Operating Mechanism. Opening and closing of power circuit breakers under service conditions is seldom performed manually, since most breakers are installed in systems designed for remote control providing specific redundancy. Various means of operation are used, such as (1) dc solenoids, (2) solenoids operated from an ac source through a dry-type rectifier, (3) compressed air, (4) high pressure oil, (5) charged spring, and (6) electric motor. *Automatic reclosing* of breakers in overhead line feeders is frequently used to restore service quickly after a line trips out because of lighting or other transitory fault. Instantaneous or time-delay reclosing may be provided with a lockout to prevent more than one to several successive reclosures, as desired. If the fault is cleared before the lockout feature operates, the reclosing device resets itself, permitting a complete cycle of reclosing at a subsequent fault.

The circuit-breaker-operating device has to cope with the increasing requirements in interrupting and current-carrying capability as well as with shorter operating times. Simplicity of design, robustness, and reliability have to ensure safe operation of this vital link between the electrical system controls and the interrupter. The principle of a pneumatic drive is sketched for an extra-high-voltage circuit breaker which functions according to the differential piston principle in Fig. 10-71. A pneumatic interlocking device in connection with the SF_6 gas system ensures that the breaker always remains in the defined open or closed position even on loss of air pressure. Besides opening and closing functions, effective damping of the highly accelerated moving parts is incorporated.

Accessories. Circuit breakers may be equipped with a wide range of accessories, either required, like pressure controls, gas-density monitors, safety valves, and position indicator, or optional, such as a choice of different release, alarms, or auxiliary contacts. To illustrate the importance of accessories for safe and reliable circuit breaker operation, Fig. 10-72 shows the SF_6 gas monitoring system of a high-voltage SF_6 outdoor breaker.

The insulation and breaking capacity of an SF_6 breaker depends on the gas density. It is assumed that the volume remains constant during temperature variations, whereas the pressure of the SF_6 is highly dependant on temperature change. Hence, to monitor the state of the gas, it is logical to supervise not the pressure but the density of the gas.

The density monitor operates according to the principle of a temperature-compensated pressure gage, the characteristics of which correspond to the constant-density line. The SF_6 gas pressure acts on a metal bellows, the movement of which is transmitted by a transfer mechanism with a bimetal disk to the microswitch.

The density monitor is set for the operating pressure. The pressure-temperature diagram shows the standard case for this type of breaker, a minimum pressure of 5 bar, measured at 20°C. The density monitor emits a signal at 5.2 bar, indicating that refilling is necessary. If the pressure drops below 5 bar, operation of the breaker is blocked.

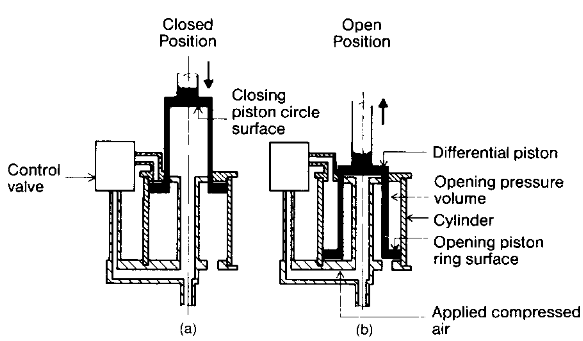

FIGURE 10-71 Principle of the drive system for an SF_6 outdoor breaker: (*a*) closed position; (*b*) open position.

10.2.5 Testing and Installation

Development and Design Testing of Circuit Breakers. Developing high voltage breakers requires attention to several different technical problems, including withstanding high voltages, short circuit interruption, continuous current capability, mechanical endurance, and environmental robustness. Testing programs are carried out to ensure that the circuit breaker is capable of withstanding these stresses. Test procedures for ac high-voltage circuit breakers are specified in IEEE C37.09[11].

High voltage. The breaker must carry current at high voltage, and be able to withstand transient surges at much higher levels (lightning strikes, for example). Typical test voltage levels are shown in Table 10-10.

Designing for these voltages requires specialized engineering software and knowledge. Dimensions are set for insulating gaps between contacts, and between live parts and the grounded surrounding structures (tanks, shields, etc.). Electromagnetic finite element analysis software is the main tool for this task. SF_6 breakers use pressurized SF_6 gas for insulation and arc quenching. This is because pressurized SF_6 insulates about 15 times better than air, meaning gaps can be much smaller for the same voltage and is vastly better for arc quenching (see Fig. 10-59).

High voltage testing requires "high voltage laboratory" capability with both power frequency "hi-pot" test capability, and also voltage surge ("lightning impulse" and "switching impulse") test capability (see Fig. 10-73).

TABLE 10.10 Typical Test Voltages for Outdoor High-voltage ac Circuit Breakers

Rated maximum voltage kV	Power frequency withstand voltage (1min. dry) kV, rms	Full wave withstand (BIL) kV, peak
15.5	50	110
38	80	200
72.5	160	350
145	310	650
170	365	750
245	425	900
362	555	1300
550	860	1800
800	960	2050

Short-circuit interruption. The most important function of circuit breakers is to interrupt short-circuit currents. This is to protect generators, transmission lines, transformers, and other components of the transmission system. Typical short-circuit requirements of high voltage systems are 25 to 63 kA, though there is an increasing need for 80+ kA. During a short circuit (fault), the circuit breaker is subjected to both high currents and voltages at the same time. Designing for this capability involves engineering simulations and computational fluid dynamic analysis. Testing is difficult, as the momentary test power requirements can exceed even that available on the transmission grid. Therefore, so-called "synthetic" techniques are used for this testing. Synthetic testing involves separate sources for the high current and high voltage, and only combining them during a very brief window of time. This greatly reduces the power requirements of simulating short circuit interruption. A typical high-voltage synthetic power lab is shown in Fig. 10-74.

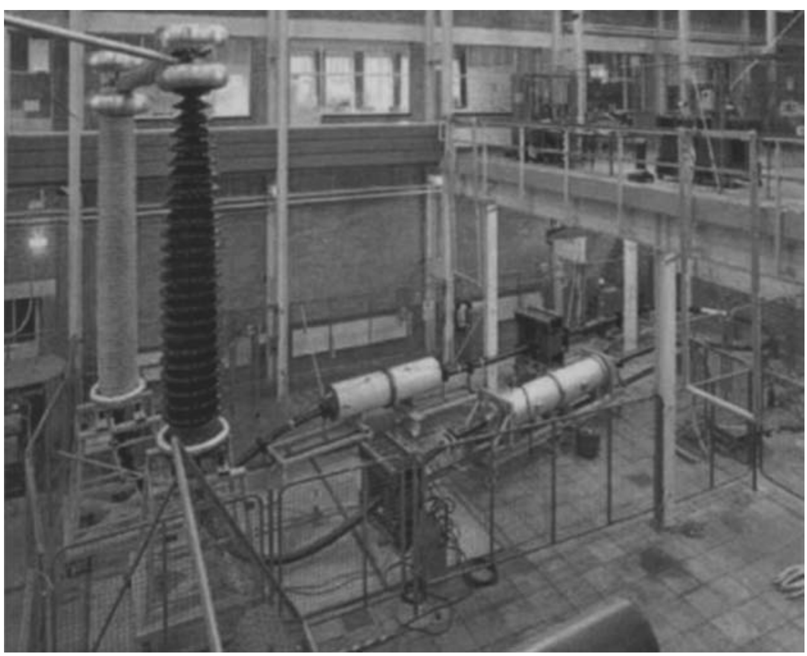

FIGURE 10-73 View of the B.V. KEMA high-voltage laboratory in Arnhem, The Netherlands. (*Courtesy of B.V. KEMA.*)

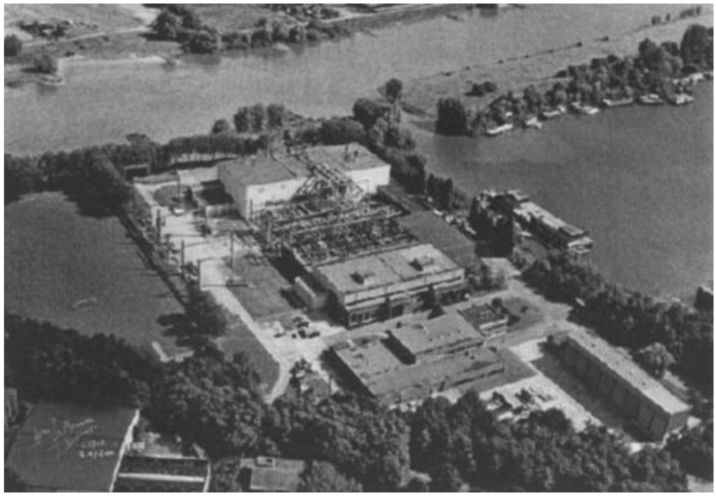

FIGURE 10-74 Aerial view of the B.V. KEMA high-power laboratory in Arnhem, The Netherlands. *(Courtesy of B.V. KEMA)*

The high current is typically supplied from dedicated "short-circuit generators," which are specialized machines in the 1000 to 3000 short-circuit MVA class (see Fig. 10-75). High voltage is supplied from a "high voltage synthetic circuit," which is a combination of capacitor banks, reactors, triggering, circuits, and computer controls (see Fig. 10-76). This synthetic circuit can produce a high voltage waveshape approximating real system recovery voltages.

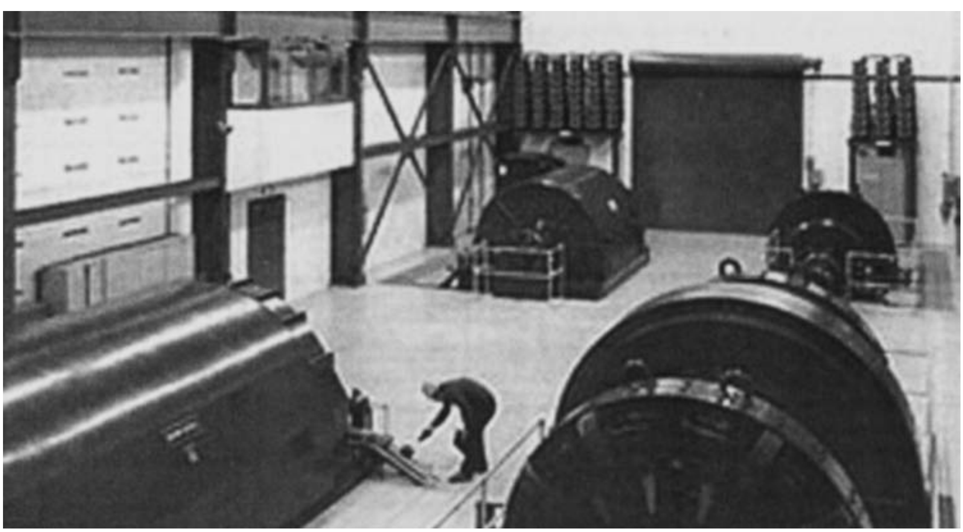

FIGURE 10-75 View of the KEMA-Powertest generator hall with 2,250 MVA and 1000 MVA short-circuit generators. *(Courtesy of KEMA-Powertest, Chalfont, Pa. USA.)*

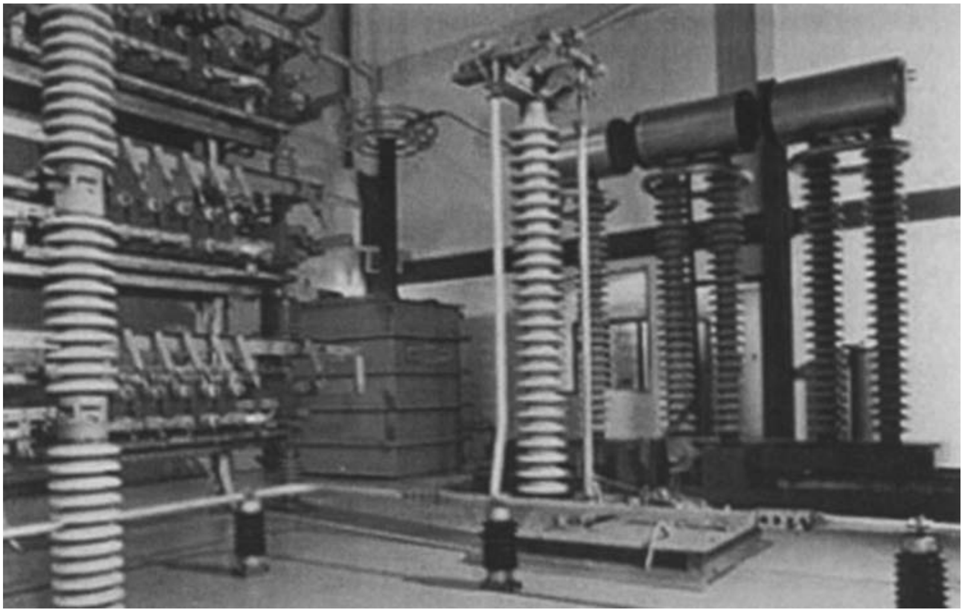

FIGURE 10-76 View of the KEMA-Powertest synthetic test circuit. *(Courtesy of KEMA-Powertest, Chalfont, Pa. USA.)*

In a real world, short-circuit interruption, a transient occurs following interruption which tries to reestablish the arc. This transient voltage must be synthesized by the test circuit and the required wave shapes differ widely between different breaker switching duties. A typical test involves initiating a short circuit with the high current circuit, and then at a "target" current zero simultaneously firing the high voltage synthetic circuit and switching out the high current circuit, (see Fig. 10-77).

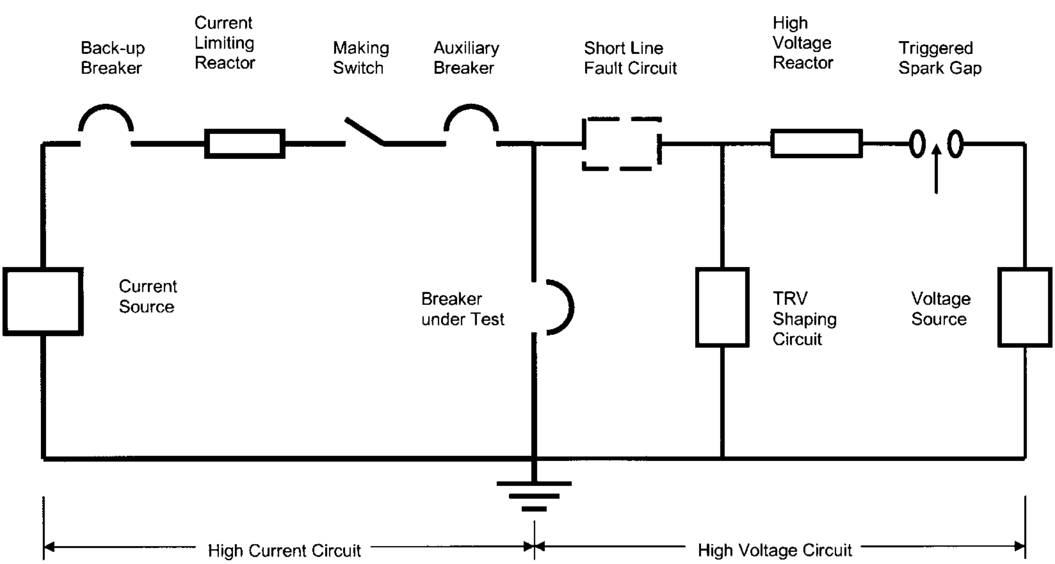

FIGURE 10-77 Parallel current injection test circuit.

The firing of the high voltage synthetic circuit provides correct short-circuit current *di/dt* at the target current zero, and also provides the correct recovery voltage waveshape after successful interruption. Variations of the basic synthetic test circuit are used to simulate different switching and interrupting duties on the power system. Unit testing—testing only one interrupting break of a multi-break circuit breaker—is accepted by all current standards, with some qualification.

Continuous current capability. Circuit breakers must carry a rated continuous load current without exceeding allowable temperature limits. This is demonstrated by testing with a suitable test transformer and voltage/current regulator.

Mechanical endurance. Circuit breakers are intended to operate for many years in service without significant amounts of maintenance. They also must be capable of withstanding many switching operations over that life. Required testing to at least 2000 switching operations is required by standards, though circuit breakers may be required to meet higher values depending on the application and required ratings.

Environmental. Circuit breakers are applied in all temperature zones and in many severe seismic zones. Climatic testing is carried out to verify operation at temperature extremes and to verify the performance of heating systems, when required. For example, SF_6 circuit breakers may require that the insulating SF_6 gas remain heated to a temperature of at least –30°C so that liquification does not reduce the gas density. Reduction of the insulating gas density below allowable levels may reduce insulating and interrupting capability such that the circuit breaker can no longer meet its rated performance (see Fig. 10-72).

Seismic withstand capability is demonstrated either by finite element analysis (FEA) or by shaker table testing, depending on the voltage class. Typically, testing is required at 245 kV and above, with FEA being acceptable below 245 kV. Standard requirements for seismic specification, testing, and application are detailed in IEEE 693[12].

Production Tests. Every circuit breaker is subjected to a series of routine production tests primarily intended to prove design conformance and quality. These tests typically include high voltage power frequency tests ("hi-pot"), mechanical operation and timing tests, fluid/gas leakage tests (when applicable), and control circuit operation verification.

Installation and field tests. These tests are carried out on-site according to specific users or manufacturer's instructions. Modern SF_6 breakers up to 245 kV are usually shipped fully assembled with a slight overpressure of SF_6, thus eliminating evacuation procedures on-site.

Service and Maintenance. With rising system voltages, currents, interrupting ratings, and the requirement for uninterrupted power supply, circuit breaker reliability becomes more and more important. Besides influencing factors of (1) design, (2) quality assurance, and (3) testing, which are mainly a responsibility of the circuit breaker manufacturer, maximum attention must be paid to the maintenance during service. Maintenance instructions for different makes and types of circuit breakers may differ considerably in details and volume, but all strive to obtain maximum breaker reliability despite longer maintenance intervals, smaller inventories of exchange parts, and shorter maintenance hours. Efforts are made to find the easiest way of handling service without influencing neighboring gear and consequently obtaining the lowest service costs. Utility maintenance shafts, standardizing groups, and circuit breaker developers have taken into account these requirements. The various steps from oil breaker to air-blast and finally the SF_6 and vacuum breakers indicate a considerable minimizing of maintenance combined with maximum reliability.

10.2.6 Low-Voltage Circuit Breakers

Application. Air circuit breakers are used on dc and ac circuits for the protection of general lighting, power, and motor circuits.

Distinction is made between various protection classes and different service and ambient conditions. For selection of a breaker, type and rating, operating speed, selectivity with fuses, and high voltage must be taken into account.

Further consideration has to be given to severe or hazardous service conditions like tropical climate or marine- or explosion-proof installations.

Reference is made to IEEE C37.13[13], C37.14[14], and C37.17[15]; UL-489[16]; and ANSI C37.16[17].

Ratings. Standard electrically and manually operated breakers are listed in ratings up to and including 5000 A ac and 12,000 A dc. Electrically operated breakers are available in higher current ratings for special applications. Standard breakers are rated on the basis of a temperature rise on the contacts and terminals not to exceed 50°C above an ambient of 40°C (class 90 insulation). Voltage ratings are 254 to 635 V ac and 250 to 3200 V dc.

The short-time current ratings are based on 3-phase symmetric short-circuit currents; the single-phase short-circuit current ratings are 87% of these values. For details, refer to the latest revisions of ANSI C37.16[17].

Assembly Variations. The breakers are usually installed in a metal-enclosed cubicle for dead-front or drawout type of construction. Metal barriers between breakers and busbars provide increased safety in service.

Hand operation by means of a lever is common, even on large breakers. Electric operation by means of a solenoid or motor mechanisms for 48, 125, or 250 V dc, or 120 or 240 V ac is obtainable on all but the smallest sizes of breakers.

Breakers are supplied with an overcurrent trip mechanism which may be of the instantaneous or the time-delay type, or a combination of both. Trip devices are adjustable over a wide range of ratings. Other trip devices and arrangements may be used, for example, undervoltage trips, shunt trips connected to overvoltage, reverse current, or overcurrent relays.

Multiple-pole circuit breakers are commonly used in practically all capacities, one pole being used for each ungrounded line of a circuit, that is, a 2-pole breaker for a 3-wire grounded circuit or a single-pole breaker for a 2-wire grounded circuit.

Breakers can usually be equipped with auxiliary contacts, alarm contacts, push-button control, position indicator, and key interlock. The widely used drawout type of breaker may be moved into and locked in the connected, test, and disconnected positions and/or completely withdrawn.

Refer to the latest revisions of IEEE C37.13[13], C37.14[14], and C37.17[15], and ANSI C37.16[17].

Air Circuit Breaker. The usual construction of an air circuit breaker (Fig. 10-71) makes use of two fixed terminals mounted one above and the other in a vertical plane, which, when the breaker is closed, are bridged under heavy pressure by a bridging member operated by a system of linkages. Auxiliary and arcing contacts close before and open after the main contacts. The arcing contacts are easily renewable. The breaker is held closed by a latch which may be tripped electrically or mechanically. Modern breakers are trip-free.

Many breakers use a solid bridging member with spring-mounted self-aligning contacts. The contact surfaces are made of silver so that oxidation will not cause excessive resistance and overheating.

Arcing contacts of modern breakers use a silver-tungsten or copper-tungsten alloy which is arc-resistant. The secondary contacts, where used, are usually of copper or silver alloy.

Barriers between poles are generally furnished with breakers on ac and dc circuits 250 V and above, and special arc chutes, quenchers, or deionizing chambers are also used throughout the available lines of air circuit breakers. These devices are made in different forms by different manufacturers and serve to improve the interrupting performance of the breaker and to shorten the arcing time.

