from starting as galling or pickup, with resulting scratching, by maintaining a fluid film separation between metal surfaces. At moderate pressures, almost any viscous liquid lubricant will do the job. Rust protection and easy removal of the lubricant are often major factors in the choice.

Lubricants for metalworking are often classified based on their interface friction coefficient, which depends on the workpiece material and the lubricant being used. The **interface friction coefficient** μ is often defined as the ratio of the friction force to the normal force at the interface. Typical values of μ for different workpiece-lubricant pairs are included in Table 13.2.3.

Shock-wave forming For short runs, it is applied in several ways. **Explosive forming,** especially for large-area drawn or formed shapes, usually requires one metal contour-control die immersed in a large container of fluid, or even in a lake or pond. Explosives manufacturers have developed means of computing the charge and the distance that it should be suspended above the blank to be formed. The space back of the blank in the die has to be evacuated. A blank-holding ring to minimize wrinkle formation in the flange area is bolted very tightly to the die, with an O-ring seal to prevent leakage.

Electrohydraulic forming is similar to explosive forming except that the shock wave is imparted electrically from a large battery of capacitors. **Magnetic forming** uses the same source of power but does not require a fluid medium. A flexible pancake coil delivers the magnetic shock pulse.

Electromagnetic Forming (EMF) In this process the energy of a pulsed magnetic field is used with a contact-free tool to join metals with good electrical conductivity and magnetic permeability, such as aluminum. The rapid discharge of a high-voltage capacitor through a coil in the tool generates an intense magnetic field, inducing eddy currents in the workpiece. The magnetic forces acting between the tool and the workpiece cause movement of the workpiece, thus permanently changing its shape (Fig. 13.2.28). This process can be used with tubular workpieces to join two tubes or to change tube shape.

BULK FORMING

The squeezing group of operations are those in which the metal is worked in compression. Resultant tensile strains occur, however; in cases where the metal is thin compared with its area and there is an

* Some more frequently used lubricants (hyphenation indicates that several components are used in the lubricant):
CL = chlorinated paraffin
EM = emulsion; listed lubricating ingredients are finely distributed in water
EP = "extreme-pressure" compounds (containing S, Cl, and P)
FA = fatty acids and alcohols, e.g., oleic acid, stearic acid, stearyl alcohol
FO = fatty oils, e.g., palm oil and synthetic palm oil
GL = glass (viscosity at working temperature in units of poise)
GR = graphite; usually in a water-base carrier fluid
MO = mineral oil (viscosity in parentheses, in units of centipoise at 40°C).
PH = phosphate (or similar) surface conversion, providing keying of lubricant
† Friction coefficients are misleading for extrusion and therefore are not quoted here.
‡ The symbol ST indicates sticking friction.

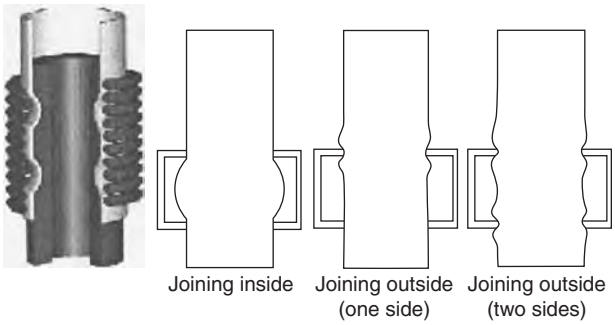

Fig. 13.2.28 Electromagnetic forming and joining of tubes. *(Source: C. Beerwald, A. Brosius, and M. Kliener, Determination of Flow Stress at Very High Strain Rates by a Combination of Magnetic Forming and FEM Calculation, International Workshop on Friction and Flow Stress in Cutting and Forming, Paris, pp. 175–182.)*

appreciable movement of the metal, there results a pyramiding of pressure toward the center of the die which may prove serious. The metal is incompressible (beyond about 1 percent), and consequently, to reduce the thickness of any volume of metal in the center of the blank, its area must be increased, which involves spreading or stretching all the metal around it. The surrounding metal acts like shrunk bands and offers a resistance increasing toward the center, and often many times the compressive resistance of the material.

Squeezing operations and particularly the squeezing of steel are practically the severest of all press operations. They may be divided into four general classifications according to severity, although in every group there will be found examples of working to the limit of what the die steels will stand, which may be taken at about 100 tons/in^2. The severer operations, such as cold bottom extrusion and wall extrusion, are limited to the softer metals. Squeezing operations ordinarily require pressure through a very short distance, the pressure starting at the compressive yield strength of the material over the surface being squeezed and rising to a maximum at bottom stroke. This maximum is greatest when the metal is thin compared with its area or when the die is entirely closed as for coining. Care must be taken, on all squeezing operations, in the setting of presses and avoidance of double blanks or extra-heavy blanks as the presses must be stiff. In squeezing solidly across bottom center the mechanical advantage is such that a small difference in thickness or setup can make a very large difference in pressure exerted. For this reason high-speed self-contained hydraulic presses, with automatic pressure-control and size blocks, are now finding favor for some of this work.

Sizing, or the flattening or surfacing of parts of forgings or castings, is usually the least severe of the squeezing group. Tolerances are ordinarily closer than for the milling operations which are supplanted. When extremely close tolerances are required, say plus or minus one-thousandth of an inch (0.025 mm), arrange substantial size blocks to take half or two-thirds of the total load. These take up uniformly the bearing-oil films and any slight deflection of the bed and bolster and minimize the error in springback due to variation in thickness, hardness, and area of the rough forging or casting. The usual amount left for squeezing is 1/32 to 1/16 in (0.8 to 1.6 mm). Presses may be selected for this service on a basis of 60 to 80 tons/in^2 (830 to 1,100 MN/m^2), although 100 tons/in^2 (1,380 MN/m^2) is more often used in the automobile trade for reserve capacities. When figuring from experimental results obtained in testing machines, the recorded loads are usually doubled in selecting a press, in order to allow for the difference among the speed of the machines, the positive action, and a safety margin.

Swaging or **cold forging** involves squeezing of the blank to an appreciably different shape. Success in performing such operations on steel usually depends upon squeezing a relatively small area with freedom to flow without restraint. Dies for this work must usually be substantially backed up with hardened steel plates. The edge of the blank after coining is usually ragged and must be trimmed for appearance.

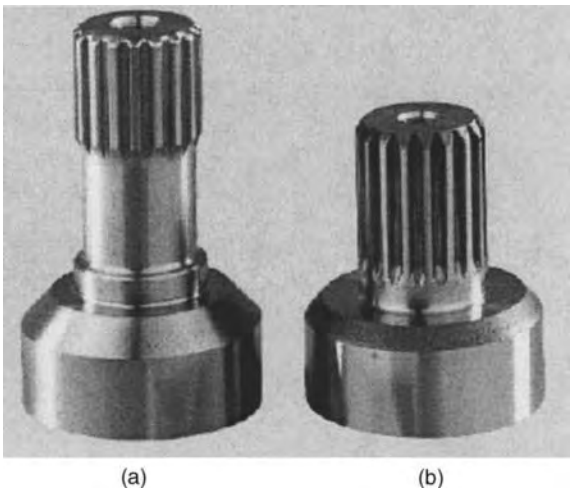

Fig. 13.2.29 Comparison of (*a*) machined and (*b*) cold-forged gearbox endpiece. *(Source: D. Landgrebe, Precision Forming and Machining, "Recent Developments in Metalforming Technology," ERC/NSM, The Ohio State University, Columbus, 2002.)*

Cold-Forging of Steel Parts More and more parts in machinery and automotive drive components are being cold-forged to net shape. Due to the work-hardening characteristics of the cold metal, the tool pressures can be several times the flow stress of the material (700 to 2,100 MPa for steels). Consequently, precise control of metal flow, good lubrication, and specially designed and shrink-fitted carbide dies are required. An example of a cold-forged transmission part is shown in Fig. 13.2.29. A machined part is also included for comparison purposes. Note that the hobbed part on the left requires longer run-out clearance that increases the part length. No such clearance is required for the cold-forged spline.

Cold-Forging of Aluminum Parts Cold-forged aluminum parts (Fig. 13.2.30) are increasingly replacing machined steel parts, primarily due to excellent formability and the lower weight of aluminum. A cold-forged aluminum column part is backward can-extruded, followed by successive ironing operations, reducing the wall thickness to 1.5 mm and enabling final forming of the bellow.

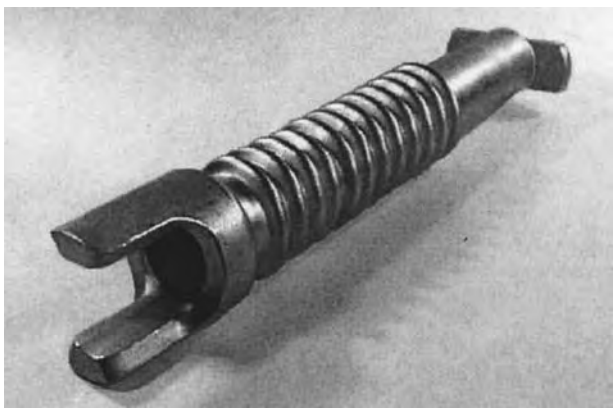

Fig. 13.2.30 Automotive steering column manufactured by cold-forging aluminum alloy. *(Source: N. Bay, Cold Forming of Aluminum—State of Art. Jour. Mater. Processing Technol.*, **71,** *1997, pp. 76–90.)*

Hot forging is similar in certain respects to the above but permits much greater movement of metal. When dies are used, hot forging may be done in drop hammers, percussion presses, power presses, or forging machines. Steam or pneumatic hammers, helve hammers, or hydraulic presses, most often employ plain anvils.

Drop hammers are rated according to weight of ram. For carbon steel they may be selected on a basis of 50 to 55 lb of ram weight per square inch of projected area (3.5 to 3.9 kg/cm^2) of the forging, including as much of the flash as is squeezed. This allowance should be increased to 60 lb/in^2 (4.2 kg/cm^2) for 0.20 carbon steel, 70 lb/in^2 (4.9 kg/cm^2) for 0.30 carbon steel, and up to about 130 lb/in^2 (9.2 kg/cm^2) for tungsten steel.

In figuring the **forging pressure,** multiply the projected area of the forging, including the portion of the flash that is squeezed, by approximately one-third of the cold compressive strength of the material. Another method gives the forging pressure at three to four times the compressive strength of the material at forging temperatures times the projected area, for presses; or at ten times the compressive strength at forging temperatures times the projected area, for hammers. The pressure builds up to a rather high figure at bottom stroke owing to the cooling of the metal particularly in the flash and to the small amount of relief for excess metal which the flash allows.

In **heading operations,** hot or cold, the length of wire or rod that can be gathered into a head, without side restraint, in a single operation, is limited to three times the diameter. In coining and then cold heading large heads, wire of about 0.08 carbon must be used to avoid excessive strain-hardening.

Forging Dies Drop-forge dies are usually of steel or steel castings. A good all-around grade of **steel** is a 0.60 percent carbon open-hearth. Dies of this steel will forge mild steel, copper, and tool steel satisfactorily if the number of forgings required is not too large. For a large number of tool-steel forgings, tool-steel dies of 0.80 to 0.90 percent carbon may be used and for extreme conditions, 3½ percent nickel steel.

Die blocks of alloy steels have special value for the production of drop forgings in large quantities. Widely used die materials and their recommended hardness are listed in Table 13.2.4. For a typical hot-working steel, the relationship between the hardness and the UTS is

HRC	*UTS, ksi (MPa)*
30	140 (960)
40	185 (1,250)
50	250 (1,700)
60	350 (2,400)

The pressure on dies can be kept as high as 80 percent of the above values. For higher tool pressures, carbide (tungsten carbide is the most common) die material is used. Carbides can withstand very high compressive pressures but have poor tensile properties. Consequently, carbide dies and inserts are always kept under compression, often by the use of shrink rings. These are some design guidelines for punches and dies:

1. *Long punch.* The punch pressure should be kept below the buckling stress σ_b

$$\sigma_b = \sigma_y\left[1 - \left(\frac{4\sigma_y}{\pi^2 E}\right)\left(\frac{L_p}{D_p}\right)^2\right]$$

where σ_y is the yield stress of the punch material, E the elastic modulus 30,000 ksi (210 GPa) for steel and 50,000 ksi (350 GPa) for tungsten carbide, L_p is the punch length and D_p is the punch diameter.

2. *Short punch.* The failure mode is plastic upset. Therefore, the punch pressure should be kept less than the yield stress of the punch material [180 ksi (1,200 MPa) for steel and 500 ksi (3,000 MPa) for tungsten carbide].

3. *Flat platen.* Flat platens fail by plastic yielding. A common formula for calculating acceptable maximum platen pressure p is

$$p = \sigma_y\,(\text{diameter of platen/diameter of workpiece})$$

4. *Die cavity.* The die pressures in a deep cavity (impression) are much higher than in a flat platen (die), resulting in die burst-out. A more conservative value of 150 ksi (1,000 MPa) is used for acceptable die pressure. If shrink rings are used, higher values of 250 ksi (1,700 MPa) for steels and 400 ksi (2,700 MPa) for tungsten carbide can be used for the inner insert.

For large massive dies or for intermittent service, chrome-nickel-molybdenum alloys are preferred. In closed die work, where the dies must dissipate considerable heat, the tungsten steels are preferred, with resulting increase in wear resistance but decrease in toughness.

For very large pieces with deep impressions, **cast-steel** dies are sometimes used. For large dies likely to spring in hardening, 0.85 **carbon steel** high in manganese is sometimes used unhardened.

Good **die-block proportions** for width and depth are as follows:

Width, in (cm)	8 (20)	10 (24)	12 (30)	14 (36)
Depth, in (cm)	6 (15)	7 (18)	7 (18)	7 or 8 (18 or 20)

For ordinary work, 1½ in (4 cm) of metal between impression and edge of block is sufficient.

Dimensions of **dovetailed die shanks:** for hammers up to 1,200 lb (550 kg) 4 in (10 cm) wide and 1⅛ in (3 cm) deep, with sides dovetailed at angles of 6° with the vertical; for hammers from 1,200 to 3,000 lb (550 to 1,360 kg) in size, 6 in (15 cm) wide and 1½ in (4 cm) deep, with 6° angles.

The **minimum draft for the impressions** is 7°, although for parts difficult to draw this may be increased up to 15°. It is not uncommon to have several drafts in the same impression.

Carbon steel and tool-steel **dies** are **hardened** by heating in a carbonizing box packed in charcoal and dipping face downward over a jet of brine. The jet is allowed to strike into the impression, thus freeing the face of steam and producing uniform hardness. After hardening, they are drawn in an oil bath to a temperature of 500 to 550°F (260 to 290°C).

The forging production per pair of dies is largely affected by the size and shape of the impression, the material forged, the material in the dies, the quality of heating of stock to be forged, and the care exercised in use. It may vary from a few hundred pieces to 50,000 or more.

Coining, Stamping, and Embossing The metal is well confined in closed dies in which it is forced to flow to fill the shape. The U.S. Mint gives the following pressures; silver quarter, 100 tons/in^2 (1,380 MN/m^2); nickel (0.25 Ni, 0.75 Cu), 90 tons/in^2 (1,240 MN/m^2); copper cent, 40 tons/in^2 (550 MN/m^2). In stamping designs, lettering, etc., in sheet metal the thickness is so little compared with the area that there is practically no relief for excess pressure. Where sharp designs are required, as in stamping panels, the dies should be arranged to strike on a narrow line [say 1/32 in (0.8 mm)] around the outline. If a sharp design is not obtained, it is often best to correct deflection in the machine by shimming or more substantial backing. Increasing the pressure only aggravates the condition and may break the press. General practice for light overall stamping is to allow 5 to 10 tons/in^2 (68 to 132 MN/m^2) of area that is to be stamped, except in areas where the yield point must be exceeded.

Extrusion is the severest of the squeezing processes. The metal is forced to flow rapidly through an orifice, being otherwise confined and subject largely to the laws of hydraulics, with allowances for restraint of flow and for work hardening. Power-press **impact extrusion** began with tin and lead collapsible tubes. It has been extended to the backward and forward extrusion of aluminum, brass, and copper in pressure ranges of 30 to 60 or more tons/in^2 (413 to 825 MN/m^2), and mild steel at pressures up to 165 tons/in^2 (2,275 MN/m^2). Hot impact extrusion of steel, as in projectile piercing, ranges from about 25 to 50 tons/in^2 (345 to 690 MN/m^2). **Forward extrusion** of long tubes, rods, and shapes usually performed hot in hydraulic presses has been extended from the softer metals to the extrusion of steels. Most work is done horizontally because of the lengths of the extrusions. Some vertical mechanical-press equipment is used in hot extrusion of steel tubing.

EQUIPMENT FOR WORKING METALS

The **mass production** industries use an extremely wide variety of machines to force materials to flow plastically into desired shapes (as compared with the more gradual methods of obtaining shapes by cutting away surplus material on machine tools). The application of working pressure may use hydraulic, pneumatic, mechanical, or electric means to apply pressing, hammering, or rolling forces. Mechanically and hydraulically actuated devices cover much the same range. In general, the mechanical equipment is faster, easier to maintain, and more efficient to operate by reason of energy-storing flywheels. The hydraulic equipment is more flexible and more easily adjusted to limited lots in pressure, positions, and strokes. Mechanical handling or feeding devices incorporated in or serving many of these more or less specialized machines further extend their productivity.

Power presses consist of a frame or substantial construction with devices for holding the dies or tools and a moving member or slide for actuating one portion of the dies. This slide usually receives its movement from a crankshaft furnished with a clutch for intermittent operation and a flywheel to supply the sudden power requirement. **Hydraulic presses** have no crankshaft, clutch, or flywheel but employ rams actuated by pumps.

The crankshaft is ordinarily the limiting factor in the pressure capacity of the machine and accordingly is often taken as the basis for tonnage ratings. There is no uniform basis for this rating, owing to variations in shaft proportions and materials and in the different relative severity of various press operations. The following valuation is tentative and is based on the shaft diameter in the main bearings. The bending strength is figured at a section through the center of the crankpin and the combined bending and torsional strength at the inside ends of the main bearings, taking the bending fulcrum at a distance out from these points equal to one-third the length of the main bearings. In the case of double-crank presses and twin-drive arrangements, the relative proportion of the torsional load must be varied to suit, but, except in the cases of long strokes, it is usually small. The working strength is based upon a stress in the extreme fibers of 28,000 lb/in^2 (193 MN/m^2). The limit bearing capacities are taken approximately at 5,000 lb/in^2 (35 MN/m^2) on the crankpins and 2,500 lb/in^2 (18 MN/m^2) average over the main bearings for ordinary steel on cast-iron press bearings with proper grooving. On the knuckle-joint-type presses with hardened tool-steel bearing surfaces and flood lubrication, the bearings will take up to about 30,000 lb/in^2 (207 MN/m^2). On eccentric-type shafts where the main bearings support right up to the oversize pin on each side, the limiting factor is the bearing load. The shaft is practically in shear, so that it has a considerable overload capacity (about $7d^2$ tons). In Table 13.2.5, uniform-diameter single crankshafts are those in which for manufacturing reasons the diameter is the same at the crankpin and at the main bearings. Other crank shafts have an oversize crankpin to balance the bending load at the center with the combined bending and torsional load at the side. The strength of the shaft is figured at midstroke, and the stroke and tonnage capacity are given in terms of the diameter d at the main bearings. Where the working load comes on only near the bottom stroke, the shaft press capacity may be figured as if the stroke were shorter in proportion.

Table 13.2.5 gives the rated capacities of a series of power presses as a function of the shaft diameter.

The speed of operation of the press depends upon the energy requirement and the crankpin velocity. The latter determines the velocity of impact on the tools. In blanking, the blow varies directly with the contact speed and the thickness and hardness of the material. In drawing operations the variation depends upon contact speed, ductility of material, lubrication, etc.

The energy required per stroke is practically the product of the average load and the working distance, plus friction allowance, assumed at about 16 percent. On short-stroke operations, such as blanking, the working energy is supplied almost entirely by slowing down the flywheel; motor and belt pull serve merely to return the flywheel to speed during the large part of the cycle in which no work is done. In drawing operations, the working period is considerable, and in many cases the belt takes the largest part of the working load. In this case, add to the available flywheel energy, the work done by the belt. This amounts, for example, to the allowable belt loading (flat or Vee), multiplied by the ratio of the belt velocity to the crankpin velocity, multiplied by the length of the working stroke on the crank circle in feet. The maximum flywheel slowdown has been assumed to be up to 10 percent for continuous

Table 13.2.5 Power-Press Shaft Capacities

Type of press crankshaft	Max stroke, in*	Capacity tons†
Single crank, single drive, uniform diameter	d‡	$2.8d^2$
Single crank, single drive, oversize crankpin	d	$3.5d^2$
Single crank, single drive, oversize crankpin	$2d$	$2.2d^2$
Single crank, single drive, oversize crankpin	$3d$	$1.6d^2$
Single crank, twin drive, oversize crankpin	$2d$	$3.5d^2$
Single crank, twin drive, oversize crankpin	$3d$	$2.7d^2$
Double crank, single drive, oversize crankpin	$0.75d$	$5.5d^2$
Double crank, single drive, oversize crankpin	d	$4.4d^2$
Double crank, single drive, oversize crankpin	$2d$	$2.5d^2$
Double crank, single drive, oversize crankpin	$3d$	$1.7d^2$
Double crank, twin drive, oversize crankpin	$1.5d$	$5.5d^2$
Double crank, twin drive, oversize crankpin	$3d$	$3.2d^2$
Single eccentric, single or twin drive	$0.5d$	$4.3d^2$

* 1 in = 2.54 cm.
† 1 ton = 8.9 kN.
‡ d = shaft diameter in main bearing.
SOURCE: F. W. Bliss Co.

operation and up to 20 percent for intermittent operation. The following formula is based upon average press-flywheel proportions and a slowdown of 10 percent. The result may be doubled for 20 percent slowdown.

The flywheel capacity per stroke at 10 percent slowdown in inch-tons equals $WD^2N^2/5{,}260{,}000{,}000$, where W is the weight of the flywheel, lb, D is the diameter, in, and N is rotation speed, r/min. (See Sec. 8.2.)

The difference between nongeared and geared presses is only in speed of operation and the relatively greater flywheel capacity.

Press frames are designed for stiffness and usually have considerable excess strength. Good practice is to figure cast-iron sections for a stress of about 2,000 to 3,000 lb/in^2 (13.8 to 20.6 MN/m^2). **C-frame presses** are subjected to an appreciable arc spring amount ordinarily of between 0.0005 and 0.002 in/ton (1.5 and 6 mm/MN), because the center of gravity of the frame section is a considerable distance back of the working centerline of the press. **Straight-sided presses** eliminate that portion of the spring or deflection which is on an arc. **Built-up frame presses** are held together with steel tie rods shrunk in under an initial tension in excess of the working load so that they minimize stretch in that portion of the press.

Power presses are built in a very wide variety of styles and sizes with shafts ranging from 1- to 21-in (2.5- to 53-cm) diam. Over a large part of this range they are built with C frames for convenience, straight-sided frames for heavier and thinner work, eccentric shafts for heavy forgings and stampings, double crankshafts for wide jobs, four-point presses for large panel work, underdrive presses in high-production plants where repairs to presses would interfere with flow of production, and knuckle-join presses for intensely high pressures at the very bottom of the stroke. All these are classified as single-action presses and are used for most of the operations previously discussed.

Double-action presses combine the functions of blank holding with drawing. In the smaller sizes, such presses have cams mounted on the cheeks of the crankshaft to actuate the outer or blank-holding slide. In larger machines, toggle mechanisms are provided to actuate the outer slide, with the advantage that the blank-holding load is taken on the frame instead of the crankshaft. Both of these types afford a considerable power saving over single-action presses equipped with drawing attachments, because the latter must add the blank-holding pressure to the working load for the full depth of the draw.

Types of presses include **foot presses,** in which the pendulum type has the lowest mechanical advantage and the longest stroke; the **lever type,** which has higher mechanical advantage and shorter strokes; **toggle** or **knuckle type,** which has the highest mechanical advantage and works through the shortest stroke with considerable advantage obtainable from the use of tie rods on fine stamping or embossing work; long-stroke rack and pinion-driven presses; triple-action drawing presses; cam-actuated presses; etc.

Screw presses consist of a conventional frame and a slide which is forced down by a steep pitch screw on the upper end of which is a flywheel or weight bar. Hand-operated machines are used for die testing and for small production stamping, embossing, forming, and other work requiring more power than foot presses. Power-driven screw presses are built with a friction drive for the flywheel and automatic control to limit the stroke. Such presses are built in comparatively large sizes and used to a considerable extent for press forging. They lack the accuracy and speed of power presses built for this work but have a safety factor which power presses have not, in that their action is not positive. In this they closely resemble a drop hammer, although their motion is slower. The energy available for work in these presses is $\frac{1}{2}I_f v^2 + \frac{1}{2}I_s v^2$, in which I_f is the moment of inertia of the flywheel, I_s is the moment of inertia of the spindle, and v is the angular velocity of both.

Self-contained fast-acting **hydraulic presses** are being increasingly used. Equipped with motor-driven variable-displacement oil hydraulic pumps, the speed and pressure of the operating ram or rams are under instant and automatic control; this is particularly advantageous for deep drawing operations. The punch can be brought into initial contact with the work without shock and moved with a uniform controlled velocity through the drawing portion of the cycle. The cold drawing of stainless steels and aluminum alloys (in which the control of drawing speed is vital), as well as the hot drawing of magnesium, is best done on hydraulic presses.

The hydraulic press is used on the rubber pad, or *Guerin,* process of blanking or forming metals, in which a laminated-rubber pad replaces one half—usually the female half—of a die. In forming aluminum the practice has developed of using inexpensive dies of soft metal, vulcanized fiber, plastic, wood, or plaster; and cast dies in industries which, like the aircraft industry, require short runs on many different sizes of shapes and parts.

The older accumulator type of hydraulic-press construction is still used for hot extrusion and some forging work.

Pneumatic Hammers A self-contained type of pneumatic forge hammer (the Bêché) has an air-operated ram with an air-compressing cylinder integral with the frame. The ram is raised by admitting compressed air beneath the ram piston; at the same time a partial vacuum is caused above it. The ram is forced down by a reversal of this action.

The **terminal velocity** (velocity at ram-workpiece contact) of the steam, pneumatic, or hydraulic assisted hammer can be calculated as follows:

$$v = \left[2hg\left(1 + \frac{Ap_m}{H}\right)\right]^{0.5}$$

where A is the area of the piston and p_m the mean pressure in the drive cylinder. The hammer energy is often calculated by dividing the energy required for plastic work by the mechanical efficiency of the hammer.

Hydraulic presses are energized by pressurized liquid, usually oil. They can deliver high tonnage but are slow. Due to large die chilling (heat loss to dies) present in hydraulic press forging, they are not usually used for hot forging, except in isothermal forging, where slow speed and large die-workpiece contact times are not a major limitation. They are specially suited to sheet metal forming operations, where slower ram speeds produce lower impact loads, speeds can be varied during the stroke, and multiple actions can be obtained for blank holder and die cushion operation.

Hammers and presses are often selected based on their characteristics such as energy, ram mass (t_{up}), force or tonnage, ram speed (stroking rate), stroke length, bed area, and mechanical efficiency. The characteristics for various hammers and presses are summarized in Table 13.2.6.

Rotary motion is used **for working sheet metal** in a variety of machines, including bending rolls (three rolls); rolling straighteners with five, seven, or more rolls; roll forming machines, in which a series of rolls in successive pairs are used to bend the strip material step by step to some desired shape; a series of two-spindle and multiple-spindle machines used for rolling beads, threads, knurls, flanges, and trimming or curling the edges of drawn shells of cylinders; seaming machines for double seaming, crimping, curling, and other operations in the production of tin cans, pieced tinware, etc.; and spinning machines for spinning, burnishing, trimming, curling, shape forming, and thickness reduction. Various production spinning operations and tool arrangements are shown in Fig. 13.2.10.

Plate-Straightening Machines The **horsepower required** for plate-straightening machines operating on steel plate is shown in Table 13.2.7.

Power required for angle-iron-straightening machines: for 4-in angles, 12 hp; for 6-in, 18 hp; for 8-in, 25 hp.

Power or hydraulic presses are used to straighten **large rolled sections.** The presses make 20 to 30 strokes per min, and the amount of flexure is regulated by inserting wedges or pieces of flat iron. The beams are supported on rolls so they can be easily handled. The **power required for presses** of this kind is as follows:

Depth of girder, in*	4	6	8	10	12	16	20	24
Horsepower (approx)†	3	4	7	11	13	19	23	35

* 1 in = 2.54 cm.
† 1 hp = 0.746 kW.

Horizontal plate-bending machines consist of two stationary rolls and a third vertical adjustable upper roll which can be fitted obliquely for

taper bending and is held in bearings with spherical seats. The diameter of the rolls can be determined approximately from the equation $r^2 = bt$, in which r is the radius of the roll, b the width of the plate or sheet, and t its thickness, all in inches.

The **power requirements** of horizontal plate and sheet bending machines are shown in Table 13.2.8.

Numerically Adaptive Bending of Tubes and Profiles (Fig. 13.2.31) Extrusions, profiles, and tubes find greater use in car and truck body structures due to their high stiffness under bending loads. The shapes are bent or curved to conform to the geometric needs of design and assembly. Therefore, new fixtures and numerically controlled machines and tooling (Fig. 13.2.31) have been developed to stretch bend the structural shapes.

Vertical plate-bending machines have a hydraulically operated piston which moves an upper and a lower pair of rolls between inclined surfaces of the stationary upright and the crosshead. The bending is done piece by piece against a second stationary upright. Heavy ship plates are rigidly clamped down and bent by a roll operated by two hydraulic pistons. For angular bends or for the production of warped surfaces, the pistons can be operated independently or together. In vertical machines, angles and other rolled shapes are bent between suitably shaped rolls. Pipes are filled with sand to prevent flattening when being bent. For some work, pipes are bent hot between suitable forms operated by hydraulic pressure.

The **rotary swaging machines** for tapering, closing in, and reducing tubes, rods, and hollow articles is essentially a cage carrying a number of rollers and revolving at high speed; e.g., 14 rolls in a cage revolving at 600 r/min will strike 8,400 blows per min on the work.

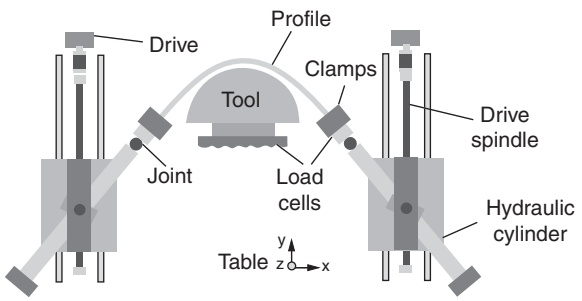

Fig. 13.2.31 Schematic of numerically controlled adaptive stretch bending machine. *(Source: M. Nock and M. Geiger, Flexible Kinematic 3D-Bending of Tubes and Profiles, International Conference on the Advanced Technology of Plasticity, Japan*, **1,** *2002, pp. 643–648.)*

A rapid succession of light blows is applied to a considerable variety of commercial **riveting** operations such as pneumatic riveting. Another method of riveting, described as spinning, involves rotating small rollers rapidly over the top of the rivet and at the same time applying pressure. Neither of these methods involves pressures as intense as those used in riveting by direct pressure, either hot or cold. Power presses and C-frame riveters, employing hydraulic pressure or air pressure of 80 to 100 lb/in^2 (550 to 690 kN/m^2), are designed to apply 150,000 lb/in^2 (1,035 MN/m^2) on the cross section of the body of the rivet for hot-working and 300,000 lb/in^2 (2,070 MN/m^2) for cold-working. The pieces joined should be pressed together by a pressure 0.3 to 0.4 times that used in riveting.

13.3 WELDING AND CUTTING

INTRODUCTION

Welded connections and assemblies represent a very large group of fabricated metal components, and only a portion of the aspects of their design and fabrication is treated here. The welding process itself is complex, involving heat and liquid-metal transfer, chemical reactions, and the gradual formation of the welded joint through liquid-metal deposition and subsequent cooling into the solid state, with attendant metallurgical transformations. Some of these items are treated in greater detail in the references and other extensive professional literature, as well as in Secs. 6.2, 6.3, and 13.1.

The material in this section will provide the engineer with an overview of the most important aspects of welded design. In order that the resulting welded fabrication be of adequate strength, stiffness, and utility, the designer will often collaborate with engineers who are experts in the broad area of design and fabrication of weldments.

ARC WELDING

Arc welding is one of several **fusion processes** for joining metal. By the generation of intense heat, the juncture of two metal pieces is melted and mixed—directly or, more often, with an intermediate molten **filler metal.** Upon cooling and solidification, the resulting welded joint metallurgically bonds the former separate pieces into a continuous structural assembly (a **weldment**). When the pieces are properly designed and fabricated, the strength properties are basically those of the individual pieces before welding.

In arc welding, the intense heat needed to melt metal is produced by an **electric arc.** The arc forms between the workpieces and an electrode that is either manually or mechanically moved along the joint; conversely, the work may be moved under a stationary electrode. The **electrode** generally is a specially prepared rod or wire that not only conducts electric current and sustains the arc, but also melts and supplies **filler metal** to the joint; this constitutes a **consumable electrode. Carbon** or **tungsten electrodes** may be used, in which case the electrode serves only to conduct electric current and to sustain the arc between tip and workpiece, and it is not consumed; with these electrodes, any filler metal required is supplied by rod or wire introduced into the region of the arc and melted there. Filler metal applied separately, rather than via a consumable electrode, does not carry electric current.

Most steel arc welding operations are performed with consumable electrodes.

Welding Process Fundamentals

Heat and Filler Metal An ac or dc power source fitted with necessary controls is connected by a work cable to the workpiece and by a "hot" cable to an electrode holder of some type, which, in turn, is electrically connected to the welding electrode (Fig. 13.3.1). When the circuit is energized, the flow of electric current through the electrode heats the electrode by virtue of its electric resistance. When the electrode tip is touched to the workpiece and then withdrawn to leave a gap between the electrode and workpiece, the arc jumping the short gap presents a further path of high electric resistance, resulting in the generation of an extremely high temperature in the region of the sustained arc. The temperature reaches about 6,500°F, which is more than adequate to melt most metals. The heat of the arc melts both the base and the filler metal, the latter being supplied via a consumable electrode or separately. The puddle of molten metal produced is called a **weld pool,** which solidifies as the electrode and arc move along the joint being welded. The resulting weldment is metallurgically bonded as the liquid metal cools, fuses, solidifies, and cools. In addition to serving its main function of supplying heat, the arc is subject to adjustment and/or control to vary the proper transfer of molten metal to the weld pool, remove surface films in the weld region, and foster gas-slag reactions or other beneficial metallurgical changes.

Filler metal composition is generally different from that of the weld metal, which is composed of the solidified mix of both filler and base metals.

Shielding and Fluxing High-temperature molten metal in the weld pool will react with oxygen and nitrogen in ambient air. These gases will remain dissolved in the liquid metal, but their solubility significantly decreases as the metal cools and solidifies. The decreased solubility causes the gases to come out of solution, and if they are trapped in the metal as it solidifies, **cavities,** termed **porosity,** are left behind. This is always undesirable, but it can be acceptable to a limited degree depending on the specification governing the welding.

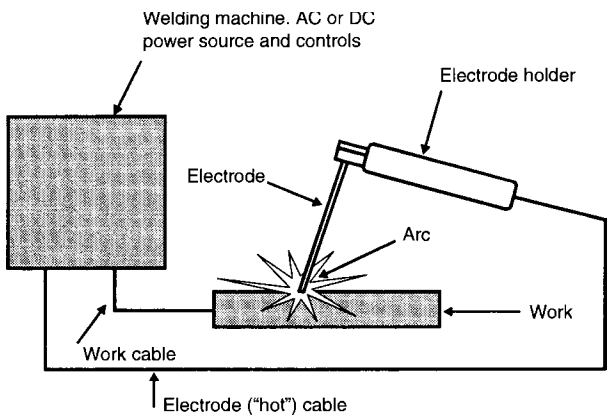

Fig. 13.3.1 Typical welding circuit.

Smaller amounts of these gases, particularly nitrogen, may remain dissolved in the weld metal, resulting in reduction in the physical properties of otherwise excellent weld metal. **Notch toughness** is degraded by nitrogen inclusions. Accordingly, the molten metal must be shielded from harmful atmospheric gas contaminants. This is accomplished by gas shielding or slag shielding or both.

Gas shielding is provided either by an external supply of gas, such as carbon dioxide, or by gas generated when the electrode flux heats up. **Slag shielding** results when the flux ingredients are melted and leave behind a slag to cover the weld pool, to act as a barrier to contact between the weld pool and ambient air. At times, both types of shielding are utilized.

In addition to its primary purpose to protect the molten metal, the shielding gas will affect arc behavior. The shielding gas may be mixed with small amounts of other gases (as many as three others) to improve arc stability, puddle (weld pool) fluidity, and other welding operating characteristics.

In the case of shielded-metal arc welding (SMAW), the "stick" electrode is covered with an extruded coating of flux. The arc heat melts the flux and generates a gaseous shield to keep air away from the molten metal, and at the same time the flux ingredients react with deleterious substances, such as surface oxides on the base metal, and chemically combine with those contaminants, creating **a slag** which floats to the surface of the weld pool. That slag crusts over the newly solidified hot metal, minimizes contact between air and hot metal while the metal cools, and thereby inhibits the formation of surface oxides on the newly deposited weld metal, or weld bead. When the temperature of the weld bead decreases, the slag, which has a glassy consistency, is chipped off to reveal the bright surface of the newly deposited metal. Minimal surface oxidation will take place at lower temperatures, inasmuch as oxidation rates are greatly diminished as ambient conditions are approached.

Fluxing action also aids in wetting the interface between the base metal and the molten metal in the weld pool edge, thereby enhancing uniformity and appearance of the weld bead.

Process Selection Criteria

Economic factors generally dictate which welding process to use for a particular application. It is impossible to state which process will always deliver the most economical welds, because the variables involved are significant in both number and diversity. The variables include, but are not limited to, steel (or other base metal) type, joint type, section thickness, production quantity, joint access, position in which the welding is to be performed, equipment availability, availability of qualified and skilled welders, and whether the welding will be done in the field or in the shop.

Shielded Metal Arc Welding

The **SMAW** process (Fig. 13.3.2), commonly known as **stick welding,** or **manual welding,** is a popular and widespread welding process. It is versatile, relatively simple to do, and very flexible in being applied. To those casually acquainted with welding, **arc welding** usually means **shielded-metal arc welding.** SMAW is used in the shop and in the field for fabrication, erection, maintenance, and repairs. Because of the relative inefficiency of the process, it is seldom used for fabrication of major structures. SMAW has earned a reputation for providing high-quality welds in a dependable fashion. It is, however, inherently slower and generally more costly than other methods of welding.

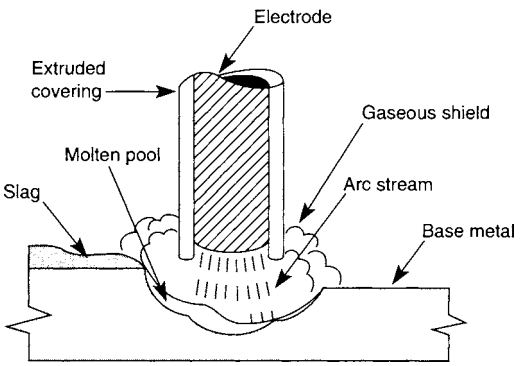

Fig. 13.3.2 SMAW process.

SMAW may utilize either direct current (dc) or alternating current (ac). Generally speaking, direct current is used for smaller electrodes, usually less than $\frac{3}{16}$-in diameter. Larger electrodes utilize alternating current to eliminate undesirable arc blow conditions.

Electrodes used with alternating current must be designed specifically to operate in this mode, in which current changes direction 120 times per second with 60-Hz power. All ac electrodes will operate acceptably on direct current. The opposite is not always true.

Flux Cored Arc Welding (FCAW)

In **FCAW,** the arc is maintained between a continuous tubular metal electrode and the weld pool. The tubular electrode is filled with flux and a combination of materials that may include metallic powder(s). FCAW may be done automatically or semiautomatically. FCAW has become the workhorse in fabrication shops practicing semiautomatic welding. Production welds that are short, change direction, are difficult to access, must be done out of position (e.g., vertical or overhead), or are part of a short production run generally will be made with semiautomatic FCAW.

When the application lends itself to automatic welding, most fabricators will select the submerged arc process (see material under "SAW"). Flux cored arc welding may be used in the automatic mode, but the intensity of arc rays from a high-current flux cored arc, as well as a significant volume of smoke, makes alternatives such as submerged arc more desirable.

Advantages of FCAW FCAW offers two distinct advantages over SMAW. First, the electrode is continuous and eliminates the built-in starts and stops that are inevitable with SMAW using stick electrodes. An economic advantage accrues from the increased operating factor; in addition, the reduced number of arc starts and stops largely eliminates potential sources of weld discontinuities. Second, increased amperages can be used with FCAW. With SMAW, there is a practical limit to the amount of current that can be used. The covered electrodes are 9 to 18 in long, and if the current is too high, electric resistance heating within the unused length of electrode will become so great that the coating ingredients may overheat and "break down." With continuous flux cored electrodes, the tubular electrode is passed through a contact tip, where electric current is transferred to the electrode. The short distance from the contact tip to the end of the electrode, known as electrode extension or **"stickout,"** inhibits heat buildup due to electric resistance. This electrode extension distance is typically 1 in for flux cored electrodes, although it may be as much as 2 or 3 in in some circumstances.

Smaller-diameter flux cored electrodes are suitable for all-position welding. Larger electrodes, using higher electric currents, usually are restricted to use in the flat and horizontal positions. Although the equipment required for FCAW is more expensive and more complicated than that for SMAW, most fabricators find FCAW much more economical than SMAW.

FCAW Equipment and Procedures Like all wire-fed welding processes, FCAW requires a power source, wire feeder, and gun and cable assembly (Fig. 13.3.3). The power supply is a dc source, although either electrode positive or electrode negative polarity may be used. The four primary variables used to determine welding procedures are voltage, wire feed speed, electrode extension, and travel speed. For a given wire feed speed and electrode extension, a specified amperage will be delivered to maintain stable welding conditions.

As wire feed speed is increased, amperage will be increased. On some equipment, the wire feed speed control is called the amperage control, which, despite its name, is just a rheostat that regulates the speed of the dc motor driving the electrode through the gun. The most accurate way, however, to establish welding procedures is to refer to the

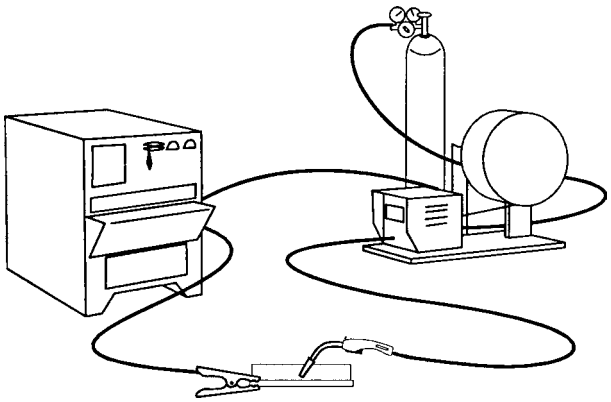

Fig. 13.3.3 FCAW and GMAW equipment.

wire feed speed (WFS), since electrode extension, polarity, and electrode diameter will also affect amperage. For a fixed wire feed speed, a shorter electrical stick-out will result in higher amperages. If procedures are set based on the wire feed speed, the resulting amperage verifies that proper electrode extensions are being used. If amperage is used to set welding procedures, an inaccurate electrode extension may go undetected.

Self-Shielded and Gas-Shielded FCAW Within the category of FCAW, there are two specific subsets: **self-shielded flux core arc welding (FCAW-S)** (Fig. 13.3.4) and **gas-shielded flux core arc welding (FCAW-G)** (Fig. 13.3.5). Self-shielded flux cored electrodes require no external shielding gas. The entire shielding system results from the flux ingredients contained in the tubular electrode. The gas-shielded variety of flux cored electrode utilizes, in addition to the flux core, an externally supplied shielding gas. Often, CO_2 is used, although other mixtures may be used.

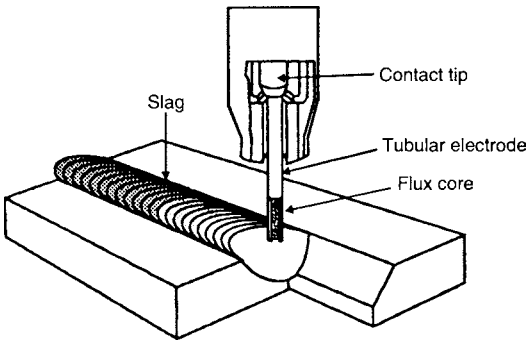

Fig. 13.3.4 Self-shielded FCAW.

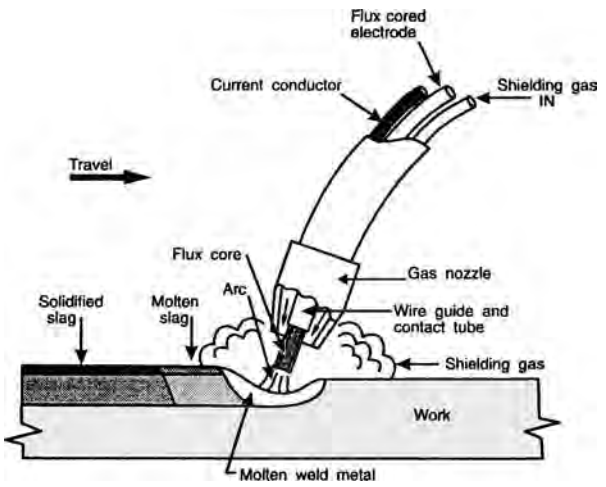

Fig. 13.3.5 Gas-shielded FCAW.

Both these subsets of FCAW are capable of delivering weld deposits featuring consistency, high quality, and excellent mechanical properties. Self-shielded flux cored electrodes are ideal for field welding operations, for since no externally supplied shielding gas is required, the process may be used in high winds without adversely affecting the quality of the weld metal deposited. With any gas-shielded processes, wind shields must be erected to preclude wind interference with the gas shield. Many fabricators with large shops have found that self-shielded flux core welding offers advantages when the shop door can be left open or fans are used to improve ventilation.

Gas-shielded flux cored electrodes tend to be more versatile than self-shielded flux cored electrodes and, in general, provide better arc action. Operator acceptance is usually higher. The gas shield must be protected from winds and drafts, but this is not difficult for most shop fabrication. Weld appearance is very good, and quality is outstanding. Higher-strength gas-shielded FCAW electrodes are available, but current practice limits self-shielded FCAW deposits to a tensile strength of 80 ksi or less.

Submerged Arc Welding (SAW)

Submerged arc welding differs from other arc welding processes in that a blanket of fusible granular flux is used to shield the arc and molten metal (Fig. 13.3.6). The arc is struck between the workpiece and a bare-wire electrode, the tip of which is submerged in the flux. The arc is completely covered by the flux and it is not visible; thus the weld is made without the flash, spatter, and sparks that characterize the open-arc processes. The flux used develops very little smoke or visible fumes.

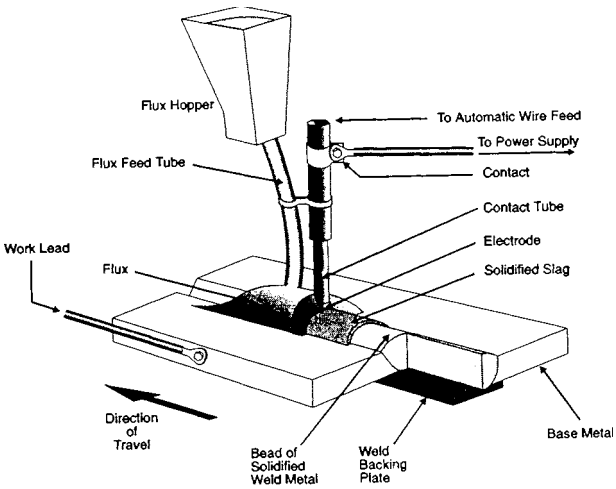

Fig. 13.3.6 SAW process.

Typically, the process is operated fully automatically, although semiautomatic operation is possible. The electrode is fed mechanically to the welding gun, head, or heads. In semiautomatic welding, the welder moves the gun, usually equipped with a flux-feeding device, along the joint.

Flux may be fed by gravity flow from a small hopper atop the torch and then through a nozzle concentric with the electrode, or through a nozzle tube connected to an air-pressurized flux tank. Flux may also be applied in advance of the welding operation or ahead of the arc from a hopper run along the joint. Many fully automatic installations are equipped with a vacuum system to capture unfused flux left after welding; the captured, unused flux is recycled for reuse.

During welding, arc heat melts some of the flux along with the tip of the electrode. The electrode tip and the welding zone are always

shielded by molten flux and a cover layer of unfused flux. The electrode is kept a short distance above the workpiece. As the electrode progresses along the joint, the lighter molten flux rises above the molten metal to form slag. The weld metal, having a higher melting (freezing) point, solidifies while the slag above it is still molten. The slag then freezes over the newly solidified weld metal, continuing to protect the metal from contamination while it is very hot and reactive with atmospheric oxygen and nitrogen. Upon cooling and removal of any unmelted flux, the slag is removed from the weld.

Advantages of SAW High currents can be used in SAW, and extremely high heat input can be developed. Because the current is applied to the electrode a short distance above the arc, relatively high amperages can be used on small-diameter electrodes. The resulting extremely high current densities on relatively small-cross-section electrodes permit high rates of metal deposition.

The insulating flux blanket above the arc prevents rapid escape of heat and concentrates it in the welding zone. Not only are the electrode and base metal melted rapidly, but also fusion is deep into the base metal. Deep penetration allows the use of small welding grooves, thus minimizing the amount of filler metal to be deposited and permitting fast welding speeds. Fast welding, in turn, minimizes the total heat input to the assembly and thus tends to limit problems of heat distortion. Even relatively thick joints can be welded in one pass with SAW.

Versatility of SAW SAW can be applied in more ways than other arc welding processes. A single electrode may be used, as is done with other wire feed processes, but it is possible to use two or more electrodes in submerged arc welding. Two electrodes may be used in parallel, sometimes called **twin arc welding,** employing a single power source and one wire drive. In **multiple-electrode SAW,** up to five electrodes can be used thus, but most often, two or three arc sources are used with separate power supplies and wire drives. In this case, the lead electrode usually operates on direct current while the trailing electrodes operate on alternating current.

Gas Metal Arc Welding (GMAW)

Gas metal arc welding utilizes the same equipment as FCAW (Figs. 13.3.3 and 13.3.7); indeed, the two are similar. The major differences are: (1) GMAW uses a solid or metal cored electrode, and (2) GMAW leaves no residual slag.

GMAW may be referred to as **metal inert gas (MIG),** solid wire and gas, **miniwire** or **microwire welding.** The shielding gas may be carbon dioxide or blends of argon with CO_2 or oxygen, or both. GMAW is usually applied in one of four ways: short arc transfer, globular transfer, spray arc transfer, and pulsed arc transfer.

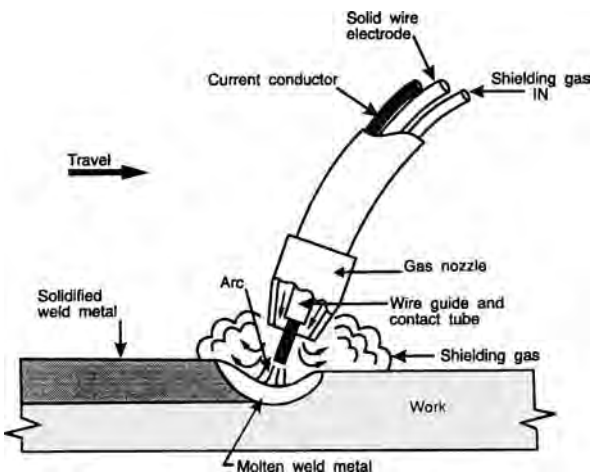

Fig. 13.3.7 GMAW welding process.

Short arc transfer is ideal for welding thin-gage materials, but generally is unsuitable for welding on thick members. In this mode of transfer, a small electrode, usually of 0.035- to 0.045-in diameter, is fed at a moderate wire feed speed at relatively low voltages. The electrode contacts the workpiece, resulting in a short circuit. The arc is actually quenched at this point, and very high current will flow through the electrode, causing it to heat and melt. A small amount of filler metal is transferred to the welding done at this time.

The cycle will repeat itself when the electrode short-circuits to the work again; this occurs between 60 and 200 times per second, creating a characteristic buzz. This mode of transfer is ideal for sheet metal, but results in significant fusion problems if applied to thick sections, when **cold lap** or **cold casting** results from failure of the filler metal to fuse to the base metal. This is unacceptable since the welded connection will have virtually no strength. Caution must be exercised if the short arc transfer mode is applied to thick sections.

Spray arc transfer is characterized by high wire feed speeds at relatively high voltages. A fine spray of molten filler metal drops, all smaller in diameter than the electrode, is ejected from the electrode toward the work. Unlike with short arc transfer, the arc in spray transfer is maintained continuously. High-quality welds with particularly good appearance are obtained. The shielding gas used in spray arc transfer is composed of at least 80 percent argon, with the balance either carbon dioxide or oxygen. Typical mixtures would include 90-10 argon-CO_2, and 95-5 argon-oxygen. Relatively high arc voltages are used with spray arc transfer. Gas metal spray arc transfer welds have excellent appearance and evidence good fusion. However, due to the intensity of the arc, spray arc transfer is restricted to applications in the flat and horizontal positions.

Globular transfer is a mode of gas metal arc welding that results when high concentrations of carbon dioxide are used. Carbon dioxide is not an inert gas; rather, it is active. Therefore, GMAW that uses CO_2 may be referred to as **MAG,** for **metal active gas.** With high concentrations of CO_2 in the shielding gas, the arc no longer behaves in a spraylike fashion, but ejects large globs of metal from the end of the electrode. This mode of transfer, while resulting in deep penetration, generates relatively high levels of spatter, and weld appearance can be poor. Like the spray mode, it is restricted to the flat and horizontal positions. Globular transfer may be preferred over spray arc transfer because of the low cost of CO_2 shielding gas and the lower level of heat experienced by the operator.

Pulsed arc transfer is a newer development in GMAW. In this mode, a background current is applied continuously to the electrode. A pulsing peak current is applied at a rate proportional to the wire feed speed. With this mode of transfer, the power supply delivers a pulse of current which, ideally, ejects a single droplet of metal from the electrode. The power supply then returns to a lower background current to maintain the arc. This occurs between 100 and 400 times per second. One advantage of pulsed arc transfer is that it can be used out of position. For flat and horizontal work, it will not be as fast as spray arc transfer. However, when it is used out of position, it is free of the problems associated with gas metal arc short-circuiting mode. Weld appearance is good, and quality can be excellent. The disadvantages of pulsed arc transfer are that the equipment is slightly more complex and is more costly.

Metal cored electrodes comprise another newer development in GMAW. This process is similar to FCAW in that the electrode is tubular, but the core material does not contain slag-forming ingredients. Rather, a variety of metallic powders are contained in the core, resulting in exceptional alloy control. The resulting weld is slag-free, as are other forms of GMAW.

The use of metal cored electrodes offers many fabrication advantages. Compared to spray arc transfer, metal cored electrodes require less amperage to obtain the same deposition rates. They are better able to handle mill scale and other surface contaminants. When used out-of-position, they offer greater resistance to the cold lapping phenomenon so common with short arc transfer. Finally, metal cored electrodes permit the use of amperages higher than may be practical with solid electrodes, resulting in higher metal deposition rates.

The weld properties obtained from metal cored electrode deposits can be excellent, and their appearance is very good. Filler metal manufacturers are able to control the composition of the core ingredients, so that mechanical properties obtained from metal cored deposits can be more consistent than those obtained with solid electrodes.

Electroslag/Electrogas Welding (ESW/EGW)

Electroslag and **electrogas welding** (Figs. 13.3.8 and 13.3.9) are closely related processes that allow high deposition welding in the vertical plane. Properly applied, these processes offer tremendous savings over alternative, out-of-position methods and, in many cases, savings over flat-position welding. Although the two processes have similar applications and mechanical setup, there are fundamental differences in the arc characteristics.

Electroslag and electrogas are mechanically similar in that both utilize **copper dams,** or shoes, that are applied to either side of a square-edged butt joint. An electrode or multiple electrodes are fed into the joint. Usually, a starting sump is applied for the beginning of the weld. As the electrode is fed into the joint, a puddle is established that progresses vertically. The water-cooled copper dams chill the weld metal and prevent its escape from the joint. The weld is completed in one pass.

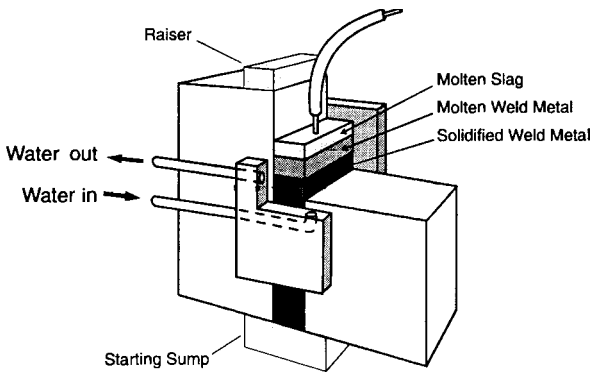

Fig. 13.3.8 ESW process.

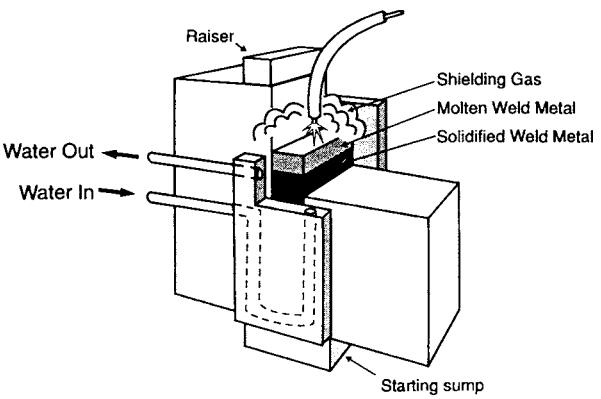

Fig. 13.3.9 EGW process.

Gas Tungsten Arc Welding (GTAW)

The **gas tungsten arc welding** process (Fig. 13.3.10), colloquially called **TIG welding,** uses a nonconsumable tungsten electrode. An arc is established between the tungsten electrode and the workpiece, resulting in heating of the base metal. If required, a filler metal is used. The weld area is shielded with an inert gas, usually argon or helium. GTAW is ideally suited to weld nonferrous materials such as stainless steel and aluminum, and is very effective for joining thin sections.

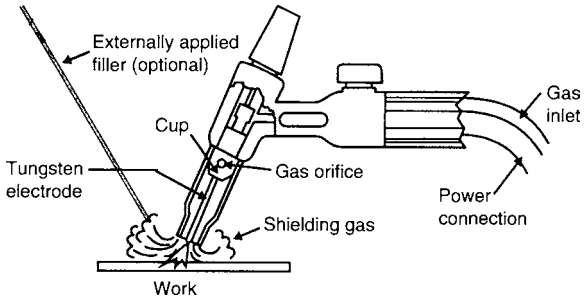

Fig. 13.3.10 Gas tungsten arc welding (GTAW).

Highly skilled welders are required for GTAW, but the resulting weld quality can be excellent. The process is often used to weld exotic materials. Critical repair welds as well as root passes in pressure piping are typical applications.

Plasma Arc Welding (PAW)

Plasma arc welding is an arc welding process using a constricted arc to generate very high, localized heating. PAW may utilize either a transferred or a nontransferred arc. In the **transferred arc mode,** the arc occurs between the electrode and the workpiece, much as in GTAW, the primary difference being the constriction afforded by the secondary gases and torch design. With the **nontransferred arc** mode, arcing is contained within the torch between a tungsten electrode and a surrounding nozzle.

The constricted arc results in higher localized arc energies than are experienced with GTAW, resulting in faster welding speeds. Applications for PAW are similar to those for GTAW. The only significant disadvantage of PAW is the equipment cost, which is higher than that for GTAW.

Most PAW is done with the transferred arc mode, although this mode utilizes a nontransferred arc for the first step of operation. An arc and plasma are initially established between the electrode and the nozzle. When the torch is properly located, a switching system will redirect the arc toward the workpiece. Since the arc and plasma are already established, transferring the arc to the workpiece is easily accomplished and highly reliable. For this reason, PAW is often preferred for automated applications.

GAS WELDING AND BRAZING

The heat for **gas welding** is supplied by burning a mixture of oxygen and a suitable combustible gas. The gases are mixed in a torch which controls the welding flame.

Acetylene is almost universally used as the combustible gas because of its high flame temperature. This temperature, about 6,000°F (3,315°C), is so far above the melting point of all commercial metals that it provides a means for the rapid localized melting essential in welding. The oxyacetylene flame is also used in cutting ferrous metals.

A **neutral flame** is one in which the fuel gas and oxygen combine completely, leaving no excess of either fuel gas or oxygen. The neutral flame has an inside portion, consisting of a brilliant cone 1⁄16 to 3⁄4 in (1.6 to 19.1 mm) long, surrounded by a faintly luminous envelope flame. When fuel gas is in excess, the flame consists of three easily recognizable zones: a sharply defined inner cone, an intermediate cone of whitish color, and the bluish outer envelope. The length of the intermediate cone is a measure of the amount of excess fuel gas. This **flame is reducing,** or **carburizing.**

When oxygen is in excess in the mixture, the flame resembles the neutral flame, but the inner cone is shorter, is "necked in" on the sides, is not so sharply defined, and acquires a purplish tinge. A slightly **oxidizing flame** may be used in braze welding and bronze surfacing, and a more strongly oxidizing flame is sometimes used in gas-welding brass, bronze, and copper. A disadvantage of a strongly oxidizing flame is that it can oxidize the surface of the base metal and thereby prevent fusion of the filler metal to the base metal.

In **braze welding,** coalescence is produced by heating above 840°F (450°C) and by using a nonferrous filler metal having a melting point below that of the base metals. Braze welding with brass (bronze) rods is used extensively on cast iron, steel, copper, brass, etc. Since it operates at temperatures lower than base metal melting points, it is used where control of distortion is necessary or lower base metal temperatures during welding are desired. Braze-welded joints on mild steel, made with rods of classifications RCuZn-B and RBCuZn-D, will show transverse tensile values of 60,000 to 70,000 lb/in^2 (414 to 483 MPa). Joint designs for braze welding are similar to those used for gas and arc welding.

In braze welding it is necessary to remove rust, grease, scale, etc., and to use a suitable flux to dissolve oxides and clean the metal. Sometimes rods are used with a flux coating applied to the outside. Additional flux may or may not be required, notwithstanding the flux coating on the rods. The parts are heated to red heat [1,150 to 1,350°F (621 to 732°C)], and the rod is introduced into the heated zone. The rod melts first and "tins" the surfaces, following which additional filler metal is added.

Welding rods for oxyacetylene braze welding are usually of the copper-zinc (60 Cu-40 Zn) analysis. Additions of tin, manganese, iron, nickel, and silicon are made to improve the mechanical properties and usability of the rods.

Brazing is another one of the general groups of welding processes, consisting of the torch, furnace, induction, dip, and resistance brazing. Brazing may be used to join almost all metals and combinations of dissimilar metals, but some combinations of dissimilar metals are not compatible (e.g., aluminum or magnesium to other metals). In brazing, coalescence is produced by heating above 840°F (450°C) but below the melting point of the metals being joined. The nonferrous filler metal used has a melting point below that of the base metal, and the filler metal is distributed in the closely fitted lap or butt joints by capillary attraction. Clean joints are essential for satisfactory brazing. The use of a flux or controlled atmosphere to ensure surface cleanliness is necessary. Filler metal may be hand-held and fed into the joint (face feeding), or preplaced as rings, washers, shims, slugs, etc.

Brazing with the silver-alloy filler metals previously was known as **silver soldering and hard soldering. Braze welding** should not be confused with brazing. Braze welding is a method of welding employing a filler metal which melts below the welding points of the base metals joined, but the filler metal *is not* distributed in the joint by capillary attraction. (See also Sec. 6.)

Torch brazing uses acetylene, propane, or other fuel gas, burned with oxygen or air. The combination employed is governed by the brazing temperature range of the filler metal, which is usually above its liquidus. Flux with a melting point appropriate to the brazing temperature range and the filler metal is essential.

Furnace brazing employs the heat of a gas-fired, electric, or other type of furnace to raise the parts to brazing temperature. Fluxes may be used, although reducing or inert atmospheres are more common since they eliminate postbraze cleaning necessary with fluxes.

Induction brazing utilizes a high-frequency current to generate the necessary heat in the part by induction. Distortion in the brazed joint can be controlled by current frequency and other factors. Fluxes or gaseous atmospheres must be used in induction bearing.

Dip brazing involves the immersion of the parts in a molten bath. The bath may be either molten brazing filler metal or molten salts, which most often are brazing flux. The former is limited to small parts such as electrical connections; the latter is capable of handling assemblies weighing several hundred pounds. The particular merit of dip brazing is that the entire joint is completed all at one time.

Resistance brazing utilizes standard resistance-welding machines to supply the heat. Fluxes or atmospheres must be used, with flux predominating. Standard spot or projection welders may be used. Pressures are lower than those for conventional resistance welding.

RESISTANCE WELDING

In resistance welding, coalescence is produced by the heat obtained from the electric resistance of the workpiece to the flow of electric current in a circuit of which the workpiece is a part, and by the application of pressure. The specific processes include **resistance spot welding, resistance seam welding, and projection welding.** Figure 13.3.11 shows diagrammatic outlines of the processes.

The resistance of the welding circuit should be a maximum at the interface of the parts to be joined, and the heat generated there must reach a value high enough to cause localized fusion under pressure.

Electrodes are of copper alloyed with such metals as molybdenum and tungsten, with high electrical conductivity, good thermal conductivity, and sufficient mechanical strength to withstand the high pressures to which they are subjected. The electrodes are water-cooled. The resistance at the surfaces of contact between the work and the electrodes must be kept low. This may be accomplished by using smooth, clean work surfaces and a high electrode pressure.

In **resistance spot welding** (Fig. 13.3.11), the parts are lapped and held in place under pressure. The size and shape of the electrodes control the size and shape of the welds, which are usually circular.

Designing for spot welding involves six elements: tip size, edge distance, contacting overlap, spot spacing, spot weld shear strength, and electrode clearance. For mild steel, the diameter of the tip face, in terms of sheet thickness t, may be taken as $0.1 + 2t$ for thin material, and as $\sqrt{t}$ for thicker material; all dimensions in inches. Edge distance should be sufficient to provide enough metal around the weld to retain it when in the molten condition. Contacting overlap is generally taken as the diameter of the weld nugget plus twice the minimum edge distance. Spot spacing must be sufficient to ensure that the welding current will not shunt through the previously made weld.

Resistance spot welding machines vary from small, manually operated units to large, elaborately instrumented units designed to produce high-quality welds, as on aircraft parts. Portable gun-type machines are available for use where the assemblies are too large to be transported to a fixed machine. Spot welds may be made singly or in multiples, the latter generally made on special purpose machines. Spacing of electrodes is important to avoid excessive shunting of welding current.

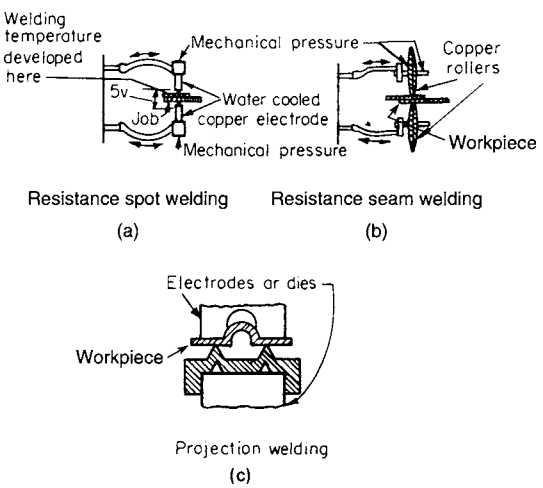

Fig. 13.3.11 (*a*) Resistance spot; (*b*) resistance seam; (*c*) projection welding.

The **resistance seam welding process** (Fig. 13.3.11) produces a series of spot welds made by circular or wheel type electrodes. The weld may be a series of closely spaced individual spot welds, overlapping spot welds, or a continuous weld nugget. The weld shape for individual welds is rectangular, continuous welds are about 80 percent of the width of the roll electrode face.

A **mash weld** is a seam weld in which the finished weld is only slightly thicker than the sheets, and the lap disappears. It is limited to thicknesses of about 16 gage and an overlap of 1½ times the sheet thickness. Operating the machine at reduced speed, with increased pressure and noninterrupted current, a strong quality weld may be secured that will

be 10 to 25 percent thicker than the sheets. The process is applicable to mild steel but has limited use on stainless steel; it cannot be used on nonferrous metals. A modification of this technique employs a straight butt joint. This produces a slight depression at the weld, but the strength is satisfactory on some applications, e.g., for the production of some electric-welded pipe and tubing.

Cleanliness of sheets is of even more importance in seam welding than in spot welding. Best results are secured with cold-rolled steel, wiped clean of oil; the next best with pickled hot-rolled steel. Grinding or polishing is sometimes performed, but not sand- or shot-blasting.

In **projection welding** (Fig. 13.3.11), the heat for welding is derived from the localization of resistance at predetermined points by means of projections, embossments, or the intersections of elements of the assembly. The projections may be made by stamping or machining. The process is essentially the same as spot welding, and the projections seem to concentrate the current and pressure. Welds may be made singly or in multiple with somewhat less difficulty than is encountered in spot welding. When made in multiple, all welds may be made simultaneously. The advantages of projection welding are (1) the heat balance for difficult assemblies is readily secured, (2) the results are generally more uniform, (3) a closer spacing of welds is possible, and (4) electrode life is increased. Sometimes it is possible to projection-weld joints that could not be welded by other means.

OTHER WELDING PROCESSES

Electron Beam Welding (EBW)

In **electron beam welding,** coalescence of metals is achieved by heat generated by a concentrated beam of high-velocity electrons impinging on the surfaces to be joined. Electrons have a very small mass and carry a negative charge. An electron beam gun, consisting of an emitter, a bias electrode, and an anode, is used to create and accelerate the beam of electrons. Auxiliary components such as beam alignment, focus, and deflection coils may be used with the electron beam gun; the entire assembly is referred to as the electron beam gun column.

The advantages of the process arise from the extremely high energy density in the focused beam which produces deep, narrow welds at high speed, with minimum distortion and other deleterious heat effects. These welds show superior strength compared with those made utilizing other welding processes for a given material. Major applications are with metals and alloys highly reactive to gases in the atmosphere or those volatilized from the base metal being welded.

A disadvantage of the process lies in the necessity for providing precision parts and fixtures so that the beam can be precisely aligned with the joint to ensure complete fusion. Gapped joints are not normally welded because of fixture complexity and the extreme difficulty of manipulating filler metal into the tiny, rapidly moving, weld puddle under high vacuum. When no filler metal is employed, it is common to use the keyhole technique. Here, the electron beam makes a hole entirely through the base metal, which is subsequently filled with melted base metal as the beam leaves the area. Other disadvantages of the process arise from the cost, complexity, and skills required to operate and maintain the equipment, and the safety precautions necessary to protect operating personnel from the X-rays generated during the operation.

Laser Beam Welding and Cutting

By using a laser, energy from a primary source (electrical, chemical, thermal, optical, or nuclear) is converted to a beam of coherent electromagnetic radiation at ultraviolet, visible, or infrared frequency. Because high-energy laser beams are coherent, they can be highly concentrated to provide the high energy density needed for welding, cutting, and heat-treating metals.

As applied to welding, **pulsed** and continuously operating solid-state **lasers** and lasers that produce **continuous-wave (cw) energy** have been developed to the point that multikilowatt laser beam equipment based on CO_2 is capable of full-penetration, single-pass welding of steel to ¾-in thickness.

Lasers do not require a vacuum in which to operate, so that they offer many of the advantages of electron beam welding but at considerably lower equipment cost and higher production rates. Deep, narrow welds are produced at high speeds and low total heat input, thus duplicating the excellent weld properties and minimal heat effects obtained from electron beam welding in some applications. The application of lasers to metals—for cutting or welding—coupled with computerized control systems, allows their use for complex shapes and contours.

Solid-State Welding

Solid-state welding encompasses a group of processes in which the weld is effected by bringing clean metal surfaces into intimate contact under certain specific conditions. In **friction welding,** one part is rotated at high speed with respect to the other, under pressure. The parts are heated, but not to the melting point of the metal. Rotation is stopped at the critical moment of welding. Base metal properties across the joint show little change because the process is so rapid.

Friction stir welding (FSW) is a recently developed solid-state welding process that utilizes a cylindrical, shouldered tool that is mounted in a machine having the appearance of a vertical mill. The tool is rotated at a high speed and pressed into the joint (Fig. 13.3.12). Friction causes the material to heat and soften, but not melt. The plasticized material is moved from the leading edge of the tool to the trailing edge, leaving behind a solid-state bond. The low temperatures involved make FSW ideal for many aluminum alloys where arc welding processes result in softened regions adjacent to the weld.

Ultrasonic welding employs mechanical vibrations at ultrasonic frequencies plus pressure to effect the intimate contact between faying surfaces needed to produce a weld. (See also Sec. 12.) The welding tool is essentially a transducer that converts electric frequencies to ultra-high-frequency mechanical vibrations. By applying the tip of the tool, or anvil, to a small area in the external surface of two lapped parts, the vibrations and pressure are transmitted to the faying surfaces. Foils, thin-gage sheets, or fine wires can be spot- or seam-welded to each other or to heavier parts. Many plastics lend themselves to being joined by ultrasonic welding. Also see Secs. 6 and 12.

Explosion Welding

Explosion welding utilizes extremely high pressures to join metals, often with significantly different properties. For example, it may be used to clad a metal substrate, such as steel, with a protective layer of a dissimilar metal, such as aluminum. Since the materials do not melt, two metals with significantly different melting points can be successfully welded by explosion welding. The force and speed of the explosion are directed to cause a series of progressive shock waves that deform the faying surfaces at the moment of impact. A magnified section of the joint reveals a true weld with an interlocking waveshape and, usually, some alloying.

THERMAL CUTTING PROCESSES

Oxyfuel Cutting (OFC) Oxyfuel cutting (Fig. 13.3.13) is used to cut steels and to prepare bevel and vee grooves. In this process, the metal is heated to its ignition temperature, or kindling point, by a series of preheat flames. After this temperature is attained, a high-velocity stream of pure oxygen is introduced, which causes oxidation or "burning" to occur. The force of the oxygen steam blows the oxides out of the joint, resulting in a clean cut. The oxidation process also generates additional thermal energy, which is radially conducted into the surrounding steel, increasing the temperature of the steel ahead of the cut. The next portion of the steel is raised to the kindling temperature, and the cut proceeds.

Carbon and low-alloy steels are easily cut by the oxyfuel process. Alloy steels can be cut, but with greater difficulty than mild steel. The level of difficulty is a function of the alloy content. When the alloy content reaches the levels found in stainless steels, oxyfuel cutting cannot be used unless the process is modified by injecting flux or iron-rich powders into the oxygen stream. Aluminum cannot be cut with the oxyfuel

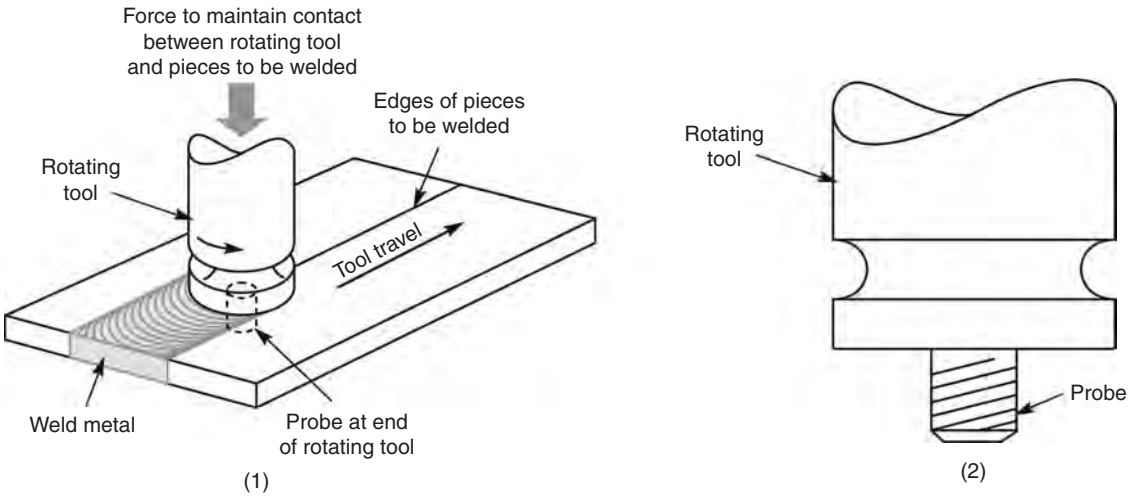

Fig. 13.3.12 (1) Schematic of friction stir welding; (2) detail of probe.

process. Oxyfuel cutting is commonly regarded as the most economical way to cut steel plates greater than ½ in thick.

A variety of **fuel gases** may be used for oxyfuel cutting, with the choice largely dependent on local economics; they include natural gas, propane, acetylene, and a variety of proprietary gases offering unique advantages. Because of its role in the primary cutting stream, oxygen is always used as a second gas. In addition, some oxygen is mixed with the fuel gas in proportions designed to ensure proper combustion.

Plasma Arc Cutting (PAC) The plasma arc cutting process (Fig. 13.3.14) was developed initially to cut materials that do not permit the use of the oxyfuel process: stainless steel and aluminum. It was found, however, that plasma arc cutting offered economic advantages when applied to thinner sections of mild steel, especially those less than 1 in thick. Higher travel speed is possible with plasma arc cutting, and the volume of heated base material is reduced, minimizing metallurgical changes as well as reducing distortion.

PAC is a thermal and mechanical process. To utilize PAC, the material is heated until molten and expelled from the cut with a high-velocity stream of compressed gas. Unlike oxyfuel cutting, the process does not rely on oxidation. Because high amounts of energy are introduced through the arc, PAC is capable of extremely high-speed cutting. The thermal energy generated during the oxidation process with oxyfuel cutting is not present in plasma; hence, for thicker sections, PAC is not economically justified. The use of PAC to cut thick sections usually is restricted to materials that do not oxidize readily with oxyfuel.

Air Arc Gouging (AAG) The air carbon arc gouging system (Fig. 13.3.15) utilizes an electric arc to melt the base material; a high-velocity jet of compressed air subsequently blows the molten material away. The air carbon gouging torch looks much like a manual electrode holder, but

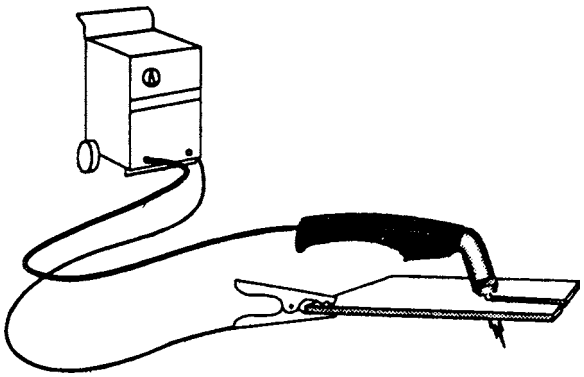

Fig. 13.3.14 Plasma arc cutting process.

it uses a carbon electrode instead of a metallic electrode. Current is conducted through the base material to heat it. A valve in the torch handle permits compressed air to flow through two air ports. As the air hits the molten material, a combination of oxidation and expulsion of metal takes place, leaving a smooth cavity behind. The air carbon arc gouging system is capable of removing metal at a much higher rate than can be deposited by most welding processes. It is a powerful tool used to remove metal at low cost.

Plasma Arc Gouging A newer development is the application of plasma arc equipment for gouging. The process is identical to plasma arc cutting, but the small-diameter orifice is replaced with a larger one,

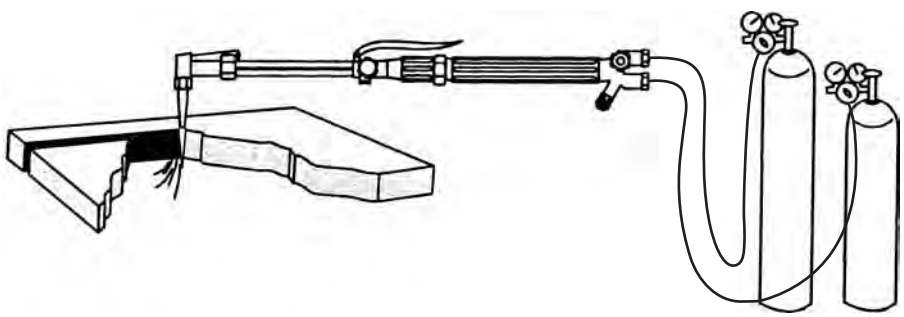

Fig. 13.3.13 Oxyfuel cutting.

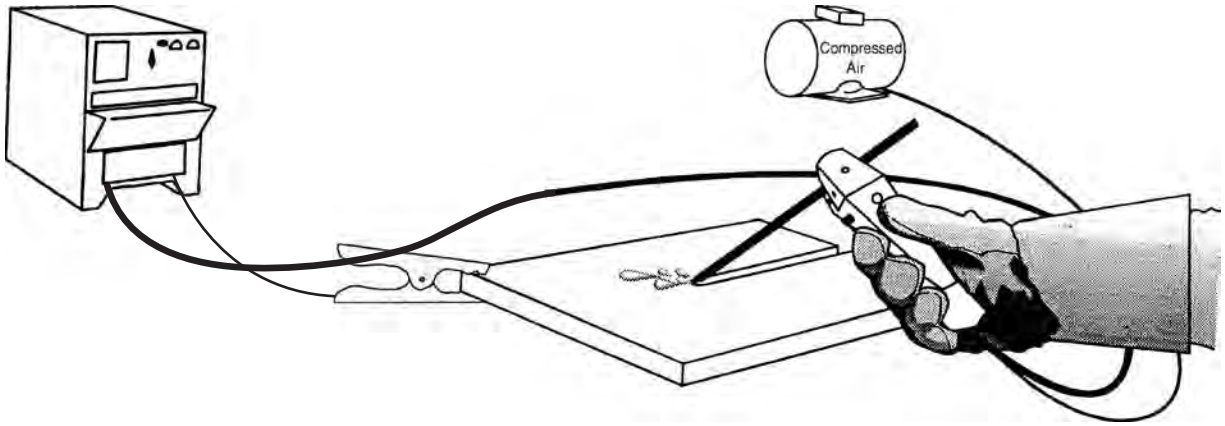

Fig. 13.3.15 Air arc gouging.

resulting in a broader arc. More metal is heated, and a larger, broader stream of hot, high-velocity plasma gas is directed toward the workpiece. When the torch is inclined to the work surface, the metal can be removed in a fashion similar to air carbon arc gouging. The applications of the process are similar to those of air carbon arc gouging.