Molded-Case Circuit Breaker. This circuit breaker is completely enclosed within a ruggedly constructed molded case of insulating material. It has received wide acceptance in the industry and is particularly adaptable in large buildings and industrial plants. The molded-case circuit breaker, in

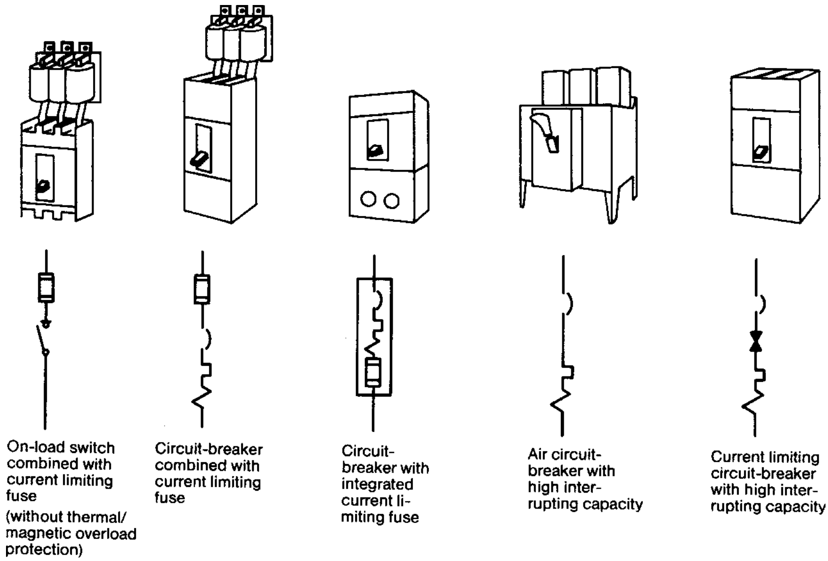

FIGURE 10-78 Methods of current-limiting in low-voltage circuits.

smaller sizes, is adaptable in home lighting circuits where convenience of automatic protection with manual reset of the breaker is desired.

Continuous current ratings range from 15 to 4000 A; the interrupting ratings are from 5 to 45 kA within the standard range. High interrupting ratings up to 200 kA are available.

For details of technical data, application, and accessories, refer to manufacturers' catalogs.

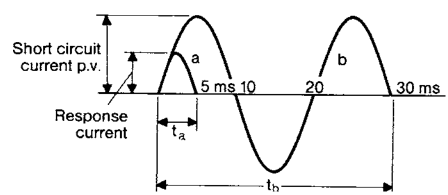

FIGURE 10-79 Current wave (*a*) with limitation, and (*b*) without limitation; t_a = total break time *a*; t_b = total break time *b*.

Current-Limiting Breaker. Low-voltage switchgear is more frequently connected to systems with high or extrahigh short-circuit currents. The standard-range circuit breaker cannot satisfy these requirements. Figure 10-78 outlines different ways to solve the problem. The current-limiting circuit breaker with high interrupting capacity offers a technically sound and economical solution.

Current-limiting breakers operate extremely fast. Interruption takes place within the first half cycle of short-circuit current, so the peak value is not reached. The total break time is less than 5 ms. Figure 10-79 illustrates the current curve, and Fig. 10-80 shows the current-limiting characteristic of a 100-A breaker. With an initial symmetric short-circuit current of 40 kA, the prospective peak value would be 82.5 kA, considering a dc component of 50% and power factor of 0.25. By using a current-limiting breaker, the peak value is limited to about 20 kA. The mechanical stress on the insulation is thus reduced considerably. The contacts in current-limiting circuit breakers are so arranged that the interruption is assisted by the electrodynamic action of the short-circuit current. The higher the short-circuit current, the faster the interruption takes place.

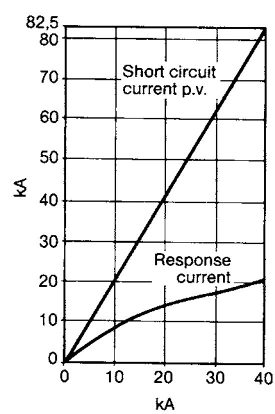

FIGURE 10-80 Current-limiting capability of a motor-protection circuit breaker, 100-A continuous current rating.

Because of the short opening time, the current-limiting circuit breaker, with suitable accessories, can be used to protect power electronic components. Rectifier circuits omitting fuses, for example can be built in this way.

10.2.7 High-Voltage Circuit Breakers

Application. High-voltage circuit breakers have been applied from 1 kV to up to 1100 kV. They are available in either live tank or dead tank design, and may incorporate various insulating and interrupting media as discussed in Sec. 10.2.1.

In today's market, SF_6 circuit breakers dominate above 38 kV, with vacuum circuit breakers being dominant in the "medium" voltage range between 15 and 38 kV. Air magnetic circuit breakers are also common up to 15 kV. Historically, oil circuit breakers were prevalent in these voltage ranges. Even though oil circuit breakers are out of production today, many remain in service.

Indoor breakers in the United States have been historically magnetic air or air-blast types. Today vacuum circuit breakers dominate for indoor application, but there are a few SF_6 types.

For guidance in circuit breaker selection and application, refer to the latest revisions of IEEE C37.12[18], C37.010[6], C37.011[7], and C37.012[8].

Ratings. Standard short circuit currents range from 12.5 to 63 kA, with some applications requiring 80 kA. Commercially available continuous current ratings range from 600 to 5000 A. Preferred ratings are defined in IEEE C37.06[3].

Ratings differentiate between indoor and outdoor service. Preferred ratings are further established for capacitive current switching, dielectric withstand and external insulation, transient recovery voltage capabilities, switching surge factors for line closing, control voltages, reclosing times, and operation endurance capabilities.

Refer to IEEE C37.04[2] and C37.06[3] for the rating structure and preferred ratings.

Oil Circuit Breakers. Oil circuit breakers are out of production today, but many remain in service. These breakers were classified as either dead tank "bulk oil" circuit breakers, or as live tank "minimum oil" circuit breakers. Oil circuit breakers use oil as both an arc quenching and insulating medium, with dead tank "bulk oil" designs using oil as the primary insulation to ground, within a grounded tank.

Dead tank "bulk oil" circuit breakers consist of a steel tank partly filled with oil, through the cover of which are high voltage entrance bushings. Contacts at the bottom of the bushings are bridged by a conducting crosshead carried by a wood or composite lift rod. The breaker typically opens by spring action, separating the interrupting contacts and also further separating an isolation break below the contact system. Accelerating springs are used to increase the speed of opening. In some designs, the crosshead is opened with a rotary motion by springs. Breakers with 3 poles in one tank were made up to 69 kV. Higher voltages had separate tanks for each pole. Figure 10-53 shows a typical dead tank "bulk oil" circuit breaker and Fig. 10-81 shows a typical interrupter.

Minimum oil circuit breakers were developed mainly in Europe to reduce the quantity of oil in circuit breakers. They were manufactured for indoor applications up through 38-kV and outdoor applications up through 800-kV, but were mainly used in the medium voltage range for indoor service. The layout of a medium voltage minimum oil circuit breaker is shown in Fig. 10-82.

Vacuum Circuit Breaker. Progress in high-vacuum technology and breaker development, combined with improved manufacturing and testing methods, has opened a growing area for vacuum breaker application, concentrating, but not limited to voltages up to 38 kV, continuous current ratings up to 3000 A, and covering all standard interrupting ranges. The principal design of a vacuum interrupter is shown in Fig. 10-83.

Two contacts are mounted on an insulating envelope from which virtually all air has been evacuated. One contact is stationary, the other movable. Vacuum interruption has the inherent advantage of moving a lightweight contact only a very small distance in an almost perfect dielectric medium. This results in safe, quiet, and fast switching or interruption of load or fault currents.

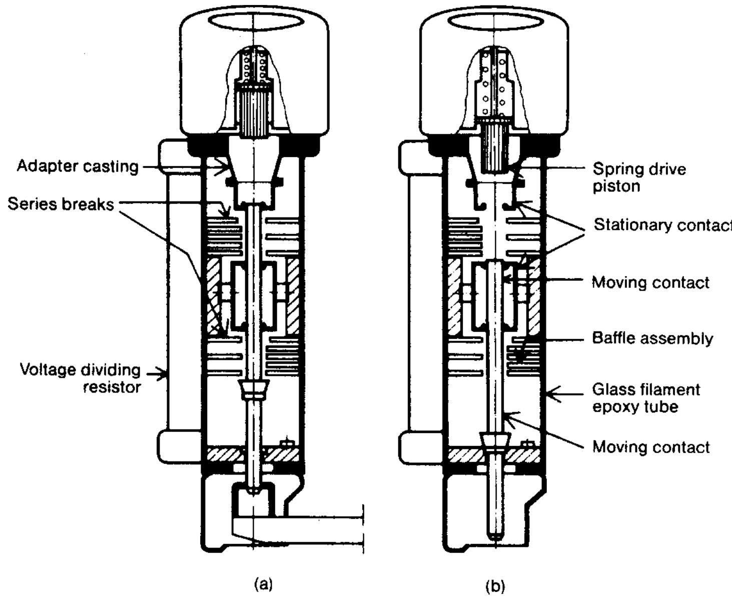

FIGURE 10-81 Details of a 161-kV outdoor oil circuit breaker interrupter: (*a*) closed position; (*b*) open position.

The moving contact is opened up to full gap distance by means of a driving mechanism. A metal-vapor arc discharge thus occurs in the contact gap through which the current flows until the next current zero. The arc is quenched at current zero.

The metal-vapor plasma is fully deionized within a few microseconds by diffusion and recombination so that the conduction path very quickly recovers its dielectric strength. Figure 10-84 shows details of a horizontal-drawout vacuum circuit breaker. One or more interrupters may be utilized in

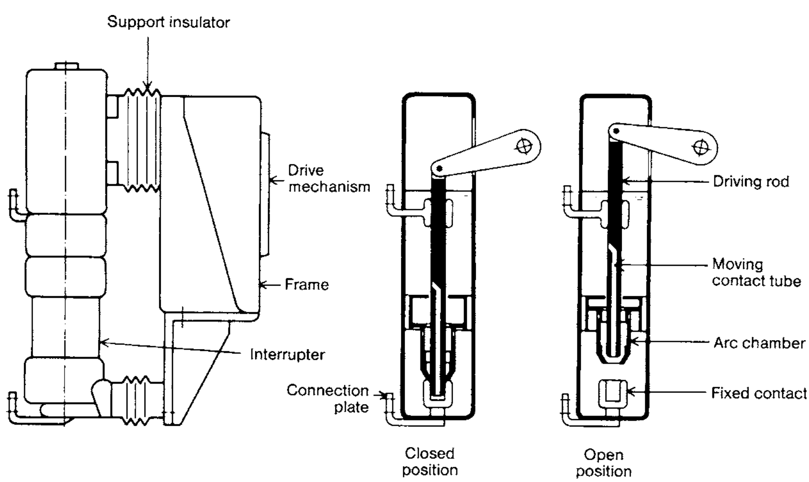

FIGURE 10-82 Outline and interrupter details of a 15-kV, 3-pole minimum-oil circuit breaker. *(Courtesy of ABB T&D Company, Inc.)*

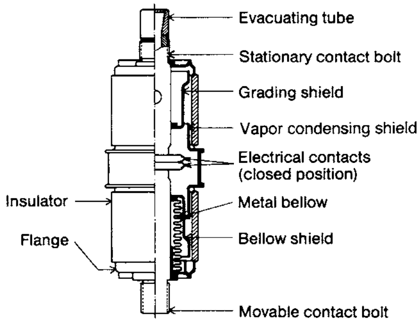

FIGURE 10-83 Partial section of vacuum interrupter 23 kV, 2000 A, 21 kA. *(ABB T&D Company, Inc.)*

series per pole. Vacuum interrupters may additionally be protected against outside influences by an insulating casing. They may also be fitted with hand- or motor-charged stored-energy-operated mechanisms.

Because of their fast closing and opening times, vacuum circuit breakers are particularly suitable for autoreclosure and synchronizing duty. Breaking of the short-circuit currents with very steep initial rise of transient recovery voltage is possible due to restoration of the dielectric strength of the contact gap within a few microseconds. The steep rise of dielectric strength over the whole current range offers a high capacitive-current-switching capability. Switching of unloaded transmission lines and cables can therefore reliably be performed.

Magnetic Air Circuit Breaker. Magnetic air circuit breakers are no longer manufactured. This type of circuit breaker is usually stored-energy mechanism-operated and interrupts the main circuit in the normal atmosphere under the influence of a strong magnetic field which acts to force the arc deep into a specially designed arc chute (see Fig. 10-85). Solenoid operating mechanisms are available. The arc chute cools and lengthens the arc to a point where the arc cannot be maintained by the voltage of the system, and interruption is accomplished. The zone between the main contacts is clear of ionized air by the time interruption is obtained in the arc chute, and so restiking at this point is no problem. Since the magnetic effect is not great at low currents such as small load, transformer magnetizing, and cable-charging current, all designs use an air-pump "puffer" actuated by the operating mechanism that blows a blast of air across the arc and thereby ensures its entering the arc chute and giving rapid interruption at the low-current values also. When the circuit breaker is opened, the arc transfers from the main arcing contacts to fixed arc runners which are within the arc chute. The magnetic field is produced by coils in the main-current circuit, in some cases wound around a magnetic core which magnetizes soft-iron plates in the sides of each arc chute. Some designs do not require an iron core.

Magnetic air breakers were available in any of the ratings of Table 2 of ANSI Standard C37.06-1987 (or earlier) through 15- kV. All were designed for use in metal-clad enclosures. Figure 10-86 shows the horizontal-drawout type of breaker in metal-clad enclosure. Although the design shown is for indoor use only, the same circuit breakers are placed in weatherproof housings for outdoor

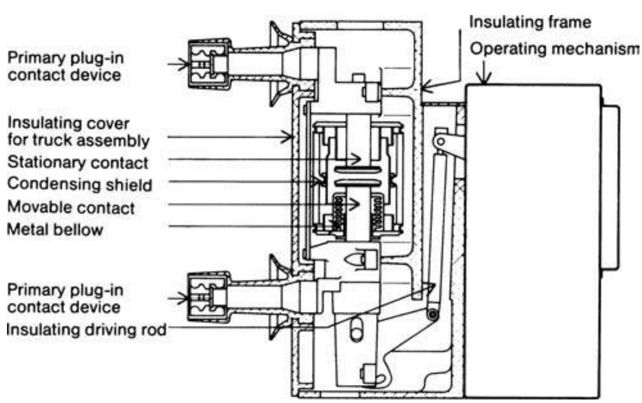

FIGURE 10-84 Outline and interrupter details of a 15-kV horizontal-drawout vacuum circuit breaker 2000A, 28 kA. *(ABB T&D Company, Inc.)*

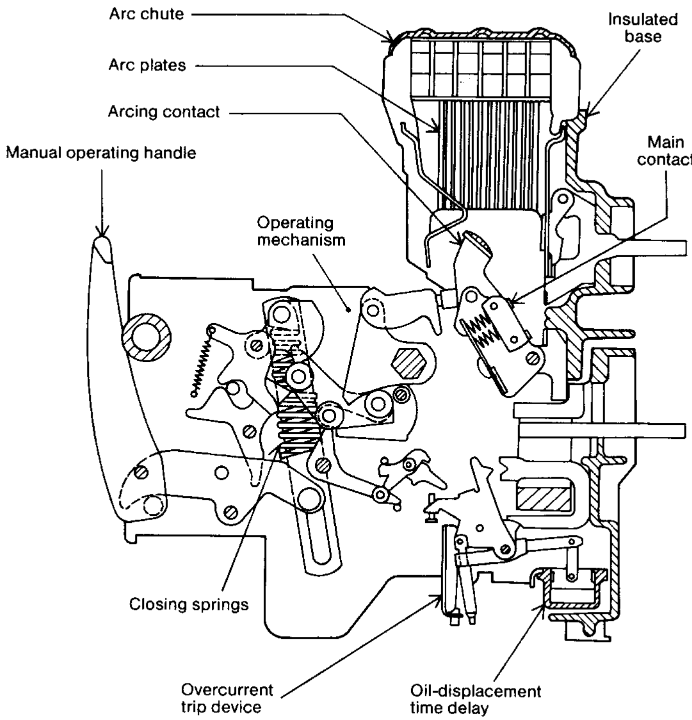

FIGURE 10-85 Typical low-voltage air circuit breaker with magnetic air chutes; breaker in the open position.

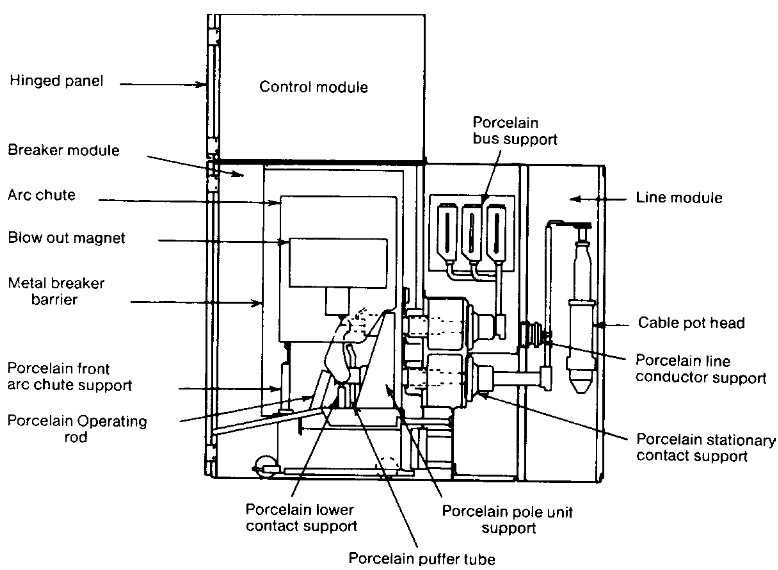

FIGURE 10-86 Horizontal-drawout, metal-clad magnetic circuit breaker in service position.

service. When they are so used, suitable heaters are put in the housings to avoid internal moisture condensation.

Air-Blast Circuit Breakers. Air-Blast circuit breakers are no longer manufactured. These breakers fulfilled the heavy-duty requirements of circuit breakers in high-voltage systems. They have been used to provide the indoor ratings up to 38 kV. They were, however, mainly used in outdoor applications up to 800 kV. Today they have been replaced by SF_6 technology at most ratings.

Air-blast circuit breakers have been used for special applications as (1) generator breakers with continuous current ratings of up to 42 kA and higher, (2) furnace breakers with an extra high number of switching operations (20 to 50 duty cycles per day), and (3) extra high interrupting currents. Air-blast circuit breakers were usually fixed-mounted, but a variety of breaker types were available truck-mounted for application in drawout metal-clad switchgear. All air-blast circuit breakers make use of dry and clean air compressed to a certain pressure, which may differ for the various make and types of breakers. The compressed air is used to operate the breaker as well as to serve as the medium for arc quenching and insulation.

Continuous current ratings up to 5000 A were possible. Total breaking time of 2 cycles (from energizing of trip coil until are extinguishing) was standard; special designs may allow for even shorter breaking time. Some 69-kV breakers are equipped with sequential isolators, but the bulk of designs did not integrate the isolator to form part of the circuit breaker. Some older designs employed separate chambers for opening and closing operation, but later air-blast breakers perform opening and closing with the same contact system. Closing resistors and/or, with some designs, opening resistors were often used. Equal voltage distribution over the multiple breakers of one pole was usually achieved by parallel capacitors.

Generator Circuit Breakers. Generator circuit breakers represent another class rated for very high continuous currents and short-circuit currents, typically at generator voltages. Generator breakers are incorporated into generator bus ducts and can include other switchgear components for measuring current, detecting faults, and grounding.

Generator breakers are available up to 50 kA nominal current and up to 220 kA interrupting current. Two technologies are employed—air blast at the higher ratings (see Fig. 10-87) and SF_6 self-blast at the lower and medium power levels (up to 120 kA). For nominal currents above 20 kA, the generator breaker is usually equipped with a forced cooling system, using water, for example. Generator breakers have been available since the 1960s.

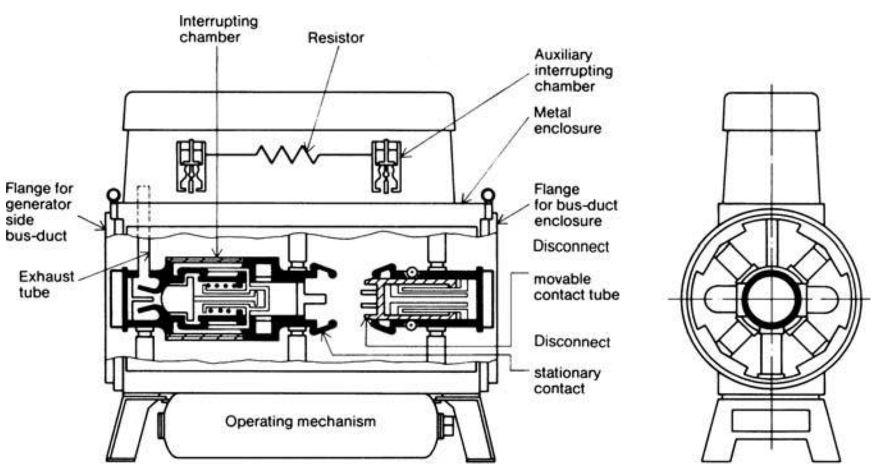

FIGURE 10-87 Outline and interrupter details of a generator air-blast circuit breaker-type DR, 36 kV, up to 50 kA with forced cooling, 200 kA.

Advantages of using generator breakers include the following:

Reduced station cost by eliminating station transformers and increasing station layout flexibility.

Simplification of operation, especially during commissioning and recommissioning; this is because the generator can be handled as a separate unit, isolated from the main and unit transformers.

Fault protection between the generator and transformer. Two zones of protection are created and generator faults are cleared by the opening of the generator breaker alone.

Unbalanced load protection of the generator.

Protection of the generator from transformer faults.

Reliability/availability increase.

Historically, generator circuit breakers have been of air-blast design with pneumatic operators. This is the technology still used today for large nuclear and fossil fuel power plants (up to 1500 MW), and large pumped storage installations. The design has a tubular housing and is horizontal.

Newer designs utilize SF_6 self-blast technology and hydraulic operators. These are rated for application to smaller power plants (gas turbine/cogen, for example) from 60 to 400 MW and smaller pumped storage installations.

SF_6 Circuit Breakers. SF_6 gas has proven to be an excellent arc quenching and insulating medium for circuit breakers. SF_6 is a very stable compound, inert up to about 500°C, non-flammable, non-toxic, odorless, and colorless. At a temperature of about 2000K SF_6 has a very high specific heat, and high thermal conductivity, which promotes cooling of the arc plasma just before and at current zero, and thus facilitates quenching of the arc. The electronegativity behavior of the SF_6, that is, the property of capturing free electrons and forming negative ions, results in high dielectric strength and also promotes rapid dielectric recovery of the arc channel after arc quenching. SF_6 breakers are available for all voltages up to 1100 kV, continuous currents up to 5000 A for conventional breakers (higher for generator breakers), and short-circuit interruption up to 80 kA.

SF_6 breakers of the indoor type have been incorporated into metal-clad switchgear (see Fig. 10-88). Outdoor designs include both dead tank (see Fig. 10-54) and live tank circuit breakers (see Figs. 10-56 and 10-57).

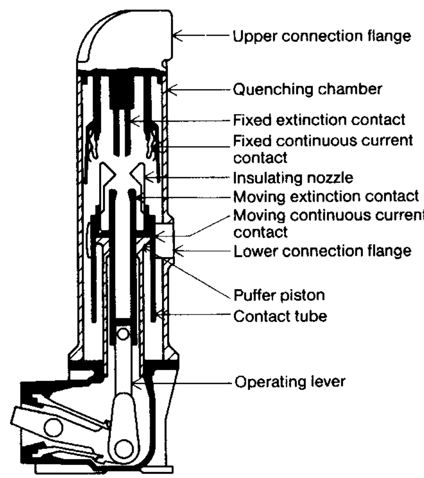

FIGURE 10-88 Section of a SF_6 puffer-piston indoor circuit breaker, 23 kV.

Over the years, SF_6 circuit breakers have reached a high degree of reliability; thus they can cope with all known switching phenomena. Their closed-gas system eliminates external exhaust during switching operations and thus perfectly adapts to environmental requirements. Their compact design considerably reduces space requirements and building and installation costs. In addition, SF_6 circuit breakers require very little maintenance.

All ratings are economically satisfied by the modular design. Each pole is equipped with one or more interrupters; stored energy, spring, hydraulic, or pneumatic driving mechanisms are provided for each pole or 3-pole unit. Gas-density monitors are standard.

Figure 10-89 illustrates the opening sequence of a typical puffer breaker. In the closed position, the current flows over the continuous current contacts and the complete volume of the breaker pole is under the same pressure of SF_6 gas.

The precompression of the SF_6 gas commences with the opening operation. The continuous current contacts separate and the current is transferred to the arcing contacts.

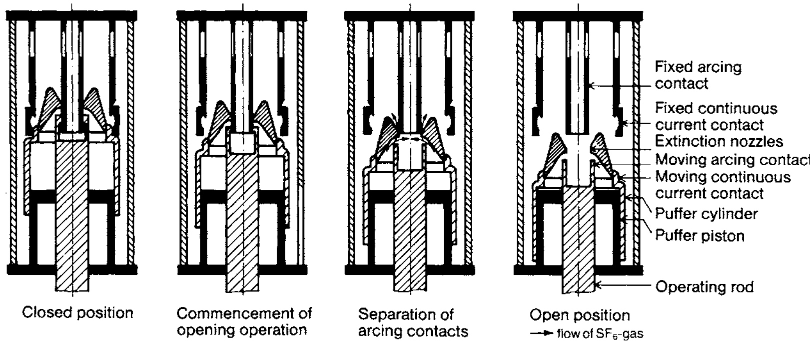

FIGURE 10-89 Principle of SF_6 puffer-type interrupter showing four positions during opening operation.

At the instant of separation of the arcing contacts, the pressure required to extinguish the arc is reached. The arc produced is drawn and at the same time exposed to the gas, which escapes through the ring-shaped space between the extinction nozzle and the moving arcing contact. The escaping gas has the effect of a double blast in both axial directions.

Until the open position is reached, SF_6 gas flows out of the puffer cylinder. The existing overpressure maintains stability of the dielectric strength until the full value of the open contacts at the rated service pressure is reached.

The *self-blast principle* of interruption is illustrated in Fig. 10-90. In the case of high-current interruption, arc energy heats the gas, resulting in a pressure rise in the static volume (heating volume) V_1. This pressure then quenches the arc at an ensuing current zero. In the low-current case an auxiliary puffer (volume, V_2) generates sufficient pressure for interruption. Necessary force requirements for the mechanical system are therefore drastically reduced.

All ancillary equipments, including the oil pump and accumulator associated with the drive, form a modular assembly that is mounted directly on the circuit breaker, thus eliminating installation of piping on the site. The *metal-enclosed GIS breaker* is provided with the necessary items to fit into the substation arrangement (see Fig. 10-91). The main equipment flanges of the breaker are fitted with contact assemblies to accept the isolator moving contacts. Other equipment modules can be coupled to the same flanges. On the fixed-contact end of the circuit breaker, provision is made for coupling two modules, facilitating the mounting of an extension module to connect the second busbar isolator.

Dead tank SF_6 breakers typically employ gas-filled *bushings*, illustrated in Fig. 10-55. Such bushings are usually integral to the circuit breaker itself and are not interchangeable with other apparatus bushings. Electrical grading is provided by a lower throat shield. Ring-type bushing current transformers are located at the base of the bushing. Potential taps are not generally available in SF_6 bushings because of the lack of a capacitive grading structure.

Porcelain alternatives, such as composites, have been used to provide greater safety (explosion resistance), easier handling (lighter and nonbrittle), seismic performance (lighter and stronger), and pollution performance.

Current transformers (CTs) for dead-tank breakers are of the ring-type bushing design. Outdoor breakers of the live-tank layout are generally provided with freestanding CTs of the paper-oil-insulated or SF_6 design (see Fig. 10-57).

For oil-filled CTs, hermetical seal of oil is either of the fixed design with gas cushion or of the pressure-free bellow type. Up to six magnetic cores can be provided per CT unit, generally in multiratios for 5- or 1-A secondary by means of secondary taps. Primary-current ratings up to 2000 A normally employ the wound-type design with two or more turns. Higher primary currents up to 6000 A require the inverted or head design, with a straight tube as single-turn primary winding and the core

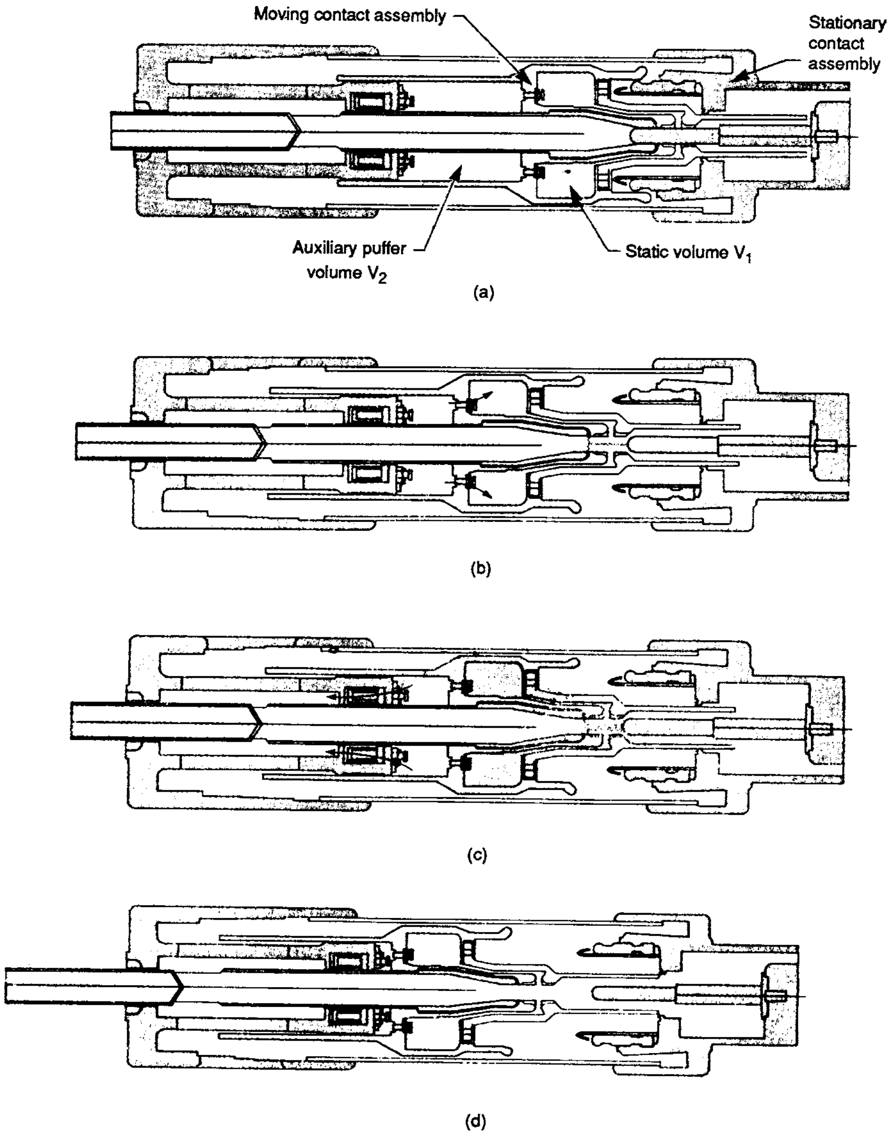

FIGURE 10-90 Self-blast principle of interruption: (*a*) full-closed position; (*b*) low-current interruption; (*c*) high-current interruption; (*d*) full-open position.

and secondary-winding assembly arranged at the CT top to limit temperature rise and to increase the mechanical withstand capability of the CT. The latter design has its full main insulation on the secondary winding.

Freestanding CTs are available for all output and accuracy requirements for modern system relaying and measuring for voltages up to 800 kV. For the upper voltage ranges, freestanding CTs are normally provided with separate potential layers. The CTs are generally dimensioned for the same dielectric and mechanical characteristics chosen for the related circuit breaker.

10.3 SWITCHGEAR ASSEMBLIES

By JEFFREY H. NELSON, MICHAEL W. WACTOR and TED W. OLSEN

Definitions of terms used in this section can be found in the IEEE standards and application guides referenced in this section and/or in the *IEEE Authoritative Dictionary of Terms*. The term "low voltage" as used in this section refers to rated voltages up to 1000 V ac and 3200 V dc. The term "medium voltage" as used in this section refers to rated voltages above 1000 V ac up to 38 kV ac.

Switchgear assemblies cover a wide range of low-voltage and high-voltage *structures that are generally factory* assembled and are divided into the following main groups: (1) metal-enclosed low-voltage power circuit breaker switchgear, (2) medium-voltage metal-clad switchgear, (3) metal-enclosed interrupter switchgear, (4) metal-enclosed bus, and (5) switchboards. ANSI/IEEE C37.20.1[1], C37.20.2[2], C37.20.3[3], C37.23[4] and NEMA PB-2[5] apply. Any of these equipment types may be rated as "arc resistant metal-enclosed switchgear" by successfully meeting the requirements of ANSI/IEEE C37.20.7[6].

10.3.1 Metal-Enclosed Low-Voltage Power Circuit Breaker Switchgear

Metal-enclosed low-voltage power circuit breaker switchgear indicates a design which contains low-voltage ac or dc power circuit breakers in individual grounded metal compartments. The circuit breakers can be either stationary or drawout; manually or electrically operated; fused or unfused; and either 3-pole, 2-pole or single-pole, construction. The switchgear may also contain associated control, instruments, metering, protective and regulating equipment as necessary. Definitions, ratings, design and production tests, construction requirements, and guidelines for application, handling, storage, and installation are covered in IEEE C37.20.1[1].

Low-voltage metal-enclosed switchgear is typically installed in industrial plants, utility and cogeneration facilities, and commercial buildings for the protection and distribution of power for loads such as lighting, machinery, motor control centers, elevators, air conditioning, blowers, compressors, fans, pumps, and motors. Low-voltage switchgear is available in ac ratings up to 635 V and 5000 A continuous and in dc ratings up to 3200 V and 12000 A continuous. Short-circuit current ratings are available up to 200 kA.

10.3.2 Metal-Clad Switchgear

The term "metal-clad switchgear" indicates a design providing metal barriers between primary sections of adjacent vertical sections and between major primary sections of each circuit. Primary sections comprise the bus compartment, the primary entrance compartment, the removable element compartment, the voltage transformer(s) compartment, and the control power transformer(s) compartment. Low-voltage control equipment such as metering, relays, instruments, and controls are located in compartments separate from the primary voltage components. To minimize the possibility of communicating faults between primary sections, the barriers between primary sections shall have no intentional openings. Barriers may be provided to segregate the voltage transformers for each polyphase circuit but not to segregate them individually. Where buses penetrate barriers, suitable bushings or other insulation is required. Definitions, ratings, design and production tests, construction requirements, and guidelines for application, handling, storage and installation are covered in IEEE C37.20.2[2].

Circuit breakers are generally the vacuum type, although air-magnetic circuit breakers were used for many years. Circuit breaker disconnection is accomplished by horizontal-drawout design, illustrated in Figs. 10-92 and 10-93, respectively. Interlocks are provided in metal-clad assemblies to prevent disconnecting or connecting the circuit breaker while in the closed position and to prevent breaker operation while moving between disconnected and connected position or vice versa. The metal-clad assembly is equipped with shutters to protect personnel from coming in contact with the high-voltage circuits when the circuit breaker is removed from the cubicle. A circuit breaker test position is standard to allow breaker control with the main contacts (primary disconnecting devices) removed from the primary circuit, but maintaining auxiliary and ground contacts between cubicle and breaker truck.

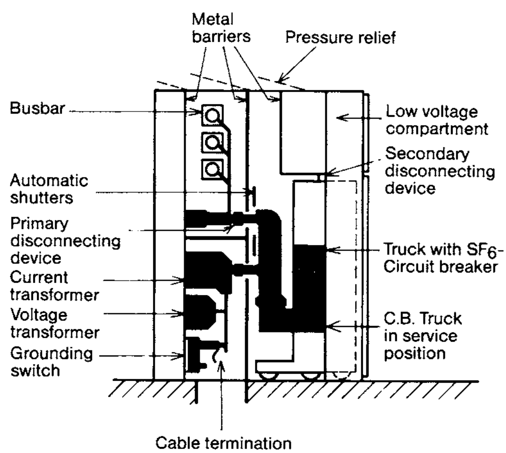

FIGURE 10-92 Side view of a 15-kV metal-clad switchgear unit with horizontal-drawout circuit breaker, interchangeable either minimum oil, SF_6 or vacuum design of equal rating.

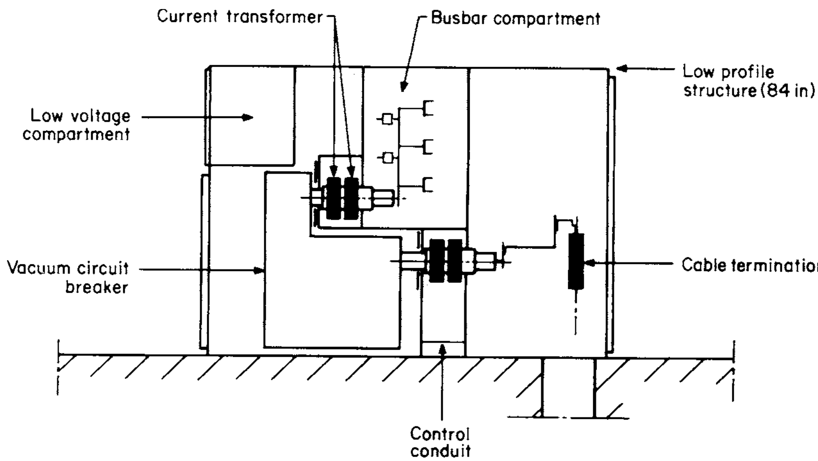

FIGURE 10-93 Side view of a 38-kV metal-clad switchgear unit with horizontal-drawout vacuum circuit breaker, type HKV, up to 3000 A, fan cooled, 22 kA.

Metal-clad switchgear is used for low- and medium-capacity circuits, for indoor and outdoor installations with nominal voltages of 2.4 to 34.5 kV and continuous current ratings typically up to 3000 A. Short-circuit withstand current ratings of the switchgear should equal the ratings of the circuit breaker used.

10.3.3 Metal-Enclosed Interrupter Switchgear

Metal-enclosed interrupter switchgear assemblies include the following equipment as required: interrupter switches, bare bus and connections, selector switches, power fuses (current-limiting or noncurrent-limiting), control and protective equipment, instrumentation, meters, and instrument transformers. The interrupter switches and power fuses may be stationary or removable (drawout). When switches and fuses are removable, mechanical interlocks are provided for proper operating sequence. Also, automatic shutters are provided which cover primary circuit elements when the removable device is in the disconnected, test or removed position.

Definitions, ratings, design and production tests, construction requirements, and guidelines for application, handling, storage, and installation for metal-enclosed interrupter switchgear are covered in IEEE C37.20.3[3].

Metal-enclosed interrupter switchgear is typically used in industrial or institutional environments where continuous load currents are low and frequent switching is not required. Interrupter switches will interrupt load currents up to their rated continuous current capability. Fuses can be installed to provide short-circuit protection. For example, if the interrupter switchgear is connected to other switching equipment fuses can be installed in the connection between the two to prevent an interruption of one assembly for a fault in the other assembly.

Typical applications for interrupter switchgear include main service disconnect, transformer primary and secondary switching, medium voltage switchgear primary and feeder circuit switching. The switching device may be manually operated or motor operated. Motor operated designs are often applied in an automatic transfer scheme.

Metal-enclosed interrupter switchgear is typically available in ac ratings above 1 kV to up to 38 kV and 2000 A continuous current. Short-circuit withstand ratings have to be equivalent to the ratings of the switching and protective equipment used or to the rating of the current transformers used.

10.3.4 Metal-Enclosed Bus

Metal-enclosed bus is an assembly of rigid conductors with associated connections, joints and insulating supports with a grounded metal enclosure. Metal enclosed buses have three basic types of construction: (1) nonsegregated-phase, (2) segregated-phase, and (3) isolated phase.

Rated voltages of ac metal-enclosed bus assemblies range from 635 V through 38 kV, and dc metal-enclosed bus assemblies range from 300 through 3200 V. Definitions, service conditions, ratings, testing, construction requirements, and application guidelines for metal-enclosed bus are covered in IEEE C37.23[4]. An informative guide for calculating losses in isolated-phase bus is also included.

Nonsegregated-Phase Metal-Enclosed Bus. *Nonsegregated-phase metal-enclosed bus* is a type of design in which all phase conductors, with their associated connections, joints, and insulating supports, are enclosed in a common metal housing without barriers between phases, see Fig. 10-94. When associated with metal-clad switchgear, the phase conductors of a non-insulated bus assembly entering the switchgear assembly and connecting to the switchgear bus shall be covered with insulating material equivalent to the switchgear insulation system. Enclosures that are totally enclosed are preferred, but ventilated enclosures can be provided in indoor applications.

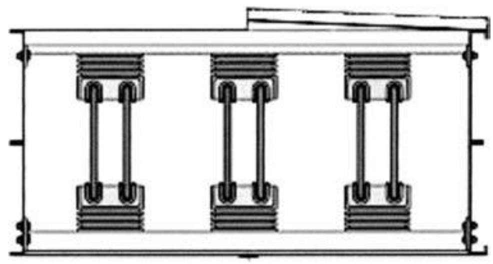

FIGURE 10-94 Typical nonsegregated-phase metal enclosed bus. *(Courtesy of Powell Industries, Inc.)*

Nonsegregated-phase metal-enclosed bus is utilized on circuits which require higher reliability than can be obtained with the application of power cables. Typical applications are the connections between transformers and switchgear assemblies, connections from switchgear assemblies to rotating apparatus, tie connections between switchgear assemblies, connections between motor control centers and large motors, and as main generator leads for small generators.

Preferred continuous self-cooled current ratings for nonsegregated-phase are available up to 12,000 A for 635 V ac and all dc voltage ratings, 6000 A for 4.75 through 15.5 kV, and 3000 A above 15.5 through 38 kV. Short-time withstand current ratings up to 85 kA rms symmetrical are available for ac ratings, and up to 120 kA for dc ratings.

Segregated-Phase Metal-Enclosed Bus. Barriers may be installed between the phase conductors to segregate the conductors and the assembly is then referred to as *"segregated-phase metal-enclosed bus,"* see Fig. 10-95. This design is also used on circuits which require a higher degree of reliability.

Segregated-phase bus is primarily used as generator leads in power plants, but it is also applied in heavy industrial environments and as tie connections in metal-enclosed substations.

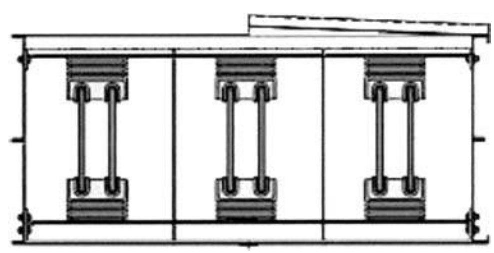

FIGURE 10-95 Typical segregated-phase metal enclosed bus. *(Courtesy of Powell Industries, Inc.)*

Preferred continuous self-cooled current ratings for segregated-phase are available up to 12,000 A for 635 V ac and all dc voltage ratings, 6000 A for 4.75 through 15.5 kV, and 3000 A above 15.5 through 38 kV. Short-time withstand current ratings up to 85 kA rms symmetrical are available for ac ratings, and up to 120 kA for dc ratings.

Isolated-Phase Metal-Enclosed Bus. *"Isolated-phase metal-enclosed bus"* is a type of design in which each phase is enclosed in an individual metal housing, and an air space is provided between the housings. It is considered to be the safest, most practical, and most economical way of preventing phase-to-phase short circuits by means of construction methods. The bus may be self-cooled or force-cooled by circulating air or liquid. Definitions, ratings, design and production tests, construction requirements, and application guidelines for metal-enclosed bus are covered in IEEE C37.23[4].