DESIGN OF WELDED CONNECTIONS

A **welded connection** consists of two or more pieces of base metal joined by weld metal. Design engineers determine joint type and generally specify weld type and the required throat dimension. Fabricators select the specific joint details to be used.

Joint Types

When pieces of steel are brought together to form a **joint,** they will assume one of the five configurations presented in Fig. 13.3.16. Joint types are descriptions of the relative positions of the materials to be joined and do not imply a specific type of weld.

Weld Types

Welds fall into three categories: fillet welds, groove welds, and plug and slot welds (Fig. 13.3.17). Plug and slot welds are used for connections that transfer small loads.

Many engineers will see or have occasion to use standard welding symbols. A detailed discussion of their proper use is found in AWS documents. A few are shown in Fig. 13.3.18.

Fillet Welds Fillet welds have a triangular cross section and are applied to the surface of the materials they join. By themselves, fillet welds do not fully fuse the cross-sectional areas of parts they join, although it is still possible to develop full-strength connections with fillet welds. The size of a fillet weld is usually determined by measuring the leg, even though the weld is designed by specifying the required throat. For equal-legged, flat-faced fillet welds applied to plates that are oriented 90° apart, the throat dimension is found by multiplying the leg size by 0.707 (for example, sin 45°).

Groove Welds Groove welds comprise two subcategories: complete joint penetration (CJP) groove welds and partial joint penetration (PJP) groove welds (Fig. 13.3.19). By definition, CJP groove welds have a throat dimension equal to the thickness of the material they join; a PJP groove weld is one with a throat dimension less than the thickness of the materials joined.

An **effective throat** is associated with a PJP groove weld. This term is used to differentiate between the depth of groove preparation and the probable depth of fusion that will be achieved. The **effective throat** on a PJP groove weld is abbreviated by *E.* The required **depth of groove preparation** is designated by a capital *S.* Since the designer may not know which welding process a fabricator will select, it is necessary only to specify the dimension for *E.* The fabricator then selects the welding process, determines the position of welding, and applies the appropriate *S* dimension, which will be shown on the shop drawings. In most cases, both the *S* and *E* dimensions will appear on the welding symbols of shop drawings, with the effective throat dimension shown in parentheses.

Sizing of Welds

Overwelding is one of the major factors of welding cost. Specifying the correct size of weld is the first step in obtaining low-cost welding. It is important, then, to have a simple method to figure the proper amount of weld to provide adequate strength for all types of connections.

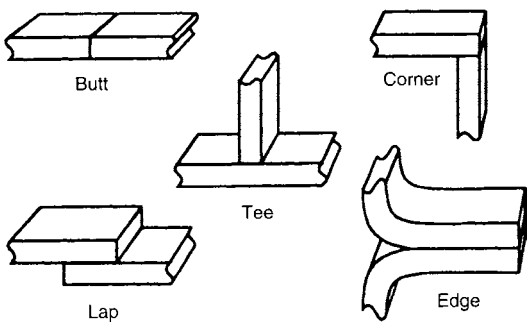

Fig. 13.3.16 Joint types.

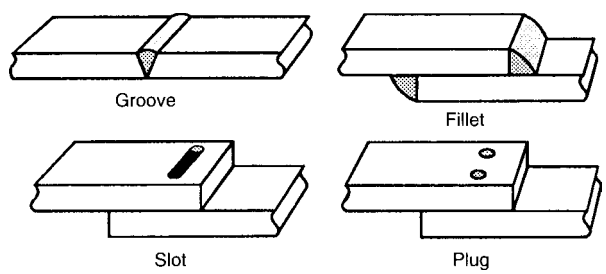

Fig. 13.3.17 Major weld types.

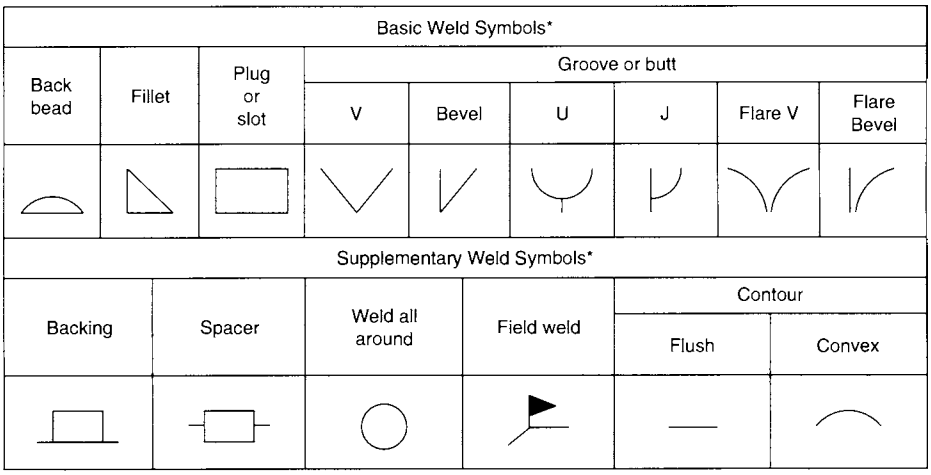

* See AWS publications for a complete listing.

Fig. 13.3.18 Some welding symbols commonly used. *(AWS.)*

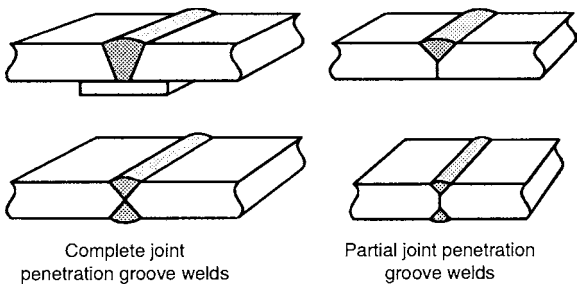

Fig. 13.3.19 Types of groove welds.

In terms of their application, welds fall into two general types: primary and secondary. **Primary welds** are critical welds that directly transfer the full applied load at the point at which they are located. These welds must develop the full strength of the members they join. Complete joint penetration groove welds are often used for these connections. **Secondary welds** are those that merely hold the parts together to form a built-up member. The forces on these welds are relatively low, and fillet welds are generally utilized in these connections.

Filler Metal Strength **Filler metal strength** may be classified as matching, undermatching, or overmatching. **Matching filler metal** has the same, or slightly higher, minimum specified yield and tensile strength as the base metal. CJP groove welds in tension require the use of matching weld metal—otherwise, the strength of the welded connection will be lower than that of the base metal. **Undermatching filler metal** deposits welds of a strength lower than that of the base metal. Undermatching filler metal may be deposited in fillet welds and PJP groove welds as long as the designer specifies a throat size that will compensate for the reduction in weld metal strength. An **overmatching filler metal** deposits weld metal that is stronger than the base metal; this is undesirable unless, for practical reasons, lower-strength filler metal is unavailable for the application. When overmatching filler metal is used, if the weld is stressed to its maximum allowable level, the base metal can be overstressed, resulting in failure in the fusion zone. Designers must ensure that connection strength, including the fusion zone, meets the application requirements.

In welding high-strength steel, it is generally desirable to utilize undermatching filler metal for secondary welds. High-strength steel may require additional preheat and greater care in welding because there is an increased tendency to crack, especially if the joint is restrained. Undermatching filler metals such as E70 are the easiest to use and are preferred, provided the weld is sized to impart sufficient strength to the joint.

Allowable Strength of Welds under Steady Loads A structure, or **weldment,** is as strong as its weakest point, and "allowable" weld strengths are specified by the American Welding Society (AWS), the American Institute of Steel Construction (AISC), and various other professional organizations to ensure that a weld will deliver the mechanical properties of the members being joined. Allowable weld strengths are designated for various types of welds for steady and fatigue loads.

CJP groove welds are considered **full-strength welds,** since they are capable of transferring the equivalent capacity of the members they join. In calculations, such welds are allowed the same stress as the plate, provided the proper strength level of weld metal is used (e.g., matching filler metal). In such CJP welds, the mechanical properties of the weld metal must at least match those of the base metal. If the plates joined are of different strengths, the weld metal strength must at least match the strength of the weaker plate.

Figure 13.3.20 illustrates representative applications of PJP groove welds widely used in the economical welding of very heavy plates. PJP groove welds in heavy material will usually result in savings in weld metal and welding time, while providing the required joint strength. The faster cooling and increased restraint, however, justify establishment of a minimum effective throat t_e (see Table 13.3.1).

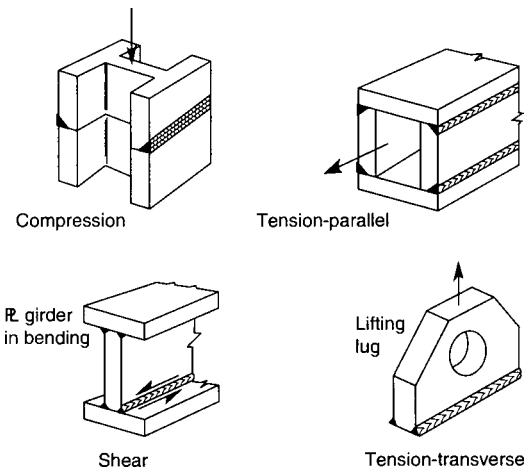

Fig. 13.3.20 Applications of partial joint penetration (PJP) groove welds.

Table 13.3.1 Minimum Fillet Weld Size ω or Minimum Throat of PJP Groove Weld t_e

Material thickness of thicker part joined, in	ω or t_e, in
*To ¼ incl.	⅛
Over ¼ to ½	3/16
Over ½ to ¾	¼
†Over ¾ to 1½	5/16
Over 1½ to 2¼	⅜
Over 2¼ to 6	½
Over 6	⅝

Not to exceed the thickness of the thinner part.
* Minimum size for bridge application does not go below 3/16 in.
† For minimum fillet weld size, table does not go above 5/16-in fillet weld for over ¾-in material.

Other factors must be considered in determining the allowable stress on the throat of a PJP groove weld. Joint configuration is one. If a V, J, or U groove is specified, it is assumed that the welder can easily reach the bottom of the joint, and the effective weld throat t_e equals the depth of the groove. If a bevel groove with an included angle of 45° or less is specified and SMAW is used, ⅛ in is deducted from the depth of the prepared groove in defining the effective throat. This does not apply to the SAW process because of its deeper penetration capabilities. In the case of GMAW or FCAW, the ⅛-in reduction in throat only applies to bevel grooves with an included angle of 45° or less in the vertical or overhead position.

Weld metal subjected to compression in any direction or to tension parallel to the axis of the weld should have the same allowable strength as the base metal. Matching weld metal must be used for compression, but is not necessary for tension parallel loading.

The existence of tension forces transverse to the axis of the weld or shear in any direction requires the use of weld metal allowable strengths that are the same as those used for fillet welds. The selected weld metal may have mechanical properties higher or lower than those of the metal being joined. If the weld metal has lower strength, however, its allowable strength must be used to calculate the weld size or maximum allowable weld stress. For higher-strength weld metal, the weld allowable strength may not exceed the shear allowable strength of the base metal.

The AWS has established the **allowable shear value** for weld metal in a fillet or PJP bevel groove weld as

$$\tau = 0.30 \times \text{electrode min. spec. tensile strength} = 0.30 \times \text{EXX}$$

and has proved it valid from a series of fillet weld tests conducted by a special Task Committee of AISC and AWS.

Table 13.3.2 lists the allowable shear values for various weld metal strength levels and the more common fillet weld sizes. These values are for equal-leg fillet welds where the effective throat t_e equals 0.707 × leg size ω. With the table, one can calculate the allowable unit force per lineal inch f for a weld size made with a particular electrode type. For example, the allowable unit force per lineal inch f for a ½-in fillet weld made with an E70 electrode is

$$f = 0.707\omega\tau = 0.707(\tfrac{1}{2}\text{ in})(0.30)(70\text{ ksi}) = 7.42\text{ kips/lin in}$$

The minimum allowable sizes for fillet welds are given in Table 13.3.1. When materials of different thickness are joined, the minimum fillet weld size is governed by the thicker material; but this size need not exceed the thickness of the thinner material unless it is required by the calculated stress.

Connections under Simple Loads For a **simple tensile, compressive, or shear load,** the imposed load is divided by weld length to obtain applied force, f, in pounds per lineal inch of weld. From this force, the proper leg size of the fillet weld or throat size of groove weld is found.

For **primary welds in butt joints,** groove welds must be made through the entire plate, in other words, **100 percent penetration.** Since a butt joint with a properly made CJP groove has a strength equal to or greater than that of the plate, there is no need to calculate the stress in the weld or to attempt to determine its size. It is necessary only to utilize matching filler metal.

With fillet welds, it is possible to have a weld that is either too large or too small; therefore, it is necessary to be able to determine the proper weld size.

Parallel fillet welds have forces applied parallel to their axis, and the throat is stressed only in shear. For an equal-legged fillet, the maximum shear stress occurs on the 45° throat.

Transverse fillet welds have forces applied transversely, or at right angles to their axis, and the throat is stressed by combined shear and normal (tensile or compressive) stresses. For an equal-legged fillet weld, the maximum shear stress occurs on the 67½° throat, and the maximum normal stress occurs on the 22½° throat.

Connections Subject to Horizontal Shear A weld joining the flange of a beam to its web is stressed in horizontal shear (Fig. 13.3.21). A designer may be accustomed to specifying a certain size fillet weld for a given plate thickness (e.g., leg size about three-fourths of the plate thickness) in order that the weld develop full plate strength. This

Table 13.3.2 Allowable Loads for Various Size Fillet Welds

	Strength level of weld metal (EXX)						
	60*	70*	80	90*	100	110*	120

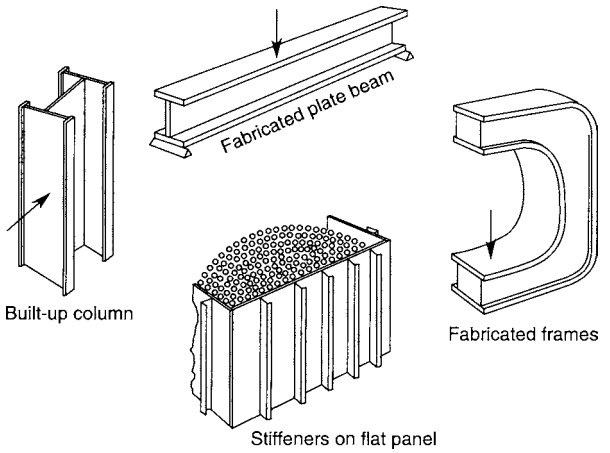

Fig. 13.3.21 Examples of welds stressed in horizontal shear.

particular joint between flange and web is an exception to this rule. In order to prevent web buckling, a lower allowable shear stress is usually used, which results in the requirement for a thicker web. The welds are in an area next to the flange where there is no buckling problem, and no reduction in allowable load is applied to them. From a design standpoint, these welds may be very small; their actual size sometimes is determined by the minimum size allowed by the thickness of the flange plate, in order to ensure the proper slow cooling rate of the weld on the heavier plate.

General Rules about Horizontal Shear Aside from joining the flanges and web of a beam, or transmitting any unusually high force between the flange and web at right angles to the assembly (e.g., bearing supports, lifting lugs), the weld between flange and web serves to transmit the horizontal shear forces; the weld size is determined by the magnitude of the shear forces. In the analysis of a beam, a shear diagram is useful to depict the amount and location of welding required between the flange and web (Fig. 13.3.22).

Figure 13.3.22 shows that (1) members with applied transverse loads are subject to bending moments; (2) changes in bending moments cause horizontal shear forces; and (3) horizontal shear forces require welds to transmit them between the flange and web of the beam.

NOTE: (1) Shear forces occur only when the bending moment is changing. (2) It is quite possible for portions of a beam to have little or no

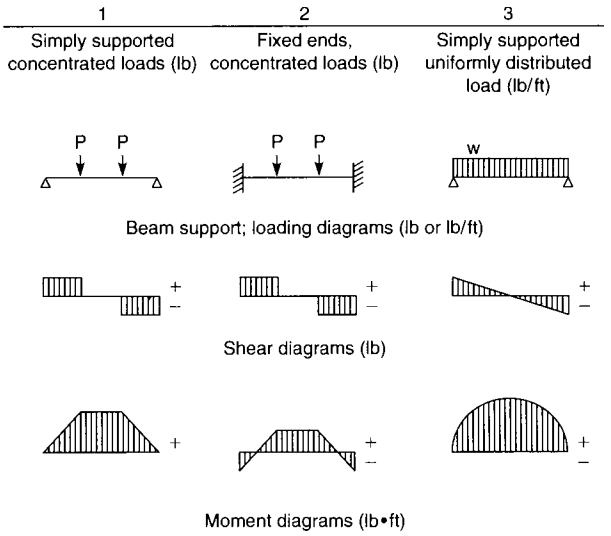

Fig. 13.3.22 Shear and moment diagrams.

shear—i.e., the middle portions of the beams 1 and 2, within which the bending moment is constant. (3) When there is a difference in shear along the length of the beam, the shear forces are usually greatest at the ends of the beam (see beam 3), so that when web stiffeners are used, they are welded continuously when placed at the ends and welded intermittently when placed elsewhere along the length of the beam. (4) Fixing beam ends will alter the moment diagram to reduce the maximum moment; i.e., the bending moment is lower in the middle, but is now introduced at the ends. For the uniform loading configuration in beam 3, irrespective of the end conditions and their effect on bending moments and their location, the shear diagram will remain unchanged, and the amount of welding between flange and web will remain the same.

Application of Rules to Find Weld Size Horizontal shear forces acting on the weld joining flange and web (Fig. 13.3.23) may be found from the following formula:

$$f = \frac{Vay}{In} \qquad \text{lb/lin in}$$

where f = force on weld, lb/lin in; V = total shear on section at a given position along beam, lb; a = area of flange held by weld, in^2; y = distance between center of gravity of flange area and neutral axis of whole section, in; I = moment of inertia of whole section, in^4; and n = number of welds joining flange to web.

Locate Welds at Point of Minimum Stress In Fig. 13.3.24*a*, shear force is high because the weld lies on the neutral axis of the section, where the horizontal shear force is maximum. In Fig. 3.3.24*b*, the shear force is resisted by the channel webs, not the welds. In this last case, the shear formula above does not enter into consideration; for the configuration in Fig. 13.3.24*b*, full-penetration welds are not required.

Determine Length and Spacing of Intermittent Welds If intermittent fillet welds are used, read the weld size as a decimal and divide this by the actual size used. Expressed as a percentage, this will give the

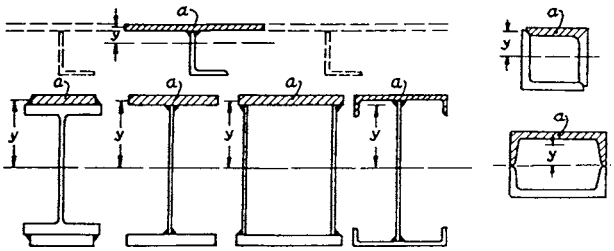

Fig. 13.3.23 Area of flange held by weld.

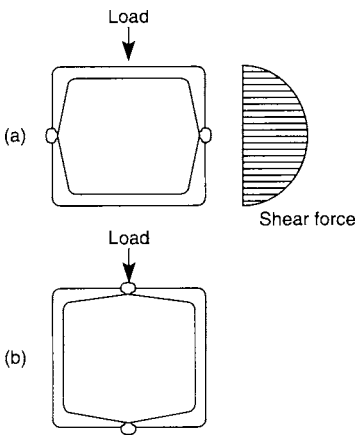

Fig. 13.3.24 Design options for placement of welds. (*a*) Welds at neutral axis; (*b*) welds at outer fibers.

length of weld to be used per unit length. For convenience, Table 13.3.3 lists various intermittent weld lengths and distances between centers for given percentages of continuous welds; or

$$\% = \frac{\text{calculated leg size (continuous)}}{\text{actual leg size used (intermittent)}}$$

Connections Subject to Bending or Twisting The problem here is to determine the properties of the welded connection in order to check the stress in the weld without first knowing its leg size. One approach suggests assuming a certain weld leg size and then calculating the stress in the weld to see if it is over- or understressed. If the result is too far off, the assumed weld leg size is adjusted, and the calculations repeated. This iterative method has the following disadvantages:

1. A decision must be made as to throat section size to be used to determine the property of the weld. Usually some objection can be raised to any throat section chosen.
2. The resulting stresses must be combined, and for several types of loading, this can become rather complicated.

Proposed Method The following is a simple method used to determine the correct amount of welding required to provide adequate strength for either a bending or a torsion load. In this method, the weld is treated as a line, having no area but having a definite length and cross section. This method offers the following advantages:

1. It is not necessary to consider throat areas.
2. Properties of the weld are easily found from a table without knowledge of weld leg size.
3. Forces are considered per unit length of weld, rather than converted to stresses. This facilitates dealing with combined-stress problems.
4. Actual values of welds are given as force per unit length of weld instead of unit stress on throat of weld.

Visualize the welded connection as a line (or lines), following the same outline as the connection but having no cross-sectional area. In Fig. 13.3.25, the desired area of the welded connection A_w can be represented by just the length of the weld. The stress on the weld cannot be determined unless the weld size is assumed; but by following the proposed procedure which treats the weld as a line, the solution is more direct, is much simpler, and becomes basically one of determining the force on the weld(s).

Use Standard Formulas to Find Force on Weld Treat the **weld as a line.** By inserting this property of the welded connection into the standard design formula used for a particular type of load (Table 13.3.4*a*), the unit force on the weld is found in terms of pounds per lineal inch of weld.

Normally, use of these standard design formulas results in a **unit stress,** lb/in^2, but with the weld treated as a line, these formulas result in a **unit force** on the weld, in lb/lin in.

For problems involving bending or twisting loads, Table 13.3.4*c* is used. It contains the section modulus S_w and polar moment of inertia J_w of some 13 typical welded connections with the weld treated as a line.

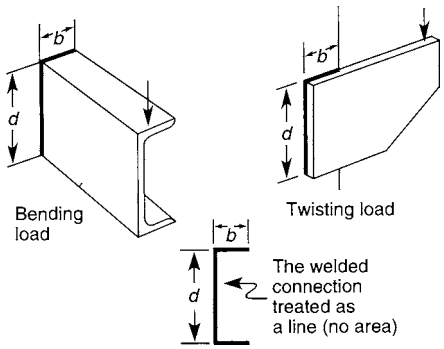

Fig. 13.3.25 Treating the weld as a line.

For any given connection, two dimensions are needed: width b and depth d. Section modulus S_w is used for welds subjected to bending; polar moment of inertia J_w for welds subjected to twisting. Section modulus S_w in Table 13.3.4*c* is shown for symmetric and unsymmetric connections. For unsymmetric connections, S_w values listed differentiate between top and bottom, and the forces derived therefrom are specific to location, depending on the value of S_w used.

When one is applying more than one load to a welded connection, they are combined vectorially, but must occur at the same location on the welded joint.

Use Allowable Strength of Weld to Find Weld Size Weld size is obtained by dividing the resulting unit force on the weld by the allowable strength of the particular type of weld used, obtained from Table 13.3.5 (steady loads) or Table 13.3.6 (fatigue loads). For a joint which has only a transverse load applied to the weld (either fillet or butt weld), the allowable transverse load may be used from the applicable table. If part of the load is applied parallel (even if there are transverse loads in addition), the allowable parallel load must be used.

Applying the System to Any Welded Connection

1. Find the position on the welded connection where the combination of forces will be maximum. There may be more than one which must be considered.
2. Find the value of each of the forces on the welded connection at this point. Use Table 13.3.4*a* for the standard design formula to find the force on the weld. Use Table 13.3.4*c* to find the property of the weld treated as a line.
3. Combine (vectorially) all the forces on the weld at this point.
4. Determine the required weld size by dividing this value (step 3) by the allowable force in Table 13.3.5 or 13.3.6.

Sample Calculations Using This System The example in Fig. 13.3.26 illustrates the application of this procedure.

Summary

The application of the following guidelines will ensure effective welded connections:

1. Properly select weld type.
2. Use CJP groove welds only where loading criteria mandate.
3. Consider the cost of joint preparation vs. welding time when you select groove weld details.
4. Double-sided joints reduce the amount of weld metal required. Verify welder access to both sides and that the double-sided welds will not require overhead welding.
5. Use intermittent fillet welds where continuous welds are not required.
6. On corner joints, prepare the thinner member.
7. Strive to obtain good fit-up and do not overweld.
8. Orient welds and joints to facilitate flat and horizontal welding wherever possible.
9. Use the minimum amount of filler metal possible in a given joint.
10. Always ensure adequate access for the welder, welding apparatus, and inspector.

Allowable Fatigue Strength of Welds

The performance of a weld under **cyclic stress** is an important consideration, and applicable specifications have been developed following extensive research by the American Institute of Steel Construction (AISC). Although sound weld metal has about the same fatigue strength as unwelded metal, the change in section induced by the weld may lower the fatigue strength of the welded joint. In the case of a CJP groove weld, reinforcement, any undercut, incomplete penetration, or a crack will act as a notch; the notch, in turn, is a **stress raiser** which results in reduced fatigue strength. A fillet weld used in lap or tee joints provides an abrupt change in section; that geometry introduces a stress raiser and results in reduced fatigue strength.

The initial AISC research was directed toward bridge structure components; Table 13.3.6 illustrates a few such combinations. Similar details arise with other classes of fabricated metal products subjected to repeated loading, such as presses, transportation equipment, and material handling devices. The principles underlying fatigue performance are relatively independent of a particular application, and the data shown can be applied to the design of weldments other than for bridge construction.

Table 13.3.6 is abstracted from an extensive tabulation in the AISC "Manual of Steel Construction," 9th ed. The table also lists the variation of allowable range of stress vs. number of stress cycles for cyclic loading. A detailed discussion of the solution of fatigue-loaded welded joints is beyond the scope of this section. The reader is referred to the basic reference cited above and to the references at the head of this section in pursuing the procedures recommended to solve problems involving welded assemblies subjected to fatigue loads.

Figure 13.3.27 is a **modified Goodman diagram** for a CJP groove butt weld with weld reinforcement left on. The category is C, and the life is 500,000 to 2 million cycles (see Table 13.3.6). The vertical axis shows maximum stress σ_{max}, and the horizontal axis shows minimum stress σ_{min}, either positive or negative. A steady load is represented by the 45° line to the right, and a complete reversal by the 45° line to the left. The region to the right of the vertical line ($K = 0$) represents tensile loading. The fatigue formulas apply to welded butt joints in plates or other

Table 13.3.4 Treating a Weld as a Line

Type of loading		Standard design formula	Treating the weld as a line
		Stress lb/in^2	Force, lb/in
Primary welds transmit entire load at this point			
	Tension or compression	$\sigma = \frac{P}{A}$	$f = \frac{P}{A_w}$
	Vertical shear	$\sigma = \frac{V}{A}$	$f = \frac{V}{A_w}$
	Bending	$\sigma = \frac{M}{S}$	$f = \frac{M}{S_w}$
	Twisting	$\sigma = \frac{TC}{J}$	$f = \frac{TC}{J_w}$
Secondary welds hold section together—low stress			
	Horizontal shear	$\tau = \frac{VA_y}{It}$	$f = \frac{VA_y}{In}$
	Torsion horizontal shear*	$\tau = \frac{T}{2At}$	$f = \frac{T}{2A}$

A = area contained within median line.
* Applies to closed tubular section only.

Table 13.3.5*a* Allowable Stresses on Weld Metal

Type of weld stress	Permissible stress*	Required strength level†‡
	Complete penetration groove welds	
Tension normal to effective throat	Same as base metal	Matching weld metal must be used. See table below.
Compression normal to effective throat	Same as base metal	Weld metal with a strength level equal to or one classification (10 ksi) less than matching weld metal may be used.
Tension or compression parallel to axis of weld	Same as base metal	Weld metal with a strength level equal to or less than matching weld metal may be used.
Shear on effective throat	0.30 × nominal tensile strength of weld metal (ksi) except stress on base metal shall not exceed 0.40 × yield stress of base metal	
	Partial penetration groove welds	
Compression normal to effective throat	Designed not to bear—0.50 × nominal tensile strength of weld metal (ksi) except stress on base metal shall not exceed 0.60 × yield stress of base metal Designed to bear. Same as base metal	Weld metal with a strength level equal to or less than matching weld metal may be used.
Tension or compression parallel to axis of weld§	Same as base metal	
Shear parallel to axis of weld	0.30 × nominal tensile strength of weld metal (ksi) except stress on base metal shall not exceed 0.40 × yield stress of base metal	
Tension normal to effective throat¶	0.30 × nominal tensile strength of weld metal (ksi) except stress on base metal shall not exceed 0.60 × yield stress of base metal	
	Fillet welds§	
Stress on effective throat, regardless of direction of application of load	0.30 × nominal tensile strength of weld metal (ksi) except stress on base metal shall not exceed 0.40 × yield stress of base metal	Weld metal with a strength level equal to or less than matching weld metal may be used
Tension or compression parallel to axis of weld	Same as base metal	
	Plug and slot welds	
Shear parallel to faying surfaces	0.30 × nominal tensile strength of weld metal (ksi) except stress on base metal shall not exceed 0.40 × yield stress of base metal	Weld metal with a strength level equal to or less than matching weld metal may be used

* For matching weld metal, see AISC Table 1.17.2 or AWS Table 4.1.1 or table below.
† Weld metal, one strength level (10 ksi) stronger than matching weld metal may be used when using alloy weld metal on A242 or A588 steel to match corrosion resistance or coloring characteristics (Note 3 of Table 4.1.4 or AWS D1.1).
‡ Fillet welds and partial penetration groove welds joining the component elements of built-up members (ex. flange to web welds) may be designed without regard to the axial tensile or compressive stress applied to them.
§ Cannot be used in tension normal to their axis under fatigue loading (AWS 2.5). AWS Bridge prohibits their use on any butt joint (9.12.1.1), or any splice in a tension or compression member (9.17), or splice in beams or girders (9.21), however, are allowed on corner joints parallel to axial force of components of built-up members (9.12.1.2 (2). Cannot be used in girder splices (AISC 1.10.8).

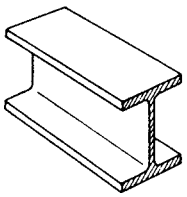
joined members. The region to the left of this line represents cycles going into compressive loading.

The fatigue formulas are meant to reduce the allowable stress as cyclic loads are encountered. The resulting allowable fatigue stress should not exceed the usual steady load allowable stress. For this reason, these fatigue curves are cut off with horizontal lines representing the steady load allowable stress for the particular type of steel used. In Fig. 13.3.27, A36 steel with E60 or E70 weld metal is cut off at 22 ksi; A441 steel with E70 weld metal at 30 ksi; and A514 with E110 weld metal at either 54 or 60 ksi, depending on plate thickness.

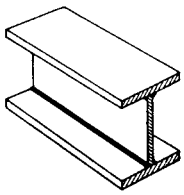
Figure 13.3.28 is a modification of Fig. 13.3.27, where the horizontal axis represents the range K of the cyclic stress. Here, two additional

Table 13.3.6 AISC Fatigue Allowable Stresses for Cyclic Loading



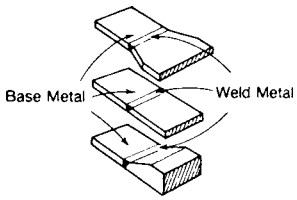
Base metal–no attachments–rolled or clean surfaces

(A)



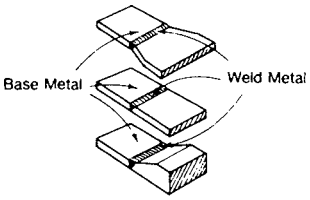
Base metal–built-up plates or shapes–connected by continuous complete penetration groove welds or fillet welds–without attachments. Note: don't use this as a fatigue allowable for the fillet weld to transfer a load. See (F) for that case.

(B)



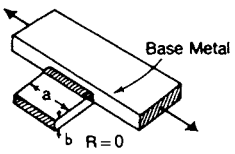
Base metal and weld metal at full penetration groove welds–changes thickness or width not to exceed a slope of 1 in 2½ (22°). Ground flush and inspected by radiography or ultrasound (B).

For 514 steel (B′)



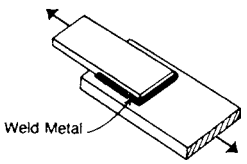
Base metal and weld metal at full penetration groove welds–changes in thickness or width not to exceed a slope of 1 in 2½ (22°). Weld reinforcement not removed inspected by radiography or ultrasound.

(C)



Longitudinal loading
Base metal–full penetration groove weld
Weld termination ground smooth
Weld reinforcement not removed
Not necessarily equal thickness

$2 < a < 12b$ or 4 in (D)
$a > 12b$ or 4 in when $b \pm 1$ in (E)
$a > 12b$ or 4 in when $b > 1$ in (E′)



Weld metal of continuous or intermittent longitudinal or transverse fillet welds

	Allowable Stress Range, σ_{sr} ksi			
Category	20,000 to 100,000 ~	100,000 to 500,000 ~	500,000 to 2×10^6 ~	Over 2×10^6 ~
A	63	37	24	24
B	49	29	18	16
B′	39	23	15	12
C	35	21	13	10 (Note 1)
D	28	16	10	7
E	22	13	8	5
E′	16	9	6	3
F	15	12	9	8

NOTE 1: Flexural stress range of 12 ksi permitted at toe of stiffener welds on flanges.

Allowable fatigue stress:

$$\sigma_{max} = \frac{\sigma_{sr}}{1 - K} \quad \text{for normal stress } \sigma \qquad \tau_{max} = \frac{\tau_{sr}}{1 - K} \quad \text{for shear stress } \tau$$

but shall not exceed steady allowables

σ_{max} or τ_{max} = maximum allowable fatigue stress
σ_{sr} or τ_{sr} = allowable range of stress from table above

$$K = \frac{\sigma_{min}}{\sigma_{max}} = \frac{M_{min}}{M_{max}} = \frac{F_{min}}{F_{max}} = \frac{\tau_{min}}{\tau_{max}} = \frac{V_{min}}{V_{max}}$$

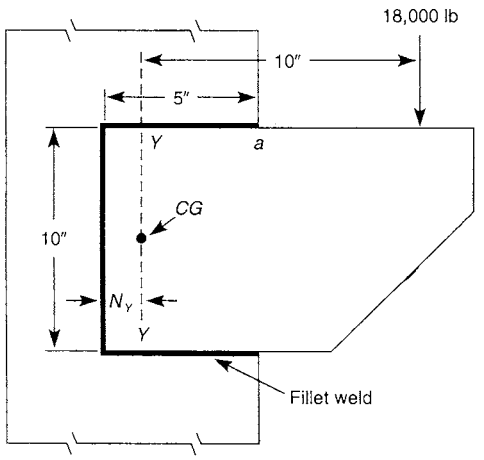
where S = shear, T = tension, R = reversal, M = stress in metal, and W = stress in weld.

SOURCE: Abstracted from AISC "Manual of Steel Construction," 9th ed., by permission.

strength levels of weld metal have been added—E80 and E90—along with equivalent strength levels of steel. Note that for a small range in stress of $K = 0.6$ to 1.0, higher-strength welds and steels show increased allowable fatigue stress. However, as the stress range increases—lower values of K—the increase is not as great, and below $K = +0.35$ all combinations of weld and steel strengths exhibit the same allowable fatigue stress.

Figure 13.3.29 represents the same welded joint as in Fig. 13.3.28, but with a lower life of 20,000 to 100,000 cycles. Here, the higher-strength welds and steels have higher allowable fatigue stresses and over a wider range. A conclusion can be drawn that the wider the range of cycling, the less useful the application of a high-strength steel. When there is a complete stress reversal, there is not much advantage in using a high-strength steel.

Step 1



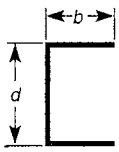
Combined forces are maximum at point a

Step 2 (Table 13.3.4a)

Twisting (horizontal component)

$$f_h = \frac{T\,C_h}{J_w} = \frac{(180{,}000)(5)}{(385.9)} = 2340 \text{ lb/in}$$

Properties of weld treated as a line (Table 13.3.4c)



$$N_Y = \frac{b^2}{2b + d} = \frac{5^2}{2 \times 5 + 10} = 1.25 \text{ in}$$

Twisting (vertical component)

$$f_v = \frac{T\,C_v}{J_w} = \frac{(180{,}000)(3.75)}{(385.9)} = 1750 \text{ lb/in}$$

Vertical shear

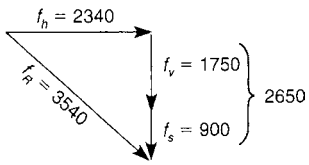
$$f_s = \frac{P}{A_w} = \frac{18{,}000}{20} = 900 \text{ lb/in}$$

$$J_w = \frac{(2b + d)^3}{12} - \frac{b^2(b + d)^2}{(2b + d)} = \frac{(2 \times 5 + 10)^3}{12} - \frac{5^2(5 + 10)^2}{(2 \times 5 + 10)} = 385.9 \text{ in}^3$$

$A_w = 20$ in

Step 3

$$f_R = \sqrt{f_v^2 + f_h^2} = \sqrt{.2340^2 + 2650^2} = 3540 \text{ lb/in}$$



Step 4 (Assume E60 electrodes; Table 13.3.2)

$$\omega = \frac{3540}{12{,}730} = 0.278 \text{ in or } \tfrac{5}{16} \text{ in leg fillet weld}$$

BASE METALS FOR WELDING

Introduction

When one is considering welding them, the nature of the base metals must be understood and recognized, i.e., their chemical composition, mechanical properties, and metallurgical structure. Cognizance of the mechanical properties of the base metal will guide the designer to ensure that the weld metal deposited will have properties equal to those of the base metal; knowledge of the chemical composition of the base metal will affect the selection of the filler metal and/or electrode; finally, the metallurgical structure of the base metal as it comes to the welding operation (hot-worked, cold-worked, quenched, tempered, annealed, etc.) will affect the weldability of the metal and, if it is weldable, the degree to which the final properties are as dictated by design requirements.

Welding specifications may address these matters, and base metal suppliers can provide additional data as to the weldability of the metal.

In some cases, the identity of the base metal is absolutely not known. To proceed to weld such metal may prove disastrous. Identification may be aided by some general characteristics which may be self-evident: carbon steel (oxide coating) vs. stainless steel (unoxidized); brush-finished aluminum (lightweight) vs. brush-finished Monel metal (heavy); etc. Ultimately, it may become necessary to subject the unknown metal to chemical, mechanical, and other types of laboratory tests to ascertain its exact nature.

Steel

Low-Carbon Steels (Carbon up to 0.30 percent) Steels in this class are readily welded by most arc and gas processes. Preheating is unnecessary unless parts are very heavy or welding is performed below 32°F (0°C). Torch-heating steel in the vicinity of welding to 70°F (21°C) offsets low temperatures. Postheating is necessary only for important structures such as boilers, pressure vessels, and piping. GTAW is usable only on killed steels; rimmed steels produce porous, weak welds. Resistance welding is readily accomplished if carbon is below 0.20 percent; higher carbon requires heat-treatment to slow the cooling rate and avoid hardness. Brazing with BAg, BCu, and BCuZn filler metals is very successful.

Medium-Carbon Steels (Carbon from 0.30 to 0.45 percent) This class of steel may be welded by the arc, resistance, and gas processes. As the rapid cooling of the metal in the welded zone produces a harder structure, it is desirable to hold the carbon as near 0.30 percent as possible. These hard areas are proportionately more brittle and difficult to machine. The cooling rate may be diminished and hardness decreased by preheating the metal to be welded above 300°F (149°C) and preferably to 500°F (260°C). The degree of preheating depends on the thickness of the section. Subsequent heating of the welded zone to 1,100 to 1,200°F (593 to 649°C) will restore ductility and relieve thermal strains. Brazing may also be used, as noted for low-carbon steels above.

High-Carbon Steels (Carbon from 0.45 to 0.80 percent) These steels are rarely welded except in special cases. The tendency for the metal heated above the critical range to become brittle is more pronounced than with lower- or medium-carbon steels. Thorough preheating of metal, in and near the welded zone, to a minimum of 500°F is essential. Subsequent annealing at 1,350 to 1,450°F (732 to 788°C) is also desirable. Brazing is often used with these steels, and is combined with the heat treatment cycle.

Low-Alloy Steels The weldability of low-alloy steels is dependent upon the analysis and the hardenability, those exhibiting low hardenability being welded with relative ease, whereas those of high hardenability requiring preheating and postheating. Sections of ¼ in (6.4 mm) or less may be welded with mild-steel filler metal and may provide joint strength approximating base metal strength by virtue of alloy pickup in the weld metal and weld reinforcement. Higher-strength alloys require filler metals with mechanical properties matching the base metal. Special alloys with creep-resistant or corrosion-resistant properties must be welded with filler metals of the same chemical analysis. Low-hydrogen-type electrodes (either mild- or alloy-steel analyses) permit the welding of alloy steels, minimizing the occurrence of underhead cracking.

Stainless Steel

Stainless steel is an iron-base alloy containing upward of 11 percent chromium. A thin, dense surface film of chromium oxide which forms on stainless steel imparts superior corrosion resistance; its passivated nature inhibits scaling and prevents further oxidation, hence the appellation "stainless." (See Sec. 6.2.)

There are five types of stainless steels, and depending on the amount and kind of alloying additions present, they range from fully austenitic to fully ferritic. Most stainless steels have good weldability and may be welded by many processes, including arc welding, resistance welding, electron and laser beam welding, and brazing. With any of these, the joint surfaces and any filler metal must be clean.

The coefficient of thermal expansion for the austenitic stainless steels is 50 percent greater than that of carbon steel; this must be taken into account to minimize distortion. The low thermal and electrical conductivity of austenitic stainless steel is generally helpful. Low welding heat is required because the heat is conducted more slowly from the joint, but low thermal conductivity results in a steeper thermal gradient and increases distortion. In resistance welding, lower current is used because electric resistivity is higher.

Ferritic Stainless Steels Ferritic stainless steels contain 11.5 to 30 percent Cr, up to 0.20 percent C, and small amounts of ferrite stabilizers, such as Al, Nb, Ti, and Mo. They are ferritic at all temperatures, do not transform to austenite, and are not hardenable by heat treatment. This group includes types 405, 409, 430, 442, and 446. To weld ferritic stainless steels, filler metals should match or exceed the Cr level of the base metal.

Martensitic Stainless Steels Martensitic stainless steels contain 11.4 to 18 percent Cr, up to 1.2 percent C, and small amounts of Mn and Ni. They will transform to austenite on heating and, therefore, can be hardened by formation of martensite on cooling. This group includes types 403, 410, 414, 416, 420, 422, 431, and 440. Weld cracks may appear on cooled welds as a result of martensite formation. The Cr and C content of the filler metal should generally match these elements in the base metal. Preheating and interpass temperature in the 400 to 600°F range is recommended for welding most martensitic stainless steels. Steels with over 0.20 percent C often require a postweld heat treatment to avoid weld cracking.

Austenitic Stainless Steels Austenitic stainless steels contain 16 to 26 percent Cr, 10 to 24 percent Ni and Mn, up to 0.40 percent C, and small amounts of Mo, Ti, Nb, and Ta. The balance between Cr and Ni + Mn is normally adjusted to provide a microstructure of 90 to 100 percent austenite. These alloys have good strength and high toughness over a wide temperature range, and they resist oxidation to over 1,000°F. This group includes types 302, 304, 310, 316, 321, and 347. Filler metals for these alloys should generally match the base metal, but for most alloys should also provide a microstructure with some ferrite to avoid hot cracking. Two problems are associated with welding austenitic stainless steels: sensitization of the weld-heat-affected zone and hot cracking of weld metal.

Sensitization is caused by chromium carbide precipitation at the austenitic grain boundaries in the heat-affected zone when the base metal is heated to 800 to 1,600°F. Chromium carbide precipitates remove chromium from solution in the vicinity of the grain boundaries, and this condition leads to intergranular corrosion. The problem can be alleviated by using low-carbon stainless-steel base metal (types 302L, 316L, etc.) and low-carbon filler metal. Alternately, there are **stabilized stainless-steel** base metals and filler metals available which contain alloying elements that react preferentially with carbon, thereby not depleting the chromium content in solid solution and keeping it available for corrosion resistance. Type 321 contains titanium and type 347 contains niobium and tantalum, all of which are stronger carbide formers than chromium.

Hot cracking is caused by low-melting-point metallic compounds of sulfur and phosphorus which penetrate grain boundaries. When present in the weld metal or heat-affected zone, they will penetrate grain boundaries and cause cracks to appear as the weld cools and shrinkage stresses develop. Hot cracking can be prevented by adjusting the composition of the base metal and filler metal to obtain a microstructure with a small amount of ferrite in the austenite matrix. The ferrite provides ferrite-austenite boundaries which control the sulfur and phosphorus compounds and thereby prevent hot cracking.

Precipitation-Hardening Stainless Steels Precipitation-hardening (PH) stainless steels contain alloying elements such as aluminum which permit hardening by a solution and aging heat treatment. There are three categories of PH stainless steels: martensitic, semiaustenitic, and austenitic. Martensitic PH stainless steels are hardened by quenching from the austenitizing temperature (around 1,900°F) and then aging between 900 and 1,150°F. Semiaustenitic PH stainless steels do not transform to martensite when cooled from the austenitizing temperature because the martensite transformation temperature is below room temperature. Austenitic PH stainless steels remain austenitic after quenching from the solution temperature, even after substantial amounts of cold work.

If maximum strength is required of martensitic PH and semiaustenitic PH stainless steels, matching, or nearly matching, filler metal should be used, and before welding, the work pieces should be in the annealed or solution-annealed condition. After welding, a complete solution heat treatment plus an aging treatment is preferred. If postweld solution treatment is not feasible, the components should be solution-treated before welding and then aged after welding. Thick sections of highly restrained parts are sometimes welded in the overaged condition. These require a full heat treatment after welding to attain maximum strength properties.

Austenitic PH stainless steels are the most difficult to weld because of hot cracking. Welding is preferably done with the parts in solution-treated condition, under minimum restraint and with minimum heat input. Filler metals of the Ni-Cr-Fe type, or of conventional austenitic stainless steel, are preferred.

Duplex Stainless Steels Duplex stainless steels are the most recently developed type of stainless steel, and they have a microstructure of approximately equal amounts of ferrite and austenite. They have advantages over conventional austenitic and ferritic stainless steels in that they possess higher yield strength and greater stress corrosion cracking resistance. The duplex microstructure is attained in steels containing 21 to 25 percent Cr and 5 to 7 percent Ni by hot-working at 1,832 to 1,922°F, followed by water quenching. Weld metal of this composition will be mainly ferritic because the deposit will solidify as ferrite and will transform only partly to austenite without hot working or annealing. Since hot-working or annealing most weld deposits is not feasible, the metal composition filler is generally modified by adding Ni (to 8 to 10 percent); this results in increased amounts of austenite in the as-welded microstructure.

Cast Iron

Even though cast iron has a high carbon content and is a relatively brittle and rigid material, welding can be performed successfully if proper precautions are taken. Optimum conditions for welding include the following: (1) A weld groove large enough to permit manipulation of the electrode or the welding torch and rod. The groove must be clean and free of oil, grease, and any foreign material. (2) Adequate preheat, depending on the welding process used, the type of cast iron, and the size and shape of the casting. Preheat temperature must be maintained throughout the welding operation. (3) Welding heat input sufficient for a good weld but not enough to superheat the weld metal; i.e., welding temperature should be kept as low as practicable. (4) Slow cooling after welding. Gray iron may be enclosed in insulation, lime, or vermiculite. Other irons may require postheat treatment immediately after welding to restore mechanical properties. ESt and ENiFe identify electrodes of steel and of a nickel-iron alloy. Many different welding processes have been used to weld cast iron, the most common being manual shielded metal-arc welding, gas welding, and braze welding.

Aluminum and Aluminum Alloys

(See Sec. 6.4.)

The **properties** that distinguish the **aluminum alloys** from other metals determine which welding processes can be used and which particular procedures must be followed for best results. Among the welding processes that can be used, choice is further dictated by the requirements of the end product and by economic considerations.

Physical properties of aluminum alloys that most significantly affect all welding procedures include low-melting-point range, approx 900 to 1,215°F (482 to 657°C), high thermal conductivity (about two to four times that of mild steel), high rate of thermal expansion (about twice that of mild steel), and high electrical conductivity (about 3 to 5 times that of mild steel). Interpreted in terms of welding, this means that, when compared with mild steel, much higher welding speeds are demanded, greater care must be exercised to avoid distortion, and for arc and resistance welding, much higher current densities are required.

Aluminum alloys are not quench-hardenable. However, weld cracking may result from excessive shrinkage stresses due to the high rate of thermal contraction. To offset this tendency, welding procedures, where possible, require a fast weld cycle and a narrow-weld zone, e.g., a highly concentrated heat source with deep penetration, moving at a high rate of speed. Shrinkage stresses can also be reduced by using a filler metal of lower melting point than the base metal. The filler metal ER4043 is often used for this purpose.

Welding procedures also call for the removal of the thin, tough, transparent film of aluminum oxide that forms on and protects the surface of these alloys. The oxide has a melting point of about 3,700°F (2,038°C) and can therefore exist as a solid in the molten weld. Removal may be by chemical reduction or by mechanical means such as machining, filing, rubbing with steel wool, or brushing with a stainless-steel wire brush. Most aluminum is welded with GTAW or GMAW. GTAW usually uses alternating current, with argon as the shielding gas. The power supply must deliver high current with balanced wave characteristics, or deliver high-frequency current. With helium, weld penetration is deeper, and higher welding speeds are possible. Most welding, however, is done using argon because it allows for better control and permits the welder to see the weld pool more easily.

GMAW employs direct current, electrode positive in a shielding gas that may be argon, helium, or a mixture of the two. In this process, the welding arc is formed by the filler metal, which serves as the electrode. Since the filler metal is fed from a coil as it melts in the arc, some arc instability may arise. For this reason, the process does not have the same precision as the GTAW process for welding very thin gages. However, it is more economical for welding thicker sections because of its higher deposition rates.

Copper and Copper Alloys

In welding **commercially pure copper,** it is important to select the correct type. Electrolytic, or "tough-pitch," copper contains a small percentage of copper oxide, which at welding heat leads to oxide embrittlement. For welded assemblies it is recommended that deoxidized, or oxygen-free, copper be used and that welding rods, when needed, be of the same analysis. The preferred processes for welding copper are GTAW and GMAW; manual SMAW can also be used. It is also welded by oxy-acetylene method and braze-welded; brazing with brazing filler metals conforming to BAg, BCuP, and RBCuZn-A classifications is also employed. The high heat conductivity of copper requires special consideration in welding; generally higher welding heats are necessary together with concurrent supplementary heating. (See also Sec. 6.4.)

Copper alloys are extensively welded in industry. The specific procedures employed are dependent upon the analysis, and reference should be made to the AWS Welding Handbook. Filler metals for welding copper and its alloys are covered in AWS specifications.

SAFETY

Welding is safe when sufficient measures are taken to protect the welder from potential hazards. When these measures are overlooked or ignored, welders can be subject to electric shock; overexposure to radiation, fumes, and gases; and fires and explosion. Any of these can be fatal. Everyone associated with welding operations should be aware of the potential hazards and help ensure that safe practices are employed. Infractions must be reported to the appropriate responsible authority.

ANSI Z49.1:2005, "Safety in Welding, Cutting, and Allied Process," available as a free download from AWS (http://www.aws.org/technical/facts), should be consulted for information on welding safety. A printed copy is also available for purchase from Global Engineering Documents (www.global.ihs.com, telephone 1-800-854-7179). From the same website, a variety of AWS Safety & Health Fact Sheets also can be downloaded.

NOTE: Oxygen is incorrectly called **air** in some fabricating shops. Air from the atmosphere contains only 21 percent oxygen and obviously is different from the 100 percent pure oxygen used for cutting. The unintentional confusion of oxygen with air has resulted in fatal accidents. When compressed oxygen is inadvertently used to power air tools, e.g., an explosion can result. While most people recognize that fuel gases are dangerous, the case can be made that oxygen requires even more careful handling.

Information about welding safety is available from American Welding Society, P.O. Box 351040, Miami, FL 33135.

13.4 MACHINING PROCESSES AND MACHINE TOOLS

INTRODUCTION

Machining processes, which include cutting, grinding, and various nonmechanical chipless processes, are desirable or even necessary for the following basic reasons: (1) Closer dimensional tolerances, surface roughness, or surface-finish characteristics may be required than are available by casting, forming, powder metallurgy, and other shaping processes; and (2) part geometries may be too complex or too expensive to be manufactured by other processes. However, machining processes inevitably waste material in the form of chips, production rates may be low, and unless carried out properly, the processes can have detrimental effects on the surface properties and performance of parts.

Traditional machining processes consist of turning, boring, drilling, reaming, threading, milling, shaping, planing, and broaching, as well as abrasive processes such as grinding, ultrasonic machining, lapping, and honing. Advanced processes include electrical and chemical means of material removal, as well as the use of abrasive jets, water jets, laser beams, and electron beams. This section describes the principles of these operations, the processing parameters involved, and the characteristics of the machine tools employed.

BASIC MECHANICS OF METAL CUTTING

The basic mechanics of chip-type machining processes (Fig. 13.4.1) are shown, in simplest two-dimensional form, in Fig. 13.4.2. A tool with a certain **rake angle** α (positive as shown) and **relief angle** moves along the surface of the workpiece at a depth t_1. The material ahead of the tool is sheared continuously along the **shear plane,** which makes an angle of ϕ with the surface of the workpiece. This angle is called the **shear angle** and, together with the rake angle, determines the chip thickness t_2. The ratio of t_1 to t_2 is called the **cutting ratio** r. The relationship between the shear angle, the rake angle, and the cutting ratio is given by the equation $\tan \phi = r \cos \alpha/(1 - r \sin \alpha)$. It can readily be seen that the shear angle is important in that it controls the thickness of the chip. This, in turn, has great influence on cutting performance. The **shear strain** that the material undergoes is given by the equation $\gamma = \cot \phi + \tan (\phi - \alpha)$. Shear strains in metal cutting are usually less than 5.

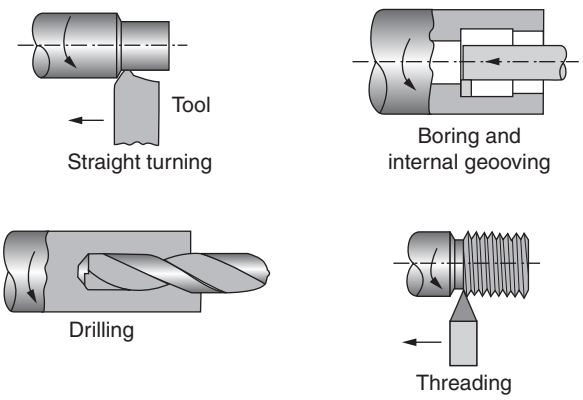

Fig. 13.4.1 Examples of chip-type machining operations.

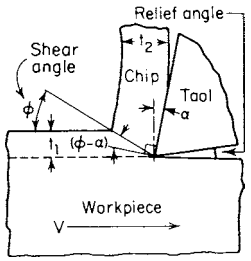

Fig. 13.4.2 Basic mechanics of metal cutting process.

Investigations have shown that the shear plane may be neither a plane nor a narrow zone, as assumed in simple analysis. Various formulas have been developed which define the shear angle in terms of such factors as the rake angle and the friction angle β. (See Fig. 13.4.3.)

Because of the large shear strains that the chip undergoes, it becomes hard and brittle. In most cases, the chip curls away from the tool. Among possible factors contributing to chip curl are nonuniform normal stress distribution on the shear plane, strain hardening, and thermal effects.

Regardless of the type of machining operation, some basic types of chips or combinations of these are found in practice (Fig. 13.4.4).

Continuous chips are formed by continuous deformation of the workpiece material ahead of the tool, followed by smooth flow of the chip along the tool face. These chips ordinarily are obtained in cutting ductile materials at high speeds.

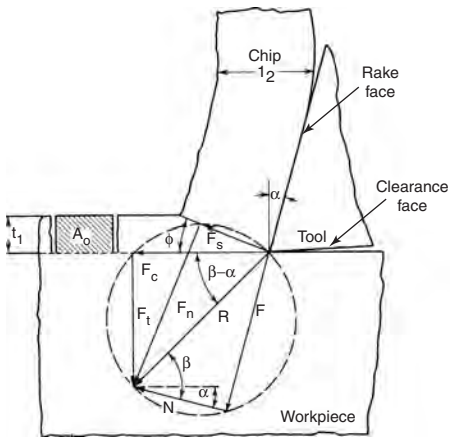

Fig. 13.4.3 Force system in metal cutting process.

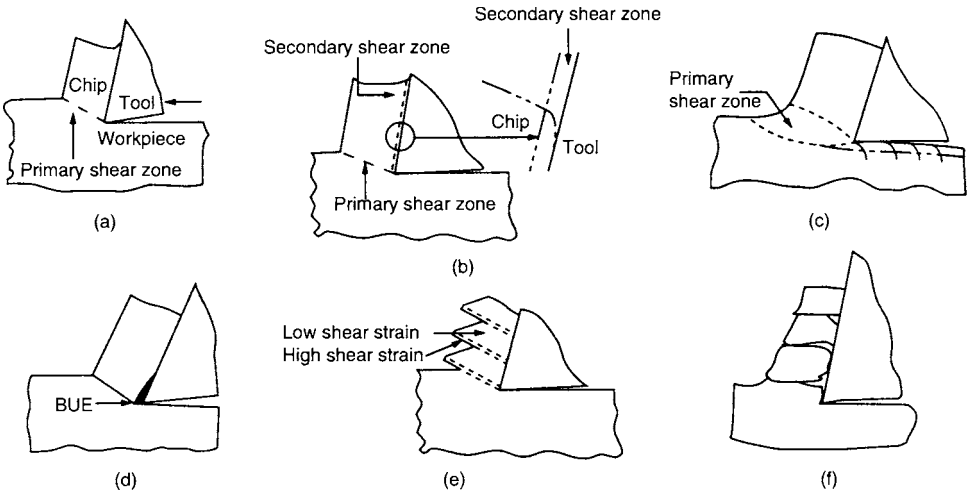

Fig. 13.4.4 Basic types of chips produced in metal cutting: (*a*) continuous chip with narrow, straight primary shear zone; (*b*) secondary shear zone at the tool-chip interface; (*c*) continuous chip with large primary shear zone; (*d*) continuous chip with built-up edge; (*e*) segmented or nonhomogeneous chip, (*f*) discontinuous chip. *(Source: After M. C. Shaw.)*

Discontinuous chips consist of segments which are produced by fracture of the metal ahead of the tool. The segments may be either loosely connected to each other or unconnected. Such chips are most often found in the machining of brittle materials or in cutting ductile materials at very low speeds or low or negative rake angles.

Inhomogeneous (serrated) chips consist of regions of large and small strain. Such chips are characteristic of metals with low thermal conductivity or metals whose yield strength decreases sharply with temperature. Chips from titanium alloys frequently are of this type.

Built-up edge chips consist of a mass of metal which adheres to the tool tip while the chip itself flows continuously along the rake face. This type of chip is often encountered in machining operations at low speeds and is associated with high adhesion between chip and tool and causes poor surface finish.

The **forces** acting on the cutting tool are shown in Fig. 13.4.3. The resultant force R has two components, F_c and F_t. The cutting force F_c in the direction of tool travel determines the amount of work done in cutting. The thrust force F_t does no work but, together with F_c, produces deflections of the tool. The resultant force also has two components on the shear plane: F_s is the force required to shear the metal along the shear plane, and F_n is the normal force on this plane. Two other force components also exist on the face of the tool: the friction force F and the normal force N.

Whereas the cutting force F_c is always in the direction shown in Fig. 13.4.3, the thrust force F_t may be in the opposite direction to that shown in the figure. This occurs when both the rake angle and the depth of cut are large, and friction is low.

From the geometry of Fig. 13.4.3, the following relationships can be derived: The **coefficient of friction** at the tool-chip interface is given by $\mu = (F_t + F_c \tan \alpha)/(F_c - F_t \tan \alpha)$. The **friction force** along the tool is $F = F_t \cos \alpha + F_c \sin \alpha$. The **shear stress** in the shear plane is $\tau = (F_c \sin \phi \cos \phi - F_t \sin^2 \phi)/A_0$, where A_0 is the cross-sectional area that is being cut from the workpiece.

The coefficient of friction on the tool face is a complex but important factor in cutting performance; it can be reduced by such means as the use of an effective cutting fluid, higher cutting speed, improved tool material and condition, or chemical additives in the workpiece material.

The net **power** consumed at the tool is $P = F_c V$. Since F_c is a function of tool geometry, workpiece material, and process variables, it is difficult reliably to calculate its value in a particular machining operation. Depending on workpiece material and the condition of the tool, **unit power** requirements in machining range between 0.2 hp·min/in^3 (0.55 W·s/mm^3) of metal removal for aluminum and magnesium alloys, to 3.5 for high-strength alloys. The power consumed is the product of unit power and rate of metal removal: P = (unit power)(vol/min).

The power consumed in cutting is transformed mostly to **heat.** Most of the heat is carried away by the chip, and the remainder is divided between the tool and the workpiece. An increase in cutting speed or feed will increase the proportion of the heat transferred to the chip. It has been observed that, in turning, the average interface **temperature** between the tool and the chip increases with cutting speed and feed, while the influence of the depth of cut on temperature has been found to be limited. Interface temperatures to the range of 1,500 to 2,000°F (800 to 1,100°C) have been measured in metal cutting. Generally the use of a cutting fluid removes heat and thus avoids temperature buildup on the cutting edge.

In cutting metal at high speeds, the chips may become very hot and cause safety hazards because of long spirals which whirl around and become entangled with the tooling. In such cases, **chip breakers** are introduced on the tool geometry, which curl the chips and cause them to break into short sections. Chip breakers can be produced on the face of the cutting tool or insert, or are separate pieces clamped on top of the tool or insert.

A phenomenon of great significance in metal cutting is **tool wear.** Many factors determine the type and rate at which wear occurs on the tool. The major critical variables that affect wear are tool temperature, type and hardness of tool material, grade and condition of workpiece, abrasiveness of the microconstituents in the workpiece material, tool geometry, feed, speed, and cutting fluid. The type of wear pattern that develops depends on the relative role of these variables.

Tool wear can be classified as (1) flank wear (Fig. 13.4.5); (2) crater wear on the tool face; (3) localized wear, such as the rounding of the cutting edge; (4) chipping or thermal softening and plastic flow of the cutting edge; (5) concentrated wear resulting in a deep groove at the edge of a turning tool, known as **wear notch.**

In general, the wear on the flank or relief side of the tool is the most dependable guide for **tool life.** A wear land of 0.060 in (1.5 mm) on high-speed steel tools and 0.015 in (0.4 mm) for carbide tools is usually used as the endpoint. The cutting speed is the variable which has the greatest influence on tool life. The relationship between tool life and cutting speed is given by the Taylor equation $VT^n = C$, where V is the cutting speed; T is the actual cutting time to develop a certain wear land, min; C is a constant whose value depends on workpiece material and process variables, numerically equal to the cutting speed that gives a tool life of 1 min; and n is the exponent whose value depends on workpiece material and other process variables.

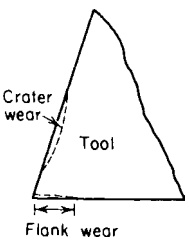

Fig. 13.4.5 Types of tool wear in cutting.

The recommended cutting speed for a high-speed steel tool is generally the one which produces a 60- to 120-min tool life. With carbide tools, a 30- to 60-min tool life may be satisfactory. Values of n typically range from 0.08 to 0.2 for high-speed steels, 0.1 to 0.15 for cast alloys, 0.2 to 0.5 for uncoated carbides, 0.4 to 0.6 for coated carbides, and 0.5 to 0.7 for ceramics.

When tool-life equations are used, caution should be exercised in extrapolation of the curves beyond the operating region for which they are derived. In a log-log plot, tool life curves may be linear over a short cutting-speed range but are rarely linear over a wide range of cutting speeds. In spite of the considerable data obtained to date, no simple formulas can be given for quantitative relationships between tool life and various process variables for a wide range of materials and conditions.

An important aspect of machining on computer-controlled equipment is **tool-condition monitoring** while the machine is in operation with little or no supervision by an operator. Most state-of-the-art machine controls are now equipped with tool-condition monitoring systems. Two common techniques involve the use of (1) transducers that are installed on the tool holder and continually monitor torque and forces and (2) acoustic emission through a piezoelectric transducer. In both methods the signals are analyzed and interpreted automatically for tool wear or chipping, and corrective actions are taken before any significant damage is done to the workpiece.

A term commonly used in machining and comprising most of the items discussed above is **machinability.** This is best defined in terms of (1) tool life, (2) power requirement, and (3) surface integrity. Thus, a good machinability rating would indicate a combination of long tool life, low power requirement, and a good surface. However, it is difficult to develop quantitative relationships between these variables. Tool life is considered as the important factor and, in production, is usually expressed as the number of pieces machined between tool changes. Various tables are available in the literature that show the machinability rating for different materials; however, these ratings are relative. To determine the proper machining conditions for a given material, refer to the machining recommendations given later in this section.

The major factors influencing **surface finish** in machining are (1) the profile of the cutting tool in contact with the workpiece, (2) fragments of built-up edge left on the workpiece during cutting, and (3) vibration and chatter. Improvement in surface finish may be obtained to various degrees by increasing the cutting speed and decreasing the feed and depth of cut. Changes in cutting fluid, tool geometry, and tool material are also important; the microstructure and chemical composition of the material have great influence on surface finish.

As a result of mechanical working and thermal effects, **residual stresses** are generally developed on the surfaces of metals that have been machined or ground. These stresses may cause warping of the workpiece as well as affect the resistance to fatigue and stress corrosion. To minimize residual stresses, sharp tools, medium feeds, and medium depths of cut are recommended.

Because of plastic deformation, thermal effects, and chemical reactions during machining processes, alterations of machined surfaces may take place which can seriously affect the **surface integrity** of a part. Typical detrimental effects may be lowering of the fatigue strength of the part, distortion, changes in stress-corrosion properties, burns, cracks, and residual stresses. Improvements in surface integrity may be obtained by post-processing techniques such as polishing, sanding, peening, finish machining, and fine grinding.

Vibration in machine tools, a very complex behavior, is often the cause of premature tool failure or short tool life, poor surface finish, damage to the workpiece, and even damage to the machine itself. Vibration may be **forced** or **self-excited.** The term **chatter** is commonly used to designate self-excited vibrations in machine tools. The excited amplitudes are usually very high and may cause damage to the machine. Although there is no complete solution to all types of vibration problems, certain measures may be taken. If the vibration is being forced, it may be possible to remove or isolate the forcing element from the machine. In cases where the forcing frequency is near a natural frequency, either the forcing frequency or the natural frequency may be raised or lowered. Damping will also greatly reduce the amplitude. Self-excited vibrations are generally controlled by increasing the stiffness and damping of the machine tool. (See also Secs. 3 and 5.)

Good machining practice requires a rigid setup. The machine tool must be capable of providing the **stiffness** required for the machining conditions used. If a rigid setup is not available, the depth of cut must be reduced. Excessive tool overhang should be avoided, and in milling, cutters should be mounted as close to the spindle as possible. The length of end mills and drills should be kept to a minimum. Tools with large nose radius or with a long, straight cutting edge increase the possibility of chatter.

CUTTING-TOOL MATERIALS

A wide variety of **cutting-tool materials** are available. The selection of a proper material depends on such factors as the cutting operation involved, the machine to be used, the workpiece material, production requirements, cost, and surface finish and accuracy desired. The major qualities required in a cutting tool are (1) hot hardness, (2) resistance to mechanical impact and thermal shock, (3) wear resistance, and (4) chemical stability and inertness to the workpiece material being machined. (See Table 13.4.1 and Figs. 13.4.6 and 13.4.7.)

Materials for cutting tools include high-speed steels, cast alloys, carbides, ceramics or oxides, cubic boron nitride, and diamond. Understanding the different types of **tool steels** (see Sec. 6.2) requires knowledge of the role of different alloying elements. These elements are added to (1) obtain greater hardness and wear resistance, (2) obtain greater impact toughness, (3) impart hot hardness to the steel such that its hardness is maintained at high cutting temperatures, and (4) decrease distortion and warpage during heat treating.

Table 13.4.1 Characteristics of Cutting-Tool Materials

	High-speed steels	Cast cobalt alloys	Carbides	Coated carbides	Ceramics	Polycrystalline cubic boron nitride	Diamond
Hot hardness	—	increasing	→	→	→	→	→
Toughness	←	increasing	—	—	—	—	—
Impact strength	←	increasing	—	—	—	—	—
Wear resistance	—	increasing	→	→	→	→	→
Chipping resistance	←	increasing	—	—	—	—	—
Cutting speed	—	increasing	→	→	→	→	→
Thermal shock resistance	←	increasing	—	—	—	—	—
Tool material cost	—	increasing	→	→	→	→	→

NOTE: These tool materials have a wide range of compositions and properties; thus overlapping characteristics exist in many categories of tool materials.

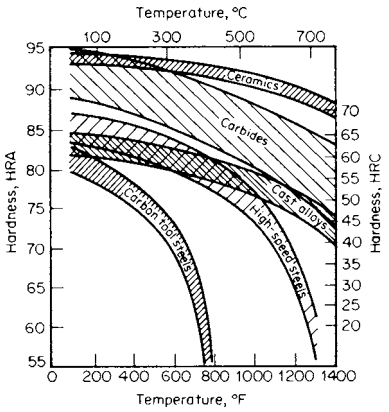

Fig. 13.4.6 Hardness of tool materials as a function of temperature.

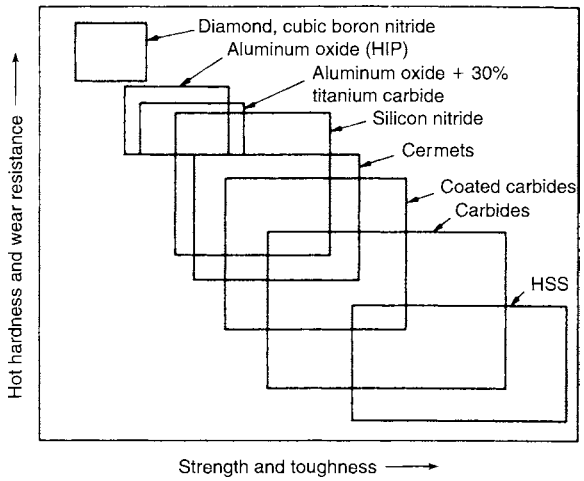

Fig. 13.4.7 Ranges of properties of various groups of tool materials.

Carbon forms a carbide with iron, making it respond to hardening and thus increasing the hardness, strength, and wear resistance. The carbon content of tool steels ranges from 0.6 to 1.4 percent. **Chromium** is added to increase wear resistance and toughness; the content ranges from 0.25 to 4.5 percent. **Cobalt** is commonly used in high-speed steels to increase hot hardness so that tools may be used at higher cutting speeds and still maintain hardness and sharp cutting edges; the content ranges from 5 to 12 percent. **Molybdenum** is a strong carbide-forming element and increases strength, wear resistance, and hot hardness. It is always used in conjunction with other alloying elements, and its content ranges to 10 percent. **Tungsten** promotes hot hardness and strength; content ranges from 1.25 to 20 percent. **Vanadium** increases hot hardness and abrasion resistance; in high-speed steels, it ranges from 1 to 5 percent.

High-speed steels are the most highly alloyed group among tool steels and maintain their hardness, strength, and cutting edge. With suitable procedures and equipment, they can be fully hardened with little danger of distortion or cracking. High-speed steel tools are widely used in operations using form tools, drilling, reaming, end-milling, broaching, tapping, and tooling for screw machines.

Cast alloys maintain high hardness at high temperatures and have good wear resistance. Cast-alloy tools, which are cast and ground into any desired shape, are composed of cobalt (38 to 53 percent), chromium (30 to 33 percent), and tungsten (10 to 20 percent). These alloys are recommended for deep roughing operations at relatively high speeds and feeds. Cutting fluids are not necessary and are usually used only to obtain a special surface finish.

Carbides have metal carbides as key ingredients and are manufactured by powder-metallurgy techniques. They have the following properties which make them very effective cutting-tool materials: (1) high hardness over a wide range of temperatures; (2) high elastic modulus, 2 to 3 times that of steel; (3) no plastic flow even at very high stresses; (4) low thermal expansion; and (5) high thermal conductivity. Carbides are used in the form of inserts or tips which are clamped or brazed to a steel shank. Because of the difference in coefficients of expansion, brazing should be done carefully. The mechanically fastened tool tips are called **inserts** (Fig. 13.4.8); they are available in different shapes, such as square, triangular, circular, and various special shapes.

There are three general groups of carbides in use: (1) tungsten carbide with cobalt as a binder, used in machining cast irons and nonferrous abrasive metals; (2) tungsten carbide with cobalt as a binder, plus a solid solution of WC-TiC-TaC-NbC, for use in machining steels;

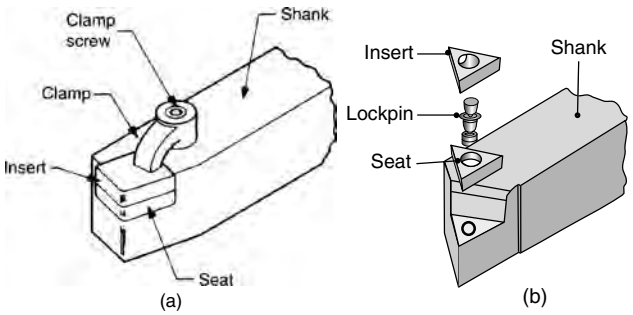

Fig. 13.4.8 (*a*) Insert clamped to shank of a toolholder; (*b*) insert clamped with wing lockpins.

and (3) titanium carbide with nickel and molybdenum as a binder, for use where cutting temperatures are high because of high cutting speeds or the high strength of the workpiece material. Carbides are classified by ISO and ANSI, as shown in Table 13.4.2 which includes recommendations for a variety of workpiece materials and cutting conditions. (See also Sec. 6.4.)

Coated carbides consist of conventional carbide inserts that are coated with a thin layer of titanium nitride, titanium carbide, titanium carbonitride, ceramic, polycrystalline diamond, or diamondlike carbon. The coating provides additional wear resistance while maintaining the strength and toughness of the carbide tool. Coatings are also applied to high-speed steel tools, particularly drills and taps. The desirable properties of individual coatings can be combined and optimized by using **multiphase coatings.** Carbide tools are now available with, e.g., a layer of titanium carbide over the carbide substrate, followed by aluminum oxide and then titanium nitride. Various alternating layers of coatings are also used, each layer being on the order of 80 to 400 μin (2 to 10 μm) thick.

Stiffness is of great importance when using carbide tools. Light feeds, low speeds, and chatter are deleterious. No cutting fluid is needed, but if one is used for cooling, it should be applied in large quantities and continuously to prevent heating and quenching.

Ceramic, or **oxide,** inserts consist primarily of fine aluminum oxide grains which have been bonded together. Minor additions of other elements help to obtain optimum properties.

Other ceramics include silicon nitride, with various additives such as aluminum oxide, yttrium oxide, and titanium carbide. Silicon-nitride-based ceramics include **sialon** (from silicon, aluminum, oxygen, and nitrogen) which has toughness, hot hardness, and good thermal-shock resistance. More recent developments include **whisker-reinforced** cutting tools, with enhanced toughness, cutting-edge strength, and thermal-shock resistance. A common whisker material is silicon carbide. Ceramic tools have very high abrasion resistance, are harder than carbides, and have less tendency to weld to metals during cutting. However, they generally lack impact toughness, and premature tool failure can result by chipping or general breakage. Ceramic tools have been found to be

Table 13.4.2 Classification of Tungsten Carbides According to Machining Applications

ISO standard	ANSI classification no. (grade)	Materials to be machined	Machining operation	Type of carbide	Characteristics of	
					Cut	Carbide
K30–K40	C1	Cast iron, nonferrous metals, and nonmetallic materials requiring abrasion resistance	Roughing	Wear-resistant grades; generally straight WC-Co with varying grain sizes	Increasing cutting speed ↓ ↑ Increasing feed rate	Increasing hardness and wear resistance ↓ ↑ Increasing strength and binder content
K20	C2		General purpose			
K10	C3		Light finishing			
K01	C4		Precision finishing			
P30–P50	C5	Steels and steel alloys requiring crater and deformation resistance	Roughing	Crater-resistant grades; various WC-Co compositions with TiC and/or TaC alloys	Increasing cutting speed ↓ ↑ Increasing feed rate	Increasing hardness and wear resistance ↓ ↑ Increasing strength and binder content
P20	C6		General purpose			
P10	C7		Light finishing			
P01	C8		Precision finishing			

NOTE: The ISO and ANSI comparisons are approximate.

effective for high-speed, uninterrupted turning operations. Tool and setup geometry is important. Tool failures can be reduced by the use of rigid tool mountings and rigid machine tools. Included in oxide cutting-tool materials are **cermets** (such as 70 percent aluminum oxide and 30 percent titanium carbide), combining the advantages of ceramics and metals.

Polycrystalline diamond is used where good surface finish and dimensional accuracy are desired, particularly on soft nonferrous materials that are difficult to machine. The general properties of diamonds are extreme hardness, low thermal expansion, high heat conductivity, and a very low coefficient of friction. The polycrystalline diamond is bonded to a carbide substrate. **Single-crystal diamond** is also used as a cutting tool to produce extremely fine surface finish on nonferrous alloys, such as copper-base mirrors.

Next to diamond, **cubic boron nitride (cBN)** is the hardest material presently available. Polycrystalline cBN is bonded to a carbide substrate and used as a cutting tool. The cBN layer provides very high wear resistance and edge strength. It is chemically inert to iron and nickel at elevated temperatures; thus it is particularly suitable for machining high-temperature alloys and various ferrous alloys. Both diamond and cBN are also used as abrasives in grinding operations.

CUTTING FLUIDS

Cutting fluids, frequently referred to as lubricants or coolants, comprise those liquids and gases which are applied to the cutting zone in order to facilitate the cutting operation. A cutting fluid is used (1) to keep the tool cool and prevent it from being heated to a temperature at which the hardness and resistance to abrasion are reduced; (2) to keep the workpiece cool, thus preventing it from being machined in a warped shape to inaccurate final dimensions; (3) through lubrication to reduce friction and power consumption, wear on the tool, and generation of heat; (4) to provide a good finish on the workpiece; (5) to aid in providing a satisfactory chip formation; (6) to wash away the chips (this is particularly desirable in deep-hole drilling, hacksawing, milling, and grinding); and (7) to prevent corrosion of the workpiece and machine tool.

Classification Cutting fluids may be classified as follows: (1) emulsions, (2) oils, and (3) solutions (semisynthetics and synthetics). Cutting fluids are also classified as light-, medium-, and heavy-duty; light-duty fluids are for general-purpose machining. Induced **air blast** may be used with internal and surface grinding and polishing operations. Its main purpose is to remove the small chips or dust, although some cooling is also obtained, especially in machining of plastics.

Emulsions consist of a soluble oil emulsified with water in the ratio of 1 part oil to 10 to 100 parts water, depending upon the type of product and the operation. Emulsions have surface-active or **extreme-pressure** additives to reduce friction and provide an effective lubricant film under high pressure at the tool-chip interface during machining. Emulsions are low-cost cutting fluids and are used for practically all types of cutting and grinding when machining all types of metals. The more concentrated mixtures of oil and water, such as 1:10, are used for broaching, threading, and gear cutting. For most operations, a solution of 1 part soluble oil to 20 parts water is satisfactory.

A variety of **oils** are used in machining. They are used where lubrication rather than cooling is essential or on high-grade finishing cuts, although sometimes superior finishes are obtained with emulsions.

Oils generally used in machining are mineral oils with the following compositions: (1) straight mineral oil, (2) with fat, (3) with fat and sulfur, (4) with fat and chlorine, and (5) with fat, sulfur, and chlorine. The more severe the machining operation, the higher the composition of the oil. Broaching and tapping of refractory alloys and high-temperature alloys, for instance, require highly compounded oils. In order to avoid staining of the metal, aluminum and copper, for example, inhibited sulfur and chlorine are used.

Solutions are a family of cutting fluids that blend water and various chemical agents such as amines, nitrites, nitrates, phosphates, chlorine, and sulfur compounds. These agents are added for purposes of rust prevention, water softening, lubrication, and reduction of surface tension. Most of these chemical fluids are coolants but some are lubricants.

The **selection** of a cutting fluid for a particular operation requires consideration of several factors: cost, the workpiece material, the difficulty of the machining operation, the compatibility of the fluid with the workpiece material and the machine tool components, surface preparation, method of application and removal of the fluid, contamination of the cutting fluid with machine lubricants, and the treatment of the fluid after use. Also important are the **biological** and **ecological** aspects of the cutting fluid used. There may be potential health hazards to operating personnel from contact with or inhalation of mist or fumes from some fluids. Recycling and waste disposal are also important problems to be considered.

Methods of Application The most common method is **flood cooling** in quantities such as 3 to 5 gal/min (about 10 to 20 L/min) for single-point tools and up to 60 gal/min (230 L/min) per cutter for multiple-tooth cutters. Whenever possible, multiple nozzles should be used. In **mist cooling** a small jet equipment is used to disperse water-base fluids as very fine droplets in a carrier that is generally air at pressures 10 to

80 lb/in^2 (70 to 550 kPa). Mist cooling has a number of advantages, such as providing high-velocity fluids to the working areas, better visibility, and improving tool life in certain instances. The disadvantages are that venting is required and also the cooling capability is rather limited.

High-pressure refrigerated coolant systems are very effective in removing heat at high rates, particularly in computer-controlled machine tools. The fluid is directed generally at the relief angle of the cutting tools and at pressures as high as 5,000 lb/in^2 (35,000 kPa). Continuous filtering of the fluid is essential to eliminate any damage to workpiece surfaces due to the impact of any contaminants that may be present in the coolant system. More recent methods of application include delivering the coolant to the cutting zone through the tool and the machine spindle.

For economic as well as environmental reasons, an important trend is **near-dry** and **dry machining.** In near-dry machining, the cutting fluid typically consists of a fine mist of air containing a very small amount of cutting fluid (including vegetable oil) and is delivered through the machine spindle. Dry machining is carried out without any fluids but using appropriate cutting tools and processing parameters. Unlike other methods, however, dry machining cannot flush away the chips being produced; an effective means to do so is to use pressurized air.