Briefly, the isolated-phase bus duct has the following features:

1. Proof against contact; locked electrical premises not necessary
2. Faults only in the form of ground faults; protection against fault spreading to more than one phase
3. Field forces, static and dynamic, only between enclosures and conductor, not between phases
4. Protection against contamination and moisture
5. No losses in surrounding conductive material (grilles, railings, concrete reinforcements, lines, etc.)

The range of bus ducts are available up through 38 kV and includes continuous current ratings from about 5 up to 25 kA self-cooled, or 40 kA with forced cooling. The momentary current ratings have to match the rating of attached equipment. With high current ratings, more attention must be paid to the following:

1. Progressive rise of conductor temperature due to skin effects
2. Heating of surrounding conducting material by the magnetic field of conductors
3. High forces on main or component conductors in the event of a short circuit

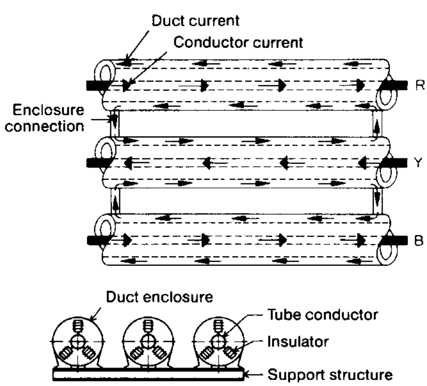

FIGURE 10-96 Three-phase arrangement of an isolated-phase bus duct and principle of enclosure connection; according to Kirchhoff's law sum of conductor currents (+) and sum of duct currents (−) is zero.

In an enclosure with sections of tube insulation (sectional enclosure), eddy currents exist with values as large as the conductor current. These give rise to heat losses, and so the magnetic field of the main conductor is not always compensated for sufficiently. An important technical feature of the bus duct, therefore, is the electrically continuous enclosure. The tubes enclosing each phase have electric conducting joints throughout their length and are short-circuited across the three phases at both ends. The enclosure thus constitutes a secondary circuit to the conductors (Fig. 10-96). The currents in the enclosures reach almost the corresponding conductor currents, depending on the resistance of the duct, but are of the opposite direction. The magnetic field outside the enclosure is almost completely eliminated, and thus there are no external losses or field forces between the phases. Connections to machines and switchgear must be adaptable and removable.

Current transformers for measurement and protection are of the bushing type or are integrated into the bus duct at a suitable place. Voltage transformers can be contained in the bus duct or mounted in separate instrument boards. The same applies to protective capacitors. Care must be taken that branch lines are adequately dimensioned with regard to thermal short-circuit strength.

The reliability of generator bus ducts can be enhanced by employing means to maintain the air pressure in the duct. Although, generally bus ducts are leakproof, the large number of dismantleable joints may cause a slight leakage and might lead to moisture condensation during a plant shutdown. Supplying the bus duct with filtered, precompressed air at slight pressure ensures that the air flow is

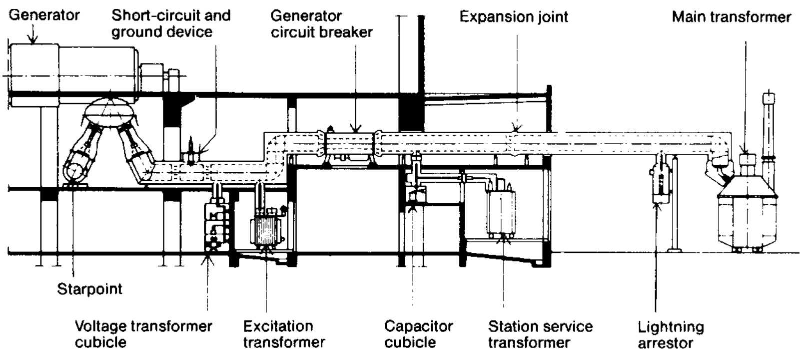

FIGURE 10-97 Generating-plant isolated-phase bus-duct arrangement with generator circuit breaker type DR.

only outward; contamination of the conductors is not possible. Drying the air by precompressing prevents condensation.

Short-circuiting and grounding facilities are required in the bus duct to protect the generator and also for maintenance grounding purposes. Manually positioned links and straps are sufficient for small unit ratings; motor-operated grounding switches are recommended for higher capacities. A typical isolated-phase bus arrangement of a power station including generator circuit breaker is shown in Fig.10-97.

10.3.5 Switchboards

Floor-mounted deadfront "*switchboards*" typically consist of an enclosure, molded case or low-voltage power circuit breakers, fusible or nonfusible switches, instruments, metering equipment, monitoring equipment and/or control equipment, and are fitted with associated interconnections and supporting structures. Switchboards can consist of one or more sections which are electrically and mechanically interconnected. Main disconnect devices can be mounted individually or be an integral part of a panel assembly. Definitions, ratings, design and production tests, construction requirements, and guidelines for application, handling, storage and installation are covered in NEMA PB-2[5].

Switchboards are typically installed in industrial plants, utility and cogeneration facilities, and commercial and residential buildings for the distribution of electricity for light, heat, and power. They are typically available in voltage ratings of 600 V or less, continuous current ratings of 6000 A or less, and short-circuit current ratings up to 200 kA.

10.3.6 Arc-Resistant Metal-Enclosed Switchgear

The term "arc-resistant switchgear" indicates a design in which the equipment has met the requirements of ANSI/IEEE C37.20.7[6]. The switchgear assembly is subjected to an internal arcing fault in key locations throughout the assembly for a specified current level and duration and the equipment performance is evaluated against five basic criteria. The arcing fault is initiated by a small wire placed across the primary conductors which vaporizes when current flows, providing an ionized air path for the arc. The preferred current level for this test is the short-circuit rating of the equipment and the preferred duration for current flow is 0.5 s. The equipment is evaluated for its ability to mitigate conditions which could be hazardous to personnel working

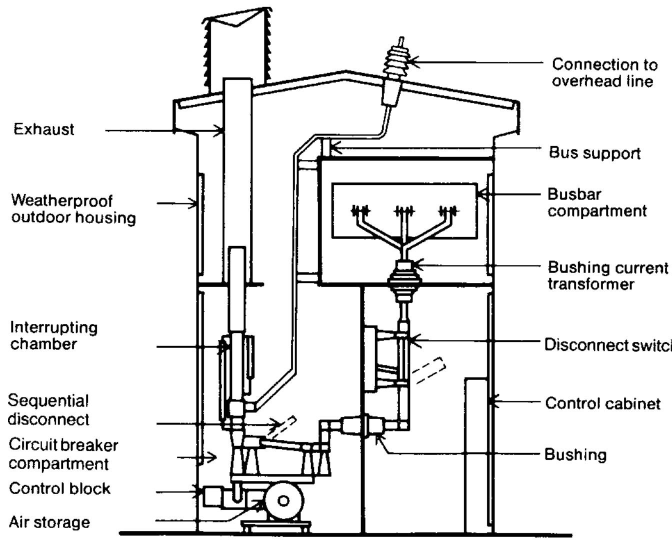

FIGURE 10-98 Metal-enclosed station-type switchgear cubicle for outdoor installation; equipped with a heavy-duty, air-blast circuit breaker, 14.4 kV, 3000 A, 50 kA.

nearby. Definitions, ratings, test requirements, and guidelines for application and installation are covered in IEEE C37.20.7[6].

10.3.7 Station-Type Switchgear

Another type of switchgear assembly that was previously used is "*station-type switchgear*." Station-type switchgear is no longer manufactured, but is briefly discussed here for historical purposes.

The term "station-type switchgear" indicates a design in which the major component parts of a circuit, such as buses, circuit breakers, disconnecting switches, and current and voltage transformers, are in separate metal housings, and the circuit breakers are of the stationary type (Fig. 10-98). Phase segregation in metal-enclosed switchgear is a type of design in which a 3-phase metal housing is divided into three single-phase compartments by means of single metal barriers.

Metal-enclosed station-type switchgear was used in industrial, commercial, and utility installations, generally for voltages of 14.4 to 69 kV, and continuous current ratings up to 5000 A.

10.4 VOLTAGE REGULATORS

BY CRAIG A. COLOPY

A primary objective of any electrical system is to provide power users with a supply voltage compatible with their utilization equipment. Every electrical device is designed to operate at a certain rated voltage for optimum efficiency and maximum length of service. An ideal electrical supply system provides constant voltage to all users under all loading conditions. No system is ideal; it is economically impractical to attempt an "ideal system" design approach. Today's ideal system is that system providing a voltage supply satisfactory to all utilization equipment, with the most economical use of available regulation equipment.

Several methods of improving the voltage profile on electric transmission or distribution systems are in use. These include transformer load-tap changers, switched and fixed capacitors, and single and three-phase step-voltage regulators. Another new approach, static var control, employing thyristor phase-angle firing control of fixed capacitors is being applied experimentally on several high-voltage transmission systems. Application of single-phase, step-voltage regulators dominates the distribution market to a great extent. They are used in substations having up to 30 MVA loads, as well as being applied to distribution feeders and laterals.

An economical means of voltage regulation is desirable to provide power users with a voltage supply compatible with utilization equipment. The following list describes the effects of unregulated voltage:

1. Resistance loads (electric stoves, irons, water heaters, toasters, etc.)
   a. Low voltage
      (1) Longer heating time.
   b. High voltage
      (1) Shorter life of heating elements.

2. Motor loads (vacuum cleaners, washing machines, fans, refrigerators, etc.)
   a. Low voltage
      (1) Increased slip-increased line current under excited motor. Results: (*a*) decreased efficiency and (*b*) motor overheating.
   b. High voltage
      (1) Overexcited motor-increased torque. Result: possible damage to coupling or appliance.

3. Electronic loads (radio and television)
   a. Low voltage
      (1) Poorer quality of reception on television sets: (*a*) picture not distinct and (*b*) decreased picture size.
   b. High voltage
      (1) Shortens life of electronic components.

4. Illumination loads (incandescent and fluorescent lighting)
   a. Low voltage
      (1) Decreased incandescent lamp efficiency; a 10% decrease in voltage results in 70% normal illumination output.
      (2) If voltage is too low, fluorescent lamps will be inoperative.
   b. High voltage
      (1) Life expectancy of bulbs decreases.

Of course, many benefits of regulated voltage provided to consumers also benefit suppliers by virtue of decreased investment per kVA distributed, increased efficiency of distribution equipment, and increased revenue. The intangible benefit of customer satisfaction must not be overlooked.

10.4.1 Methods of Regulation

The first regulators were induction-type machines. These appeared very early in the development of the electric power industry and were used extensively for a number of years. An induction regulator consists of a rotor and a stator much like a motor. Like step regulators, induction regulators take voltage from the source and add to or subtract from it to hold the load voltage steady. Output voltage is changed by mechanically adjusting the position of the rotor relative to the stator. The rotor does not rotate continuously but has its position changed as required by a small, internal self-contained motor. This motor responds to a signal from a control circuit.

Step-type voltage regulators, the precursors of modern design, were introduced in the early 1930s. The first step-type regulators were developed from the autobooster concept. A 2400-/120- V distribution transformer connected as an autotransformer gives a 5% boost. Adding a center tap to the secondary (series) winding gives two $2^1/_2$% steps. Adding two more taps give four $1^1/_4$ steps. A preventive autotransformer (or bridging reactor) divides these steps in half to give the modern $^5/_8$% steps. In a ±10% regulator, thirty-two $^5/_8$% steps, 16 above and 16 below neutral, provide regulation to all types of loads. Step-type voltage regulators are actually tapped autotransformers. An autotransformer is a transformer in which part of one winding is common to both the primary and the secondary circuits associated with that winding. In other words, the primary (exciter) winding is both electrically and magnetically connected to the secondary (series) winding. The exciter winding is common to both primary and secondary; the series winding is connected in series with load (output) current. Step-type voltage regulators are commonly provided in both single-phase and three-phase styles.

Transformer load-tap changers (commonly referred to as LTC transformers) are actually combination transformers and step-type regulators. The tap-changing mechanism is mounted in an oil-filled compartment which is commonly sealed from the core and coil. Tap changing is accomplished by a gang-operated, three-phase oil switch providing simultaneous regulation of the three-phase voltages.

Fixed and switched capacitors are not voltage regulators in the electrical definition of the device. Capacitors are used to improve the line-voltage profile by connecting a "bank" of capacitors in shunt. These shunt capacitors first improve an otherwise lagging power factor "seen" by a source. The effect of the improved power factor will be reduced line losses and improved regulation. The use of capacitors beyond that required to attain unity power factor will result in a leading component of current in the line inductance, causing voltage on the line to rise. As long as total line current remains lagging, capacitors provide an improved voltage profile. When total current is leading, however, shunt capacitors increase line current (and line losses) and may cause a large voltage rise, resulting in excessively high voltage.

Static var systems (SVS) involve effectively regulating (or fine tuning) the reactive compensation afforded by the shunt capacitors by virtue of phase-angle firing control of thyristors. Basically, the thyristor conduction period will establish the capacitive (leading) current. The control system used is very rapid relative to system fluctuations, permitting optimization of the application. Other features of SVS, especially its use in improving system stability, have made it feasible for exploration on transmission systems. Thus far, SVS application at distribution voltages has been justified only for very large bulk power supplies.

Method of Step-Voltage-Regulator Operation. A typical step-voltage regulator (Fig. 10-99) involves a shunt winding, a series winding, and a bridging reactor or preventive autotransformer.

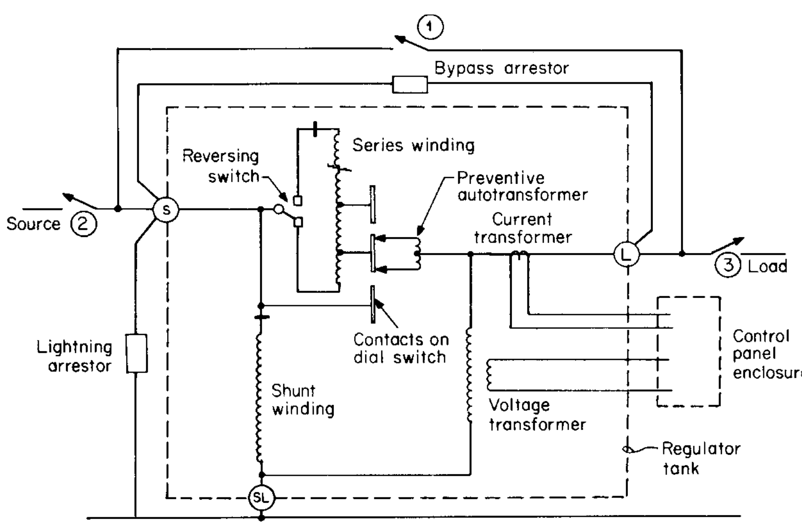

FIGURE 10-99 Wiring diagram of a typical distribution step-voltage regulator showing both external and internal connections, with preventive autotransformer shown on a nonbridging position: (1) bypass switch; (2) source switch; (3) load switch.

Taps, each representing essentially $1^1/_4\%$ voltage, are affixed to the series winding and brought to a specially designed dial switch.

The *main transformer* comprises the *shunt winding* and the *series winding* (Fig. 10-100*a*). The series winding most often is rated at 10% voltage of the shunt winding. Usually eight taps on the series winding are brought to a *dial-switch* assembly as individual contacts, with the voltage difference between contacts being $1^1/_4\%$ voltage.

The terminals of a center-tapped *preventive autotransformer* are able to transit (slide) between the dial switch contacts in a manner which avoids momentary loss of load. As one finger advances to the next step, arcing results because of the inductive nature of the reactor, but load current is maintained (Fig. 10-100*b*) through the finger which does not part contact. When the parting finger remakes on the adjacent contact, a bridging condition is established (Fig. 10-100*c*). A circulating current is established through the preventive autotransformer (PA), or a center tapped bridging reactor, and load voltage is seen to be the average voltage of the taps being bridged. To minimize the arc duration, a *quick-break mechanism* accelerates the moving contacts. The rapid separation of the contacts and the use of contact tips composed of a tungsten-carbon alloy mitigate the attendant ablation of contact material.

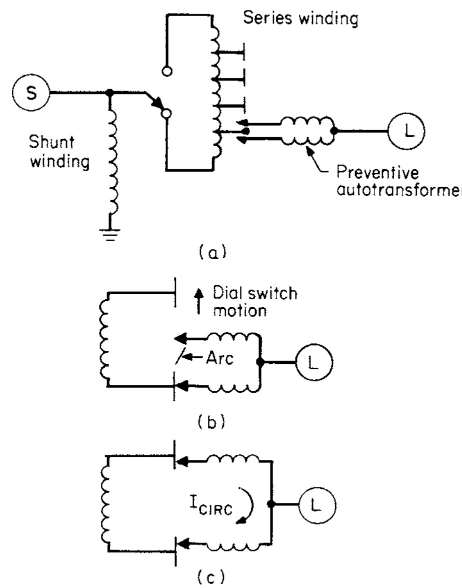

FIGURE 10-100 Operations of the internal mechanisms of the regulator.

A *reversing switch* permits the polarity of the series winding to be reversed relative to the shunt winding, thereby accommodating plus and minus regulation with the same series winding.

A *voltage transformer* and *current transformer* are used to provide voltage and current supplies, respectively necessary for the control to perform its function.

Dielectric protection of the series winding is afforded by the *bypass arrestor.* A surge propagated on the line will be shunted past the regulator. *Lightning arrestors,* often provided at both the source and the load terminals, similarly protect the regulator from overvoltage surge conditions.

Other external appurtenances will include the three bushings (source, load, and SL or common), a *tap position indicator* display of the present operating position of the regulator, and a *control panel enclosure.*

Regulator Control Circuitry. This technology has progressed from a mechanically driven regulating relay beam to highly sophisticated, microprocessor-based digital control circuitry. All regulator controls comprise three major parts:

1. A *voltage-sensing device* which monitors the output voltage of the regulator and sends a signal to the motor drive circuity
2. An *amplifying or switching section,* with or without time delay, which delays and/or transmits the signal
3. A *motor drive circuit* which responds to the signal by closing relay contacts or actuating electronic switches that cause the tap-changing motor to operate the tap changer correct the voltage

The important functions of the typical regulator control are shown in the block diagram in Fig. 10-101.

An *auxiliary voltage source,* such as a nominal 120-V tertiary winding on the main coil and/or a separate voltage transformer, will be provided to supply power to the tap changer motor and the base voltage for deriving the regulator output voltage. This 120 V is scaled down in a *sensing trans-*

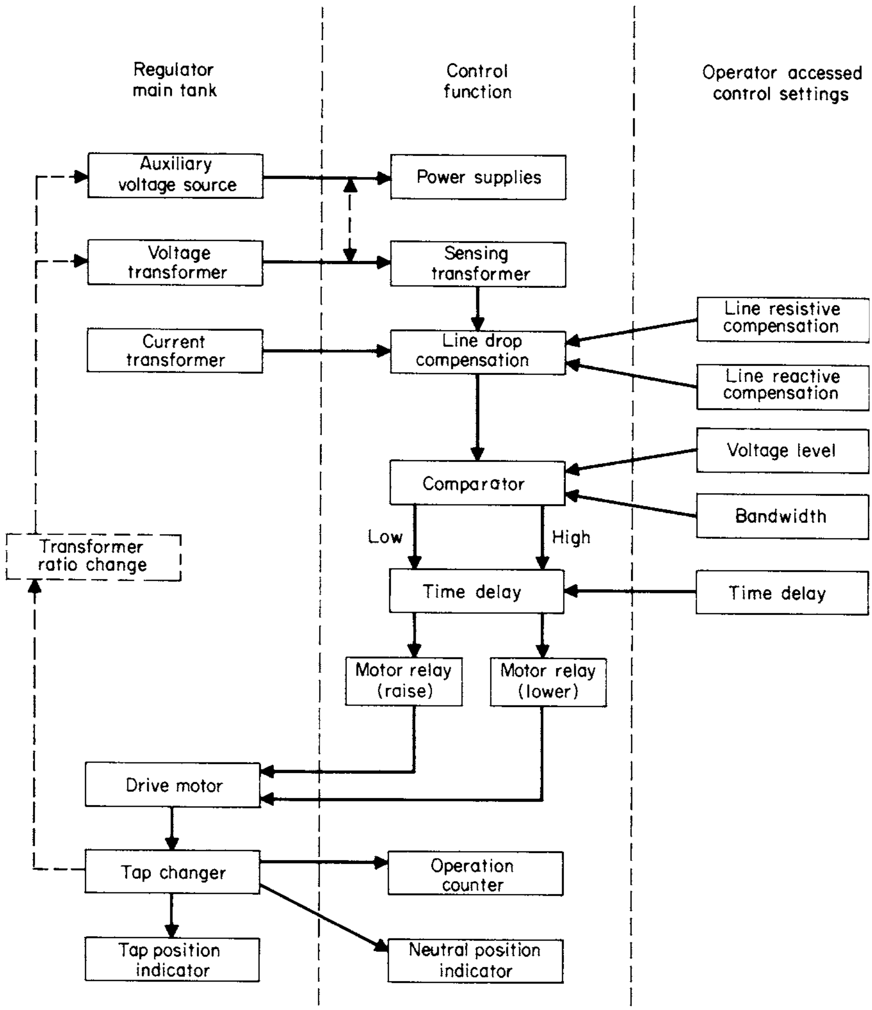

FIGURE 10-101 Regulator control functions.

former which may itself be tapped to facilitate ratio adjustment if the voltage source is not exactly as required. The output of the sensing transformer will, by operator selection, be altered to reflect the voltage drop between the regulator and the load. This drop, which is a function of the load current and the line impedance, is modeled by knowing the current from a *current transformer* and established *line resistive compensation* and *line reactive compensation* parameters.

The voltage, now compensated for line drop, is related in a *comparator* to the desired voltage level as established by a *voltage-level* setting and a *bandwidth* or tolerable voltage range limits setting.