MACHINE TOOLS

The general types of **machine tools** are lathes; turret lathes; screw, boring, drilling, reaming, threading, milling, and gear-cutting machines; planers and shapers; broaching, cutting-off, grinding, and polishing machines. Each of these is subdivided into many types and sizes. General items common to all machine tools are discussed first, and individual machining processes and equipment are treated later in this section.

Automation is the application of special equipment to control and perform manufacturing processes with little or no manual effort. It is applied to the manufacturing of all types of goods and processes, from the raw material to the finished product. Automation involves many activities, such as handling, processing, assembly, inspecting, and packaging. Its primary objective is to lower manufacturing cost through controlled production and quality, lower labor cost, reduced damage to work by handling, higher degree of safety for personnel, and economy of floor space. Automation may be partial, such as gaging in cylindrical grinding, or it may be total.

The conditions which play a role in decisions concerning automation are rising production costs, high percentage of rejects, lagging output, scarcity of skilled labor, hazardous working conditions, and work requiring repetitive operation. Factors which must be carefully studied before deciding on automation are high initial cost of equipment, maintenance problems, and type of product. (See also Sec. 16.)

Mass production with modern machine tools has been achieved through the development of self-contained **power-head** production units and the development of **transfer** mechanisms. Power-head units, consisting of a frame, electric driving motor, gearbox, tool spindles, etc., are available for many types of machining operations. Transfer mechanisms move the workpieces from station to station by various methods. Transfer-type machines can be arranged in several configurations, such as a straight line or a U pattern. Various types of machine tools for mass production can be built from components; this is known as the **building-block** principle. Such a system combines flexibility and adaptability with high productivity. (See **machining centers.**)

Numerical control (NC), which is a method of controlling the motions of machine components by numbers, was first applied to machine tools in the 1950s. Numerically controlled machine tools are classified according to the type of cutting operation. For instance, in drilling and boring machines, the positioning and the cutting take place sequentially (point to point), whereas in die-sinking machines, positioning and cutting take place simultaneously. The latter are often described as **continuous-path** machines, and since they require more exacting specifications, they give rise to more complex problems. Machines now perform over a very wide range of cutting conditions without requiring adjustment to eliminate chatter, and to improve accuracy. Complex contours can be machined which would be almost impossible by any other method. A large variety of programming systems has been developed.

The control system in NC machines has been converted to computer control with various software. In **computer numerical control** (CNC), a microcomputer is a part of the control panel of the machine tool. The advantages of computer numerical control are ease of operation, simpler programming, greater accuracy, versatility, and lower maintenance costs.

Further developments in machine tools are **machining centers.** This is a machine equipped with as many as 200 tools and with an automatic tool changer (Fig. 13.4.9). It is designed to perform various operations on different surfaces of the workpiece, which is placed on a pallet capable of as much as five-axis movement (three linear and two rotational). Machining centers, which may be vertical or horizontal spindle, have flexibility and versatility that other machine tools do not have, and thus they have become the first choice in machine selection in modern manufacturing plants and shops. They have the capability of tool and part checking, tool-condition monitoring, in-process and postprocess gaging, and inspection of machined surfaces. **Universal machining centers** are the latest development, and they have both vertical and horizontal spindles. **Turning centers** are a further development of computer-controlled lathes and have great flexibility. Many centers are now constructed on a **modular** basis, so that various accessories and peripheral equipment can be installed and modified depending on the type of product to be machined.

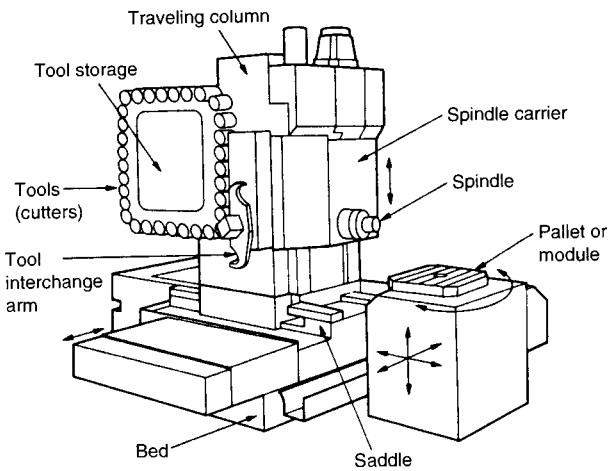

Fig. 13.4.9 Schematic of a horizontal spindle machining center, equipped with an automatic tool changer. Tool magazines can store 200 different cutting tools.

An approach to optimize machining operations is **adaptive control.** While the material is being machined, the system senses operating conditions such as forces, tool-tip temperature, rate of tool wear, and surface finish, and converts these data into feed and speed control that enables the machine to cut under optimum conditions for maximum productivity. Combined with numerical controls and computers, adaptive controls are expected to result in increased efficiency of metalworking operations.

With the advent of sophisticated computers and various software, modern manufacturing has evolved into **computer-integrated manufacturing (CIM).** This system involves the coordinated participation of computers in all phases of manufacturing. **Computer-aided design** combined with **computer-aided manufacturing (CAD/CAM)** results in a much higher productivity, better accuracy and efficiency, and reduction in design effort and prototype development. CIM also involves the management of the factory, inventory, and labor, and it integrates all these activities, eventually leading to untended factories.

The highest level of sophistication is reached with a **flexible manufacturing system (FMS).** Such a system is made of **manufacturing cells** and an automatic materials-handling system interfaced with a central computer. The manufacturing cell is a system in which CNC machines are used to make a specific part or parts with similar shape. The workstations, i.e., several machine tools, are placed around an **industrial robot** which automatically loads, unloads, and transfers the parts. FMS has the capability to optimize each step of the total manufacturing operation, resulting in the highest possible level of efficiency and productivity.

The proper design of **machine-tool structures** requires analysis of such factors as form and materials of structures, stresses, weight, and manufacturing and performance considerations. The best approach to obtain the ultimate in machine-tool accuracy is to employ both improvements in structural stiffness and compensation of deflections by use of special controls. The C-frame structure has been used extensively in the past because it provides ready accessibility to the working area of the machine. With the advent of computer control, the box-type frame with its considerably improved static stiffness becomes practical since the need for manual access to the working area is greatly reduced. The use of a box-type structure with thin walls can provide low weight for a given stiffness. The light-weight-design principle offers high dynamic stiffness by providing a high natural frequency of the structure through combining high static stiffness with low weight rather than through the use of large mass. (Dynamic stiffness is the stiffness exhibited by the system when subjected to dynamic excitation where the elastic, the damping, and the inertia properties of the structure are involved; it is a frequency-dependent quantity.)

TURNING

Turning is a machining operation for all types of metallic and nonmetallic materials and is capable of producing circular parts with straight or various profiles. The cutting tools may be single-point or form tools. The most common machine tool used is a **lathe;** modern lathes are computer-controlled and can achieve high production rates with little labor. The basic operation is shown in Fig. 13.4.10, where the workpiece is held in a chuck and rotates at N r/min; a cutting tool moves along the length of the piece at a feed f (in/r or mm/r) and removes material at a radial depth d, reducing the diameter from D_0 to D_f.

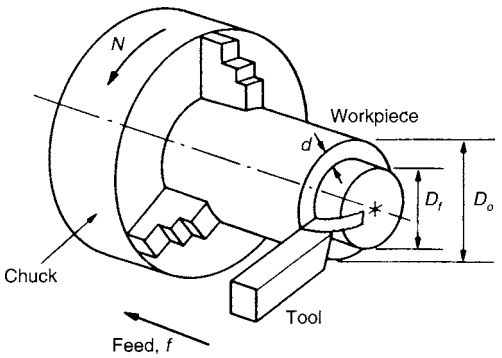

Fig. 13.4.10 A turning operation on a round workpiece held in a three-jaw chuck.

Lathes generally are considered to be the oldest member of machine tools, having been first developed in the late eighteenth century. The most common lathe is called an engine lathe because it was one of the first machines driven by Watt's steam engine. The basic lathe has the following main parts: bed, headstock, tailstock, and carriage. The types of lathes available for a variety of applications may be listed as follows: engine lathes, bench lathes, horizontal turret lathes, vertical lathes, and automatics. A great variety of lathes and attachments are available within each category, also depending on the production rate required.

It is common practice to specify the size of an engine lathe by giving the **swing** (diameter) and the **distance between centers** when the tailstock is flush with the end of the bed. The maximum swing over the ways is usually greater than the nominal swing. The **length of the bed** is given frequently to specify the overall length of the bed. A lathe size is indicated thus: 14 in (356 mm) (swing) by 30 in (762 mm) (between centers) by 6 ft (1,830 mm) (length of bed). Lathes are made for light-, medium-, or heavy-duty work.

All geared-head lathes, which are single-pulley (belt-driven or arranged for direct-motor drive through short, flat, or V belts, gears, or silent chain), increase the power of the drive and provide a means for obtaining 8, 12, 16, or 24 spindle speeds. The teeth may be of the spur, helical, or herringbone type and may be ground or lapped after hardening.

Variable speeds are obtained by driving with adjustable-speed dc shunt-wound motors with stepped field-resistance control or by electronics or motor-generator system to give speed variation in infinite steps. AC motors driving through infinitely variable speed transmissions of the mechanical or hydraulic type are also in general use.

Modern lathes, most of which are now computer-controlled **(turning centers),** are built with the speed capacity, stiffness, and strength capable of taking full advantage of new and stronger tool materials. The main drive-motor capacity of lathes ranges from fractional to more than 200 hp (150 kW). Speed preselectors, which give speed as a function of work diameter, are introduced, and variable-speed drives using dc motors with panel control are standard on many lathes. Lathes with contour facing, turning, and boring attachments are also available.

Tool Shapes for Turning

The standard **nomenclature** for single-point tools, such as those used on lathes, planers, and shapers, is shown in Fig. 13.4.11. Each tool consists of a shank and point. The point of a single-point tool may be formed by grinding on the end of the shank; it may be forged on the end of the shank and subsequently ground; a tip or insert may be clamped or brazed to the end of the shank (see Fig. 13.4.8). The **best tool shape** for each material and each operation depends on many factors. For specific information and recommendations, the various sources listed in the References should be consulted. See also Table 13.4.3.

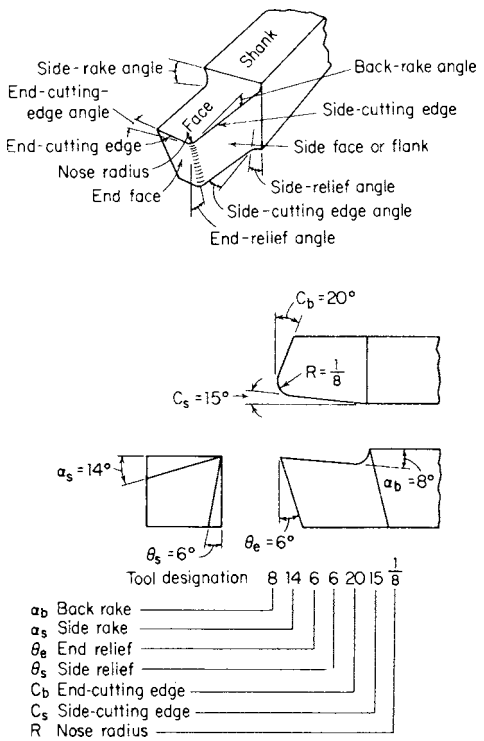

Fig. 13.4.11 Standard nomenclature for single-point cutting tools.

Positive **rake angles** improve the cutting operation with regard to forces and deflection; however, a high positive rake angle may result in early failure of the cutting edge. Positive rake angles are generally used in lower-strength materials. For higher-strength materials, negative rake angles may be used. **Back rake** usually controls the direction of chip flow and is of less importance than the **side rake.** The purpose of **relief angles** is to avoid interference and rubbing between the workpiece and tool flank surfaces. In general, they should be small for high-strength materials and larger for softer materials. Excessive relief angles may weaken the tool. The **side cutting-edge angle** influences the length of chip contact and the true feed. This angle is often limited by the workpiece geometry, e.g., the shoulder contour. Large angles are apt to cause tool chatter. Small **end cutting-edge angles** may create excessive force normal to the workpiece, and large angles may weaken the tool point. The purpose of the **nose radius** is to give a smooth surface finish and to obtain longer tool life by increasing the strength of the cutting edge. The nose radius should be tangent to the cutting-edge angles. A large nose radius gives a stronger tool and may be used for roughing cuts; however, large radii may lead to tool chatter. A small nose radius reduces forces and is therefore preferred on thin or slender workpieces.

Turning Recommendations Recommendations for tool materials, depth of cut, feed, and cutting speed for turning a variety of materials are given in Table 13.4.4. The cutting speeds for high-speed steels for turning, which are generally M2 and M3, are about one-half those for uncoated carbides. A general **troubleshooting guide** for turning operations is given in Table 13.4.5. The range of applicable cutting speeds and feeds for a variety of tool materials is shown in Fig. 13.4.12.

High-Speed Machining To increase productivity and reduce machining costs, there is a continuing trend to increase cutting speeds, especially in turning, milling, boring, and drilling. High-speed machining is a general term used to describe this trend, where speeds typically range as follows: High speed: up 6,000 ft/min (1,800 m/min): very high speed: up to 60,000 ft/min (18,000 m/min); and ultrahigh-speed, higher than this range. Because of the high speeds involved, important considerations in these operations include inertia effects, spindle design, bearings, and power; stiffness and accuracy of the machine tools; selection of appropriate cutting tools; and chip removal systems.

Hard Turning and Machining As workpiece hardness increases, its machinability decreases and there may be difficulties with traditional machining operations regarding surface finish, surface integrity, and tool life. With advances in cutting tools and the availability of rigid and powerful machine tools and work-holding devices, however, it is now possible to machine hard materials, including heat-treated steels, with high dimensional accuracy. Hard machining can compete well with grinding processes and has been shown to be economical for parts such as shafts, gears, pinions, and various automotive components.

Ultraprecision Machining To respond to increasing demands for special parts with surface finish and dimensional accuracies on the order of a nanometre (10^{-9} m), several important developments have been taking place in advanced machining. A common example of ultraprecision machining is **diamond turning,** typically using a single-crystal diamond cutting tool and rigid machine tools. Applications for such parts and components are in the computer, electronic, nuclear, and defense industries.

Turret Lathes

Turret lathes are used for the production of parts in moderate quantities and produce interchangeable parts at low production cost. Turret lathes may be chucking, screw machine, or universal. The universal machine may be set up to machine bar stock as a screw machine or have the work held in a chuck. These machines may be semiautomatic, i.e., so arranged that after a piece is chucked and the machine started, it will complete the machining cycle automatically and come to a stop. They may be horizontal or vertical and single- or multiple-spindle; many of these lathes are now computer-controlled and have a variety of features.

The basic principle of the turret lathe is that, with standard tools, setups can be made quickly so that combined, multiple, and successive cuts can be made on a part. By **combined** cuts, tools on the cross slide operate simultaneously with those on the turret, e.g., facing from the cross slide and boring from the turret. **Multiple** cuts permit two or more tools to operate from either or both the cross slide or turret. By **successive** cuts, one tool may follow another to rough or finish a surface; e.g., a hole may be drilled, bored, and reamed at one chucking. In the tool-slide machine only roughing cuts, such as turn and face, can be made in one machine.

Ram-type turret lathes have the turret mounted on a ram which slides in a separate base. The base is clamped at a position along the bed to suit a long or short workpiece. A cross slide can be used so that combined cuts can be taken from the turret and the cross slide at the same time. Turret and cross slide can be equipped with manual or power feed. The short stroke of the turret slide limits this machine to comparatively short light work, in both small and quantity-lot production.

Saddle-type turret lathes have the turret mounted on a saddle which slides directly on the bed. Hence, the length of stroke is limited only by the length of bed. A separate square-turret carriage with longitudinal and transverse movement can be mounted between the head and the hex-turret saddle so that combined cuts from both stations at one time are possible. The saddle type of turret lathe generally has a large hollow vertically faced turret for accurate alignment of the tools.

Screw Machines

When turret lathes are set up for bar stock, they are often called **screw machines.** Turret lathes that are adaptable only to bar-stock work are

Table 13.4.4 General Recommendations for Turning Operations

		General-purpose starting conditions			Range for roughing and finishing

Table 13.4.5 General Troubleshooting Guide for Turning Operations

Problem	Probable causes
Tool breakage	Tool material lacks toughness; improper tool angles; machine tool lacks stiffness; worn bearings and machine components; cutting parameters too high
Excessive tool wear	Cutting parameters too high; improper tool material; ineffective cutting fluid; improper tool angles
Rough surface finish	Built-up edge on tool; feed too high; tool too sharp, chipped, or worn; vibration and chatter
Dimensional variability	Lack of stiffness of machine tool and work-holding devices; excessive temperature rise; tool wear
Tool chatter	Lack of stiffness of machine tool and work-holding devices; excessive tool overhang; machining parameters not set properly

constructed for light work. As with turret lathes, they have spring collets for holding the bars during machining and friction fingers or rolls to feed the bar stock forward. Some bar-feeding devices are operated by hand and others semiautomatically.

Automatic screw machines may be classified as single-spindle or multiple-spindle. Single-spindle machines rotate the bar stock from which the part is to be made. The tools are carried on a turret and on cross slides or on a circular drum and on cross slides. Multiple-spindle machines have four, five, six, or eight spindles, each carrying a bar of the material from which the piece is to be made. Capacities range from ⅛ to 6 in (3 to 150 mm) diam of bar stock.

Feeds of forming tools vary with the width of the cut. The wider the forming tool and the smaller the diameter of stock, the smaller the feed. On multiple-spindle machines, where many tools are working simultaneously, the feeds should be such as to reduce the actual cutting time to a minimum. Often only one or two tools in a set are working up to capacity, as far as actual speed and feed are concerned.

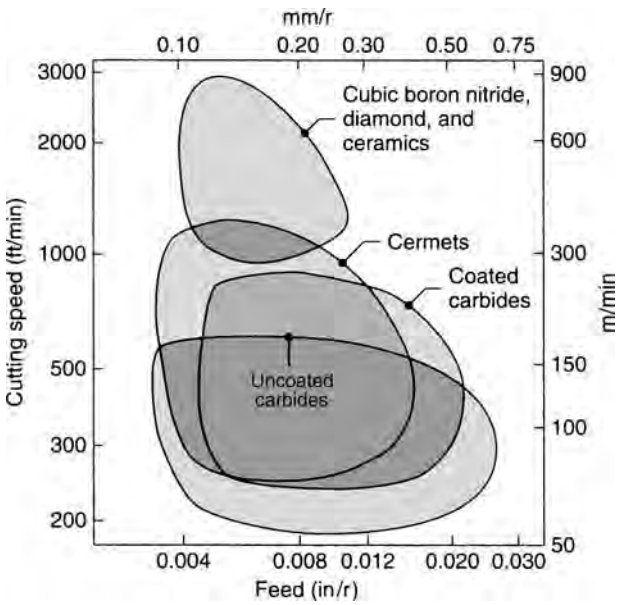

Fig. 13.4.12 Range of applicable cutting speeds and feeds for various tool materials.

BORING

Boring is a machining process for producing internal straight cylindrical surfaces or profiles, with process characteristics and tooling similar to those for turning operations.

Boring machines are of two general types, horizontal and vertical, and are frequently referred to as horizontal boring machines and vertical boring and turning mills. A classification of boring machines comprises horizontal boring, drilling, and milling machines; vertical boring and

turning mills; vertical multispindle cylinder boring mills; vertical cylinder boring mills; vertical turret boring mills (vertical turret lathes); carwheel boring mills; diamond or precision boring machines (vertical and horizontal); and jig borers.

The **horizontal type** is made for both precision work and general manufacturing. It is particularly adapted for work not conveniently revolved, for milling, slotting, drilling, tapping, boring, and reaming long holes, and for making interchangeable parts that must be produced without jigs and fixtures. The machine is universal and has a wide range of speeds and feeds, for a face-mill operation may be followed by one with a small-diameter drill or end mill.

Vertical boring mills are adapted to a wide range of faceplate work that can be revolved. The advantage lies in the ease of fastening a workpiece to the horizontal table, which resembles a four-jaw independent chuck with extra radial T slots, and in the lessened effect of centrifugal forces arising from unsymmetrically balanced workpieces.

A jig-boring machine has a single-spindle sliding head mounted over a table adjustable longitudinally and transversely by lead screws which roughly locate the work under the spindle. Precision setting of the table may be obtained with end measuring rods, or it may depend only on the accuracy of the lead screw. These machines, made in various sizes, are used for accurately finishing holes and surfaces in definite relation to one another. They may use drills, rose or fluted reamers, or single-point boring tools. The latter are held in an adjustable **boring head** by which the tool can be moved eccentrically to change the diameter of the hole.

Precision-boring machines may have one or more spindles operating at high speeds for the purpose of boring to accurate dimensions such surfaces as wrist-pin holes in pistons and connecting-rod bushings.

Boring Recommendations Boring recommendations for tool materials, depth of cut, feed, and cutting speed are generally the same as those for turning operations (see Table 13.4.4). However, tool deflections, chatter, and dimensional accuracy can be significant problems because the boring bar has to reach the full length to be machined and space within the workpiece may be limited. Boring bars have been designed to dampen vibrations and reduce chatter during machining.

DRILLING

Drilling is a commonly employed hole-making process that uses a **drill** as a cutting tool for producing round holes of various sizes and depths. Drilled holes may be subjected to additional operations for better surface finish and dimensional accuracy, such as reaming and honing, described later in this section.

Drilling machines are intended for drilling holes, tapping, counterboring, reaming, and general boring operations. They may be classified into a large variety of types.

Vertical drilling machines are usually designated by a dimension which roughly indicates the diameter of the largest circle that can be drilled at its center under the machine. This dimensioning, however, does not hold for all makes of machines. The sizes begin with about 6 and

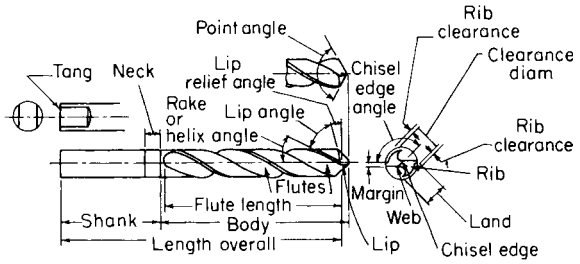

Fig. 13.4.13 Straight shank twist drill.

continue to 50 in. Heavy-duty drill presses of the vertical type, with all-geared speed and feed drive, are constructed with a box-type column instead of the older cylindrical column.

The size of a **radial drill** is designated by the length of the arm. This represents the radius of a piece which can be drilled in the center.

Twist drills (Fig. 13.4.13) are the most common tools used in drilling and are made in many sizes and lengths. For years they have been grouped according to numbered sizes, 1 to 80, inclusive, corresponding approximately to Stub's steel wire gage; some by lettered sizes A to Z, inclusive; some by fractional inches from 1/64 up, and the group of millimetre sizes.

Straight-shank twist drills of fractional size and various lengths range from 1/64 in diam to 1 1/4 in by 1/64 in increments; to 1 1/2 in by 1/32 in; and to 2 in by 1/16 in. **Taper-shank drills** range from 1/8 in diam to 1 3/4 in by 1/64 increments; to 2 1/4 in by 1/32 in; and to 3 1/2 in by 1/16 in. Larger drills are made by various drill manufacturers. Drills are also available in metric dimensions.

Tolerances have been set on the various features of all drills so that the products of different manufacturers will be interchangeable in the user's plants.

Twist drills are decreased in diameter from point to shank (back taper) to prevent binding. If the web is increased gradually in thickness from point to shank to increase the strength, it is customary to reduce the helix angle as it approaches the shank. The shape of the groove is important, the one that gives a straight cutting edge and allows a full curl to the chip being the best. The **helix angles** of the flutes vary from 10 to 45°. The standard **point angle** is 118°. There are a number of **drill grinders** on the market designed to give the proper angles. The point may be ground either in the **standard** or the **crankshaft** geometry. The drill geometry for high-speed steel twist drills for a variety of workpiece materials is given in Table 13.4.6.

Among the common **types of drills** (Fig. 13.4.14) are the combined drill and countersink or **center drill,** a short drill used to center shafts before squaring and turning: the **step drill,** with two or more diameters; the **spade drill** which has a removable tip or bit clamped in a holder on the drill shank, used for large and deep holes; the **trepanning tool** used to cut a core from a piece of metal instead of reducing all the metal

Table 13.4.6 Recommended Drill Geometry for High-Speed Steel Twist Drillls

Material	Point angle, deg	Lip relief angle, deg	Chisel edge angle, deg	Helix angle, deg	Point grind
Aluminum alloys	90–118	12–15	125–135	24–48	Standard
Magnesium alloys	70–118	12–15	120–135	30–45	Standard

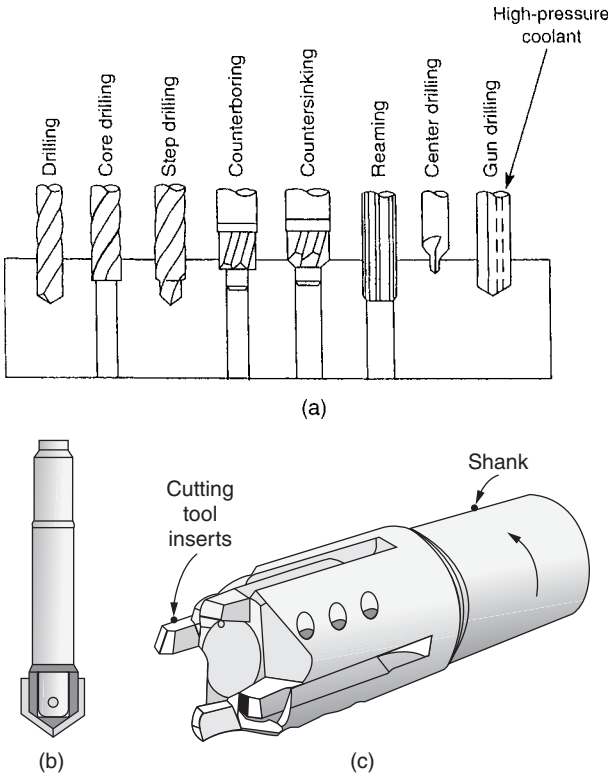

Fig. 13.4.14 (*a*) Various types of drills and drilling and reaming operations; (*b*) spade drill; (*c*) trepanning tool with four cutting-tool inserts.

removed to chips; the **gun drill,** run at a high speed under a light feed, and used to drill small long holes; the **core drill** used to bore out cored holes; the **oil-hole drill,** having holes or tubes in its body through which oil is forced to the cutting lips; **three-** and **four-fluted drills,** used to enlarge holes after a leader hole has been cored, punched, or drilled with a two-fluted drill; **twist drills** made from flat high-speed steel or drop-forged to desired shape and then twisted. Drills are also made of solid carbide or of high-speed steel with an insert of carbide to form the chisel edge and both cutting edges. They are used primarily for drilling abrasive or very hard materials.

Drilling Recommendations The most common tool material for drills is high-speed steel M1, M7, and M10. General recommendations for speeds and feeds in drilling a variety of materials are given in Table 13.4.7. Hole depth is also a factor in selecting drilling parameters. A general **troubleshooting guide** for drilling is given in Table 13.4.8.

Table 13.4.8 General Troubleshooting Guide for Drilling Operations

Problem	Probable causes
Drill breakage	Dull drill; drill seizing in hole because of chips clogging flutes; feed too high; lip relief angle too small
Excessive drill wear	Cutting speed too high; ineffective cutting fluid; rake angle too high; drill burned and strength lost when sharpened
Tapered hole	Drill misaligned or bent; lips not equal; web not central
Oversize hole	Same as above; machine spindle loose; chisel edge not central; side pressure on workpiece
Poor hole surface finish	Dull drill; ineffective cutting fluid; welding of workpiece material on drill margin; improperly ground drill; improper alignment

REAMING

A **reamer** is a multiple-cutting edge tool used to enlarge or finish holes, and to provide accurate dimensions as well as good finish. Reamers are of two types: (1) rose and (2) fluted.

The **rose reamer** is a heavy-bodied tool with end cutting edges. It is used to remove considerable metal and to true up a hole preparatory to flute reaming. It is similar to the three- and four-fluted drills. Wide cylindrical lands are provided back of the flute edges.

Fluted reamers cut principally on the periphery and remove only 0.004 to 0.008 in (0.1 to 0.2 mm) on the bore. Very narrow cylindrical margins are provided back of the flute edges, 0.012 to 0.015 in (0.3 to 0.4 mm) wide for machine-finish reaming and 0.004 to 0.006 in (0.1 to 0.15 mm) for hand reaming, to provide free cutting of the edges due to the slight body taper and also to pilot the reamer in the hole. The hole to be flute- or finish-reamed should be true. A rake of 5° is recommended for most reaming operations. A reamer may be straight or helically fluted. The latter provides much smoother cutting and gives a better finish.

Expansion reamers permit a slight expansion by a wedge so that the reamer may be resharpened to its normal size or for job shop use; they provide slight variations in size. **Adjustable reamers** have means of adjusting inserted blades so that a definite size can be maintained through numerous grindings and fully worn blades can be replaced with new ones. **Shell reamers** constitute the cutting portion of the tool which fits interchangeably on arbors to make many sizes available or to make replacement of worn-out shells less costly. Reamers float in their holding fixtures to ensure alignment, or they should be piloted in guide bushings above and below the work. They may also be held rigidly, such as in the tailstock of a lathe.

The **speed** of high-speed steel reamers should be two-thirds to three-quarters and **feeds** usually are two or three times that of the corresponding drill size. The most common tool materials for reamers are M1, M2, and M7 high-speed steels and C2 carbide.

Table 13.4.7 General Recommendations for Drilling

Workpiece material	Surface speed		Feed, mm/r (in/r) Drill diameter		r/min	
	m/min	ft/min	1.5 mm (0.060 in)	12.5 mm (0.5 in)	1.5 mm	12.5 mm
Aluminum alloys	30–120	100–400	0.025 (0.001)	0.30 (0.012)	6,400–25,000	800–3,000
Magnesium alloys	45–120	150–400	0.025 (0.001)	0.30 (0.012)	9,600–25,000	1,100–3,000
Copper alloys	15–60	50–200	0.025 (0.001)	0.25 (0.010)	3,200–12,000	400–1,500
Steels	20–30	60–100	0.025 (0.001)	0.30 (0.012)	4,300–6,400	500–800
Stainless steels	10–20	40–60	0.025 (0.001)	0.18 (0.007)	2,100–4,300	250–500
Titanium alloys	6–20	20–60	0.010 (0.0004)	0.15 (0.006)	1,300–4,300	150–500
Cast irons	20–60	60–200	0.025 (0.001)	0.30 (0.012)	4,300–12,000	500–1,500
Thermoplastics	30–60	100–200	0.025 (0.001)	0.13 (0.005)	6,400–12,000	800–1,500
Thermosets	20–60	60–200	0.025 (0.001)	0.10 (0.004)	4,300–12,000	500–1,500

NOTE: As hole depth increases, speeds and feeds should be reduced. Selection of speeds and feeds also depends on the specific surface finish required.

THREADING

Threads may be formed on the outside or inside of a cylinder or cone (1) with single-point threading tools (see Fig. 13.4.1), (2) with threading chasers, (3) with taps, (4) with dies, (5) by thread milling, (6) by thread rolling, and (7) by grinding. There are numerous types of taps, such as hand, machine screw, pipe, and combined pipe tap and drill. Small taps usually have no radial relief. They may be made in two, three, or four flutes. Large taps may have still more flutes.

The **feed** of a tap depends upon the lead of the screw thread. The **cutting speed** depends upon numerous factors: Hard tough materials, great length of hole, taper taps, and full-depth thread reduce the speed; long chamfer, fine pitches, and a cutting fluid applied in quantity increase the speed. Taps are cut or formed by grinding. The ground-thread taps may operate at much higher speeds than the cut taps. Speeds may range from 3 ft/min (1 m/min) for high-strength steels to 150 ft/min (45 m/min) for aluminum and magnesium alloys. Common high-speed steel tool materials for taps are M1, M7, and M10.

Threading dies, used to produce external threads, may be solid, adjustable, spring-adjustable, or self-opening die heads. Replacement chasers are used in die heads and may be of the fixed or self-opening type. These chasers may be of the radial type, hobbed or milled; of the tangenital type; or of the circular type. Emulsions and oils are satisfactory for most threading operations.

For thread rolling, see Sec. 13.2.

MILLING

Milling is one of the most versatile machining processes and is capable of producing a variety of shapes involving flat surfaces, slots, and contours (Fig. 13.4.15). **Milling machines** use cutters with multiple teeth in contrast with the single-point tools of the lathe and planer.

Milling-machine classification is based on design, operation, or purpose. **Knee-and-column** type milling machines have the table and saddle supported on the vertically adjustable knee gibbed to the face of the column. The table is fed longitudinally on the saddle, and the latter transversely on the knee to give three feeding motions.

Knee-type machines are made with horizontal or vertical spindles. The **horizontal** universal machines have a swiveling table for cutting helices. The plain machines are used for jobbing or production work, the universal for toolroom work. **Vertical** milling machines with fixed or sliding heads are otherwise similar to the horizontal type. They are used for face or end milling and are frequently provided with a rotary table for making cylindrical surfaces.

The **fixed-bed** machines have a spindle mounted in a head dovetailed to and sliding on the face of the column. The table rests directly on the bed. They are simple and rigidly built and are used primarily for high-production work. These machines are usually provided with work-holding fixtures and may be constructed as plain or multiple-spindle machines, simple or duplex.

Planer-type millers are used only on the heaviest work. They are used to machine a number of surfaces on a particular part or group of parts arranged in series in fixtures on the table.

Milling Cutters

Milling cutters are made in a wide variety of shapes and sizes. The nomenclature of tooth parts and angles is standardized as in Fig. 13.4.16. Milling cutters may be classified in various ways, such as purpose or use of the cutters (Woodruff keyseat cutters, T-slot cutters, gear cutters, etc.); construction characteristics (solid cutters, carbide-tipped cutters, etc.); method of mounting (arbor type, shank type, etc.); and relief of teeth. The latter has two categories: profile cutters which produce flat, curved, or irregular surfaces, with the cutter teeth sharpened on the land; and formed cutters which are sharpened on the face to retain true cross-sectional form of the cutter.

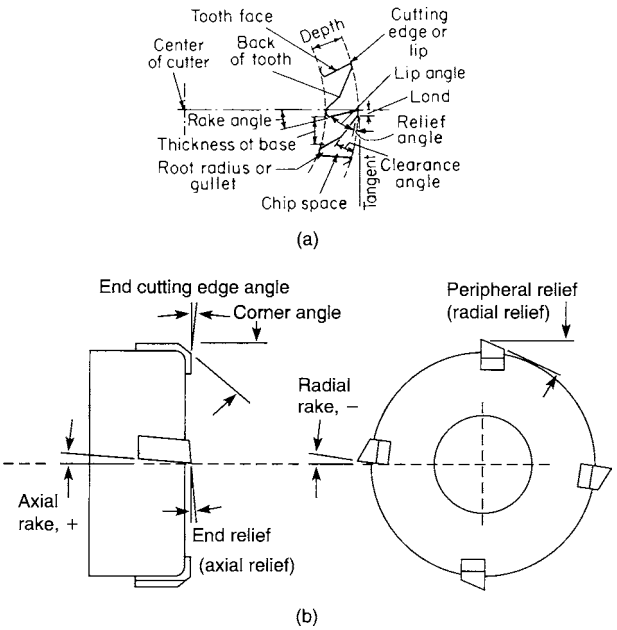

Fig. 13.4.16 (*a*) Plain milling cutter teeth; (*b*) face milling cutter.

Two kinds of milling are generally considered to represent all forms of milling processes: **peripheral (slab)** and **face** milling. In the peripheral-milling process the axis of the cutter is parallel to the surface milled, whereas in face milling, the cutter axis is generally at a right angle to the surface. The peripheral-milling process is also divided into two types: **conventional (up) milling** and **climb (down) milling.** Each has its advantages, and the choice depends on a number of factors such as the type and condition of the equipment, tool life, surface finish, and machining parameters.

Milling Recommendations Recommendations for tool materials, feed per tooth, and cutting speed for milling a variety of materials are

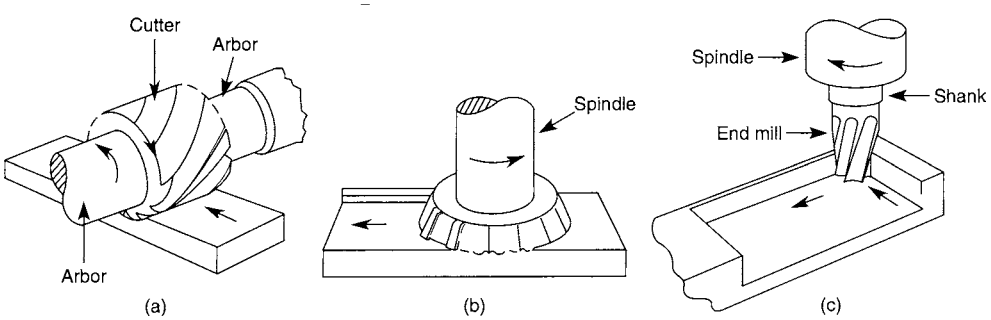

Fig. 13.4.15 Basic types of milling cutters and operations. (*a*) Peripheral milling; (*b*) face milling; (*c*) end milling.

Table 13.4.9 General Recommendations for Milling Operations

Workpiece material	Cutting tool	General-purpose starting conditions: Feed, mm/tooth (in/tooth)	General-purpose starting conditions: Speed, m/min (ft/min)	Range of conditions: Feed, mm/tooth (in/tooth)	Range of conditions: Speed, m/min (ft/min)
Low-C and free-machining steels	Uncoated carbide, coated carbide, cermets	0.13–0.20 (0.005–0.008)	120–180 (400–600)	0.085–0.38 (0.003–0.015)	90–425 (300–1,400)
Alloy steels					
Soft	Uncoated, coated, cermets	0.10–0.18 (0.004–0.007)	90–170 (300–550)	0.08–0.30 (0.003–0.012)	60–370 (200–1,200)
Hard	Cermets, PcBN	0.10–0.15 (0.004–0.006)	180–210 (600–700)	0.08–0.25 (0.003–0.010)	75–460 (250–1,500)
Cast iron, gray					
Soft	Uncoated, coated, cermets, SiN	0.10–0.20 (0.004–0.008)	120–760 (400–2,500)	0.08–0.38 (0.003–0.015)	90–1,370 (300–4,500)
Hard	Cermets, SiN, PcBN	0.10–0.20 (0.004–0.008)	120–210 (400–700)	0.08–0.38 (0.003–0.015)	90–460 (300–1,500)
Stainless steel, austenitic	Uncoated, coated, cermets	0.13–0.18 (0.005–0.007)	120–370 (400–1,200)	0.08–0.38 (0.003–0.015)	90–500 (300–1,800)

Table 13.4.10 General Troubleshooting Guide for Milling Operations

Problem	Probable causes
Tool breakage	Tool material lacks toughness; improper tool angles; cutting parameters too high
Tool wear excessive	Cutting parameters too high; improper tool material; improper tool angles; improper cutting fluid
Rough surface finish	Feed too high; spindle speed too low; too few teeth on cutter; tool chipped or worn; built-up edge; vibration and chatter
Tolerances too broad	Lack of spindle stiffness; excessive temperature rise; dull tool; chips clogging cutter
Workpiece surface burnished	Dull tool; depth of cut too low; radial relief angle too small
Back striking	Dull cutting tools; cutter spindle tilt; negative tool angles
Chatter marks	Insufficient stiffness of system; external vibrations; feed, depth, and width of cut too large
Burr formation	Dull cutting edges or too much honing; incorrect angle of entry or exit; feed and depth of cut too high; incorrect insert geometry
Breakout	Lead angle too low; incorrect cutting edge geometry; incorrect angle of entry or exit; feed and depth of cut too high

given in Table 13.4.9. A general **troubleshooting guide** for milling operations is given in Table 13.4.10.

GEAR MANUFACTURING

(See also Sec. 8.)

Gear Cutting Most gear-cutting processes can be classified as either **forming or generating.** In a forming process, the shape of the tool is reproduced on the workpiece; in a generating process, the shape produced on the workpiece depends on both the shape of the tool and the relative motion between the tool and the workpiece during the cutting operation. In general, a generating process is more accurate than a forming process.

In the **form cutting** of gears, the tool has the shape of the space between the teeth. For this reason, form cutting will produce precise tooth profiles only when the cutter is accurately made and the tooth space is of constant width, such as on spur and helical gears. A form cutter may cut or finish one of or all the spaces in one pass. Single-space cutters may be disk-type or end-mill-type milling cutters. In all single-space operations, the gear blank must be retracted and indexed, i.e., rotated one tooth space, between each pass.

Single-space form milling with disk-type cutters is particularly suitable for gears with large teeth, because, as far as metal removal is concerned, the cutting action of a milling cutter is more efficient than that of the tools used for generating. Form milling of spur gears is done on machines that retract and index the gear blank automatically.

For the same tooth size (pitch), the shape (profile) of the teeth on an involute gear depends on the number of teeth on the gear. Most gears have active profiles that are wholly, partially, or approximately involute,

Table 13.4.11

No. of cutter	1	2	3	4	5	6	7	8
No. of teeth	135–∞	55–134	35–54	27–34	21–26	17–20	14–16	12 and 13
For more accurate gears, 15 cutters are available								
No. of cutter	1	1½	2	2½	3	3½	4	4½
No. of teeth	135–∞	80–134	55–79	42–54	35–41	30–34	26–29	23–25
No. of cutter	5	5½	6	6½	7	7½	8	
No. of teeth	21 and 22	19 and 20	17 and 18	15 and 16	14	13	12	

and, consequently, accurate form cutting would require a different cutter for each number of teeth. In most cases, satisfactory results can be obtained by using the eight cutters for each pitch that are commercially available. Each cutter is designed to cut a range of tooth numbers; the no. 1 cutter, for example, cuts from 135 teeth to a rack, and the no. 8 cuts 12 and 13 teeth. (See Table 13.4.11.)

In a **gear generating machine,** the generating tool can be considered as one of the gears in a conjugate pair and the gear blank as the other gear. The correct relative motion between the tool arbor and the blank arbor is obtained by means of a train of indexing gears within the machine.

One of the most valuable properties of the involute as a gear-tooth profile is that if a cutter is made in the form of an involute gear of a given pitch and any number of teeth, it can generate all gears of all tooth numbers of the same pitch and they will all be conjugate to one another. The generating tool may be a pinion-shaped cutter, a rack-shaped (straight) cutter, or a hob, which is essentially a series of racks wrapped around a cylinder in a helical, screwlike form.

On a **gear shaper,** the generating tool is a pinion-shaped cutter that rotates slowly at the proper speed as if in mesh with the blank; the cutting action is produced by a reciprocation of the cutter parallel to the work axis. These machines can cut spur and helical gears, both internal and external; they can also cut continuous-tooth helical (herringbone) gears and are particularly suitable for cluster gears, or gears that are close to a shoulder.

On a **rack shaper** the generating tool is a segment of a rack that moves perpendicular to the axis of the blank while the blank rotates about a fixed axis at the speed corresponding to conjugate action between the rack and the blank; the cutting action is produced by a reciprocation of the cutter parallel to the axis of the blank. Since it is impracticable to have more than 6 to 12 teeth on a rack cutter, the cutter must be disengaged from the blank at suitable intervals and returned to the starting point, the blank meanwhile remaining fixed. These machines can cut both spur and helical external gears.

A gear-cutting **hob** (Fig. 13.4.17) is basically a worm, or screw, made into a generating tool by cutting a series of longitudinal slots or "gashes" to form teeth; to form cutting edges, the teeth are "backed off," or relieved, in a lathe equipped with a backing-off attachment. A hob may have one, two, or three threads; on involute hobs with a single thread, the generating portion of the hob-tooth profile usually has straight sides (like an involute rack tooth) in a section taken at right angles to the thread.

In addition to the conjugate rotary motions of the hob and workpiece, the hob must be fed parallel to the workpiece axis for a distance greater than the face width of the gear. The feed, per revolution of the workpiece, is produced by the feed gears, and its magnitude depends on the material, pitch, and finish desired; the feed gears are independent of the indexing gears. The hobbing process is continuous until all the teeth are cut.

The same machines and the same hobs that are used for cutting spur gears can be used for helical gears; it is only necessary to tip the hob axis so that the hob and gear pitch helices are tangent to one another and to correlate the indexing and feed gears so that the blank and the hob are advanced or retarded with respect to each other by the amount required to produce the helical teeth. Some hobbing machines have a differential gear mechanism that permits the indexing gears to be selected as for spur gears and the feed gearing to be chosen independently.

The threads of worms are usually cut with a disk-type milling cutter on a thread-milling machine and finished, after hardening, by grinding.

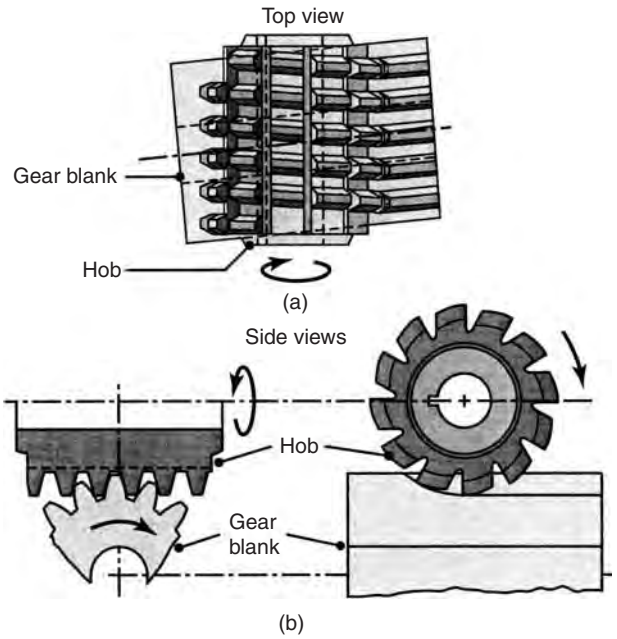

Fig. 13.4.17 A gear-cutting hob.

Worm gears are usually cut with a hob on the machines used for hobbing spur and helical gears. Except for the gashes, the relief on the teeth, and an allowance for grinding, the hob is a counterpart of the worm. The hob and workpiece axes are inclined to one another at the shaft angle of the worm and gear set, usually 90°. The hob may be fed in to full depth in a radial (to the blank) direction or parallel to the hob axis.

Although it is possible to approximate the true shape of the teeth on a straight bevel gear by taking two or three cuts with a form cutter on a milling machine, this method, because of the taper of the teeth, is obviously unsuited for the rapid production of accurate teeth. Most straight bevel gears are roughed out in one cut with a form cutter on machines that index automatically and then finished to the proper shape on a generator.

The generating method used for straight bevel gears is analogous to the rack-generating method used for spur gears. Instead of using a rack with several complete teeth, however, the cutter has only one straight cutting edge that moves, during generation, in the plane of the tooth of a basic crown gear conjugate to the gear being generated. A crown gear is the rack among bevel gears; its pitch surface is a plane, and its teeth have straight sides.

The generating cutter moves back and forth across the face of the bevel gear like the tool on a shaper; the "generating roll" is obtained by rotating the gear slowly relative to the tool. In practice two tools are used, one for each side of a tooth; after each tooth has been generated, the gear must be retracted and indexed to the next tooth.

The machines used for cutting spiral bevel gears operate on essentially the same principle as those used for straight bevel gears; only the

cutter is different. The spiral cutter is basically a disk that has a number of straight-sided cutting blades protruding from its periphery on one side to form the rim of a cup. The machines have means for indexing, retracting, and producing a generating roll; by disconnecting the roll gears, spiral bevel gears can be form cut.

Gear Shaving For improving the surface finish and profile accuracy of cut spur and helical gears (internal and external), gear shaving, a free-cutting gear finishing operation that removes small amounts of metal from the working surfaces of the teeth, is employed. The teeth on the shaving cutter, which may be in the form of a pinion (spur or helical) or a rack, have a series of sharp-edged rectangular grooves running from tip to root. The intersection of the grooves with the tooth profiles creates cutting edges; when the cutter and the workpiece, in tight mesh, are caused to move relative to one another along the teeth, the cutting edges remove metal from the teeth of the work gear. Usually the cutter drives the workpiece, which is free to rotate and is traversed past the cutter parallel to the workpiece axis. Shaving requires less time than grinding, but ordinarily it cannot be used on gears harder than approximately 400 HB (42 HRC).

Gear Grinding Machines for the grinding of spur and helical gears utilize either a forming or a generating process. For form grinding, a disk-type grinding wheel is dressed to the proper shape by a diamond held on a special dressing attachment; for each number of teeth a special index plate, with V-type notches on its periphery, is required. When grinding helical gears, means for producing a helical motion of the blank must be provided.

For grinding-generating, the grinding wheel may be a disk-type, double-conical wheel with an axial section equivalent to the basic rack of the gear system. A master gear, similar to the gear being ground, is attached to the workpiece arbor and meshes with a master rack; the generating roll is created by rolling the master gear in the stationary rack.

Spiral bevel and hypoid gears can be ground on the machines on which they are generated. The grinding wheel has the shape of a flaring cup with a double-conical rim having a cross section equivalent to the surface that is the envelope of the rotary cutter blades.

Gear Rolling The cold-rolling process is used for the finishing of spur and helical gears for automatic transmissions and power tools; in some cases it has replaced gear shaving. It differs from cutting in that the metal is not removed in the form of chips but is displaced under heavy pressure. (See Sec. 13.2.)

There are two main types of cold-rolling machines, namely, those employing dies in the form of racks or gears that operate in a parallel-axis relationship with the blank and those employing worm-type dies that operate on axes at approximately 90° to the workpiece axis. The dies, under pressure, create the tooth profiles by the plastic deformation of the blank.

When racks are used, the process resembles thread rolling; with gear-type dies the blank can turn freely on a shaft between two dies, one mounted on a fixed head and the other on a movable head. The dies have the same number of teeth and are connected by gears to run in the same direction at the same speed. In operation, the movable die presses the blank into contact with the fixed die, and a conjugate profile is generated on the blank. On some of these machines the blank can be fed axially, and gears can be rolled in bar form to any convenient length.

On machines employing worm-type dies, the two dies are diametrically opposed on the blank and rotate in opposite directions. The speeds of the blank and the dies are synchronized by change gears, like the blank and the hob on a hobbing machine; the blank is fed axially between the dies.

PLANING AND SHAPING

Planers are used to rough and finish large flat surfaces, although arcs and special forms can be made with proper tools and attachments. Surfaces to be finished by scraping, such as ways and long dovetails and, particularly, parts of machine tools, are, with few exceptions, planed. With fixtures to arrange parts in parallel and series, quantities of small parts can be produced economically on planers. **Shapers** are used for miscellaneous planing, surfacing, notching, key seating, and production of flat surfaces on small parts. The tool is held in a holder supported on a clapper on the end of a ram which is reciprocated hydraulically or by crank and rocker arm, in a straight line.

BROACHING

Broaching is a production process whereby a cutter, called a **broach,** is used to finish internal or external surfaces such as holes of circular, square, or irregular section, keyways, the teeth of internal gears, multiple spline holes, and flat surfaces. Broaching round holes gives greater accuracy and better finish than reaming, but since the broach may be guided only by the workpiece it is cutting, the hole may not be accurate with respect to previously machined surfaces. Where such accuracy is required, it is better practice to broach first and then turn other surfaces with the workpiece mounted on a mandrel. The broach is usually long and is provided with many teeth so graded in size that each takes a small chip when the tool is pulled or pushed through the previously prepared leader hole or past the surface.

The main features of the broach are the pitch, degree of taper or increase in height of each successive tooth, relief, tooth depth, and rake.

The **pitch** of the teeth, i.e., the distance from one tooth to the next, depends upon tooth strength, length of cut, shape and size of chips, etc. The pitch should be as coarse as possible to provide ample chip clearance, but at least two teeth should be in contact with the workpiece at all times. The formula $p = 0.35\sqrt{l}$ may be used, where p is pitch of the roughing teeth and l the length of hole or surface, in. An average pitch for small broaches is ⅛ to ¼ in (3.175 to 6.35 mm) and for large ones ½ to 1 in (12.7 to 25.4 mm). Where the hole or other surface to be broached is short, the teeth are often cut on an angle or helix, so as to give more continuous cutting action by having at least two teeth cutting simultaneously.

The degree of **taper,** or increase in size per tooth, depends largely on the hardness or toughness of the material to be broached and the finish desired. The degree of taper or feed for broaching cast iron is approximately double that for steel. Usually the first few teeth coming in contact with the workpiece are undersize but of uniform taper to take the greatest feeds per tooth, but as the finished size is approached, the teeth take smaller and smaller feeds with several teeth at the finishing end of nearly zero taper. In some cases, for soft metals and even cast iron, the large end is left plain or with rounded lands a trifle larger than the last cutting tooth so as to burnish the surface. For medium-sized broaches, the taper per tooth is 0.001 to 0.003 in (0.025 to 0.076 mm). Large broaches remove 0.005 to 0.010 in (0.127 to 0.254 mm) per tooth or even more. The teeth are given a **front rake** angle of 5 to 15° to give a curl to the chip, provide a cleaner cut surface, and reduce the power consumption. The **land** back of the cutting edge, which may be 1/64 to 1/16 in (0.4 to 1.6 mm) wide, usually is provided with a land relief varying from 1 to 3° with a clearance of 30 to 45°.

The heavier the feed per tooth or the longer the surface being broached, the greater must be the **chip clearance** or space between successive teeth for the chips to accumulate. The root should be a smooth curve.

Broaches are generally made of M2 or M7 high-speed steel; carbide is also used for the teeth of large broaches. Broaches of complicated shape are likely to warp during the heat-treating process. For this reason, in hardening, they are often heated in a vertical cylindrical furnace and quenched by being hung in an air blast furnished from small holes along the side of pipes placed vertically about the broach.

Push broaches are usually shorter than pull broaches, being 6 to 14 in (150 to 350 mm) long, depending on their diameter and the amount of metal to be removed. In many cases, for accuracy, four to six broaches of the push type constitute a set used in sequence to finish the surface being broached. Push broaches usually have a large cross-sectional area so as to be sufficiently rigid. With **pull broaches,** pulling tends to straighten the hole, whereas pushing permits the broaches to follow any irregularity of the leader hole. Pull broaches are attached to the crosshead of the broaching machine by means of a key slot and key, by a threaded connection, or by a head that fits into an automatic broach

puller. The threaded connection is used where the broach is not removed from the drawing head while the workpiece is placed over the cutter, as in cutting a keyway. In enlarging holes, however, the small end of the pull broach must first be extended through the reamed, drilled, or cored hole and then fixed in the drawing head before being pulled through the workpiece.

Broaching Machines Push broaching is done on machines of the press type with a sort of fixture for holding the workpiece and broach or on presses operated by power. They are usually vertical and may be driven hydraulically or by screw, rack, or crank. The pull type of broach may be either vertical or horizontal. The ram may be driven hydraulically or by screw, rack, or crank. Both are made in the duplex- and multiple-head type.

Processing Parameters for Broaching Cutting speeds for broaching may range from 5 ft/min (1.5 m/min) for high-strength materials to as high as 30 to 50 ft/min (9 to 15 m/min) for aluminum and magnesium alloys. The most common tool materials are M2 and M7 high-speed steels and carbides. An emulsion is often used for broaching for general work, but oils may also be used.

CUTTING OFF

Cutting off involves parting or slotting bars, tubes, plate, or sheet by various means. The machines come in various types such as a lathe (using a single-point cutting tool), hacksaws, band saws, circular saws, friction saws, and thin abrasive wheels. Cutting off may also be carried out by shearing and cropping, as well as using flames and laser beams.

In **power hacksaws,** the frame in which the blade is strained is reciprocated above the workpiece which is held in a vise on the bed. The cutting feed is effected by weighting the frame, with 12 to 50 lb (55 to 225 N) of force from small to large machines; adding weights or spring tension giving up to 180 lb (800 N); providing a positive screw feed or a friction screw feed; and by a hydraulic feed mechanism giving forces up to 300 lb (1.34 kN) between the blade and workpiece. With highspeed steel blades, cutting speeds range from about 30 strokes per minute for high-strength materials to 180 strokes per minute for carbon steels.

Hacksaw **blades** for hand frames are made 8,10, and 12 in long, 7/16 to 9/16 in wide, and 0.025 in thick. Number of teeth per inch for cutting soft steel or cast iron, 14; tool steel and angle iron, 18; brass, copper, and heavy tubing, 24; sheet metal and thin tube, 32. Blades for power hacksaws are made of alloy steels and of high-speed steels. Each length is made in two or more widths. The coarsest teeth should be used on large workpieces and with heavy feeds.

Band saws, vertical, horizontal, and universal, are used for cutting off. The kerf or width of cut is small with a consequently small loss in expensive material. The teeth of band saws, like those of hacksaws, are set with the regular alternate type, one bent to the right and the next to the left; or with the alternate and center set, in which one tooth is bent to the right, the second to the left, and the third straight in the center. With high-speed steel saw blades, band speeds range from about 30 ft/min (10 m/min) for high-temperature alloys to about 400 (120) for carbon steels. For aluminum and magnesium alloys the speed ranges up to about 1,300 ft/min (400 m/min) with high-carbon blades. The band speed should be decreased as the workpiece thickness increases.

Circular saws are made in a wide variety of styles and sizes. Circular saws may have teeth of several shapes, as radial face teeth for small fine-tooth saws; radial face teeth with a land for fine-tooth saws; alternate bevel-edged teeth to break up the chips, with every other tooth beveled 45° on each side with the next tooth plain; alternate side-beveled teeth; and one tooth beveled on the right, the next on the left, and the third beveled on both sides, each leaving slightly overlapping flats on the periphery of the teeth. The most common high-speed steels for circular saws are M2 and M7; saws also may have welded carbide teeth for better performance.

Abrasive cutoff wheels are made of thin resinoid or rubber bonded abrasives. The wheels operate at surface speeds of 12,000 to 16,000 ft/min (3,600 to 4,800 m/min). These wheels are used for cutting off tubes, shapes, and hardened high-speed steel.

Friction sawing machines are used largely for cutting off structural shapes. Peripheral speeds of about 20,000 ft/min (6,000 m/min) are used. The wheels may be plain on the periphery, V-notched, or with milled square notches.

ABRASIVE PROCESSES

(See also Sec. 6.)

Abrasive processes consist of a variety of operations in which the tool is made of an abrasive material, the most common examples of which are grinding (using wheels, known as **bonded abrasives**), honing, and lapping. An abrasive is a small, nonmetallic hard particle having sharp cutting edges and an irregular shape. Abrasive processes, which can be performed on a wide variety of metallic and nonmetallic materials, remove material in the form of tiny chips and produce surface finishes and dimensional accuracies that are generally not obtainable through other machining or manufacturing processes.

Grinding wheels have characteristics influenced by (1) type of abrasive; (2) grain size; (3) grade; (4) structure; and (5) type of bond. (See Figs. 13.4.18 and 13.4.19.)

Selection of Abrasive Although a number of natural abrasives are available, such as emery, corundum, quartz, garnet, and diamond, the most commonly used abrasives in grinding wheels are **aluminum oxide** and **silicon carbide,** the former being more commonly used than the latter. Aluminum oxide is softer than silicon carbide, and because of its friability and low attritious wear it is suitable for most applications. Silicon carbide is used for grinding aluminum, magnesium, titanium, copper, tungsten, and rubber. It is also used for grinding very hard and brittle materials such as carbides, ceramics, and stones. **Diamond** and **cubic boron nitride** grains are used to grind very hard materials and are known as **superabrasives.**

Selection of **grain size** depends on the rate of material removal desired and the surface finish. Coarse grains are used for fast removal of stock; fine grain for low removal rates and for fine finish. Coarse grains are also used for ductile materials and a finer grain for hard and brittle materials.

The **grade** of a grinding wheel is a measure of the strength of its bond. The force that acts on the grain in grinding depends on process variables (such as speeds, depth of cut, etc.) and the strength of the work material. Thus a greater force on the grain will increase the possibility of dislodging the grain; if the bond is too strong, the grain will tend to get dull, and if it is too weak then wheel wear will be high. If glazing occurs, the wheel is **acting hard;** reducing the wheel speed or increasing the work speed or the depth of cut causes the wheel to **act softer.** If the wheel breaks down too rapidly, reversing this procedure will make the wheel act harder. Harder wheels are generally recommended for soft work materials, and vice versa.

A variety of **bond** types are used in grinding wheels; these are generally categorized as **organic** and **inorganic.** Organic bonds are materials such as resin, rubber, shellac, and other similar bonding agents. Inorganic materials are glass, clay, porcelain, sodium silicate, magnesium oxychloride, and metal. The most common bond type is the vitrified bond which is composed of clay, glass, porcelain, or related ceramic materials. This type of bond is brittle and produces wheels that are rigid, porous, and resistant to oil and water. The most flexible bond is rubber which is used in making very thin, flexible wheels. Wheels subjected to bending strains should be made with organic bonds. In selecting a bonding agent, attention should be paid to its sensitivity to temperature, stresses, and grinding fluids, particularly over a period of time. The term **reinforced** as applied to grinding wheels indicates a class of organic wheels which contain one or more layers of strengthening fabric or filament, such as fiberglass. This term does not cover wheels with reinforcing elements such as steel rings, steel cup backs, or wire or tape winding. Fiberglass and filament reinforcing increases the ability of wheels to withstand operational forces when cracked.

The **structure** of a wheel is important in two aspects: It supplies a clearance for the chip, and it determines the number of cutting points on the wheel.

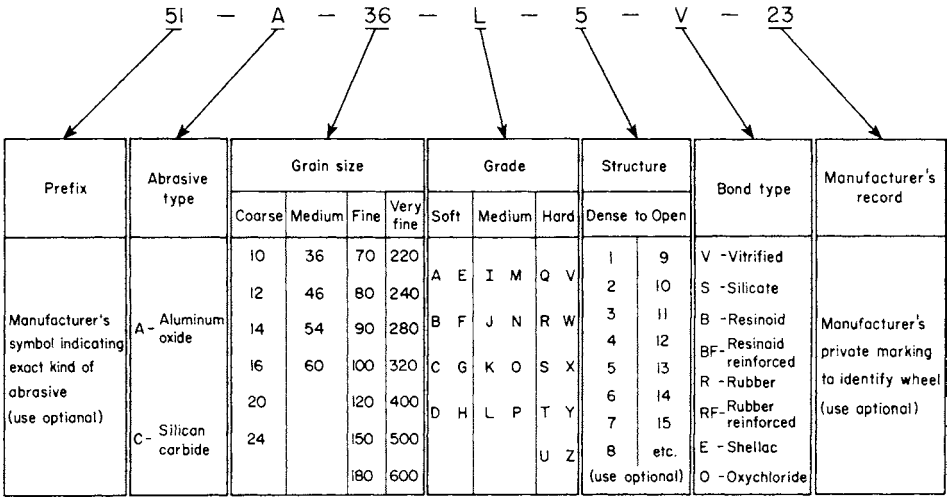

Fig. 13.4.18 Standard marking system chart for aluminum oxide and silicon carbide bonded abrasives.

In addition to wheel characteristics, grinding wheels come in a very large variety of shapes and dimensions. They are classified as **types,** such as type 1: straight wheels, type 4: taper side wheels, type 12: dish wheels, etc.

The **grinding ratio** is defined as the ratio of the volume of material removed to the volume of wheel wear. The grinding ratio depends on parameters such as the type of wheel, workpiece speed, wheel speed, cross-feed, down-feed, and the grinding fluid used. Values ranging from a low of 2 to over 200 have been observed in practice. A high grinding ratio, however, may not necessarily result in the best surface integrity of the part.

Wheel Speeds Depending on the type of wheel and the type and strength of bond, wheel speeds for standard applications range between 4,500 and 16,000 surface ft/min (1,400 and 4,800 m/min). The lowest speeds are for low-strength, inorganic bonds whereas the highest speeds are for high-strength organic bonds. The majority of surface grinding operations are carried out at speeds from 5,500 to 6,500 ft/min (1,750 to 2,000 m/min). The trend is toward high-efficiency grinding where wheel speeds from 12,000 to 18,000 ft/min (3,600 to 5,500 m/min) are employed.

It has been found that, by increasing the wheel speed, the rate of material removal can be increased, thus making the process more economical. This, of course, requires special grinding wheels to withstand the high stresses. Design changes or improvements involve items such as a composite wheel with a vitrified bond on the outside and a resinoid bond toward the center of the wheel; elimination of the central hole of the wheel by providing small bolt holes; and clamping of wheel segments instead of using a one-piece wheel. Grinding machines for such high-speed applications have requirements such as rigidity, high work and wheel speeds, high power, and special provisions for safety.

Workpiece speeds depend on the size and type of workpiece material and on whether it is rigid enough to hold its shape. In surface grinding, table speeds generally range from 50 to 100 ft/min (15 to 30 m/ min); for cylindrical grinding, work speeds from 70 to 100 ft/min (20 to 30 m/min), and for internal grinding they generally range from 75 to 200 ft/min (20 to 60 m/min).

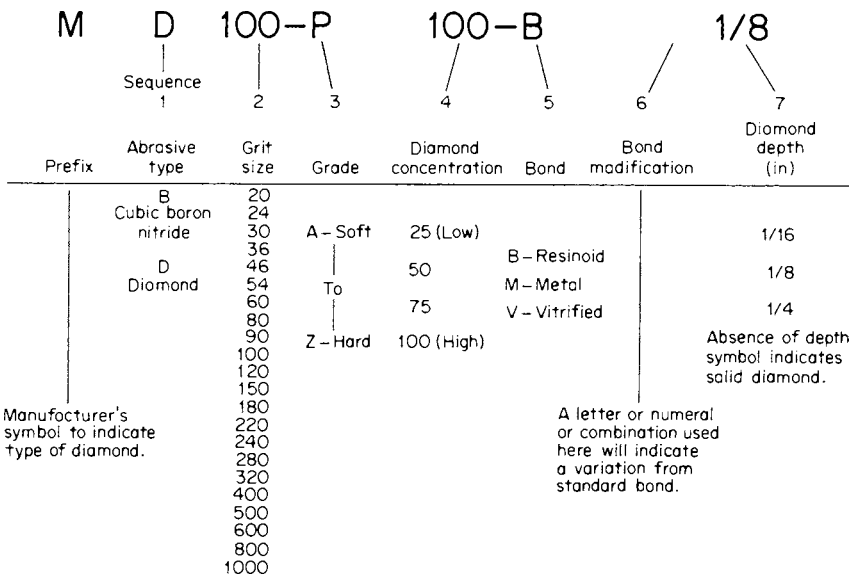

Fig. 13.4.19 Standard marking system chart for diamond tool and cubic boron nitride (cBN) bonded abrasives.

Cross-feed depends on the width of the wheel. In roughing, the workpiece should travel past the wheel ¾ to ⅞ of the width of the wheel for each revolution of the work. As the workpiece travels past the wheel with a helical motion, the preceding rule allows a slight overlap. In finishing, a finer feed is used, generally 1/10 to ¼ of the width of the wheel for each revolution of the workpiece.

Depth of Cut In the roughing operation, the depth of cut should be all the wheel will stand. This varies with the hardness of the material and the diameter of the workpiece. In the finishing operation, the depth of cut is always small: 0.0005 to 0.001 in (0.013 to 0.025 mm). Good results as regards finish are obtained by letting the wheel run over the workpiece several times without cross-feeding.

Grinding Allowances From 0.005 to 0.040 in (0.13 to 1 mm) is generally removed from the diameter in rough grinding in a cylindrical machine. For finishing, 0.002 to 0.010 in (0.05 to 0.25 mm) is common. Workpieces can be finished by grinding to a tolerance of 0.0002 in (0.005 mm) and a surface roughness of 50+ μin R_q (1.2 μm).

In situations where grinding leaves unfavorable surface **residual stresses,** the technique of **gentle** or **low-stress** grinding may be employed. This generally consists of removing a layer of about 0.010 in (0.25 mm) at depths of cut of 0.0002 to 0.0005 in (0.005 to 0.013 mm) with wheel speeds that are lower than the conventional 5,500 to 6,500 ft/min.

Truing and Dressing In **truing,** a diamond supported in the end of a soft steel rod held rigidly in the machine is passed over the face of the wheel two or three times to remove just enough material to give the wheel its true geometric shape. **Dressing** is a more severe operation of removing the dull or loaded surface of the wheel. Abrasive sticks or wheels or steel star wheels are pressed against and moved over the wheel face.

Safety If not stored, handled, and used properly, a grinding wheel can be a very dangerous tool. Because of its mass and high rotational speed, a grinding wheel has considerable energy and, if it fractures, it can cause serious injury and even death to the operator or to personnel nearby. A safety code B7.1 entitled "The Use, Care, and Protection of Abrasive Wheels" is available from ANSI; other safety literature is available from the Grinding Wheel Institute and from the National Safety Council.

The salient features of safety in the use of grinding wheels may be listed as follows: Wheels should be stored and handled carefully; a wheel that has been dropped should not be used. Before it is mounted on the machine, a wheel should be visually inspected for possible cracks; a simple "ring" test may be employed whereby the wheel is tapped gently with a light nonmetallic implement and if it sounds cracked, it should not be used. The wheel should be mounted properly with the required blotters and flanges, and the mounting nut tightened not excessively. The label on the wheel should be read carefully for maximum operating speed and other instructions. An appropriate guard should always be used with the machine, whether portable or stationary.

Newly mounted wheels should be allowed to run idle at the operating speed for at least 1 min before grinding. The operator should always wear safety glasses and should not stand directly in front of a grinding wheel when a grinder is started. If a grinding fluid is used, it should be turned off first before stopping the wheel to avoid creating an out-of-balance condition. Because for each type of operation and workpiece material there usually is a specific type of wheel recommended, the operator must make sure that the appropriate wheel has been selected.

Grinders

Grinding machines may be classified as to purpose and type as follows: for **rough removal of stock,** the swinging-frame, portable, flexible shaft, two-wheel stand, and disk; **cutting off** or parting, the cutting-off machine; **surface finishing,** band polisher, two-wheel combination, two-wheel polishing machine, two-wheel buffing machine, and semiautomatic polishing and buffing machine; **precision grinding,** tool post, cylindrical (plain and universal), crankshaft, centerless, internal, and surface (reciprocating table with horizontal or vertical wheel spindle, and rotary table with horizontal or vertical wheel spindle); **special form** grinders, gear or worm, ball-bearing balls, cams, and threads; and **tool and cutter** grinders for single-point tools, drills, and milling cutters, reamers, taps, dies, knives, etc.

Grinding equipment of all types (many with computer controls) has been improved during the past few years so as to be more rigid, provide more power to the grinding wheel, and provide automatic cycling, loading, clamping, wheel dressing, and automatic feedback.

Centerless grinders are used to good advantage where large numbers of relatively small pieces must be ground and where the ground surface has no exact relation to any other surface except as a whole; the work is carried on a support between two abrasive wheels, one a normal grinding wheel, the second a rubber-bonded wheel, rotating at about 1/20th the grinding speed, and is tilted 3 to 8° to cause the work to rotate and feed past the grinding wheel (see also Sec. 6).

The **cylindrical grinder** is a companion machine to the engine lathe; shafts, cylinders, rods, studs, and a wide variety of other cylindrical parts are first roughed out on the lathe, then finished accurately to size by the cylindrical grinder. The work is carried on centers, rotated slowly, and traversed past the face of a grinding wheel.

Universal grinders are cylindrical machines arranged with a swiveling table so that both straight and taper internal and external work can be ground. **Drill grinders** are provided with rests so mounted that by a simple swinging motion, correct cutting angles are produced automatically on the lips of drills; a cupped wheel is usually employed. **Internal grinders** are used for finishing the holes in bushings, rolls, sleeves, cutters, and the like; spindle speeds from 15,000 to 30,000 r/min are common.

Horizontal surface grinders range from small capacity, used mainly in tool making or small production work, to large sizes used for production work.

Vertical surface grinders are used for producing flat surfaces on production work. **Vertical** and **horizontal disk grinders** are used for surfacing. Grinding machines are used for **cutting off** steel, especially tubes, structural shapes, and hard metals. A thin resinoid or rubber-bonded wheel is used, with aluminum oxide abrasive for all types of steel, aluminum, brass, bronze, nickel, Monel, and Stellite; silicon carbide for cast iron, copper, carbon, glass, stone, plastics, and other nonmetallic materials; and diamond for cemented carbides and ceramics.

Belt grinders use a coated abrasive belt running between pulleys. Belt grinding is generally considered to be a roughing process, but finer finishes may be obtained by using finer grain size. Belt speeds generally range from 2,000 to 10,000 ft/min (600 to 3,000 m/min) with grain sizes ranging between 24 and 320, depending on the workpiece material and the surface finish desired. The process has the advantage of high-speed material removal and is applied to flat as well as irregular surfaces.

Although grinding is generally regarded as a finishing operation, it is possible to increase the rate of stock removal whereby the process becomes, in certain instances, competitive with milling. This type of grinding operation is usually called **creep-feed grinding.** It uses equipment such as reciprocating table or vertical-spindle rotary table surface grinders with capacities up to 300 hp (220 kW). The normal stock removal may range up to ¼ in (6.4 mm) with wheel speeds between 3,400 and 5,000 surface ft/min (1,000 and 1,500 m/min).

Finishing Operations

Polishing is an operation by which scratches or tool marks or, in some instances, rough surfaces left after forging, rolling, or similar operations are removed. It is not a precision operation. The nature of the polishing process has been debated for a long time. Two mechanisms appear to play a role: One is fine-scale abrasion, and the other is softening of surface layers. In addition to removal of material by the abrasive particles, the high temperatures generated because of friction soften the asperities of the surface of the workpiece, resulting in a smeared surface layer. Furthermore, chemical reactions may also take place in polishing whereby surface irregularities are removed by chemical attack.

Polishing is usually done in stages. The first stage is rough polishing, using abrasive grain sizes of about 36 to 80, followed by a second stage, using an abrasive size range of 80 to 120, a third stage of size 150 and finer, etc., with a final stage of buffing. For the first two steps the polishing wheels are used dry. For finishing, the wheels are first worn down a little and then coated with tallow, oil, beeswax, or similar substances. This step is partly polishing and partly buffing, as additional

abrasive is often added in cake form with the grease. The cutting action is freer, and the life of the wheel is prolonged by making the wheel surface flexible. Buffing wheels are also used for the finishing step when tallow, etc., containing coarse or fine abrasive grains is periodically rubbed against the wheel.

Polishing wheels consisting of wooden disks faced with leather, turned to fit the form of the piece to be polished, are used for flat surfaces or on work where it is necessary to maintain square edges. A large variety of other types of wheels are in common use. Compress wheels are used extensively and are strong, durable, and easily kept in balance. They consist of a steel center the rim of which holds a laminated surface of leather, canvas, linen, felt, rubber, etc., of various degrees of pliability. Wheels of solid leather disks of walrus hide, buffalo hide, sheepskin, or bull's neck hide, or of soft materials such as felt, canvas, and muslin, built up of disks either loose, stitched, or glued, depending on the resiliency or pliability required, are used extensively for polishing as well as buffing. **Belts** of cloth or leather are often charged with abrasive for polishing flat or other workpieces. Wire brushes may be used with no abrasive for a final operation to give a satin finish to nonferrous metals.

For most polishing operations speeds range from 5,000 to 7,500 surface ft/min (1,500 to 2,250 m/min). The higher range is for high-strength steels and stainless steels. Excessively high speeds may cause burning of the workpiece and glazing.

Mirrorlike finishes may be obtained by **electropolishing,** a process that is the reverse of electroplating; it is particularly useful for polishing irregularly shaped workpieces which otherwise would be difficult to polish uniformly. A more recent specialized process is **magnetic-field polishing,** in which fine abrasive polishing particles are suspended in a magnetic fluid. This process is effective for polishing ceramic balls, such as ball bearings. The **chemical-mechanical polishing** process combines the actions of abrasive particles, suspended in a water-based solution, with a chemistry selected to cause controlled corrosion. It produces exceptionally flat surfaces with very fine surface finish, particularly important in polishing silicon wafers for the semiconductor industry.

Buffing is a form of finish polishing in which the surface finish is improved; very little material is removed. The powdered abrasives are applied to the surface of the wheel by pressing a mixture of abrasive and tallow or wax against the face for a few seconds. The abrasive is replenished periodically. The wheels are made of a soft pliable material, such as soft leather, felt, linen, or muslin, and rotated at high speed.

A variety of buffing compounds are available: aluminum oxide, chromium oxide, soft silica, rouge (iron oxide), pumice, lime compounds, emery, and crocus. In cutting down nonferrous metals, Tripoli is used; and for steels and stainless steels, aluminum oxide is the common abrasive. For coloring, soft silica, rouge, and chromium oxide are the more common compounds used. Buffing speeds range from 6,000 to 10,000 surface ft/min (1,800 to 3,000 m/min); the higher speeds are for steels, although the speed may be as high at 12,000 surface ft/min (3,600 m/min) for coloring brass and copper.

Lapping is a process of producing extremely smooth and accurate surfaces by rubbing the surface which is to be lapped against a mating form which is called a **lap.** The lap may either be charged with a fine abrasive and moistened with oil or grease, or the fine abrasive may be introduced with the oil. If a part is to be lapped to a final accurate dimension, a mating form of a softer material such as soft close-grained cast iron, copper, brass, or lead is made up. Aluminum oxide, silicon carbide, and diamond grits are used for lapping. Lapping requires considerable time. No more than 0.0002 to 0.0005 in (0.005 to 0.013 mm) should be left for removal by this method. Surface plates, rings, and plugs are common forms of laps. For most applications grit sizes range between 100 and 800, depending on the finish desired. For most efficient lapping, speeds generally range from 300 to 800 surface ft/min (150 to 240 m/min) with pressures of 1 to 3 lb/in^2 (7 to 21 kPa) for soft materials and up to 10 lb/in^2 (70 kPa) for harder materials.

Honing is an operation similar to lapping. Instead of a metal lap charged with fine abrasive grains, a honing stone made of fine abrasives is used. Small stones of various cross-sectional shapes and lengths are manufactured for honing the edges of cutting tools. Automobile cylinders are honed for fine finish and accurate dimensions. This honing usually follows a light-finish reaming operation or a precision-boring operation using diamonds or carbide tools. The tool consists of several honing stones adjustable at a given radius or forced outward by springs or a wedge forced mechanically or hydraulically and is given a reciprocating (25 to 40 per min) and a rotating motion (about 300 r/min) in the cylinder which is flooded with kerosine.

Hones operate at speeds of 50 to 200 surface ft/min (15 to 60 m/min) and use universal joints to allow the tool to center itself in the workpiece. The automatic pressure-cycle control of hone expansion, in which the pressure is reduced in steps as the final finish is reached, removes metal 10 times as fast as with the spring-expanded hone. Rotational and reciprocating movements are provided to give an uneven ratio and thus prevent an abrasive grain from ever traversing its own path twice.

Superfinishing is a honing process. Formed honing stones bear against the workpiece previously finished to 0.0005 in (0.013 mm) or at the most to 0.001 in (0.025 mm) by a very light pressure which gradually increases to several pounds per square inch (1 lb/in^2 = 0.0069 MPa) of stone area in proportion to the development of the increased area of contact between the workpiece and stone. The workpiece or tool rotates and where possible is reciprocated slowly over the surface which may be finished in a matter of 20 s to a surface quality of 1 to 3 μin (0.025 to 0.075 μm). Superfinishing is applied to many types of workpieces such as crankshaft pins and bearings, cylinder bores, pistons, valve stems, cams, and other metallic moving parts.

Deburring involves removing burrs (thin ridges, generally triangular, resulting from operations such as punching and blanking of sheet metals, and from machining and drilling) along the edges of a workpiece. Several deburring operations are available, the most common ones being manual filing, wire brushing, using abrasives (emery paper, belts, abrasive blasting), and vibratory and barrel finishing. Deburring operations can also be carried out using programmable robots.

MACHINING AND GRINDING OF PLASTICS

The low strength of thermoplastics permits high cutting speeds and feeds, but the low heat conductivity and greater resilience require increased reliefs and less rake in order to avoid undersize cutting. Hard and sharp tools should be used. Plastics are usually abrasive and cause the tools to wear or become dull rapidly. Dull tools generate heat and cause the tools to cut to shallow depths. The depth of cut should be small. When high production justifies the cost, diamond turning and boring tools are used. Diamond tools maintain sharp cutting edges and produce an excellent machined surface. They are particularly advantageous when a more abrasive plastic such as reinforced plastic is machined.

A cutting fluid, such as a small blast of air or a stream of water, improves the **turning** and cutting of plastics as it prevents the heating of the tool and causes the chips to remain brittle and to break rather than become sticky and gummy. A zero or slightly negative back rake and a relief angle of 8 to 12° should be used. For thermoplastics cutting speeds generally range from 250 to 400 ft/min (75 to 120 m/min) and for thermosetting plastics from 400 to 1,000 ft/min (120 to 300 m/min). Recommended tool materials are M2 and T5 high-speed steels and C2 carbide.

In **milling** plastics, speeds of 400 to 1,000 ft/min (120 to 300 m/min) should be used, with angles similar to those on a single-point tool. From 0 to 10° negative rake may be used. Good results have been obtained by hobbing plastic gears with carbide-tipped hobs. Recommended tool materials are M2 and M7 high-speed steels and C2 carbide.

In **drilling,** speeds range from 150 to 400 ft/min (45 to 120 m/min), and the recommended drill geometry is given in Table 13.4.6. Tool materials are M1, M7, and M10 high-speed steel. Usually the drill cuts undersize; drills 0.002 to 0.003 in (0.05 to 0.075 mm) oversize should be used.

In **sawing** plastics, either precision or buttress tooth forms may be used, with a pitch ranging from 3 to 14 teeth/in (1.2 to 5.5 teeth/cm),

the thicker the material the lower the number of teeth per unit length of saw. Cutting speeds for thermoplastics range from 1,000 to 4,000 ft/min (300 to 1,200 m/min) and for thermosetting plastics from about 3,000 to 5,500 ft/min (900 to 1,700 m/min), with the higher speeds for thinner stock. High-carbon-steel blades are recommended. An air blast is helpful in preventing the chips from sticking to the saw. Abrasive saws operating at 3,500 to 6,000 ft/min (1,000 to 1,800 m/min) are also used for cutting off bars and forms.

Plastics are tapped and threaded with standard tools. Ground M1, M7, or M10 high-speed steel **taps** with large polished flutes are recommended. **Tapping speeds** are usually from 25 to 50 ft/min (8 to 15 m/min); water serves as a good cutting fluid as it keeps the material brittle and prevents sticking in the flutes. **Thread cutting** is generally accomplished with tools similar to those used on brass.

Reaming is best accomplished in production by using tools of the expansion or adjustable type with relatively low speeds but high feeds. Less material should be removed in reaming plastics than in reaming other materials.

Polishing and **buffing** are done on many types of plastics. Polishing is done with special compounds containing wax or a fine abrasive. Buffing wheels for plastics should have loose stitching. Vinyl plastics can be buffed and polished with fabric wheels of standard types, using light pressures.