If the compensated voltage exceeds the high limit (or is less than the low limit), a *time delay* is activated. Requiring the voltage to remain out-of-band for a period of typically 30 to 60 s assures that the voltage-level change is of sufficient duration to warrant regulator action.

After the preset delay is satisfied, a *drive motor* is powered and runs the *tap changer* to the next position. Tap-changer motion advances the *operation counter,* moves the *tap position indicator* pointer, and causes illumination of a special *neutral position indicator* light, if in neutral position.

Of course, the new tap position in turn causes a *transformer ratio change,* altering the input to the sensing transformer and closing the control function loop.

10.4.2 Application of Regulators

The rating of single-phase step-voltage regulators is a simple function of the rated range of regulation and the current. For example, a 100-A regulator with a ±10% range of regulation for a 7620-V system will be rated

$$100 \text{ A} \times 0.10 \times 7620 \text{ V} = 76.2 \text{ kVA}$$

Early recognition that this is 10% of circuit kVA will avoid later difficulties.

The ampere rating of regulators can be increased by limiting the range of regulation to accommodate higher line currents. By limiting the range of regulation, the portion of series winding through which line current passes is decreased. This decrease in the portion of series winding "seeing" load current decreases the internal regulator losses. By decreasing losses, heating inside the regulator is decreased. Consequently, the regulator may carry more load current for the same temperature rise. For example, a 100-A regulator, ±10%, may be operated at ±5% regulation at 160 A. Limit-switched taps and overload capabilities are, by ANSI standards, 8 $^3/_4$% (110%), 7$^1/_2$% (120%), 6$^1/_4$% (135%), 5% (160%), to a limit of 668 A.

Oil-immersed step-type regulators, by ANSI standards, are rated at 55°C average winding temperature rise. A 65°C hot-spot winding temperature is also specified in regulator standards. The short-circuit withstand capacity of standard regulators is 25 times normal full-load current for 2 s.

Using single-phase regulators in three-phase installations is a very common application. Configuring the regulators in wye, closed delta, and open delta are acceptable alternatives, depending on system conditions.

The wye connection is invariably used on grounded-neutral 4-wire systems. Regulator sizing is a straightforward adaptation of single-phase principles.

The use of three single-phase regulators in closed delta requires that recognition be made of how current will flow in the regulator. Especially important is the fact that system line current and regulator series winding current are not the same. The application will be specified based on load current, but the current in the regulator series winding will establish the regulator size required. Also, the closed-delta application results in a ±15% range of regulation in the line voltage for a ±10% range section on the individual single-phase regulators. Another point which is significant when modeling for line-drop compensation or sensing a power reversal is to note that the current and voltage signals from the regulators will be displaced by 30° (lead or lag) at unity power factor of the load.

An open-delta connection is sometimes used to save expense. This system is like a wye connection in that line current and series winding current are identical, but like a delta in that the 30° phase shift occurs; in fact, in this case the shift is leading in one regulator and lagging in the other.

The various regulator connections utilize the installed kVA of regulators with differing efficiency. For each 1000 kVA of system capacity, the use of ±10% regulators will require total regulator capacity of as given in the following table:

Grounded wye	100 kVA
Closed delta	123 kVA
Open delta	115 kVA

Another important consideration when applying single-phase regulators in three-phase installations is that certain single-phase regulator connections may be unsafe. In deciding on the proper and safe connection for a given application, three basic phenomena should be considered (1) third harmonics, (2) system line surges, and (3) line faults.

For instance, when single-phase regulators are grounded on an ungrounded system, a resonant circuit is possible between the third-harmonic magnetizing reactance of the regulators and line capacitance. This resonance can intensify third-harmonic voltages to unsafe levels. A similar situation can occur when regulators are ungrounded on either a grounded or an ungrounded system. To protect from line surges, regulator connection is unimportant as long as a bypass arrester and line-to-ground arresters are used. Line-to-ground fault problems may be serious when regulators are ungrounded on a grounded system or grounded on an ungrounded system. A problem may also occur when regulators are connected in either open- or closed-delta configuration on a grounded system. Table 10-11 summarizes safe and unsafe single-phase regulator connections. A feature of regulators is that they may be bypassed in service such that load interruption is not necessary during installation procedures. It is critical that proper switching procedures be followed to avoid the extremely high circulating current which will appear in the series winding if bypassing occurs at other than the neutral tap position. When placing a regulator on the line (see Fig. 10-101), three switches are commonly used: a source switch, load switch, and bypass switch. To place the regulator in service, first the source switch is closed. The regulator is checked out by running the tap changer in the raise and lower directions. The regulator is returned to the neutral position, and the load switch is closed. Caution must be taken to make sure that the regulator will not make an automatic tap change when the load switch is closed. After the load switch is closed, the bypass switch may be opened. To take the regulator out of service, the procedure is reversed. First the regulator is run to the neutral position, the bypass switch is closed, the load switch is opened, and then finally the source switch is opened. Once again, caution must be taken to prevent the regulator from making an automatic tap change during this switching procedure by assuring isolation of the control power.

Regulators may be paralleled if and only if sufficient loop impedance exists to limit circulating currents, based on the maximum difference in the voltages of the two circuits V_1 and V_2. Equally important, the percent impedances of the two circuits must be equal or very close. The common practice is that the two impedances must be close enough so that circulating current does not exceed 10% of rated current when operating on equal voltage taps. For impedance Z_1 of circuit 1 and Z_2 of circuit 2, percent circulating current is given approximately by

$$\%\ \text{circulating current} = \frac{Z_1 - Z_2}{Z_1 + Z_2} \times 100$$

When regulators are paralleled, it is necessary that the tap-changing mechanisms be on as nearly the same tap position as possible. If they are not, a circulating current of magnitude $I_c = (V_1 - V_2)/(Z_1 + Z_2)$ will flow in the loop. The most widely used method for paralleling regulators is the "current-balance" method. Circulating current is separated from load current by means of auxiliary current transformers. This current is fed into the voltage reference circuit to cause the unit to change taps to reduce the circulating current.

Regulators are often applied in series, or cascaded, on the same feeder. In this application, two or more regulators operate to control the voltage profile along with a distribution line. The most important

TABLE 10-11 Safe and Unsafe Regulator Connections

Regulator connection	System connection	Effect: Third harmonic	Effect: Line surges	Effect: Line ground	Conclusion
Grounded Y	Grounded	S	S_1	S	S
Ungrounded Y	Grounded	U	S_1	U	U
Delta	Grounded	S	S_1	S_2	S_2
Open delta	Grounded	S	S_1	S_2	S_2
Grounded Y	Ungrounded	U	S_1	U	U
Ungrounded Y	Ungrounded	U	S_1	S	U
Delta	Ungrounded	S	S_1	S	S
Open delta	Ungrounded	S	S_1	S	S

Key: S = Safe; S_1 = safe if suitable bypass series winding protection is supplied; S_2 = conditionally safe—overexcitation of regulators may lead to their failure if fault allowed to persist; U = unsafe.

consideration in such applications is the time-delay settings on the regulator controls. The modern solid-state control is adjustable from at least 15 to 105 s. When regulators are cascaded, the first regulator (at or closest to the substation) should be set with the shortest time delay, with progressively longer delays farther away from the station. If the settings are reversed, the farthest regulator would attempt to correct all voltage fluctuations first. As the load change appeared at the other regulators on the line, each would attempt to compensate for it in order. When finally the substation unit reacted, it would raise the overall voltage level, making it necessary for each successive unit down the line to back down accordingly.

Setting of the regulator control must be accomplished with care to assure proper regulator operation and proper supply voltage for the users.

The voltage-level setting is the voltage which the regulator is to maintain at its output, expressed on a 120- V base. (Note that this will be the voltage at the "load center" if line-drop compensation is used, as explained later.)

To avoid a hunting condition of the regulator, a *bandwidth* is set to define the limits of acceptable voltage about the voltage-level setting. The stated bandwidth is the total range, such that a regulator set for 120 V with a 2-V bandwidth will be "in-band" if the output is in the range of 119 to 121 V. The bandwidth setting must be larger than the voltage change expected from a single tap change or a hunting situation will occur. Beyond this, it is a qualitative judgment; a lower setting will maintain a closer output voltage tolerance, a higher setting will reduce tap-changer operations, extending the regulator life.

The *time delay* is the time duration outside of the prescribed band required before tap-changer actuation. As noted earlier, this is very important in cascaded operations. Otherwise, it will be set at typically 30 to 60 s to avoid unduly quick responses to line-voltage fluctuations.

The use of *line-drop compensation* will cause the regulator to hold the voltage-level setting at a point remote from the regulator, rather than at the regulator location. The classic illustration of the application of line-drop compensation involves a "load center" some miles from the substation. It is required to hold a given voltage at the load. Given that the line is inductive in nature, this implies holding a higher voltage at the substation, the incremental voltage increase being a function of the line impedance (resistive and reactive) and the line current. Thus, the two line-drop compensation settings are the resistive and reactive models of the line, calibrated in a 0- to 24-V basis, reflecting the drop to be anticipated (on a 120-V base) between the regulator and the load when the system is carrying rated regulator current.

Tables are provided with the regulators to use in determining the proper settings. A simplified example demonstrates the procedure:

1. The wye-connected regulators are rated 76.2 kVA, 7620 V (= 100 A).
2. The load center is 4 mi from the regulators.
3. The feeder to the load center is 2/0 ACSR on 36 in center spacing.

The solution to this example is as follows:

1. Tables provided with the regulator will show
   - ***a.*** Line resistance $\simeq$ 0.90 Ω/mi
   - ***b.*** Line reactance $\simeq$ 0.77 Ω/mi
2. Calculate compensation as
   - ***a.*** $$\frac{\text{CT primary rating}}{\text{Voltage transformer ratio}} \times R/\text{mi} \times \text{miles} = R \text{ comp set}$$
   - ***b.*** $$\frac{\text{CT primary rating}}{\text{Voltage transformer ratio}} \times X/\text{mi} \times \text{miles} = X \text{ comp set}$$

$$R_{\text{comp set}} = 5.7 \text{ or } 6 \text{ V}$$

$$X_{\text{comp set}} = 4.9 \text{ or } 5 \text{ V}$$

Thus the required 120 V will be held at the load. Changes in load current are automatically compensated.

Each line-drop compensation application needs individual consideration. Conditions which would invalidate this example are single-phase or delta connection or the regulators. Also, the example of a precise load center is seldom encountered in practice. For this reason, the setting of line-drop compensation must often be tempered with knowledge of actual system conditions.

Several control accessories are available to provide more sophisticated feeder loading control. These devices have served to make modern feeder regulators the "nerve center" of the distribution system. A *voltage-limit control* device provides automatic limit of regulator output voltage. Settings for both upper and lower limits protect against extremely heavy, light, or unusual loading conditions. A review of the use of line-drop compensation may show that at the highest anticipated loading, the voltage at the regulator is too high for proper customer utilization. Then an upper-limit voltage-limit control may be required to protect a load close to the regulator by overriding the line-drop compensation function. A *reverse power flow detector* can monitor source-side voltage with an internal source-side voltage supply, detect a reversal of power flow direction, and "turn the regulator around" electrically so that it regulates in the proper direction. A *voltage-reduction control,* which can be operated locally or from a remote control, provides automatic voltage reduction in preselected percentages. This is particularly useful where system capacity is close to peak load; studies have shown that a 5% voltage reduction can reduce system load by almost 5%.

10.4.3 Regulator Developments

Innovation associated with step-voltage regulators has concentrated in recent years on the electronic control. The very nature of digital controls now offered routinely with new step-voltage regulators facilitates the mathematical manipulation of the measured line voltage and current into additional system parameters of interest to the user. Thus, controls are available which will display voltage, current, power factor, kW, kvar, various time-integrated demand quantities, and other conditions of interest.

An additional feature available on many controls is the ability to serially communicate this information to a remote-terminal unit (RTU) so that the regulator control becomes the sensory apparatus of the supervisory control and data acquisition (SCADA) system, eliminating the need for multiple transducers and the attendant analog signals.

10.5 POWER CAPACITORS

By JEFFREY H. NELSON and ROBERT L. KLEEB

Definitions of terms used in this section can be found in the IEEE standards and application guides referenced in this section and/or in the *IEEE Authoritative Dictionary of Terms.*

10.5.1 System Benefits of Power Capacitors

Power capacitors provide several benefits to power systems. Among these include power factor correction, system voltage support, increased system capacity, reduction of power system losses, reactive power support, and power oscillation damping.

Power Factor Correction. In general, the efficiency of power generation, transmission, and distribution equipment is improved when it is operated near unity power factor. The least expensive way to achieve near unity power factor is with the application of capacitors. Capacitors provide a static source of leading reactive current and can be installed close to the load. Thus, the maximum efficiency may be realized by reducing the magnetizing (lagging) current requirements throughout the system. Table 10-1 is a simple tool that can be used to determine the kilovars (kvar) required for correcting the system power factor. From Table 10-12, find the row that corresponds to the existing power factor and the column that corresponds to the desired power factor and select the kilowatt multiplier where these intersect. Then simply multiply this factor by the power system load in kilowatts to determine the kilovars required to be installed to achieve the desired power factor.

For example, with a load of 200 kW at 77% power factor, how many capacitor kilovars are needed to correct to a power factor of 95%? At the point where the row for the 77% existing power factor and the column for the desired power factor of 95% intersect, we find a kilowatt multiplier of 0.5. Therefore, the following calculation can be made to determine the kvar required to achieve 95% power factor.

Example

$$\begin{aligned} 3\text{Ø kvar} &= 3\text{Ø load (kW)} \times \text{kilowatt multiplier} \\ &= 200\text{ kW} \times 0.5 \\ &= 100\text{ kvar} \end{aligned} \tag{10-76}$$

System Voltage Support. Power systems are predominately inductive in nature and during peak load conditions or during system contingencies there can be a significant voltage drop between the voltage source and the load. Application of capacitors to a power system results in a voltage increase back to the voltage source, and also past the application point of the capacitors in a radial system. The actual percentage increase of the system voltage is dependent upon the inductive reactance of the system at the point of application of the capacitors. The short-circuit impedance at that point is approximately the same as the inductive reactance; therefore, the 3-phase short-circuit current at that location can be used to determine the approximate voltage rise. The following rule-of-thumb equation is commonly used

$$\Delta V \approx \frac{\text{kvar}_\text{C}}{\text{kVA}_\text{SC}} \times 100\% \tag{10-77}$$

where ΔV = percent voltage rise at the point of the capacitor installation, kvar_C = capacitor 3-phase kvar, kVA_SC= system 3-phase short-circuit kVA at the point of the capacitor installation.

$$\text{kVA}_\text{SC} = \sqrt{3} \times V_{LL} \times I_{SC} \tag{10-78}$$

where V_{LL} = system line-to-line (phase-to-phase) voltage, I_{SC} = is the 3-phase short-circuit current at the point of the capacitor installation.

Increased System Capacity. The application of shunt or series capacitors can affect the power system capacity.

Application of shunt capacitors reduces the inductive reactive current on the power system, and thus reduces the system kVA loading. This can have the effect of increasing system to serve additional load.

Series capacitors are typically used to increase the power carrying capability of transmission lines. Series capacitors insert a voltage in series with the transmission line that is opposite in polarity to the voltage drop across the line, which decreases the apparent reactance and increases the power transfer capability of the line.

Power System Loss Reduction. The installation of capacitors can reduce the current flow in a power system. Since losses are proportional to the square of the current, a reduction in current will lead to reduced system losses.

Reactive Power Support. Capacitors can help support steady-state stability limits and reactive power requirements at generators.

Power Oscillation Damping. Controlled series capacitors can provide an active damping for power oscillations that many large power systems experience. They can also provide support after significant disturbances to the power system and allow the system to remain in synchronous operation.

10.5.2 Capacitor Units

The terms capacitor unit, power capacitor or capacitor may be used interchangeably.

The base standard which covers the ratings and requirements for capacitor units is IEEE 18[1]. This standard applies to capacitors rated 216 V or higher, 2.5 kvar or more, and designed for shunt connection on alternating current (ac) power systems operating at a nominal power frequency of 50 or 60 Hz. IEEE 18 covers service conditions, ratings and capabilities, manufacturing, and testing of shunt capacitor units.

IEEE 824[2] specifies ratings, capabilities and testing requirements in addition to IEEE 18[1] for capacitor units to be utilized in series capacitor banks.

IEEE 1531[3] covers considerations to take into account when specifying units to be used in a harmonic filter bank.

There are typically two voltage classes of capacitor units applied and they are divided into the categories of low-voltage capacitors (below 1000 V) and high-voltage capacitors (1000 V and above).

Low-Voltage Capacitor Units. Low-voltage capacitor units are typically applied in industrial power systems. They are generally available in voltage ratings from 240 to 600 V over the range of 2.5 to 100 kvar 3-phase. Low-voltage capacitors are typically dry type, metalized polypropylene film (see Fig. 10-102). Typical voltage and kvar ratings are listed in IEEE 18[1].

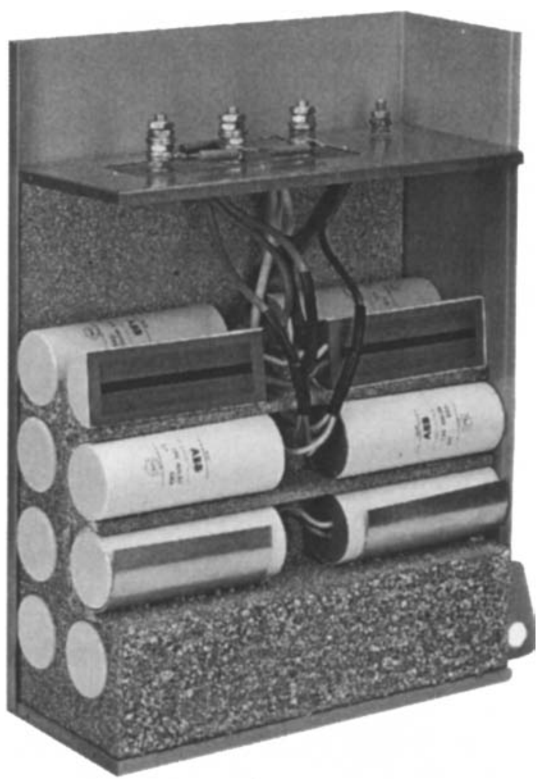

FIGURE 10-102 Typical low-voltage capacitor unit with self-healing metalized polypropylene capacitor elements, liquid-free enclosure and 3-phase connection terminals.

High-Voltage Capacitor Units. High-voltage capacitor units are typically connected to industrial power systems or to utility transmission and distribution power systems. The units are generally available in voltage ratings from 2.4 to 25 kV. Modern manufacturing techniques continue to decrease the size of high-voltage capacitor units which continues to increase the available kvar ratings for units. Typical voltage and kvar ratings are listed in IEEE 18[1].

The capacitor elements in present day high-voltage capacitor units are manufactured using an *all-film dielectric*, typically two layers of polypropylene film between two layers of thin aluminum foil. The capacitor elements are connected in a series/parallel combination to achieve the desired voltage and kvar rating. The elements are placed in a metal enclosure with bushings for external connections and impregnated with a dielectric fluid, usually under vacuum. The unit is then hermetically sealed (see Fig. 10-103).

Capacitor Unit Ratings. IEEE 18[1] establishes the following standard ratings for capacitor units, as applied under the normal service conditions and ambient temperatures defined in the standard:

1. Voltage, rms (terminal-to-terminal)
2. Terminal to case (or ground) insulation class
3. Reactive power
4. Number of phases
5. Frequency

Capacitors are intended to be operated at or below their rated voltage. They are designed to operate at overvoltages of 10% for bank contingencies, such as the failure of an individual unit or element, or system contingencies, such as a high voltage. Note that the overvoltage capability of the individual capacitor elements inside the unit is 110% of its portion of the unit voltage rating. The capacitor unit is capable of operating continuously under contingency conditions provided that the peak voltage

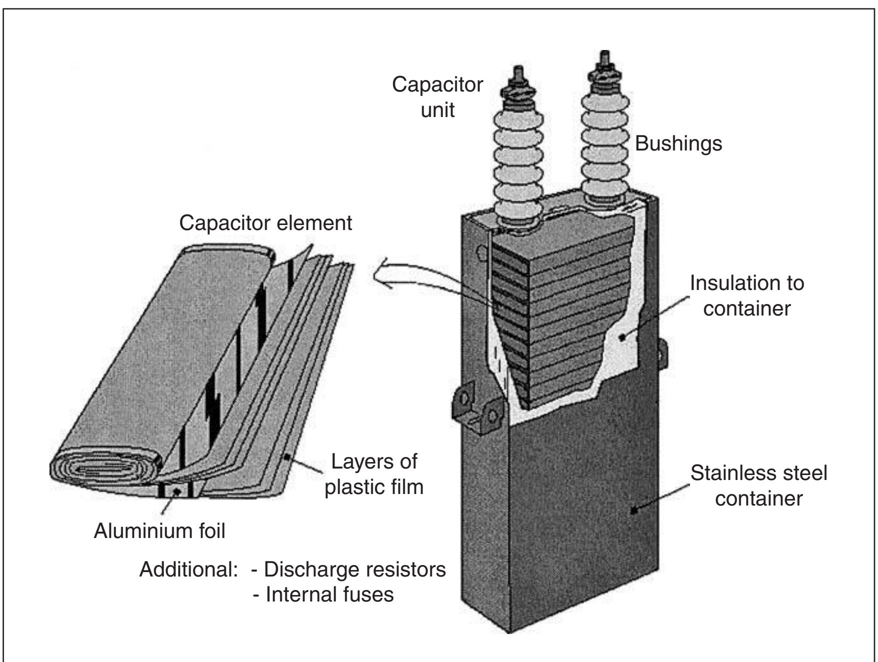

FIGURE 10-103 Typical high-voltage capacitor unit.

does not exceed 120% of rated peak voltage, including harmonics. The maximum peak voltage rating of the capacitor including harmonics, but excluding transients, is equal to

$$V_{pk} = 1.2\sqrt{2}(V_{rms} \text{ rated}) \tag{10-79}$$

Also, the unit is designed to operate continuously if the current does not exceed 135% of nominal rms current based on rated kvar and rated voltage, and the kvar output does not exceed 135% of rated kvar. The total rms current is equal to

$$I_{rms} = \sqrt{(I_1)^2 + (I_2)^2 + (I_3)^2 + \cdots + (I_n)^2} \tag{10-80}$$

where n = harmonic number.