Thermoplastics and thermosets can be **ground** with relative ease, usually by using silicon carbide wheels. As in machining, temperature rise should be minimized.

MACHINING AND GRINDING OF CERAMICS

The technology of machining and grinding of ceramics, as well as composite materials, has advanced rapidly, resulting in good surface characteristics and product integrity. Ceramics can be machined with carbide, high-speed steel, or diamond tools, although care should be exercised because of the brittle nature of ceramics and the resulting possible surface damage. **Machinable ceramics** have been developed which minimize machining problems. Grinding of ceramics is usually done with diamond wheels.

ADVANCED MACHINING PROCESSES

In addition to the mechanical methods of material removal described above, there are a number of other important processes which may be preferred over conventional methods. Among the important factors to be considered are the hardness of the workpiece material, the shape of the part, its sensitivity to thermal damage, residual stresses, tolerances, and economics. Some of these processes produce a heat-affected layer on the surface; improvements in surface integrity may be obtained by postprocessing techniques such as polishing or peening. Almost all machines are now computer-controlled.

Electric-discharge machining (EDM) is based on the principle of erosion of metals by spark discharges. Figure 13.4.20 gives a schematic diagram of this process. The spark is a transient electric discharge through the space between two charged electrodes, which are the tool and the workpiece. The discharge occurs when the potential difference between the tool and the workpiece is large enough to cause a breakdown in the medium (which is called the **dielectric fluid** and is usually a hydrocarbon) and to procure an electrically conductive spark channel. The breakdown potential is usually established by connecting the two electrodes to the terminals of a capacitor charged from a power source. The spacing between the tool and workpiece is critical; therefore, the feed is controlled by servomechanisms. The dielectric fluid has the additional functions of providing a cooling medium and carrying away particles produced by the electric discharge. The discharge is repeated rapidly, and each time a minute amount of workpiece material is removed.

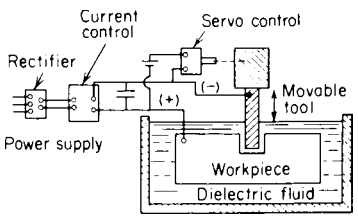

Fig. 13.4.20 Schematic diagram of the electric-discharge machining process.

The rate of metal removal depends mostly on the average current in the discharge circuit; it is also a function of the electrode characteristics, the electrical parameters, and the nature of the dielectric fluid. In practice, this rate is normally varied by changing the number of discharges per second or the energy per discharge. Rates of metal removal may range from 0.01 to 25 in^3/h (0.17 to 410 cm^3/h), depending on surface finish and tolerance requirements. In general, higher rates produce rougher surfaces. Surface finishes may range from 1,000 μin R_q (25 μm) in roughing cuts to less than 25 μin (0.6 μm) in finishing cuts.

The response of materials to this process depends mostly on their thermal properties. Thermal capacity and conductivity, latent heats of melting and vaporization are important. Hardness and strength do not necessarily have significant effect on metal removal rates. The process is applicable to all materials which are sufficiently good conductors of electricity. The tool has great influence on permissible removal rates. It is usually made of graphite, copper-tungsten, or copper alloys. Tools have been made by casting, extruding, machining, powder metallurgy, and other techniques and are made in any desired shape. Tool wear is an important consideration, and in order to control tolerances and minimize cost, the ratio of tool material removed to workpiece material removed should be low. This ratio varies with different tool and workpiece material combinations and with operating conditions. Therefore, a particular tool material may not be best for all workpieces. Tolerances as low as 0.0001 to 0.0005 in (0.0025 to 0.0127 mm) can be held with slow metal removal rates. In machining some steels, tool wear can be minimized by reversing the polarity and using copper tools. This is known as "no-wear EDM."

The electric-discharge machining process has numerous applications, such as machining cavities and dies, cutting small-diameter holes, blanking parts from sheets, cutting off rods of materials with poor machinability, and flat or form grinding. It is also applied to sharpening tools, cutters, and broaches. The process can be used to generate almost any geometry if a suitable tool can be fabricated and brought into close proximity to the workpiece.

Thick plates may be cut with **wire EDM** (Fig. 13.4.21). A slowly moving wire travels a prescribed path along the workpiece and cuts the metal with the sparks acting like saw teeth. The wire, usually about 0.01 in (0.25 mm) in diameter, is made of brass, copper, or tungsten and is generally used only once. The process is also used in making tools and dies from hard materials, provided that they are electrically conducting.

Electric-discharge grinding (EDG) is similar to the electric-discharge machining process with the exception that the electrode is in the form of

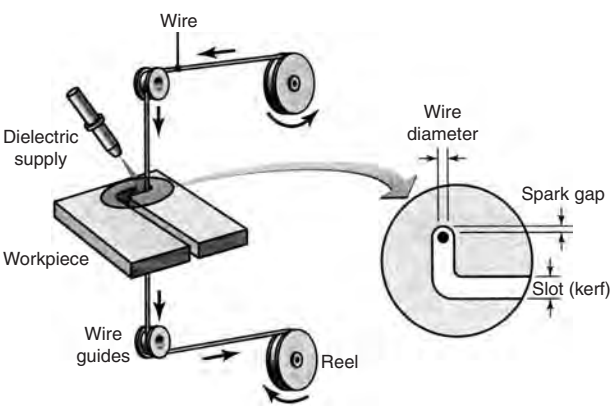

Fig. 13.4.21 Schematic diagram of the wire EDM process.

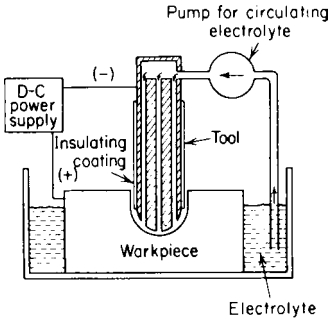

Fig. 13.4.22 Schematic diagram of the electrochemical machining process.

a grinding wheel. Removal rates are up to 1.5 in^3/h (25 cm^3/h) with practical tolerances on the order of 0.001 in (0.025 mm). A graphite or brass electrode wheel is operated around 100 to 600 surface ft/min (30 to 180 m/min) to minimize splashing of the dielectric fluid. Typical applications of this process are in grinding of carbide tools and dies, thin slots in hard materials, and production grinding of intricate forms.

The **electrochemical machining (ECM)** process (Fig. 13.4.22) uses electrolytes which dissolve the reaction products formed on the workpiece by electrochemical action; it is similar to a reverse electroplating process. The electrolyte is pumped at high velocities through the tool. A gap of 0.005 to 0.020 in (0.13 to 0.5 mm) is maintained. A dc power supply maintains very high current densities between the tool and the workpiece. In most applications, a current density of 1,000 to 5,000 A is required per in^2 of active cutting area. The rate of metal removal is proportional to the amount of current passing between the tool and the workpiece. Removal rates up to 1 in^3/min (16 cm^3/min) can be obtained with a 10,000-A power supply. The penetration rate is proportional to the current density for a given workpiece material.

The process leaves a burr-free surface. It is also a cold machining process and does no thermal damage to the surface of the workpiece. Electrodes are normally made of brass or copper; stainless steel, titanium, sintered copper-tungsten, aluminum, and graphite have also been used. The electrolyte is usually a sodium chloride solution up to 2.5 lb/gal (300 g/L); other solutions and proprietary mixtures are also available. The amount of overcut, defined as the difference between hole diameter and tool diameter, depends upon cutting conditions. For production applications, the average overcut is around 0.015 in (0.4 mm). The rate of penetration is up to 0.750 in/min (20 mm/min).

Very good surface finishes may be obtained with this process. However, sharp square corners or sharp corners and flat bottoms cannot be machined to high accuracies. The process is applied mainly to round or odd-shaped holes with straight parallel sides. It is also applied to cases where conventional methods produce burrs which are costly to remove. The process is particularly economical for materials with a hardness above 400 HB.

The **electrochemical grinding (ECG)** process (Fig. 13.4.23) is a combination of electrochemical machining and abrasive cutting where most of the metal removal results from the electrolytic action. The process consists of a rotating cathode, a neutral electrolyte, and abrasive particles in contact with the workpiece. The equipment is similar to a conventional grinding machine except for the electrical accessories. The cathode usually consists of a metal-bonded diamond or aluminum oxide wheel. An important function of the abrasive grains is to maintain a space for the electrolyte between the wheel and workpiece.

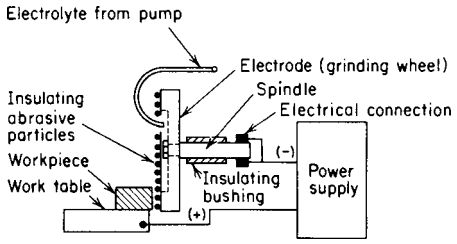

Fig. 13.4.23 Schematic diagram of the electrochemical grinding process.

Surface finish, precision, and metal-removal rate are influenced by the composition of the electrolyte. Aqueous solutions of sodium silicate, borax, sodium nitrate, and sodium nitrite are commonly used as electrolytes. The process is primarily used for tool and cutter sharpening and for machining of high-strength materials.

A combination of the electric-discharge and electrochemical methods of material removal is known as **electrochemical discharge grinding (ECDG).** The electrode is a pure graphite rotating wheel which electrochemically grinds the workpiece. The intermittent spark discharges remove oxide films that form as a result of electrolytic action. The equipment is similar to that for electrochemical grinding. Typical applications include machining of fragile parts and resharpening or form grinding of carbides and tools such as milling cutters.

In **chemical machining (CM)** material is removed by chemical or electrochemical dissolution of preferentially exposed surfaces of the workpiece. Selective attack on different areas is controlled by masking or by partial immersion. There are two processes involved: chemical **milling** and chemical **blanking.** Milling applications produce shallow cavities for overall weight reduction, and are also used to make tapered sheets, plates, or extrusions. Masking with paint or tapes is common. Masking materials may be elastomers (such as butyl rubber, neoprene, and styrene-butadiene) or plastics (such as polyvinyl chloride, polystyrene, and polyethylene). Typical blanking applications are decorative panels, printed-circuit etching, and thin stampings. Etchants are solutions of sodium hydroxide for aluminum, and solutions of hydrochloric and nitric acids for steel.

Ultrasonic machining (USM) is a process in which a tool is given a high-frequency, low-amplitude oscillation, which, in turn, transmits a high velocity to fine abrasive particles that are present between the tool and the workpiece. Minute particles of the workpiece are chipped away on each stroke. Aluminum oxide, boron carbide, or silicone carbide grains are used in a water slurry (usually 50 percent by volume), which also carries away the debris. Grain size ranges from 200 to 1,000 (see Sec. 6 and Figs. 13.4.18 and 13.4.19).

The equipment consists of an electronic oscillator, a transducer, a connecting cone or toolholder, and the tool. The oscillatory motion is obtained most conveniently by magnetostriction, at approximately 20,000 Hz and a stroke of 0.002 to 0.005 in (0.05 to 0.13 mm). The tool material is normally cold-rolled steel or stainless steel and is brazed, soldered, or fastened mechanically to the transducer through a toolholder. The tool is ordinarily 0.003 to 0.004 in (0.075 to 0.1 mm) smaller than the cavity it produces. Tolerances of 0.0005 in (0.013 mm) or better can be obtained with fine abrasives. For best results, roughing cuts should be followed with one or more finishing operations with finer grits. The ultrasonic machining process is used in drilling holes, engraving, cavity sinking, slicing, broaching, etc. It is best suited to materials which are hard and brittle, such as ceramics, carbides, borides, ferrites, glass, precious stones, and hardened steels.

In **water jet machining (WJM),** water is ejected from a nozzle at pressures as high as 200,000 lb/in^2 (1,400 MPa) and acts as a saw. The process is suitable for cutting and deburring of a variety of materials such as polymers, paper, and brick in thicknesses ranging from 0.03 to 1 in (0.8 to 25 mm) or more. The cut can be started at any location, wetting is minimal, and no deformation of the rest of the piece takes place. Abrasives can be added to the water stream to increase material removal rate, and this is known as **abrasive water jet machining (AWJM).**

In **abrasive-jet machining** (AJM), material is removed by fine abrasive particles (aluminum oxide or silicon carbide) carried in a high-velocity stream of air, nitrogen, or carbon dioxide. The gas pressure ranges up to 120 lb/in^2 (800 kPa), providing a nozzle velocity of up to 1,000 ft/s (300 m/s). Nozzles are made of tungsten carbide or sapphire. Typical applications are in drilling, sawing, slotting, and deburring of hard, brittle materials such as glass.

In **laser-beam machining (LBM),** material is removed by converting electric energy into a narrow beam of light and focusing it on the

workpiece. The high energy density of the beam is capable of melting and vaporizing all materials, and consequently, there is a thin heat-affected zone. The most commonly used laser types are CO_2 (pulsed or continuous-wave) and Nd:YAG. Typical applications include cutting a variety of metallic and nonmetallic materials, drilling (as small as 0.0002 in or 0.005 mm in diameter), and marking. The efficiency of cutting increases with decreasing thermal conductivity and reflectivity of the material. Because of the inherent flexibility of the process, programmable and computer-controlled laser cutting is now becoming important, particularly in cutting profiles and multiple holes of various shapes and sizes on large sheets. Cutting speeds may range up to 25 ft/ min (7.5 m/min).

The **electron-beam machining (EBM)** process removes material by focusing high-velocity electrons on the workpiece. Unlike lasers, this process is carried out in a vacuum chamber and is used for drilling small holes, scribing, and cutting slots in all materials, including ceramics.

13.5 SURFACE TEXTURE DESIGNATION, PRODUCTION, AND QUALITY CONTROL

by Ali M. Sadegh

REFERENCES: American National Standards Institute, "Surface Texture," ANSI/ ASME B 46.1-1985, and "Surface Texture Symbols," ANSI Y 14.36-1978. Broadston, "Control of Surface Quality," Surface Checking Gage Co., Hollywood, CA. ASME, "Metals Engineering Design Handbook," McGraw-Hill SME, "Tool and Manufacturing Engineers Handbook," McGraw-Hill.

Rapid changes in the complexity and precision requirements of mechanical products since 1945 have created a need for improved methods of determining, designating, producing, and controlling the surface texture of manufactured parts. Although standards are aimed at standardizing methods for measuring by using stylus probes and electronic transducers for surface quality control, other descriptive specifications are sometimes required, i.e., interferometric light bands, peak-to-valley by optical sectioning, light reflectance by commercial glossmeters, etc. Other parameters are used by highly industrialized foreign countries to solve their surface specification problems. These include the high-spot counter and bearing area meter of England (Talysurf); the total peak-to-valley, or R_1, of Germany (Perthen); and the R or average amplitude of surface deviations of France. In the United States, peak counting is used in the sheet-steel industry, instrumentation is available (Bendix), and a standard for specification, SAE J-911, exists.

Surface texture control should be considered for many reasons, among them being the following:

1. Advancements in the technology of metal-cutting tools and machinery have made the production of higher-quality surfaces possible.
2. Products are now being designed that depend upon proper quality control of critical surfaces for their successful operation as well as for long, troublefree performance in service.
3. Remote manufacture and the necessity for controlling costs have made it preferable that finish requirements for all the critical surfaces of a part be specified on the drawing.
4. The design engineer, who best understands the overall function of a part and all its surfaces, should be able to determine the requirement for surface texture control where applicable and to use a satisfactory standardized method for providing this information on the drawing for use by manufacturing departments.
5. Manufacturing personnel should know what processes are able to produce surfaces within specifications and should be able to verify that the production techniques in use are under control.
6. Quality control personnel should be able to check conformance to surface texture specifications if product quality is to be maintained and product performance and reputation ensured.

DESIGN CRITERIA

Surfaces produced by various processes exhibit distinct differences in texture. These differences make it possible for honed, lapped, polished, turned, milled, or ground surfaces to be easily identified. As a result of its unique character, the surface texture produced by any given process can be readily compared with other surfaces produced by the same process through the simple means of comparing the average size of its irregularities, using applicable standards and modern measurement methods. It is then possible to predict and control its performance with considerable certainty by limiting the range of the average size of its characteristic surface irregularities. Surface texture standards make this control possible.

Variations in the texture of a critical surface of a part influence its ability to resist wear and fatigue; to assist or destroy effective lubrication; to increase or decrease its friction and/or abrasive action on other parts, and to resist corrosion, as well as affect many other properties that may be critical under certain conditions.

Clay has shown that the load-carrying capacity of nitrided shafts of varying degrees of roughness, all running at 1,500 r/min in diamond-turned lead-bronze bushings finished to 20 μin (0.50 μm), varies as shown in Fig. 13.5.1. The effects of roughness values on the friction between a flat slider on a well-lubricated rotating disk are shown in Fig. 13.5.2.

Surface texture control should be a normal design consideration under the following conditions:

1. For those parts whose roughness must be held within closely controlled limits for optimum performance. In such cases, even the process may have to be specified. Automobile engine cylinder walls, which should be finished to about 13 μin (0.32 μm) and have a circumferential (ground) or an angular (honed) lay, are an example. If too rough, excessive wear occurs, if too smooth, piston rings will not seat properly, lubrication is poor, and surfaces will seize or gall.
2. Some parts, such as antifriction bearings, cannot be made too smooth for their function. In these cases, the designer must optimize the tradeoff between the added costs of production and various benefits derived from added performance, such as higher reliability and market value.

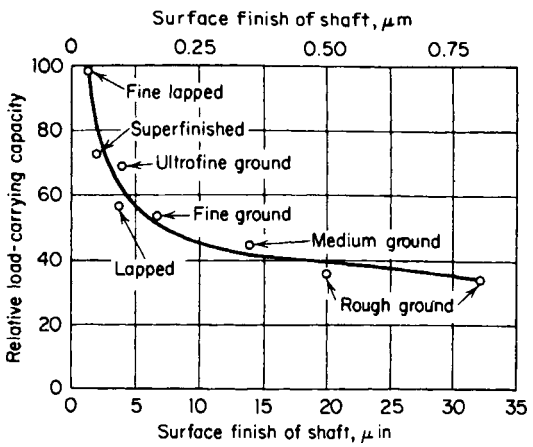

Fig. 13.5.1 Load-carrying capacity of journal bearings related to the surface roughness of a shaft. *(Clay, ASM Metal Progress, Aug. 15, 1955.)*

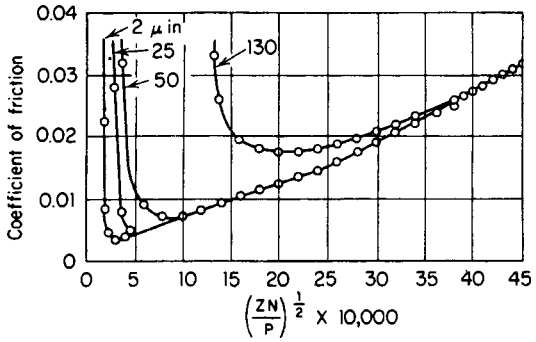

Fig. 13.5.2 Effect of surface texture on friction with hydrodynamic lubrication using a flat slider on a rotating disk. Z = oil viscosity, cP; N = rubbing speed, ft/min; P = load, lb/in^2.

3. There are some parts where surfaces must be made as smooth as possible for optimum performance regardless of cost, such as gages, gage blocks, lenses, and carbon pressure seals.

4. In some cases, the nature of the most satisfactory finishing process may dictate the surface texture requirements to attain production efficiency, uniformity, and control even though the individual performance of the part itself may not be dependent on the quality of the controlled surface. Hardened steel bushings, e.g., which must be ground to close tolerance for press fit into housings, could have outside surfaces well beyond the roughness range specified and still perform their function satisfactorily.

5. For parts which the shop, with unjustified pride, has traditionally finished to greater perfection than is necessary, the use of proper surface texture designations will encourage rougher surfaces on exterior and other surfaces that do not need to be finely finished. Significant cost reductions will accrue thereby.

It is the designer's responsibility to decide which surfaces of a given part are critical to its design function and which are not. This decision should be based upon a full knowledge of the part's function as well as of the performance of various surface textures that might be specified. From both a design and an economic standpoint, it may be just as unsound to specify too smooth a surface as to make it too rough—or to control it at all if not necessary. Wherever normal shop practice will produce acceptable surfaces, as in drilling, tapping, and threading, or in keyways, slots, and other purely functional surfaces, unnecessary surface texture control will add costs which should be avoided.

Whereas each specialized field of endeavor has its own traditional criteria for determining which surface finishes are optimum for adequate performance, Table 13.5.1 provides some common examples for design review, and Table 13.5.6 provides data on the surface texture ranges that can be obtained from normal production processes.

DESIGNATION STANDARDS, SYMBOLS, AND CONVENTIONS

The precise definition and measurement of surface texture irregularities of machined surfaces are almost impossible because the irregularities are very complex in shape and character and, being so small, do not lend themselves to direct measurement. Although both their shape and length may affect their properties, control of their average height and direction usually provides sufficient control of their performance. The standards do not specify the surface texture suitable for any particular application, nor the means by which it may be produced or measured. Neither are the standards concerned with other surface qualities such as appearance, luster, color, hardness, microstructure, or corrosion and wear resistance, any of which may be a governing design consideration.

The standards provide definitions of the terms used in delineating critical surface-texture qualities and a series of symbols and conventions suitable for their designation and control. In the discussion which follows, the reference standards used are "Surface Texture" (ANSI/ ASME B46.1-1985) and "Surface Texture Symbols" (ANSI Y 14.36-1978).

The basic ANSI symbol for designating surface texture is the checkmark with horizontal extension shown in Fig. 13.5.3. The symbol with the triangle at the base indicates a requirement for a machining allowance, in preference to the old f symbol. Another, with the small circle in the base, prohibits machining; hence surfaces must be produced without the removal of material by processes such as cast, forged, hot- or cold-finished, die-cast, sintered- or injection-molded, to name a few. The surface-texture requirement may be shown at A; the machining allowance at B; the process may be indicated above the line at C;

Table 13.5.1 Typical Surface Texture Design Requirements

the roughness width cutoff (sampling length) at D, and the lay at E. The ANSI symbol provides places for the insertion of numbers to specify a wide variety of texture characteristics, as shown in Table 13.5.2.

Control of **roughness,** the finely spaced surface texture irregularities resulting from the manufacturing process or the cutting action of tools or abrasive grains, is the most important function accomplished through the use of these standards, because roughness, in general, has a greater effect on performance than any other surface quality. The roughness-height index value is a number which equals the arithmetic average deviation of the minute surface irregularities from a hypothetical perfect surface, expressed in either millionths of an inch (microinches, μin, 0.000001 in) or in micrometres, μm, if drawing dimensions are in metric, SI units. For control purposes, roughness-height values are taken from Table 13.5.3, with those in boldface type given preference.

The term *roughness cutoff,* a characteristic of tracer-point measuring instruments, is used to limit the length of trace within which the asperities of the surface must lie for consideration as roughness. Asperity spacings greater than roughness cutoff are then considered as waviness.

Waviness refers to the secondary irregularities upon which roughness is superimposed, which are of significantly longer wavelength and are usually caused by machine or work deflections, tool or workpiece vibration, heat treatment, or warping. Waviness can be measured by a dial indicator or a profile recording instrument from which roughness has been filtered out. It is rated as maximum peak-to-valley distance and is indicated by the preferred values of Table 13.5.4. For fine waviness control, techniques involving contact-area determination in percent (90, 75, 50 percent preferred) may be required. Waviness control by interferometric methods is also common, where notes, such as "Flat within XX helium light bands," may be used. Dimensions may be determined from the precision length table (see Sec. 1).

Lay refers to the direction of the predominant visible surface roughness pattern. It can be controlled by use of the approved symbols given in Table 13.5.5, which indicate desired lay direction with respect to the boundary line of the surface upon which the symbol is placed.

Flaws are imperfections in a surface that occur only at infrequent intervals. They are usually caused by nonuniformity of the material, or they result from damage to the surface subsequent to processing, such as scratches, dents, pits, and cracks. Flaws should not be considered in surface texture measurements, as the standards do not consider or classify them. Acceptance or rejection of parts having flaws is strictly a matter of judgment based upon whether the flaw will compromise the intended function of the part.

To call attention to the fact that surface texture values are specified on any given drawing, a note and typical symbol may be used as follows:

$\sqrt{}$ Surface texture per ANSI B46.1

Values for nondesignated surfaces can be limited by the note

$\overset{xx}{\sqrt{}}$ All machined surfaces except as noted

MEASUREMENT

Two general methods exist to measure surface texture: **profile methods** and **area methods.** Profile methods measure the contour of the surface in a plane usually perpendicular to the surface. Area methods measure an area of a surface and produce results that depend on area-averaged properties.

Table 13.5.2 Application of Surface Texture Values to Surface Symbols

(63) 1.6	Roughness average rating is placed at the left of the long leg. The specification of only one rating shall indicate the maximum value and any lesser value shall be acceptable. Specify in micrometres (microinches).
(63) 1.6 (32) 0.8	The specification of maximum value and minimum value roughness average ratings indicates permissible range of value rating. Specify in micrometres (microinches).
(32) 0.8 0.05	Maximum waviness height rating is placed above the horizontal extension. Any lesser rating shall be acceptable. Specify in millimetres (inches).
(32) 0.8 0.05 − 100	Maximum waviness spacing rating is placed above the horizontal extension and to the right of the waviness height rating. Any lesser rating shall be acceptable. Specify in millimetres (inches).
(63) 1.6 3.5	Machining is required to produce the surface. The basic amount of stock provided for machining is specified at the left of the short leg of the symbol. Specify in millimetres (inches).
(63) 1.6	Removal of material by machining is prohibited.
(32) 0.8 ⊥	Lay designation is indicated by the lay symbol placed at the right of the long leg.
(32) 0.8 2.5 (0.100)	Roughness sampling length or cutoff rating is placed below the horizontal extension. When no value is shown, 0.80 mm is assumed. Specify in millimetres (inches).
(32) 0.8 ⊥0.5	Where required, maximum roughness spacing shall be placed at the right of the lay symbol. Any lesser rating shall be acceptable. Specify in millimetres (inches).

Table 13.5.3 Preferred Series Roughness Average Values R_a, μm and μin

μm	μin	μm	μin	μm	μin	μm	μin	μm	μin
0.012	0.5	0.125	5	0.50	20	2.00	80	8.0	320
0.025	1	0.15	6	0.63	25	2.50	100	10.0	400
0.050	**2**	**0.20**	**8**	**0.80**	**32**	**3.20**	**125**	**12.5**	**500**
0.075	3	0.25	10	1.00	40	4.0	160	15.0	600
0.10	**4**	0.32	13	1.25	50	5.0	200	20.0	800
		0.40	**16**	**1.60**	**63**	**6.3**	**250**	**25.0**	**1,000**

Table 13.5.4 Preferred Series Maximum Waviness Height Values

mm	in	mm	in	mm	in
0.0005	0.00002	0.008	0.0003	0.12	0.005
0.0008	0.00003	0.012	0.0005	0.20	0.008
0.0012	0.00005	0.020	0.0008	0.25	0.010
0.0020	0.00008	0.025	0.001	0.38	0.015
0.0025	0.0001	0.05	0.002	0.50	0.020
0.005	0.0002	0.08	0.003	0.80	0.030

Another categorization is by **contact methods** and **noncontact methods.** Contact methods include stylus methods (tracer-point analysis) and capacitance methods. Noncontact methods include light section microscopy, optical reflection measurements, and interferometry.

Replicas of typical standard machined surfaces provide less accurate but often adequate reference and control of rougher surfaces with R_a over 16 μin.

The United States and 25 other countries have adopted the **roughness average** R_a as the standard measure of surface roughness. (See ANSI/ASME B46.1-1985.)

PRODUCTION

Various production processes can produce surfaces within the ranges shown in Table 13.5.6. For production efficiency, it is best that critical areas requiring surface texture control be clearly designated on drawings so that proper machining and adequate protection from damage during processing will be ensured.

SURFACE QUALITY VERSUS TOLERANCES

It should be remembered that surface quality and tolerances are distinctly different attributes that are controlled for completely separate purposes. **Tolerances** are established to limit the range of the size of a part at the time of manufacture, as measured with gages, micrometres,

Table 13.5.5 Lay Symbols

Lay symbol	Interpretation	Example showing direction of tool marks
=	Lay approximately parallel to the line representing the surface to which the symbol is applied	⊥	Lay approximately perpendicular to the line representing the surface to which the symbol is applied	X	Lay angular in both directions to line representing the surface to which symbol is applied	M	Lay multidirectional	C	Lay approximately circular relative to the center of the surface to which the symbol is applied	R	Lay approximately radial relative to the center of the surface to which the symbol is applied	P	Lay particulate, nondirectional, or protuberant	
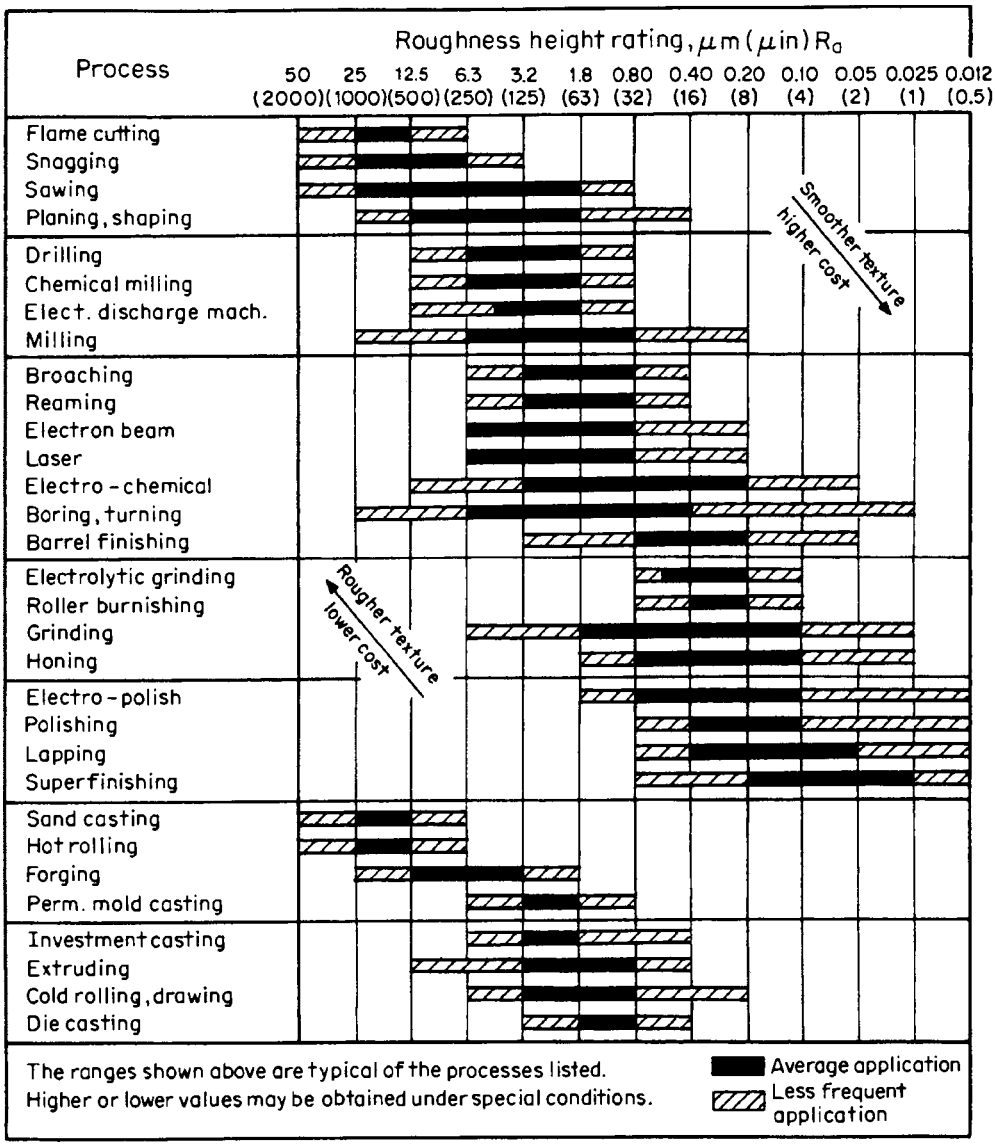
Table 13.5.6 Surface-Roughness Ranges of Production Processes



or other traditional measuring devices having anvils that make contact with the part. **Surface quality** controls, on the other hand, serve to limit the minute surface irregularities or asperities that are formed by the manufacturing process. These lie under the gage anvils during measurement and **do not use up tolerances.**

QUALITY CONTROL (SIX SIGMA)

Quality control is a system that outlines the policies and procedures necessary to improve and control the various processes in manufacturing that will ultimately lead to improved business performance.

Six Sigma is a quality management program to achieve "six sigma" levels of quality. It was pioneered by Motorola in the mid-1980s and has spread to many other manufacturing companies. In statistics, sigma refers to the standard deviation of a set of data. Therefore, **six sigma** refers to six standard deviations. Likewise, **three sigma** refers to three standard deviations. In probability and statistics, the standard deviation is the most commonly used measure of statistical dispersion; i.e., it measures the degree to which values in a data set are spread. The standard deviation is defined as the square root of the variance, i.e., the root mean square (rms) deviation from the average. It is defined in this way to give us a measure of dispersion.

Assuming that defects occur according to a standard normal distribution, this corresponds to approximately 2 quality failures per million parts manufactured. In practical application of the six sigma methodology, however, the rate is taken to be 3.4 per million.

Initially, many believed that such high process reliability was impossible, and **three sigma** (67,000 defects per million opportunities, or DPMO) was considered acceptable. However, market leaders have measurably reached six sigma in numerous processes.

13.6 WOODCUTTING TOOLS AND MACHINES

by Richard W. Perkins

REFERENCES: Davis, Machining and Related Characteristics of United States Hardwoods, *USDA Tech. Bull.* 1267. Harris, "A Handbook of Woodcutting," Her Majesty's Stationery Office, London. Koch, "Wood Machining Processes," Ronald Press. Kollmann, Wood Machining, in Kollmann and Côté, "Principles of Wood Science and Technology," chap. 9, Springer-Verlag.

SAWING

Sawing machines are classified according to basic machine design, i.e., band saw, gang saw, chain saw, circular saw. Saws are designated as **ripsaws** if they are designed to cut along the grain or **crosscut** saws if they are designed to cut across the grain. A **combination** saw is designed to cut reasonably well along the grain, across the grain, or along a direction at an angle to the grain **(miter).** Sawing machines are often further classified according to the specific operation for which they are used, e.g., **headsaw** (the primary log-breakdown saw in a sawmill), **resaw** (saw for ripping cants into boards), **edger** (saw for edging boards in a sawmill), **variety saw** (general-purpose saw for use in furniture plants), **scroll saw** (general-purpose narrow-band saw for use in furniture plants).

The thickness of the saw blade is designated in terms of the Birmingham wire gage (BWG) (see Sec. 8.2). Large-diameter [40 to 60 in (1.02 to 1.52 mm)] circular-saw blades are tapered so that they are thicker at the center than at the rim. Typical headsaw blades range in thickness from 5 to 6 BWG [0.203 to 0.220 in (5.16 to 5.59 mm)] for use in heavy-duty applications to 8 to 9 BWG [0.148 to 0.165 in (3.76 to 4.19 mm)] for lighter operations. Small-diameter [6 to 30 in (152 to 762 mm)] circular saws are generally flat-ground and range from 10 to 18 BWG [0.049 to 0.134 in (1.24 to 3.40 mm)] in thickness. Band-saw and gang-saw blades are flat-ground and are generally thinner than circular-saw blades designed for similar applications. For example, typical wide-band-saw blades for sawmill use range from 11 to 16 BWG [0.065 to 0.120 in (1.65 to 3.05 mm)] in thickness. The thickness of a band-saw blade is determined by the cutting load and the diameter of the band wheel. Gang-saw blades are generally somewhat thicker than band-saw blades for similar operations. Narrow-band-saw blades for use on scroll band saws range in thickness from 20 to 25 BWG [0.020 to 0.035 in (0.51 to 0.89 mm)] and range in width from ⅛ to about 1¾ in (3.17 to 44.5 mm) depending upon the curvature of cuts to be made.

The considerable amount of heat generated at the cutting edge results in compressive stresses in the rim of the saw blade of sufficient magnitude to cause mechanical instability of the saw blades. Circular-saw blades and wide-band-saw blades are commonly prestressed (or **tensioned**) to reduce the possibility of buckling. Small circular-saw blades for use on power-feed rip-saws and crosscut saws are frequently provided with **expansion slots** for the same purpose.

The **shape of the cutting portion of the sawtooth** is determined by specifying the hook, face bevel, top bevel, and clearance angles. The optimum tooth shape depends primarily upon cutting direction, moisture content, and density of the workpiece material. Sawteeth are, in general, designed in such a way that the portion of the cutting edge which is required to cut across the fiber direction is provided with the maximum effective rake angle consistent with tool strength and wear considerations. Ripsaws are designed with a hook angle between some 46° for inserted-tooth circular headsaws used to cut green material and 10° for solid-tooth saws cutting dense material at low moisture content. Ripsaws generally have zero face bevel and top bevel angle; however, spring-set ripsaws sometimes are provided with a moderate top bevel angle (5 to 15°). The hook angle for crosscut saws ranges from positive 10° to negative 30°. These saws are generally designed with both top and face bevel angles of 5 to 15°; however, in some cases top and face bevel angles as high as 45° are employed. A compromise design is used for combination saws which embodies the features of both ripsaws and crosscut saws in order to provide a tool which can cut reasonably well in all directions. The clearance angle should be maintained at the smallest possible value in order to provide for maximum tooth strength. For ripsawing applications, the clearance angle should be about 12 to 15°. The minimum satisfactory clearance angle is determined by the nature of the work material, not from kinematical considerations of the motion of the tool through the work. In some cases of cutoff, combination, and narrow-band-saw designs where the tooth pitch is relatively small, much larger clearance angles are used in order to provide the necessary gullet volume.

A certain amount of clearance between the saw blade and the generated surface **(side clearance** or **set)** is necessary to prevent frictional heating of the saw blade. In the case of solid-tooth circular saws and band or gang saws, the side clearance is generally provided either by deflecting alternate teeth **(spring-setting)** or by spreading the cutting edge **(swage-setting).** The amount of side clearance depends upon density, moisture content, and size of the saw blade. In most cases, satisfactory results are obtained if the side clearance S is determined from the formula S [in (mm)] $= A/2[f(g - 5) - f(g)]$, where g = gage number (BWG) of the saw blade, $f(n)$ = dimension in inches (mm) corresponding to the gage number n, and A has values from Table 13.6.1. Certain specialty circular saws such as planer, smooth-trimmer, and miter saws are hollow-ground to provide side clearance. Inserted-tooth saws, carbide-tipped saws, and chain-saw teeth are designed so that sufficient side clearance is provided for the life of the tool; consequently, the setting of such saws is unnecessary.

Table 13.6.1 Values of *A* for Computing Side Clearance

	Workpiece material			
	Specific gravity less than 0.45		Specific gravity greater than 0.55	
Saw type	Air dry	Green	Air dry	Green
Circular rip and combination	0.90	1.00	0.85	0.95
Glue-joint ripsaw	0.80	—	0.60	—
Circular crosscut	0.95	1.05	0.90	1.00
Wide-band saw	0.55	0.65	0.30	0.40
Narrow-band saw	0.65	—	0.55	—

The **tooth speed** for sawing operations ranges from 3,000 to 17,000 ft/min (15 to 86 m/s) approx. Large tooth speeds are in general desirable in order to permit maximum work rates. The upper limit of permissible tooth speed depends in most cases on machine design considerations and not on considerations of wear or surface quality as in the case of metal cutting. Exceptionally high tooth speeds may result in charring of the work material, which is machined at slow feed rates.

In many sawing applications, **surface quality** is not of prime importance since the sawed surfaces are subsequently machined, e.g., by planing, shaping, sanding; therefore, it is desirable to operate the saw at the largest feed per tooth consistent with gullet overloading. Large values of feed per tooth result in lower amounts of work required per unit volume of material cut and in lower amounts of wear per unit tool travel. Large-diameter circular saws, wide-band saws, and gang saws for ripping green material are generally designed so that the feed per tooth should be about 0.08 to 0.12 in (2.03 to 3.05 mm). Small-diameter circular saws are designed so that the feed per tooth ranges from 0.03 in (0.76 mm) for dense hardwoods to 0.05 in (1.27 mm) for low-density softwoods. Narrow-band saws are generally operated at somewhat smaller values of feed per tooth, e.g., 0.005 to 0.04 in (0.13 to 1.02 mm).

Smaller values of feed per tooth are necessary for applications where surface quality is of prime importance, e.g., glue-joint ripsawing and variety-saw operations. The degree of gullet loading is measured by the **gullet-feed index (GFI),** which is computed as the feed per tooth times the depth of face divided by the gullet area. The maximum GFI depends primarily upon species, moisture content, and cutting direction. It is generally conceded that the maximum GFI for ripsawing lies between 0.3 for high-density, low-moisture-content material and 0.4 for low-density, high-moisture-content material. For specific information, see Telford, *For. Prod. Res. Soc. Proc.,* 1949.

Saws vary considerably in design of the **gullet shape.** The primary design considerations are gullet area and tooth strength; however, special design shapes are often required for certain classes of workpiece material, e.g., for ripping frozen wood.

Materials Saw blades and the sawteeth of solid-tooth saws are generally made of a nickel tool steel. The bits for inserted-tooth saws were historically plain carbon tool steel; however, high-speed steel bits or bits with a cast-alloy inlay (e.g., Stellite) are sometimes used in applications where metal or gravel will not be encountered. Small-diameter circular saws of virtually all designs are made with cemented-carbide tips. This type is almost imperative in applications where highly abrasive material is cut, namely, in plywood and particleboard operations.

Prod. Res. Soc.,* 1949.

An approximate relation for computing the power P, ft · lb/min (W), required to saw is

$$P = kvb(A + Bt_a)/p$$

where k is the kerf, in (m); v is the tooth speed, ft/min (m/s); p is the tooth pitch, in (m); A and B are constants for a given sawing operation, lb/in (N/m) and lb/in^2 (N/m^2), respectively; and t_a is the average chip thickness, in (m). The average chip thickness is computed from the relation $t_a = \gamma f_t \times d/b$, where f_t is the feed per tooth; d is the depth of face; b is the length of the tool path through the workpiece; and γ has the value 1 except for saws with spring-set or offset teeth, in which case γ has the value 2. The constants A and B depend primarily upon cutting direction (ripsawing, crosscutting), moisture content below the fiber-saturation point and specific gravity of the workpiece material, and tooth shape. The values of A and B (see Table 13.6.2) depend to some degree upon the depth of face, saw diameter, gullet shape, gullet-feed index, saw speed, and whether the tool motion is linear or rotary; however, the effect of these variables can generally be neglected for purposes of approximation.

Computers are now utilized in sawmills where raw logs are first processed into rough-cut lumber. With suitable software, the mill operator can input key dimensions of the log and receive the cutting pattern which provides a mix of cross sections of lumber so as to maximize the yield from the log. The saving in waste is sizable, and this technique is especially attractive in view of the decreasing availability of large-caliper old stand timber, together with the cost of same.

PLANING AND MOLDING

Machinery Planing and molding machines employ a rotating cutterhead to generate a smooth, defect-free surface by cutting in a direction approximately along the grain. A **surfacer** (or **planer**) is designed to machine boards or panels to uniform thickness. A **facer** (or **facing planer**) is designed to generate a flat (plane) surface on the wide faces of boards. The **edge jointer** is intended to perform the same task on the edges of boards in preparation for edge-gluing into panels. A **planer-matcher** is a heavy-duty machine designed to plane rough boards to uniform width and thickness in one operation. This machine is commonly used for dressing dimension lumber and producing millwork. The **molder** is a high-production machine for use in furniture plants to generate parts of uniform cross-sectional shape.

Recommended Operating Conditions It is of prime importance to adjust the operating conditions and knife geometry so that the machining defects are reduced to a satisfactory level. The most commonly encountered defects are torn (chipped) grain, fuzzy grain, raised and loosened grain, and chip marks. **Torn grain** is caused by the wood splitting ahead of the cutting edge and below the generated surface. It is generally associated with large cutting angle, large chip thickness, low moisture content, and low workpiece material density. The **fuzzy-grain** defect is characterized by small groups of wood fibers which stand up above the generated surface. This defect is caused by incomplete severing of the wood by the cutting edge and is generally associated with small cutting angles, dull knives, low-density species, high moisture content, and (often) the presence of abnormal wood known as reaction wood. The **raised-grain** defect is characterized by an uneven surface where one portion of the annual ring is raised above the remaining part. **Loosened grain** is similar to raised grain; however, loosened grain is characterized by a separation of the early wood from the late wood which is readily discernible to the naked eye. The raised- and loosened-grain defects are attributed to the crushing of springwood cells as the

Table 13.6.2 Constants for Sawing-Power Estimation

Material			Tool		Constants			
Species	Specific gravity	Moisture content, %	Angles[e]	Sawing situation	A, lb/in	A, N/m	B, lb/in^2 × 10^{-3}	B, N/m^2 × 10^{-6}

knife passes over the surface. (Edge-grain material may exhibit a defect similar to the raised-grain defect if machining is performed at a markedly different moisture content from that encountered at some later time.) Raised and loosened grains are associated with dull knives, excessive jointing of knives [the jointing land should not exceed 1/32 in (0.79 mm)], and high moisture content of workpiece material. **Chip marks** are caused by chips which are forced by the knife into the generated surface as the knife enters the workpiece material. Chip marks are associated with inadequate exhaust, low moisture content, and species (e.g., birch, Douglas fir, and maple have a marked propensity toward the chip-mark defect).

Depth of cut is an important variable with respect to surface quality, particularly in the case of species which are quite prone to the torn-grain defect (e.g., hard maple, Douglas fir, southern yellow pine). In most cases, the depth of cut should be less than 1/16 in (1.59 mm). The number of **marks per inch (marks per metre)** (reciprocal of the feed per cutter) is an important variable in all cases; however, it is most important in those cases for which the torn-grain defect is highly probable. The marks per inch (marks per metre) should be between 8 and 12 (315 and 472) for rough planing operations and from 12 to 16 (472 to 630) for finishing cuts. Slightly higher values may be necessary for refractory (brittle) species or for situations where knots or curly grain are present. It is seldom necessary to exceed a value of 20 marks per inch (787 marks per metre). The **clearance angle** should in all cases exceed a value of 10°. When it is desired to hone or joint the knives between sharpenings, a value of about 20° should be used. The optimum **cutting angle** lies between 20 and 30° for most planing situations; however, in the case of interlocked or wavy grain, low moisture content, or species with a marked tendency toward the torn-grain defect, it may be necessary to reduce the cutting angle to 10 or 15°.

BORING

Machinery The typical general-purpose wood-boring machine has a single vertical spindle and is a hand-feed machine. Production machines are often of the vertical, multiple-spindle, adjustable-gang type or the horizontal type with two adjustable, independently driven spindles. The former type is commonly employed in furniture plants for boring holes in the faces of parts, and the latter type is commonly used for boring dowel holes in the edges and ends of parts.

Tool Design A wide variety of tool designs is available for specialized boring tasks; however, the most commonly used tools are the taper-head drill, the spur machine drill, and the machine bit. The **taperhead** drill is a twist drill with a point angle of 60 to 90°, lip clearance angle of 15 to 20°, chisel-edge angle of 125 to 135°, and helix angle of 20 to 40°. Taper-head drills are used for drilling screw holes and for boring dowel holes along the grain. The **spur machine** drill is equivalent to a twist drill having a point angle of 180° with the addition of a pyramidal point (instead of a web) and spurs at the circumference. These drills are designed with a helix angle of 20 to 40° and a clearance angle of 15 to 20°. The **machine bit** has a specially formed head which determines the configuration of the spurs. It also has a point. Machine bits are designed with a helix angle of 40 to 60°, cutting angle of 20 to 40°, and clearance angle of 15 to 20°. Machine bits are designed with spurs contiguous to the cutting edges **(double-spur machine bit),** with spurs removed from the vicinity of the cutting edges **(extension-lip machine bit),** and with the outlining portion of the spurs removed **(flat-cut machine bit).**

The purpose of the spurs is to aid in severing wood fibers across their axes, thereby increasing hole-wall smoothness when boring across the grain. Therefore, drills or bits with spurs (double-spur machine drill and bit) are intended for boring across the grain, whereas drills or bits without spurs (taper-head drill, flat-cut machine bit) are intended for boring along the grain or at an angle to the grain.

Taper-head and spur machine drills can be sharpened until they become too short for further use; however, machine bits and other bit styles which have specially formed heads can only be sharpened a limited number of times before the spur and cutting-face configuration is significantly altered. Since most wood-boring tools are sharpened by filing the clearance face, it is important to ensure that sufficient clearance is maintained. The clearance angle should be at least 5° greater than the angle whose tangent (function) is the feed per revolution divided by the circumference of the drill point.

Recommended Operating Conditions The most common defects are tearing of fibers from the end-grain portions of the hole surface and charring of hole surfaces. Rough hole surfaces are most often encountered in low-density and ring-porous species. This defect can generally be reduced to a satisfactory level by controlling the chip thickness. Charring is commonly a problem in high-density species. It can be avoided by maintaining the peripheral speed of the tool below a level which depends upon density and moisture content and by maintaining the chip thickness at a satisfactory level. Large chip thickness may result in excessive tool temperature and therefore rapid tool wear; however, large chip thickness is seldom a cause of hole charring. The following recommendations pertain to the use of spur-type drills or bits for boring material at about 6 percent moisture content across the grain. For species having a specific gravity less than 0.45, the chip thickness should be between 0.015 and 0.030 in (0.38 and 0.76 mm), and the peripheral speed of the tool should not exceed 900 ft/min (4.57 m/s). For material of specific gravity between 0.45 and 0.65, satisfactory results can be obtained with values of chip thickness between 0.015 and 0.045 in (0.38 and 1.14 mm) and with peripheral speeds less than 700 ft/min (3.56 m/s). For material of specific gravity greater than 0.65, the chip thickness should lie between 0.015 and 0.030 in (0.38 and 0.76 mm) and the peripheral speed should not exceed 500 ft/min (2.54 m/s). Somewhat higher values of chip thickness and peripheral speed can be employed when the moisture content of the material is higher.

SANDING

(See also Secs. 6.7 and 6.8.)

Machinery Machines for production sanding of parts having flat surfaces are multiple-drum sanders, automatic-stroke sanders, and wide-belt sanders. **Multiple-drum** sanders are of the endless-bed or rollfeed type and have from two to six drums. The drum at the infeed end is fitted with a relatively coarse abrasive (40 to 100 grit), takes a relatively heavy cut [0.010 to 0.015 in (0.25 to 0.38 mm)], and operates at a relatively slow surface speed [3,000 to 3,500 ft/min (15.24 to 17.78 m/s)]. The drum at the outfeed end has a relatively fine abrasive paper (60 to 150 grit), takes a relatively light cut [about 0.005 in (0.13 mm)], and operates at a somewhat higher surface speed [4,000 to 5,000 ft/min (20.3 to 25.4 m/s)]. **Automatic-stroke** sanders employ a narrow abrasive belt and a reciprocating shoe which forces the abrasive belt against the work material. This machine is commonly employed in furniture plants for the final white-sanding operation prior to finish coating. The automatic-stroke sander has a relatively low rate of material removal (about one-tenth to one-third of the rate for the final drum of a multiple-drum sander) and is operated with a belt speed of 3,000 to 7,500 ft/min (15.2 to 38.1 m/s). **Wide-belt** sanders are commonly used in board plants (plywood, particle board, hardboard). They have the advantage of higher production rates and somewhat greater accuracy than multiple-drum sanders [e.g., feed rates up to 100 ft/min (0.51 m/s) as opposed to about 35 ft/min (0.18 m/s)]. Wide-belt sanders operate at surface speeds of approximately 5,000 ft/min (25.4 m/s) and are capable of operating at depths of cut of 0.006 to 0.020 in (0.15 to 0.51 mm) depending upon workpiece material density.

Abrasive Tools The abrasive tool consists of a **backing** to carry the **abrasive** and an **adhesive** coat to fix the abrasive to the backing. Backings are constructed of paper, cloth, or vulcanized fiber or consist of a cloth-paper combination. The adhesive coating (see also Sec. 6) is made up of two coatings; the first coat **(make coat)** acts to join the abrasive material to the backing, and the second coat **(size coat)** acts to provide the necessary support for the abrasive particles. Coating materials are generally animal glues, urea resins, or phenolic resins. The choice of material for the make and size coats depends upon the required flexibility of the tool and the work rate required of the tool. Abrasive materials (see also Sec. 6) for woodworking applications are garnet, aluminum oxide, and silicon carbide. **Garnet** is the most commonly used abrasive mineral

Table 13.6.3 Recommendations for Common Whitewood Sanding Operations

		Abrasive									
		Backing		Adhesive		Mineral			Grit size		
		Material	Weight	Make coat	Size coat	1st drum	2d drum	3d drum	1st drum	2d drum	3d drum

SOURCE: Graham, *Furniture Production,* July and Aug., 1961; and Martin, *Wood Working Digest,* Sept. 1961.

because of its low cost and acceptable working qualities for low-work-rate situations. It is generally used for sheet goods, for sanding softwoods with all types of machines, and for sanding where the belt is loaded up (as opposed to worn out). **Aluminum oxide** abrasive is used extensively for sanding hardwoods, particleboard, and hardboard. **Silicon carbide** abrasive is used for sanding and polishing between coating operations and for machine sanding of particleboard and hardboard. Silicon carbide is also frequently used for the sanding of softwoods where the removal of raised fibers is a problem. The size of the abrasive particles is specified by the mesh number (the approximate number of openings per inch in the screen through which the particles will pass). (See Commercial Std. CS217-59, "Grading of Abrasive Grain on Coated Abrasive Products," U.S. Government Printing Office.) Mesh numbers range from about 600 to 12. Size may also be designated by an older system of symbols which range from 10/0 (mesh no. 400) through 0 (mesh no. 80) to 4½ (mesh no. 12). Some general recommendations for common white wood sanding operations are presented in Table 13.6.3.

13.7 PRECISION CLEANING

by Charles Osborn

IMPORTANCE OF CLEANLINESS

Long ignored, and still somewhat underestimated, the importance of part **cleanliness** is rapidly coming to the fore in today's high-tech products, especially as we head further into nanotechnologies. Historically many manufacturers have dismissed part cleaning as an insignificant part of the process. Many learn all too late that their highly engineered, closely toleranced device is rendered inoperable by a tiny particle, often so small that it can't be seen with the naked eye. Suddenly they are faced with a steep learning curve, for myriad equipment, chemistry, staffing, and environmental issues await them. This material will help you become familiar with some of the

procedures, equipment, and terms that you will encounter on blueprint requirements.

Parts cleaning covers a wide spectrum, ranging from "gross" cleaning of heavy industrial components to "critical" cleaning for the space program components. Many factors must be considered in deciding which processes best fit your particular situation. Applications run the gamut from outer-space/aerospace (oxygen delivery systems to both rocket motors and breathing apparatus for astronauts) to inner space (pharmaceuticals and hip replacements in the medical field). Increasingly the automotive industry is requiring verifiable cleanliness levels for fuel injector components and other metering devices used in antilock brake components.

SELECTING A CLEANLINESS LEVEL

Ultimately, fit, form, and function determine the type and amounts of **contaminates** that can cause improper operation of moving parts or can restrict the flow of fluids. If the limits governing your parts have been established for you, it remains only to institute processes to ensure compliance. If, however, *you* are asked to establish cleanliness limits for a given part, the task is more challenging. You begin by gathering an array of parts, some that "work" well in the application and others that don't. Perform cleanliness testing on each to establish the current level of cleanliness for each case. With this information you now have benchmarks from which you can establish minimum levels of acceptance. This can be done by referring to an industry standard such as International Standard ISO 14952 Part 2, "Surface Cleanliness of Fluid Systems—Cleanliness Levels."

There are two main contaminate types, **particles** and **nonvolatile residues.** There are two types of particles: **hard** and **soft**.

Hard particles are defined as (but not limited to) metal chips, scale from heat treatment, grinding debris, e.g., aluminum oxide, rust, and weld slag. Hard particles, by their very nature, will be detrimental to precision assemblies. When probed with a dental pick, they will maintain their shape and mass and not crumble or smear into separate smaller parts. If small orifices are present, the absolute maximum acceptable particle size is ≅70 percent of the diameter of the smallest downstream office.

Soft particles are fragile and break up when gently probed with a dental pick. They may also exhibit a pasty or gummy consistency. They are generally not considered as solids and may not be of great concern in your application (you will need to evaluate this for your application). Natural fibers such as hair of bits of shop rags are called **linters** and are a subclass of soft particle. Linters are organic fibers whose length exceeds the width by a 10 : 1 ratio. Linters would be of concern if you have small metering orifices that could become clogged or obstructed by an accumulation of linters without regard to size.

The second contaminate classification **nonvolatile residue,** may consist of both particles and hydrocarbons but is usually thought of in terms of residual hydrocarbon films. If either is present in oxygen service applications, fire and/or explosion could result. Highly sensitive systems may ignite if there is even a slight residue left from inadequate rinsing of aqueous cleaning solution. A reference covering nonvolative residue is published by the SAE: "ARP 1176, Oxygen System and Component Cleaning and Packaging."®

There are three levels of cleanliness: **gross, precision,** and **critical. Gross cleaning** is performed primarily to remove scale from heat treating, other rust, and metal chips. Cleanliness is generally verified by a visual examination and may be aided with a 2 to 10 × loupe under normal lighting conditions. Borescopes are often used to gain access to cored passageways and cavities.

Precision cleaning is performed in a clean-room environment of ≥ class 100,000 but ≤ 1,000 to remove minute contaminants. Verification involves use of equipment to both quantify and qualify the cleanliness level.

Critical cleaning is performed in clean rooms rated at class 100 or better, and only on the most sensitive components.

ENVIRONMENT

Selection of the environment that best suits your application is not always obvious. A common statement found in many industry specifications is the following: **The environment you clean and test in must be compatible with the requirements of the parts.** Put another way, the environment must be clean enough to allow you to achieve the cleanliness level that you need on your parts.

Gross cleaning is typically performed in a **clean area,** which is defined as space physically separated from other manufacturing operations, e.g., machining, finishing, and welding, with means to prevent entry of airborne particles and fumes. A portable laminar flow bench or hood is acceptable in most cases. The following are basic **clean-area protocols:**

Sticky mats at every entrance
No food, drink, or smoking
No oils or greases
No cardboard or wood
No wool sweaters
No sandpaper or abrasives
Clean-room gloves required when handling cleaned parts

Precision cleaning is performed in a **clean-room** environment of ≥ class 100,000 but ≤ 1,000. A reference that outlines the exact parameters of a clean room and how to test for them is FED-STD-209, "Airborne Particulate Cleanliness Classes in Clean Rooms and Clean Zones."

	Class limits				
Class name	0.1 μm/ft³	0.2 μm/ft³	0.3 μm/ft³	0.5 μm/ft³	5 μm/ft³
1	35	7.5	3.0	1.0	—
10	350	75	30	10	—
100	—	750	300	100	—
1,000	—	—	—	1,000	7.0
10,000	—	—	—	10,000	70
100,000	—	—	—	100,000	1,750

The limits shown designate specific concentrations of particles per unit volume of airborne particles with sizes equal to and larger than the particle sizes shown.

The following are basic **clean-room protocols:**

All those that apply to a clean room, plus the following:
No pencils are to be used—pens only.
No drawings or paper is used unless necessary and only in sealed or laminated plastic sheets.
Everyone entering shall wear clean room garments of monofilament polyethylene such as Tyvek® or GoreTex®. Basic coverage would be full-body suits, booties, and head covering.
Gloves that touch anything other than cleaned parts must be changed.

SELECTION OF A CLEANING METHOD

Many factors must be considered in selecting an appropriate cleaning method. Influencing factors include part geometry and sizes, presence of blind holes and cored passageways, all of which may be compounded by the presence of delicate components such as microcircuitry and highly polished surfaces. Component material is important especially if noncorrosion-resistive or highly reactive materials are involved.

As important as the component features are, the nature of the contaminates will have a direct bearing on how they are best removed. There are two type of contaminates, **polar** and **nonpolar.** Example of **polar soil** are inks, metals, and their oxides, and they are best removed in water-based solutions (see Table 13.7.1) **Nonpolar soils** such as mineral oil,

Table 13.7.1 Aqueous Cleaner Effectiveness

Type of cleaner	pH	Contaminates
Acidic	0–2	Metal oxides, scales
Mild acidic	2–5.5	Inorganic salts, soluble metal
Neutral	5.5–8.5	Light oils, small particles
Mild alkaline	8.5–11	Oils, particles, films
Alkaline	11–12.5	Oils, fats, proteins
Corrosive alkaline	12.5–14	Heavy grease

greases, and wax are more easily removed in organic solvents. There are many cleaning methods, but extreme methods may not be necessary to achieve high levels of cleanliness. Surprising results can be achieved with simple equipment if it is set up in the proper environment with controls in place. Regardless of the method chosen, there are some basic elements that remain constant in the production of clean parts. Environment, already discussed, is paramount in achieving cleanliness. Filtration of all fluids at the point of use is essential during rinsing and drying. Deionized (DI) water of at least 50,000 Ω ranging up to 18,000,000 Ω must be used for rinsing to ensure that parts dry spot-free.

Drying can be the biggest problem in the process, especially when aqueous-based solution are used. Commons methods of drying include compressed air (provided there are adequate filtering systems), vacuum chambers, convection ovens fitted with filtration devices, and centrifugal units utilizing spinning baskets. Care of parts after cleaning is just as important as the cleaning process itself; don't place clean parts in dirty containers. Packaging components in 4- to 6-mil-thick polyethylene bags sealed closed with an impulse heat sealer are industry standard. Most bags purchased from catalog vendors are not clean; insist on certified bags to at least class 100 to ensure cleanliness is maintained.

Components sensitive to static electricity will need to be packaged in antistatic material, and metallized or Saran coated films may be necessary as a vapor barrier in very humid conditions.

Parts made form non-corrosion-resistant metals may require additions to the bagging material to ensure parts don't oxidize during shipping and storage. Using vacuum to evacuate the air or back-filling with inert gas is effective. Insertion of clean-room-quality desiccant packets is also acceptable, as well as dipping or spraying with preservative oils, provided that the oil delivery systems are properly cleaned and verified. If nonvolatile residue (NVR) is a concern, ultralow out-gassing material will be needed to ensure no residues are redeposited onto the parts.

Manual washing is the oldest and most basic cleaning method and can be as simple as scrubbing a part with a brush, using solvents or aqueous solutions, and drying with compressed shop air.

Advantages Equipment is readily available and inexpensive; there is minimal operator training required.

Disadvantages It may not be adequate on components with inaccessible passageways; direct exposure of operators to the chemicals is possible. Brush bristle size may be larger than the pores holding the contaminates.

Mechanical blasting consists of a cabinet outfitted with doors on one or both sides for moving the work in and out, with a viewing panel placed just above a port. Rubber gloves are used to manipulate the workpiece and protect the operator's hands and arms. A hose and nozzle system delivers the **media** propelled by compressed air on demand which the operator activates with foot pedal. The physical impact of the media upon the workpiece imparts a cleaning action along the substrate. There are numerous types of media ranging from aluminum oxide with a Moh's hardness of 9 to sodium bicarbonate with Moh's hardness of 2.5.

Advantages It is excellent at removing heavy oxides and scale; very versatile; removes a wide variety of soils; and is able to change and impact desirable surface finishes.

Disadvantages Inherently loud and messy, it is undesirable to be near clean areas. It can result in warped and damaged parts if exposed too long or if wrong media are used. Additional cleaning methods are required to remove the residual media and achieve high levels of cleanliness.

Vapor Degreasing The process uses a holding tank with a controlled heat source that is used to boil the solvent. The vapor from the heated solvent rises, surrounding the part, penetrating the pores, and washes away the debris. A water-cooled chill ring at the top of the unit condenses the vapor back to liquid. It settles into a collection tank, is filtered, and flows back to the boiling tank.

Advantages It is a one-step process; parts are cleaned and dried in the same operation.

Disadvantages Even with good ventilation there is always a possibility that some vapors may escape, exposing workers. Traditional chlorinated solvents—trichloroethylene, perchloroethylene, and carbon tetrachloride—are heavily regulated by the EPA. *N*-propyl bromide is a more user-friendly substitute.

Ultrasonics Ultrasonics couple a tank with an electronic transducer that convert electric energy to intense high-frequency vibrations. These vibrations form bubbles in the tank solution that expand and then collapse against the surface of the part, dislodging contaminants. This method is very effective in penetrating blind holes and cavities. These units can be operated with aqueous or semiaqueous solutions, and other solvents are best suited to cleaning hard substrates. Often they are coupled with sonic rinse tanks and drying chambers. There units run at from 20 to 110 kHz.

Advantages They are very effective in removing small particulates down to ≅ 25 μm, especially in inaccessible cavities and blind holes. Megasonic units (700 kHz to 1.2 MHz) can remove particles down to the 0.15-μm range.

Disadvantages Cavitation can occur on softer substrates and erode the parent material, usually in the form of a "starburst" pattern. When solvents are used, the entire system will need to be "explosion-proof," which dramatically increases the cost of equipment.

CO_2 Cleaning High-purity CO_2 is contained in special siphon cylinders and metered through a specially designed nozzle, producing a jet of fine "dry ice" and effectively becoming a mechanical blast system with a medium that disappears as it sublimes from a solid to a gas. When first emitted from the nozzle, the crystals of dry ice impact the surface of the workpiece, imparting mechanical cleaning actions. At the same time, as the crystals sublime from a solid to a gas, a solvency action takes place that dissolves light oils.

Advantages Capital equipment is low-cost and easy to install. There are very few negative health issues and so very little regulation. There are virtually no waste disposal issues. It is effective in removing solid particles down to 0.1 μm. The system employs no water, so there are no drying issues.

Disadvantages It is only effective on very light oils and particles.

TEST METHODS AND ANALYSIS

There are many test methods, but in general they can be categorized as **gross, precision,** and **critical.**

Examples of **gross** testing are as follows:

Visibly clean parts are nominally free of oil, grease, moisture, slag, rust, and other foreign material when viewed with a naked eye by a person with normal visual acuity, corrected or uncorrected, in normal room light.

Water break testing is a basic method of quickly and inexpensively determining the presence of oils and films. DI water is sprayed onto the subject part; if it "beads up" (as on a freshly waxed car surface), the work is considered to have residual oils or films still present and will require further cleaning. If the water forms large "puddles" or "sheets" for 10 to 15 s, it is considered clean

Black light or **ultraviolet light** from 3,200 to 3,900 Å will cause most oils and solid particles to fluoresce. Simply place the workpiece in a dark room and expose it to the light; contaminates will glow, ranging in color from bright white in the case of lint to yellow-green for hydrocarbons.

Conductivity is an inexpensive and quick method of determining the presence of contaminates, especially nonvolatile residue. The procedure is to submerge the study piece in a clean container of 18-MΩ water at 100 to 120°F for 5 min. The conductivity of the soak water is measured with a meter, and if the reading is less than 5 μmho, it is considered free of hydrocarbons.

In the **precision** class, the most widely used technique is the **extraction** method; commonly referred to as **Millipore** or **patch testing.**

This method can detect contaminates down to 0.01 mg when weight tests are performed and 5 μm using microscopic techniques. The part to be tested is sprayed with filtered solvent from a pressurized container, and

the resulting effluent is collected and strained through a preweighed filter, using vacuum. The filter is dried and then weighed or scanned with a microscope to qualify the nature and quantify the amount of the debris. Variations in collection techniques are allowed to accommodate inaccessible areas, such as tubing and vessels, by filing them with solvent and manually agitating, then draining the solution into the filter funnel assembly.

International Standard ISO 14952-3, "Analytical Procedures for the Determination of Nonvolatile Residues and Particulate," is a excellent reference regarding these techniques.

A short list of equipment needed to collect and analyze a sample follows:

50X to 100X microscope with measuring device
Analytical balance accurate to 0.1 mg
$<$5-μm membrane filters (with grids if counting particles)
Vacuum flask, filter holder base, grounded clamp, and funnel
Petri dishes
Pressurized solvent dispenser
Vacuum pump capable of 26 inHg
Convection oven
Forceps with flat blades
Collection container

If the application is approaching the **critical** classification, exotic verification methods may be necessary: optical particle counting, scanning electron microscope, total organic carbon analysis, and contact angle measurement. Details are available in the literature.

INTERPRETATION AND USE OF DATA

There is a "cost of cleanlines," and it almost becomes exponential as the requirements tighten. Time spent identifying the contamination and preventing it at the source is definitely worthwhile. Identification of contaminates requires a good microscope. Establishing and monitoring cleanliness levels of the cleaning processes can ensure repeatable results and serve as a baseline for continuous improvements and maximization of the cleaning process.

Even after precision cleaning, a part may still not be absolutely clean. Nothing is perfectly clean, and some contaminates are nearly impossible to remove. Small amounts of contamination may not harm your device; the challenge is to determine an acceptable level and to repeatably achieve it.

REGULATORY CONSIDERATIONS

Many of the chemicals used for cleaning and testing are highly regulated substances, and they are far too numerous to even begin to list here. Before you go too far in setting up a process, be sure to check with local officials to ensure operation within the codes, and learn who has oversight: local, state, or federal authorities. Setting up and registering for a "waste stream" permit can also take a considerable amount of time and money; it's best to have the appropriate authorities involved at the beginning so that the proposed operations and processes may proceed smoothly and without delay.

GENERAL

A **displacement pump** (also called **positive-displacement,** or just **p-d**) is a pump which imparts energy to the pumpage (the material pumped) by trapping a fixed volume at suction (inlet) conditions, compressing it to discharge pressure, then pushing it into the discharge (outlet) line. A displacement pump does not rely on velocity to achieve pumping action, as does a centrifugal pump or ejector.

Displacement pumps fall into two major classes: reciprocating and rotary, as illustrated in Fig. 14.1.1.

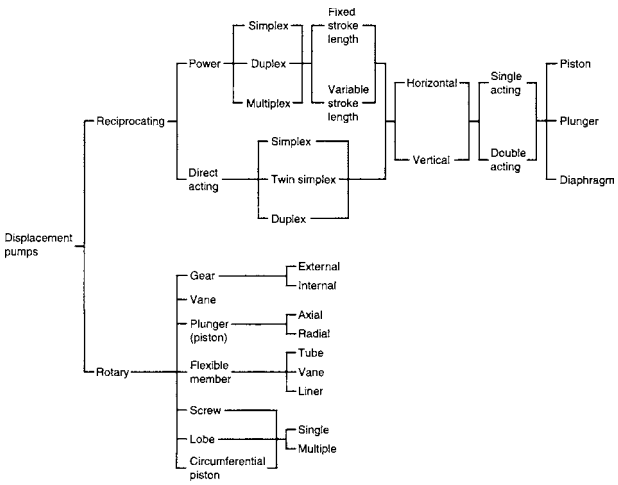

Fig. 14.1.1 Classification diagram of displacement pumps.

Uses and Applications

Displacement pumps serve primarily in applications of low capacity and high pressure, those mostly beyond the capabilities of centrifugal pumps. Some of these services could be performed by centrifugals, but not without an increase in power requirements and/or maintenance. Because displacement pumps achieve high pressures with low pumpage velocities, they are well-suited for abrasive-slurry and high-viscosity services. A reciprocating pump must have special fittings to be suitable for most slurries.

Net Positive Suction Head

Net positive suction head (NPSH), also called **net positive inlet pressure (NPIP)** and **net inlet pressure (NIP),** is the difference between suction pressure and vapor pressure, at the pump suction nozzle, when the pump is running. In a reciprocating pump, NPSH is required to push the suction valve from its seat and to overcome the friction losses and acceleration head within the pump liquid end. In a rotary pump, NPSH is required to push the pumpage into the cavities created by the pumping elements.

If sufficient NPSH is not provided by the system, the pumpage will begin to flash (boil) as it flows into the pump. The vapor will cause a deterioration of pump performance. As the vapor flows into regions of higher pressure in the pump, it condenses back to a liquid. This collapse of the vapor bubbles occurs with significant impact, impinging upon metal surfaces with enough energy to break out small pieces of the metal. This is called **cavitation** damage. The shock created by the bubble collapse may be severe enough to crack a fluid cylinder or break a crankshaft.

All pumps require the system to provide some NPSH. The NPSH provided by the system is called NPSHA (the A is for available). The NPSH required by the pump is called NPSHR. For displacement pumps, NPSHR is normally expressed in pressure units (lb/in^2 or kPa).

Since water usually contains dissolved air, the vapor pressure of the solution is higher than for deaerated water, but this is often overlooked when NPSH calculations are performed. The Hydraulic Institute recommends an NPSH margin of 3 lb/in^2 (20 kPa) for power pumps in systems where the pumpage has been exposed to a gas other than the liquid's own vapor. A liquid (such as propane) at its bubble point in the suction vessel requires no such margin.

RECIPROCATING PUMPS

A **reciprocating pump** is a displacement pump which reciprocates the pumping element (piston, plunger, or diaphragm). The capacity of a reciprocating pump is proportional to its speed, and is relatively independent of discharge pressure.

A **power pump** is one that reciprocates the pumping element with a crankshaft or camshaft (see Figs. 14.1.2 and 14.1.3). It requires a driver which has a rotating shaft, such as a motor, engine, or turbine. A constant-speed power pump will deliver essentially the same capacity at any pressure within the capability of the driver and the strength of the pump.

A **direct-acting** pump is a reciprocating pump driven by a fluid which has a differential pressure (see Fig. 14.1.4). The motive fluid pushes on

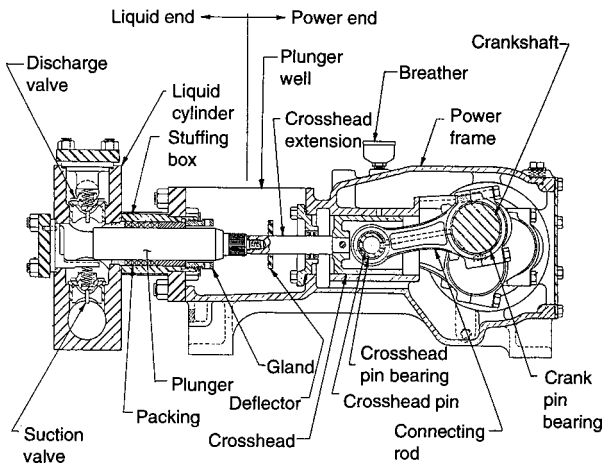

Fig. 14.1.2 Horizontal power pump.

a piston (or diaphragm) which pushes the pumping element through a rod (or directly on the pumpage).

Reciprocating pumps are classified by the following features:

Drive end (power or direct-acting)

Orientation of centerline of the pumping element (horizontal or vertical)

Number of discharge strokes per cycle of each drive rod (single-acting or double-acting)

Pumping element (piston, plunger, or diaphragm)

Number of drive rods (simplex, duplex, triplex, quintuplex, etc.)

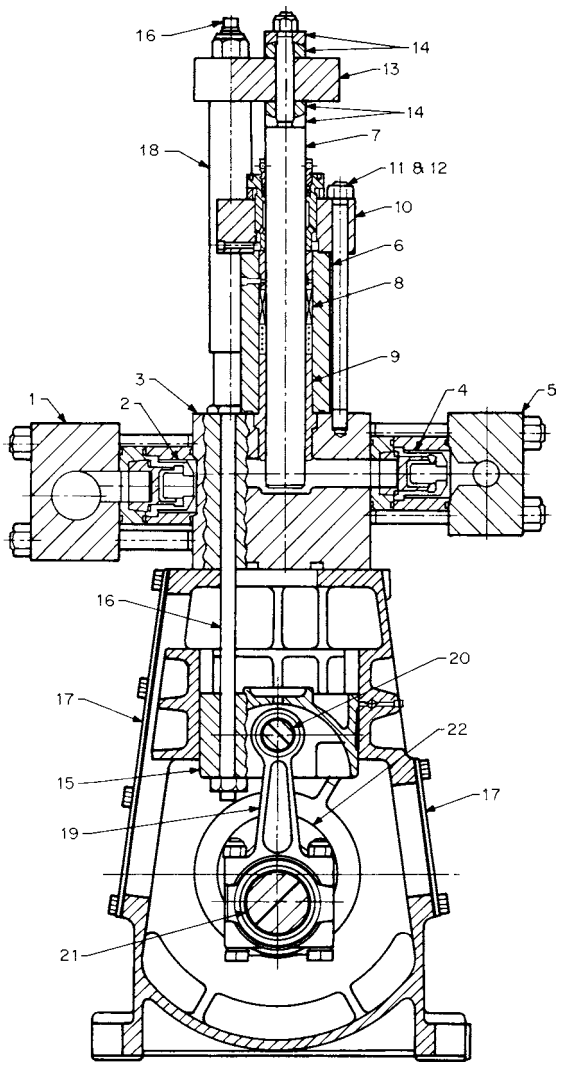

Fig. 14.1.3 Vertical power pump. *(Ingersoll-Rand Company.)*

Uses and Applications for Reciprocating Pumps

The justification for selecting a reciprocating pump instead of a centrifugal or rotary is cost, including costs of power and maintenance.

Reciprocating pumps are best suited for high-pressure/low-capacity services. Such services include high-pressure water-jet cleaning and cutting; glycol injection and charge, as well as amine and lean oil charge, in gas processing; ammonia and carbamate charging for fertilizer production; nuclear-reactor charging and standby control; oil-field saltwater injection and disposal; oil well blowout preventers; pipelines (slurries and crude oil, and injection of ammonia and light hydrocarbons); steel and aluminum mill hydraulic systems; knockout drums in process plants; hydrostatic testing; process slurries; metering; food and chemical homogenizing; well-drilling mud; and car washes.

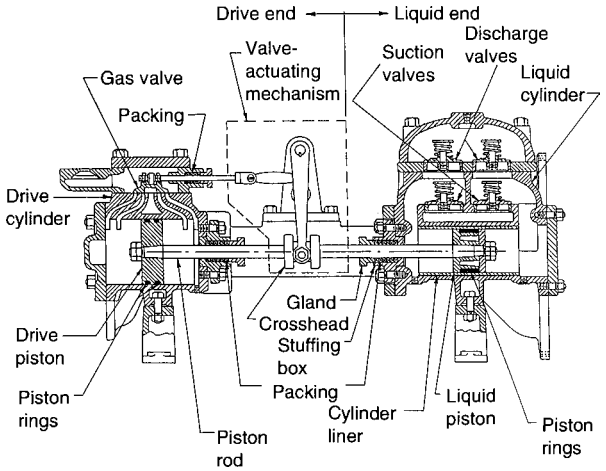

Fig. 14.1.4 Horizontal direct-acting gas-driven pump.

Applications that practically mandate reciprocating units are abrasive and/or viscous slurries above about 500 lb/in^2 (3500 kPa). Examples of these services range from powdered coal to peanut butter.

High-Pressure Applications

Hand-powered pumps, for pressures to 40,000 lb/in^2 (300 MPa), are used for small jacks, deadweight testers, and hydrostatic testing of small components. Small, air-driven direct-acting pumps are used for low-flow, high-pressure systems such as hydrostatic testing. The liquid pressure is approximately the air pressure multiplied ("intensified") by the ratio of the air piston area to the liquid plunger area. They are very simple and will stall and hold a fixed pressure without using power; but when pumping, they consume relatively large amounts of air. Available up to 10 hp (7 kW), the most popular sizes are up to 2 hp (1.5 kW). Pressures range to 100,000 lb/in^2 (700 MPa).

Hydraulically driven **intensifiers** operate on the same principle, but are more efficient, and because of the higher pressures commonly available from hydraulic systems, can produce high pressures with lower intensification ratios. Intensifiers are available to 300,000 lb/in^2 (2100 MPa) for laboratory-scale hydrostatic applications. Intensifier systems for water jetting are available from 30,000 to 60,000 lb/in^2 (210 MPa to 410 MPa) up to 200 hp (150 kW). They are powered by electric motors or diesel engines. Figure 14.1.5 shows the pumping end of an intensifier.

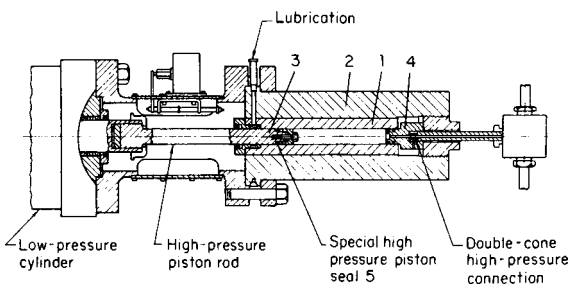

Fig. 14.1.5 Pumping end of a direct-acting, liquid-driven, "intensifier" pump. The check valves are in the tubing.

Power pumps (usually triplex or quintuplex) are available from about 5 to 150 hp (5 to 100 kW) with pressures to 40,000 lb/in^2 (280 MPa), and up to 2,000 hp (1,500 kW) at 20,000 lb/in^2 (140 MPa). Power pumps are efficient and mechanically simple. Figure 14.1.6 shows a power pump liquid end for a 36,000 lb/in^2 (250 MPa) water-jetting pump.

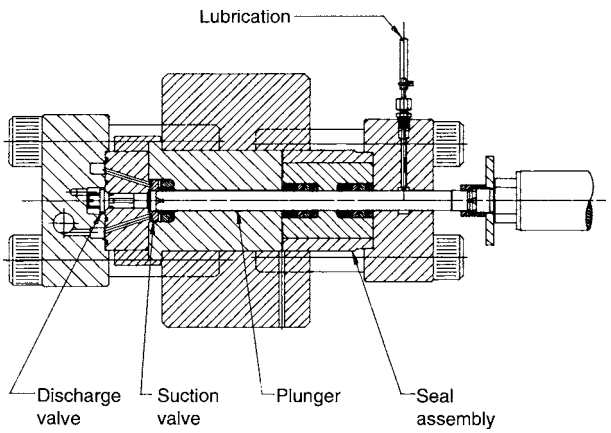

Fig. 14.1.6 Power pump liquid end for 36,000 lb/in^2 (250 MPa) water jetting. *(NLB Corporation.)*

Slurry Applications

The standard reciprocating pump is not designed to handle slurries. Modifications to standard designs, and in some cases special designs, are required to achieve satisfactory operation and component life.

To achieve satisfactory packing and plunger life, abrasive slurry must be prevented from entering the packing. Methods include a wiper ring between the pumpage and packing, a long throat bushing, injection of a clean liquid into the throat area, insertion of a diaphragm or floating piston between the plunger and the pumpage, and complete removal of the valve assembly from the stuffing box area. This last arrangement requires a liquid column between the valve assembly and the stuffing box, which increases the clearance volume and acceleration head within the pump.

Special pump valves are usually required for slurries. Depending on the nature of the solids, they can be ball, bell, bevel seat with elastomer insert, wing-guided with reduced seating area, or disk with special seating surfaces. Special construction can prevent the slurry from contacting the packing, but the valves cannot avoid contact with the slurry.