The kvar output of the capacitor increases as the square of the applied voltage

$$\text{kvar}_{E_2} = \text{kvar}_{E_1}\frac{(E_2)^2}{(E_1)^2} \tag{10-81}$$

For example, a 200-kvar, 7200-V capacitor unit will supply 242 kvar at 7920 V

$$\text{kvar}_{E_2} = 200\,\frac{(7920)^2}{(7200)^2}$$

$$\text{kvar}_{E_2} = 242 \text{ kvar}$$

Transient Overvoltage and Overcurrent Withstand Capabilities. When the installation of a switched rack or bank is contemplated, other nearby capacitor equipment must be evaluated.

Capacitor banks switched in a back-to-back configuration can create very high peak magnitude and high frequency current transients.

Also, when switching a capacitor bank without any type of transient suppression a voltage transient is generated, typically in the range of 300 to 800 Hz. This undamped voltage transient can couple through a power transformer to a lower voltage system and be transmitted several miles away. If a capacitor bank is installed on the lower voltage system, a resonant condition may exist. If the resonant frequency of the LC circuit on the high-voltage bus where the capacitor bank is being switched is approximately equal to the LC circuit at the lower voltage capacitor bank, the voltage transient will be magnified. This phenomenon is known as voltage magnification.

These switching conditions could result in high overvoltage and overcurrent transients. The use of series reactors, preinsertion inductors or resistors, and/or special switching devices is sometimes required to reduce these transients to safe levels.

Transient overvoltage and overcurrent capabilities for shunt capacitors are covered in IEEE 1036[4]. Prior to 2002, they were covered in IEEE 18[1].

Capacitance Tolerance. In the 2002 revision to IEEE 18, the allowable capacitance tolerance for shunt capacitor units was changed to 0% from +10% of the nominal value based on rated kvar, voltage and frequency, measured at 25°C uniform case and internal temperature. In previous versions of IEEE 18, the allowable capacitance tolerance was 0% to +15%. However, with today's modern manufacturing practices, capacitance tolerances typically do not exceed +5% for standard units.

A tighter tolerance may be specified for units to be utilized in a harmonic filter capacitor bank, for example, −2% to +2% of the nominal capacitance. This tolerance may be applied to the capacitance of the entire harmonic filter bank instead of the individual units.

Capacitance tolerances for series capacitors are specified on a per phase basis for the entire bank in IEEE 824.

Discharge Resistors. Under certain conditions, when line voltage is removed from a power capacitor, the possibility exists that the unit will retain an extremely high charge even days later. This characteristic of retaining such a charge is demonstrated by the high efficiency and low-loss operation of a power capacitor. To eliminate this hazard, all power capacitors contain internal-discharge resistors. This resistor assembly will reduce the terminal voltage from line voltage to 50 V within 5 min of deenergization for a capacitor rated higher than 600 V ac, and within 1 min for capacitors rated 600 V ac or less.

Capacitor Unit Losses. Present-day high-voltage capacitors operate at a lower watts loss per kvar than do low-voltage capacitors. For example, capacitors that utilize an *all-film dielectric* may operate will losses of less than 0.1 W per kvar. Low-voltage capacitors using *metalized polypropylene dielectric* may experience losses of near 0.5 W per kvar.

The cost of operating high-voltage capacitors is lower per kvar than low-voltage capacitors because of the basic difference in dielectric materials which allows high-voltage capacitor to be operated more efficiently.

Capacitor Tank Rupture. Capacitor tank rupture of high-voltage capacitors will occur if the total energy applied to the capacitor unit under failure conditions is greater than the ability of the capacitor tank to withstand such energy. Tank-rupture curves are essential to the correct selection of fuse links for overcurrent protection of externally fused capacitors. A typical tank rupture curve is shown in Fig. 10-104.

Temperature. Although very efficient, power capacitors do consume some power and generate heat. This heat must be adequately ventilated when enclosed or exposed to higher than normal ambient temperatures.

The maximum operating temperature for power capacitors is specified in IEEE 18 for various mounting arrangements. The minimum operating temperature is $-40°C$.

Capacitor applications must be designed for adequate overvoltage and "corona" capabilities, since the partial discharge (corona) characteristics vary with temperature. It is necessary to consider the full range of temperatures to which the capacitors will be exposed, in both the energized and deenergized modes.

10.5.3 Shunt Capacitors

The most common application of power capacitors is shunt connected capacitors and they are either energized continuously or switched on and off during load cycles.

Common Shunt Capacitor Connections. Figure 10-105 shows four of the most common capacitor connections: 3-phase grounded wye, 3-phase ungrounded wye, 3-phase delta, and single phase. Grounded or ungrounded wye connections are usually made on medium and high-voltage systems, whereas delta and single-phase connections are usually made on low-voltage systems.

Grounded-wye capacitors can bypass some line surges to ground and therefore exhibit a certain degree of self-protection from transient voltages and lightning surges. The grounded-wye connection also provides a low impedance path for harmonics.

If the capacitors are electrically connected ungrounded-wye, the maximum fault current would be limited to 3-times line current. If the available fault current exceeds the tank rupture curve the use of current limiting fuses must be considered.

Low-Voltage Shunt Capacitors. Low-voltage shunt capacitors are typically applied in industrial power systems, in voltage ratings from 240 to 600 V over the range of 2.5 to 100 kvar 3-phase. They can be used for power factor improvement and voltage support on low voltage systems where adjustable speed drives, power electronics, and other industrial equipment are applied.

Low-voltage capacitors made with metalized polypropylene are self-healing. That is, the conductors consist of very thin layers of metal deposited on the film dielectric. In the event of short circuit, the conductor vaporizes to eliminate the fault with negligible loss of capacitance and continued operation. External fuses are not required on these units although some users add them for additional protection of their connections and ground faults.

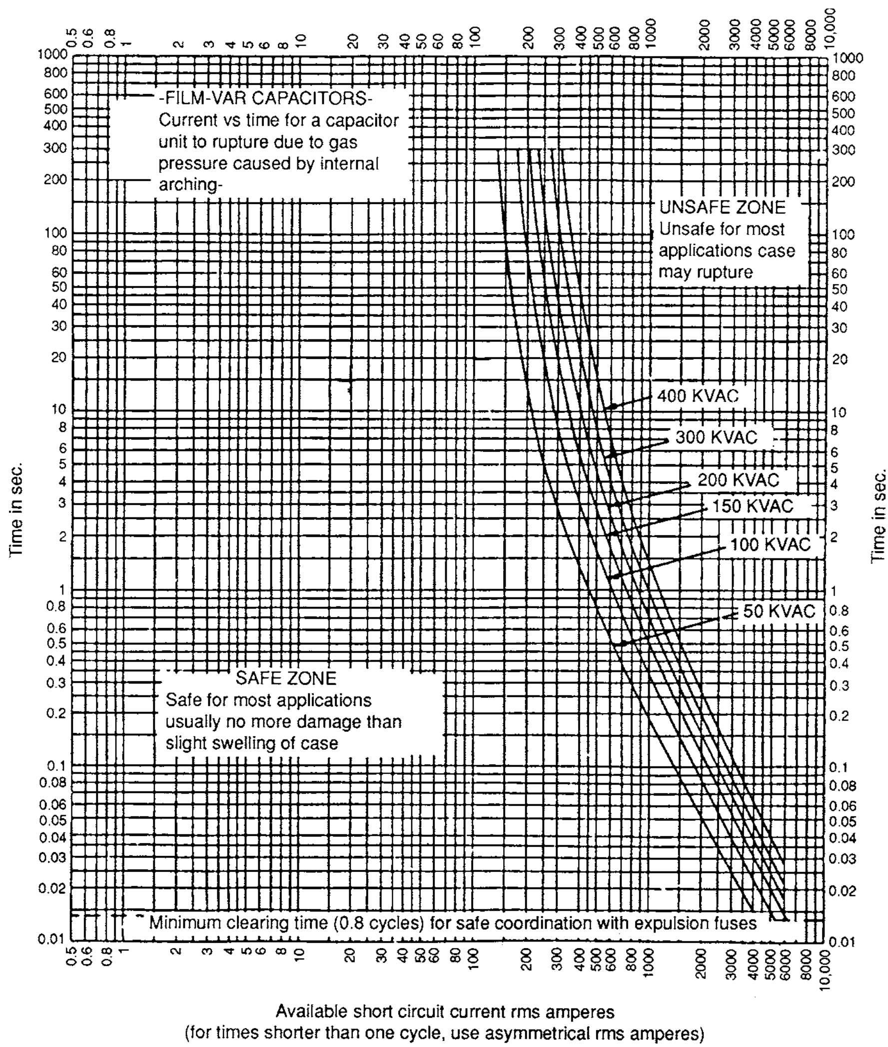

FIGURE 10-104 High-voltage capacitor tank-rupture curve.

Distribution Shunt Capacitors. Capacitors for overhead distribution systems can be pole-mounted typically in banks of 300 to 3600 kvar at nearly any system voltage up to 34.5 kV phase-to-phase. Pad-mounted capacitor equipments are used for underground distribution systems in the same range of sizes and voltage ratings. See Fig. 10-106 for a typical pole-mounted capacitor bank.

The majority of the power capacitor equipment installed on medium voltage distribution systems is connected grounded wye. With the grounded-wye connection, tanks and frames of switching equipment are at ground potential. This provides increased personnel safety. Grounded-wye connections provide for faster fuse operation in case of a capacitor failure.

Distribution shunt capacitors can be protected with individual unit fuses or group fused. Tank rupture curves are essential to the correct selection of fuse links for overcurrent protection of any capacitor installation. Fuse selections should be based upon the coordination of the fuse-link maximum clearing curve (Fig. 10-107) and the high-voltage capacitor tank-rupture curve (Fig. 10-104).

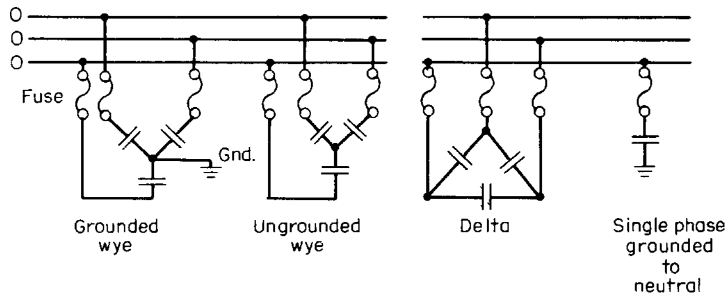

FIGURE 10-105 Common methods for connecting power-factor capacitors.

Several fundamental principles must be observed in the selection of fuses for capacitor applications:

1. The fuse link must be capable of continuously carrying 135% of the nominal capacitor current as a minimum. Higher values may be required when high harmonic currents are present.
2. The fuse cutout must have sufficient interrupting capacity to successfully handle the available fault current, clearing voltage, and available energy before the capacitor tank ruptures.
3. The fuse link must withstand, without damage, the normal transient current during bank energization or de-energization. Similarly, it must withstand the capacitor unit's discharge current during a terminal-to-terminal short.
4. For ungrounded-wye banks, maximum fault current is usually limited to 3 times normal line current. The fuse link must clear within 5 min at 95% of available fault current.

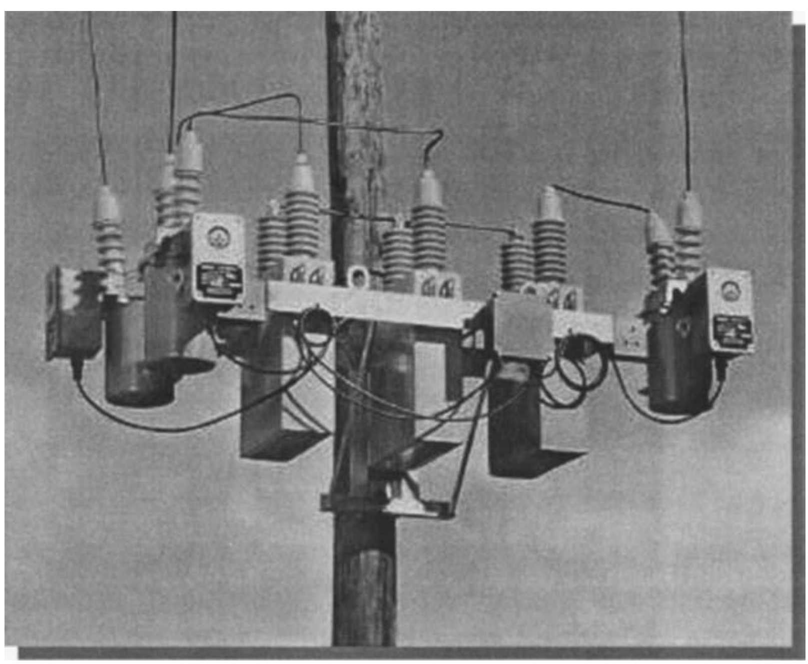

FIGURE 10-106 Typical pole-mounted distribution capacitor bank.

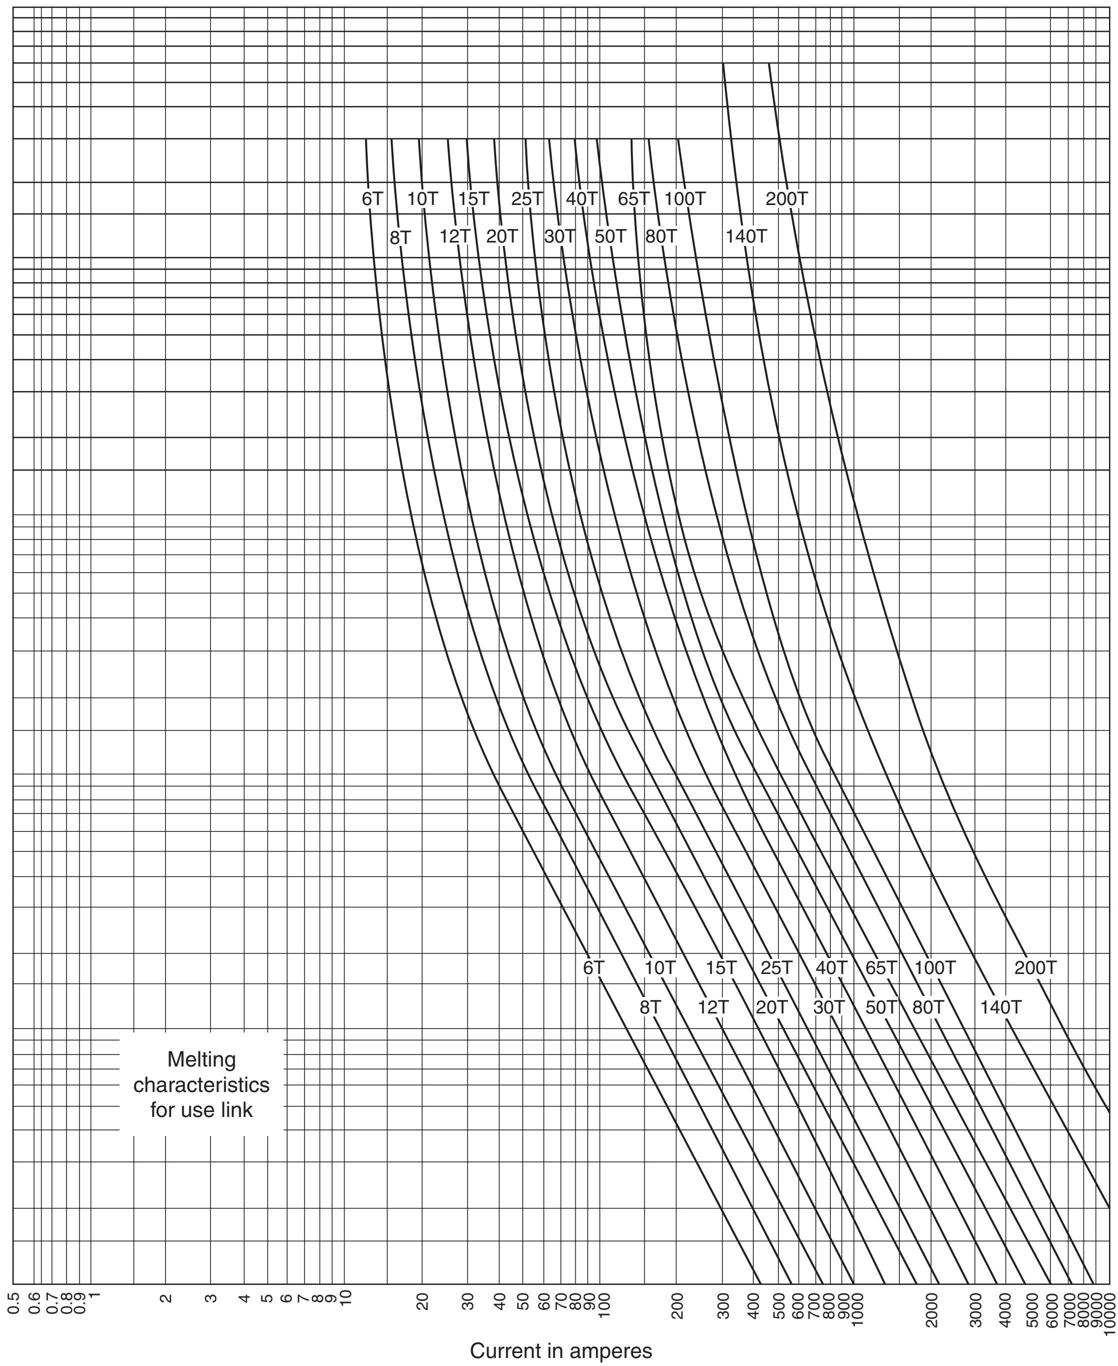

FIGURE 10-107 Typical time-current curve for an expulsion fuse.

5. For effective capacitor protection, maximum asymmetric rms fault current should not exceed the current value at the intercept point of the capacitor tank-rupture time-current characteristic (TCC) curve and the minimum time shown on the fuse maximum-clearing TCC curve.
6. The maximum-clearing TCC curve of the fuse link must coordinate with the tank-rupture TCC curve of the capacitor unit.

For more detailed information on the application of shunt capacitors in distributions systems refer to IEEE 10364[4]. For application guidance on external fuses for shunt capacitors refer to IEEE C37.48[5].

Substation Shunt Capacitor Banks. Substation shunt capacitor banks are usually installed grounded-wye, ungrounded-wye or delta. Delta connected shunt banks are usually at lower voltages, for example, 2400 V. Grounded-wye shunt capacitor bank installations are typically more economical than ungrounded-wye banks because the neutral does not have to be insulated for the system voltage. This advantage increases with system voltage. Also, the transient recovery voltages (TRV) for grounded-wye banks are less than ungrounded-wye, thus reducing the TRV requirements for switching equipment.

A disadvantage of grounded-wye shunt capacitor banks is that there is a possibility of high-frequency switching transients in the ground grid that could induce transients in relay and control cables resulting in erroneous relay operations.

Ungrounded-wye shunt capacitor banks may be applied at any system voltage as long as the insulation and TRV requirements are considered.

For shunt banks that have only one series group, it is more desirable to install an ungrounded wye bank. In a grounded wye bank with one series group, if one unit completely shorts and the phase-to-ground fault current is too high it will rupture the unit. With an ungrounded-wye bank, the fault current is limited to three times the bank current.

There are three common substation shunt capacitor bank types utilized today: externally fused, internally fused, and fuseless. These three types are briefly described in this section.

For more detailed information on the application and protection of substation shunt capacitor banks, refer to IEEE 1036[4], IEEE C37.99[6] and IEEE C37.48[5].

Externally Fused Shunt Capacitor Banks. An externally fused shunt capacitor bank is made up of series groups of parallel connected capacitor units. Each unit is individually fused with an expulsion or current-limiting fuse mounted external to the unit. A typical schematic for an externally fused shunt capacitor bank is shown in Fig. 10-108.

A capacitor unit voltage rating is chosen usually to limit the number of series groups to as few as possible, while achieving the desired voltage rating of the bank. This usually results in the simplest design and highest sensitivity for unbalance protection.

Fewer series groups may mean more units in parallel in each series group. This could require the use of current limiting unit fuses instead of expulsion type fuses. When a unit fails in an externally fused bank the other units in parallel with it will discharge into the failed unit through its individual fuse. When the energy from this discharge exceeds the energy capability of an expulsion fuse, the user will have to specify current limiting fuses which have a higher energy capability. To avoid this, the user can specify a lower voltage rating for the units and design the bank with more series groups and fewer units in parallel. Another option is to split the bank in two sections, called a double-wye configuration. For principles of fuse selection for the individual units, refer to the earlier section on distribution shunt capacitors. For more detailed guidance on fusing refer to IEEE C37.48[5] and IEEE C37.48.1[7].

It is also important to keep a minimum number of units in parallel in each series group. When a fuse operates and removes a unit from a series group the voltage will increase on the remaining units in parallel with it. It is desirable to have enough units in parallel that the 110% overvoltage capability will not be exceeded for the loss of one unit. There are curves available to help determine the voltage on remaining capacitor units in a series group based on the percentage of capacitor units removed from the series group. These curves are located in IEEE 1036[4], which covers the application of shunt capacitors. The curves were previously located in an appendix of IEEE 18[1], but were removed from the 2002 revision.

A typical externally-fused shunt capacitor bank is shown in Fig. 10-109.

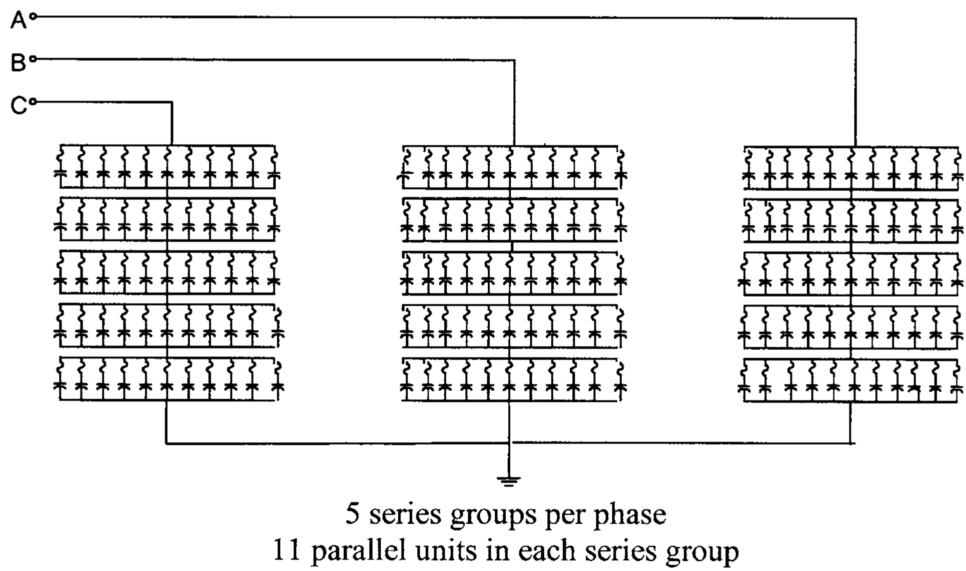

FIGURE 10-108 Schematic of a typical externally fused shunt capacitor bank.

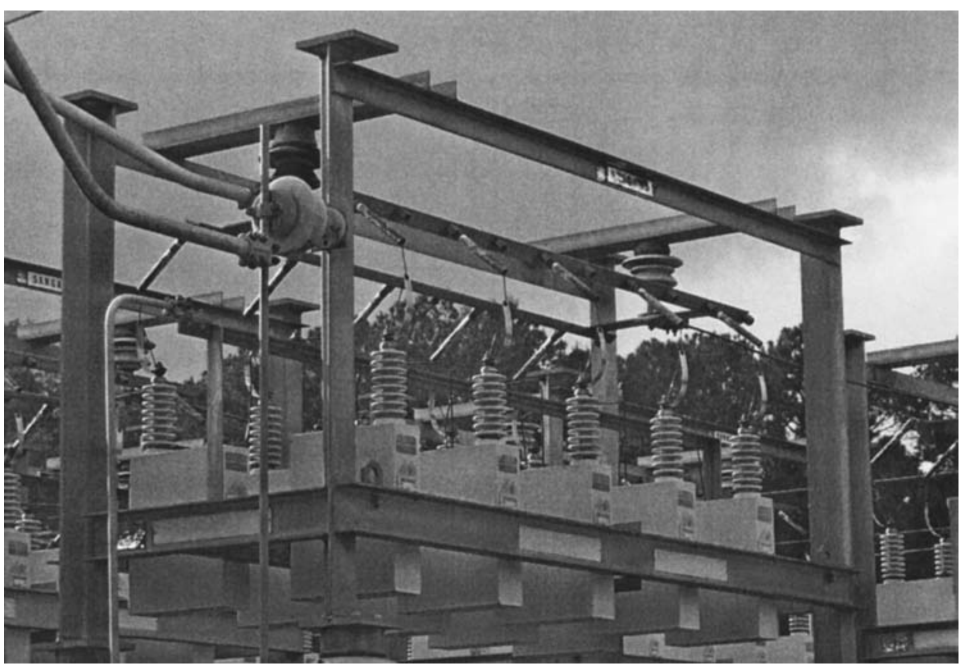

FIGURE 10-109 Typical externally fused shunt capacitor bank.

Internally Fused Shunt Capacitor Banks. An internally fused capacitor bank is made up of series and/or parallel connected capacitor units. The units are made up of capacitor elements connected in series/parallel combinations to achieve the desired rated voltage and kvar rating. A fuse is put in series with each element inside the unit case. An internally fused unit is shown schematically in Fig. 10-110. When a failure of a capacitor element occurs, its individual fuse will operate to isolate the element. The unit typically has a large number of elements in parallel so that the loss of one element does not have a significant increase in voltage on the remaining elements in parallel with the failed element. The kvar rating of internally fused units is typically much larger than externally fused units.

Internally fused capacitor banks typically have fewer units in parallel and more series groups than externally fused capacitor banks. A typical schematic for an internally fused shunt capacitor bank is shown in Fig. 10-111. It is usually desirable to have at least two units

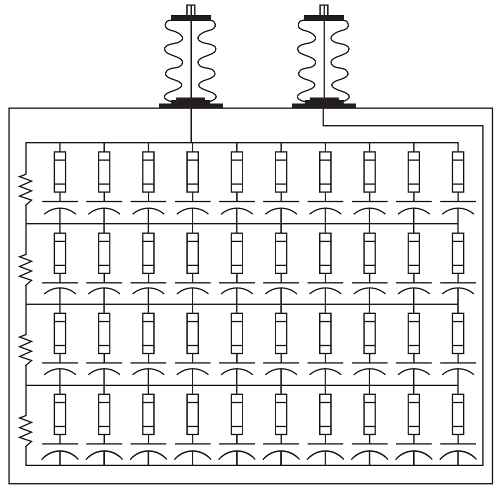

FIGURE 10-110 Internal connection diagram of a typical internally fused capacitor unit.

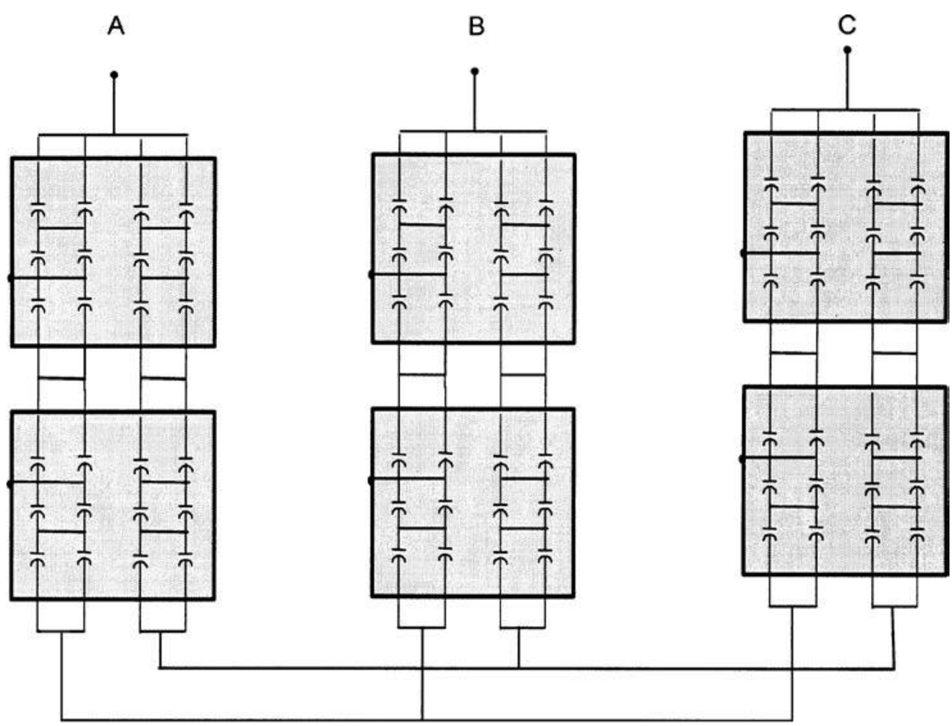

FIGURE 10-111 Schematic of a typical internally fused shunt capacitor bank.

in parallel. If one unit has a large number of failed elements, the unit in parallel will help keep down the terminal-to-terminal voltage. The maximum number of capacitor units that can put in parallel is determined by the energy capability of the internally fused unit.

A typical internally fused capacitor bank is shown in Fig. 10-112.

Fuseless Shunt Capacitor Banks. A fuseless shunt capacitor bank is not simply an externally fused capacitor bank with the fuses removed. It is a different arrangement of capacitor units designed to operate without fuses. A fuseless shunt capacitor bank is made up of units connected in series phase-to-ground or phase-to-neutral. This arrangement of units is called a series string. The unit voltage is selected to achieve the desired voltage rating of the bank. The kvar rating of the unit is chosen to achieve a desired reactive output per each string. Then the bank kvar rating can be increased in these increments by putting multiple series strings of capacitors in parallel. A schematic for a typical fuseless

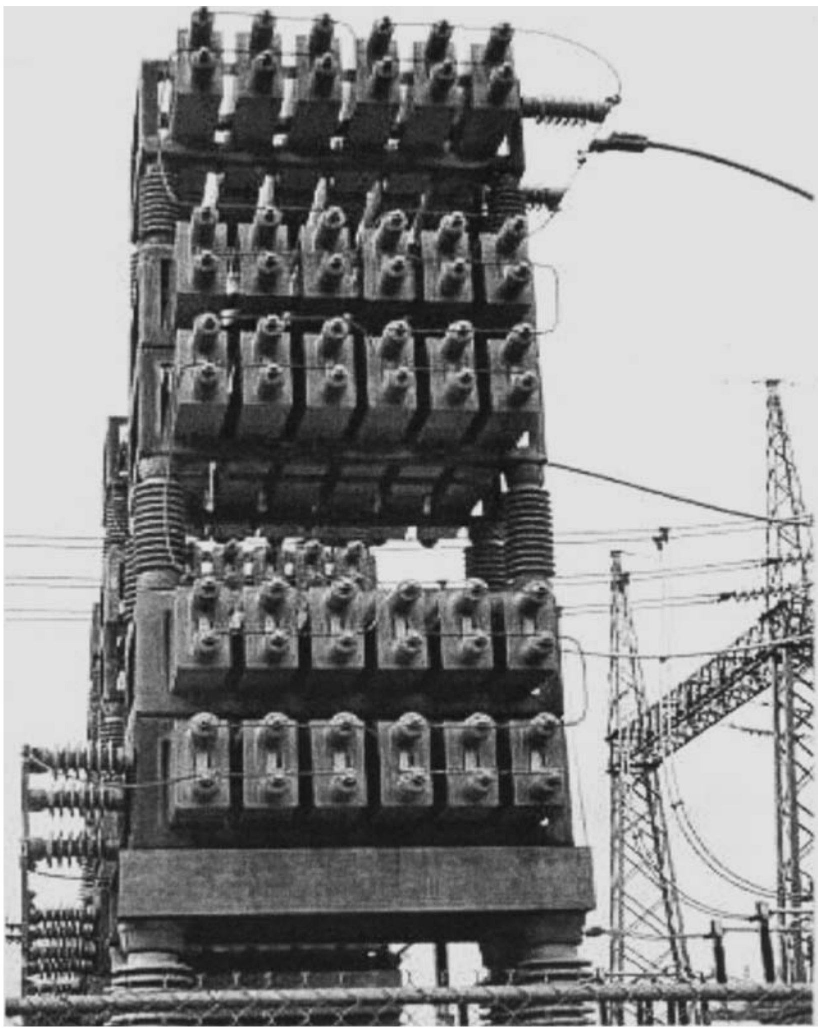

FIGURE 10-112 Example of an internally fused shunt capacitor bank.

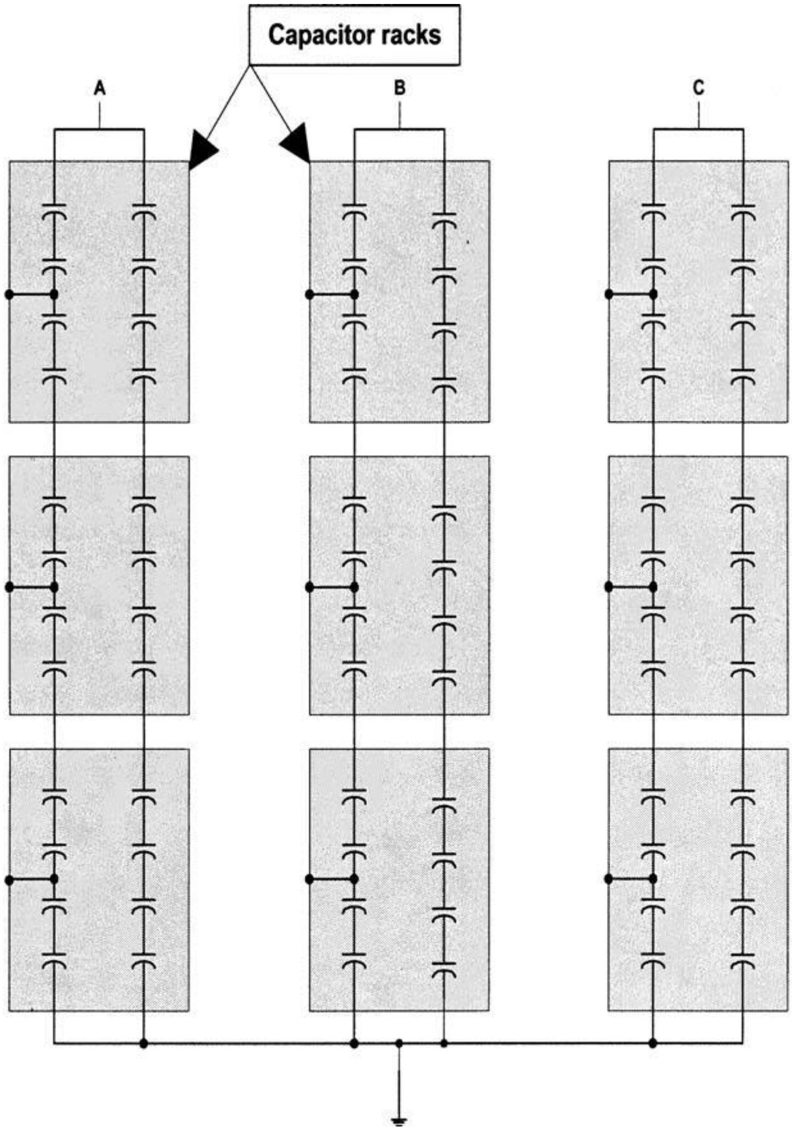

FIGURE 10-113 Schematic of a typical fuseless shunt capacitor bank (Two parallel series strings of twelve units in series.)

shunt capacitor bank is shown in Fig. 10-113. The fuseless capacitor bank is made up of parallel groups of series units, while the externally fused bank is made up of series groups of parallel units.

Fuseless capacitor bank installations were made possible with the design of the *all-film dielectric* capacitor unit, described earlier in the Sec. 10.5.2. The common failure mode of an element in an all-film dielectric unit is for it to fail shorted. When it shorts, the aluminum foil melts and welds together creating a low resistance point that will continue to carry the current through the capacitor indefinitely.

Typically, kvar ratings of units in fuseless capacitor banks are larger than units used in externally fused capacitor banks. This is because fuseless banks do not have the same design consideration of keeping a minimum number of units in parallel as discussed previously for externally fused banks. With the units connected in series, if one element in a unit fails, the voltage will increase proportionately across the remaining elements in series with it. For example, if a unit has 10 series groups of elements inside each unit and there are 5 units in a series string, then there will be 50 elements in series phase-to-neutral. If one element fails then the voltage on the remaining elements in series will increase by 1/50th of the total phase-to-neutral voltage. The unbalance protection would usually be set to trip when the overvoltage has exceeded the 110% capability of the elements.

When designing a fuseless bank and choosing the rated voltage and kvar of the units, keep in mind the continuous current capability and the transient current capability of the units. With the series string design of a fuseless bank, there are typically fewer parallel paths for these currents.

A typical fuseless shunt capacitor bank is shown in Fig. 10-114.

Harmonic filter shunt capacitor banks. Non-linear devices or loads, such as rectifiers and arc furnaces, can create harmonic distortion on the power system. Excessive harmonic voltages or currents can create problems for equipment and the electrical system in general. One common way to eliminate these harmonics is to install a passive harmonic filter near the device or load to shunt some of the harmonic current and thereby reduce the harmonic current flowing into the system. A schematic for a typical harmonic filter capacitor bank is shown in Fig. 10-115. The need for harmonic filters can be on low, medium, or high voltage electrical systems.

For low-voltage systems, the dry-type, metalized film capacitors are typically used and an inductor is used to create an LC circuit approximately tuned to the frequency of the harmonic being generated.

For medium and high voltage systems, the all-film, oil-filled dielectric capacitors are commonly used and, depending on the system voltage, a dry-type or oil-filled reactor is used to create an LC circuit approximately tuned to the frequency of the harmonic being generated. The capacitor portion for medium- and high-voltage harmonic filter banks can be externally fused, internally fused, or fuseless.

Harmonic filter capacitor banks may look similar to conventional shunt capacitor banks, but there are different criteria to consider when designing a harmonic filter bank. In general, the following should be considered when designing a harmonic filter bank:

1. Reactive power (kvar) requirements
2. Harmonic limitations
3. Normal system conditions, including ambient harmonics
4. Normal harmonic filter conditions
5. Contingency system conditions, including ambient harmonics
6. Contingency harmonic filter conditions

For detailed guidance in designing low, medium, and high voltage harmonic filter capacitor banks refer to IEEE 1531[3].

A typical harmonic filter shunt capacitor bank is shown in Fig. 10-116.

Protective Relaying for Shunt Capacitor Banks. Protection of shunt capacitor banks includes bank and system protection schemes.

Bank protection schemes usually involve some type of unbalance protection to trip the bank for overvoltage due to unit (element) failures, overcurrent protection for faults in the bank other than in units, and phase overcurrent or negative sequence protection for rack-to-rack flashovers in a phase-over-phase bank design.

System protection schemes can involve phase voltage relays for system overvoltage conditions, bus overcurrent, ground-overcurrent, or differential protection for faults in the capacitor installation

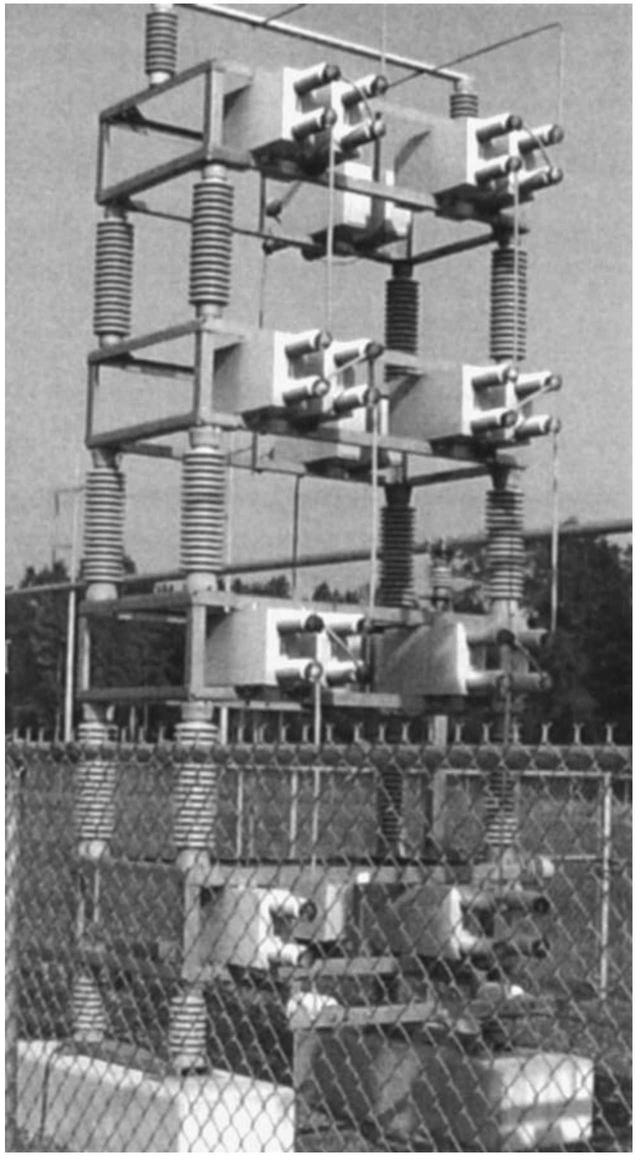

FIGURE 10-114 Example of a fuseless shunt capacitor bank.

or major capacitor bank failure, harmonic overload protection for excessive harmonic currents in the system, undervoltage relays for system outages, and breaker failure relays.

The following is a list of basic considerations for protection of shunt capacitor banks:

1. Type of shunt capacitor bank (externally fused, internally fused, or fuseless)
2. Bank connection (grounded wye, ungrounded wye, double wye, etc.)

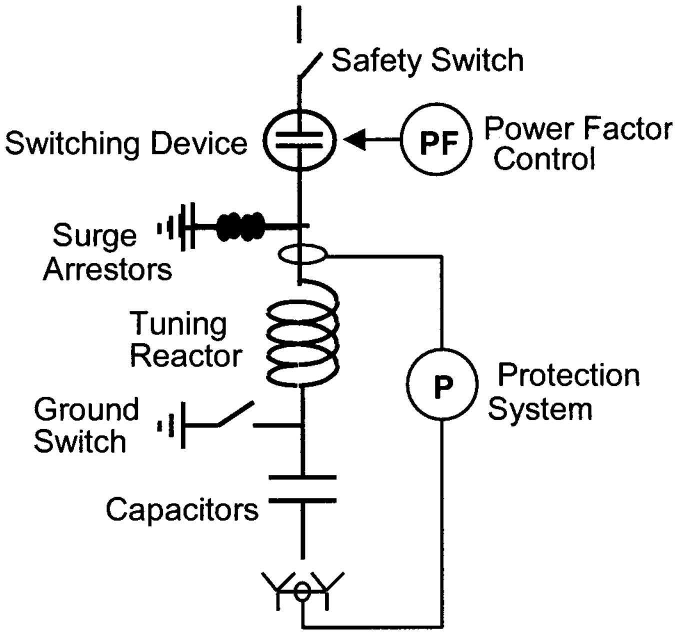

FIGURE 10-115 Typical schematic of a harmonic filter shunt capacitor bank.

FIGURE 10-116 Typical high-voltage harmonic filter shunt capacitor bank.