Problems and How to Avoid Them

Reciprocating pumps have some disadvantages, the most common being pulsating flow. Because of the pulsation, special consideration must be given to system design. Guidelines are provided later in this section.

In most applications, the initial and maintenance costs for a reciprocating pump will be greater than for a centrifugal or rotary pump. The packing in a typical power pump lasts about 2,500 hours, less than a mechanical seal on a rotating shaft.

Most problems with reciprocating pumps can be minimized by selecting pumps to operate at conservative speeds, by carefully designing the pumping system, by careful operating procedures, and by maintenance practices which preserve the alignment of the plunger (or rod) with the stuffing box.

Liquid-End Components

All reciprocating pumps contain one or more pumping elements (pistons, plungers, or diaphragms) that reciprocate into and out of the pumping chambers. (In reciprocating pump terminology, a **piston** is a cylindrical disk which mounts on a rod. A **plunger** is just a smooth rod.) Each pumping chamber contains at least one suction and one discharge valve.

The liquid cylinder is the major pressure-retaining part of the liquid end, and forms the major portion of the pumping chamber.

A piston pump is normally equipped with a replaceable liner (sleeve) that absorbs the wear from the piston rings. Because a plunger contacts only stuffing-box components, plunger pumps do not require liners.

Sealing between the pumping chamber and atmosphere is accomplished by a **stuffing box** (Fig. 14.1.7). The stuffing box contains rings of packing that conform to and seal against the stuffing box bore and the rod (or plunger).

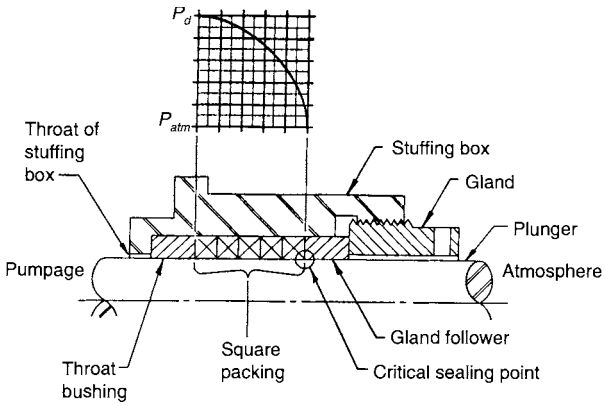

Fig. 14.1.7 Reciprocating pump stuffing box (nonlubricated) showing pressure gradient during discharge stroke.

The valves in a reciprocating pump are simply check valves which are opened by the liquid differential pressure. Most valves are springloaded. They have a variety of shapes, including spheres, hemispheres, and disks. Disks may be center-guided, outside-diameter-guided, or wing-guided. Figures 14.1.8 through 14.1.13 illustrate some of the valves used in reciprocating pumps.

The Pumping Cycle

As the pumping element reverses from the discharge stroke to the suction stroke, liquid within the pumping chambers expands, and the pressure drops. Since most liquids are relatively incompressible, little movement of the element is required to reduce the pressure. When the pressure drops sufficiently below suction pressure, the differential pressure (suction pressure minus chamber pressure) pushes the suction valve open. This occurs when the element is moving slowly, so that the valve opens slowly and smoothly as the velocity of the element increases. Liquid then flows through the valve and follows the element on its suction stroke. As the element decelerates near the end of the stroke, the suction valve returns to its seat. When the element stops, the suction valve closes.

The pumping element then reverses and starts its discharge stroke. The liquid trapped in the pumping chamber is compressed until chamber pressure exceeds discharge pressure by an amount sufficient to push the discharge valve from its seat. The action of the discharge valve, during the discharge stroke, is then the same as that of the suction valve during the suction stroke.

Power Pumps

The drive end of a power pump is called a **power end** (see Fig. 14.1.2). Its function is to convert rotary motion from a driver into reciprocating motion for the liquid end. The main component of the power end is the **power frame,** which supports all other power end parts and, usually, the liquid end. The second major component of the power end is the **crankshaft** (sometimes a camshaft). The crankshaft transmits power from the driver to the connecting rods.

The **connecting rod** is driven by a throw (journal) of the crankshaft on one end, and drives a crosshead on the other. The crankshaft moves in pure rotating motion, the crosshead in pure reciprocating motion. The connecting rod is the link between the two. **Main bearings** support the shaft in the power frame.

The **crosshead** transmits the force from the connecting rod into the pumping element. It is fastened directly to a plunger or piston rod, or to a rod called an **extension, stub,** or **pony rod.** The other end of this rod is fastened to the pumping element.

Power pump overall efficiencies normally range from 85 to 94 percent, higher than any other type of pump.

Selection Graphs Different manufacturers produce these graphs in different configurations. All graphs consist of straight lines since displacement is directly proportional to speed. Figure 14.1.14 shows one such graph for a triplex power pump. Displacement is plotted against crankshaft speed for the different plunger diameters available in the pump. The pressures listed are those at which each plunger size would operate to load the power end to its rated value (4,500 lbf or 20,000 N).

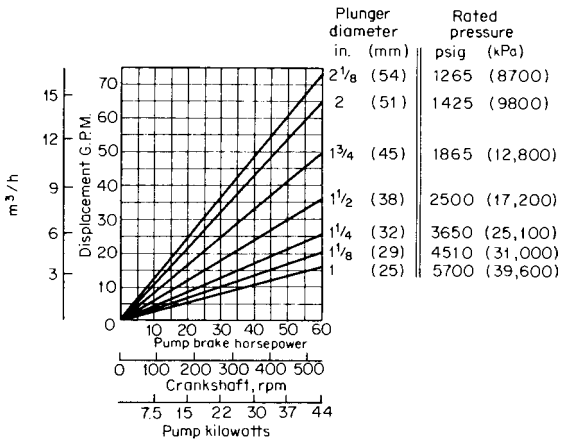

Fig. 14.1.14 Power pump selection graph. *(Ingersoll-Rand Company.)*

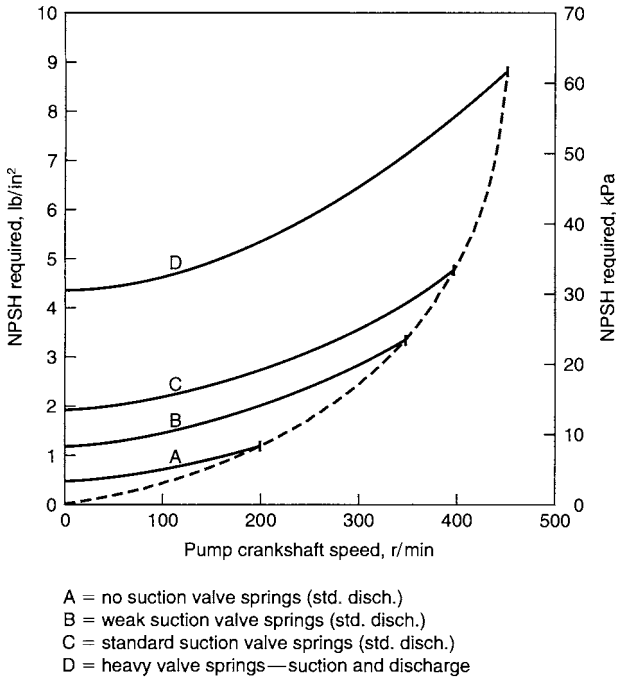
NPSH Curves Figure 14.1.15 provides insight into power pump NPSHR characteristics, valve action, and the effect of valve springs on pump performance. These curves are for a 3-in (76-mm) stroke, horizontal, triplex plunger power pump with $2^1/_4$-in-diameter (57-mm) plungers, and with suction valves that operate vertically. The valves are wing-guided, and have a diameter approximately equal to the plunger diameter.

Because the axis of the suction valve is vertical, the valve can operate without a spring if the pump speed is kept low. Curve A represents the NPSH requirements with no springs on the suction valves. NPSHR at 100 r/min is only 0.7 lb/in^2 (5 kPa) (1.6 ft or 0.5 m of water), less than for most centrifugals.



A = no suction valve springs (std. disch.)
B = weak suction valve springs (std. disch.)
C = standard suction valve springs (std. disch.)
D = heavy valve springs—suction and discharge

Fig. 14.1.15 NPSH curves for a 3-in- (75-mm-) stroke triplex power pump.

The speed of the pump in this configuration is limited by the ability of the suction valve to keep up with the plunger. Since there is no spring to push the valve back onto its seat, gravity is the only force tending to close the valve against the entering fluid. If the pump is run too fast, the valve will still be off its seat when the plunger reverses to the discharge stroke. The liquid will then momentarily flow backward through the seat, and the valve will be slammed onto the seat, sending a shock wave into the suction manifold and piping. At that moment, the plunger is moving at a finite velocity, but the discharge valve is still closed. The pressure in the pumping chamber will quickly exceed discharge pressure, and the discharge valve will be driven from its seat. A shock wave will be transmitted from the pumping chamber through the discharge manifold, and into the discharge line. The vertical line at the end of Curve A indicates the maximum speed for proper suction valve operation.

Curve B is for weak springs added to the suction valves. Because both spring force and valve weight must now be overcome to open the suction valve, NPSHR has increased about 100 percent over Curve A. These springs get the suction valves onto their seats quicker, so that operation is smooth at higher speeds.

If speeds beyond the end of Curve B are desired, stronger suction valve springs are required. Stronger springs allow operation to 400 r/min. NPSH requirements are about 3 times those of Curve A, ranging from about 2 to 5 lb/in^2 (14 to 35 kPa).

Curves A through C represent a pump equipped with the same (standard) discharge valve spring. Only the suction spring has been changed.

If operation is required at speeds exceeding the limits of Curve C, extra-strong springs are required on both suction and discharge valves. As shown by Curve D, NPSHR is about double that required for the standard springs, ranging from about 4.5 to 9 lb/in^2 (31 to 62 kPa).

The dashed line passing through the ends of the NPSH curves illustrates the dramatic increase of NPSHR as pump speed is increased. When it is necessary to change suction springs, NPSHR increases approximately as the **square** of speed.

To minimize the problem of dissolved air, the NPSH tests that produced these curves were performed with water at, or near, its boiling point in the suction vessel.

Reciprocating pumps, under the correct conditions, can operate with a suction pressure below atmospheric. Such a situation, though, can lead to air being drawn through the stuffing box packing and into the pumping chamber on the suction stroke. This air will cause as many problems as air entrained in the pumpage. Capacity will drop, the pump may operate noisily, the system may vibrate, and damage may occur to pump and system components.

This inward air leakage can be reduced by an external sealing liquid, such as lubricating oil, being directed onto the plunger surface or into the packing.

Test Criteria for NPSH Power pump NPSH tests are performed by holding the pump speed and discharge pressure constant, and varying the NPSH available (NPSHA) in the system. Capacity remains constant for all NPSHA values above a certain point. Below this NPSHA value, capacity beings to fall. NPSHR is defined as the NPSH available when the capacity has dropped 3 percent.

Acceleration Head Because the velocities in the suction and discharge piping are not constant, the pumpage must accelerate a number of times for each revolution of the crankshaft. Since the liquid has mass and, therefore, inertia, energy is required to produce the acceleration. This energy is returned to the system upon deceleration. Sufficient pressure, however, must be provided to accelerate the liquid on the suction side of the pump to prevent cavitation in the suction pipe and/or the pumping chambers. The drop in pressure, below the average, on the suction side, caused by this acceleration, is called **acceleration head.**

An approximation of acceleration head for power pumps is given by the equation $h_a = LvNC/gK$, where h_a = acceleration head, ft (m) of liquid being pumped; L = actual length of suction line (not equivalent length), ft (m); v = average liquid velocity in suction line, ft/s (m/s); N = speed of pump crankshaft, r/min; C = constant, depending on type of pump; g = gravitational constant, ft/s^2 (m/s^2); and K = fluid compressibility correction factor. Values for the constants C and K are:

Pump type	C
Simplex, single-acting	0.400
Duplex, single-acting	0.200
Triplex	0.066
Quintuplex	0.040
Septuplex	0.028
Nonuplex	0.022

Fluid	K
Slightly compressible liquids such as deaerated water	1.4
Most liquids	1.5
Highly compressible liquids (such as ethane)	2.5

Note that increasing the pump speed, without changing the suction line, increases h_a as the square of speed, because both v and N increase proportionately with speed.

Because this equation does not adequately compensate for pumpage and system elasticity, it is recommended only for short, rigid suction lines.

To reduce acceleration head in a suction line, a bottle or suction stabilizer may be installed in the pipe, adjacent to the pump.

Figure 14.1.16 shows the theoretical flow rates for various types of power pumps during one revolution of the crankshaft. Pumps with an odd number of cranks have the same flow variations for both single-acting and double-acting liquid ends (except the simplex). Flow curves for septuplex and nonuplex pumps are similar to the quintuplex curve, with

	Number of plungers
A = Simplex - double acting	1
Max. rate of flow above mean 59.96%	
Min. rate of flow below mean 100.0 %	
B = Duplex - double acting - cranks 90° apart	2
Max. rate of flow above mean 26.72%	
Min. rate of flow below mean 21.56%	
C = Triplex - single acting - cranks 120° apart	3
Max. rate of flow above mean 6.64%	
Min. rate of flow below mean 18.42%	
D = Quintuplex - single acting - cranks 72° apart	5
Max. rate of flow above mean 1.88%	
Min. rate of flow below mean 5.63%	
Septuplex - single acting - cranks $51\frac{4}{7}$° apart	7
Max. rate of flow above mean 1.2%	
Min. rate of flow below mean 2.8%	
Nonuplex - single acting - cranks 40° apart	9
Max. rate of flow above mean 0.7%	
Min. rate of flow below mean 1.5%	

Fig. 14.1.16 Flow-rate variations in reciprocating power pumps.

more but smaller variations, as indicated in the tabulation. The values tabulated will vary slightly with variations in the ratio of connecting rod length to stroke length. These curves indicate flow-rate variations, not **pressure pulsations.** Pressure pulsations are a product of the acceleration created by the pump and the mass of the pumpage in the system.

Actual flow rates may vary considerably from these curves, particularly with high-speed pumps, where valve closing and opening may lag the crankshaft rotation as much as 15°, and at high pressures, where liquid compression may cause a further lag of 5° to 10° (or more for a large clearance volume).

Power Pump Speeds Probably the most controversial factor in the selection of power pumps is the maximum allowable speed. Some manufacturers, for example, offer 3-in- (76-mm-) stroke triplex pumps for operation at 500 r/min. One builder of portable water-jetting units routinely operates this size pump at 600 r/min. Most users of this size pump, in continuous-duty applications, prefer to operate it no faster than about 400 r/min.

Top speeds quoted by one manufacturer for the 3-in-stroke triplex increased over a period of years from 150 to 520 r/min. Although improvements in power end and liquid end construction made the pump capable of operating at higher speeds, albeit with shorter packing life, a major obstacle to higher speeds is system design. Initially, some thought that a smaller pump, running faster to achieve the same capacity, would produce less pulsation in the suction and discharge pipes. Unfortunately, the opposite is true.

The velocity variation in the piping for a triplex pump is 25 percent, regardless of the pump size or speed (see Fig. 14.1.16). For the same capacity, a smaller pump, running faster, will produce the same maximum and minimum flow rates and more pulses per second. Since the acceleration head is proportional to frequency, doubling the pump speed doubles the acceleration head, thereby reducing the NPSH available from the system. Also, doubling the speed requires a much stiffer valve spring, thereby significantly increasing the NPSHR of the pump. If the NPSHA drops below the NPSHR, cavitation and pounding will occur.

The best solution for excessive acceleration is an effective dampener in the suction line; but such devices often are less effective at higher frequencies, due to the inertia of their moving parts and inertia of the liquid inside them, which must oscillate for them to function.

Through field observations, the author developed a set of **maximum recommended speeds** for plunger-type power pumps in continuous-duty services. These speeds, as adopted by API 674, are shown in Fig. 14.1.17, along with the Hydraulic Institute basic speeds. Intermittent and cyclic operation is often satisfactory above these speeds. Lower speeds may be dictated by factors such as pump construction, system design, low NPSHA, entrained gas, high temperature, entrained solids, high viscosity, and requirements for a low sound level.

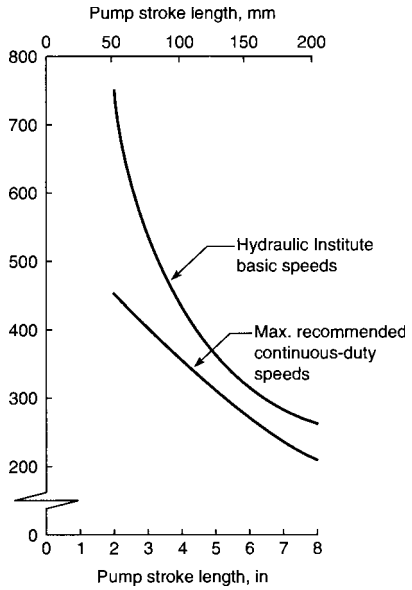


Fig. 14.1.17 Maximum recommended speeds for plunger-type power pumps in continuous-duty services.

The **minimum speed** of a power pump is determined by its ability to provide sufficient lubrication to all bearing surfaces in the power end. Some units can run satisfactorily at 20 r/min. Others must be maintained at 100 r/min or more.

Plunger load (also called **frame load** and **rod load**) is the force transmitted to the power end by one plunger. For a single-acting pump, the discharge plunger load is calculated by multiplying discharge pressure by the cross-sectional area of one plunger. Suction plunger load is the suction pressure multiplied by the plunger area.

A power pump is rated by the maximum discharge plunger load that the power end is capable of absorbing when the suction pressure is zero. Some units are rated for continuous operation, some for intermittent operation, and some are rated both ways.

Torque Characteristics For fixed suction and discharge pressures, a power pump requires an **average** input torque that is independent of speed (except for increases at very low and very high speeds). The torque actually has a variation that mirrors the discharge flow-velocity curve. A power pump will require the same torque at one-half or one-quarter rated speed and, therefore, will require one-half or one-quarter rated power, respectively. Figure 14.1.18 illustrates the variation of average torque with speed for a typical triplex power pump.

The curve for full-load torque in Fig. 14.1.18 is for starting against full discharge pressure. Breakaway torque is about 150 percent of average full-load running torque. As speed is increased, and proper lubrication is established in the power end and packing, torque drops to the full-load, full-speed value, and is thereafter constant up to full speed.

For a start-up that is easier on equipment, pump discharge is piped back to the suction vessel, making the discharge pressure near suction pressure. The no-load curve in Fig. 14.1.18 illustrates the resulting torque requirements imposed by the pump on the drive train. Breakaway torque is approximately 25 percent of full-load torque. This will vary, depending on the type of packing and bearings in the pump and the length of time the pump has been idle. As speed increases, the torque drops to less than 10 percent of the full-load torque.

Packing The component normally requiring the most maintenance on reciprocating pumps is packing. Although the life of packing in a power pump is typically about 2,500 h (3 months), some installations, with special stuffing box arrangements, have experienced lives of more than 18,000 h (2 years), at discharge pressures to 4,000 lb/in^2 (28 MPa).

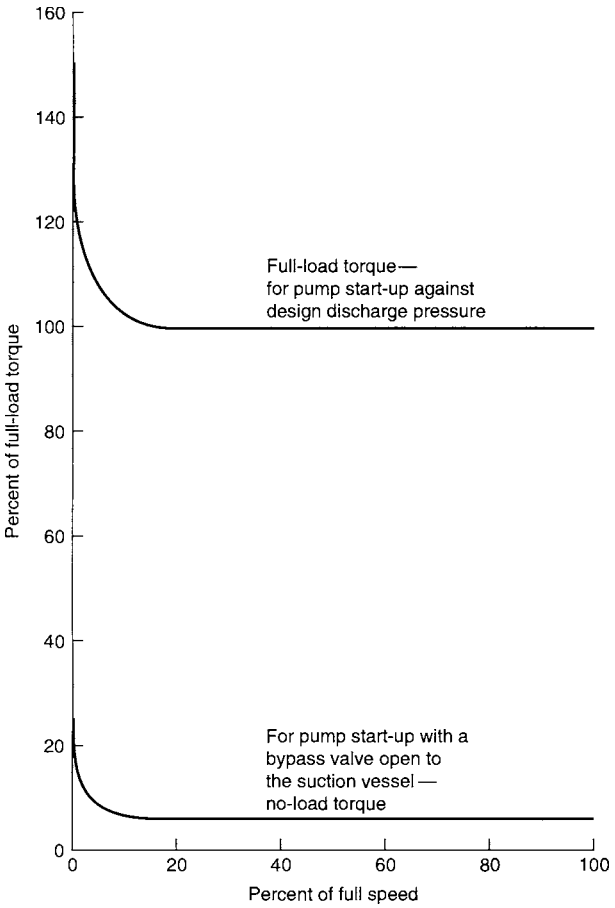

Fig. 14.1.18 Torque-speed curves for a typical triplex power pump.

Short packing life can result from any of the following conditions: (1) misalignment of plunger (or rod) with stuffing box; (2) worn plunger, rod, stuffing-box bushings, or stuffing-box bore; (3) improper packing for the application; (4) insufficient or excessive lubrication; (5) packing gland too tight or too loose; (6) excessive speed or pressure; (7) high or low temperature of pumpage; (8) excessive friction (too much packing); (9) packing running dry (pumping chamber gas-bound); (10) shock conditions caused by entrained gas or cavitation, broken or weak valve springs, or system problems; (11) solids from the pumpage, environment, or lubricant; (12) improper packing installation or break-in; and (13) icing caused by volatile liquids that refrigerate and form ice crystals on leakage to atmosphere, or by pumpage at temperatures below 32°F (0°C). As is evident from this list, short packing life can indicate problems elsewhere in the pump or system.

To achieve a low leakage rate, the clearance between the plunger (or rod) and packing must be essentially zero. This requires that the sealing rings be relatively soft and pliant. Because the packing is pliant, it tends to flow into the stuffing box clearances, especially between the plunger and follower bushing. If this bushing does not provide an effective barrier, the packing will extrude, and leakage will increase.

A set of square or V-type packing rings will experience a pressure gradient, during operation, as indicated in Fig. 14.1.7. The last ring of packing, adjacent to the gland-follower bushing, will experience the largest axial loading, resulting in greater deformation, tighter sealing and, therefore, the largest pressure drop. The gap between the plunger and the follower must be small enough to prevent packing extrusion. Most packing failures originate at this critical sealing point.

Because this last ring of packing is the most critical, does the most sealing, and generates the most friction, it requires more lubrication than the others. In a nonlubricated arrangement (Fig. 14.1.7), this ring must rely on the plunger to drag some of the pumpage back to it in order to provide cooling and lubrication. Therefore, to maximize packing life, the overall stack height of the packing should not exceed the stroke length of the pump.

Because the last ring of packing requires more lubrication than do the others, lubrication of the packing from the atmospheric side is more effective than injecting oil into a lantern ring located in the center of the packing. Care must be exercised to get the lubricant onto the plunger surface and close enough to the last ring, so that the stroke of the plunger will carry the lubricant under the ring.

During the first few hours of pump operation with new packing, each stuffing box should be monitored for temperature. It is normal for some boxes to run warmer than others—as much as 50°F (30°C) above the pumping temperature. Only if this exceeds the maximum temperature rating of the packing are steps required to reduce box temperature.

The best lubricant for packing in most services has been found to be steam cylinder oil.

The concepts that a higher discharge pressure requires more rings of packing and that a larger number of rings lasts longer are true for long-stroke, low-speed machines, but have been disproven in a number of moderate- to high-speed power-pump applications. Unless they are profusely lubricated, the larger number of rings create additional frictional heat and wipe lubricant from the plunger surface, thus depriving some rings of lubrication. On numerous saltwater injection pumps operating at pressures above 4,000 lb/in^2 (28 MPa), Chesney reported that packing life was only two weeks with twelve rings of packing in each stuffing box. With three rings in each box, packing life was approximately 6 months.

Plungers Next to packing, the plunger is the component of a power pump that typically requires most frequent replacement. The high speed of the plunger and the friction load of the packing tend to wear the plunger surface. For longer life, plungers are sometimes hardened, although it is more common to apply a hard coating. Such coatings are of chrome, various ceramics, nickel-based alloys, or cobalt-based alloys. Desired characteristics of the coatings include hardness, smoothness, high bond strength, low porosity, corrosion resistance, and low cost. No one coating optimizes all characteristics.

Ceramic coatings are harder than the metals, but are brittle, porous, and sometimes lower in bond strength. Porosity contributes to shorter packing life. Mixing of hard particles, such as tungsten carbide, into the less-hard nickel or cobalt alloys has resulted in longer plunger life at the expense of shorter packing life.

Stuffing Boxes Various stuffing box designs (various lubrication and bleed-off arrangements to minimize leakage and extend packing life) are shown in Fig. 14.1.19.

The most significant advance in packing arrangements in recent years has been spring loading. Spring loading is applied most to V-ring (chevron) packing but also works well with square packing. The spring must be located on the pressure side of the packing. Springs of various types can be used, including single-coil, multiple coil, wave-washer, belleville, and thick-rubber-washer. The force provided by the spring is small compared to the force imposed on the packing by discharge pressure. The major functions of the spring are to provide a small preload to help set the packing, and to hold all bushings and packing in place during operation.

Spring loading of packing has the following advantages:

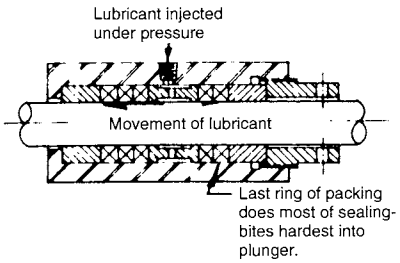
Requires no adjustment of the gland. The gland is tightened until it bottoms, then is locked. This removes one of the biggest variables in packing life: personnel skill.

Alloys expansion. If the packing expands during the initial break-in, the spring allows for the expansion.

Adjusts for wear. As the packing wears, adjustment automatically occurs from inside the box. The problem of transmitting gland movement through the top packing ring is eliminated.

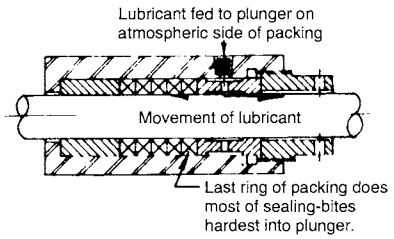
Provides a cavity. The spring cavity provides an annular space for the injection of a clean liquid for slurry applications.

Ⓐ Standard Lubricated Stuffing Box



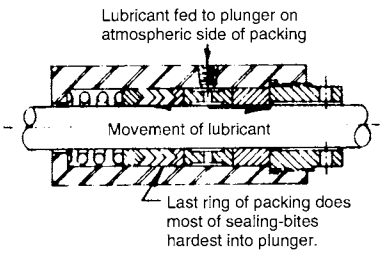
1. Good design.
2. Most of lubricant migrates into pumpage.
3. Packing may be square, chevron, or nonadjustable.

Ⓑ Alternate Lubricated Stuffing Box



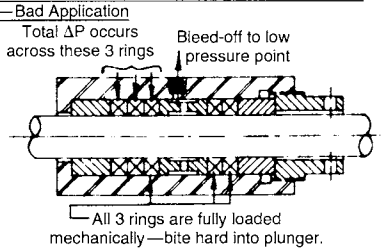
1. Good design—performs better than standard arrangement in most cases.
2. Puts lubricant under last ring—where it's needed most.
3. Allows use of low-pressure and drip-type lubricators.
4. Very little lubricant migrates into pumpage.
5. Packing may be square, chevron, or nonadjustable.

Ⓒ Spring-Loaded Packing



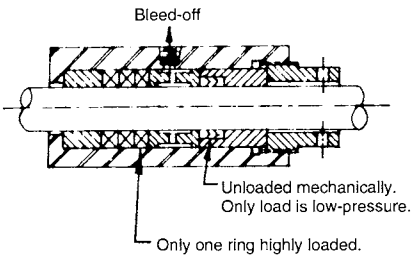
1. Good design—long life—minimal leakage.
2. Puts lubricant under last ring—where it's needed most.
3. Allows use of low-pressure and drip-type lubricators.
4. No adjustment required (self adjusting).

Ⓓ Standard Box Used to Bleed Pumpage to Low-Pressure Point—Bad Application



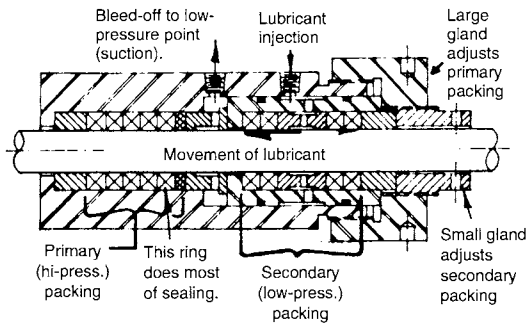
1. High friction causes excess heat.
2. Short life of packing and plungers.
3. Improper use of standard box—poor application.

Ⓔ Modified Gland Follower to Allow Bleed-Off to Low Pressure Point



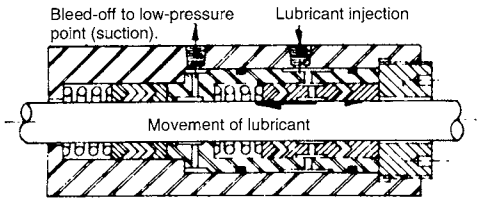
1. Less friction and lower temp. than "D".
2. Longer life of packing and plungers.
3. Big improvement over "D", but secondary packing not adjustable to compensate for wear.

Ⓕ Two-Gland Stuffing Box—Lubricated



1. The old standard for high-pressure, critical services.
2. Provides independent adjustment of primary and secondary packing. (Proper adjustment requires skilled mechanic.)
3. Full-size secondary packing.
4. Positive packing lubrication.
5. Negligible leakage to atmosphere.
6. Long packing and plunger life.
7. Excellent for volatile fluids.

Ⓖ Double Tandem Spring-Loaded Packing



1. The best design available for most high-pressure, critical services.
2. Combines best features of two-gland box and spring-loaded packing—negligible leakage, long life, and the packing is self-adjusting.

Fig. 14.1.19 Various stuffing box designs for reciprocating pumps.

Eliminates the need for a gland, if allowed by pump design. The stuffing box assembly (if a separate component) can be disassembled and reassembled on a workbench.

Disadvantages of spring-loading packing are associated with the cavity created by the spring. Since this cavity communicates directly with the pumping chamber, the additional clearance volume will cause a reduction in volumetric efficiency if the pumpage is sufficiently compressible. This cavity also provides a place for vapors to accumulate. If the pump design does not provide for venting this space, a further reduction in volumetric efficiency may occur.

Spring-loaded packing is the reciprocating pump's equivalent to the mechanical seal for rotating shafts. Leakage is low, life is extended, and adjustments are eliminated. Packing sets can be stacked in tandem (they must be independently supported) for a stepped pressure reduction, or to capture leakage from the primary packing that should not escape to the environment.

Controlled-Volume Pumps A **controlled-volume** pump (also called a **metering, proportioning,** or **chemical-injection** pump) is a power pump with an adjustable stroke length (or adjustable *effective* stroke length). It is used to provide an accurate, and adjustable, capacity. The capacity can be changed manually, as shown in Fig. 14.1.20, or with an electric, pneumatic, or hydraulic controller.

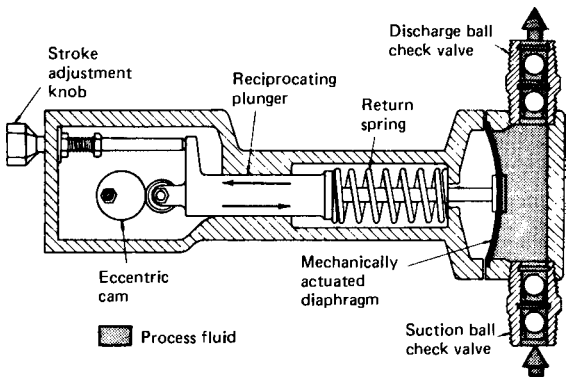


Fig. 14.1.20 Controlled-volume pump with mechanically actuated diaphragm and manual-adjustment stroke length. *(Reprinted from James P. Poynton, "Metering Pumps: Selection and Application," Marcel Dekker, Inc., Copyright 1983. Used by permission.)*

Such pumps can develop pressures to 30,000 lb/in^2 (200 MPa) with capacity controlled with ± 1 percent. The piston or plunger may come in direct contact with the pumpage, or may be separated from the pumpage by a diaphragm. The diaphragm may be flat, tubular, or conical. It can be actuated mechanically, as shown in Fig. 14.1.20, or hydraulically, as shown in Fig. 14.1.21. Mechanically actuated diaphragms are generally limited to capacities of 25 gal/h (100 L/h) and pressures of 250 lb/in^2 (1,700 kPa).

Direct-Acting Pumps

The direct-acting pump (see Fig. 14.1.4) has some of the same advantages as the power pump, plus others. These units are also well suited for high-pressure, low-flow applications. Discharge pressures normally range from 100 to 5,000 lb/in^2 (0.7 to 35 MPa), but may exceed 10,000 lb/in^2 (70 MPa). Capacity is proportional to speed from stall to maximum speed, affected little by discharge pressure. Speed is controlled by controlling the motive fluid. The unit is normally self-priming, particularly the low-clearance-volume type.

Direct-acting pumps are negligibly affected by hostile environments, such as corrosive fumes, because of the absence of a bearing housing, crankcase, or oil reservoir (except for units requiring lubricators). Some direct-acting pumps, inundated by floodwater, have continued to operate without adverse effects. The direct-acting pump is quiet, simple to maintain, and its low speed often results in a long life.

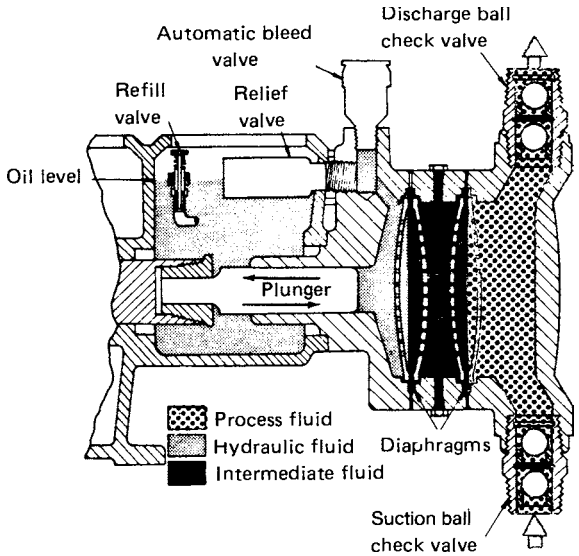

Fig. 14.1.21 Controlled-volume pump with hydraulically actuated double diaphragms. *(Reprinted from James P. Poynton, "Metering Pumps: Selection and Application," Marcel Dekker, Inc., Copyright 1983. Used by permission.)*

Since the direct-acting pump was originally designed to be driven by steam (initially, most pumps were), it was known as a **steam pump**—not for the pumped fluid, but for the motive fluid. Other fluids are now also used to drive direct-acting pumps. Fuel gas, which would otherwise be throttled through a pressure regulator for plant use, is often piped through a direct-acting pump to provide "free" pumping. Compressed air is frequently used to drive small pumps for services such as hydrostatic testing and chemical metering. Hydraulic oil is used to drive **intensifiers** for high-pressure water-jetting.

Direct-acting air-driven diaphragm pumps handle a variety of liquids at pressures up to the pressure of the driving air. This pump, as shown in Fig. 14.1.22, has no stuffing box or packing, and therefore has no leakage, unless a diaphragm fails. Failure of a diaphragm may result in pumpage in the exhaust air and/or air in the pumpage.

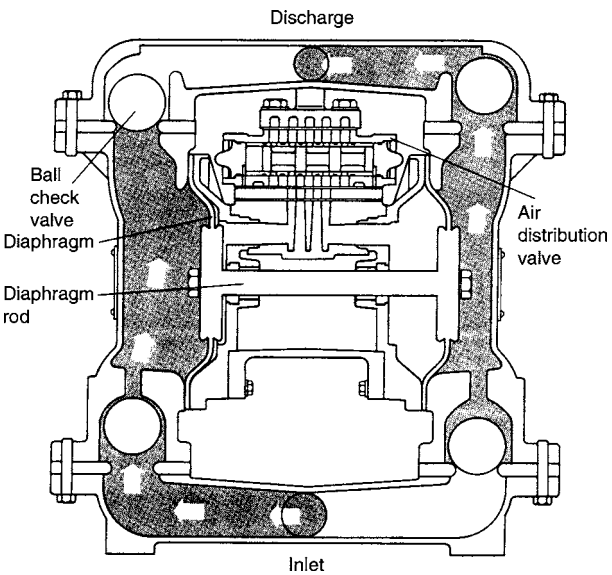

Fig. 14.1.22 Direct-acting, air-driven diaphragm pump. *(Used by permission of Warren Rupp, Inc., a unit of IDEX Corp., Mansfield, OH.)*

Direct-acting pumps operate at speeds that normally range from 0 to 50 cycles/min, depending on the stroke length. The ability of these units to operate at speeds down to zero (i.e., stall conditions) is desirable for some applications.

The direct-acting pump has a low thermal efficiency when driven by a gas (such as steam or air). The mechanical efficiency (output force divided by input force) is high; but because the unit has no device to store energy (such as a flywheel), the motive gas must remain at full inlet pressure in the drive cylinder through the entire stroke. At the end of the stroke, the gas expands to exhaust pressure, but no work is performed during this expansion. Hence, the thermal energy of the gas is lost to friction. Steam pumps consume about 100 lb/h of steam for each hydraulic horsepower (hhp) (60 kg/h · kW) developed on the liquid end. When natural gas or air is the motive fluid, consumption is about 3,500 std. $ft^3/h \cdot hhp$ (130 $m^3/h \cdot kW$).

The **drive end** (or steam end, or gas end) of a direct-acting pump converts the differential pressure of the motive fluid to reciprocating motion for the liquid end. It is similar in construction to the liquid end, containing a piston (or diaphragm) and valving. The major difference is that the valve is mechanically actuated by a control system which senses the location of the drive piston, causing the valve to reverse the flow of the motive fluid when the drive piston reaches the end of its stroke.

The main component of the drive end is the drive cylinder. This cylinder forms the major portion of the pressure boundary, and supports the other drive end parts.

Mechanical Efficiency—Direct-Acting Pumps For a direct-acting pump, mechanical efficiency is the ratio of the force transmitted to the liquid by the piston (or plunger or diaphragm) to the force transmitted to the drive piston (or diaphragm) by the motive fluid. For double-acting pumps, the differential pressures are used at both ends of the pump, and since fluid friction losses in valves and ports must be charged to the pump, the pressures are as measured at the inlet and outlet ports. In equation form:

$$\eta_m = \frac{A_L \, \Delta p_L}{A_{\text{dr}} \, \Delta p_{\text{dr}}} \tag{14.1.1}$$

where η_m = mechanical efficiency of pump, A_L = area of liquid piston or plunger, Δp_L = differential pressure across liquid end, A_{dr} = area of drive piston, and Δp_{dr} = differential pressure across drive end.

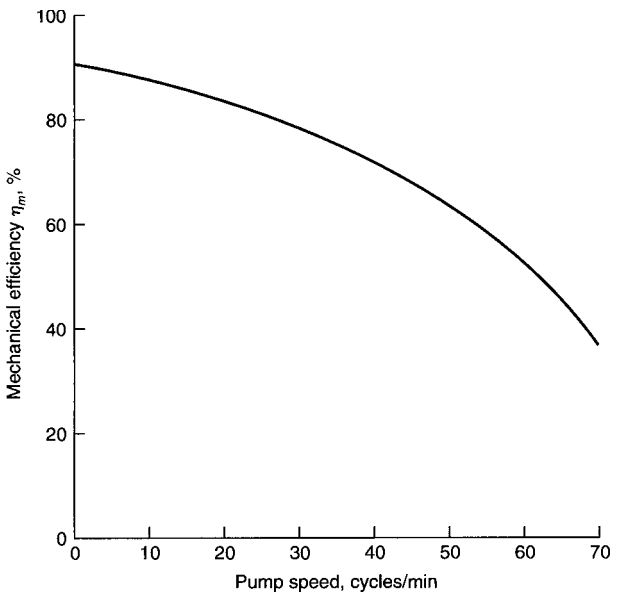

Fig. 14.1.23 Mechanical efficiency of a direct-acting pump.

The area of the piston rod is usually small relative to the piston area, and is often ignored. However, it must be considered when the rod area becomes a significant portion of the piston area.

The mechanical efficiency of a typical direct-acting pump is shown in Fig. 14.1.23. Note that η_m rises as speed is reduced. It is this characteristic that allows the unit to be controlled by throttling the motive fluid. The reduction in the available differential driving pressure forces the pump to operate more efficiently, i.e., at a lower speed.

ROTARY PUMPS

Rotary pumps are displacement pumps which have rotating pumping elements, such as gears, lobes, screws, vanes, or rollers. They do not contain inlet and outlet check valves, as do reciprocating pumps. They are built for capacities from a fraction of a gallon per minute (cubic metre per hour) (for domestic oil burners) to about 15,000 gal/min (3,000 m^3/h) (for marine cargo service). Though used for pressures up to 20,000 lb/in^2 (140 MPa), their particular field is for pressures of 25 to 500 lb/in^2 (170 to 3,500 kPa).

Most rotary pumps rely on close running clearances to prevent the pumpage from leaking from the discharge side back to the suction side of the pump. Because of the close clearances, the pumpage must be clean. Most rotary pumps are noted for their ability to handle viscous liquids, and many actually *require* a viscous liquid to achieve peak performance. Viscosity affects the mechanical efficiency, volumetric efficiency, and NPSHR of a rotary pump.

The **rotor** is the pumping element of the rotary pump, and is usually the feature by which the pump is classified.

Gears The teeth of the gear trap and displace the pumpage. If the teeth are on the outside of the gear, as shown in Fig. 14.1.24, it is called an **external gear**. As the teeth disengage, suction pressure pushes liquid

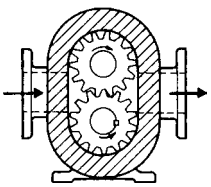

Fig. 14.1.24 External-gear rotary pump. *(Reprinted from "Hydraulic Institute Standards for Centrifugal, Rotary and Reciprocating Pumps," 14th ed., copyright 1983, with the permission of Hydraulic Institute.)*

into the cavities between the teeth. The teeth then carry the liquid around to the discharge side of the pump. As the teeth engage, the fluid is pushed into the discharge line. In the most common type of gear pump, one of the pumping gears drives the other pumping gear. This direct contact between the teeth requires the pumpage to be a good lubricant. In some units, though, the two pumping gears are driven by gears (called **timing gears**) mounted on the two shafts external to the pumpage. With this arrangement, the two pumping gears do not contact each other, and the unit is more suitable for liquids with low lubricity. This arrangement does, however, require a larger, more complex pump.

If the teeth are on the inside of a ring, as shown in Fig. 14.1.25, it is called an **internal gear.** In this unit, the larger internal-tooth gear

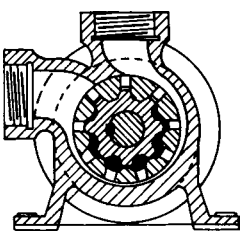

Fig. 14.1.25 Internal-gear rotary pump.

drives the smaller external-tooth gear. Both gears transfer liquid from the suction to the discharge.

Both external- and internal-gear rotary pumps are used in lubrication systems of engines, compressors, and larger pumps.

Lobe pumps are similar in construction and pumping action to external gear pumps, but one lobe does not drive the other. They do not even touch each other, and therefore must have their shafts independently driven by external timing gears. The lobes are often made of elastomers, and operate at low speeds. These units are used to transfer delicate items such as cherries and other foods—and even live fish. Figure 14.1.26 shows a rotary pump with three-lobe rotors.

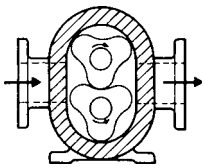

Fig. 14.1.26 Three-lobe rotary pump. *(Reprinted from "Hydraulic Institute Standards for Centrifugal Rotary and Reciprocating Pumps," 14th ed., copyright 1983, with the permission of Hydraulic Institute.)*

Screw pumps are constructed with one, two, or three screws. The single-screw pump is more commonly called a progressing-cavity pump, and is discussed separately below. The two-screw pump, as illustrated by Fig. 14.1.27, is used to handle liquids with viscosities to greater than 1,000,000 SSU (200,000 mm^2/s), with capacities to about 15,000 gal/min (3,000 m^3/h), pressures to 3,500 lb/in^2 (25 MPa), and temperatures to 600°F (300°C). It is particularly suited for high-viscosity liquids.

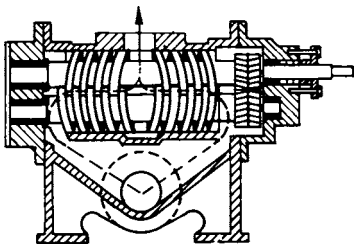

Fig. 14.1.27 Two-screw rotary pump.

The three-screw rotary pump, as illustrated in Fig. 14.1.28, is available, in the smaller sizes, for operation up to 8,000 r/min for use in lubrication systems on turbines, compressors, and centrifugal pumps. Larger units are found in such services as crude oil pipelines.

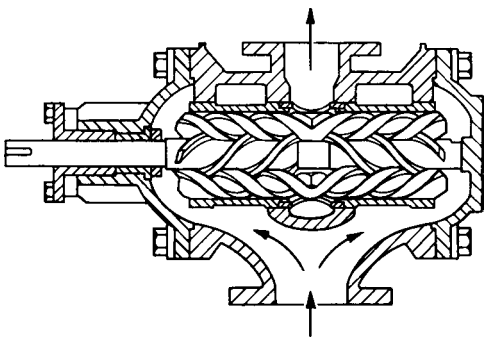

Fig. 14.1.28 Three-screw rotary pump.

A **progressing-cavity** pump is illustrated in Fig. 14.1.29. The rotor is made of polished steel, and in the shape of a single-lead screw. The stator, usually made of elastomer, is in the shape of a double-lead screw. As the rotor turns, its axis prescribes a circle. This characteristic requires the rotor to be driven by an internal universal joint (or equivalent). The pumpage moves through the pump in a spiral. The rubber stator makes this unit well-suited for abrasive services.

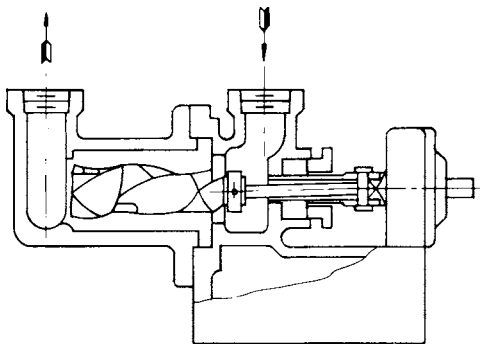

Fig. 14.1.29 Progressing-cavity (single-screw) rotary pump. *(Hydraulic Institute.)*

Figure 14.1.30 illustrates a **sliding vane** rotary pump. The single rotor contains multiple vanes which slide in radial slots. The rotor and casing are eccentric. The vanes maintain contact with the casing by centrifugal force and pressure. These units are typically available for capacities to 1,000 gal/min (200 m^3/h), viscosities to 500,000 SSU (100,000 mm^2/s), and pressures to 350 lb/in^2 (2.5 MPa). Some sliding-vane pumps are suitable for low-lubricity liquids such as light hydrocarbons.

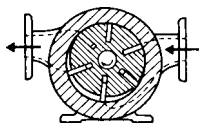

Fig. 14.1.30 Sliding-vane rotary pump. *(Reprinted from "Hydraulic Institute Standards for Centrifugal, Rotary and Reciprocating Pumps," 14th ed., copyright 1983, with the permission of Hydraulic Institute.)*

Flexible Member Some rotary pumps are built with flexible vanes, liners, and tubes. The flexible tube pump, also called a **peristaltic** pump, is shown in Fig. 14.1.31.

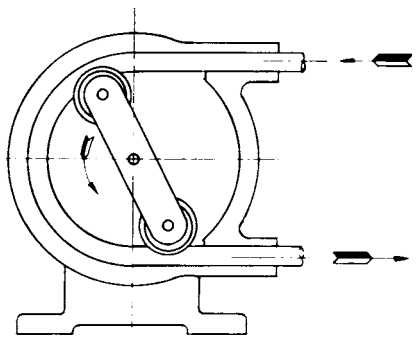

Fig. 14.1.31 Flexible-tube (peristaltic) rotary pump. *(Hydraulic Institute.)*

A **radial-plunger** rotary pump is shown in Fig. 14.1.32. An **axial-plunger** rotary pump (also called an **axial-piston** or **swash-plate** pump) is shown in Fig. 14.1.33. In these pumps, the inner body rotates, causing each plunger to alternately accept pumpage from the inlet and deliver it to the discharge port. In the radial pump, the length of stroke

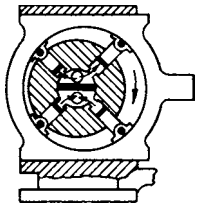

Fig. 14.1.32 Radial-plunger rotary pump.

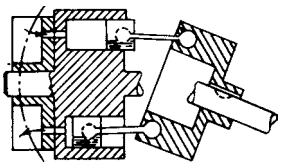

Fig. 14.1.33 Axial-plunger (swash-plate) rotary pump.

of each plunger is established by the eccentricity of the rotor. In the axial pump, the stroke length is established by the angle of the plate or shaft. On some pumps, the eccentricity (or angle) is adjustable, providing variable displacement. Rotary plunger pumps are used in hydraulic systems to provide power to hydraulic motors and cylinders.

Circumferential-Piston Pump Although sometimes considered a lobe pump, this unit (shown in Fig. 14.1.34) differs from the lobe unit in that there is no close clearance between the two rotors. Close clearance does exist, though, between each rotor and adjacent stationary parts.

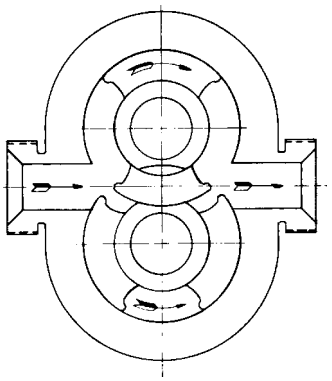

Fig. 14.1.34 Circumferential-piston rotary pump. *(Hydraulic Institute.)*

The **casing** (also called a **body** or **housing**) is the main pressure-retaining component of a rotary pump. It supports the rotor, contains the suction and discharge nozzles, and usually forms a portion of the boundaries of the pumping chambers.

The **bearings** of a rotary pump may be internal or external. If internal, they are lubricated by the pumpage. If the pumpage is not suitable for bearing lubrication, the bearings must be external. External bearings require two pumpage seals on each shaft. Some rotary pumps contain four seals.

Figure 14.1.35 shows typical **rotary pump performance curves.** Capacity, mechanical efficiency, and power are plotted against pressure.

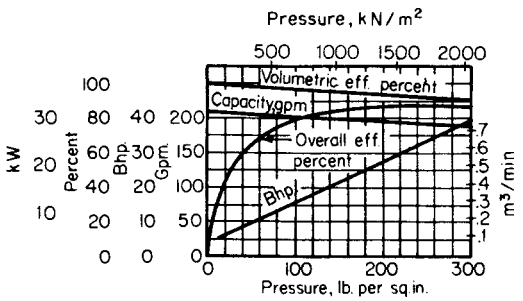

Fig. 14.1.35 Rotary pump performance curves for a herringbone gear pump at 600 r/min with a 400-SSU (90-mm²/s) liquid.

The difference between displacement and capacity is called **slip.** Power input is the sum of power output and power losses (due to friction and slip).

As defined by the Hydraulic Institute, the NPSH required by a rotary pump is that value of NPSHA when cavitation noise, a sharp drop in capacity, or a 5 percent reduction in capacity occurs, whichever occurs first.

Increased Running Clearances An increase in the clearances between the rotating parts, and/or between the rotating and stationary parts, of a rotary pump will cause the slip to increase. An increase in slip causes the volumetric efficiency to drop, the mechanical efficiency to drop, and the NPSHR to rise. If the unit is running at a constant speed, the lower volumetric efficiency (lower capacity) will result in a lower discharge pressure if the system head varies with capacity.

VOLUMETRIC EFFICIENCY

Volumetric efficiency η_v of a displacement pump is the ratio of capacity Q to displacement D: $\eta_v = Q/D$. Capacity is the volume flow rate in the suction pipe. Displacement is the volume swept by the pumping elements per unit time. For a single-acting triplex plunger pump, displacement may be calculated as follows: $D = 3(\pi/4)d^2LN$, where D = displacement; d = diameter of plunger; L = stroke length; and N = crankshaft speed, r/min.

To predict the capacity of a reciprocating pump, in the selection process, it is necessary to predict the volumetric efficiency. Volumetric efficiency may be calculated with the following equation:

$$\eta_v = 1 - \frac{S}{D'} - \frac{C}{D'}\left(\frac{v_s}{v_d} - 1\right) \qquad (14.1.2)$$

where η_v = volumetric efficiency; S = slip through both suction and discharge valves, typically about 3 percent of D'; D' = displacement of one pumping element during one stroke; C = clearance volume (dead space) in the pumping chamber (when the pumping element is at the end of the discharge stroke); v_s = specific volume of pumpage at suction conditions; and v_d = specific volume of the pumpage at discharge conditions.

Although volumetric efficiency has an effect on mechanical efficiency, in reciprocating pumps the two do not necessarily move in unison. It is possible to have a high η_m with a low η_v (due to liquid compressibility), or a low η_m with a high η_v (such as would occur in a high-suction-pressure, low-differential-pressure application).

The same equation can be applied to rotary pumps, but usually $v_s = v_d$, so that Eq. (14.1.2) reduces to $\eta_v = 1 - S/D'$. For a rotary pump, S = leakage of pumpage from the discharge side of the pump to the suction side. Because rotary pumps have no check valves, they must rely on close clearances to restrict slip. Slip is a function of the differential pressure, the viscosity of the pumpage, and the clearance between the parts. Slip in a rotary pump is usually a higher fraction of displacement than in a reciprocating pump.

POWER OUTPUT AND INPUT

The **power output** (also called **hydraulic power, hydraulic horsepower,** and **water horsepower**) of any pump is the usable power it imparts to the pumpage. It is the product of capacity and differential pressure.

In U.S. units, $P_o = Q \times \Delta p/1{,}714 = Q(p_d - p_s)/1{,}714$, where P_o = power output, hp; Q = pump capacity, gal/min; Δp = pump differential pressure, lb/in²; p_d = pump discharge pressure, lb/in²; and p_s = pump suction pressure, lb/in².

In metric units, $P_o = Q \times \Delta p/3{,}600 = Q(p_d - p_s)/3{,}600$, where P_o = power output, kW; Q = pump capacity, m³/h; Δp = pump differential pressure kPa; p_d = pump discharge pressure, kPa; and p_s = pump suction pressure, kPa.

The **power input** (sometimes called **brake horsepower**) is the power required to drive power and rotary pumps. Normally, the power input includes the losses in an integral gear unit, but not the losses in a separate

gear unit or variable-speed drive. V-belt losses may be included. If the mechanical efficiency is known, power input may be calculated by dividing the power output by the mechanical efficiency.

MECHANICAL EFFICIENCY—POWER AND ROTARY PUMPS

Mechanical efficiency (also called **pump efficiency** and **overall efficiency**) of a power-driven pump is the ratio of output power P_o to input power P_i: $\eta_m = P_o/P_i$.

As shown in Fig. 14.1.36, mechanical efficiency drops as the frame load is reduced, because the power output falls faster than friction losses, and becomes a smaller part of the power input. Mechanical efficiency is zero when the differential pressure is zero.

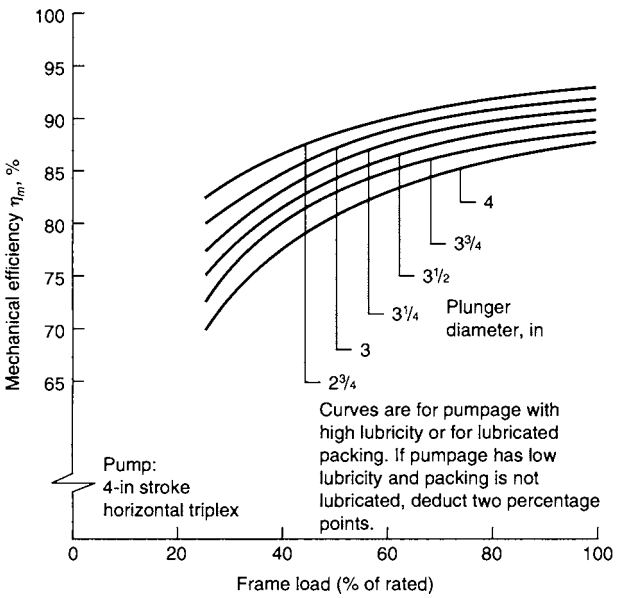

Fig. 14.1.36 Mechanical (overall) efficiency of a triplex power pump.

PULSATION DAMPENERS

A **pulsation dampener** is a device which reduces the pressure pulsations created, in a suction or discharge pipe, by the interaction of a pump and a system. The dampener performs this function by reducing the velocity variations of the pumpage in the pipe.

Most reciprocating pumps, and many rotary pumps, create a variation in the velocity of the pumpage in the piping. Unless the suction and discharge vessels are very close to the pump, these velocity variations will be converted by the system into pressure variations. To reduce these pulses, a small vessel can be installed in the suction and/or discharge line. Such a vessel mounted in the discharge line is called a **pulsation dampener.** If the suction pressure is high enough, this same type of device can be used in the suction line, but a special dampener, called a **suction stabilizer** will perform the dual function of reducing pulses and separating free gas from the pumpage.

For optimum effectiveness, each dampener must be installed close to the pipe and adjacent to the pump. There must be minimal restriction between the dampener and pipe. For a low suction pressure, a simple air-filled standpipe is often adequate. For the discharge side, and for high suction pressures, the dampener often contains a diaphragm or bladder that is precharged with nitrogen to about 70 percent of system pressure.

SYSTEM DESIGN

A properly designed system is necessary for a satisfactory installation. Improper design will result in a system that vibrates and is noisy. Pulsations may be severe enough to damage pump components and instrumentation.

Field experience and information from the Hydraulic Institute standards are condensed below into a list of general design guidelines for the (1) suction vessel, (2) suction piping, and (3) discharge piping. The asterisks in the following lists show features that *do not* apply to rotary pumps that produce a uniform flow rate (constant velocity).

The suction vessel should:

Be large enough to provide sufficient retention time to allow free gas to rise to the liquid surface.

Have the feed and return lines enter below the minimum liquid level.

Include a vortex breaker over the outlet (pump suction) line and/or provide sufficient submergence to preclude vortex formation.

Contain a weir plate to force gas bubbles toward the surface. The top of the weir must be sufficiently below the minimum tank level to avoid disturbance.

The suction piping should:

Be as short and direct as possible.

Be one or two pipe sizes larger than the pump suction connection.

Have an average liquid velocity less than the values in Fig. 14.1.37.*

Contain a minimum number of turns, which should be long-radius elbows or laterals.*

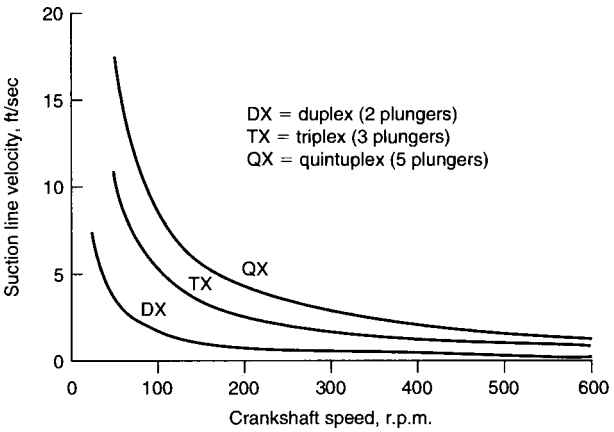

Fig. 14.1.37 Suction line velocities for constant acceleration head, for reciprocating power pumps.

Be designed to preclude the collection of vapor in the piping. (There should be no high points, unless vented. The reducer at the pump should be the eccentric type, installed with the straight side up.)

Be designed so that NPSHA, allowing for acceleration head, exceeds NPSHR.

Include a suitable suction stabilizer/gas separator located in the suction pipe adjacent to the pump liquid end if the acceleration head is excessive or the pumpage contains free gas.

Contain a full-opening block valve so that flow to the pump is not restricted.

Not include a strainer or filter unless regular maintenance is assured. (The starved condition resulting from a plugged strainer can cause more damage to a pump than solids.)

The discharge piping should:

Be one or two pipe sizes larger than the pump discharge connection.

Have an average velocity less than 3 times the maximum suction line velocity.

Contain a minimum number of turns, using long-radius elbows and laterals where practical.

Include a suitable pulsation dampener (or provisions for adding one) adjacent to the pump liquid end.*

Contain a relief valve, sized to pass full pump capacity at a pressure that does not exceed 110 percent of cracking pressure (the opening pressure of the relief valve). The discharge from the relief valve should be piped back to the suction vessel so that gases liberated through the valve are not fed back into the pump.

Contain a bypass line and valve so that the pump may be started against negligible discharge pressure.

Contain a check valve to prevent the imposition of system pressure on the pump during start-up.

The features of a good system are illustrated in Fig. 14.1.38.

Remedies for Low NPSHA/High NPSHR

In designing the suction system for a displacement pump, if NPSHA is found to be less than NPSHR, a remedy may be found in the following list:

Increase the diameter of the suction line.

Reduce the length of the suction line by providing a more direct route, or by moving the pump closer to the suction vessel.

Install a suction bottle or stabilizer adjacent to the pump liquid end. A fabricated bottle has often been successfully used at pressures below about 50 lb/in^2 (300 kPa), but maintenance of a liquid level is required.

A section of rubber hose in the suction line, adjacent to the pump, will often reduce the acceleration head.

Elevate the suction vessel or the level of liquid in the suction vessel.

Reduce temperature of pumpage. (If the pumpage is at bubble point in the vessel, it must be cooled after it leaves the vessel.)

Reduce speed of the pump, or select a larger pump running slower.

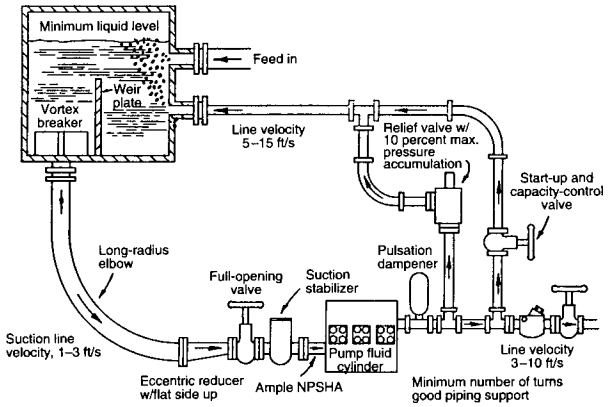

Fig. 14.1.38 A good system for a reciprocating pump.

At a lower speed, it may be possible to operate a reciprocating pump with light suction valve springs, or none at all.)

If the above steps are insufficient, impractical, or impossible, a booster pump must be provided. A booster for a displacement pump is normally a centrifugal, although direct-acting reciprocating and rotary pumps are sometimes used. The NPSHR of the booster must be less than that available from the system. The head of the booster should exceed the main pump NPSHR plus suction-line losses by about 20 percent. The booster should be installed near the suction vessel, and a pulsation bottle or stabilizer should be installed in the suction line, adjacent to the main pump, to protect the booster from pulsating flow.

14.2 CENTRIFUGAL PUMPS

by Terry L. Henshaw

NOMENCLATURE AND MECHANICAL DESIGN

The term "centrifugal pumps" as used here includes radial-flow, mixed-flow, and axial-flow (propeller) pumps. Centrifugal pumps are sometimes called **impeller pumps.**

A centrifugal pump consists primarily of a vane-carrying wheel, called the **impeller,** and a **casing** (Fig. 14.2.1). The impeller imparts velocity to the **pumpage,** with most of that velocity being converted to pressure inside the impeller and casing. The casing guides the pumpage to and from the impeller.

If a pump contains a single impeller, it is called a **single-stage** pump (Figs. 14.2.1 and 14.2.2). When two or more impellers are arranged in series (for higher pressure), it is called a **multistage** pump (Figs. 14.2.9 and 14.2.12).

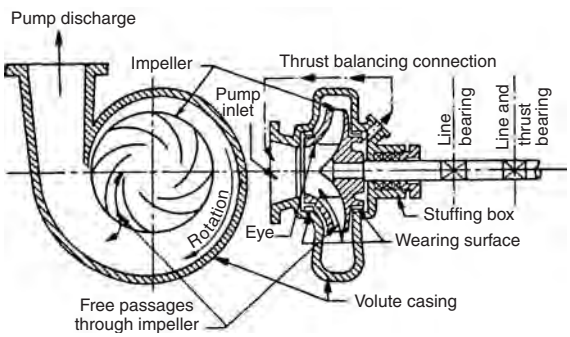

Fig. 14.2.1 Single-stage single-suction overhung pump with volute casing.

Size designations of centrifugal pumps usually contain the nominal sizes of the discharge and suction nozzles, and sometimes the approximate maximum diameter of the impeller—or the number of stages. For example, in U.S. units, a 2 × 3 × 8 pump would have a 2-in discharge

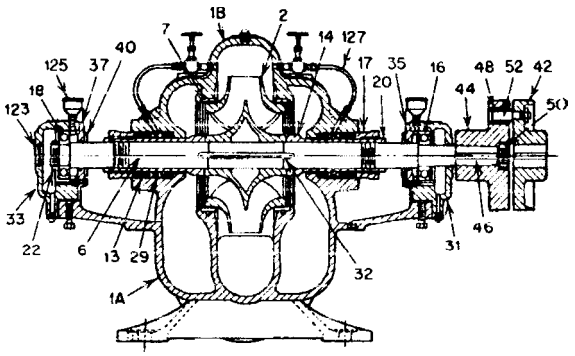

Fig. 14.2.2 Horizontal single-stage double-suction between-bearings pump with a volute casing. (Numbers refer to parts listed in Table 14.2.1.)

nozzle, a 3-in suction nozzle, and an 8-in (approximately) maximum-diameter impeller.

If the impeller is mounted near the middle of the shaft, with a bearing near each end of the shaft, the pump is said to be of the **between-bearings** design (Fig. 14.2.2). If the impeller is mounted at the end of the shaft, with both bearings between the impeller and the coupling, the pump is called **overhung** or **cantilevered** (Fig. 14.2.1).

If the pump shaft is horizontal, it is a **horizontal pump.** If the shaft is vertical, it's a **vertical pump.**

Table 14.2.1 is a list of names used to describe centrifugal pump parts that are discussed below.

Table 14.2.1 Recommended Names of Centrifugal-Pump Parts
(These parts are called out in Figs. 14.2.2, 14.2.4, and 14.2.7)

Item no.	Name of part	Item no.	Name of part
1	Casing	33	Bearing housing (outboard)
1A	Casing (lower half)	35	Bearing cover (inboard)
1B	Casing (upper half)	36	Propeller key
2	Impeller	37	Bearing cover (outboard)
4	Propeller	39	Bearing bushing
6	Pump shaft	40	Deflector
7	Casing ring	42	Coupling (driver half)
8	Impeller ring	44	Coupling (pump half)
9	Suction cover	46	Coupling key
11	Stuffing-box cover	48	Coupling bushing
13	Packing	50	Coupling lock nut
14	Shaft sleeve	52	Coupling pin
15	Discharge bowl	59	Handhole cover
16	Bearing (inboard)	68	Shaft collar
17	Gland	72	Thrust collar
18	Bearing (outboard)	78	Bearing spacer
19	Frame	85	Shaft-enclosing tube
20	Shaft-sleeve nut	89	Seal
22	Bearing lock nut	91	Suction bowl
24	Impeller nut	101	Column pipe
25	Suction-head ring	103	Connector bearing
27	Stuffing-box-cover ring	123	Bearing end cover
29	Lantern ring	125	Grease (oil) cup
31	Bearing housing (inboard)	127	Seal piping (tubing)
32	Impeller key		

Impellers

An impeller is either **single-suction** (Fig. 14.2.1) or **double-suction** (Fig. 14.2.2). A single-suction impeller can have a **radial-flow** (Fig. 14.2.1), a **mixed-flow** (Fig. 14.2.3), or an **axial-flow** (Fig. 14.2.4) profile. A **closed impeller** has full **shrouds** (sidewalls) enclosing the vanes (Figs. 14.2.1 and 14.2.2), an **open impeller** has no shrouds, and a **semi-open impeller** has partial shrouds (Figs. 14.2.8 and 14.2.11). A semi-open impeller is often called an open impeller.

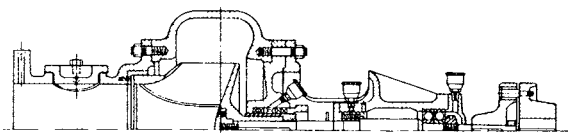

Fig. 14.2.3 End-suction pump with a mixed-flow impeller and removable suction and stuffing-box heads.

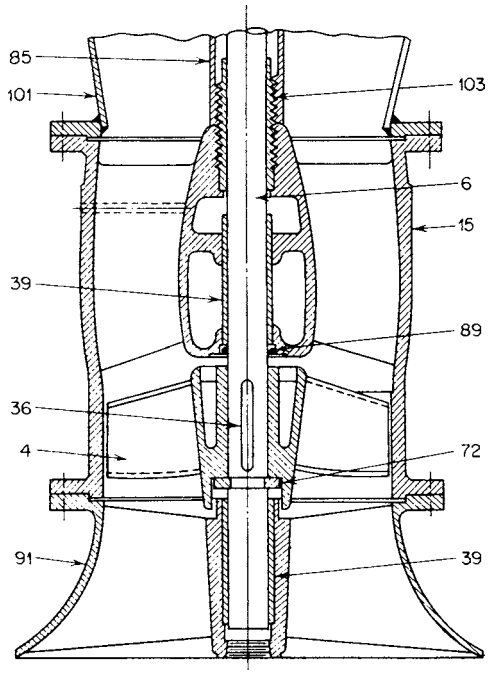

Fig. 14.2.4 Vertical wet-pit diffuser pump bowl assembly with an axial-flow impeller (Numbers refer to parts listed in Table 14.2.1.)

Some impellers are designed for specific applications. Impellers for sewage have blunt edges and large passages to minimize clogging from rags and other fibrous matter. Paper stock impellers are open and may have screw conveyor vanes that extend into the suction nozzle. Impellers for abrasive slurries have thick vanes for extended life.

Casings

The casing usually is either of the **volute** (Fig. 14.2.1) or **diffuser** (guide-vane) (Fig. 14.2.5) design, although some casings are circular. Diffuser pumps were once commonly called turbine pumps, but this term has recently been more selectively applied to vertical diffuser pumps, now called **vertical turbine pumps** (Fig. 14.2.9).

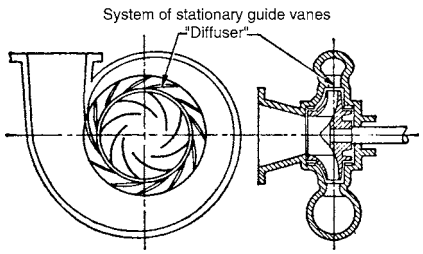

Fig. 14.2.5 Single-stage single-suction pump with a multivane diffuser in a volute casing.

If the casing separates along a plane that is parallel to the axis of the shaft, the casing is said to be **axially split** (Fig. 14.2.2). If it parts in a plane that is at a right angle to the axis, it is called **radially split** (Figs. 14.2.6 and 14.2.7).

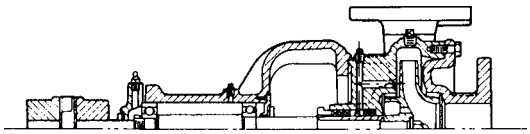

Fig. 14.2.6 Single-stage end-suction pump with a radially split casing.

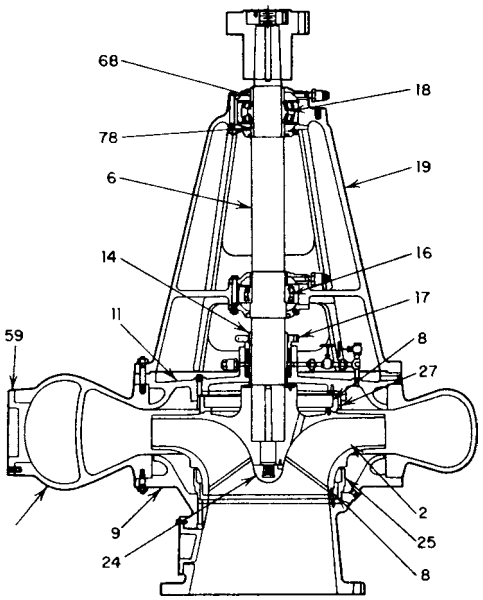

Fig. 14.2.7 Vertical end-suction pump with a double-volute radially split casing. (Numbers refer to parts listed in Table 14.2.1.)

Multistage pumps also are made with both axially split casings (Figs. 14.2.12 and 14.2.13) and radially split casings (Fig. 14.2.14). The axially split units are limited to approximately 2,000 lb/in^2 (15 MPa). Higher-pressure pumps consist of a radially split outer casing **(barrel)** that contains a radially split (Fig. 14.2.14) or axially split inner casing assembly.

The location of the suction (inlet) nozzle determines whether the pump is classified as **end suction, side suction, bottom suction,** or **top suction.**

End-suction pumps usually have radially split casings. A cover (head) is bolted to the casing on the suction side and/or the back side. A **suction cover (casing suction head)** contains the suction nozzle. A back cover contains the seal or packing, and is called a **stuffing-box cover, casing cover,** or **stuffing-box head.** Both designs are illustrated in Figs. 14.2.3 and 14.2.7.

The discharge nozzle of end-suction single-stage horizontal pumps is usually in a top-vertical position (Fig. 14.2.6), although with some units the casing can be rotated so the discharge nozzle is top horizontal, bottom horizontal, or bottom vertical. Most double-suction, axially split pumps (Fig. 14.2.2) have a side discharge nozzle and either a side or bottom suction nozzle. The bottom-suction units are rarely made in sizes below a 10-in (25-mm) discharge nozzle.

If the casing is supported by a foot directly below the casing, it is said to be **foot mounted** (Fig. 14.2.2). If the support is under the bearing housing, it is called **frame mounted** (Fig. 14.2.8). If the casing is supported at the centerline of the shaft, it is a **centerline-mounted** pump.

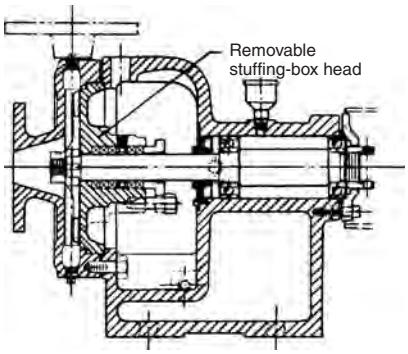

Fig. 14.2.8 End-suction frame-mounted pump with a semi-open impeller and a removable stuffing-box head.

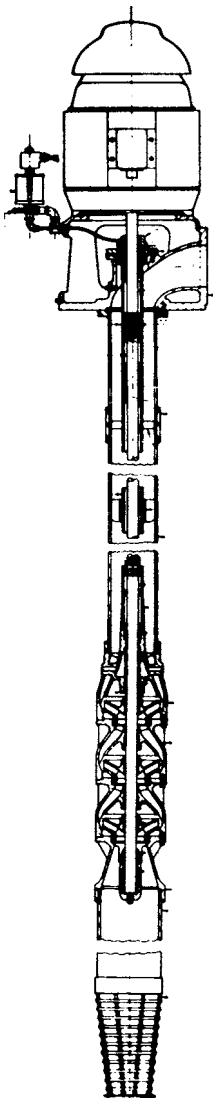

Fig. 14.2.9 Vertical turbine multistage pump with closed impellers and oil-lubricated enclosed line shaft.

Centerline support is provided for high-temperature services, so that coupling alignment is retained as the casing expands at the higher temperature.

With most pumps the liquid flows to the unit through piping, but some vertical pumps are submerged in their suction supply. Vertical pumps are therefore called either **dry-pit** or **wet-pit** type (Fig. 14.2.9). The pumpage from a wet-pit pump may discharge above or below its support surface, creating designations of **above-grade discharge** (Fig. 14.2.9) and **below-grade discharge.**

Wearing Rings

Wearing rings (wear rings) (Figs. 14.2.2 and 14.2.7) are used with closed impellers to restrict the leakage of the pumpage from the discharge side to the suction side of the impeller. These rings may be integral with the casing and/or impeller, or may be separate parts. The stationary ring is called a **casing ring** or **cover ring.** The rotating ring, on the impeller, is called the **impeller ring.** Normally only small pumps have integral casing rings. Integral impeller rings are common on small pumps and on high-speed, high-energy pumps. High-energy, and some lower-energy multistage, pumps have experienced loosening and breakage of separate impeller rings, resulting in pump failures. Therefore, these units are often made with integral impeller rings, with hard surfaces to extend the life.

Although available in a variety of configurations, the most common ring configurations are the flat type (Fig. 14.2.6) and the L type (Fig. 14.2.3).

The simple semi-open-impeller pump of Fig. 14.2.8 minimizes leakage from the discharge side to the suction side with a small axial clearance between the impeller and casing. **Pump-out vanes** on the back of the impeller reduce axial thrust and pressure on the seal.

Shafts

The shaft in a centrifugal pump supports and drives the impeller and other rotating parts, and is, in turn, supported by the bearings. Because rubbing contact can lead to accelerated wear, or seizure, of wearing rings, the shaft may be larger than needed to transmit the torque, so as to reduce radial deflection of rotating parts. The diameter may be large enough to prevent contact between wearing rings and between the shaft and internal bushings.

The "dry" first **critical speed** of a rotor is related to its static deflection in the horizontal position. A shaft for a multistage pump, designed for a static deflection of, for instance, 0.006 in. (0.15 mm), will have a dry first critical speed of about 2,400 r/min. If operated within 20 percent of 2,400 r/min, excessive vibration and damage can occur. Such a pump, operating at 3,600 r/min, or faster, will be running above this dry critical speed. Smooth wearing rings and internal bushings can increase the actual ("wet") critical speed to a value above running speed. Subsequent wear of these surfaces (increased radial clearances), or grooves in the surfaces, will cause the wet critical speed to drop. If the wet critical speed is within 20 percent of running speed, excessive vibration and damage can result.

Shaft Sleeves

Pump shafts are often protected from erosion, corrosion, and wear at the sealing device, at leakage joints, and at liquid passages by **shaft sleeves** (Fig. 14.2.2). The most common application is at the stuffing box. Shaft sleeves serving other purposes are given specific names that indicate their purposes. For example, a sleeve between two impellers, which, in conjunction with a bushing, limits leakage between the impellers, is called an **interstage** (or distance) **sleeve.**

Bearings

(See also Sec. 8.)

Centrifugal pumps are provided with **rolling-contact** (ball and roller) **bearings** (Figs. 14.2.2, 14.2.6, and 14.2.7), and **fluid-film** (hydrodynamic) sliding **bearings** (Fig. 14.2.14). Their functions are to position the rotor and to absorb residual radial and axial forces created by the rotor.

The typical horizontal pump contains ball bearings (Fig. 14.2.2), lubricated by either grease or oil. If the rating of the ball bearings is exceeded (or by user preference), the pump is provided with fluid-film bearings. Some pumps are available with a combination of sleeve radial- and ball axial-thrust bearings, or sleeve radial and tilting-pad axial-thrust bearings (Fig. 14.2.14).

A **tilting-pad** (axial) **thrust bearing** requires a pressure-lubrication system, with its attendant components of pumps, filters, coolers, gages, and switches, which significantly increases the complexity and cost of the installation.

Some pumps contain internal fluid-film bearings that are lubricated by the pumpage. Examples include vertical turbine pumps (Fig. 14.2.9) and sealless pumps. These bearings can be damaged by solids or gas in the pumpage.

For a between-bearings pump, the bearing nearer the coupling is called the **inboard bearing.** The one farther from the coupling is called the **outboard bearing.** For an overhung pump, the bearing nearer the impeller is the inboard bearing; the one farther from the impeller is the outboard bearing.

Couplings

(See also Sec. 8.)

Some centrifugal pumps are constructed with the impeller mounted directly on the end of the driver shaft (Fig. 14.2.10). These units are called **close-coupled,** and require no coupling.

If the pump shaft and driver shaft are separate pieces, the two shafts must be connected by a mechanical coupling. If the pump and driver each contains its own bearing system, the coupling must be flexible. **Flexible couplings** are available in designs such as gear or grid, which require lubrication, and disk or diaphragm, which require no lubrication.

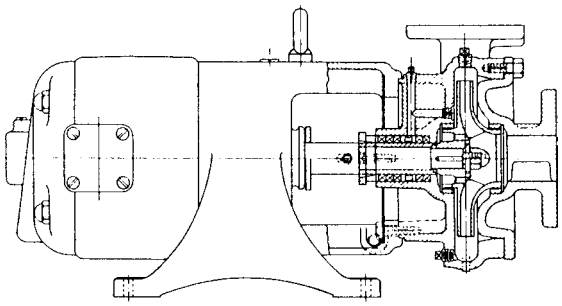

Fig. 14.2.10 Close-coupled (motor-mounted) pump.

If the pump shaft relies on the driver shaft for support, the coupling must be a **rigid coupling.**

Sealing Devices

(See also Sec. 8.)

Packing is just fancy square rope, available in a variety of fibers, or foil, cut and formed into rings that fit snugly into the bore of the **stuffing box** and onto the surface of the shaft or sleeve (Figs. 14.2.2 and 14.2.6). Packing is held in the stuffing box by a **gland** (Figs. 14.2.2 and 14.2.6), which, in turn is retained and adjusted by gland bolts or studs and nuts.

Packed stuffing boxes have the primary function of minimizing leakage at the point where the shaft passes through the casing, although packing also provides radial support to the shaft, reducing vibration and radial deflection thereby reducing bending of the shaft (which reduces the probability of a fatigue failure of the shaft).

Packing on a rotating shaft (or sleeve) must be allowed to leak, or it will overheat and fail. Leakage must be a tiny stream, or at least a fast drip. If the pressure at the "throat" of the stuffing box (normally suction pressure) is below atmospheric pressure, the packing must prevent air from leaking into the pump. The rings of packing must therefore be separated by a **lantern ring (seal cage)** (Figs. 14.2.2 and 14.2.6), and clean, cool liquid must be provided to the lantern ring at a positive pressure. This "sealing liquid" flows along the shaft (or sleeve) both into the pump and to the atmosphere. If the pumpage is clean, cool water, the sealing liquid can be fed from the discharge of the pump into the lantern ring; either through external piping (Fig. 14.2.2), or through an internal passage (Fig. 14.2.6).

If the pumpage is hot, a slurry, toxic, flammable, or otherwise it should not be allowed to flow into the packing or escape to the atmosphere. A clean, cool sealing liquid must be provided to a lantern ring, at a pressure higher than throat pressure.

Mechanical seals are used in centrifugal pumps when the leakage rate from packing is unacceptable, the requirement for manual adjustment is undesirable, or a longer-life sealing device is desired. A mechanical seal provides no radial support for the pump rotor, so should be used only when the shaft and bearings provide adequate rigidity and support.

All mechanical seals leak. The leakage may be so small as to be visibly undetectable. In fact, a seal *must* leak, or it will overheat and fail prematurely. The sealing faces rely on a thin film of liquid between the faces for cooling and lubrication. Some of this liquid leaks past the faces.

For decades, a mechanical seal was required to fit inside the bore of a stuffing box that was designed for packing. This required the seal cross section to be small, and provided an inadequate environment for the seal, both contributing to shorter seal life. Newer pump designs provide larger cavities for seals, allowing more robust cross sections and a better environment, resulting in longer seal life.

A centrifugal pump seal chamber normally contains only one mechanical seal, but safety and environmental concerns have lead to seal chambers containing two seals. These dual arrangements can be provided in the **double seal** arrangement, in which the seals are mounted back to back (Fig. 14.2.11) or face to face, or in the **tandem seal**

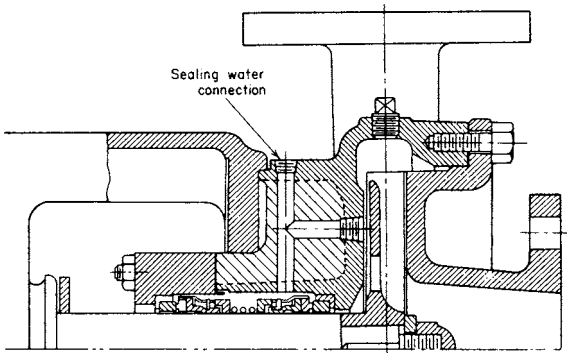

Fig. 14.2.11 Single-stage end-suction pump with semi-open impeller and double mechanical seal.

arrangement, in which both seals face the same direction. The back-to-back double seal requires a liquid between the seals at a pressure above the throat pressure. The barrier liquid between tandem seals is normally at atmospheric pressure.

Power plant boiler feed pumps are often equipped with a long labyrinth-type throttle bushing for a seal. Cool condensate is injected near the center of the bushing, flowing both into the pump and to the atmosphere. The atmospheric leakage is collected and returned to the system. Such a seal has high leakage, but a longer life than packing or a mechanical seal.

Sealless Pumps

Sealless centrifugal pumps can be provided for services where no leakage to the atmosphere can be tolerated. These pumps are available in both **canned-motor** and **magnet-drive** designs. In the canned-motor design, the motor rotor is inside the pump, surrounded by the pumpage, separated from the motor stator by a thin "can." The motor rotor is connected directly to the pump impeller. In the magnet-drive design, there are two sets of magnets, separated by a thin can. The inner set is connected to the pump impeller. The outer set is coupled to the pump driver. As the outer set rotates, lines of flux pass through the can and rotate the inner set. Both designs utilize fluid-film bearings that are lubricated by the pumpage.

HYDRAULIC THRUST

Radial thrust on an impeller is created by a nonuniform pressure around the periphery of the impeller. In a **single-volute** casing (Fig. 14.2.1), when the pump is operating at or near its capacity correspondent to peak efficiency **(best efficiency point, bep),** both velocity and pressure are uniform around the impeller, resulting in zero hydraulic radial thrust. At capacities both above and below bep, a nonuniform pressure distribution creates a radial force (thrust), which will increase shaft deflection and bearing loads. To reduce radial thrust, casings may be designed with a **double volute** (Fig. 14.2.7) or a **diffuser** (Fig. 14.2.5).

Axial thrust is created by pressures acting axially on impeller shrouds and vanes. A double-suction impeller creates very little axial thrust. A single-suction impeller can create a significant axial thrust. This thrust is created by near-discharge pressure acting on a back shroud that is larger than the front shroud, and by vanes that twist and extend into the impeller eye. The thrust can be balanced by a back wearing ring and **balance holes** (Figs. 14.2.6 and 14.2.10) drilled through the back shroud, allowing the pumpage to flow from the back balance chamber into the impeller eye. For suction pressures near atmospheric, the back wearing ring diameter is normally equal to or larger than the front (eye) ring. For higher suction pressures on overhung pumps, the back ring may be reduced in diameter to compensate for the thrust created by the higher suction pressure pushing on the end of the shaft.

Most multistage pumps are built with single-suction impellers. To balance the axial thrust of these impellers, two arrangements are used: (1) The impellers all face in the same direction and are mounted in the ascending order of the stages. The axial thrust is balanced by a hydraulic balancing device (Figs. 14.2.12 and 14.2.14). (2) An even number of single-suction impellers is used, one half of these facing in a direction opposite to the second half (Fig. 14.2.13). This mounting of single-suction impellers back to back is frequently called **opposed impellers.**

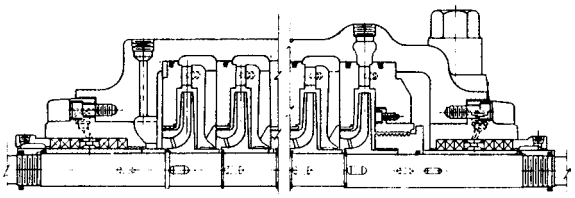

Fig. 14.2.12 Multistage pump with axially split casing, single-suction impellers facing one direction, and hydraulic axial balancing device.

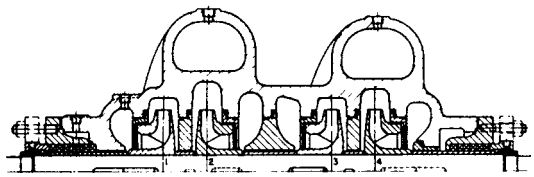

Fig. 14.2.13 Four-stage pump with opposed impellers.

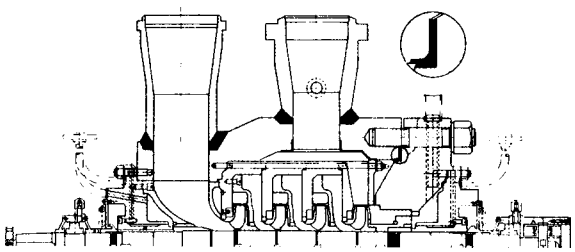

Fig. 14.2.14 Double-casing multistage pump with radially split inner and outer casing.

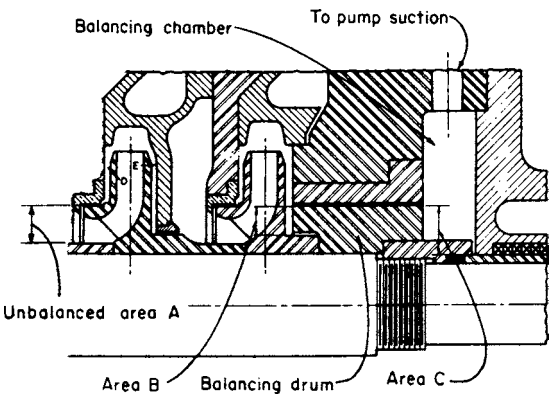

Fig. 14.2.15 Balancing drum.

Hydraulic balancing devices may take the form of (1) a **balancing drum,** (2) a **balancing disk,** or (3) a combination of these two. The **balancing drum** is illustrated in Fig. 14.2.15. The balancing chamber at the back of the last-stage impeller is separated from the pump interior by a drum mounted on the shaft. The drum is separated by a small radial clearance from the stationary portion of the balancing device,

called the **balancing drum head,** which is fixed to the pump casing. The balancing chamber is connected either to the pump suction or to the vessel from which the pump takes its suction. The forces acting on the balancing drum are (1) toward the discharge end—the discharge pressure multiplied by the front balancing area (area *B*) of the drum; (2) toward the suction end—the back pressure in the balancing chamber multiplied by the back balancing area (area *C*) of the drum. The first force is greater than the second, thereby counterbalancing the axial thrust exerted upon the single-suction impellers. The drum diameter can be selected to balance the axial thrust completely or to balance 90 to 95 percent of this thrust, depending on whether a slight thrust load in a specific direction on the thrust bearing is desirable.

The operation of the simple **balancing disk** is illustrated in Fig. 14.2.16. The rotating disk is separated from the balancing-disk head by a small axial clearance. The leakage through this clearance flows into the balancing chamber and from there either to the pump suction or to the

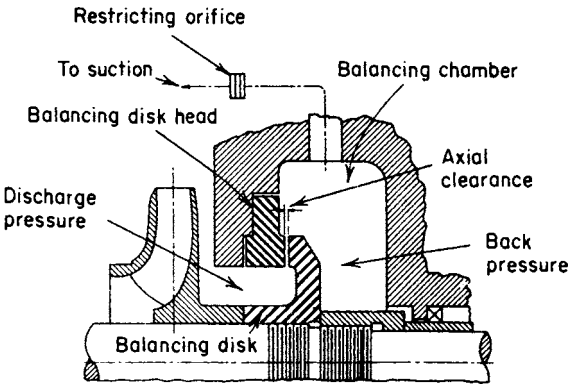

Fig. 14.2.16 Simple balancing disk.

suction vessel. The back of the balancing disk is subject to the balancing-chamber back pressure, whereas the disk face experiences a range of pressures. These vary from discharge pressure at its smallest diameter to back pressure at its periphery. The inner and outer disk diameters are chosen so that the difference between the total force acting on the disk face and that acting on its back will balance the impeller axial thrust. If the axial thrust of the impellers should exceed the thrust acting on the disk during operation, the latter is moved toward the disk head, reducing the axial clearance. The amount of leakage through this clearance is reduced so that the friction losses in the leakage return line are also reduced, lowering the back pressure in the balancing chamber. This automatically increases the pressure difference acting on the disk and moves it away from the disk head, increasing the clearance. Now the pressure builds up in the balancing chamber, and the disk is again moved toward the disk head until an equilibrium is reached. To ensure proper balancing-disk operation, the change in back pressure must be of an appreciable magnitude. This is accomplished by introducing a restricting orifice in the leakage return line.

The **combination disk and drum** (Fig. 14.2.14) incorporates portions rotating within radial clearances of stationary portions and a disk face rotating within an axial clearance of another portion of the stationary part. The radial clearance remains constant regardless of any axial displacement of the rotor within the casing. Such displacement, however, changes the axial clearance within the balancing device. These changes cause changes in the leakage, which in turn change the pressure drop across the radial clearances and thus increase or decrease the average value of the pressure acting on the disk face. These changes in the intermediate pressure on the disk face act to move the balancing device in whichever direction is required to restore equilibrium and axial balance.

HYDRAULIC PERFORMANCE

The performance of a centrifugal pump is generally described in terms of the following **characteristics:** (1) rate of flow, or **capacity** *Q,* expressed in units of volume per unit of time, most frequently ft^3/s, gal/min, or m^3/h ($1\ ft^3/s = 449$ gal/min; $1\ m^3/h = 4.403$ gal/min); (2) increase of energy content in the fluid pumped, or **head** *H*, expressed in units of energy per unit of mass, usually ft · lb/lb or, more simply, ft, or m; (3) input **power** *P,* expressed in units of work per unit of time, bhp or kW; (4) **efficiency** η, the ratio of useful work performed to power input, (5) **rotative speed** *N,* in r/min.

Since the parameters indicated are all mutually interdependent, it is customary to represent the performance of a centrifugal pump by means of **characteristic curves** similar to that shown in Fig. 14.2.17. While it is possible, within certain limits, for the pump designer to regulate the shape of these curves to suit the needs of a particular application, this is essentially a function of design capacity, head, and speed and hence for

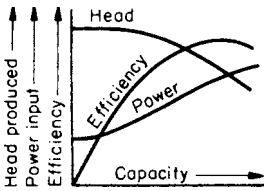

Fig. 14.2.17 Typical characteristic curves at constant speed.

a standard production unit is determined by test and is not subject to modification. For any given capacity on such a characteristic curve, the relationship between performance characteristics is expressed by the equation $\eta = \gamma QH/3{,}960P$, where η is efficiency expressed as a decimal, γ is the specific gravity of the fluid pumped, Q is in gal/min, H in ft, and P in bhp. In metric units, $\eta = \gamma QH/367P$, where Q is in m^3/h and H in metres and P in kW.

Inasmuch as the actual performance of centrifugal pumps is determined by testing, it is highly desirable to be able to use the results of past tests as a basis for predicting the performance of future designs. To this end, an interesting and widely used characteristic number known as **specific speed,** $N_s = N\sqrt{Q}/H^{3/4}$, has been developed. In this expression, values of *N, Q,* and *H* are all for the point of best efficiency. While not dimensionless, N_s can be made dimensionless by the appropriate selection of units. Specific speed is of interest to both the pump designer and the pump user essentially in two ways: (1) All geometrically similar pumps, regardless of their size, will have identical specific speeds (but all pumps of the same specific speed will not necessarily be geometrically similar). (2) Within reasonable limits, pump geometry and performance can be predicted as a function of N_s and Q. For N in r/min, Q in gal/min, and H in ft, the practical range of N_s is approximately 500 to 15,000. In metric units Q is in m^3/s and H is in metres, so that this range becomes approximately 10 to 300 ($N_{sm} = N_s/51.66$) The shape of the profiles for impellers varies over the range of specific speeds, as shown in Fig. 14.2.18. The commercially attainable efficiencies also vary with

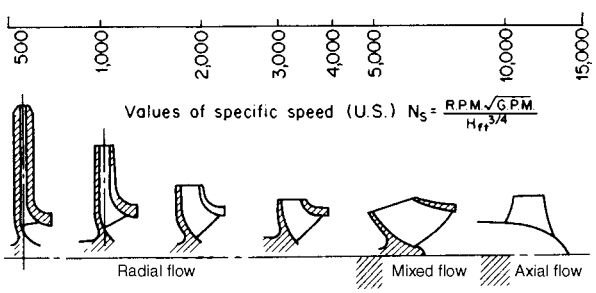

Fig. 14.2.18 Approximate impeller shapes versus specific speed.

the specific speed (Fig. 14.2.19). It must be remembered that these efficiencies are attainable at the capacity at best efficiency. The actual capacity may differ from this best-efficiency flow. In addition, the general shape of the characteristic curves will vary widely from one end of this range to the other, as illustrated by Figs. 14.2.24 and 14.2.25.

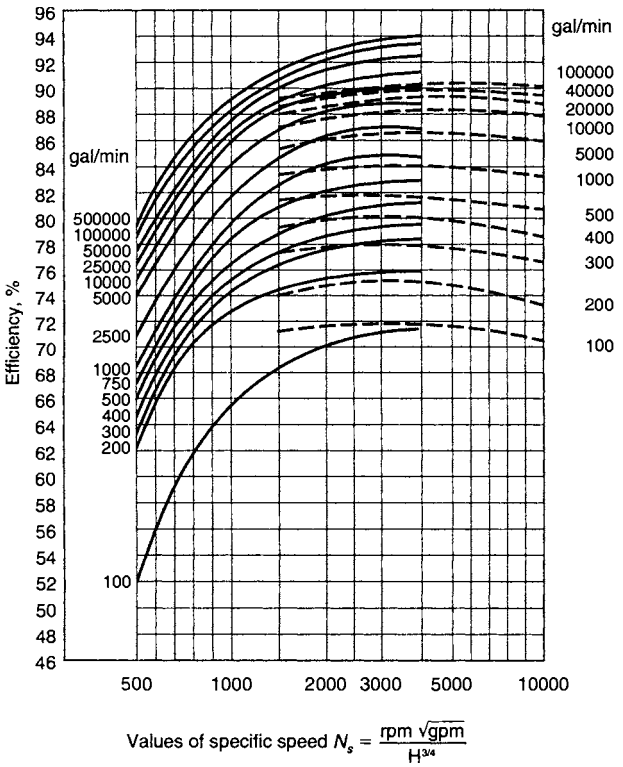

Fig. 14.2.19 Efficiencies of single-stage end-suction and double-suction centrifugal pumps (solid lines) and wet pit pumps (dashed lines).

Hydraulic Design

The purpose of a centrifugal pump in any fluid-handling system is to add energy to the fluid, and since it is a dynamic machine, the pump depends entirely on changes in velocity to provide the energy. While the measurable evidence of energy addition is in most cases largely in the form of static pressure, this is partially the result of velocity reductions and constraints occurring in the diffuser and to this extent represents a conversion from the velocity energy produced by the impeller. Thus, any discussion of centrifugal-pump theory generally becomes a discussion of velocities occurring at various points within the pump.

The true velocity relationships existing within a pump are extremely complex; but for practical purposes, a one-dimensional analysis serves to illustrate the basic concepts and, indeed, has served as the basis of design for virtually all centrifugal pumps ever built.

For radial and mixed-flow impellers ($500 \le N_s \le 7{,}500$ or $10 \le N_{sm} \le 150$) the velocities at the inlet and outlet of the impeller are shown by the vector diagrams in Fig. 14.2.20. The head produced by such an impeller is represented by

$$H = \eta_H (U_2 V_{u2} - U_1 V_{u1})/g \qquad (14.2.1)$$

where H = head, ft (m); U = circumferential velocity of impeller at radius being considered, ft/s (m/s), V_u = average value of the circumferential component of absolute fluid velocity, ft/s (m/s), and $g = 32.174$ ft/s^2

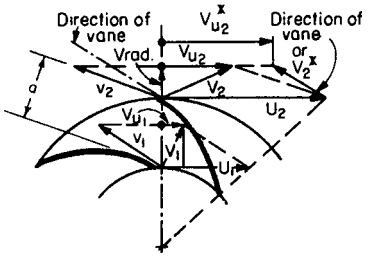

Fig. 14.2.20 Velocity diagram of a radial-flow impeller.

(9.80 m/s^2). Subscript 1 refers to the impeller inlet section, and subscript 2 to the impeller discharge section. The coefficient η_H is the hydraulic efficiency of the rotating-vane system and, for the range of specific speeds indicated above, will generally fall between 0.85 and 0.95. This hydraulic efficiency is considerably higher than pump efficiency η since it does not include mechanical losses due to bearing or packing friction, volumetric losses due to internal wearing-ring clearances, impeller-disk friction, or fluid-friction losses due to velocity conversion or boundary-layer considerations ahead of or following the impeller. For pumps in this specific-speed range, the hydraulic losses $1 - \eta_H$ will generally be between one-quarter and three-quarters of total pump losses $1 - \eta$.

For pumps arranged with an axial inlet to the impeller (such as that shown in Fig. 14.2.7), it is generally assumed that the entering flow will have no rotational component, and V_{u1} is therefore zero. Equation (14.2.1) can thus be reduced to

$$H = \eta_H U_2 V_{u2}/g \qquad (14.2.2)$$

In practice, Eq. (14.2.2) will provide a close approximation to total head for any pump up to a specific speed of 2,000 ($N_{sm} \approx 40$) since the term $U_1 V_{u1}$ in Eq. (14.2.1) is very small compared with $U_2 V_{u2}$.

It should also be noted in Fig. 14.2.20 that the relative velocity v_2 does not coincide in direction with the vane angle at the impeller discharge. The angular difference between v_2 and the direction of the vane is due to the irrotational nature of the flow between the vanes. The effect of this difference can be taken into account as the vector difference $V_{u2}{}^* - V_{u2} = Na/229$, where a is the shortest distance in inches taken in the radial plane between the discharge tip of any vane and the upper surface of the following vane. ($V_{u2}{}^* - V_{u2} = Na/19{,}100$, where a is in mm and velocities are in m/s.)

The foregoing relationships provide the basis for determining impeller diameters and vane angles required to produce a given total head requirement at a specified rotative speed. It is equally necessary, of course, to provide in the design for handling a specified flow volume, and this is readily accomplished by providing the necessary cross-sectional area A between vanes to pass the required flow at velocities previously determined. A useful relationship for this purpose, in light of the units commonly employed in pump design, is $Q = AV/0.321$, where Q is in gal/min, V in ft/s, and A in in^2 ($Q = AV/278$, where Q is in m^3/h, V in m/s, and A in mm^2).

Upon leaving the impeller, the liquid pumped enters either (1) a system of diffusing vanes surrounded by an outer casing or (2) directly into a casing designed to contain the fluid and control its velocities. Where diffusing vanes are used, they are designed on the basis of velocity relationships very similar to those employed in impeller design but with the objective being to slow the fluid down to convert velocity energy to pressure energy and, further, to reduce frictional losses in the discharge system following the diffuser. Where the impeller discharges directly into the casing, this component of the machine is most frequently designed in the form of a volute to provide constant velocity all around the impeller periphery up to the point of entry into the discharge nozzle. From this point, commonly called the **casing throat,** to the discharge flange or to the inlet of a succeeding stage, the velocity is gradually reduced. Special circumstances related to pump design or application often result in modifications to the constant-velocity design

of such a casing, and variations may be found covering the entire range from constant velocity to constant area. In addition, many casings are now designed with one or more spiral vanes placed in such a way as to approximate a condition of geometric similarity in relation to the impeller, which is advantageous when a pump is operated at capacities other than those for which it is designed. A casing of this nature represents an effort by the designer to obtain an optimum balance between the desirable geometric similarity of the diffuser discharge and the manufacturing simplicity and generally high efficiency of the volute-type casing. The most common form of such a casing is the double-volute type discussed under Hydraulic Thrust.

For **axial-flow impellers** ($7{,}500 \leq N_s \leq 15{,}000$ or $150 \leq N_{sm} \leq 300$) velocity relationships can be approximated in a manner similar to that used for lower-specific-speed pumps, but refinement of these approximations is approached in a somewhat different manner, largely because of the considerable body of knowledge available in the form of airfoil data which can be applied. Velocity diagrams for pumps of this type are shown in Fig. 14.2.21.

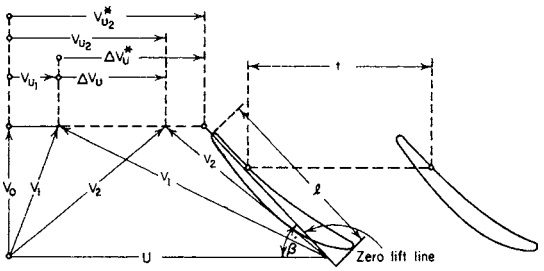

Fig. 14.2.21 Velocity diagram of an axial-flow vane system.

Considering a cylindrical stream tube intersecting the vanes of an axial-flow impeller, we can rewrite Eq. (14.2.1) in the form

$$H = \eta_H U \Delta V_u / g \tag{14.2.3}$$

where ΔV_u represents the increase in the tangential component of the absolute velocity as the fluid passes through the impeller. For pumps in this specific-speed range, η_H will generally fall between 0.80 and 0.90 and $1 - \eta_H$ will generally be between one-half and three-quarters of $1 - \eta$.

As in the case of radial-flow impellers, the relative velocity v_2 at the impeller exit does not coincide with the vane angle. In this case, the necessary correction can be applied by means of the expression

$$\Delta V_u = 2\Delta V_u^* / [(t/l)(2/\pi K)(1/\sin\beta) + 1] \tag{14.2.4}$$

where t is vane spacing, l is vane length, β is the discharge vane angle, and K is the coefficient determined from Fig. 14.2.22, which provides

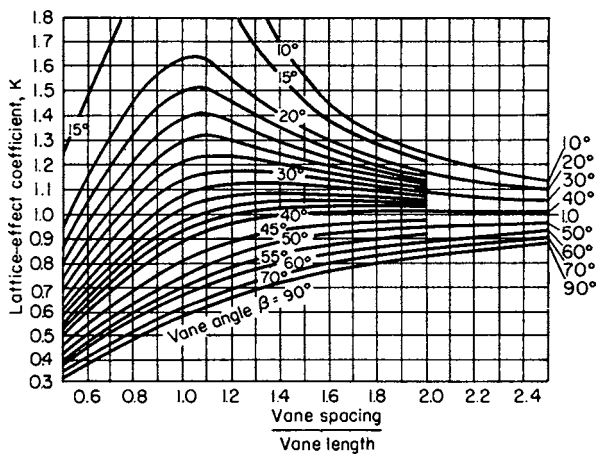

Fig. 14.2.22 Lattice-effect coefficient. *(Weinig.)*

for the fact that the impeller blades are, in effect, arranged in a continuous lattice.

In the design of axial-flow pumps, it is generally assumed that the head developed by the blade elements within all the cylindrical stream tubes between the impeller hub and its outer diameter will be the same. For this condition to be achieved, it will be evident from Eq. (14.2.3) that since U will vary directly with the radius, ΔV_u must vary inversely with the radius. Thus vane camber (or curvature) will be greater near the hub than at the periphery. It is further generally assumed that the axial velocity is constant throughout the impeller, and to satisfy this condition, the blade angles will be greater at the hub than at the periphery, giving rise to the twist of the vane.

By designing the vane element at the hub, the periphery, and any reasonable number of radial stations between, it is possible to define the vane over its entire surface to produce the total head desired. The design capacity can be simply established from the constant axial velocity and the annular area between the hub and the periphery.

Axial-flow impellers will almost invariably discharge into a vaned diffuser designed primarily to convert into pressure the tangential component of the absolute velocity leaving the impeller, thus producing a uniform, nonrotating velocity profile at the pump discharge or at the entrance to any succeeding stage.

Pump Application

In applying any centrifugal pump to a fluid-handling system, the engineer generally has two variables in the pump which may be used to effect a match between it and the system, namely, speed of operation and impeller diameter. (In axial-flow pumps, impeller diameter cannot conveniently be changed, but similar results can be accomplished within a limited range by reducing vane length.) To take advantage of these variables, it is necessary to understand the similarity relationships which govern pump behavior.

The effect of change in speed can be most readily explained by referring back to Eq. (14.2.1). For a fixed impeller diameter, it will immediately be evident that any increase in rotative speed will result in a directly proportional increase in the peripheral velocities of the impeller at both inlet and outlet, U_1 and U_2, respectively. Furthermore, since the directions of both the relative and absolute velocities v and V, respectively, are controlled by the vane angles, it follows that both the inlet and outlet velocity diagrams remain geometrically similar, in other words, as pump speed changes, all fluid velocities change in direct proportion. Thus the effect of a speed change on pump capacity can be represented for two speeds, N_1 and N_2 by

$$Q_1/Q_2 = N_1/N_2$$

Referring again to Eq. (14.2.1), it will be evident that the change in head will be proportional to the square of the change in speed, resulting in

$$H_1/H_2 = (N_1/N_2)^2$$

Also, since P is proportional to QH, then

$$P_1/P_2 = Q_1H_1/Q_2H_2 = (N_1/N_2)^3$$

The effect of a reduction in impeller diameter is for practical purposes, identical to that of a reduction in speed, and the above equations can all be rewritten in the same form, substituting D_1 and D_2 for N_1 and N_2. In this case, however, there is somewhat less latitude for change, the practical limit for cut-down being approximately 25 to 30 percent in the case of low-specific-speed impellers and decreasing from this value as specific speed increases.

From the foregoing it should be noted that running a pump at speeds far below its normal rated speed would be uneconomical since the pump would obviously be overdesigned for the service. Conversely, the same pump could not be run at speeds far above its rating since it would soon exceed its power capability. Thus the normal approach to pump application calls for selection of a unit which will meet the system requirements at or near the pump's maximum rated speed and preferably as close to maximum impeller diameter as possible.

A further aspect of the similarity laws, of interest primarily to pump designers, is the matter of geometrically similar pumps, or as they are commonly called, **factors of each other.** Assuming two such pumps with a size ratio f, then **at the same rotative speed** $H_1/H_2 = f^2$, which is the same as for a change in speed of the same ratio. In the case of capacity, however, we have, in addition to the linear increase due to velocity change, a further increase due to the change in the cross-sectional area of all fluid channels which is proportional to the square of the size factor, resulting in the relationship $Q_1/Q_2 = f^3$. The ratio of power requirements therefore becomes $P_1/P_2 = f^5$.

To simplify selection of pumps, it is customary to plot, for any given speed, performance curves to show pump characteristics over the available range of impeller diameters rather than at the single diameter which would be implicit in a curve of the type shown in Fig. 14.2.17. A typical rating curve of this nature is shown in Fig. 14.2.23. Such rating

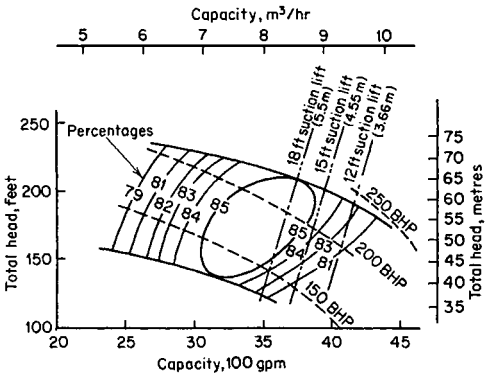

Fig. 14.2.23 Rating curve of 10-in double-suction single-stage pump.

curves will vary widely in their nature with changes in N_s, and an understanding of these variations is essential to the selection of properly sized pump drivers and, in many cases, proper design of discharge piping and/or the determination of limiting ranges of pump operation. Some idea of the diversity of characteristics which is available can be obtained by a comparison between Figs. 14.2.24 and 14.2.25, both of which are plotted entirely in percentages of design values occurring at the point of best efficiency.

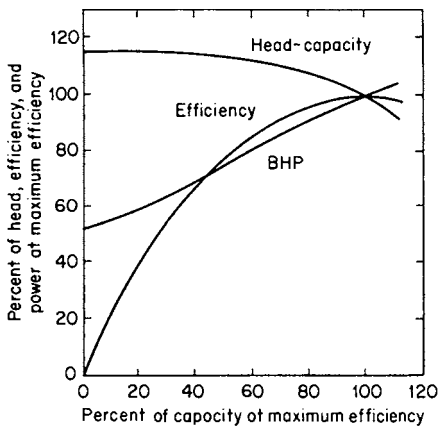

Fig. 14.2.24 Typical characteristics for $N_s = 1{,}550$ ($N_{sm} = 30$).

In the case of the lower-specific-speed pump shown in Fig. 14.2.24, a driving motor selected for the rated condition would be more than adequate at lower capacities, and discharge piping would be subjected to only modest overpressures. On the other hand, if the pump shown in

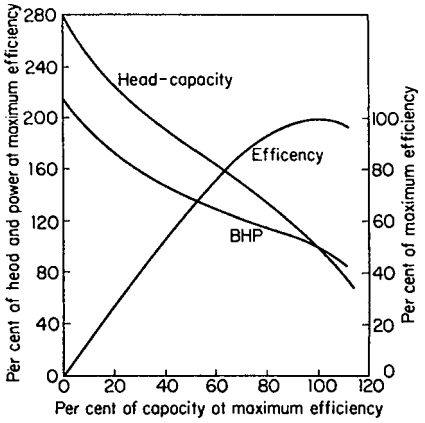

Fig. 14.2.25 Typical characteristics for $N_s = 10{,}000$ ($N_{sm} = 194$).

Fig. 14.2.25 is to be operated at reduced capacities, then both motor size and discharge piping must be designed for the minimum flows to be encountered.

NPSH

In order for a pump to deliver its rated output, it is obviously necessary that it be supplied with fluid at its inlet at the same rate. It is further necessary that the absolute pressure (including velocity head, $V^2/2g$) of the fluid at the inlet exceed the vapor pressure by an amount sufficient to overcome (1) any entrance or frictional losses between the point of entry into the pump and the impeller, and (2) the shock losses occurring at the impeller inlet. This gives rise to the definition of **net positive suction head (NPSH)** which is the absolute pressure at the pump inlet expressed in feet (metres) of liquid, plus velocity head, minus the vapor pressure of the fluid at pumping temperature, and corrected to the elevation of the pump centerline in the case of horizontal pumps or to the entrance to the first-stage impeller for vertical pumps.

NPSH required is determined by the pump manufacturer and is a function of both pump speed and pump capacity. **NPSH available** represents the energy level of the fluid over the vapor pressure at the pump inlet and is determined entirely by the system preceding the pump. Unless NPSH available at least equals NPSH required at any condition of operation, some of the fluid will vaporize in the pump inlet and bubbles of vapor will be carried into the impeller. These bubbles will collapse violently at some point downstream of the pump inlet (usually at some point within the impeller) and produce very sharp, crackling noises, frequently accompanied by physical damage of adjacent metal surfaces. This phenomenon is known as **cavitation** and is generally highly undesirable.

A term similar to that used for pump specific speed has been developed for pump NPSHR characteristics and has been identified as **suction specific speed,** $S = N\sqrt{Q}/H_{sv}^{3/4}$, where H_{sv} is NPSH. For double-suction impellers, $S = N\sqrt{Q/2}/H_{sv}^{3/4}$. The value S, like N_s, is expressed simply as a number and, for general-purpose pumps, does not generally exceed 10,000, where N is in r/min, Q is in gal/min, and H_{sv} is in ft. When Q is in m³/s and H_{sv} is in metres, the equivalent value S_m is 194.

Within the limits of NPSH capabilities, it is desirable to select a pump of the highest specific speed since this will produce the highest pump speed and consequently use the smallest pump. As a convenience in accomplishing this, the Hydraulic Institute has published two charts indicating the recommended NPSH as a function of pump capacity and operating speed and, conversely, the maximum recommended operating speed for different capacities if the NPSH value is known or first selected. These charts are based on a recommended value of suction specific speed of 8,500 ($S_m = 165$). The chart for double-suction pumps is reproduced in Fig. 14.2.26.

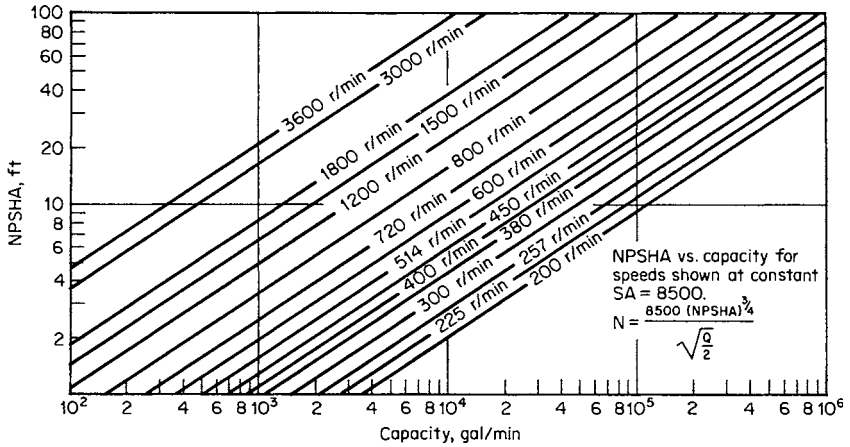

Fig. 14.2.26 Recommended maximum operating speeds for double-suction pumps. *(Hydraulic Institute Standards.)*

Recirculation A better understanding has been recently reached of the flow pattern in a pump impeller when the pump is operated at capacities below that at its best efficiency. All pumps exhibit the phenomenon of recirculation which is a flow reversal at the inlet or at the discharge tips of the impeller. The capacities at which flow recirculation occurs at the suction or discharge are not necessarily coincidental. It is now possible to predict the flow patterns that must exist to produce this flow reversal. Depending on the size and speed of the pump, the effects of recirculation can be very damaging not only to the operation but also to the life of the impeller and casing. The symptoms associated with recirculation and a method for calculating the capacity at which it takes place at both the suction and discharge of the impeller are given in Fraser, "Recirculation in Centrifugal Pumps," ASME Winter Annual Meeting, Nov. 16, 1981, Washington, D.C.

System Head Curve

Just as the head characteristic of a pump is represented by a curve indicating reducing head developed with increasing capacity, the head requirements of the system served by the pump can be depicted by a curve showing increased head requirements for increased flow, i.e., a **system-head curve** (Fig. 14.2.27). The capacity at which a pump will operate in this system is that at which the pump head curve intersects the system-head curve.

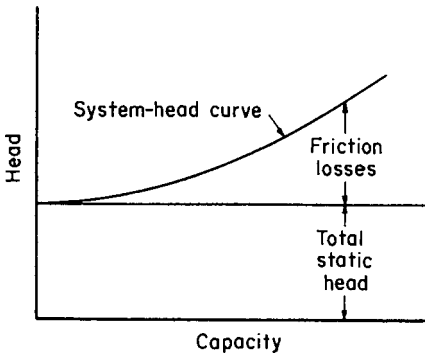

Fig. 14.2.27 System-head curve.

Every system-head curve consists of (1) a total static head (which may in some cases be equal to zero) plus (2) friction losses. The total static head $H_{stat} = H_d - H_s + P_d - P_s$, where H_d and H_s are the elevations at the system's termination and origin, respectively, and P_d and P_s are the gage pressures at the same points.

The **friction losses** are the sum of the line losses and fitting losses.

In complex pumping systems, such as municipal water-supply operations, both the total static-head and the friction-loss components may be variable, e.g., the former by changes in reservoir levels and the latter by the particular combination of lines being served at any given moment. This results in upper and lower limits of system-head requirements, and the intersection of these limiting curves with the pump head curve will define the capacity range over which the pump will be required to operate.

Since the capacity at which a pump will operate corresponds to the intersection of the system-head curve with the pump head-curve, any changes in pump capacity can only be obtained by varying one or the other of these two curves (Fig. 14.2.28). Thus the capacity of a centrifugal pump operating in a system can be regulated by (1) changing the pump speed or (2) throttling in the discharge piping. The former method is preferable whenever the driver permits it, because throttling always involves an appreciable waste of power.

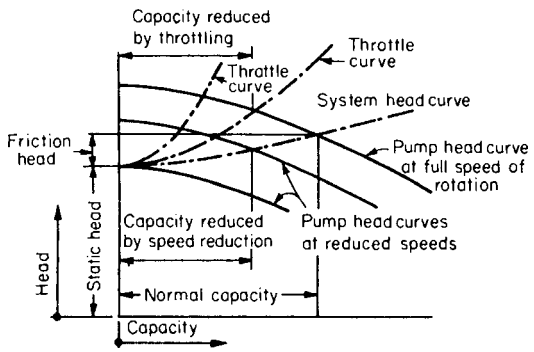

Fig. 14.2.28 Pump operation in a system.

Pump capacity should never be permitted to be reduced to zero because the fluid within the pump would have to absorb the entire power input and therefore would heat up rapidly with injurious effects on the pump. A bypass line should be provided from the pump discharge line to permit a predetermined amount of liquid to flow through the pump if the discharge valve is closed entirely. This bypass may be operated manually or automatically.

Centrifugal pumps may sometimes be operated in **parallel** or in **series.** To construct the head-capacity curve of two pumps in parallel, it is merely necessary to add the capacities of the individual pumps for various total heads. The head-capacity curve of two pumps in series is constructed by adding the individual pump heads for various capacities.

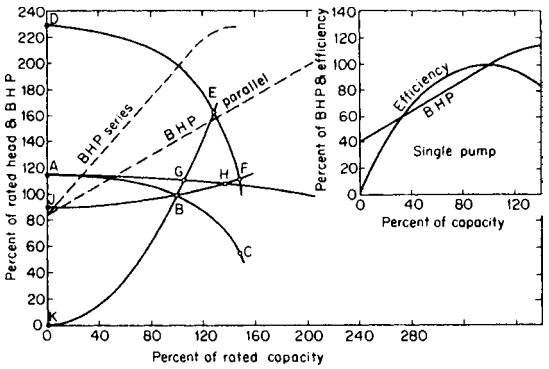

Fig. 14.2.29 Series and parallel operation of centrifugal pumps.

Figure 14.2.29 shows series and parallel operation of two centrifugal pumps with both flat and steep system-head curves.

Performance on Other Than Water

Selection of drivers, as well as pumps, is also influenced by **properties of the fluid** handled. The required pump power varies directly with the specific gravity of the liquid and is influenced in a more complex manner by viscosity. The effect of viscosity is illustrated in Fig. 14.2.30. For the example shown in the chart, the pump in question has a best-efficiency-point (bep) of 750 gal/min (170 m^3/h) at 100-ft (30-m) head. When handling a fluid having a viscosity of 1,000 SSU (220 cS), its capacity is reduced to 95 percent of that of water for all capacities. Its head is reduced to 96, 94, 92, and 89 percent of its head on cold water at 60, 80, 100, and 120 percent of the bep capacity, and its efficiency is reduced to 63.5 percent of its efficiency on water for all capacities. Thus, if the pump had a bep efficiency on cold water of 70 percent, it would now deliver 712.5 gal/min (161.8 m^3/h) at 92-ft (28.0-m) head with an efficiency of 44.5 percent at the bep.

MATERIALS OF CONSTRUCTION

Centrifugal pumps are available in many common metals and alloys, as well as porcelain, glass, and synthetics. A listing of materials recommended for various services can be found in the Standards of the Hydraulic Institute. Table 14.2.2 has some of the materials commonly used for pump parts.

INSTALLATION, OPERATION, MAINTENANCE

Proper installation, operation, and maintenance of centrifugal pumps will vary widely over the complete range of services to which the pumps may be applied, and satisfactory results in these areas can be fully achieved only by following the manufacturer's instructions for the size and type of unit involved. There are, however, certain general considerations that should be observed and will seldom need to be modified under any circumstances.

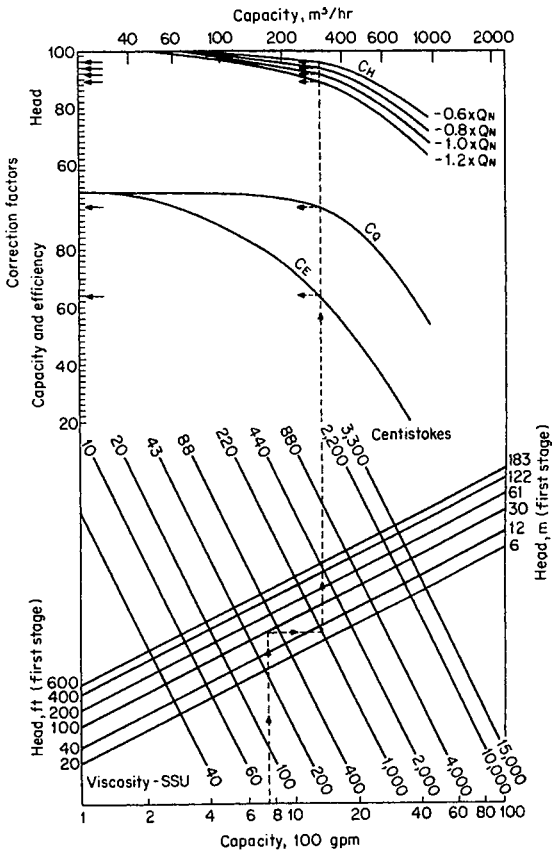

Fig. 14.2.30 Performance-correction chart for effect of viscosity. *(Hydraulic Institute.)*

In general, the location selected for installation should be as close to the source of the fluid as possible, consistent with the requirement that adequate space be made available to provide accessibility for operation, inspection, and maintenance.

Shaft Alignment

Alignment of the driver shaft with the pump shaft is crucial for component longevity. Misaligned shafts will result in vibration and shorter life of bearings and seals. For a horizontal **separately coupled pump** (one in

Table 14.2.2 Materials for Various Fittings

Gland	Bronze	Cast iron	Bronze

which the pump and driver bolt independently to a baseplate), the coupling can be precisely aligned when the unit is idle, but become misaligned when the pump runs. Running misalignment can be caused by temperature changes in the driver, pump, and connected piping; by hydraulic forces produced by the piping; and by the torque between the driver and the pump. Piping should be supported so as to minimize piping loads on the pump, and any expansion joint should be installed so as not to transmit any force to the pump.

Supporting the Pump

To retain coupling alignment, a separately coupled unit must be supported by a rigid **baseplate** (and pedestals) and by a **foundation** of concrete (or an equivalent support).

A single-stage in-line pump is typically designed to be supported solely by the piping, like a valve. The driver mounts directly on the pump, and moves with the pump as the pump moves with the piping, thereby retaining shaft alignment. Such a unit does not require a baseplate or foundation, although the piping support must be adequate for the additional weight of the pump and driver.

Priming

A centrifugal pump is primed when the casing, all impellers, and the seal chambers are filled with the liquid to be pumped. Failure to evacuate all air, or other gases, from the pump can result in wear or seizure of wear rings and bushings, and accelerated wear of mechanical seals. If the suction supply is above atmospheric pressure, priming is accomplished by venting the pump at all high points in the casing and seal chambers. If the suction supply is below atmospheric pressure, priming must be accomplished by providing a vacuum at all the high points; by providing a foot valve, below the suction liquid level, and filling the pump and suction line with liquid; or by providing a priming chamber in the suction line.

Starting

The normal starting sequence is as follows: (1) open valves in all auxiliary sealing, cooling, flushing, and bypass lines; (2) open suction valve; (3) close discharge valve for low-specific-speed pumps where no check valve is installed after the pump, or open discharge valve for high-specific-speed pumps or wherever a discharge check valve has been provided; (4) prime or vent as necessary; (5) energize the driver; and (6) open discharge valve if it was previously closed in step 3.

Following start-up and until stable operation has been adequately established, it is desirable to monitor bearing temperature, stuffing-box leakage, and other outward symptoms of the unit's behavior. Securing of the pump is accomplished by a reversal of the start-up sequence, encompassing steps 6, 5, 3, and 1, in that order.

Minimum Flow

Until the early 1970s there were only four factors to consider when setting an acceptable minimum flow for centrifugal pumps:

Higher radial thrust developed by single-volute pumps at reduced flows.

Temperature rise in the liquid pumped as capacity is reduced.

Desire to avoid overload of drivers on high-specific-speed pumps, which have a rising power requirement as capacity is reduced.

For pumps handling liquids with significant amounts of dissolved or entrained air or gas, there is the need to maintain sufficiently high velocities in the pump casing to wash out this air or gas with the liquid.

Since then, the phenomenon of internal recirculation in the impeller has been discovered. The recirculation occurs at flows less than the capacity at best efficiency. Problems include pressure pulsations at the suction and discharge and rapid deterioration of the pump and casing. The unfavorable effects of this internal recirculation have brought a fifth factor into the picture when setting minimum flows. This is discussed more fully above under "Recirculation."

Each of the effects mentioned above may dictate a different minimum operating capacity. Obviously, the final decision must be based on the greatest of the individual minimums. The internal recirculation usually sets the recommended minimum. Assuming that the pump is properly furnished with the necessary instrumentation, such as flowmeters, pressure gages with sufficient sensitivity to show pulsations, and vibration- and noise-monitoring equipment, an experienced test engineer should be able to pinpoint the onset of internal recirculation.

If the flow demand of the service in which the pump is installed is expected to fall below the minimum permissible flow, some means must be provided to accommodate the difference between the minimum permissible flow and that required by the service. This is accomplished by installing a bypass in the discharge line from the pump, located on the pump side of the check and gate valves and leading to some lower pressure point in the installation where excess heat absorbed through operation at low flows may be dissipated. A valve is located in this bypass line. For small installations, the bypass valve is operated as fully open or fully closed. For large installations, a modulating valve is usually used to bypass the difference between the required flow and the minimum permissible.

Unnecessary Maintenance

A generally accepted cardinal rule is that as long as operation continues normal, the unit should be left alone. Thus, except in special circumstances, periodic overhauls are not recommended. The amount and degree of maintenance likely to be required are influenced primarily by the nature of the service to which the pump is applied, and maintenance practices must therefore be determined largely by the user as a result of personal experience.

Notation

a = speed of sound
A = piston area
A_v = valve flow area, cell area
c_p = constant pressure specific heat
c_v = constant volume specific heat
C = clearance volume (decimal)
d = depth of ring section, diameter
D = diameter
e = eccentricity
E = modulus of elasticity (lb/in^2)
f = valve resistance, in velocity heads
g = ring free gap less end clearance (in)

g_c = gravitational constant
ghp = gas horsepower
h = enthalpy
H_p = polytropic head (ft · lb/lbm or kJ/kg)
k = ratio of specific heats
K = area constant (decimal)
L = length, leakage coefficient, connecting rod length
L_{eq} = equivalent length of pipe
m = mass
MW = molecular weight
n = polytropic coefficient
N_m = number of lobes on main rotor
n_s = number of stages
n_v = number of vanes
N = rotational speed
N_s = specific speed
P = pressure
Q = heat flow, volume flow at inlet conditions
r = compression ratio (P_2/P_1)
r_s = pressure ratio per stage
r_t = pressure ratio across entire compressor
r_δ = ratio of cylinder pressure at bottom dead center to inlet pressure
R = gas constant [for air 53.34 ft · lbf/(lbm · R)], crank radius
s = entropy, stress
sg = specific gravity relative to air
T = absolute temperature, thrust
T_v = vane thickness
U = piston velocity, peripheral velocity
V = volume
V_i = built-in volume ratio
$\overline{V}$ = velocity
W = work, mass flow
Z = compressibility factor

Greek

α = ratio of piston area over valve flow area
β = blade angle, degrees
λ = wave length
Δ = pressure loss, differential pressure (lb/in^2)

Compressed-Air and Gas Usage

Compressed-air is used for machine and tool operation, drilling, painting, soot blowing, pneumatic conveying, food processing, instrument operations, and in situ operations (e.g., underground combustion). Pressures range from 25 psig (172 kPa) to 60,000 psig (413,790 kPa). The largest usage is at 90 to 110 psig which is the normal plant air-pressure range.

Gas compressors are used for refrigeration, air conditioning, heating, pipeline conveying, natural gas gathering, catalytic cracking, polymerization, and in other chemical processes.

Standard Units and Conditions

In the ISO system, the standard unit of pressure for compressors is the kilopascal (kPa). In some countries this is the only unit which can appear on the compressor pressure gages by law. In Europe, the European Committee of Manufacturers of Compressors, Vacuum Pumps and Pneumatic Tools (PNEUROP) and, in the United States, the Compressed Air and Gas Institute (CAGI) prefer the bar as the standard unit of pressure. PNEUROP and CAGI have selected as standard conditions 1 bar (14.5 lb/in^2) (100 kPa), 20°C (68°F), and 0 percent relative humidity. The unit of flow in the ISO system is m^3/s. Other units still in common usage are m^3/h, m^3/min, and L/s. In the United States the most commonly used units are ft^3/min (cfm) and ft^3/h (cfh). Power is normally expressed in kilowatts (PNEUROP) and horsepower (CAGI).

Thermodynamics of Compression

Most compressors are analyzed using the ideal-gas law and assuming constant specific heat. Real-gas deviations are handled by applying a compressibility factor (also called *super compressibility*). The ideal-gas law will give satisfactory results for nonhydrocarbon gases for pressures to approximately 1,000 psig (6,900 kPa) at normal temperatures. Most hydrocarbon gases and refrigerants deviate strongly from the ideal-gas laws even at moderate pressures. For these cases, thermodynamics property tables, Mollier Charts, or compressibility charts should be used. Unfortunately these are not available for many gases of industrial importance. In this case a generalized compressibility chart is used. Compressibility charts for various gases can be found in Loomis, "Compressed Air and Gas Data," 3d ed., Ingersoll-Rand, and Rollins, "Compressed Air and Gas Handbook," 5th ed., Compressed Air and Gas Institute.

Adiabatic Analysis

The equation of state for an ideal gas is:

$$PV = mRT \tag{14.3.1}$$

The first law of thermodynamics for a steady-flow process is (per unit mass):

$$Q = (h_2 - h_1) + \frac{\overline{V}_2^2 - \overline{V}_1^2}{2g_c} + W \tag{14.3.2}$$

Neglecting the kinetic energy of the gas and assuming constant specific heat, for a reversible adiabatic process, Eq. (14.3.2) becomes:

$$W = c_p(T_1 - T'_2) \tag{14.3.3}$$

Substituting $(P_2/P_1)^{(k-1)/k}$ for T'_2/T_1 and $k/(k-1)$ for c_p/R, Eq. (14.3.3) becomes:

$$W = P_1V_1 \frac{k}{1-k}\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \tag{14.3.4}$$

The same results can be obtained by evaluating $W = \int V\,dp$ on an idealized P-V diagram (Fig. 14.3.1).

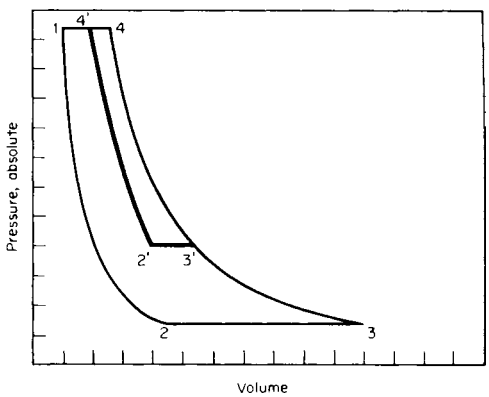

Fig. 14.3.1 Idealized indicator diagram for a positive-displacement compressor.

The isentropic efficiency (ratio of isentropic work to actual work) is given by:

$$\eta_c = T_1 \frac{(P_2/P_1)^{(k-1)/k} - 1}{T_2 - T_1} \tag{14.3.5}$$

Polytropic Process

As an alternative to the adiabatic analysis, a polytropic process can be defined as

$$PV^n = C \tag{14.3.6}$$

All the adiabatic equations apply if $(n - 1)/n$ is substituted for $(k - 1)/k$ where

$$\frac{n-1}{n} = \frac{k-1}{k}\frac{1}{\eta_p}$$

If the inlet and discharge temperatures and pressures are known, n can be calculated from:

$$n = \frac{1}{1 - \ln (T_2/T_1)/\ln (P_2/P_1)} \tag{14.3.7}$$

where n is directly related to the heat transferred during the process by

$$n = \frac{C_p(T_2 - T_1) - Q}{C_v(T_2 - T_1) - Q} \tag{14.3.8}$$

The reversible work done along the polytropic path is called the **polytropic work.**

The polytropic efficiency η_p (ratio of polytropic work to actual work) is given by:

$$\eta_p = \frac{\frac{k-1}{k} \ln (P_2/P_1)}{\ln (T_2/T_1)} \tag{14.3.9}$$

The polytropic efficiency and the isentropic efficiency can be related by:

$$\eta_c = \frac{r^{(k-1)/k} - 1}{r^{(k-1)(k\eta_p)} - 1} \tag{14.3.10}$$

Equation (14.3.10) is strictly valid only for ideal gases with constant specific heats. However, because the real-gas errors occur in both the numerator and denominator, the equation gives reasonably accurate results for real gases which deviate moderately from ideal gases.

Positive-displacement compressors are almost universally analyzed using the adiabatic model. Dynamic compressors are analyzed using both the adiabatic and polytropic models with the trend toward the polytropic model. The advantage of the polytropic model is that the discharge temperature is immediately available and η_p is essentially constant for different gases. The polytropic efficiency is independent of the thermodynamic state of the gas. Also, the total polytropic head is the sum of the polytropic heads for the stages. This is not the case for isentropic heads. The advantage of the isentropic model is that the isentropic work can be read immediately from thermodynamic tables or charts. Comparing adiabatic efficiencies at different pressure ratios is not a valid procedure.

Real-Gas Effects

Deviations from the ideal-gas law are accounted for by introducing a compressibility factor

$$Z = \frac{PV}{RT} \tag{14.3.11}$$

The isentropic work of compression for a real gas becomes:

$$W = P_1V_1 \frac{k}{1-k}\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right]\frac{Z_1 + Z_2}{2Z_1} \tag{14.3.12}$$

where Z_1 and Z_2 are the compressibilities at conditions 1 and 2. Compressibility will also affect the volume flow of the compressor because of the reexpansion of the clearance volume gas.

Multistaging and Intercooling

Temperature rise and mechanical stresses limit the maximum pressure differential across a single stage of any compressor type. The pressure rise across a dynamic compressor stage is further limited by the available polytropic head which the stage can develop. The volumetric efficiency of a reciprocating compressor decreases with increasing pressure ratio placing a practical limit on the maximum ratio per stage.

Multistaging is used to overcome these limitations and to save power. With perfect intercooling and no pressure losses between stages, theoretically the minimum power is obtained when

$$r_s = \sqrt[n]{r_t} \tag{14.3.13}$$

where n_s = the number of stages; r_s = the pressure ratio per stage; and r_t = the ratio across the compressor.

For every 10°F of imperfect intercooling, the horsepower increases approximately 1 percent. Perfect intercooling is achieved when the temperature of the gas leaving the intercooler equals the temperature of the gas at the compressor inlet. The maximum theoretical work that can be saved by perfect intercooling is:

$$W = \left(\frac{k}{1-k}P_1V_1\right)\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - n_s\left(\frac{P_2}{P_1}\right)^{(k-1)/n_sk} + n_s - 1\right] \tag{14.3.14}$$

On the ideal indicator diagram (Fig. 14.3.1), this is area 3′4 4′2′.

In practice, perfect intercooling is seldom obtained. Normal practice is to cool the interstage gas to within 15°F to 20°F of the inlet gas. For water-cooled machines, the coldest water available should be used for intercooling.

Positive-Displacement Compressors Versus Dynamic Compressors

Positive-displacement compressors collect a fixed volume of gas within a chamber and compress it by reducing the chamber volume. The ideal work for such a process is given by Eq. (14.3.4). The work could also be obtained from the area enclosed by an ideal indicator diagram (Fig. 14.3.1). The actual horsepower, taking into account real-gas deviations, is

$$\text{hp} = \frac{144\,P_1V_1k}{33{,}000(1-k)}\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \times \frac{1}{\eta_c}\left(\frac{Z_1 + Z_2}{2Z_1}\right) \tag{14.3.15}$$

with pressures in lbf/in^2 and volumes in ft^3/min. With the volume rate V in m^3/s and the pressures in pascals (dropping the 144/33,000), the power will be in watts.

For a given volume flow, the ideal power is affected by inlet pressure, the k value of the gas, and the compression ratio. The ideal power is not affected by the inlet temperature of the gas or its molecular weight.

The actual power is increased due to losses through the intake and discharge valves or ports as can be seen on the indicator diagram Fig. 14.3.2.

Additional losses are caused by turbulence within the compression chamber, preheating of the inlet gas, and leakage from the compression chamber. The isentropic compression efficiency (ratio of isentropic work to actual compression work) can be determined from the indicator diagram or calculated from Eq. (14.3.5) provided that there is no liquid injection. In addition to the thermodynamic losses, the mechanical losses must be added to the power requirement.

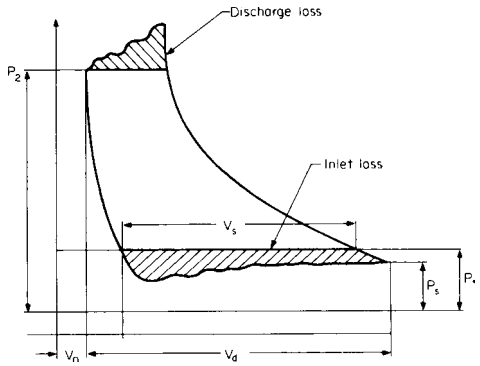

Fig. 14.3.2 Typical indicator diagram showing intake and discharge losses.

Volumetric efficiency is defined for positive-displacement compressors as

$$\eta_v = \frac{\text{actual delivery at intake conditions}}{\text{compressor displacement}}$$

For multistaging compressors, only the first-stage displacement is used.

Positive-displacement compressors are essentially constant-volume, variable-pressure machines as shown in Fig. 14.3.3. For fixed inlet and discharge pressures and varying speed, positive-displacement compressors are essentially constant-torque machines.

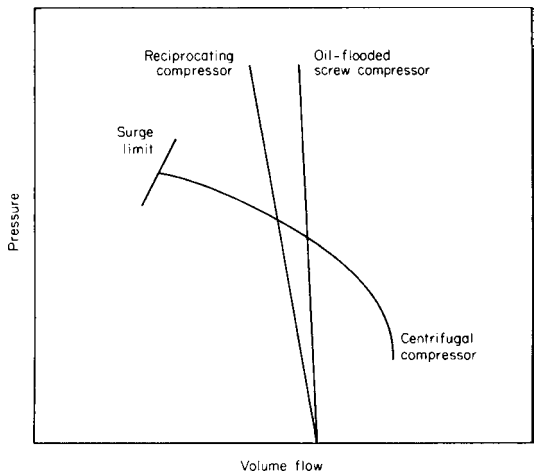

Fig. 14.3.3 Pressure capacity curves for different compressor types.

Dynamic compressors operate by transferring momentum to the gas via a high-speed rotor. The process is steady flow with the work given by Eq. (14.3.4). Head is defined as the energy per unit mass of the fluid. Head is imparted to the fluid through the change in magnitude and radius of the velocity components of the fluid as it passes through the rotor. The head developed by the rotor is

$$H = (U_1 V_{U1} - U_2 V_{U2})/g_c \qquad (14.3.16a)$$

where U_1 and U_2 are the linear velocity of the rotor at radii 1 and 2. V_{U1} and V_{U2} are the fluid tangential velocity at radii 1 and 2.

The polytropic head required for a given compression ratio is

$$H_p = \frac{Z_{\text{ave}} RT_1[r^{(n-1)/n} - 1]}{(n-1)/n} \qquad (14.3.16b)$$

The gas horsepower on a CFM basis is

$$\text{ghp} = Q_1 P_1[r^{(n-1)/n} - 1]\frac{n}{229\eta_p(n-1)}\left(\frac{Z_1 + Z_2}{2Z_1}\right) \qquad (14.3.17)$$

and on a mass flow basis:

$$\text{ghp} = \frac{WH_p}{33{,}000\eta_p} \qquad (14.3.18)$$

With H_p in J/kg and W in kg/s, the power in kilowatts is

$$\text{kW} = H_p\left(\frac{W}{\eta_p}\right) \qquad (14.3.19)$$

Mechanical losses must be added to the gas power to obtain the shaft power. Volumetric efficiency is not defined for dynamic compressors.

For a fixed impeller design and a fixed speed, the energy that is transferred to a unit mass of fluid as it passes through the impeller (i.e., the head) is constant. Pressure rise and power vary directly with inlet gas density independent of the cause of the density change. An increase in k will cause the pressure rise to decrease but will not affect the power.

A centrifugal compressor is essentially a constant-pressure, variable-capacity machine (see Fig. 14.3.3). An axial compressor is a constant-capacity, variable-pressure machine over a significant discharge pressure range. Dynamic compressors at least qualitatively follow the fan laws.

$$\frac{Q_1}{Q_2} = \frac{N_1}{N_2} \qquad \frac{H_{p1}}{H_{p2}} = \left(\frac{N_1}{N_2}\right)^2 \qquad \frac{\text{ghp}_1}{\text{ghp}_2} = \left(\frac{N_1}{N_2}\right)^3$$

The geometry of a dynamic compressor is dictated by the required flow, polytropic head, and speed. The specific speed is a dimensionless parameter used to select the proper geometry.

$$N_s = \frac{NQ^{(1/2)}}{H_p^{(3/4)}} \qquad (14.3.20)$$

For specific speeds from 400 to 900, radial impellers are used. Between 800 and 1,400, mixed-flow impellers are preferred. For specific speeds above 1,400, axial impellers are normally used.

Surging

All dynamic compressors have a minimum flow point called the **surge limit** below which the operation of the machine is unstable. The surge limit is a function of the compressor type, design pressure ratio, gas properties, inlet temperature, blade angle, and speed. Operation at or below the surge limit must be avoided. The existence of the surge limit makes it essential to know the demand curve for the particular installation involved.

Reciprocating Compressors

Reciprocating compressors as shown in Figs. 14.3.4 and 14.3.5 range in size from fractional cfm to 15,000 cfm (25,485 m^3/h) with discharge pressures as high as 60,000 psig (413,790 kPa). The majority of

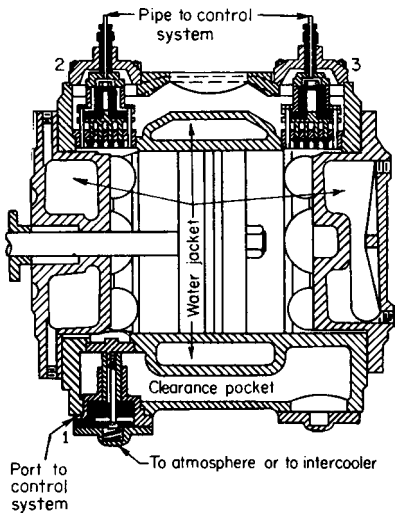

Fig. 14.3.4 Cross section of gas-compressor cylinder, showing water jackets, clearance pocket with pneumatic control, and suction-valve lift devices.

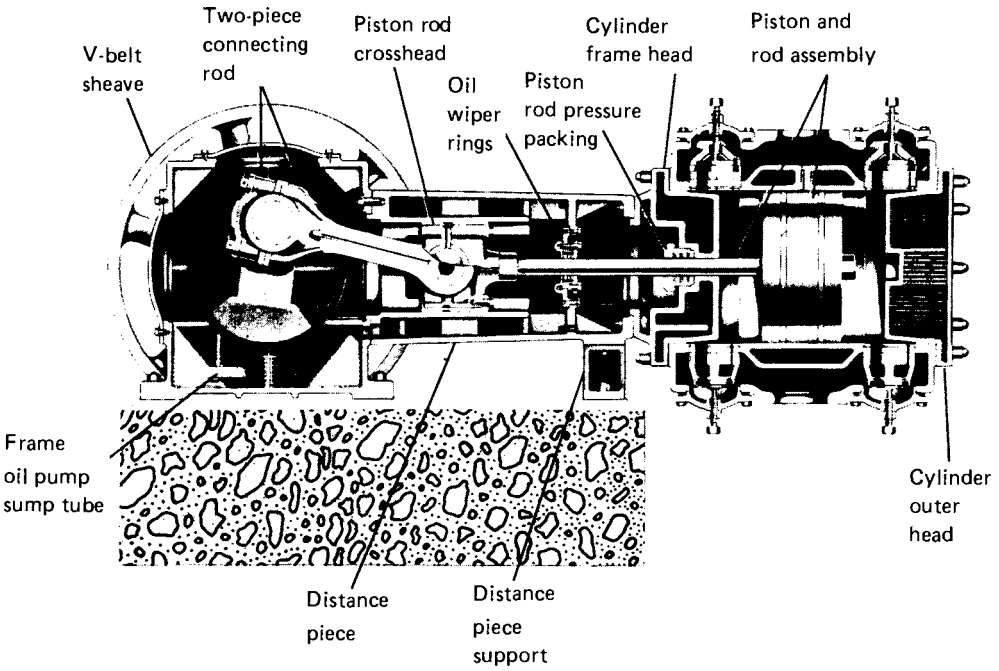

Fig. 14.3.5 Single-stage double-acting reciprocating compressor.

applications fall in the pressure range of 10 to 300 psig (690 to 2,069 kPa) and capacities less than 2,500 cfm (4,250 m^3/h). Single-acting compressors (which compress gas on one side of the piston only) have their widest application below 50 hp (37 kW). Larger compressors are usually double-acting (both sides of the piston are used to compress gas). Most plant air systems operate at 100 to 150 psig. Oil-flooded screw compressors dominate this market. Above 200 psig, reciprocating compressors dominate.

Single-stage compressors of 100 hp (75 kW) operating at 125 psig were once common. Modern practice is to use multistaging with intercooling for pressures above 80 psig and sizes as low as 10 hp (7.5 kW). The intercooling saves power, and the reduced discharge temperatures improve safety and prolong compressor life.

The capacity of a reciprocating compressor is determined by the first-stage displacement multiplied by the volumetric efficiency.

$$\eta_v = (1 + C)(r_\delta)^{(1/k)} - \frac{C(r)^{(1/k)}}{(Z_2/Z_1)} - L \qquad (14.3.21)$$

where $r_\delta = P_s/P_1$; $r = P_2/P_1$; and L = a leakage coefficient = 0.05 for lubricated compressors and 0.10 for nonlubricated. P_s = the pressure that exists in the cylinder when the piston is at bottom dead center. C is the clearance volume as a decimal fraction and includes valve passage volumes up to the sealing elements (point P_2V_c in Fig. 14.3.2). Clearance volume for normal service is 5 to 15 percent. High-pressure machines have as small a clearance volume as practical whereas pipeline compressors may have 100 percent clearance. The indicator volumetric efficiency from Fig. 14.3.2 is V_s/V_d. In general, this will be greater than the value obtained by Eq. (14.3.21).

The compression efficiency varies between 0.85 and 0.95. The mechanical efficiency falls in the range 0.88 to 0.95. The overall efficiency is the product of the compression and mechanical efficiencies.

The discharge temperature can be calculated from Eq. (14.3.22):

$$T_2 = T_1\left[1 + \frac{(P_2/P_1)^{(k-1)/k} - 1}{\eta_c}\right] \qquad (14.3.22)$$

If the inlet pressure is varied while holding the discharge pressure constant, the horsepower of the compressor will pass through a maximum value. This can be seen by substituting displacement times η_v for V_1 in the horsepower equation (14.3.12). For correct sizing of the driver, it is necessary to know the range of inlet pressures as well as discharge pressure. Interstage pressures are selected approximately by Eq. (14.3.13) with empirical adjustments made for interstage piping, intercooler, and valve losses. The loss of volume due to condensation in the intercoolers should be accounted for.

Valve losses can be approximated by:

$$\Delta = 1.26 \times 10^{-6} \alpha f U_{\text{ave}}^2 \,\text{sg}\left(\frac{P}{Z}\right) \text{lbs/in}^2 \qquad (14.3.23)$$

where α = ratio of piston area to valve flow area; f = valve resistance in velocity heads ($\cong$4); sg = specific gravity relative to air; and U_{ave} = average piston speed, ft/s.

The piston velocity as a function of time is:

$$U = R\omega\left(\sin \omega t + \frac{R}{2L}\sin 2\,\omega t\right) \qquad (14.3.24)$$

where R = crank radius; L = connecting rod length; and ω = crank speed (rad/s).

If there were no sealing elements in the valves, the velocity through the valves would be:

$$U_v = \left(\frac{A}{A_v}\right)U$$

This pulsating velocity is amplified by the valve sealing elements so that pulsating flow is inherent in reciprocating compressors. The full wavelength for a double-acting cylinder is $\lambda = 60\,a/2N$, where a is the speed of sound. For a single-acting cylinder, it is two times this value. Pipes with total equivalent lengths equal to multiples of $\lambda/4$ should be avoided.

For a double-acting cylinder, the major problems occur at $\lambda/4$ and $3\lambda/4$ although resonance can occur at the other multiples of $\lambda/4$. Equivalent length L_{eq} is given by

$$L_{\text{eq}} = \frac{\lambda}{360}\tan^{-1}\left(\frac{2\pi V}{S\lambda}\right) \qquad (14.3.25)$$

where V = equivalent cylinder and passage volume; and S = cross-sectional flow area of the pipe.

If it is not feasible to avoid the designated lengths, a volume bottle or an orifice can be installed in the piping system. If an orifice is used, it should be 1/2 the pipe diameter and located at a node (one node occurs at the open end of the pipe). A volume bottle should be located as close to the cylinder as possible. Von Nimitz ("Pulsation and Vibration Control Requirements in the Design of Reciprocating Compressor and Pump Installations," Proceedings of the 1982 Purdue Compressor Technology Conference, Purdue University) recommends the following equations for sizing:

$$V_s = 4\text{PD}\left(\frac{kT_s}{\text{MW}}\right)^{1/4} \qquad V_d = \frac{V_s}{R^{1/k}} \qquad (14.3.26)$$

PD is the total double-acting displacement volume of all cylinders to be manifolded to the surge bottle (ft^3). Subscript s refers to suction, d to discharge. R is the compression ratio. Temperatures are in degrees Rankine.

Compressor Valves

The valve lift area is defined as the product of the sealing element lift and the sum of the valve seat peripheries. The flow coefficient can be determined by measuring the pressure drop through the valve in a wind tunnel. Once the flow coefficient is determined, the "equivalent," or effective, flow area can be derived. The flow coefficient equals the square of the lift area divided by the square of the equivalent area. Poppet valves (Fig. 14.3.6) are ideal for low-speed compressors used in low compression ratios, such as pipeline applications. Concentric ring valves (Fig. 14.3.7) are used in process, natural gas, and high-pressure applications, and can better tolerate certain types of contamination than some of the other valve designs. Plate valves (Fig. 14.3.8) are used in a wide variety of applications including gas gathering, compressed natural gas, pipeline, gas storage, process, and fuel booster applications.

Valve lift ranges from approximately 0.039 in (1.0 mm) to 0.157 in (4.0 mm) in plate valve and concentric ring valves, and approximately 0.098 in (2.5 mm) to 0.25 in (6.3 mm) in poppet valves.

Springs are used to close the sealing element against the valve seat in the last few degrees of crank angle, before the piston momentarily stops and reverses direction. This prevents backflow from slamming the valve closed, which can damage or destroy the sealing element. A single sealing element design, such as a plate valve, is the simplest to control.

Most compressor valve designs now use sealing elements made of nylon, peek, or other nonmetallic materials. Some designs, however, still use steel sealing elements. These are less common.

Adequate valve lift and spring load may be calculated on the basis of pressure, specific gravity of the gas, speed of the compressor, and mean velocity of the gas through the valve.

Piston Rings

Reciprocating compressors employ compression rings, oil rings, and rider rings. Compression rings are always present, but whether oil rings or rider rings are used will depend on the type of compressor and its service.

The standard compression ring is the one-piece square-cut or angle-cut ring although two-piece and segmental rings are sometimes used. The one-piece ring usually has a rectangular cross section, but occasionally the cylinder contact face is crowned to prevent edge loading and to improve lubrication. Cast-iron rings are still widely used but are being displaced in many applications by filled TFE rings. Carbon-filled TFE rings are preferred for process compressors. For air compressors, carbon, glass, and bronze fillers are used. TFE rings can be used from −450 to 500°F (−268 to 260°C). Bronze-filled TFE is good for higher-temperature operations because of its higher thermal conductivity. Carbon-filled TFE is preferred for oil-free service. Many compressors that handle gases with corrosive components (e.g., H_2S) use piston rings made of cloth-reinforced thermoset laminates with molybdenum disulfide added to improve the lubricity. Polyamide, polyimide, and poly(amide-imide) rings work well with marginal or no lubrication.

A one-piece ring must be stretched over the piston to install it in the piston groove. The maximum stress occurs 180° from the joint and is given by Koppers Research and Engineering Staff ("Engineers Handbook of Piston Rings, Seal Rings, Mechanical Shaft Seals," 8th ed., Koppers Company, Inc.) as:

$$S_o = \frac{0.424E(8d - g)/d}{(D/d - 1)^2} \quad \text{lb/in}^2 \qquad (14.3.27)$$

When closed to the cylinder diameter, the ring is stressed to supply the initial seating pressure. The maximum stress (180° from the joint) is given by the Koppers "Engineers Handbook" as:

$$S_c = \frac{0.482E(g/d)}{(D/d - 1)^2} \quad \text{lb/in}^2 \qquad (14.3.28)$$

Oil rings are used in lubricated compressors to scrape oil from the cylinder wall and to meter a small quantity of oil to the compression rings. The oil rings may be above or below the wrist pin. Operating conditions for oil rings are less severe than for compression rings.

Nonlubricant compressors use rider rings to prevent piston cylinder contact. To prevent pressure buildup in front of the rider rings, longitudinal grooves are cut into the rings. Usually two or more rider rings are required.

Below 300 lb/in^2 differential, two compression rings and one or two oil rings are normally used. From 300 to 600 lb/in^2 differential, three to four compression rings are used. From 600 to 1,500 lb/in^2 differential, four to five rings are used. Above 1,500 lb/in^2, six or more rings may be required.

Piston-Rod Packing

Double-acting compressors are driven through a crosshead (Fig. 14.3.5) and require a rod packing to seal the piston rod connecting the piston to the crosshead. The operating conditions for rod packings are more severe than those for piston rings. In a double-acting compressor, the piston rings seal against the pressure differential across the stage whereas the rod packing seals the differential between discharge pressure and atmospheric pressure.

Rod packings use the same materials as piston rings. Metallic packing can tolerate rod wear of 0.15 percent of the rod diameter, with less

tolerance above 2,000 lb/in^2 (13,790 kPa). The rod should be hardened to Rockwell 40 C and ground to a 10-rms or less finish.

Nonlubricated Cylinders

NL-1 class does not permit any direct lubrication and tolerates the minute contamination introduced along the piston rod. This can be eliminated by an additional spacer and rod wiper, qualifying the cylinder as a class NL-2. The pistons for this service use various Teflon rings and riders. The life of carbon rings is reduced by low humidities. The cylinder should have a ground 10- to 16-rms finish and a minimum hardness of Rockwell 20 C.

Cylinder Lubrication

Lubricants serve to (1) prevent wear by providing a supporting film between the rubbing surfaces, (2) seal close clearances, (3) protect against corrosion, and (4) transmit heat of friction and minute wear particles away from points of contact. Industrial cylinders and packings require force-feed lubricators. Viscosity is the best index of suitability: general service at pressures below 500 lb/in^2 (3,448 kPa) requires 400 SSU (86 centistokes) at 100°F (38°C) (SAE 40); 700 SSU (151 centistokes) for 2,000 lb/in^2 (13,793 kPa); and 1,000 SSU (216 centistokes) (SAE 50) for 8,000 lb/in^2 (55,000 kPa) operations. These oils have very high viscosity at 40°F (4.5°C), which will result in poor lubrication. Good winterizing practice provides continuous circulation of warm jacket water and an immersed electric heater in the oil reservoir. Crankcase oils should include a foam inhibitor, sludge dispersant, and rust inhibitor. Phosphorous extreme-pressure agents are added to high-pressure lubricants to avoid wear and scuff damage. Castor-bean and rapeseed oils are additives resistant to solvent action of condensing hydrocarbons.

Cellulube, Houghto-safe, Pydraul AC, Anderol, and Fluorolubes are used to resist the hazard of exothermic reaction in air compression. The crankcase lubricant consumption for 10 plants over a score of years averaged 20,000 bhp/(h)(gal). Table 14.3.1 shows lubricant requirements for general-process and natural-gas operations.

Table 14.3.1 Lubrication Required for Compressor Cylinders

Range of cylinder diam, in	Film thickness, μm	10^3 hp/(h) per gal	Pints per cylinder per day per 100 hp of load	Oil drops/ min
24–36	0.40	13	1.5	13
15–23	0.45	19	1.0	9
10–14	0.55	24	0.8	7
7–9	0.60	32	0.6	5
4–7	1.20	24	0.8	7
3–5	1.40	27	0.7	6

NOTE: Based on 12,500 drops per pint of SAE 40 oil at 75°F with vacuum-type lubricator. Reduced drop count to roughly one-half for pressure-type lubricator. Example: 500 bhp, 20-in cylinder, requires 5 pint/day and feed of 45 drops/min. Each installation will vary on lubrication requirements. Manufacturers' recommendations on oil type and quantity should be followed.

General Lubricant Issues

The choice of lubricant is important, in particular in those compressor designs (screw, scroll, rolling piston, rotary vane, etc.) where the lubricant comes into direct contact with the working fluid. Some gases, such as heavy hydrocarbons and chlorinated refrigerants (HCFCs) are highly soluble in oil, and can significantly affect operational viscosity. They can also affect compressor capacity, as the gas comes out of solution in the lubricant during cyclic pressure fluctuations. Synthetic lubricants such as polyalkylene glycol (PAG), polyalfaolefins (PAO), and polyolesters (POE) are commonly used. Care must be taken to select oil such that its viscosity remains within limits after full saturation of gas in the oil.

Because of the adverse environmental effects of chlorinated refrigerants (HCFCs), chlorine-free hydrofluorocarbon (HCF) refrigerants (R410A etc.) have been made in order to reduce global warming and ozone depletion. The removal of the chlorine causes the refrigerant/lubricant mix to lose some lubricity, and consequently an increase in component wear can occur.

The elastomer material in sealing elements (O rings, lip seals, etc.) is commonly affected by both the operating gas and the lubricant. The results include shrinkage, hardening, or chemical breakdown, and can cause failure to seal if compatibility is not thoroughly checked.

Chemical compounds (additives) are added to lubricants in order to enhance their properties. These include anticorrosion agents, EP (extreme pressure) agents, oxidation inhibitors, stabilizers, and antiwear additives. Care should be taken to ensure that these chemicals do not attack materials such as bearings in the compressor.

The choices of lubricant, operating temperatures, viscosity range, and replacement intervals are usually clearly specified by the compressor manufacturer.

Compressor Accessories

Most state laws and safe practice require a relief valve ahead of the first stop valve in every positive-displacement compressor. It is set to release at 1.25 times normal discharge or at the maximum working pressure of the cylinder, whichever is lower. The relief-valve piping system sometimes includes a manual vent valve and/or a bypass valve to the suction to facilitate start-up and shutdown operations. Quick line-sizing equations are (1) line connection, d/1.75; (2) bypass, d/4.5; (3) vent, d/6.3; (4) relief-valve port, d/9.

Volume flow is controlled by variable-speed drivers; steam engines can operate at 20 percent of rated speed and gas engines at 60 percent, and electric-motor speed can be varied by means of eddy-current and hydraulic couplings and special wound rotors with rheostats, which are both costly and inefficient. Unloading can be applied by means of valve-lift and clearance pockets, as shown in Figs. 14.3.4 and 14.3.9. Utility air plants are throttled with suction unloaders, as shown in Fig. 14.3.10. Suction throttling and bypass controls are used in process operations.

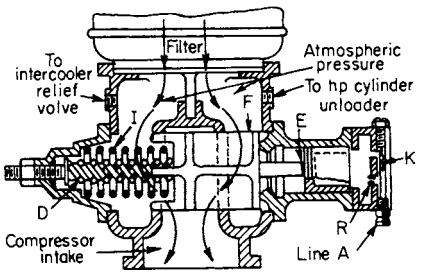

Fig. 14.3.10 Air suction unloader. Piston E moves to closed position as line A pressure reaches design point.

Cylinder Cooling

Single-acting compressors, especially smaller ones, are usually air cooled by fins cast into the cylinder. Cooling air is drawn across the fins by a fan. Double-acting compressors usually have cylinders that are water jacketed.

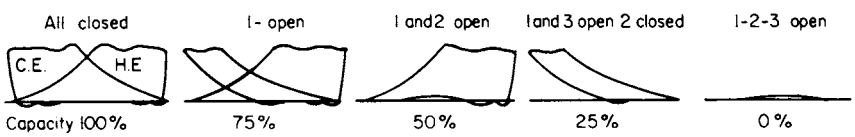

Fig. 14.3.9 Cards from a compressor with combination clearance and suction-valve bypass control.

The principal purpose of a jacket-water system is to normalize cylinder-casting strains. It has some effect on compressor efficiency due to reduced preheating of the air. This effect is reduced as the compressor speed is increased. The heat rejection to the jacket water is approximated by:

$$H_j = 4(t_{ag} - t_{aw}) + 100 \text{ Btu}/(\text{bhp} \cdot \text{h}) \qquad (14.3.29)$$

where t_{ag} and t_{aw} represent the average gas and water temperature, respectively, usually 155 and 140°F, respectively, and a rejection of 160 Btu/(bhp · h). Where the temperature rise is between 2 and 5°F, the jacket-water requirement is 160 bhp/(500 × 3.2 × t_w), or 0.1 gal/(min · bhp). The use of cold water in jacket-water systems causes condensation on the cylinder walls, washing of lubricant, and excessive ring wear.

Rotary-Vane Compressors

Figure 14.3.11 is a section through a typical rotary-vane compressor. The displacement can be calculated using the following formula.

$$V_{th} = 2eL(\pi D - T_v N_v)N \qquad (14.3.30)$$

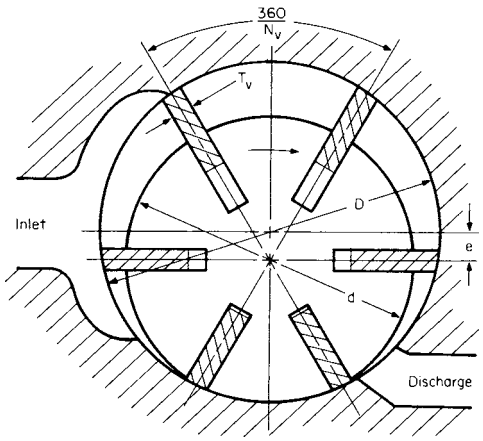

Fig. 14.3.11 Section through a typical vane compressor with N_v vanes.

Rotary-vane compressors have a built-in volume ratio V_i. This means that they will compress the gas within the compression chamber to $P_1(V_i)^n$ before opening the compression chamber to the discharge port. P_1 is the inlet pressure, and V_i is the ratio of the volume of the compression chamber at the inlet cutoff point to the volume at the point just prior to the opening of the discharge port. If the operating-pressure ratio does not match the built-in ratio, overcompression or undercompression will take place as indicated in Fig. 14.3.12. For this case the ideal work should be calculated as:

$$W_{\text{ideal}} = \frac{P_1 V_1}{1 - n}[V_i^{n-1} - n] - P_2 \frac{V_1}{V_i} \qquad (14.3.31)$$

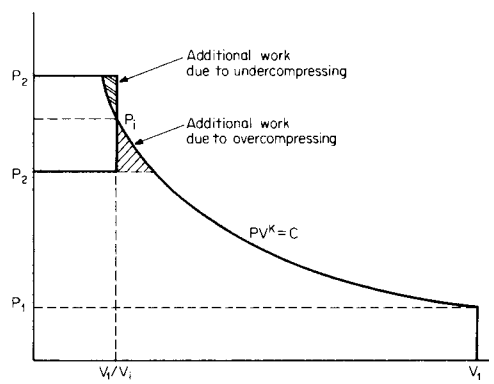

Fig. 14.3.12 Idealized *PV* diagram for a compressor with a built-in volume ratio (also referred to as a *built-in pressure ratio*).

The ratio of this work over the ideal work required for a perfectly matched compressor can be read from Fig. 14.3.16. For example, the theoretical work for an air compressor with $V_i = 2$ operating at $P_2 = 0.8P_i$ theoretically will require 2.5 percent more work than it would if it were designed so that the built-in ratio matched the operating ratio.

However, normal practice is to base efficiencies on a power calculated as though the compressor built-in ratio matches the operating ratio.

Rotary-vane compressors may be dry, lubricated, or oil-flooded. Prior to 1960 two-stage, oil-flooded vane compressors up to 900 cfm (1,530 m^3/h) compressing to 150 psig (10.3 bar) (1,034 kPa) were used in portable compressors. They are now usually limited to less then 100 cfm (170 m^3/h) air compressors and to small refrigeration compressors and boosters.

Vane materials may be phenolic (micarta, polyamid-imides, polyimides, Ryton) or metal (aluminum-silicon alloy).

The major limitations of vane compressors are imposed by vane-tip friction, vane-bending stress, and vane-length limitations. Maximum vane tip speeds are approximately 65 ft/s (20 m/s). Normally 6 to 8 vanes are used although as many as 20 vanes have been used. The trade-off is between reduced pressure differential per cell and increased friction. The eccentricity ratio is normally $e = 0.07D$ for low pressure (25 psig) (172 kPa) and $e = 0.05D$ for higher pressures (50 psig) (345 kPa). For service over 50 psig, the compressors are usually multistaged.

Assuming an injected oil temperature of 140°F (60°C) and no intercooling, a two-stage vane air compressor operating at 100 psig will have an adiabatic efficiency (including mechanical losses) of 60 to 72 percent. The discharge temperature will be approximately 90 to 95°C or 200°F. Oil-flooded vane compressors normally use synthetic lubricants. The high shearing rates and vane tip temperatures rapidly oxidize petroleum based lubricants.

Rolling-Piston Compressors

Superficially, the rolling-piston compressor (Fig. 14.3.13) resembles the sliding-vane compressor. However, its kinematics and performance are quite different from those of the sliding-vane compressor. The rolling-piston compressor consists of an eccentric, a rolling piston, a vane, a cylinder, and a discharge valve. The motion of the rolling piston with respect to the eccentric and cylinder is controlled by the various friction forces action on the piston. Compression and suction occur

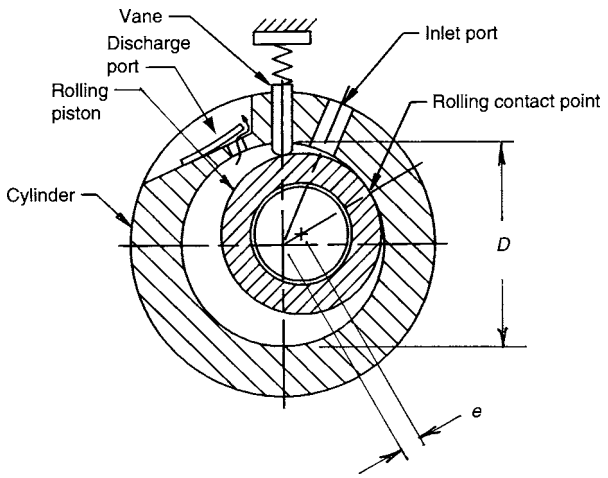

Fig. 14.3.13 Section through a typical rolling piston compressor.

simultaneously in different chambers. A cycle covers two revolutions of the eccentric. Rolling-piston compressors are usually used in refrigeration systems, typically 0.25 hp (180 W) to 0.75 hp (550 W). Typical values for volumetric and power efficiencies are 0.90 and 0.84 to 0.86, respectively. The eccentricity is normally about 0.09 × D. The piston diameter is approximately 0.81 × D and the length-to-diameter ratio is

approximately 0.5. The compressor displacement can be calculated from Eq. (14.3.30) with $N_v = 1$.

Rotary, Twin-Screw, Oil-Flooded Compressors

Figure 14.3.14 is a cross section of an oil-flooded, rotary-screw compressor. The principle of operation can be determined from Fig. 14.3.15. The displacement of a twin-screw compressor is

$$V_{th} = KD^3 \frac{L}{D} C_{th} N \tag{14.3.32}$$

where $K = N_m(A_{mg} + A_{fg})D^2$; D = the main rotor diameter; L = the rotor length; N_m = the number of lobes on the main rotor; A_{mg} = the area of one groove on the main rotor; and A_{fg} = the area of one groove on the secondary rotor. C_{th} is an overlap constant (between 0.95 and 1.0 for most designs) which corrects for the overlapping of the filling and compressing processes.

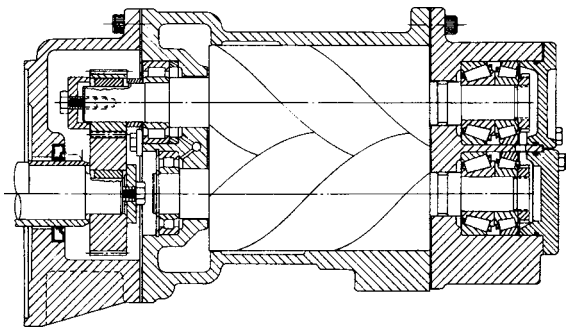

Fig. 14.3.14 Cross section of a typical single-stage, oil-flooded, twin-screw compressor.

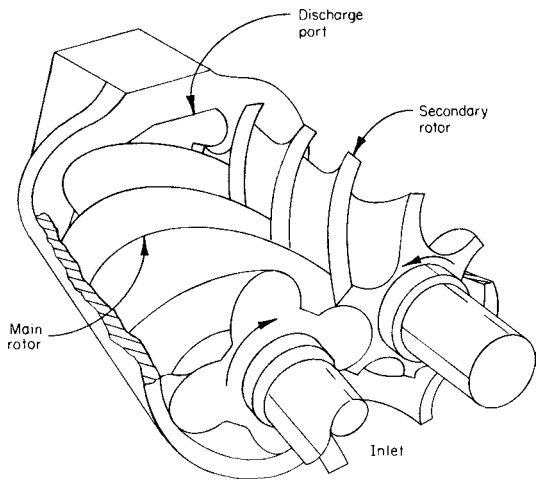

Fig. 14.3.15 Operating principle of a twin-screw compressor.

C_{th} depends on the wrap angle, the profile, and the number of lobes. Lobe combinations of (4 and 5), (4 and 6), (5 and 6), and (5 and 7) are used. The most common design uses the (4 and 6) combination. Typical values for C_{th} and K are given in Table 14.3.2. A complete cycle (filling and compressing) takes place over approximately 750° of main rotor rotation. The number of compression cycles per revolution of the main rotor equals the number of lobes on the male rotor. The discharge process for adjacent grooves overlaps by approximately 40°, giving an inherently smooth discharge process.

Table 14.3.2 Typical Constants for Different Lobe Combinations (300° Male Wrap)

N_m/N_f	3/4	4/5	4/6	5/6	5/7
C_{th}	0.954	0.973	0.969	0.984	0.980
K	0.530	0.439	0.507	0.454	0.468

Rotary-screw compressors have a built-in volume ratio V_i (typically 4.4 for single-stage air compressors and 1.9 to 3.5 for refrigeration compressors). For an inlet pressure of P_1, the compressor will have a built-in pressure of $P_1 V_i^n$. The effect on the P-V diagram and on the theoretical power can be found from Fig. 14.3.12 and Fig. 14.3.16. In practice, the increased discharge port losses associated with higher built-in volume ratios (smaller port area) skew the results in Fig. 14.3.16. In practice, it is more efficient, at least in air compressors, to have the built-in ratio slightly lower than the theoretical ratio. Single-stage, twin-screw air compressors rarely have built-in pressure ratios greater than 9, and most are designed with ratios of 7 to 8. An air compressor designed for 100 psig can operate at 175 psig with a loss in adiabatic efficiency of approximately 5 and 4 percent loss of volumetric efficiency.

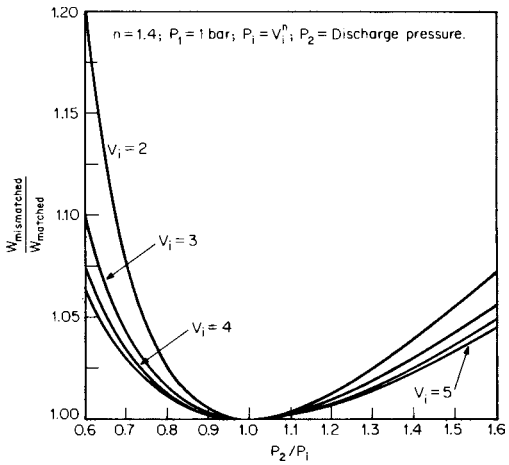

Fig. 14.3.16 The effect of the built-in volume ratio on theoretical work of compression for a compressor operating off the design point.

Adiabatic efficiency (including mechanical losses in the air end) vary from 70 percent for small sizes (80 mm) to 88 percent for large (300 mm) slow-running compressors. An average value for a midsize compressor is 0.78 to 0.75 based on an injection temperature of inlet temperature plus 50°F. Accuracy in manufacturing the rotors is critical to achieving good efficiency. The heat absorbed by the cooling oil can be estimated by:

$$Q_h = \text{power}\left[1 - \frac{\eta_c(T_2 - T_1)}{T_1(r^{(k-1)/k} - 1)}\right] \tag{14.3.33}$$

where power = the shaft power to the compressor. T_2 is normally 70 to 90°F over T_1.

For most applications, tip speeds range from 15 to over 60 m/s, with rotor sizes from 40 to 600 mm, and L/D ratio from 1 to 2.2. Oil-flooded screw compressors dominate the portable-compressor market and the low-pressure plant air market, while reciprocating compressors dominate the higher-pressure applications. In industrial refrigeration the screw compressor finds its widest application in the 300 to 1,000 kW range.

In heat-pump applications, the screw compressor's zero-clearance volume is an advantage over reciprocating compressors. Reciprocating compressors lose volumetric efficiency as the outside temperature drops (the compression ratio increases) requiring supplemental heat to compensate for the lost capacity. Refrigeration screw compressors are

now available with a secondary suction port known as an **economizer connection.** This allows for two-temperature-level operation. At full-load operation, the system COP is improved significantly. As the compressor is unloaded, the improvement is lost.

Capacity can be controlled by on-line/off-line operation, inlet throttling, slide-valve or turn-valve operation, or speed regulation. Stationary air-compressors are normally controlled by on-line/off-line operation or inlet throttling with unload below 50 percent capacity. The air-oil sump is usually blown down to atmospheric pressure at unload.

Portable compressors are normally controlled by a combination of inlet throttling and speed regulation; the air-oil sumps are not blown down.

Refrigeration compressors are controlled by inlet throttling or more often by a slide valve or turn valve. A compressor with a slide valve is shown in Fig. 14.3.17. The effect on power consumption for each type of capacity control can be found from Fig. 14.3.18.

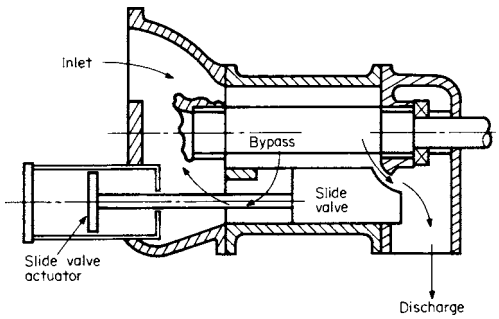

Fig. 14.3.17 Principle of slide-valve operation. As the valve is moved toward the discharge end of the compressor, the point of inlet cutoff is delayed.

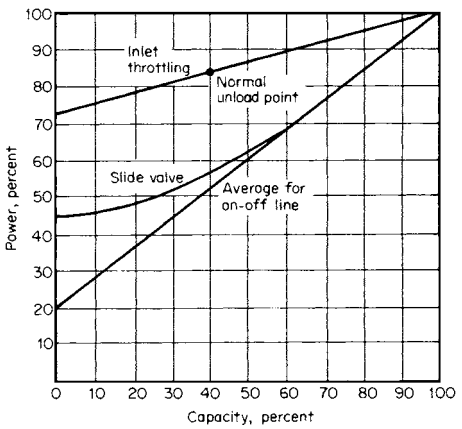

Fig. 14.3.18 Comparison of different capacity control methods for oil-flooded screw compressors operating at constant speed.

The discharge temperature for an air compressor must be kept high enough to prevent condensation in the lubricant during part-load operation. This is usually accomplished by a thermal valve set to maintain the minimum injection temperature at 140 to 165°F (60 to 76°C). Standard oil separators limit oil carryover to 5 ppm or less. Optional treatment can reduce the levels further.

The capacity loss of an oil-flooded, twin-screw compressor with altitude is quite small compared to a normal reciprocating compressor. The approximate capacity correction for altitude can be read from Fig. 14.3.19.

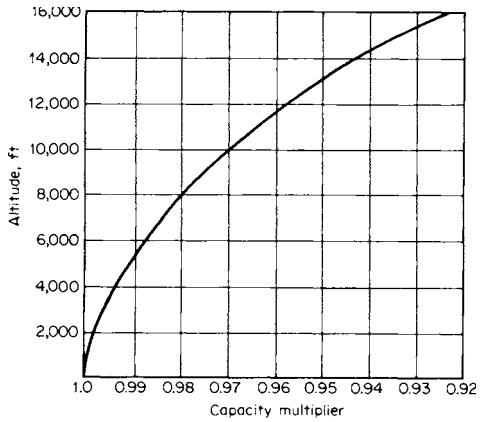

Fig. 14.3.19 Altitude correction for capacity, single-stage, oil-flooded screw compressor.

Rotary Single-Screw Compressors

The operating principle of the single-screw compressor can be determined from Fig. 14.3.20. Lundberg and Glanvall give the displacement as:

$$\beta = \arcsin \frac{B - D/2}{R}$$

$$\Omega = \pi - 2\beta$$

$$C = 2R \sin \frac{\Omega}{2}$$

$$\gamma = \frac{\alpha \Omega}{\xi}$$

$$t = R - \frac{B - D/2}{\sin (\beta + \gamma)}$$

$$u = B - \frac{D}{2} + \frac{t}{2} \sin (\beta + \gamma)$$

$$V = \sum_{\alpha=\alpha 1}^{\xi} AU \, \Delta\alpha$$

The rotary single-screw compressor is an oil-flooded compressor with a built-in volume ratio. The compressions for each star wheel are almost in phase so the gross effect as far as the discharge piping is that there are six discharges per revolution of the main rotor.

The single-screw compressor is used in the refrigeration industry where the low bearing load on the main rotor is an advantage. It is also being used as an air compressor in the smaller sizes.

Adiabatic efficiency of a single-screw compressor will be 2 to 5 percent lower than that of a comparable twin-screw compressor. The effect of off design operation on theoretical power can be found from Fig. 14.3.16. Capacity control is identical to the twin-screw compressor.

Dry Rotary Twin-Screw Compressors

A dry rotary, twin-screw compressor has timing gears to separate the rotors which may or may not be coated. The typical compressor is water-jacketed. Seals prevent gas leakage along the shafts and seal the oil to the bearings and timing gears. Sleeve bearings are most common, but some units have antifriction bearings. The displacement is the same as for the oil-flooded screw. Tip speeds vary from 80 to 140 m/s. Sizes range from approximately 400 to 20,000 cfm, and in special applications as high as 60,000 ft^3/min. As a result of practical limitations, the discharge temperature is limited to 400°F, which determines the maximum permitted pressure ratio across each stage. Two-stage compressors are almost always intercooled. With intercooling to 15°F they approach

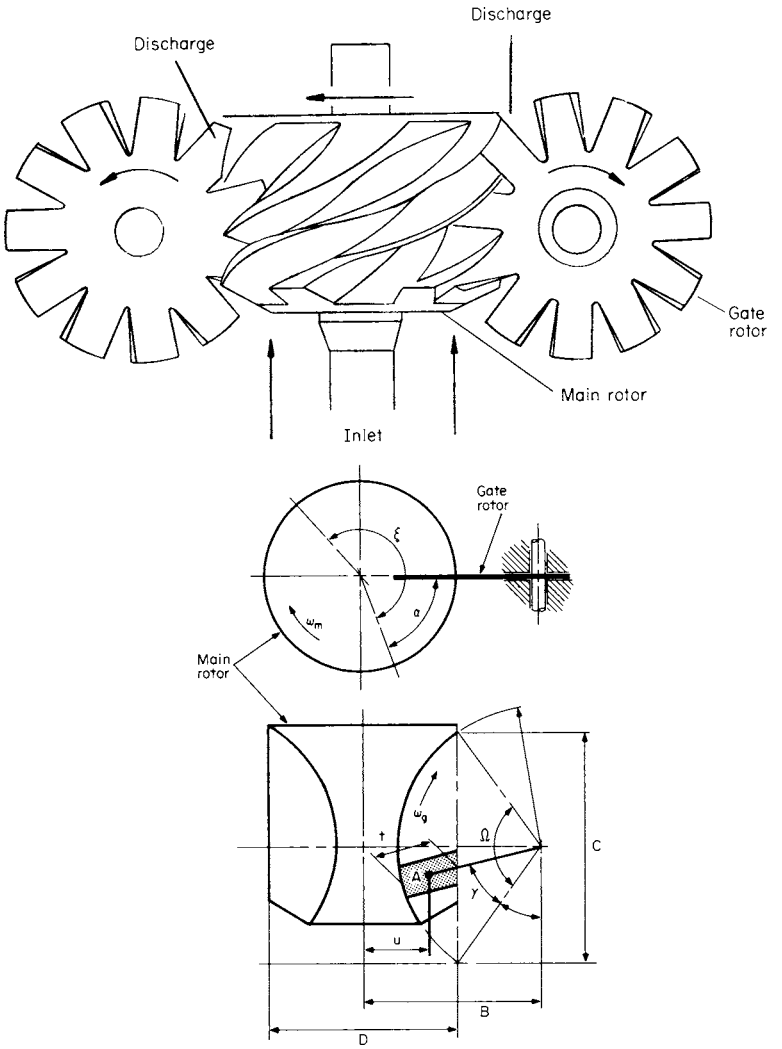

Fig. 14.3.20 Principle of operation and geometry of a single-screw compressor. *(Lundberg and Glanvall, "A Comparison of SRM and Globoid Type Screw Compressors at Full Load," Proceedings of the 1978 Purdue Compressor Technology Conference, Purdue University, W. Lafayette, IN.)*

adiabatic efficiency (based on zero intercooling) including mechanical-loss ranges from 72 to 80 percent. While oil-flooded screw compressors can be controlled to very low capacities by inlet throttling, dry screw compressors cannot. The resulting pressure ratio causes excessive temperature increase across the compressor.

Orbiting Scroll Compressors

This is a positive-displacement compressor, which is common in air conditioning and heat pump applications, primarily in the 5 to 50 hp (3 to 37 kW) range.

The compression is achieved by two identical scrolls (typically involutes of circles phased 180° apart), whereby one of the scrolls is stationary, and the other orbits without rotating. The filling, compression, and discharging process usually takes 900 to 1100° of shaft rotation, depending on the number of wraps. The orbiting scroll is driven by the crankshaft and prevented from rotating by an Oldham ring. A typical scroll is shown in Fig. 14.3.21.

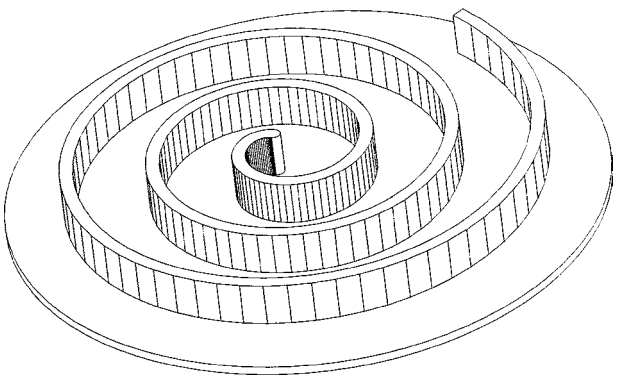

Fig. 14.3.21 View of a typical scroll element.

The movement of the orbiting scroll causes pockets between flanks of the scrolls to get progressively smaller, until the volume reaches its internal limit (internal volume ratio, see "Screw Compressors"), finishing the process by discharging the gas. Different stages of the compression process are illustrated in Fig. 14.3.22.

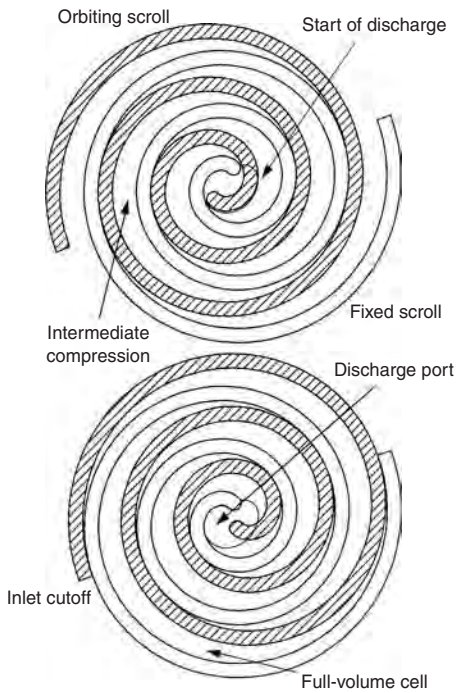

Fig. 14.3.22 Scroll compression stages (moving scroll orbits clockwise).

The flow rate of a scroll compressor given by the equation

$$Q = 2A_{fv}H_vN\eta_v$$

where A_{fv} is the area of one of a full-volume cell (Fig. 14.3.22) and H_v is the height of the scroll vanes.

In the noncompliant version, both scrolls are held rigidly, with a small clearance between the flanks and tips. This design is susceptible to damage from particle throughput and hydraulic locking. The compliant version overcomes these issues by "floating" the scrolls into contact with each other. Axial contact is achieved by back pressure on the stationary scroll, while contact on the flanks is achieved by centrifugal force. This allows the scrolls to yield to the excessive forces without causing damage. There is, however, a potential for increased scroll wear, in particular if used with some of the latest chlorine-free refrigerants, which reduce the lubricity of the oil.

The internal leakage across the tip of the scroll vanes and along the vane flanks affects the compressor performance, more so in the noncompliant case. The leakage across the vane tips is significantly greater and damaging to performance than that along the flanks. For this reason, a groove is usually machined into the tip of the scroll vanes, and a sealing strip inserted.

Dynamic Compressors

A typical centrifugal compressor is shown in Fig. 14.3.23. The optimum range of operation can be found from Fig. 14.3.24. An estimate of the polytropic efficiency can be obtained from Fig. 14.3.25 or calculated from

$$\eta_p = 0.014 \ln (Q) + 0.600 \qquad (14.3.34)$$

where Q is in cubic feet per minute.

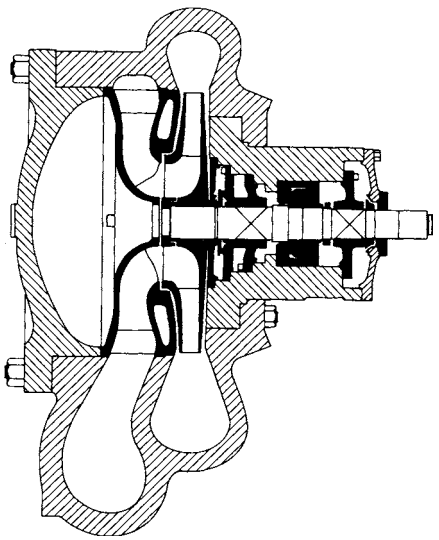

Fig. 14.3.23 Single-stage, cantilever-design centrifugal compressor.

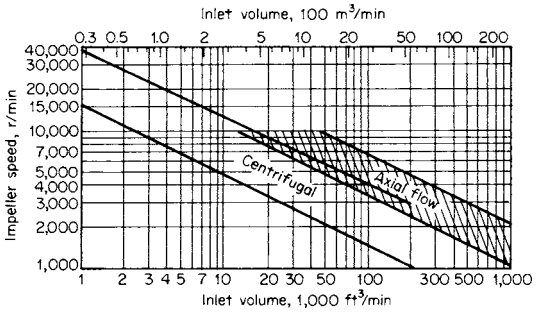

Fig. 14.3.24 Range of speed versus inlet capacity for near-optimum dynamic compressor efficiency. *(Loomis, "Compressed Air and Gas Data," 3rd ed., Ingersoll-Rand, pp. 4–28.)*

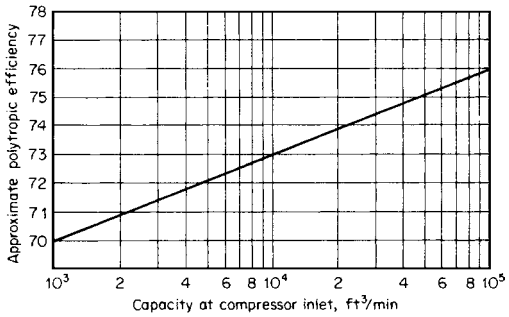

Fig. 14.3.25 Approximate polytropic efficiency versus compressor inlet capacity. *(Rollins, "Compressed Air and Gas Handbook," 4th ed., Compressed Air and Gas Institute, pp. 3–71.)*

For normal industrial compressors, $H_p = 10{,}000$ ft · lb/lb (30 kJ/kg) per stage although much higher values can be obtained.

The required speed can be estimated from:

$$N = \frac{(g_c H_p/\mu)^{0.5}}{\pi D} \qquad (14.3.35)$$

The pressure coefficient ($\mu = g_c H_p/U^2$) varies from 0.4 to 0.7 (in the high-efficiency range). In the absence of specific data, use 0.55 for estimating.

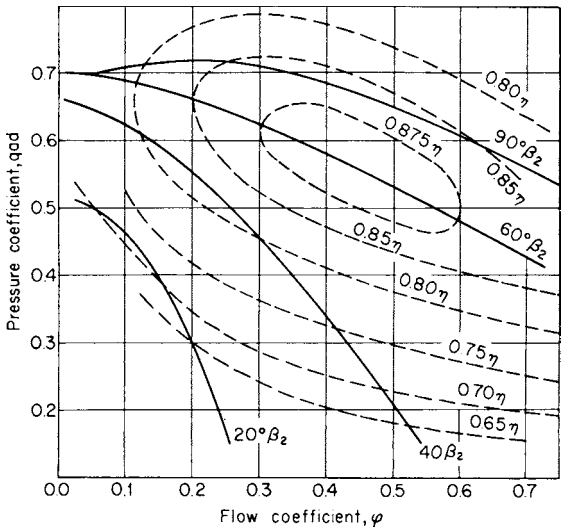

Fig. 14.3.26 Basic characteristics of centrifugal compressor, showing effects of backward-leaning impeller blades. *(After Balje, ASME 51-F-12.)*

The diameter is determined by the required flow and can be estimated from the flow coefficient $\varphi = Q/ND^3 \propto V/U$, where V is the axial inlet velocity. The normal range of φ is 0.15 to 0.4 with the optimum at 0.3.

The slope of the μ-φ curve (and the $H_p \cdot Q$ curve) is strongly dependent on the backward lean of the impeller blades as shown in Fig. 14.3.26. $\beta_2 = 90°$ is a radial blade. Normal closed industrial impeller blades will have an angle of 65 to 55°. It should be noted that an increase in density of the gas will flatten the slope.

A typical axial compressor is shown in Fig. 14.3.27. The range of application can be found from Fig. 14.3.18. Axial compressors are more efficient than centrifugals (as much as 5 percent) but have a much narrower range of operation. The surge limit will vary from 85 to 95 percent of design flow. For a given stage, the polytropic head will be about one-half that developed by a centrifugal stage, i.e., $\mu = 0.3$. Axial compressors are used only for air or clean gas. They find their major application in refineries, butadiene plants, and ethylene oxide plants. Jet-engine compressors are axial-flow compressors.

Thrust Pressures

A double-inlet and an open impeller have no axial thrust, whereas a semienclosed impeller, with a frontal shroud, can impose substantial thrust, evaluated by:

$$T_A = Y(A_1 - A_2)\Delta(\text{lb/in}^2) + 0.8(A_2 - A_3)\Delta(\text{lb/in}^2) - P_1A_3$$

where A_1 = full impeller area; A_2 = impeller area less the area of the inlet-eye seal; A_3 = shaft area through the seal, all in in^2; and Δ (lb/in^2) = pressure differential per stage. Y is the percentage of Δ (lb/in^2) acting in back of a single-stage disk: (1) Without a frontal shroud and a plain back, $Y = 0.35$; (2) with 0.060-in back ribs, $Y = 0.28$; (3) with $^1/_4$-in equalizer holes at half radius and about 2 in apart, $Y = 0.22$; and (4) with deep scallops, $Y = 0.18$. For fully shrouded impellers, as used in multiple stage, $Y = 1.00$. These thrusts are balanced by opposing impeller inlet ends or, more generally, by a balancing drum wherein an equal and opposite thrust is created, equal to the product of the compressor Δ (lb/in^2) and the area of the drum. Stepanoff ("Turboblowers," Wiley) shows that radial impellers create a radial thrust, caused by the uneven volute-pressure distribution, which is:

$$T_R = 0.36\,\Delta(\text{lb/in}^2)\,db$$

where d = the impeller diameter; and b = the width, including the shrouds, both in inches.

Applicable Standards

Many national and international standards are available for guidance regarding construction, testing, packaging, and reliability. These include API, ANSI, ASME, CAGI, SAE, and international standards. Examples of coverage include construction (API 616, API 618, and API 619), testing (ASME PTC 9), and safety and packaging (API 670, ASME 19.3).

Compressor manufacturers commonly make a list of exceptions to stipulations in the various standards, or offer these as options at an additional cost. Therefore, it is important—if guidelines are to be drawn from specific standards—that the customer and manufacturer agree on compliance or exceptions to all relevant sections of the applicable standards, including construction, testing, test interpretation, and packaging features.

INTRODUCTION

High-vacuum pumps can be broadly divided into two categories: transfer pumps and capture pumps. In regard to transfer pumps, i.e., pumps that transfer the gas from a reservoir into the atmosphere, it can be said that the world *pump* is a historical misnomer. Such pumps could easily be called *rarefied gas compressors*. After all, to turn a device from a compressor into a vacuum pump, it is only necessary to place the reservoir at the inlet instead of at the discharge. However, because high-vacuum systems deal with small pressure differences (usually 1 atmosphere), enormous compression ratios, and very small mass flows, specialized designs are necessary. Because of very low mass flows involved at the very low pressures (or densities), it is possible to employ devices that do not exhaust the pumped gas but keep it out of the gas phase inside the pump.

Vacuum can be produced by a few basic methods: by mechanical displacement using pistons, vanes, lobes, and so on; by fluid ejectors and turbomachinery devices; by chemical reactions leaving solid residue; by ionizing the gas and driving the ions into a solid target with high electric fields; and by freezing the gas at cryogenic temperatures. In addition, high-vacuum engineering deals with gas flows ranging from the "normal" continuum conditions to the region of molecular flow. In the latter range, the gas molecules collide mainly with the walls of the vacuum vessel or conduits rather than with each other. This produces high compression ratios across short sections of conductors (pipes, elbows, etc.), but at extremely small pressure differences. In molecular flow conditions, there is no genuine pressure gradient inside the pipe, and molecules can flow as easily upstream as downstream. In such conditions it is often more useful to think in terms of densities rather than pressures.

Before proceeding to the description of the most common devices for producing high vacuum, it may be useful to note that high vacuum engineers, as a result of an independent historical development, use concepts and terminology differing from those associated with compressors. For example, *throughput,* a product of volumetric flow and pressure, is used instead of *mass flow,* because the gas is assumed to be always at room temperature. Instead of *volumetric flow,* vacuum engineers use *pumping speed,* which is associated with the rate of pressure reduction in a reservoir during evacuation. Also, when displaying the performance of the pump, they plot pumping speed versus inlet pressure (which is the dependent variable), rather than vice versa as is the custom in other mechanical engineering fields. Instead of speaking about resistance of lines, pipes, conduits, etc., they use the reciprocal concept of conductance.

The usual pascal unit for pressure can be used for designating the level of high vacuum, but millibar and torr are also used. Currently, in United States, the use of torr (equivalent of old mm Hg) is more common, while in Europe, mbar (1/1,000 of an atmosphere) is more frequent. One torr is equal to 133.3 Pa or 1.333 mbar. The pumping speed is measured in litres per second (L/s) and conductance in torr · L/s · torr (torr · L/s of throughput per torr of pressure difference), which, abbreviated, is also L/s (1 L/s = 2.12 ft^3/s).

Pumping speed S which primarily involves the size of the pump, is defined by the following equation:

$$t = V/S(\ln P_1/P_2) \quad \text{or} \quad t = V/S(2.3 \log P_1/P_2)$$

where t is the time period of evacuation, V is the volume of the vacuum chamber, P_1 the initial pressure in the chamber, and P_2 the reduced pressure (see Fig. 14.4.1). This relationship works well in typical systems when leaks and gas evolution are neglected. In the presence of a leak from atmosphere into the chamber, the equation should be modified into:

$$t = V/S[\ln(P_1 - P_f)/(P_2 - P_f)]$$

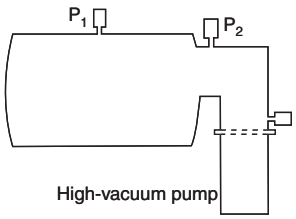

Fig. 14.4.1 Schematic view of a vacuum chamber with three pressure gages and a pump.

where P_f is the final pressure due to the leak. In practice, vacuum pumps are never used at zero flow condition, because there always remains some residual gas evolution from internal surfaces exposed to high vacuum. With that in mind, the "ultimate" pressure achieved in a vacuum system after a long period of pumping can be written as follows:

$$P = \sum(Q_i/S_i)_{\text{ext}} + \sum(Q_i/S_i)_{\text{int}} + \sum(P_{2i}/k_i)$$

The first term is the summation of contributions of gas evolutions from external sources, where Q_i and S_i are throughputs and pumping speeds for various gases. The second term is the summation of corresponding gas evolutions in the inlet areas of the pump itself, P_{2i} represents corresponding discharge pressures, k_i is the limiting compression ratio for each gas, and the subscript i means "for each gas."

PUMP SELECTION

There are a few common ways vacuum systems are used: rapid, repetitive evacuation to a given pressure for a process of short duration; long term processing of some material in a vacuum environment in the presence of substantial continuous or slowly diminishing gas evolution; or evacuation and complete isolation of a vacuum chamber or a container from the outside world. Each of these requires a different pumping system in regard to the type and size of pumps used. Figure 14.4.2 is a graph that can be used for the approximate evaluation of time required to reach a certain pressure depending on the volume of the vacuum chamber and the pumping speed of the pump. Because of the great range of variation of pressure (or density) during an evacuation of a container to high vacuum levels, it is usually necessary to pump initially with coarse vacuum pumps in order to remove the bulk of the gas. Then, when the amount of mass flow (throughput) is reduced to a tolerable level, pumps designed for pumping at high-vacuum conditions are engaged. This is reflected in Fig. 14.4.2 with the label "High Vacuum Valve Opens."

At the initial conditions in continuum flow, transfer-type pumps tend to have the same pumping speed for all gases, but when the molecular flow is approached, the rate of pumping begins to be different for various gases. This is especially true of capture-type pumps. Many technical articles and textbooks often omit this word of caution. In addition to the

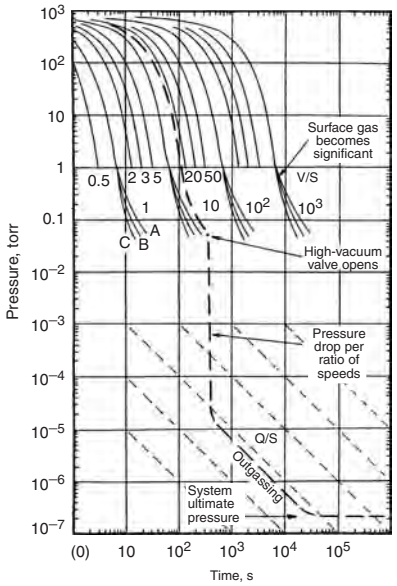

Fig. 14.4.2 Evacuation process, from atmosphere to the high-vacuum region, shown on a log-log graph. Letters A, B, and C correspond to sand-blasted mild steel, 100-grit-finish stainless steel, and prebaked stainless steel chamber walls. The point called "high vacuum chamber opens" indicates the start of high-vacuum engagement. (*Reprinted from Hablanian, "High-Vacuum Technology," p. 133, Marcel Decker.)*

differences in pump performance, conductance values of conduits are also different for different gases. In common vacuum systems, engineering experience can be used for design with reasonable accuracy, but in unusual installations, laborious estimations must be made to evaluate the expected combined performance of pumps and systems.

The most significant performance aspects of pumps are: pumping speed (related to volumetric flow), maximum steady-state throughput

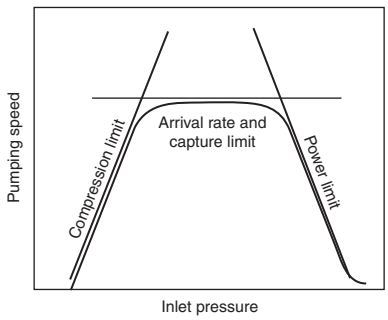

Fig. 14.4.3 General basic limitations of pump (or compressor) performance.

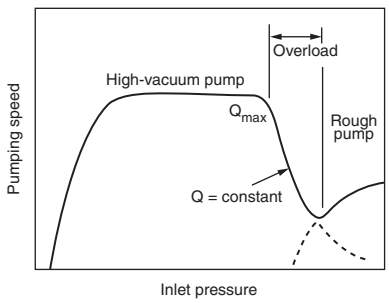

Fig. 14.4.4 Traditional way of presenting performance of a high-vacuum/rough-vacuum pump combination. Q_{max} is the highest permissible steady-state gas flow for the high-vacuum pump.

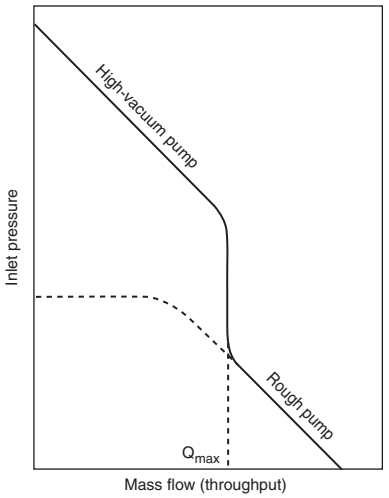

Fig. 14.4.5 Typical performance of a high vacuum pump (see Fig. 14.4.4), where the achieved vacuum level is plotted versus mass flow (inlet pressure increasing downward).

capacity (related to mass flow and power), and the ultimate pressure capability (related to limiting compression ratios and system gas evolution rates, called *outgassing*). This is indicated in Fig 14.4.3. A typical performance curve for a transfer-type high-vacuum pumping system is shown in Fig. 14.4.4 in the traditional mode, and the same data are shown in Fig. 14.4.5, where the degree of achieved vacuum is shown on the vertical axis versus the imposed mass flow (throughput).

COARSE-VACUUM PUMPS

For the last 100 years, the common pump for producing high vacuum, beginning at atmosphere, has been the oil-sealed rotary-vane, positive-displacement-type pump shown in Fig. 14.4.6. To achieve high compression ratios, as high as 100,000 to 1 in a single stage, oil is introduced continuously into the pumping space and exhausted with the pumped gas. Oil is used for several functions: for lubrication, for flooding the exhaust space under the exit valve (so-called dead space), to seal the tight spaces between the rotor and stator, to serve as a heat transfer medium for cooling the rotor, to flush particular matter out of the pump, and sometimes to actuate auxiliary valves. A two-stage pump, such as

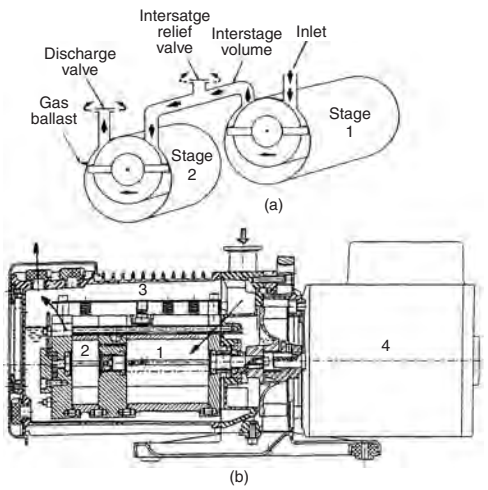

Fig. 14.4.6 (*a*) Two-stage-pump flow diagram. (*b*) Cross section of a two-stage, oil-sealed, rotary-vane rough-vacuum pump. (*Courtesy of Alcatel Vacuum Technology.)*

the one shown in Fig. 14.4.6, when attached to a small reservoir, can produce inlet pressures below 1×10^{-3} torr while exhausting to atmosphere. However, it should be noted that the pumping action itself does not cease at that point for gases that are not present in high quantities in atmosphere. For example, helium from the vacuum chamber is pumped by such pumps at partial pressures of at least 10^{-10} torr.

Pumps of that type are not made in very large sizes (they become expensive, noisy, and power consuming). To achieve lower pressures, such pumps are often used in series with pumps of high pumping speed such as Roots blowers, screw pumps, and other cam-type pumps. In many applications, the presence of oil films at the inlet side of the pump is objectionable, because at molecular flow conditions, oil molecules can travel into the vacuum system and produce contamination. To prevent this, "oil-free" vacuum pumps have been developed, which do not include deliberate introduction of oil into the vacuum space. This is usually achieved by using several stages in series. Typically, it takes three or four stages in series to produce performance similar to that of a single-stage oil-sealed pump. For smaller "dry" pumps, multistaged scroll and diaphragm pumps are also used.

TURBOMOLECULAR PUMPS

There are two types of pumps in this category: so-called drag pumps and turbomolecular pumps. **Drag pumps** function by adding momentum to "stationary" gas molecules during a collision with the fast-moving solid surface of the rotor, thereby moving the molecules toward the discharge side of the pump. Three early versions of drag pumps are shown in Fig. 14.4.7. There is no basic difference between the three types; they differ only in the general geometric arrangement. All three concepts are utilized in modern pumps in a variety of combinations. **Turbomolecular pumps** are essentially axial-flow compressors designed for pumping rarefied gases, typically intended for molecular flow conditions at the inlet to the pump. The basic structure in shown in Fig. 14.4.8, and a typical

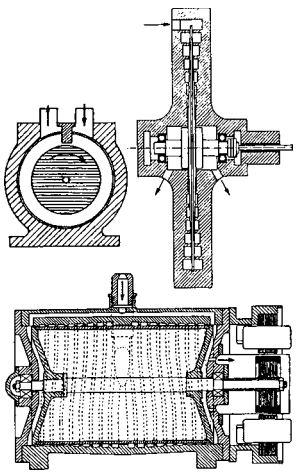

Fig. 14.4.7 Three early versions of molecular drag high-vacuum pumps.

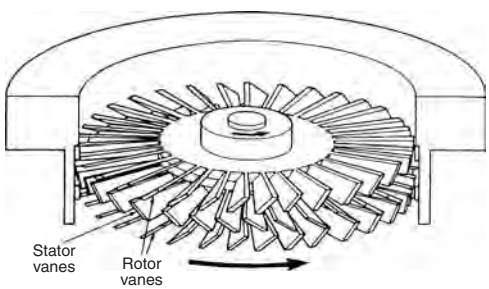

Fig. 14.4.8 Partial cross section of an axial-flow pump. Two rotors and one stator are shown.

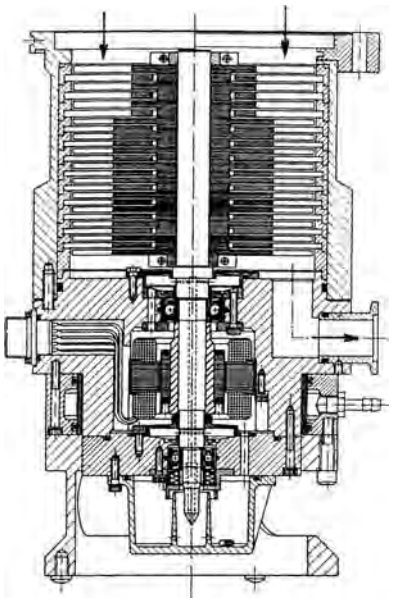

Fig. 14.4.9 Cross section of a typical axial-flow pump (with 13 bladed rotors).

pump construction in shown in Fig. 14.4.9. The rotors of such pumps are usually made of strong aluminum alloys to reduce the rotational moment of inertia. The peripheral velocities of the rotor are usually in the 200 to 300 m/s range. Usually, the rotor is supported by ceramic ball bearings lubricated by special low-vapor-pressure grease. To avoid even a suspicion of possible contamination, magnetic bearings are often used, with auxiliary dry bearings engaged only during starting and stopping periods.

For the drag pump, the pumping speed of a stationary channel placed in close proximity to the moving surface of the rotor can be estimated by comparing the forward flow, due to the velocity of the rotor, to the backflow, resulting from the developing pressure difference. Neglecting leakages, the maximum compression ratio K obtained a channel of certain size and length is derived to be $K_{\max} = e^{S_o/C}$, where S_o is pumping speed and C is conductance. In molecular flow, this indicates the dependency of compression ratios on the conductance, and thus on the molecular weight of the gas. The obtained compression ratios are much smaller for lighter gases. In practice, such drag channels work best for small flows, a few litres per second. In viscous flow conditions, the pressure differences obtained in small pumps are in the range of a few torr per circular loop (which may be called a "stage").

The mechanism of pumping of the turbomolecular pumps is not completely different from that of axial-flow compressors, but in molecular flow, because of the reduced amount of backflow, the compression ratios obtained in high vacuum are much higher than those customary in compressor technology (as high as 10 : 1 per rotor-stator pair). The volumetric displacement of the bladed rotor can be estimated from the velocity in the pumping direction, times the projected pumping area, times a capture coefficient (ratio of pumped molecules to reflected ones). For pumping speed estimates of typical turbomolecular pumps, with first-row blade angles at 45°, the capture coefficient is near 0.6 for air or nitrogen.

Because of the high compression ratios obtained in high-vacuum pumps, the volumetric flow at the discharge side of the pump is rather low. Also, the flow tends to get into the viscous range. Therefore, it makes sense to combine the characteristics of drag pumps and turbine-type pumps into a hybrid design. An example of such a pump is shown in Fig. 14.4.10. Figure 14.4.11 shows the comparative performances of a conventional turbomolecular pump for helium (left side) and a hybrid pump (right side). A significant improvement is obtained without an increase of pump size or motor power.

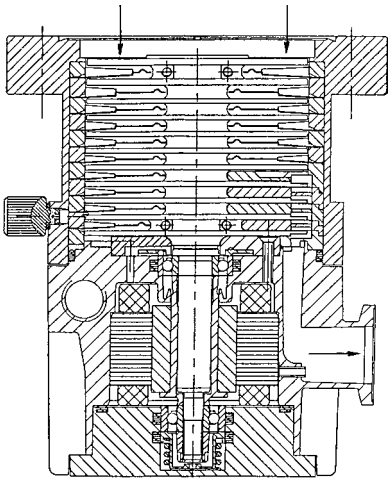

Fig. 14.4.10 A comparison of an axial flow pump and a hybrid pump. On the left side of the vertical axis there are 11 bladed rotors (interspersed with 10 bladed stators). On the right side is the hybrid pump with 7 bladed rotors and 4 solid discs rotating in 4 drag channels connected in series. (Varian V-60.)

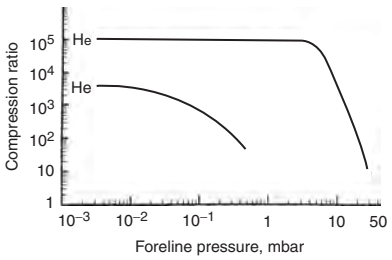

Fig. 14.4.11 Compression ratios for two pump types (Fig. 14.4.10), for helium, depending on the pressure of helium at the exit. Upper curve, hybrid pump (Varian V-250); bottom curve, all-axial pump (V-200.)

Turbomolecular pumps are usually manufactured in sizes from 50 to 2,000 L/s, but they can be made larger.

VAPOR JET PUMPS (DIFFUSION PUMPS)

Vapor jet pumps (often called *diffusion pumps*) have been the most commonly used pumps for production of high vacuum throughout the major part of the twentieth century and into the twenty-first century. The principle of operation of vapor jet pumps is illustrated in Fig. 14.4.12. The pumping action is due to the momentum transfer from a high-velocity

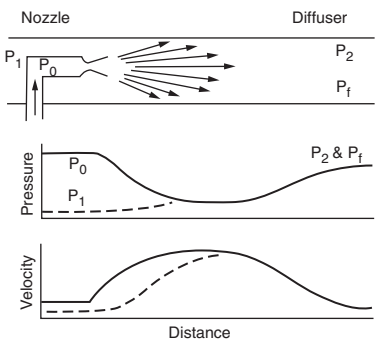

Fig. 14.4.12 Pumping effect of a fluid jet. Solid lines are for the motive fluid, dashed lines for pumped gas; P_0, P_1, are initial pressures and P_f is final pressure.

fluid jet to ambient gas molecules. The device is basically similar to steam ejectors but is highly specialized to function at molecular flow conditions at its inlet port. Figure 14.4.13 is a schematic drawing of a modern pump that has three downward-directed nozzles and one horizontal one, called an *ejector,* all connected in series. The motive fluid used is usually an oil-like substance having a molecular weight in the range of 400 to 500 (for example: tetramethyl-tetraphenyl-trisiloxane). Such fluids must have a very low vapor pressure at room temperature but be capable of producing a few torr of boiler pressure without undergoing excessive thermal decomposition at typical temperatures of 200 to 240°C). They should be also nontoxic and noncorrosive and have a viscosity range at water-cooling temperature that permits draining back into the boiler by gravity.

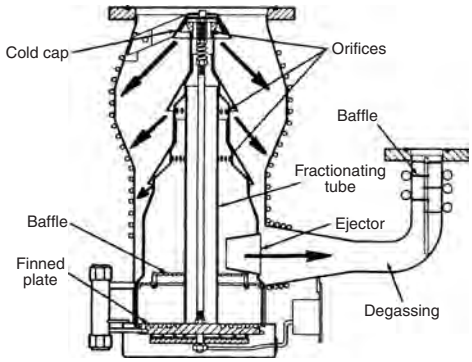

Fig. 14.4.13 Schematic cross section of a four-stage vapor jet pump (Varian).

The practical pressure difference that can be sustained by high-vacuum jet pumps is 0.5 to 1 torr, so they must be operated only when attached to a backing pump that provides necessary primary vacuum. Also, in order to prevent a possibility of rapid deterioration of and even combustion of the fluid, vapor jet pumps cannot be exposed to atmospheric air while at operating temperature. Therefore, they must be protected from an accidental air release by appropriate valves. An example of a system arrangement is shown in Fig. 14.4.14. In operation, the fluid is vaporized in the boiler by electric heaters, the vapor issues from the nozzles at velocities of a few hundred metres per second, and then condenses at the water-cooled walls and returns to the boiler.

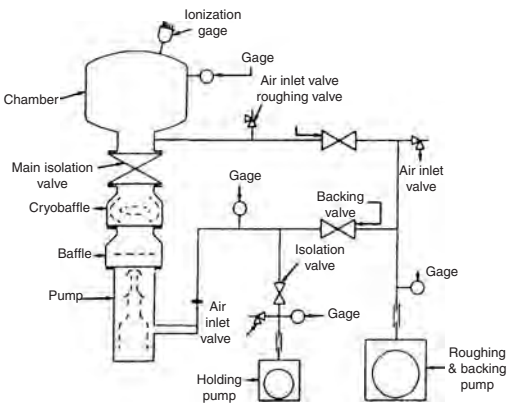

Fig. 14.4.14 Typical arrangement of valves for a vapor-jet pump system.

A typical performance curve of a vapor-jet pump is shown in Fig. 14.4.15. Such performance curves are usually measured by using total-pressure gages, with air as the pumped gas. The decay of the pumping speed at the left of the graph represents the onset of compression ratio limits. The region called "overload" in the graph should never

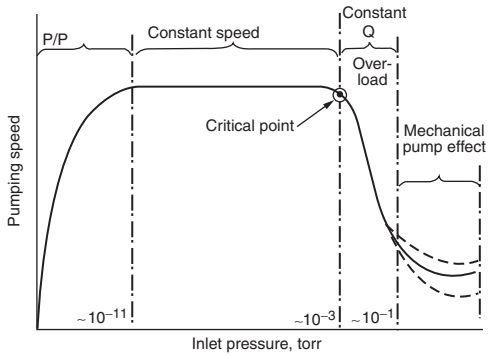

Fig. 14.4.15 Pumping speed versus inlet pressure in four different performance regions.

be used in any continuous operation. Here, the reduction of pumping speed is caused by a complete collapse of function in one of the jets (usually one near the inlet). The overloaded vapor stream may not reach the wall and may produce a serious amount of backstreaming into the vacuum chamber. At the inlet of the pump, a small number of vapor molecules can leave the condensed liquid and migrate into the chamber. To prevent this possibility of contamination, water-cooled baffles and traps cooled to cryogenic temperature are used, as shown in Fig. 14.4.14.

Vapor-jet pumps are made in sizes ranging from 50 to 50,000 L/s, corresponding to inlet diameters from 2 to 36 in. The larger pumps may use five or six stages instead of the four shown in Fig. 14.4.13.

There also exist so-called diffusion-ejector pumps, which utilize motive fluids of lower molecular weight and have higher boiler pressures. These pumps extend the full pumping speed region of operation toward higher inlet pressures. Such pumps are made in sizes from 4,000 to 12,000 L/s.

CRYOGENIC PUMPS

One way of creating high vacuum is to lower the temperature of the gas until it condenses into a liquid or a solid. In industrial practice, instead of cooling the entire chamber, it is sufficient to use a cryocooled pump. The vapor pressure curves in Fig. 14.4.16 demonstrate that it is not practical to cool gases of low molecular weight by condensation alone. Therefore, some internal surfaces of cryopumps are usually cooled by gaseous helium refrigeration to temperatures of 10 to 20 K combined with surfaces covered with absorbent layers. A schematic drawing of a typical cryopump is shown in Fig. 14.4.17. Inside the pump is a two-stage cryogenerator consisting of two connected reciprocating pistons filled with heat exchange materials. The pump is connected to a special helium compressor, which is used to circulate helium through the expander assembly and to recompress it. Industrial cryopumps utilize specially modified refrigeration

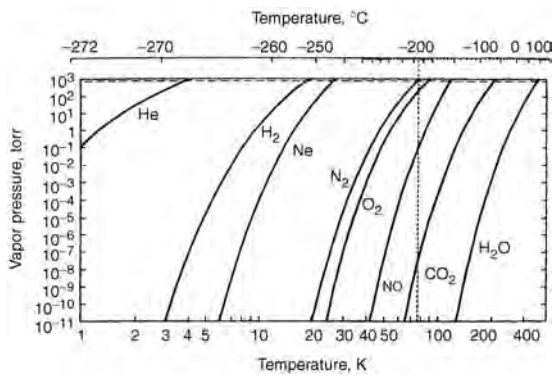

Fig. 14.4.16 Vapor pressure curves of some common gases.

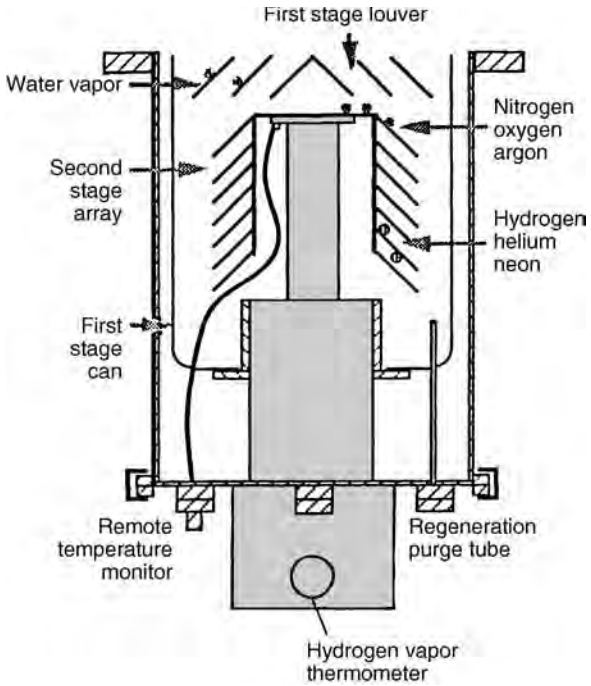

Fig. 14.4.17 Schematic drawing of a typical cryopump.

compressors. Effective filtering devices must be used to prevent lubricating oil from reaching areas cold enough to freeze the lubricant.

The pumping surfaces of a cryopump are arranged in three distinct varieties. The first is a metal surface kept at 50 to 80 K. It may be shaped as a cylinder with the closed end attached to the first stage of refrigeration and the open end connected to a baffle structure. This part of the pump can condense the water vapor, which is one of the main gases left in a vacuum system after an initial evacuation by coarse vacuum pumps. The second section is a metal surface attached to the second stage of the refrigerator, which is kept at 10 to 20 K. This section is used for pumping such gases as nitrogen, oxygen, and argon. The third section is at the same temperature as the second but includes a layer of charcoal (or activated alumina) bonded to the inner surfaces of the second-stage cryoarrays. Charcoal may have internal surface area approaching 1,000 m^2/g as well as small enough pores to hold molecules of light gases.

The pumping speed of a condensation and sorption pump depends on the arrival rate of the gas, capture probability, and surface area. Figure 14.4.18 shows an example of the performance of an industrial cryopump having an inlet diameter of 20 cm. From the kinetic theory of gases, the maximum pumping speed can be calculated to be for hydrogen 44.6 L/s for each square centimetre of surface; the corresponding value for water vapor is 14.9 and for nitrogen 11.9, provided that access to the surface is not impeded by conductance limitations. In practice, full pumping speed may be realized for water vapor because of the open exposure of the cooled baffle at the inlet, but the speed for nitrogen is typically 3 L/s · cm^2 and for hydrogen 5.6 L/s · cm^2. Because the gas is not removed form the pump, the pumping speed will decline in time. For example, for the pump of Fig. 14.4.18, the decline of pumping speed for hydrogen begins after about 7,000 torr-L of gas are pumped. The values given for pumping speed are measured under ideal conditions. In use, the actual speed may depend on amounts and types of gases previously pumped. Cryopumps do not have a continuously functioning exhaust port, therefore they become saturated after a certain period of operation.

At high-vacuum inlet pressures, they can function continuously for several months, but eventually regeneration becomes necessary. The need for regeneration arises when the pump cannot maintain expected

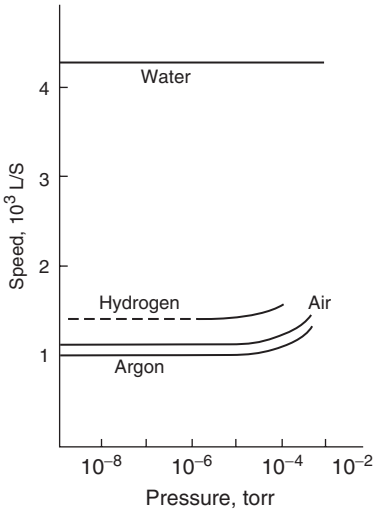

Fig. 14.4.18 Pumping speed of a cryopump for different gases.

pressure or evacuation time. Regeneration requires warming of the pump and may take several hours. It involves several steps of gradual warming and purging so as not to drive certain unwanted gases into the inlet space, and so as to properly manage the disposal of dangerous gases.

GETTER AND ION PUMPS

When gases are rarefied to high-vacuum and ultrahigh-vacuum levels, a surface can hold larger quantities of the gases, as compared to the amount of the gas in space. Properly prepared surfaces (with and without additional absorbing layers) can then be used as a pumping medium. Many chemically active materials can be used to enhance the quantity of gas held on the surface, a process called *gettering.* Often the material used is titanium. To produce a pumping surface, all that is needed is to form a fresh (unoxidized) layer of material on a sufficiently large surface. An example of a simple arrangement of a gettering pump is shown in Fig. 14.4.19. As is the case with cryopumps, the performance

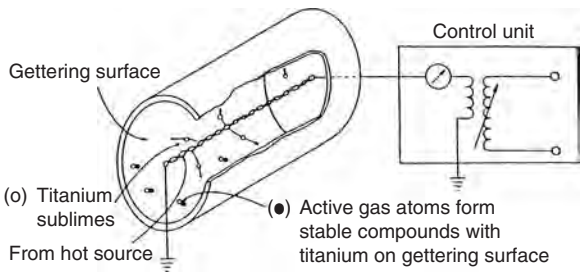

Fig. 14.4.19 Typical arrangement of titanium gettering pump.

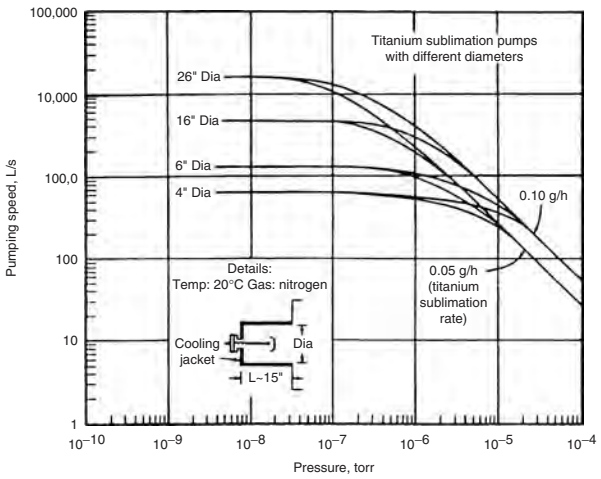

Fig. 14.4.20 Pumping speeds of gettering pumps of various sizes.

of a gettering pump cannot be predicted exactly because of its dependency on the mixture of gases, the presence of chemically inert gases, the temperature, and the previous history of the surface. Approximate pumping speeds are shown in Table 14.4.1, where it can be seen that the inert gases are not pumped. In Fig. 14.4.20 actual pumping speeds are shown for air for pumps of various sizes.

There also exist so-called nonevaporated getter pumps. In such pumps the active material is not evaporated, but remains in a specially prepared, very porous intermetallic compound. The pumping action involves an adsorption event followed by diffusion of the pumped gas into the material. The material is in the form of thick films deposited on a ribbon of nickel-iron or stainless steel. A common composition for the pumping compound is 84% zirconium and 16% aluminum and may include other transition metals. In operation, the gettering action is activated by heating, which produces structural transformation in the material, making it porous. Then, it may have real physical area 100 times greater than the projected area. Figure 14.4.21 is an example of a pumping cartridge placed in a cylinder that can be attached to a vacuum chamber at the top flange.

To provide pumping action for inert gases, ion-getter or sputter-ion pumps were developed. A basic cell of such a pump is shown in Fig. 14.4.22. Electrons are emitted from the essentially cold cathode by the action of the electric field of 5 to 7 kV applied between the electrodes. Long trajectories of electrons are produced by the action of the magnet, to improve chances of collision and subsequent ionization. Positive ions bombard the anode at high energies, producing the phenomenon called sputtering, which is an ejection of atoms from the titanium cathode surface. The deposited titanium film reacts with active gases; inert gases are pumped when highly accelerated ions collide with and penetrate the surface structure. The details of pumping mechanisms of sputter-ion pumps are more complex than outlined here, but it is clear that various gases are pumped in different ways, at different pumping

Table 14.4.1 Typical* Pumping Speeds per Square Centimetre of Titanium Sublimation Surface for Various Gases (L/s)

Surface temperature (°C)	H_2	N_2	O_2	CO	CO_2	H_2O	CH_4	A	He
20	20	30	60	60	50	20	0	0	0
−195	65	65	70	70	60	90	0	0	0

*Actual speeds vary with the condition of the deposits; usable speed is reduced by the conductance between the pumping area and the process area in the vacuum chamber.

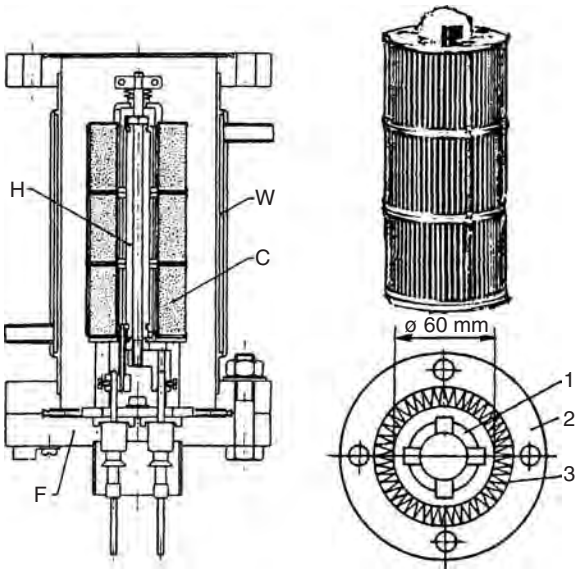

Fig. 14.4.21 The view of a nonevaporated getter pump. H and 1—electric heater, W—water cooling (for large pumps), C and 3—the getter ribbon; 2—inlet flange.

speeds and different saturation effects. Some pumping speed values are shown in Table 14.4.2. It is also clear that eventually cathodes become exhausted and must be replaced.

For practical designs of sputter-ion pumps the cells are between 15 and 25 mm, which is suitable for magnetic fields of 1 to 1.5 kG. The pumping speed of a cell is between 0.3 and 2 L/s. Multiple cell structures are used for larger pumps. Pumps are commonly manufactured in speeds up to 200 L/s. They are delivered prepumped and sealed to keep internal surfaces clean. To achieve ultrahigh vacuum, the entire vacuum system, including the pumps, is backed for several hours at temperatures up to 400°C, while being pumped by some clean auxiliary pumps.

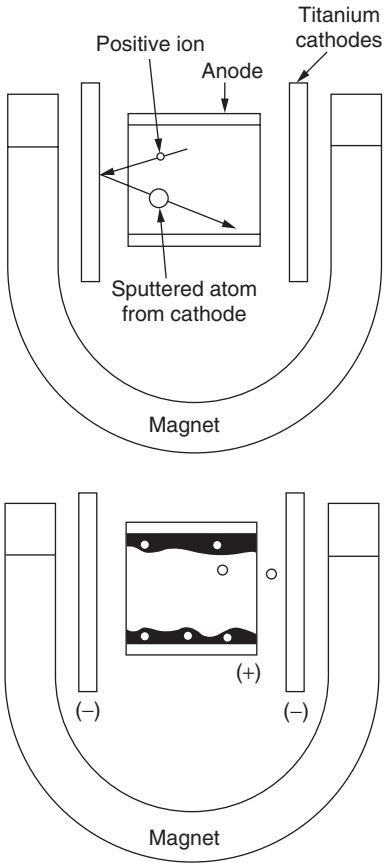

Fig. 14.4.22 Basic cell of an ion-getter pump.

Table 14.4.2 Relative Pumping Speeds of Ion-Getter Pumps for Various Gases*

Gas	Diode pump (3.5 kV)	Triode pump (5.2 kV)	Diode pump with slotted cathode (7.3 kV)	Diode pump with Mo and Ti cathodes
H_2	2.5–3.0	2.0	2.7

FAN TYPES AND NOMENCLATURE

Any device which produces a current of air may be called a fan. This discussion will be limited to fans which have a rotating impeller to produce the flow and a stationary casing to guide the flow into and out of the impeller (see Fig. 14.5.1). The form of the casing or the impeller may vary widely.

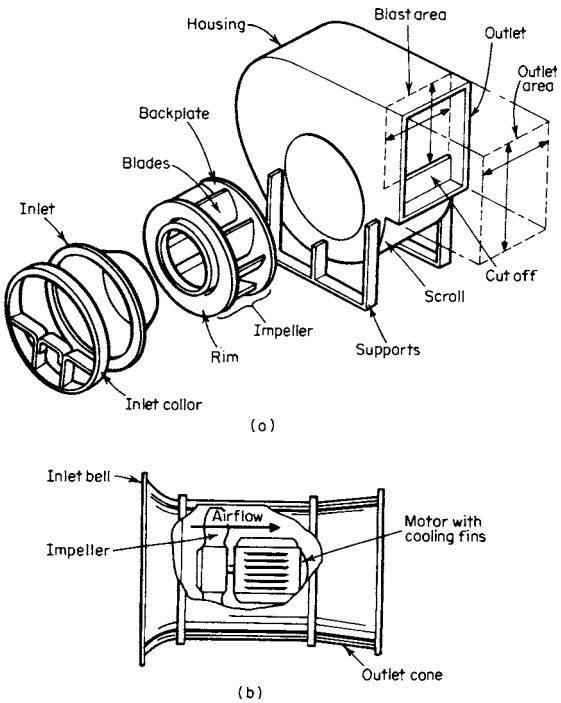

Fig. 14.5.1 Elements of fans and preferred terminology. (*a*) Centrifugal fans; (*b*) axial fans. *(Based on AMCA Publ. 201.)*

Fan Classification

One of the characteristics by which fans are classified is the nature of the flow through the blade passages of the impeller. Axial flow, radial flow, mixed flow, and cross flow are all possible in fan impellers. Certain fan names result from these classifications. Other fan names derive from other characteristics.

Propeller fans, tube-axial fans, and vane-axial fans all utilize **axial-flow impellers,** but their casings differ. Propeller fans may be mounted in a ring or panel. Tube-axial fans and vane-axial fans both use tubular casings, but for vane-axial fans they are equipped with stationary guide vanes. A great deal of the energy transferred to the air in axial-flow machines is in kinetic form. Some of this kinetic energy can be transformed into pressure energy by straightening the swirl, e.g., with vanes, or by reducing the exit velocity, e.g., with a diffuser. Propeller fans effect very little transformation and hence have very low pressure-producing capability. Vane-axial fans can be equipped for maximum transformation as well as high transfer of energy and hence have high pressure-producing potential depending on tip speed and blade angles. High hub ratios promote high energy transfer.

Centrifugal fans and tubular centrifugal fans both utilize **radial-flow impellers.** Centrifugal fans usually employ a volute or scroll-type casing, the flow entering the casing axially and leaving tangentially. Tubular centrifugals use tubular casings so that the flow both entering and leaving the casing is axial. A considerable portion of the energy transferred to the air in a radial-flow machine is due to centrifugal action; hence the name centrifugal fan. Since centrifugal action varies with blade depth, the pressure-producing capability of radial-flow fans will vary with this factor as well as tip speed and blade angles.

Mixed-flow impellers can be used in either axial or scroll-type casings. They are characterized as mixed flow because both axial and radial flow take place in the blading. Mixed-flow impellers used in axial-flow casings have a hub similar to a pure axial-flow impeller, but the inlet portion of the blading extends down over the face of the hub, thereby giving some radial guidance. Mixed-flow impellers used in scroll-cased fans have blades which give most of the axial guidance in the inlet portion and most of the radial guidance in the discharge portion.

In a **cross-flow impeller,** the air passes through the blading twice, entering more or less tangentially through the tip, passing across the impeller and out the other side. The casings are designed to provide this transverse flow. Cross-flow fans are also known as tangential fans or transverse-flow fans. Pressure-producing potential is low and depends on the formation of a vortex as the air leaves the impeller.

Fan Details

Propeller fans and other **axial fans** may use blades shaped to airfoil sections or blades of uniform thickness. Blading may be fixed, adjustable at standstill, or variable in operation. Propeller fans have very small hubs. Hub-to-tip diameter ratios ranging from 0.4 to 0.7 are common in vane-axial fans. The larger the hub, the more important it is to have an inner cylinder approximately the hub size located downstream of the impeller. The guide vanes of a vane-axial fan are located in the annular space between the tubular casing and the inner cylinder. Diffusers are generally used between the fan and the discharge ductwork.

Centrifugal fans use various types of blading. Forward-curved blades are shallow and curved so that both the tip and the heel point in the direction of rotation. Radial and radial-tip blades both are radial at the tip, but the latter are curved at the heel to point in the direction of rotation. Backward-curved and backward-inclined blades point in the direction opposite rotation at the tip and in the direction of rotation at the heel. All the above blades are of uniform thickness and are designed for radial flow. Airfoil blades have backward-curved chord lines so that the leading edge of the airfoil is at the heel pointing forward and the trailing edge at the tip pointing backward with respect to rotation. Impellers for all blade shapes are usually shrouded and may have single or double inlets. Blade widths are related to the inlet-to-tip-diameter ratio. Tip angles may vary widely, but heel angles should be set to minimize entrance losses. Scroll casings may be fitted with a streamlined inlet bell, an inlet cone, or simply a collar.

Tubular centrifugals may be designed for backward-curve, air foil, or mixed-flow impellers. An inlet bell and discharge guide vanes are required for good performance.

Cross-flow fans utilize impellers with blading similar to that of a forward-curved centrifugal, but the end shrouds have no inlet holes. Blade-length-to-tip-diameter ratios are limited only by structural considerations.

Power roof ventilators may use either axial- or radial-flow impellers. The casings will include either a propeller fan mounting ring or a tubular casing to guide the flow for an axial-flow impeller. If a radial-flow impeller is used, an inlet bell is required, but the scroll case may be replaced by the ventilator hood.

Plenum fans and **plug fans** are fans without traditional casings. Plenum fans are used to move air through a system. They utilize centrifugal impellers and their drives are inside the plenum. Plug fans are used to circulate air or gas within a chamber or system. They may have either centrifugal or axial impellers and their drives are outside the chamber.

All fan types may have direct or indirect drive arrangements. Various standards including arrangement numbers have been adopted by AMCA. Arr. 1 signifies an overhung impeller on a fan shaft with two bearings on a base; Arr. 3 signifies an impeller on a fan shaft between bearings; Arr. 4 is for overhung impeller on a motor shaft; Arr. 7 is Arr. 3 with a motor base; Arr. 8 is Arr. 1 with an extended base for motor; Arr. 9 is Arr. 1 with motor mounted on side of unit; Arr. 10 is Arr. 1 with motor mounted inside of base. Rotation is specified as cw or ccw when viewed from the drive side. All fans can be equipped with variable-speed drives, variable inlet vanes, or dampers, but controllable-pitch axials do not need speed or vane control.

FAN PERFORMANCE AND TESTING

The conventional terms used to describe fan performance in the United States are defined below.

Fan Air Density Air density is the mass per unit volume of the air. The density of a perfect gas is a function of its molecular weight, temperature, and pressure as indicated by

$$\rho_x = \frac{M}{386.7}\frac{529.7}{T_x}\frac{b_x}{29.92}$$

where the subscript x indicates the plane of the measurements. For dry air this reduces to

$$\rho_x = 1.325 b_x / T_x$$

This expression will usually be accurate enough even when moist air is involved. Fan air density is the density of the air corresponding to the total pressure and total temperature at the fan inlet

$$\rho = \rho_1$$

Fan Capacity Volume flow rate is usually determined from pressure measurements, e.g., a velocity-pressure traverse taken with a Pitot static tube or a pressure drop across a flowmeter. The average velocity pressure for a Pitot traverse is

$$p_{vx} = (\sum \sqrt{p_{vxr}}/n)^2$$

where subscript x indicates the plane of the measurements, subscript r indicates a reading at one station, n is the number of stations, and Σ is the summation sign. The corresponding capacity is:

$$\dot{Q}_x = 1{,}097 A_x \sqrt{p_{vx}/\rho_x}$$

For a flowmeter

$$\dot{Q}_x = 1{,}097 C A_x Y \sqrt{\Delta p/\rho_x}/F$$

where C = coefficient of discharge of meter, Y = expansion factor for gas, Δp = measured pressure drop, and F = velocity-of-approach factor for the meter installation. Fan capacity is the volumetric flow rate at fan air density

$$\dot{Q} = \dot{Q}_x \rho_x / \rho$$

Fan Total Pressure Fan total pressure is the difference between the total pressure at the fan outlet and the total pressure at the fan inlet

$$p_t = p_{t2} - p_{t1}$$

When the fan draws directly from the atmosphere.

$$p_{t1} = 0$$

When the fan discharges directly to the atmosphere,

$$p_{t2} = p_{v2}$$

If either side of the fan is connected to ductwork, etc., and the measuring plane is remote, the measured values should be corrected for the approximate pressure drop

$$p_{t2} = p_{tx} + \Delta p_{2-x} \qquad p_{t1} = p_{tx} + \Delta p_{x-1}$$

Fan Velocity Pressure Fan velocity pressure is the pressure corresponding to the average velocity at the fan outlet

$$p_v = \left(\frac{\dot{Q}_2/A_2}{1{,}097}\right)^2 \rho_2$$

Fan Static Pressure Fan static pressure is the difference between the fan total pressure and the fan velocity pressure. Therefore, fan static pressure is the difference between the static pressure at the fan outlet and the total pressure at the fan inlet

$$p_s = p_t - p_v = p_{s2} - p_{t1}$$

Fan Speed Fan speed is the rotative speed of the impeller.

Compressibility Factor The compressibility factor is the ratio of the fan total pressure p_t' that would be developed with an incompressible fluid to the fan total pressure p_t that is developed with a compressible fluid, all other conditions being equal:

$$K_p = \frac{p_t'}{p_t} = \frac{[n/(n-1)][(p_{t2a}/p_{t1a})^{(n-1)/n} - 1]}{(p_{t2a}/p_{t1a}) - 1}$$

Compressibility factor can be determined from test measurements using

$$x = p_t/p_{t1a}$$
$$z = [(\gamma - 1)/\gamma]\,6356H/\dot{Q}p_{t1a}$$
$$K_p = [z \log (1 + x)]/[x \log (1 + z)]$$

Fan Power Output Fan power output is the product of fan capacity and fan total pressure and compressibility factor

$$H_o = \dot{Q}p_t K_p/6{,}356$$

Fan Power Input Fan power input is the power required to drive the fan and any elements in the drive train which are considered a part of the fan. Power input can be calculated from appropriate measurements for a dynamometer, torque meter, or calibrated motor.

Fan Total Efficiency Fan total efficiency is the ratio of the fan power output to the fan power input

$$\eta_t = \dot{Q}p_t K_p/6{,}356H$$

Fan Static Efficiency Fan static efficiency is the fan total efficiency multiplied by the ratio of fan static pressure to fan total pressure

$$\eta_s = \eta_t p_s/p_t$$

Fan Sound Power Level Fan sound power level is 10 times the logarithm (base 10) of the ratio of the actual sound power in watts to 10^{-12} watts,

$$L_w = 10 \log (W/10^{-12})$$

The total sound power level of a fan is usually assumed to be 3 dB higher than either the inlet or outlet component. The casing component varies with construction but will usually range from 15 to 30 dB less than the total.

The frequency content of fan noise is usually expressed in octave bands, but may be given in narrow bands or even as an overall value. The sound power level can be calculated from sound pressure measurements or sound intensity measurements. The reverberant room method utilizes a known sound source to calibrate the room and a microphone to measure the sound pressures. The sound intensity method utilizes two microphones in a sound-intensity probe to measure the sound intensities over an enveloping surface. The in-duct method utilizes anechoic terminations to facilitate sound pressure measurements without end reflections.

Head The difference between head and pressure is important in fan engineering. Both are measures of the energy in the air. Head is energy per unit weight and can be expressed in ft · lb/lb, which is often abbreviated to ft (of fluid flowing). Pressure is energy per unit volume and can be expressed in ft · lb/ft^3, which simplifies to lb/ft^2 or force per unit area. The use of the inch water gage (in wg) is a convenience in fan engineering reflecting the usual methods of measurement. It sounds like a head measurement but is actually a pressure measurement corresponding to 5.192 lb/ft^2, the pressure exerted by a column of water 1 inch high. Pressures can be converted into heads and vice versa:

$$p = \rho h/5.192 \qquad h = 5.192p/\rho$$

For instance, for air at 0.075 lbm/ft^3 density, 1 in wg corresponds to 69.4 ft of air. That is, a column of air at that density would exert a pressure of 5.192 lb/ft^2. Lighter air would exert less pressure for a given head. For a given pressure, the head would be higher with lighter air. Although it is not widely used in the United States, head is commonly used in a number of European countries.

Fans, like other turbomachines, can be considered constant-head-constant-capacity (volumetric) machines. This means that a fan will develop the same head at a given capacity regardless of the fluid handled, all other conditions being equal. Of course, this also means that a fan will develop a pressure proportional to the density at a given capacity, all other conditions being equal.

All the preceding equations are based on the U.S. Customary Units listed under Symbols. If **SI units** are to be used, certain numerical coefficients will have to be modified. For instance, substitute $\sqrt{2}$ for 1,097 in the flow equations when using Pa for pressure, kg/m^3 for density, and m^3/s for capacity. Similarly, substitute 1.0 for 6,356 in the power equations when using Pa for pressure, m^3/s for capacity, and W for power.

Common metric practice in fan engineering leads to other numerical coefficients. When mm wg is used for pressure, m^3/s for capacity, kW for power, and kg/m^3 for density, substitute 4.424 for 1,097 in the flow equations and 102.2 for 6,356 in the power equations.

The preceding discussion utilized what may be termed the **volume-flow-rate-pressure** approach to expressing fan performance. An alternative, the **mass-flow-rate-specific-energy** approach is equally valid but not generally used in the United States. Refer to ASME PTC-11 for additional details.

FAN AND SYSTEM PERFORMANCE CHARACTERISTICS

The performance characteristics of a fan are best described by a graph. The conventional method of graphing fan performance is to plot a series of curves with capacity as abscissa and all other variables as ordinates. System characteristics can be plotted in a similar manner.

System Characteristics

Most systems served by a fan have characteristics which can be described by a parabola passing through the origin; i.e., the energy required to produce flow through the system (which can be expressed as pressure or head) varies approximately as the square of the flow. In some cases, the system characteristics will not pass through the origin because the energy required to produce flow through an element of the system may be controlled at a particular value, e.g., with venturi scrubbers. In some cases, the system characteristic will not be parabolic because the flow through an element of the system is laminar rather than turbulent, e.g., in some types of filters. Whatever the case, the system designer should establish the characteristics by determining the energy requirements at various flow rates. The energy requirement (pressure drops or head losses) for each element can be determined by reference to handbook or manufacturer's literature or by test.

The true measure of the energy requirement for a system element is the total pressure drop or the total head loss. Only if the entrance velocity for the element equals the exit velocity will the change in static pressure equal the total pressure drop. There are some advantages in using static pressure change, but the system designer is usually well advised to use total pressure drops to avoid errors in fan selection. The sum of the total pressure losses for elements on the inlet side of the fan will equal $-p_{t1}$. This should include energy losses at the entrance to the system but not the energy to accelerate the air to the velocity at the fan inlet, which is chargeable to the fan. The sum of the total pressure losses for elements on the discharge side of the fan will equal p_{t2}. This should include the kinetic energy of the stream issuing from the system. The total system requirement will be the arithmetic sum of all the appropriate losses or the algebraic difference $p_{t2} - p_{t1}$, which is also p_t.

A system characteristic curve based on total pressure is plotted in Fig. 14.5.2. A characteristic based on static pressure is also shown. The latter recognizes the definition of fan static pressure so that the only difference is the velocity pressure corresponding to the fan outlet velocity. This system could operate at any capacity provided a fan delivered the exact pressure to match the energy requirements shown on the system curve for that capacity. The advantages of plotting the system characteristics on the fan graph will become evident in the following discussions.

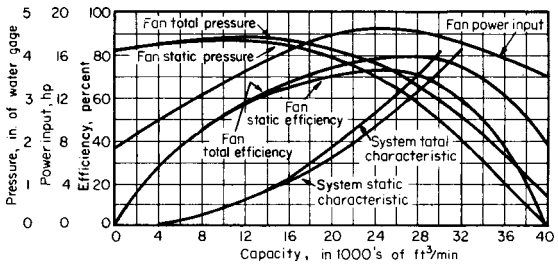

Fig. 14.5.2 Fan and system characteristics.

Fan Characteristics

The constant-speed performance characteristics of a fan are illustrated in Fig. 14.5.2. These characteristics are for a particular size and type of fan operating at a particular speed and handling air of a particular density. The fan can operate at any capacity from zero to the maximum shown, but when applied on a particular system the fan will operate only at the intersection of the system characteristics with the appropriate fan pressure characteristic. For the case illustrated, the fan will operate at $Q = 27{,}300$ ft^3/min and $p_t = 3.4$ in wg or $p_s = 3$ in wg, requiring $H = 18.3$ hp at the speed and density for which the curves were drawn. The static efficiency at this point of operation is 73 percent, and the total efficiency is 80 percent. If the system characteristic had been lower, it would have intersected the fan characteristic at a higher capacity and the fan would have delivered more air. Contrariwise, if the system characteristic had been higher, the capacity of the fan would have been less. Capacity reduction can be accomplished, in fact, by creating additional resistance, as with an outlet damper.

Figure 14.5.3 illustrates the characteristics of a fan with damper control, variable inlet vane control, and variable speed control. These particular characteristics are for a backward-curved centrifugal fan, but the general principles apply to all fans. Outlet dampers do not affect the flow to the fan and therefore can alter fan performance only by adding resistance to the system and producing a new intersection. Point 1 is for wide-open dampers. Points 2 and 3 are for progressively closed dampers. Note that some power reduction accompanies the capacity reduction for this particular fan. Variable-inlet vanes produce inlet whirl, which reduces pressure-producing capability. Point 4 is for wide-open inlet vanes and corresponds to point 1. Points 5 and 6 are for progressively closed vanes. Note that the power reduction at reduced capacity is better for vanes than for dampers. Variable speed is the most efficient means of capacity control. Point 7 is for full speed and points 8 and 9 for progressively reduced speed. Note the improved power savings over other methods. Variable speed also has advantages in terms of lower noise and reduced erosion potential but is generally at a disadvantage regarding first cost.

Figure 14.5.4 illustrates the characteristics of a fan with variable pitch control. These characteristics are for an axial-flow fan, but comparisons to the centrifugal-fan ratings in Fig. 14.5.3 can be made. Point 10 corresponds to points 1, 4, or 7. Reduced ratings are shown at points 11 and 12 obtained by reducing the pitch. Power savings can be almost as good as with speed control. Notice that in all methods of capacity control, operation is at the intersection of a system characteristic with a fan characteristic. With variable vanes, variable speed, and variable pitch, the fan characteristic is modified. With damper control, the effect could be considered a change in fan characteristics, but it generally makes more sense to consider it a change in system characteristics.

Fan-System Matching

It has already been observed in the discussions of both system and fan characteristics that the point of operation for **one fan** on a particular system will be at the intersection of their characteristics. Stated another way, the energy required by the system must be provided by the fan exactly. If the fan delivers too much or too little energy, the capacity will be more or less than desired. The effects of utilizing dampers, variable speed, variable-inlet vanes, and variable pitch were illustrated, but in all cases the fan was preselected. The more general case is the one involving the selection or design of a fan to do a particular job. The

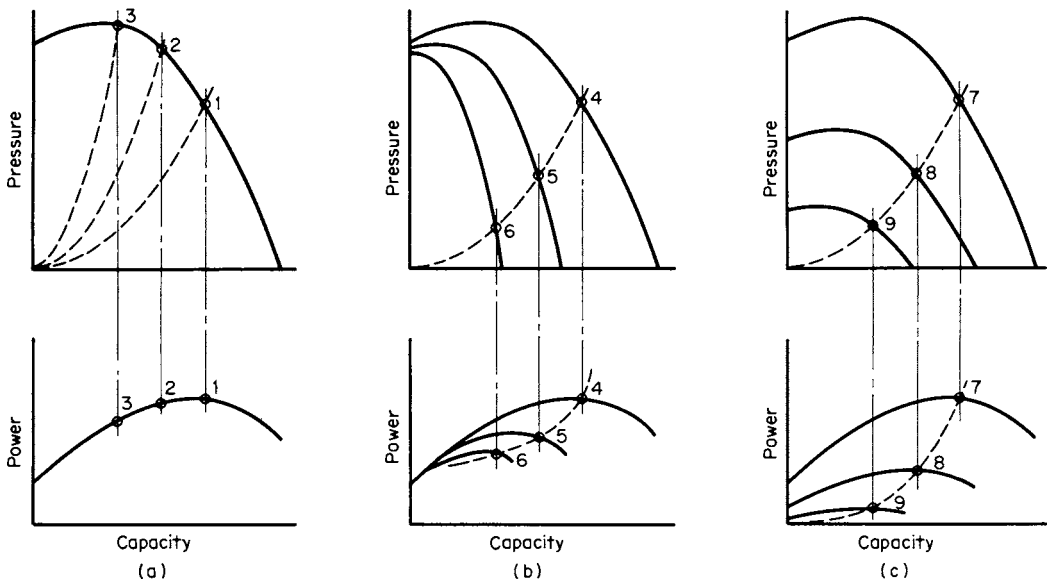

Fig. 14.5.3 Fan characteristics with (*a*) damper control, (*b*) variable-inlet vane control, (*c*) variable speed control.

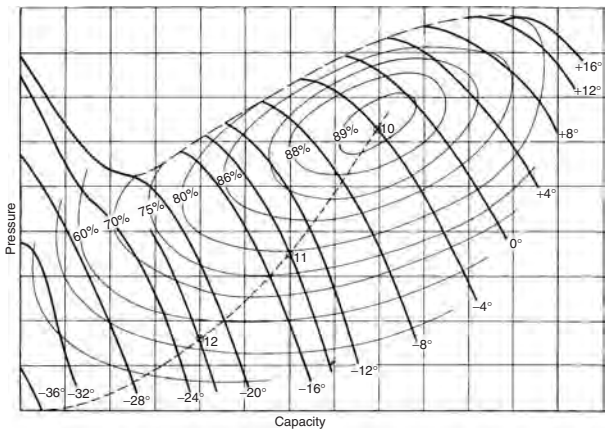

Fig. 14.5.4 Characteristics of an axial-flow fan with variable-pitch control.

design of a fan from an aerodynamicist's point of view is beyond the scope of this discussion. Fortunately, most fan problems can be solved by selecting a fan from the many standard lines available commercially. Again, the crux of the matter is to match fan capability with system requirements.

Most fan manufacturers have several standard lines of fans. Each line may consist of various sizes all resembling each other. If the blade angles and proportions are the same, the line is said to be **homologous.** There is only one fan size in a line of homologous fans that will operate at the maximum efficiency point on a given system. If the fan is too big, operation will be at some point to the left of peak efficiency on a standard characteristic plot. If the fan is too small, operation will be to the right of peak. In either case it will be off peak. A slightly undersized fan is often preferred for reasons of cost and stability.

Selecting and rating a fan from a catalog is a matter of fan-system matching. When it is recognized that many of the catalog sizes may be able to provide the capacity and pressure, selection becomes a matter of trying various sizes and comparing speed, power, cost, etc. The choice is a matter of evaluation.

There are various reasons for using **more than one fan** on a system. Supply and exhaust fans are used in ventilation to avoid excessive pressure build-up in the space being served. Forced and induced-draft fans are used to maintain a specified draft over the fire. Two fans may fit the available space better than one larger fan. Capacity control by various fan combinations may be more economical than other control methods. Multistage arrangements may be necessary when pressure requirements exceed the capabilities of a single-stage fan. Standby fans are frequently required to ensure continuous operation.

When two fans are used, they may be located quite remote from each other or they may be close enough to share shaft and bearings or even casings. Double-width, double-inlet fans are essentially two fans in parallel in a common housing. Multistage blowers are, in effect, two or more fans in series in the same casing. Fans may also be in series but at opposite ends of the system. Parallel-arrangement fans may have almost any amount of their operating resistance in common. At one extreme, the fans may have common inlet and discharge plenums. At the other extreme, the fans may both have considerable individual ductwork of equal or unequal resistance.

Fans in **series** must all handle the same amount of gas by weight measurements, assuming no losses or gains between stages. The combined total pressure will be the sum of the individual fans' total pressures. The velocity pressure of the combination can be defined as the pressure corresponding to the velocity through the outlet of the last stage. The static pressure for the combination is the difference between its total and velocity pressures and is therefore not equal to the sum of the individual fan static pressures. The volumetric capacities will differ whenever the inlet densities vary from stage to stage. Compression in one stage will reduce the volume entering the next if there is no reexpansion between the two. As with any fan, the pressure capabilities are also influenced by density.

The combined total pressure-capacity characteristic for two fans in series can be drawn by using the volumetric capacities of the first stage for the abscissa and the sum of the appropriate total pressures for the ordinate. Because of compressibility, the volumetric capacities of the second stage will not equal the volumetric capacities of the first stage. The individual total pressures must be chosen accordingly before they are combined. If the gas can be considered incompressible, the pressures for the two stages may be read at the same capacity. In the area near free delivery, it may be necessary to estimate the negative pressure characteristics of one of the fans in order to combine values at the appropriate capacity.

Fans in **parallel** must all develop sufficient pressure to overcome the losses in any individual ductwork, etc., as well as the losses in the common portions of the system. When such fans have no individual ductwork but discharge into a common plenum, their individual velocity pressures are lost and the fans should be selected to produce the same fan static pressures. If fan velocity pressures are equal, the fan total pressures will be equal in such cases. When the fans do have individual ducts but they are of equal resistance and joined together at equal velocities, the fans should be selected for the same fan total pressures. If fan velocity pressures are equal, fan static pressures will be equal in this case. If the two streams join together at unequal velocities, there will be a transfer of momentum from the higher-velocity stream to the lower-velocity stream. The fans serving the lower-velocity branch can be selected for a correspondingly lower total pressure. The other fan must be selected for a correspondingly higher total pressure than if velocities were equal.

The combined pressure-capacity curves for two fans in parallel can be plotted by using the appropriate pressures for ordinates and the sum of the corresponding capacities for abscissa. Such curves are meaningful only when a combined-system curve can be drawn. In the area near shutoff, it may be necessary to estimate the negative capacity characteristics of one of the fans in order to combine values at the appropriate pressure.

Figure 14.5.5 illustrates the combined characteristics of two fans with slightly different individual characteristics (*A-A* and *B-B*). The combined characteristics are shown for the two fans in series (*C-C*) and in parallel (*D-D*). Only total-pressure curves are shown. This is always correct for series arrangements but may introduce slight errors for parallel arrangements. An incompressible gas has been assumed. The questionable areas near shutoff or free delivery have been omitted. Two different system characteristics (*E-E* and *F-F*) have been drawn on the

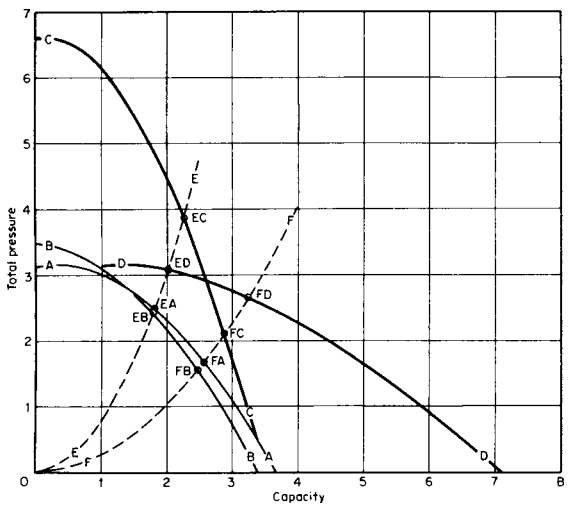

Fig. 14.5.5 Combined characteristics of fans in series and parallel.

chart. With the two fans in series, operation will be at point *EC* or *FC* if the fan is on system *E* or *F*, respectively. Parallel arrangement will lead to operation at *ED* or *FD*. Single-fan operation would be at the point indicated by the intersection of the appropriate fan and system curves provided the effect of an inoperative second fan is negligible. Some sort of bypass is required around an inoperative fan in series whereas an inoperative fan in parallel need only be dampered shut. Parallel operation yields a higher capacity than series operation on system *F*, but the reverse is true on system *E*. For the type of fan and system characteristics drawn there is only one possible point of operation for any arrangement.

Fan Laws

The fan laws are based on the experimentally demonstrable fact that any two members of a homologous series of fans have performance curves which are homologous. At the same point of rating, i.e., at similarly situated points of operation on their characteristic curves, efficiencies are equal and other variables are interrelated according to the fan laws. If size and speed are considered independent variables and if compressibility effects are ignored, the fan laws can be written as follows:

$$\begin{aligned}\eta_{tc} &= \eta_{tb}\\ \dot{Q}_c &= \dot{Q}_b(D_c/D_b)^3(N_c/N_b)\\ p_{tc} &= p_{tb}(D_c/D_b)^2(N_c/N_b)^2(\rho_c/\rho_b)\\ H_c &= H_b(D_c/D_b)^5(N_c/N_b)^3(\rho_c/\rho_b)\\ L_{wc} &= L_{wb} + 70\log(D_c/D_b) + 50\log(N_c/N_b)\\ &\quad + 20\log(\rho_c/\rho_b)\end{aligned}$$

The above laws are useful, but they are dangerous if misapplied. The calculated fan must have the same point of rating as the known fan. When in doubt, it is best to reselect the fan rather than attempt to use the fan laws.

The fan designer utilizes the fan laws in various ways. Some of the more useful relationships in addition to those above derive from considering fan capacity and fan total pressure as the independent variables. This leads to specific diameter, specific speed, and specific sound power level:

$$\begin{aligned}D_s &= D(p_t/\rho)^{1/4}/\dot{Q}^{1/2}\\ N_s &= N\dot{Q}^{1/2}/(p_t/\rho)^{3/4}\\ L_{ws} &= L_w - 10\log\dot{Q} - 20\log p_t\end{aligned}$$

D_s, N_s, and L_{ws} are the diameter, speed, and sound power level of a homologous fan which will deliver 1 ft^3/min at 1 in wg at the same point of rating as Q and p_t for D and N. D_s and N_s can be used to advantage in fan selection. They can also be used by a designer to determine how well a line will fit in with other lines. This is illustrated in Fig. 14.5.6. Each segment represents a particular fan line. Note the trends for each kind of fan. Incidentally, some fan engineers utilize different formulas for specific diameter and specific speed

$$D_{se} = Dp_{te}^{1/4}/\dot{Q}^{1/2} \qquad N_{se} = N\dot{Q}^{1/2}/p_{te}^{3/4}$$

where p_{te} is the equivalent total pressure based on standard air. This makes $D_{se} = D_s \times 1.911$ and $N_{se} = N_s \times 6.978$.

Specific sound power level is useful in predicting noise levels as well as in comparing fan designs. There appears to be a lower limit of L_{ws} in the vicinity of 45 dB for the more efficient types ranging to 70 dB or more for cruder designs. Actual sound power levels can be figured from

$$L_w = L_{ws} + 10\log\dot{Q} + 20\log p_t$$

Another useful parameter which derives from the fan laws is orifice ratio

$$R_o = \dot{Q}/D^2(p_t/\rho)^{1/2}$$

This ratio can be plotted on a characteristic curve for a known fan. If the ratio is determined for a calculated homologous fan, the point of rating can be established by inspection. Other ratios can be used in the same manner including p_v/p_t, $p_t/\dot{Q}^2$, D_s, and N_s.

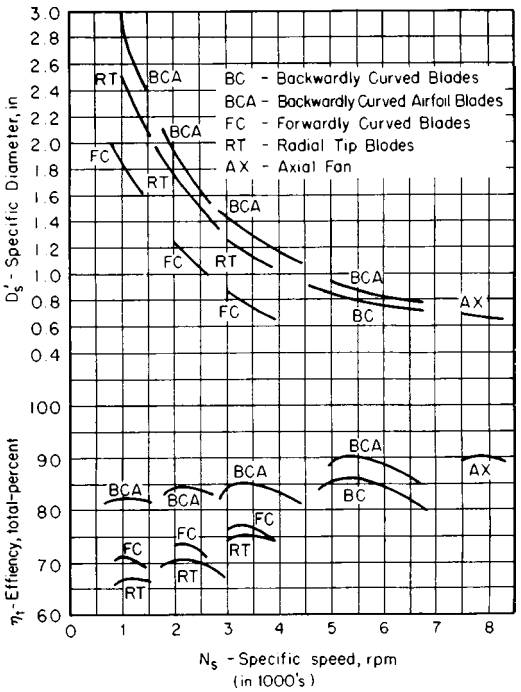

Fig. 14.5.6 Specific diameter and efficiency versus specific speed for single-inlet fan types.

Stability Considerations

The flow through a system and its fan will normally be steady. If the fluctuations occasioned by a temporary disturbance are quickly damped out, the fan system may be described as having a **stable** operating characteristic. If the unsteady flow continues after the disturbance is removed, the operating characteristic is **unstable.**

To ensure stable operation the slopes of the pressure-capacity curves for the fan and system should be of opposite sign. Almost all systems have a positive slope; i.e., the pressure requirement or resistance increases with capacity. Therefore, for stable operation the fan curve should have a negative slope. Such is the case at or above the design capacity.

When the slopes of the fan and system characteristics are of opposite sign, any system disturbance tending to produce a temporary decrease in flow is nullified by the increase in fan pressure. When the slopes are of the same sign, any tendency to decrease flow is strengthened by the resulting decrease in fan pressure. When fan and system curves coincide over a range of capacities, the operating characteristics are extremely unstable. Even if the curves exactly coincide at only one point, the flow may vary over a considerable range.

There may or may not be any obvious indication of unstable operation. The pressure and power fluctuations that accompany unsteady flow may be so small and rapid that they cannot be detected by any but the most sensitive instruments. Less rapid fluctuations may be detected on the ordinary instruments used in fan testing. The changes in noise which occur with each change in flow rate are easily detected by ear as individual beats if the beat frequency is below about 10 Hz. In any event, the overall noise level will be higher with unsteady flow than with steady flow.

The conditions which accompany unsteady flow are variously described as pulsations, hunting, surging, or pumping. Since these conditions occur only when the operating point is to the left of maximum pressure on the fan curve, this peak is frequently referred to as the **surge point** or **pumping limit.**

Pulsation can be prevented by rating the fan to the right of the surge point. Fans are usually selected on this basis, but it is sometimes necessary to control the volume delivered to the value below that at the surge

point. This may lead to pulsation, particularly if the fan pressure exceeds 10 in wg.

If the required capacity is less than that at the pumping limit, pulsation can be prevented in various ways, all of which in effect provide a negatively sloping fan curve at the actual operating point. To accomplish this effect the required pressure must be less than the fan capabilities at the required capacity. One method is to bleed sufficient air for actual operation to be beyond the pumping limit. Other possible methods are the use of pitch, speed, or vane control for volume reduction. In any of these cases, the point of operation on the new fan curve must be to the right of the new surge point. Although in the section on Capacity Control dampers were considered a part of the system, they may also be considered a part of the fan if located in the right position. Accordingly, pulsations may be eliminated in a supply system if the damper is on the inlet of the blower. Similarly, dampering at the outlet of the exhauster may control pulsation in exhaust systems.

Another condition frequently referred to as instability is associated with flow separation in the blade passages of an impeller and is evidenced by slight discontinuities in the performance curve. There may be a small range of capacities at which two distinctly different pressures may be developed depending on which of the two flow patterns exists. Such a condition usually occurs at capacities just to the left of peak efficiency. Still another condition of unsteady flow may develop at extremely low capacities. This is known as **blowback** or **puffing** because air puffs in and out of a portion of the inlet. Operation in the blowback range should be avoided, particularly with high-energy fans.

A different type of unsteady flow may occur when two or more fans are used in parallel. If the individual fan characteristics exhibit a dip in pressure between shutoff and design, the combined characteristic will contain points where the point of operation of the individual fans may be widely separated even for identical fans. If the system characteristic intersects the combined-fan characteristic at such a point, the individual fans may suddenly exchange loads. That is, the fan operating at high capacity may become the one operating at low capacity and vice versa. This can produce undesirable shocks on motors and ducts. Careful matching of fan to system is required for either forward-curved centrifugals or most axials for this reason.

Fan Applications

The selection of a particular size and type of fan for a particular application involves considerations of aerodynamic, economic, and functional suitability. Many of the factors involved in aerodynamic suitability have been discussed above. Determination of economic suitability requires an evaluation of first cost and operating costs. The functional suitability of various types of fans with respect to certain applications is discussed below.

Heating, ventilating, and **air-conditioning systems** may require supply and exhaust or return air fans. Historically, high-efficiency centrifugal fans, using either backward-curved or airfoil blades have been used for supply on duct systems. In low-pressure applications these types can be used without sound treatment. In high-pressure applications, sound treatment is almost always required. Axials have long been used for shipboard ventilation because they generally can be made smaller than centrifugals. Both adjustable axials and tubular centrifugals have proved popular on duct systems for exhaust service in building ventilation. Centrifugals with variable inlet vanes and axials with pitch control are being used for supply in variable-air-volume systems. Propeller fans and power roof ventilators are used for either supply or exhaust systems when there is little or no ductwork. Heating, ventilating, and air-conditioning applications are considered clean-air service. Various classes of construction are available in standard lines for different pressure ranges. Both direct and indirect drive are used, the latter being most common.

Industrial exhaust systems generally require fans that are less susceptible to the unbalance that may result from dirty-gas applications than the clean-air fans used for heating, ventilating, and air conditioning. Simple, rugged, industrial exhausters are favored for applications up to 200 hp. They have a few radial blades and relatively low efficiency. Most are V-belt-driven. Extra-heavy construction may be required where significant material passes through the fan.

Process air requirements can be met with either centrifugal or axial fans; the latter may be used in single or double stage. The higher pressure ratings are usually provided by a single-stage centrifugal fan with radial blades, known as a pressure blower. These units are generally direct connected to the driver. They not only compete with centrifugal compressors but resemble them.

Large industrial process and **pollution-control systems** involving more than about 200 hp are generally satisfied with a somewhat more sophisticated fan than an industrial exhauster or pressure blower. Centrifugal fans with radial-tip blades are frequently used on the more severe service. For the less severe requirements, backward-curved or airfoil blades may be used. Rugged fixed-pitch axials have also been used. Industrial fans are usually equipped with inlet boxes and independently mounted bearings and are usually direct-driven. Journal bearings are usually preferred. Inlet-box damper control can be used to approximate the power saving available from variable-inlet vane control. Variable-speed hydraulic couplings may be economically justified in some cases. Special methods or special construction may be required to provide protection against corrosion or erosion. These fans tend to take on the name of the application such as sintering fan, scrubber exhaust fan, etc.

Mechanical draft systems may utilize any of the fan types described in connection with the above applications. Ventilating fans, industrial exhausters, and pressure blowers have been used for forced draft, induced draft, and primary air service on small steam-generating units. The large generating units are generally equipped with the most efficient fans available consistent with the erosion-corrosion potential of the gas being handled.

Both centrifugals and axials are used for forced and induced draft. Axials have predominated in Europe, and there is a growing trend throughout the rest of the world toward axials. Centrifugals have been used almost exclusively in the United States until very recently.

Forced-draft centrifugals invariably have airfoil blade impellers. Induced-draft centrifugals may have airfoil-blade impellers, but for scrubber exhaust, radial-tip blades are more common. This is due, in part, to the high pressures required for scrubber operation and in part to the erosion-corrosion potential downstream of a scrubber. Gas recirculating fans are usually of the radial-tip design. Forced-draft control may be by variable speed but is more likely to be variable vanes on centrifugal fans. Variable inlet vanes or inlet-box dampers may be used to control induced-draft fans. All large centrifugals are direct-connected and have independent pedestal-mounted bearings. Journal bearings are almost always used.

Forced-draft axials are likely to be of the variable-pitch full-airfoil-section design. Hydraulic systems are almost always used for pitch control, but pneumatic and mechanical systems have been tried. Bearings are usually of the antifriction type. Fixed-pitch axials are usually used for induced-draft duty. Control is by variable-inlet vanes. Either journal or antifriction bearings may be used.

Other Systems

Fans are incorporated in many different kinds of machines. Electronic equipment may require cooling fans to prevent hot spots. Driers use fans to circulate air to carry heat to, and moisture away from, the product. Air-support structures require fans to inflate them and maintain the supporting pressure. Ground-effect machines use fans to provide the lift pressure. Air conditioners and other heat exchangers incorporate fans. Aerodynamic, economic, and functional considerations will dictate the type and size of fan to be used.

Tunnel ventilation can be achieved by using either axial or centrifugal fans. Transverse ventilation utilizes supply and exhaust fans connected to the tunnel by ductwork. These fans are rated in the manner described above. Another method utilizes specially tested and rated axial fans called **jet fans.** The fans, which are placed in the tunnel, increase the momentum of some of the air flowing with the traffic. This air induces additional flow.

ELECTRICAL AND MAGNETIC UNITS

System of Units The International System of Units (**SI**) is being adopted universally. The SI system has its roots in the metre, kilogram, second (mks) system of units. Since a centimetre, gram, second (**cgs**) system has been widely used, and may still be used in some instances, Tables 15.1.1 and 15.1.2 are provided for conversion between the two systems. Basic SI units have been adopted by the General Conference on Weights and Measures (CPGM) as base quantities, that is, quantities that are not derived from other quantities. The base units are metre, kilogram (mass), second, ampere, kelvin (thermodynamic temperature), and candela (luminous intensity). Other SI units are derived from these basic units.

Electrical Units

(See Table 15.1.1.)

Current (I, i) The SI unit of current is the **ampere,** which is equal to one-tenth the absolute unit of current (**abampere**). The abampere of current is defined as follows: if 0.01 metre (1 centimetre) of a circuit is bent into an arc of 0.01 metre (1 centimetre) radius, the current is 1 abampere if the magnetic field intensity at the center is 0.01257 ampere per metre (1 oersted), provided the remainder of the circuit produces no magnetic effect at the center of the arc. One **international ampere** (9.99835 amperes) (dc) will deposit 0.001118 gram per second of silver from a standard silver solution.

Quantity (Q) The **coulomb** is the quantity of electricity transported in one second by a current of one ampere.

Potential Difference or Electromotive Force (V, E, emf) The **volt** is the difference of electric potential between two points of a conductor carrying a constant current of one ampere, when the power dissipated between these points is equal to one watt.

Resistance (R, r) The **ohm** is the electrical resistance between two points of a conductor when a constant difference of potential of one volt, applied between these two points, produces in this conductor a current of one ampere, this conductor not being the source of any electromotive force.

Resistivity (ρ) The resistivity of a material is the dc resistance between the opposite parallel faces of a portion of the material having unit length and unit cross section.

Conductance (G, g) The **siemens** is the electrical conductance of a conductor in which a current of one ampere is produced by an electric potential difference of one volt. One siemens is the reciprocal of one ohm.

Conductivity (γ) The conductivity of a material is the dc conductance between the opposite parallel faces of a portion of the material having unit length and unit cross section.

Capacitance (C) is that property of a system of conductors and dielectrics which permits the storage of electricity when potential difference exists between the conductors. Its value is expressed as a ratio of a quantity of electricity to a potential difference. A capacitance value is always positive. The **farad** is the capacitance of a capacitor between the plates of which there appears a difference of potential of one volt when it is charged by a quantity of electricity equal to one coulomb.

Permittivity or dielectric constant (ε_0) is the electrostatic energy stored per unit volume of a vacuum for unit potential gradient. The permittivity of a vacuum or free space is 8.85×10^{-12} farads per metre.

Relative permittivity or dielectric constant (ε_r) is the ratio of electrostatic energy stored per unit volume of a dielectric for a unit potential gradient to the permittivity (ε_0) of a vacuum. The relative permittivity is a number.

Self-inductance (L) is the property of an electric circuit which determines, for a given rate of change of current in the circuit, the emf induced in the same circuit. Thus $e_1 = -L di_1/dt$, where e_1 and i_1 are in the same circuit and L is the coefficient of self-inductance.

The **henry** is the inductance of a closed circuit in which an electromotive force of one volt is produced when the electric current varies uniformly at a rate of one ampere per second.

Mutual inductance (M) is the common property of two associated electric circuits which determines, for a given rate of change of current in one of the circuits, the emf induced in the other. Thus $e_1 = -M di_2/dt$ and $e_2 = -M di_1/dt$, where e_1 and i_1 are in circuit 1; e_2 and i_2 are in circuit 2; and M is the mutual inductance.

The **henry** is the mutual inductance of two separate circuits in which an electromotive force of one volt is produced in one circuit when the electric current in the other circuit varies uniformly at a rate of one ampere per second.

If M is the mutual inductance of two circuits and k is the coefficient of coupling, i.e., the proportion of flux produced by one circuit which links the other, then $M = k(L_1L_2)^{1/2}$, where L_1 and L_2 are the respective **self-inductances** of the two circuits.

Energy (J) in a system is measured by the amount of work which a system is capable of doing. The **joule** is the work done when the point of application of a force of one newton is displaced a distance of one metre in the direction of the force.

Power (W) is the time rate of transferring or transforming energy. The **watt** is the power required to do work at the rate of one joule per second.

Active power (W) at the points of entry of a single-phase, two-wire circuit or of a polyphase circuit is the time average of the values of the instantaneous power at the points of entry, the average being taken over a complete cycle of the alternating current. The value of active power is given in **watts** when the rms currents are in amperes and the rms potential differences are in volts. For sinusoidal emf and current, $W = EI \cos \theta$, where E and I are the rms values of volts and currents, and θ is the phase difference of E and I.

Reactive power (Q) at the points of entry of a single-phase, two-wire circuit, or for the special case of a sinusoidal current and sinusoidal potential difference of the same frequency, is equal to the product obtained by multiplying the rms value of the current by the rms value of the potential difference and by the sine of the angular phase difference by which the current leads or lags the potential difference. $Q = EI \sin \theta$. The unit of Q is the **var** (volt-ampere-reactive). One kilovar $= 10^3$ var.

Apparent power (VA) at the points of entry of a single-phase, two-wire circuit is equal to the product of the rms current in one conductor multiplied by the rms potential difference between the two points of entry. Apparent power $= VA$.

Table 15.1.1 Electrical Units

Quantity	Symbol	Equation	SI unit	SI unit symbol	CGS unit	Ratio of magnitude of SI to cgs unit
Current	I, i	$I = E/R$; $I = E/Z$; $I = Q/t$	Ampere	A	Abampere	10^{-1}
Quantity	Q, q	$Q = it$; $Q = CE$	Coulomb	C	Abcoulomb	10^{-1}
Electromotive force	E, e	$E = IR$; $E = W/Q$	Volt	V	Abvolt	10^{8}
Resistance	R, r	$R = E/I$; $R = \rho l/A$	Ohm	Ω	Abohm	10^{9}
Resistivity	ρ	$\rho = RA/l$	Ohm-metre	Ω · m	Abohm-cm	10^{11}
Conductance	G, g	$G = \gamma A/l$; $G = A/\rho l$	Siemens	S	Abmho	10^{-9}
Conductivity	γ	$\gamma = 1/\rho$; $\gamma = l/RA$	Siemens/metre	S/m	Abmho/cm	10^{-11}
Capacitance	C	$C = Q/E$	Farad	F	Abfarad*	10^{-9}
Permittivity	ε		Farads/metre	F/m	Stat farad*/cm	8.85×10^{-12}
Relative permittivity	ε_r	$\varepsilon_r = \varepsilon/\varepsilon_0$	Numerical		Numerical	1
Self-inductance	L	$L = -N(d\phi/dt)$	Henry	H	Abhenry	10^{9}
Mutual inductance	M	$M = K(L_1L_2)^{1/2}$	Henry	H	Abhenry	10^{9}
Energy	J	$J = eit$	Joule	J	Erg	10^{7}
	kWh	kWh = kW/3,600; 3.6 MJ	Kilowatthour	kWh		36×10^{12}
Active power	W	$W = J/t$; $W = EI \cos\theta$	Watt	W	Abwatt	10^{7}
Reactive power	jQ	$Q = EI \sin\theta$	Var	var	Abvar	10^{7}
Apparent power	VA	$VA = EI$	Volt-ampere	VA		
Power factor	pf	pf = W/VA; pf = $W/(W + jQ)$				1
Reactance, inductive	X_L	$X_L = 2\pi fL$	Ohm	Ω	Abohm	10^{9}
Reactance, capacitive	X_C	$X_C = 1/(2\pi fC)$	Ohm	Ω	Abohm	10^{9}
Impedance	Z	$Z = E/I$; $Z = R + j(X_L - X_C)$	Ohm	Ω	Abohm	10^{9}
Conductance	G	$G = R/Z^2$	Siemens	S	Abmho	10^{-9}
Susceptance	B	$B = X/Z^2$	Siemens	S	Abmho	10^{-9}
Admittance	Y	$Y = I/E$; $Y = G + jB$	Siemens	S	Abmho	10^{-9}
Frequency	f	$f = 1/T$	Hertz	Hz	Cps, Hz	1
Period	T	$T = 1/f$	Second	s	Second	1
Time constant	T	L/R; RC	Second	s	Second	1
Angular velocity	ω	$\omega = 2\pi f$	Radians/second	rad/s	Radians/second	1

* 1 Abfarad (EMU units) = 9×10^{-20} stat farads (ESU units).

Power factor (pf) is the ratio of power to apparent power. pf = W/VA = $\cos\theta$, where θ is the phase difference between E and I, both assumed to be sinusoidal.

The **reactance** (X) of a portion of a circuit for a sinusoidal current and potential difference of the same frequency is the product of the sine of the angular phase difference between the current and potential difference times the ratio of the rms potential difference to the rms current, there being no source of power in the portion of the circuit under consideration. $X = (E/I) \sin\theta = 2\pi fL$ ohms, where f is the frequency, and L the inductance in henries; or $X = 1/2\pi fC$ ohms, where C is the capacitance in farads.

The **impedance** (Z) of a portion of an electric circuit to a completely specified periodic current and potential difference is the ratio of the rms value of the potential difference between the terminals to the rms value of the current, there being no source of power in the portion under consideration. $Z = E/I$ ohms.

Admittance (Y) is the reciprocal of impedance. $Y = I/E$ siemens. Conductance is the real part of admittance.

The **susceptance** (B) of a portion of a circuit for a sinusoidal current and potential difference of the same frequency is the product of the sine of the angular phase difference between the current and the potential difference times the ratio of the rms current to the rms potential difference, there being no source of power in the portion of the circuit under consideration. $B = (I/E) \sin\theta$. Susceptance is the imaginary part of admittance.

Magnetic Units

(See Table 15.1.2.)

Magnetic flux (Φ, ϕ) is the magnetic flow that exists in any magnetic circuit.

The **weber** is the magnetic flux which, linking a circuit of one turn, produces in it an electromotive force of one volt as it is reduced to zero at a uniform rate in one second.

Magnetic flux density (β) is the ratio of the flux in any cross section to the area of that cross section, the cross section being taken normal to the direction of flux.

Table 15.1.2 Magnetic Units

Quantity	Symbol	Equation*	SI unit	SI unit symbol	CGS unit	Ratio of magnitude of SI to cgs unit
Magnetic flux	Φ, ϕ	$\phi = F/R$	Weber	wb	Maxwell	10^{8}
Magnetic flux density	β	$\beta = \phi/A$	Tesla	T	Gauss	10^{4}
Pole strength	Q_m	$Q_m = F/\beta$; $Q_m = Fl/NI\mu_0\mu_r$	Ampere-turns-metre	A·m		
			Unit pole		Unit pole	0.7958×10^{7}
Magnetomotive force	$\mathcal{F}$	$\mathcal{F} = NI$	Ampere-turns	A	Gilbert	1.257
Magnetic field intensity	H	$H = \mathcal{F}/l$	Ampere-turns per metre	A/m	Oersted	0.01257
Permeability air	μ_0	$\mu_0 = \beta/H$	Henry per metre	H/m	Gilbert per oersted	1.257×10^{-6}
Relative permeability	μ_r	$\mu_r = \mu/\mu_0$	Numeric		Numeric	1
Reluctivity	γ	$\gamma = 1/\mu_r$	Numeric		Numeric	1
Permeance	P	$P = \mu_0\mu_r A/l$	Henry	H		7.96×10^{7}
Reluctance	R	$R = l/\mu_0\mu_r A$	1/Henry	1/H		1.257×10^{-8}

* l = length in metres; A = area in square metres; F = force in newtons; N = number of turns.

The **tesla** is the magnetic flux density given by a magnetic flux of one weber per square metre.

Unit magnetic pole, when concentrated at a point and placed one metre apart in a vacuum from a second unit magnetic pole, will repel or attract the second unit pole with a force of one **newton.**

The **weber** is the magnetic flux produced by a unit pole.

Magnetomotive force ($\mathcal{F}$, mmf) produces magnetic flux and corresponds to electromotive force in an electric circuit.

The **ampere** (turn) is the unit of mmf.

Magnetic field intensity (H) at a point is the vector quantity which is measured by a mechanical force which is exerted on a unit pole placed at the point in a vacuum.

An **ampere per metre** is the unit of field intensity.

Permeability (μ) is the ratio of unit magnetic flux density to unit magnetic field intensity in air (B/H). The permeability of air is 1.257×10^{-6} **henry per metre.**

Relative permeability (μ_r) is the ratio of the magnetic flux in any element of a medium to the flux that would exist if that element were replaced with air, the magnetomotive force (mmf) acting on the element remaining unchanged ($\mu_r = \mu/\mu_0$).

The relative permeability is a number.

Permeance (P) of a portion of a magnetic circuit bounded by two equipotential surfaces, and by a third surface at every point of which there is a tangent having the direction of the magnetic induction, is the ratio of the flux through any cross section to the magnetic potential difference between the surfaces when taken within the portion under consideration. The equation for the permeance of the medium as defined above is $P = \mu_0\mu_r A/l$. Permeance is the **reciprocal of reluctance.**

Reluctivity (γ) of a medium is the reciprocal of its permeability.

Reluctance (R) is the **reciprocal of permeance.** It is the resistance to magnetic flow. In a homogeneous medium of uniform cross section, reluctance is equal to the length divided by the product of the area and permeability, the length and area being expressed in metre units. $R = l/A\mu_0\mu_r$, where $\mu_0 = 1.257 \times 10^{-6}$.

CONDUCTORS AND RESISTANCE

Resistivity, or **specific resistance,** is the resistance of a sample of the material having both a length and cross section of unity. The two most common resistivity samples are the centimetre cube and the cir mil·ft. If l is the length of a conductor of uniform cross section a, then its resistance is

$$R = \rho l/a \tag{15.1.1}$$

where ρ is the resistivity. With a cir mil·ft ρ is the resistance of a cir mil·ft and a is the cross section, cir mils. Since $v = la$ is the volume of a conductor,

$$R = \rho l^2/v = \rho v/a^2 \tag{15.1.2}$$

A **circular mil** is a unit of area equal to that of a circle whose diameter is 1 mil (0.001 in). It is the unit of area which is used almost entirely in this country for wires and cables. To obtain the cir mils of a solid cylindrical conductor, square its diameter expressed in mils. For example, the diameter of 000 AWG solid copper wire is 410 mils and its cross section is $(410)^2 = 168{,}100$ cir mils. The diameter in mils of a solid cylindrical conductor is the square root of its cross section expressed in cir mils.

A **cir mil · ft** is a conductor having a length of 1 ft and a uniform cross section of 1 cir mil. In terms of the copper standard the resistance of a cir mil·ft of copper at 20°C is 10.371 Ω. As a first approximation 10 Ω may frequently be used.

At 60°C a cir mil·in of copper has a resistance of 1.0 Ω. This is a very convenient unit of resistivity for magnet coils since the resistance is merely the length of copper in inches divided by its cross section in cir mils.

Temperature Coefficient of Resistance The resistance of the pure metals increases with temperature. The resistance at any temperature t°C is

$$R = R_0(1 + \alpha t) \tag{15.1.3}$$

where R_0 is the resistance at 20°C and α is the **temperature coefficient of resistance.** For copper, $\alpha = 0.00393$.

With any initial temperature t_1, the resistance at temperature t°C is

$$R = R_1[1 + \alpha_1(t - t_1)] \tag{15.1.4}$$

where R_1 is the resistance at temperature t_1°C and α_1 is the temperature coefficient of resistance at temperature t_1 [see Eq. (15.1.5)].

For any initial temperature t_1 the value of α_1 is

$$\alpha_1 = 1/(234.5 + t_1) \tag{15.1.5}$$

Inferred Absolute Zero Between 100 and 0°C the resistance of copper decreases at a rate which is practically uniform and which if continued would give a resistance of zero at −234.5°C (an easy number to remember). If the resistance at t_1°C is R_1 and the resistance at t_2°C is R_2, then

$$R_2/R_1 = (234.5 + t_2)/(234.5 + t_1) \tag{15.1.6}$$

EXAMPLE. The resistance of a copper coil at 25°C is 4.26 Ω. Determine its resistance at 45°C. Using Eq. (15.1.4) and $\alpha_1 = 1/(234.5 + 25) = 0.00385$, $R = 4.26[1 + 0.00385(45 - 25)] = 4.59$ Ω. Using Eq. (15.1.6) $R = 4.26(234.5 + 45)/(234.5 + 25) = 4.26 \times 1.077 = 4.59$ Ω.

The inferred absolute zero for aluminum is −228°C.

Materials The materials generally used for the transmission and distribution of electrical energy are copper, aluminum, and sometimes iron and steel. For resistors and heaters, iron, steel, commercial alloys, and carbon are most used.

Copper is the most widely used electrical conductor. It has high conductivity, relatively low cost, good resistance to oxidation, is readily soldered, and has good mechanical characteristics such as tensile strength, toughness, and ductility. Its tensile strength together with its low linear temperature coefficient of expansion are desirable characteristics in its use for overhead transmission lines. The international copper standard for 100 percent conductivity annealed copper is a density of 8.89 g/cm^3 (0.321 lb/in^3) and resistivity is given in Table 15.1.3. ASTM specifications for minimum conductivities of copper wire are as follows:

Conductor diam, in	Soft or annealed	Medium hard drawn	Hard drawn
0.040–0.324	98.16%	96.60%	96.16%
0.325–0.460	98.16%	97.66%	97.16%

Aluminum is used to considerable extent for high-voltage transmission lines, because its weight is one-half that of copper for the same conductance. Moreover, the greater diameter reduces corona loss. As it has 1.4 times the linear temperature coefficient of expansion, changes in sag with temperature are greater. Because of its lower melting point, spans may fail more readily with arc-overs. In aluminum cable steel-reinforced (ACSR), the center strand is a steel cable, which gives added tensile strength. Aluminum is used occasionally for bus bars because of its large heat-dissipating surface for a given conductance. The greater cross section for a given conductance requires a greater volume of insulation for a given voltage. When the ratio of the cost of aluminum to the cost of copper becomes economically favorable, aluminum is often used for insulated wires and cables. The international aluminum standard for 62 percent conductivity aluminum is a density of 2.70 g/cm^3 (0.0976 lb/in^3) and resistivity as given in Table 15.1.3.

Steel, either **galvanized** or **copper-covered** ("copperweld"), is used for high-voltage transmission spans where tensile strength is more important than high conductance. Steel is also used for third rails.

Copper alloys and **bronzes** are of increasing importance as electrical conductors. They have lower electrical conductivity but greater tensile strength and are resistant to corrosion. **Hitenso, Calsum bronzes, Signal bronze, Phono-electric,** and **Everdur** are bronzes containing phosphorus, silicon, manganese, or zinc. Their conductivities vary from 20 to 85

Table 15.1.3 Properties of Metals and Alloys
(See Table 15.1.27 for properties of resistor alloys)

Metals	Resistivity, 20°C		Temperature coefficient of resistance at 20°C

† 0°C.

percent of 100 percent conductivity copper, and they have tensile strengths up to 130,000 lb/in^2, about twice that of hard-drawn copper. Such alloys were frequently used for trolley wires. Copper alloys having lower conductivity are usually classified as resistor materials.

In Table 15.1.3 are given the electrical properties of some of the pure metals and alloys.

American Wire Gage (AWG) The AWG (formerly Brown & Sharpe gage) is based on a constant ratio between diameters of successive gage numbers (Table 15.1.4). The ratio of any diameter to the next smaller is 1.123, and the corresponding ratio of cross sections is $(1.123)^2 = 1.261$, or 1¼ approximately. $(1.123)^6$ is 2.0050, so that diameters differing by 6 gage numbers have a ratio of approximately 2; cross sections differing by 3 gage numbers also have a ratio of approximately 2. The ratio of cross sections differing by 2 numbers is $(1.261)^2 = 1.590$, or 1.6 approximately. The ratio of cross sections differing by 10 numbers is approximately 10. The gage ordinarily extends from no. 40 to 0000 (4/0). Wires larger than 0000 must be stranded, and their cross section is given in cir mils.

The diameter of no. 10 wire is 102.0 mils. As an approximation this may be considered as being 100 mils; the cross section is 10,000 cir mils; the resistance is 1 Ω per 1,000 ft; and the weight of 1,000 ft is

Table 15.1.4 Working Table, Standard Annealed Copper Wire, Solid

SOURCE: From *NBS Cir.* 31.

31.4(10π) lb. Also the weight of 1,000 ft of no. 2 is 200 lb. These facts give many short cuts in estimating resistances and weights of various gage numbers.

Lay Cables In order to obtain sufficient flexibility, wires larger than 0000 are stranded, and they are designated by their circular mils (Table 15.1.5). Smaller wires may be stranded also since sizes as small as no. 4 when insulated are usually too stiff for easy handling. Lay cables are made up geometrically as shown in Fig. 15.1.1. Six strands will just fit around the single central conductor; the number of strands in each succeeding layer increases by 6. The number of strands that can thus be laid up are 1, 7, 19, 37, 61, 91, 127, etc. In order to obtain sufficient flexibility with large cables, the strands themselves frequently consist of stranded cable.

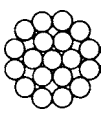

Fig. 15.1.1 Makeup of a 19-strand cable.

The **resistance of cables** is readily computed from Eq. (15.1.1), using the cir mil ft as the unit of resistivity.

EXAMPLE. Determine the resistance of 3,500 ft of 800,000 cir mil cable at 20°C. *Answer:* ρ (of a cir mil · ft) = 10.37. $R = 10.37 \times 3{,}500/800{,}000 = 0.0454\ \Omega$.

$\rho = 10\ \Omega$/cir mil · ft is often sufficiently accurate for practical purposes.

ELECTRICAL CIRCUITS

Figure 15.1.2 shows standard symbols for electrical circuit diagrams.

Ohm's law states that, with a steady current, the current in a circuit is **directly** proportional to the **total** emf acting in the circuit and is **inversely** proportional to the total resistance of the circuit. The law may be expressed by the following three equations:

$$I = E/R \tag{15.1.7}$$

$$E = IR \tag{15.1.8}$$

$$R = E/I \tag{15.1.9}$$

where E is the emf, V; R the resistance, Ω; and I the current, A.

Series Circuits The combined resistance of a number of series-connected resistors is the sum of their separate resistances. When batteries or other sources of emf are connected in series, the total emf of the combination is the sum of the separate emfs. The open-circuit emf of a battery is the total generated emf and can be measured at the battery terminals only when no current is being delivered by the battery. The internal resistance is the resistance of the battery alone. The current in a circuit connected in series with a source of emf is $I = E/(R + r)$, where E is the open-circuit emf, R the external resistance, and r the internal resistance of the source of emf.

Parallel Circuits The combined conductance of a number of parallel-connected resistors is the sum of their separate conductances.

$$G = G_1 + G_2 + G_3 + \cdots \tag{15.1.10}$$

$$\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots \tag{15.1.11}$$

The equivalent resistance for two parallel resistors having resistances R_1, R_2 is

$$R = R_1R_2/(R_1 + R_2) \tag{15.1.12}$$

The equivalent resistance for three parallel resistors having resistances R_1, R_2, R_3 is

$$R = \frac{R_1R_2R_3}{R_1R_2 + R_2R_3 + R_3R_1} \tag{15.1.13}$$

and for four parallel resistors having resistances R_1, R_2, R_3, R_4

$$R = \frac{R_1R_2R_3R_4}{R_1R_2R_3 + R_2R_3R_4 + R_3R_4R_1 + R_4R_1R_2} \tag{15.1.14}$$

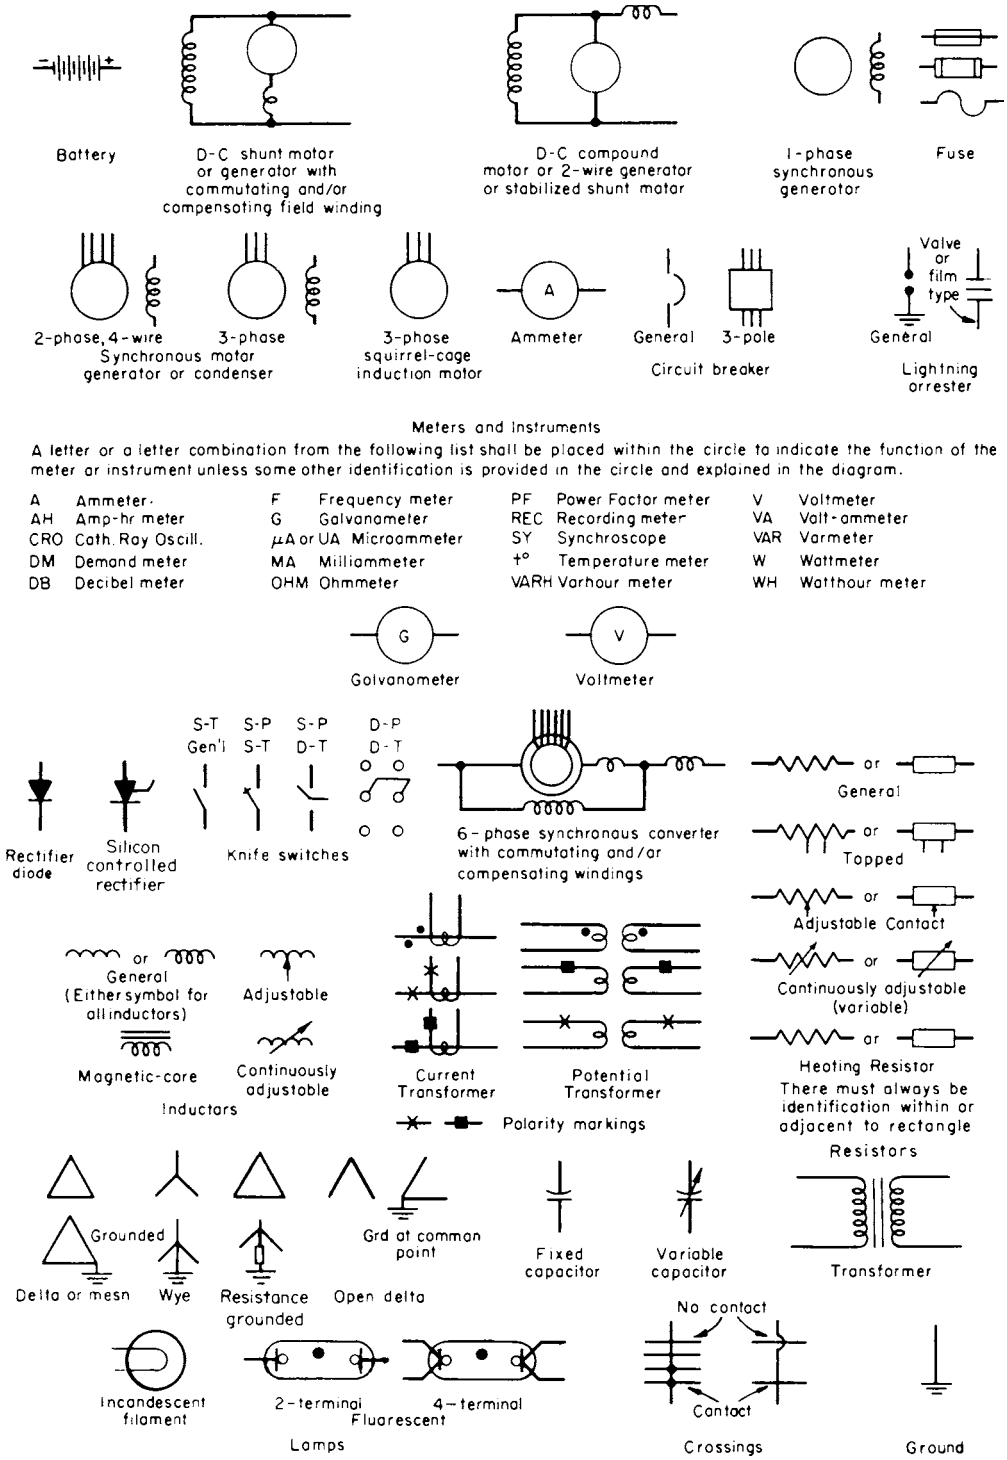

Fig. 15.1.2 Diagrammatic symbols for electrical machinery and apparatus. *(American Standard, "Graphic Symbols for Electrical and Electronic Diagrams," ANS/IEEE, 315, 1975.)*

To obtain the resistance of combined series and parallel resistors, the equivalent resistance of each parallel portion is obtained separately and then these equivalent resistances are added to the series resistances according to the principles stated above.

Kirchhoff's laws (derived from Ohm's law) make it possible to solve many circuit networks that would otherwise be difficult to solve. The first law states that: *In any branching network of wires the algebraic sum of the currents in all the wires that meet at a point is zero.* The second law states that: *The sum of all the electromotive forces acting around a complete circuit is equal to the sum of the resistances of its separate parts multiplied each by the strength of the current in it, or the total change of potential around any closed circuit is zero.*

In applying Kirchhoff's laws the following rules should be observed. Currents going toward a junction should be preceded by a plus sign. Currents going away from a junction should be preceded by a minus sign. A rise in potential should be preceded by a plus sign. (This occurs in going through a source of emf from the negative to the positive terminal, and in going through resistance in opposition to the direction of current.) A drop in potential should be preceded by a minus sign. (This occurs in going through a source of emf from the positive to the negative terminal and in going through resistance in conjunction with the current.)

The application of Kirchhoff's laws is illustrated by the following example.

EXAMPLE. Determine the three currents I_1, I_2, and I_3 in the circuit network (Fig. 15.1.3). The arrows show the assumed directions of the three currents.

Applying Kirchhoff's second law to circuit *abcdea,*

$$+4 + 0.2I_1 + 0.5I_1 - 3I_2 + 2 - 0.1I_2 + I_1 = 0$$

or

$$+6 + 1.7I_1 - 3.1I_2 = 0 \qquad \text{(I)}$$

and for *edcfge*,

$$-2 + 0.1I_2 + 3I_2 + I_3 + 3 + 0.3I_3 = 0$$

or

$$+1 + 3.1I_2 + 1.3I_3 = 0 \qquad \text{(II)}$$

Applying Kirchhoff's first law to junction *c,*

$$-I_1 - I_2 + I_3 = 0 \qquad \text{(III)}$$

Solving (I), (II), and (III) simultaneously gives $I_1 = -2.56$, $I_2 = +0.53$, and $I_3 = -2.03$. The minus signs before I_1 and I_3 show that the actual directions of these two currents are opposite the assumed directions.

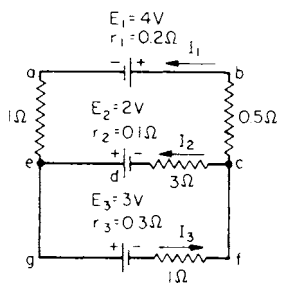

Fig. 15.1.3 Electric network and Kirchhoff's laws.

Electrical Power With direct currents the electrical power is given by the product of the volts and amperes. That is,

$$P = EI \quad \text{W} \qquad (15.1.15)$$

Also, by substituting for E and I Eqs. (8) and (7),

$$P = I^2R \quad \text{W} \qquad (15.1.16)$$

$$P = E^2/R \quad \text{W} \qquad (15.1.17)$$

The watt is too small a unit for many purposes. Hence, the **kilowatt** (kW) is used. 746 watts = 1 hp = 0.746 kW; 1 kW = 1.340 hp. The **kilowatthour (kWh)** is the common engineering unit of electrical energy.

Joule's Law When an electric current flows through resistance, the number of heat units developed is proportional to the square of the current, directly proportional to the resistance, and directly proportional to the time that the current flows. $h = i^2rt$, where h = number of joules; i = current, A; r = resistance, Ω; and t = time, s. h (in Btu) = $0.0009478i^2rt$.

MAGNETISM

Magnetic Circuit The magnetic circuit is analogous to the electric circuit in that the flux Φ is proportional to the magnetomotive force $\mathcal{F}$ and inversely proportional to the reluctance $\mathcal{R}$ or magnetic resistance. Thus

$$\Phi = \mathcal{F}/\mathcal{R} \qquad (15.1.18)$$

Compare with Eq. (15.1.7). Φ is in webers, where the weber is the SI unit of flux, $\mathcal{F}$ in ampere-turns, and $\mathcal{R}$ in SI reluctance units. In the cgs system, ϕ is in maxwells, $\mathcal{F}$ is in gilberts, and $\mathcal{R}$ is in cgs reluctance units.

$$\mathcal{R} = l/\mu_r\mu_v A \qquad (15.1.19)$$

where μ_r is **relative permeability** (commonly called permeability, μ), a property of the magnetic material, and μ_v is the permeability of evacuated space = $4\pi \times 10^{-7}$, and A is in square metres. In the cgs system $\mu_v = 1$

$$\mathcal{R} = \frac{l}{\mu_r(4\pi \times 10^{-7})A} = \frac{l}{\mu_r(1.257 \times 10^{-6})A} \qquad (15.1.20)$$

l is in metres and A in square metres.

The unit of **flux density** in the SI system is the tesla, which is equal to the number of webers per square metre taken perpendicular to their direction. One ampere-turn between opposite faces of a metre cube of a magnetic medium produces μ_r tesla. For air, $\mu_r = 4\pi \times 10^{-7}$. In the cgs system the unit of flux density is gauss = 10^4T (see Table 15.1.2).

Magnetic-circuit calculations cannot be made with the same degree of accuracy as electric-circuit calculations because of several factors. The cross-sectional dimensions of the magnetic circuit are large relative to its length; magnetic paths are irregular, and their geometry can only be approximated as with the air gap of electric machines, which usually have slots on one or both sides of the gap.

Magnetic flux cannot be confined to definite magnetic paths, but a considerable proportion usually takes paths external to the circuit giving magnetic leakage (see Fig. 15.1.7). The relative permeability of iron varies over wide ranges with the flux density and with the previous magnetic condition (see Fig. 15.1.5). These variations of relative permeability cannot be expressed by any simple equation. Although the foregoing factors prevent the obtaining of extremely high accuracy in magnetic calculations, yet, with experience, it is possible to design magnetic circuits with a precision that is satisfactory for all practical purposes.

The **magnetomotive force** $\mathcal{F}$ in Eq. (15.1.18) is expressed in ampere-turns = NI, where N is the number of turns linked with the circuit and I is the current, A. The unit of reluctance is the reluctance of a 1-m cube of air. The total reluctance is proportional to the length and inversely proportional to the cross-sectional area of the magnetic circuit, which is analogous to electrical resistance. Hence the reluctance of any given path of uniform cross section A is $l/A\mu$, where l = length of path, cm; A = its cross section, cm^2; and μ = permeability. Reluctances in series are added to obtain their combined reluctance. Ohm's law of the magnetic circuit becomes

$$\Phi = \frac{NI}{l_1/A_1\mu_1 + l_2/A_2\mu_2 + l_3/A_3\mu_3 \cdots} \text{ Mx} \qquad (15.1.21)$$

where l_1, A_1, μ_1, etc., are the lengths, cross sections, and relative permeabilities of each series part of the circuit.

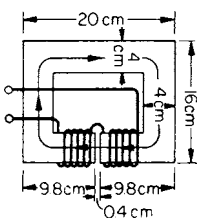

Fig. 15.1.4 Magnetic circuit.

EXAMPLE. In Fig. 15.1.4 is shown a magnetic circuit of cast steel with a 0.4-cm air gap. The cross section of the core is 4 cm square. There are 425 turns wound on the core and the current is 10 A. The relative permeability of the steel at the operating flux density is 1,100. Assume that the path of the flux is as shown, the average path at the corners being quarter circles. Neglect fringing at the air gap and any leakage. Determine the flux and the flux density.

Using the SI system, the length of the iron is 0.522 m, the length of the air gap is 0.004 m, and the cross section of the iron and air gap is 0.0016 m^2.

$$\Phi = \frac{425 \times 10}{\dfrac{0.522}{1{,}100 \times 4\pi \times 10^{-7} \times 0.0016} + \dfrac{0.004}{4\pi \times 10^{-7} \times 0.0016}} = 0.00191 \text{ Wb}$$

Using the cgs system, the length of the magnetic path in the iron = 12 + 8 + 8 + 5.8 + 5.8 + 4π = 52.2 cm. From Eq. (15.1.21),

$$\Phi = \frac{0.4\pi \times 425 \times 10}{[52.2/(16 \times 1{,}100)] + (0.4/16)} = 191{,}000 \text{ Mx}$$

$$B = \frac{191{,}000}{16} = 11{,}940 \text{ G}$$

Magnetization and Permeability Curves The magnetic permeability of air is a constant and is taken as unity. The relative permeability of iron and other magnetic substances varies with the flux density. In Fig. 15.1.5 is shown a magnetization curve for cast steel in which the flux density B in tesla is plotted as a function of the field intensity, amperes

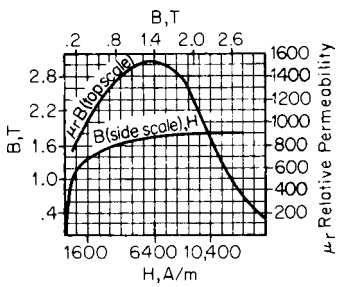

Fig. 15.1.5 Magnetization and relative-permeability curves for cast steel.

per metre, H. Also the relative permeability $\mu_r = B/H$ is plotted as a function of the flux density B. Note the wide range over which the relative permeability varies. No satisfactory equation has been found to express the relation between magnetizing force and flux density and between relative permeability and flux density. If an attempt is made to solve Eq. (15.1.21) for flux, the factors μ_1, μ_2, etc., are unknown since they are functions of the flux density, which is being determined. The simplest method is one of trial and error, i.e., a value of flux, and the corresponding permeability, is first assumed, the equation solved for the flux, and if the computed flux differs widely from the assumed flux, a second approximation is made, etc. In nearly all magnetic designs either the flux or flux density is the independent variable, and it is required to find the necessary ampere-turns to produce them. Let the flux $\Phi = BA$ where B is the flux density, G. Then

$$\Phi = BA = 0.4\pi NI(l/A\mu_r)$$

and

$$NI = Bl/\mu_0\mu_r = 0.796Bl/\mu_r \times 10^6 \qquad (15.1.22)$$

Equation (15.1.22) shows that the necessary ampere-turns are proportional to the **flux density** and the length of path and are inversely proportional to the relative permeability.

With air and nonmagnetic substances μ_r [Eq. (15.1.22)] becomes unity, and

$$NI = 0.796Bl \times 10^6 \qquad (15.1.23)$$

in metre units. With inch units

$$NI = 0.313B'l' \qquad (15.1.24)$$

where B' is the flux density, Mx/in^2; and l' the length of the magnetic path, in.

EXAMPLE. The average flux density in the air gap of a generator is 40,000 Mx/in^2, and the effective length of the gap is 0.2 in. How many ampere-turns per pole are necessary for the gap?

$$NI = 0.313 \times 40{,}000 \times 0.2 = 2{,}500$$

Since the relation of μ_r to flux density B in Eq. (15.1.22) is not simple, the relation of ampere-turns per unit length of magnetic circuit to flux density is ordinarily shown graphically. Typical curves of this character are shown in Fig. 15.1.6, inch units being used although scales of tesla, and ampere turns per metre are also given. To determine the number of ampere-turns necessary to produce a given total flux in a magnetic circuit composed of several parts in series having various lengths, cross sections, and relative permeabilities, determine the flux density if the cross section is fixed, or otherwise choose a cross section to give a suitable flux density. From the magnetization curve obtain the ampere-turns necessary to drive this **flux density** through a unit length of the portion of the circuit considered and multiply by the length. Add together the ampere-turns required for each series part of the magnetic circuit to obtain the total ampere-turns necessary to give the assumed flux.

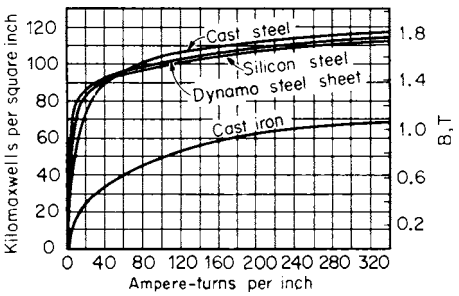

Fig. 15.1.6 Typical magnetization curves.

It is desirable to operate magnetic circuits at as high flux densities as is practicable in order to reduce the amount of iron and copper. The air gaps of dynamos are operated at average densities of 40,000 to 50,000 Mx/in^2. Higher densities increase the exciting ampere-turns and tooth losses. At 45,000 Mx/in^2 the flux density in the teeth may be as high as 120,000 to 130,000 Mx/in^2. The flux densities in transformer cores are limited as a rule by the permissible losses. At 60 Hz and with silicon steel the maximum density is 60,000 to 70,000 Mx/in^2, at 25 Hz the density may run as high as 75,000 to 90,000 Mx/in^2. With laminated cores, the net iron is approximately 0.9 the gross cross section.

Magnetic Leakage It is impossible to confine all magnetic flux to any desired path since there is no known insulator of magnetic flux. Figure 15.1.7 shows the magnetic circuit of a modern four-pole dynamo.

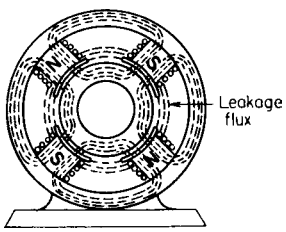

Fig. 15.1.7 Magnetic circuit of a four-pole dynamo with leakage flux.

A considerable proportion of the useful magnetic flux leaks between the pole shoes and cores, rather than across the air gap. The ratio of the maximum flux, which exists in the field cores, to the useful flux, i.e., the flux that crosses the air gap, is the **coefficient of leakage**. This

coefficient must always be greater than unity and in carefully designed dynamos may be as low as 1.15. It is frequently as high as 1.30. Although the geometry of the leakage-flux paths is not simple, the leakage flux may be determined by approximations with a fair degree of accuracy.

Magnetic Hysteresis The magnetization curves shown in Figs. 15.1.5 and 15.1.6 are called **normal curves.** They are taken with the magnetizing force continuously increased from zero. If at any point the magnetizing force be decreased, a greater value of flux density for any given magnetizing force will result. The effect of carrying iron through a complete cycle of magnetization, both positive and negative, is shown in Fig. 15.1.8.

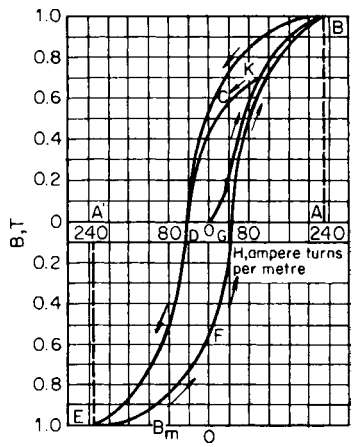

Fig. 15.1.8 Hysteresis loop for dynamo steel.

The curve *OKB*, taken with increasing values of magnetizing force per centimetre *H*, is the **normal induction** curve. If after the magnetizing force has reached the value *OA*, it is decreased, the magnetic flux density *B* will decrease in accordance with curve *BCD*, between *A* and *O* the values being much greater than those given by the normal curve, i.e., the flux density lags the magnetizing force. At zero magnetizing force, the flux density is *OC*, call the **remanence.** A negative magnetizing force *OD*, called the **coercive force,** is required to bring the flux density to zero. If the magnetizing force is increased negatively to *OA′*, the flux density will be given by the curve *DE*. If the magnetizing force is increased positively from *A′* to *A*, the flux density will be given by the curve *EFGB*, which is similar to the curve *BCDE*. *OF* is the negative remanence and *OG* again is the coercive force. The complete curve is called a **hysteresis loop.** When the normal curve reaches the point *K*, if the magnetizing force is then decreased, another hysteresis loop, a portion of which is shown at *KL*, will be obtained. It is seen that the flux density lags the magnetizing force throughout.

The energy dissipated per cycle is proportional to the area of the loop and is equal to $(1/4\pi)\int H\,dB$ ergs/(Hz)(cm^3). For moderately high densities the energy loss per cycle varies according to the **Steinmetz law**

$$W = 10\eta B_m^{1.6} \qquad \text{W}\cdot\text{s/m}^3 \qquad (15.1.25)$$

where B_m is the maximum value of the flux density, T (Fig. 15.1.8). Table 15.1.6 gives values of the Steinmetz coefficient η for common magnetic steels.

Table 15.1.6 Steinmetz Coefficients

Hard tungsten steel	0.058	Ordinary sheet iron	0.004
Hard cast steel	0.025	Pure iron	0.003
Forged steel	0.020	Annealed iron sheet	0.002
Cast iron	0.013	Best annealed sheet	0.001
Electrolytic iron	0.009	Silicon steel sheet	0.00046
Soft machine steel	0.009	Permalloy	0.0001
Annealed cast steel	0.008		

A permanent increase in the hysteresis constant occurs if the temperature of operation remains for some time above 80°C. This phenomenon is known as **aging** and may be much reduced by proper annealing of the iron. Silicon steels containing about 3 percent silicon have a lower hysteresis loss, somewhat larger eddy-current loss, and are practically nonaging.

Eddy-current losses, also known as Foucault-current losses, occur in iron subjected to cyclic magnetization. Eddy-current losses are reduced by laminating the iron, which subdivides the emf and increases greatly the length of path of the parasitic currents. Eddy currents also have a screening effect, which tends to prevent the flux penetrating the iron. Hence laminating also allows the full cross section of the iron to be utilized unless the frequency is too high.

Eddy-current loss in sheets is given by

$$P_e = (\pi t f B_m)^2/6\rho 10^{16} \qquad \text{W/cm}^3 \qquad (15.1.26)$$

where t = thickness, cm; f = frequency, Hz; B_m = the maximum flux density, G; ρ = the resistivity, $\Omega \cdot$ cm.

Relations of Direction of Magnetic Flux to Current Direction The direction of the magnetizing force of a current is at right angles to its direction of flow. Magnetic lines about a cylindrical conductor carrying current exist in circular planes concentric with and normal to the conductor. This is illustrated in Fig. 15.1.9*a*. The $\oplus$ sign, corresponding to the feathered end of the arrow, indicates a direction of current away from the observer; a $\odot$ sign, corresponding to the tip of an arrow, indicates a direction of current toward the observer.

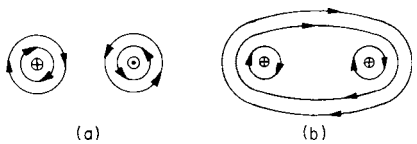

Fig. 15.1.9 Currents in (*a*) opposite directions, (*b*) in the same direction.

Corkscrew Rule The direction of the current and that of the resulting magnetic field are related to each other as the forward travel of a corkscrew and the direction in which it is rotated.

Hand Rule Grasp the conductor in the right hand with the thumb pointing in the direction of the current. The fingers will then point in the direction of the lines of flux.

The applications of these rules are illustrated in Fig. 15.1.9. If the currents in parallel conductors are in opposite directions (Fig. 15.1.9*a*), the conductors tend to move apart; if the currents in parallel conductors are in the same direction (Fig. 15.1.9*b*), the conductors tend to come together. The magnetic lines act like stretched rubber bands and, in attempting to contract, tend to pull the two conductors together.

The relation of the direction of current in a solenoid helix to the direction of flux is shown in Fig. 15.1.10. Figure 15.1.11 shows the

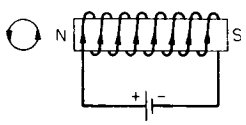

Fig. 15.1.10 Direction of current and poles in a solenoid.

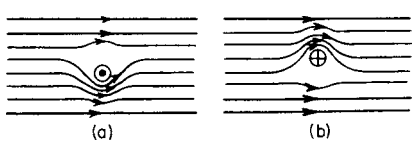

Fig. 15.1.11 Effect of a current on a uniform magnetic field.

effect on a uniform field of placing a conductor carrying current in that field and normal to it. In (*a*) the direction of the current is toward the observer. By applying the corkscrew rule it is seen that the current weakens the field immediately above it and strengthens the field immediately below it. The reverse is true in (*b*), where the direction of the current is away from the observer.

Figure 15.1.11 is illustrative of the force developed on a conductor carrying current in a magnetic field. In (*a*) the conductor will tend to move upward owing to the stretching of the magnetic lines beneath it. Similarly, the conductor in (*b*) will tend to move downward. This principle is the basis of motor action. (See also "Magnets.")

BATTERIES

In an **electric cell,** or **battery,** chemical energy is converted into electrical energy. The word *battery* may be used for a single cell or for an assembly of cells connected in series or parallel. A battery utilizes the potential difference which exists between different elements. When two different elements are immersed in electrolyte an emf exists tending to send current within the cell from the negative pole, which is the more highly electropositive, to the positive pole. The **poles,** or **electrodes** of a battery form the junction with the external circuit.

If the external circuit is closed, current flows from the battery at the **positive electrode,** or **anode,** and enters the battery at the **negative electrode,** or **cathode.**

In a **primary battery** the chemically reacting parts **require renewal;** in a **secondary battery,** the electrochemical processes **are reversible** to a high degree and the chemically reacting parts are restored after partial or complete discharge by reversing the direction of current through the battery. See Table 15.1.7 for a summary of battery types and applications.

Electromotive force of a battery is the total potential difference existing between the electrodes on open circuit. When current flows, the potential difference across the terminal drops because of the resistance drop within the cell and because of **polarization.**

Polarization When current flows in a battery, hydrogen is deposited on the cathode. This produces two effects, both of which reduce the terminal voltage of the battery. The hydrogen in contact with the cathode constitutes a hydrogen battery which opposes the emf of the battery; the hydrogen bubbles reduce the contact area of the electrolyte with the cathode, thus increasing the battery resistance. The most satisfactory method of reducing polarization is to have present at the cathode some compound that supplies negative ions to combine with the positive hydrogen ions at the plate. In the Leclanché cell, manganese peroxide in contact with the carbon cathode serves as a depolarizer, its oxygen ion combining with the hydrogen ion to form water.

If E is the emf of the cell, E_p the emf of polarization, r the internal resistance, V the terminal voltage, when current I flows, then

$$V = (E - E_p) - Ir \tag{15.1.27}$$

Primary Batteries

Dry Cells A dry cell is one in which the electrolyte exists in the form of a jelly, is absorbed in a porous medium, or is otherwise restrained from flowing from its intended position, such a cell being completely portable and the electrolyte nonspillable. The Leclanché cell consists of a cylindrical zinc container which serves as the negative electrode and is lined with specially prepared paper, or some similar absorbent material, to prevent the mixture of carbon and manganese dioxide, which is tamped tightly around the positive carbon electrode, from coming in contact with the zinc. The absorbent lining and the mixture are moistened with a solution of zinc chloride and sal ammoniac. In smaller cells (Fig. 15.1.12) the manganese-carbon mixture is often

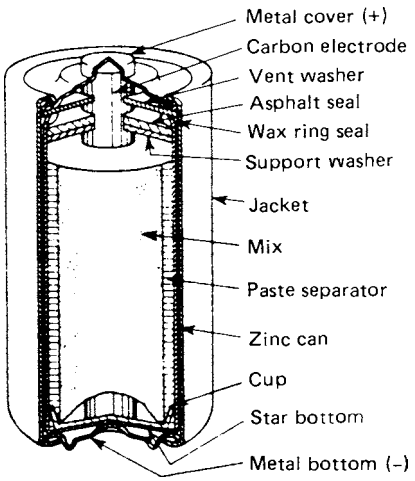

Fig. 15.1.12 Cross section of a standard round zinc-carbon cell. *(From "Standard Handbook for Electrical Engineers," Fink and Carrol, McGraw-Hill, NY, copyright 2000.)*

Table 15.1.7 Battery Types and Applications

Battery type	Cell type	Nominal cell voltage	Capacity, wH/kg	Applications
		Primary		
Leclanché (zinc-carbon)	Dry	1.5	22–44	Flashlights, emergency lights, radios
Zinc-mercury (Ruben)	Dry	1.34	90–110	Medical, marine, space, laboratory, and emergency devices
Zinc-alkaline-manganese dioxide	Dry	1.5	66	Models, cameras, shavers, lights
Silver or cuprous chloride-magnesium	Wet		55–120	Disposable devices: torpedoes, rescue beacons, meteorological balloons
		Secondary		
Lead-acid	Wet	2		Automotive, industrial trucks, railway, station service
Lead-calcium	Wet	2		Standby
Edison (nickel-iron)	Wet	1.2		Industrial trucks; boat and train lights
Nickel-cadmium	Wet	1.2	28	Engine starting, emergency lighting, station service
Silver oxide-cadmium	Wet	1.4	45–65	Space
Silver-zinc	Wet	1.55	90–155	Models, photographic equipment, missiles

molded into a cylinder around the carbon electrode, the whole is then set into the zinc cup, and the space between the molded mixture and the zinc is filled with electrolyte made into a paste in such a manner that it can be solidified by either standing or heating. The top of the cell is closed with a sealing compound, and the cell is placed in a cardboard container. The emf of a dry cell when new is 1.4 to 1.6 V.

In **block assembly** the dry cells, especially in the smaller sizes, are assembled in series and sealed in blocks of insulating compound with only two terminals and, sometimes, intermediate taps brought out. This type of battery is used for radio B and C batteries. Another construction is to build the battery up of layers in somewhat the manner of the old voltaic pile. Each cell consists of a layer of zinc, a layer of treated paper, and a flat cake of the manganese-carbon mixture. The cells are separated by layers of a special material which conducts electricity but which is impervious to electrolyte. A sufficient number of such cells are built up to give the required voltage and the whole battery is sealed into the carton.

Leclanché cells (carbon-zinc dry cells), in use for over 100 years, are still the most widely used of all dry-cell batteries because of their low cost, reliable performance, and ready availability. They are available in sizes ranging from small penlight batteries to large assemblies of cells in series or parallel connections for special high-voltage or high-current applications.

The **efficiency** of a standard-size dry battery depends on the rate at which it is discharged. Up to a certain rate the lower the discharge rate, the greater the efficiency. Above this rate the efficiency decreases (see *Natl. Bur. Stand. Circ.* 79, p. 39).

When used efficiently, a 6-in dry cell will give over 30 A · h of service. As ordinarily used, however, the dry cell give no more than 8 to 10 A · h of service and at times even less. The 1¼- by 2¼-in flashlight battery is usually employed with a lamp taking 0.25 to 0.35 A. Under these conditions 3 A · h or thereabouts may be expected if the battery is used for not more than an hour or so a day. The so-called "heavy-duty" radio battery will give about 8 to 10 A · h when efficiently used.

For the best results 6-in dry cells should not be used for current drains of over 0.5 A except for very short periods of time. Flashlight batteries should not be used for higher than the preceding current drain, and heavy-duty radio batteries will give best results if the current drain is kept below 25 mA.

Dry cells should be stored in a cool, dry place. Extreme heat during storage will shorten their life. The cell will not be injured by being frozen but will be as good as new after being brought back to normal temperature. In extreme cold weather dry cells may not give more than half of their normal service. At a temperature of about −30°F they freeze solid and give neither voltage nor current.

The amperage of a dry cell by definition is the current that it will give when it is short-circuited (at about 70°F) through an ammeter which with its leads has a resistance of 0.01 Ω.