3. Capacitor bank design and arrangement of units
4. Normal and contingency system conditions
5. Point of connection to the power system
6. Capacitor unit capabilities
7. Overvoltage on remaining capacitor units
8. Installation grounding for grounded banks (single-point or peninsula grounding)

For detailed guidance on the protection of conventional and harmonic filter shunt capacitor banks refer to IEEE C37.99[6].

10.5.4 Series Capacitor Banks

Fixed (Conventional) Series Capacitors. A fixed series capacitor bank is an assembly of different components inserted in series with a power line to reduce the apparent reactance, increase the power transfer capability and improve system stability. The major components of a fixed series capacitor bank include capacitors, varistors, bypass gaps, bypass switches, discharge current limiting reactors, insulated structures, and protection and control systems. The inserted reactance is primarily established by the reactance of the capacitors. A schematic for a typical fixed series capacitor bank is shown in Fig. 10-117. The capacitors can be of the externally fused, internally fused, or fuseless design. Series capacitor banks are more commonly applied on higher voltage transmission systems, but they have been applied on distribution systems. See Fig. 10-118 for a typical high-voltage series capacitor bank.

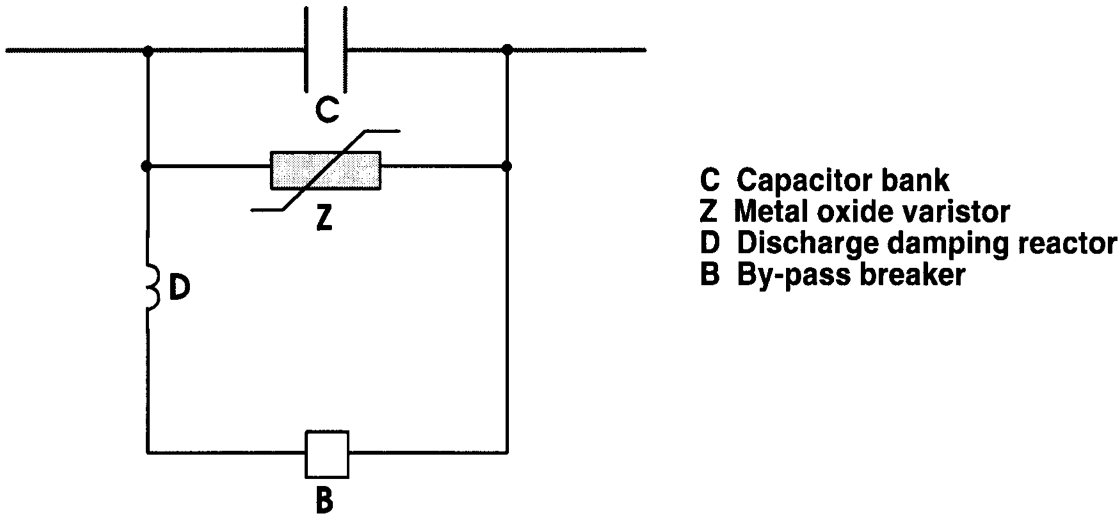

FIGURE 10-117 Schematic of fixed conventional series capacitor bank.

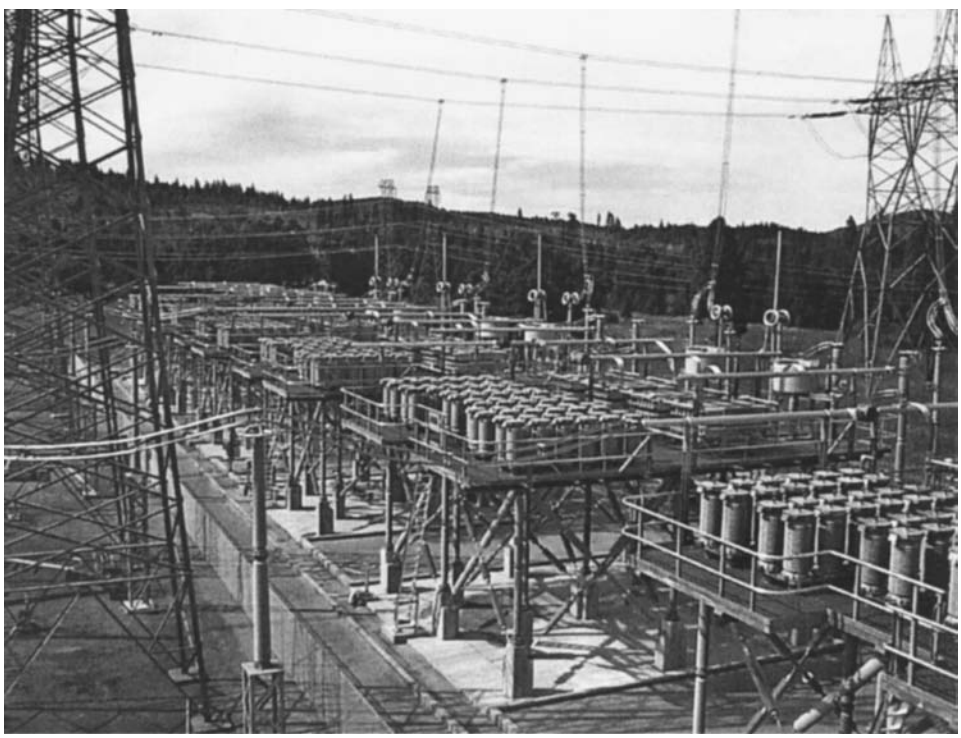

FIGURE 10-118 Typical fixed series transmission series capacitor bank.

For detailed information on the design, application, and protection of fixed transmission series capacitor banks, refer to IEEE 824[2,8]. There currently is also an IEEE working group preparing a guide for the specification of fixed transmission series capacitor banks.

For information on distribution series capacitors the user can refer to an IEEE Transactions paper written by the IEEE Series Capacitor Working Group[9].

General information about the protection of series capacitor banks can be found in the IEEE Special Publication TP-126-0[10]. There currently is also an IEEE working group preparing a guide for protection of transmission line series capacitors. When published, the document will be designated IEEE C37.116, *Guide for Protective Relay Application of Transmission-Line Series Capacitors*.

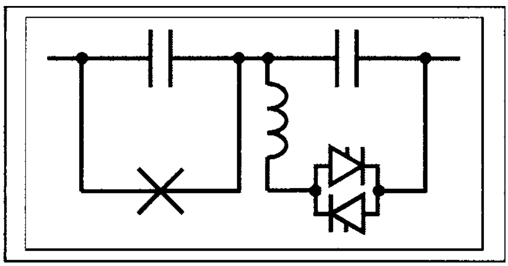

FIGURE 10-119 Typical schematic of a thyristor-controlled series capacitor bank.

Thyristor-Controlled Series Capacitors (TCSC). A thyristor-controlled series capacitor (TCSC) is a series capacitor bank paralleled with a thyristor-controlled reactor. In the controlled operation mode, periodic gating results in thyristor currents at a frequency higher than the power frequency which add with the line current. This boosts the capacitor voltage beyond the level that would be obtained by the line current alone. Also, controlled operation provides dynamic var compensation to control line current or through power. A schematic for a TCSC bank is shown in Fig. 10-119. The ability to control TCSC reactance rapidly provides a degree of transient stability and subsynchronous resonance mitigation, which is an advantage a TCSC has over a fixed series capacitor bank. A typical TCSC is shown in Fig. 10-120.

For detailed information on thyristor-controlled series capacitors, refer to IEEE 1534 [11].

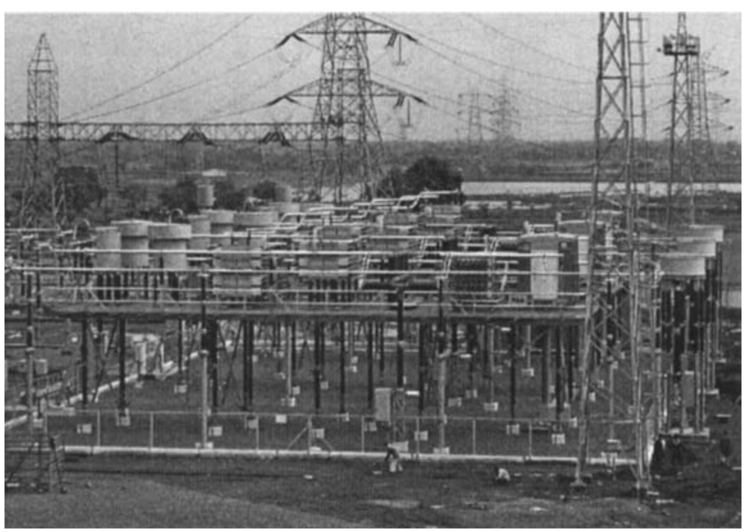

FIGURE 10-120 Typical thyristor-controlled series capacitor bank.

10.5.5 Capacitor Switching Equipment

This chapter will not go into the details of specifying equipment used to switch and protect capacitor banks. But a bibliography of documents providing rating, application, and specification information on switching equipment for shunt and series capacitors is provided at the end of this chapter for the user's reference.

10.6 FUSES AND SWITCHES

BY JON HILGENKAMP

10.6.1 Fuses

General Classifications. Fuses can be classified into three categories. The first is low-voltage fuses operating up through 600 V ac. Most devices are tested and approved by Underwriters' Laboratories, Inc., and are marketed in a wide variety of characteristics and physical configurations. The second classification is medium-voltage through 69 kV, and the third is high-voltage fuses through 500 kV. These fuses are used by electric utilities to protect transmission-distribution-class equipment and by large industrial complexes which have their own electrical distribution systems.

Low-Voltage Fuses. Low-voltage fuse standards are established by ANSI, NEMA, or Underwriters' Laboratories (see Table 10-13). Their characteristics include a voltage class, an ampere rating, and an interrupting rating and, for some classes of fuses, a current-limiting rating. Cartridge fuses are classified in the following voltage classes: not over 250 V ac, not over 300 V ac, and not over 600 V ac. Fuses should not be used for dc applications unless recommended by the manufacturer. Most low-voltage fuses must be used in accordance with the National Electrical Code. Exceptions include those

TABLE 10-13 Class of Low-Voltage Fuses and Applicable Standards

K	UL 198D and ANSI C97.1
R	UL 198E
T	UL 198H

used in ships, railways, aircraft, and automotive vehicles other than mobile homes and recreational vehicles.

The standard lines of low-voltage fuses are available in several steps of ampere capacity, each of which is a different physical size (see Table 10-14).

TABLE 10-14 Typical Dimension Grouping of Fuses

L	600	2501–3000
L	600	3001–4000
L	600	4001–5000
L	600	5001–6000

A minimum of 10,000-A interrupting capacity is typical in low-voltage fuses, but some sizes and types are capable of interrupting up to 200,000 A ac or 100,000 A dc. The interrupting rating is the highest rms symmetric alternating current which the fuse can interrupt at rated voltage.

Low-voltage current-limiting fuses are designed so that non-current-limiting fuses cannot be inserted into the fuse holder as a direct replacement. Thus, Class K fuses which are interchangeable with Class H fuses are not permitted the "current-limiting" label.

A low-voltage current-limiting fuse successfully and safely interrupts all available currents within its specified interrupting rating and, within its current-limiting range, limits the clearing time at rated voltage to an interval equal to or less than the first major current loop. These fuses also limit peak let-through current to a value less than the normal peak current that would be possible without current-limiting availability. The current-limiting characteristics of current-limiting fuses are expressed by two electrical measurements: (1) maximum peak let-through current, the maximum instantaneous value of current passed by the fuse during time of operation; and (2) maximum clearing I^2t (amperes-squared-seconds), an expression of the energy available as a result of current flow during the clearing time of operation.

Limiters are time-delay fusible connectors designed to be installed in low-voltage network-mains cables at street-junction points. They are rated in cable sizes and have time-current characteristics to (1) allow the cable fault to burn itself clear if it does so promptly, without blowing the limiter; (2) blow before the cable insulation away from the fault is damaged and prevent the failure from spreading beyond the junction; and (3) obtain adequate selectivity so that, when installed in a network, only those limiters connected to the faulted cable blow (see Fig. 10-121 for limiter characteristics).

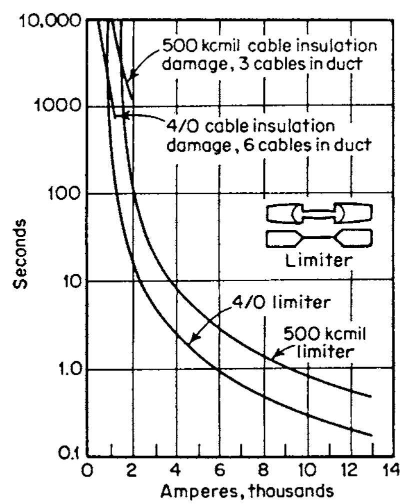

FIGURE 10-121 Time-current characteristics of low-voltage limiters for No. 4/0 and 500 Mcmil network cables.

The usual applications of limiters are at the street-corner junctions of low-voltage network mains, multiple-transformer secondary cables, multiple-service cables, and intervault ties of building interior networks.

In recent years, combinations of low-voltage circuit breakers and low-voltage current-limiting fuses have been devised to provide improved short-circuit protection, especially on motor branch circuits where contactors have low interrupting ratings.

Medium- and High-Voltage Fuses. A medium-voltage fuse is defined as any fuse (above 600 V and less than 69 kV) or fuse device used to isolate an electric short circuit from an electrical distribution system. A *high-voltage fuse* is defined as any fuse rated above 69 kV and less than 230 kV used for this same purpose. Specific classes of fuses or fused devices are

Enclosed cutouts and fuses
Open cutouts and fuses
Open-link cutouts and fuses
Current-limiting fuses
Power fuses
Oil-immersed protective links

See Table 10-15.

TABLE 10-15 Classes of High-Voltage Fuses or Fused Devices and Applicable Standards

Class device	Standard
Distribution cutouts and fuse links	ANSI C37.42
Distribution oil cutouts and fuse links	ANSI C37.44
Power fuses	ANSI C37.46
Current-limiting fuses	ANSI C37.47

These fuses are used to protect potential transformers, distribution or power transformers, and lateral taps from main distribution feeder circuits. They are often used as sectionalizing devices on main feeder circuits. The ampacity and interrupting rating of these devices range up to 720 A, 500 mVA at 14,400 V, and 250 A, 2000 mVA at 138,000 V. Fuses are generally used in electrical series with other fuses or circuit-protective devices. Care must be taken in coordinating the time-current characteristics for proper isolation of the electric circuit during fault and overload conditions.

Distribution fuse links for use with expulsion cutouts are available with many different time-current characteristics. Figure 10-122 shows the minimum melting time-current characteristics for ANSI Type K fuse links.

In an effort to standardize fuse-link characteristics, ANSI has adopted time-current characteristics for two basic fuse-link types: Type K (fast) and Type T (slow). These fuse links are designed so as to have the same time-current characteristics regardless of manufacturer. A wide variety of non-standardized fuse-link characteristics are also available. Fuse-link characteristics are usually based on tests at an ambient temperature of 25°C and no initial load. For characteristics at other ambients or for preloading variations, consult the individual manufacturer.

The characteristics of various medium- and high-voltage protective devices used on distribution power systems are

1. Expulsion cutouts
   a. *Open type:* 20-kA asymmetric maximum interrupting current (IC), 5 to 35 kV, violent in operation at high faults, low cost, both initial and refusing. Maximum continuous-current rating of 200 A; can be fitted with a solid blade for conversion to a disconnect switch with a rating of 300 A. Figure 10-123 shows a typical open-type cutout.
   b. *Enclosed type:* 8- to 10-kA asymmetric maximum interrupting current, used primarily where safety codes dictate use. Enclosed cutouts are no longer manufactured and are being replaced with open-type cutouts.
   c. *Open link:* 1200-A maximum interrupting current, 50-A maximum continuous current, applied on rural lines and/or small transformers.

2. *Oil cutouts:* Considerable application in the past, especially in underground vaults; however, low interrupting current now poses serious underrating problems.

3. *Liquid fuses:* Nonviolent, low interrupting current (8 to 10 kA maximum).

4. *Power fuses:* Reduced arc energy, somewhat less violent than cutouts on high faults, rated to 20-kA interrupting current; both initial purchase and replacement expensive. Figure 10-124*a* shows an indoor-type power fuse.

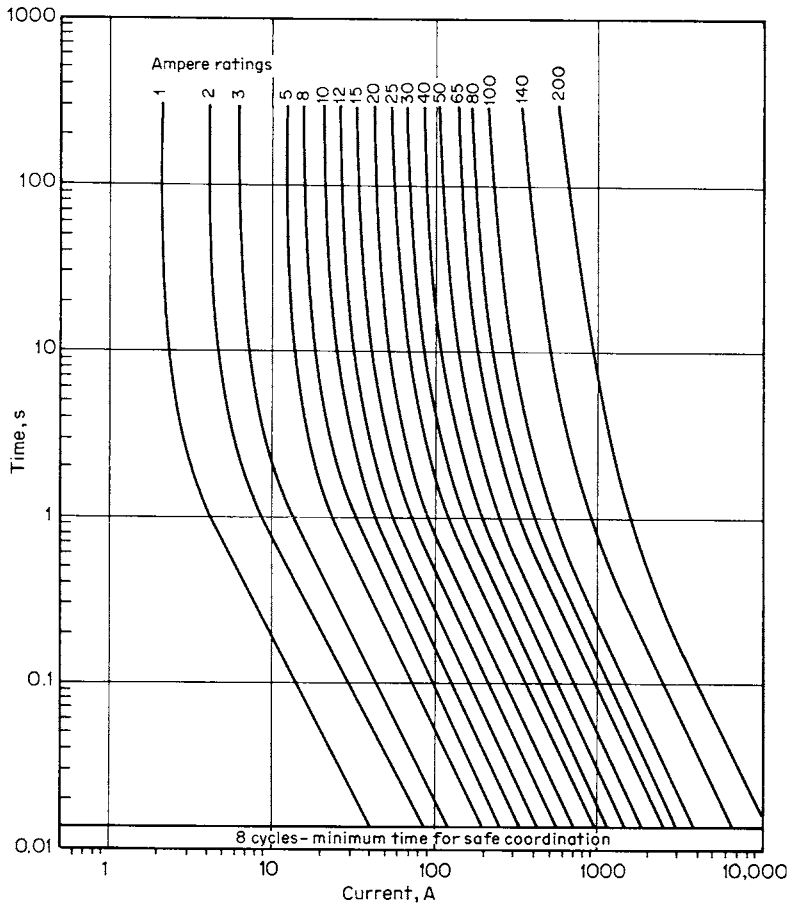

FIGURE 10-122 Minimum melting time-current characteristics of a NEMA Type K fuse. *(A. B. Chance Company.)*

5. *Under-oil protective link:* 4000-A asymmetric maximum interrupting current, violent in operation, low cost, contaminates insulating oil.
6. *General-purpose current-limiting fuses:* Nonviolent, current-limiting, high interrupting current (50 kA), requires coordination study, generated peak arc voltage, not affected by system transient recovery voltage, both initial purchase and replacement expensive.
7. *High-range backup current-limiting fuses:* Current-limiting, high interrupting current (50 kA), requires a low-current interrupting device in series, operates only at high currents, does not affect existing system coordination, low refusing cost on majority of outages because of only blowing expulsion link, not affected by system transient recovery voltage.
8. *Vacuum fuses:* Function with no external arcing or violence. They are nonrenewable and the associated cost is high. They have not found widespread application.
9. *SF_6 fuses:* Function with no external arcing or violence. They utilize rotating-arc technology and have a 12.5-kA interrupting current rating.

All expulsion-principle fuses depend on arc-quenching material—bone fiber, liquid solutions, or boric acid powder—to develop water vapor and/or other gases to cool the arc from the melted fuse

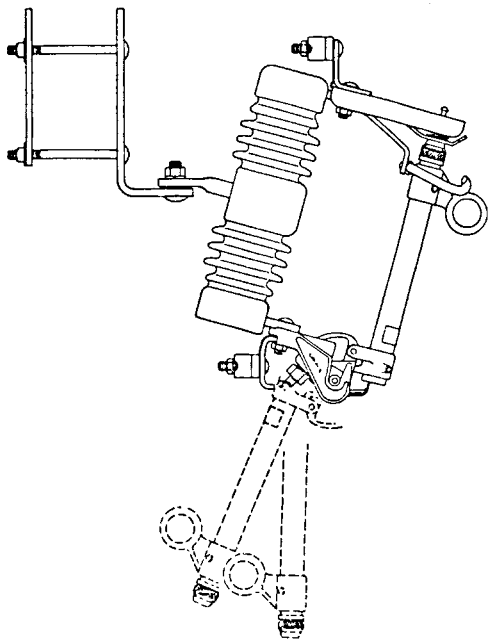

FIGURE 10-123 Open-type distribution fuse cutout. *(A. B. Chance Company.)*

link. These fuses have no energy-limiting ability and require a natural current-zero crossing to successfully interrupt a short-circuit current. Figure 10-124*b* shows a cross section of a power-type fuse.

Current-Limiting Fuses. High-voltage current-limiting fuses for use on distribution systems have two distinct classes: (1) *general-purpose current-limiting fuses,* devices which will successfully interrupt currents which will melt the fusible element in 1 h—these are sometimes referred to as full-range fuses, but this is not an industry-accepted designation; and (2) *backup current- limiting fuses,* devices which have a definite minimum interrupting rating as specified by the manufacturer. These devices require other protective devices in electrical series to protect the backup current-limiting fuse from currents below its minimum interrupting rating. Recently, a new type of backup current-limiting fuse has entered the market. This device, which is referred to as a *fuse limiter,* combines the series fuse and the current-limiting fuse into one convenient package that handles just like a cutout. The fuse limiter is available at 15 and 25 kV, and in current ratings through 20 A. It is specifically designed for protecting overhead distribution transformers (see Fig. 10-125).

Three important parameters should be known about high-voltage current-limiting fuses:

1. *Continuous current rating:* The maximum current that the fuse is designed to carry continuously.
2. *Peak arc voltage:* Maximum voltage generated by the current-limiting fuse. If wire-wound, the voltage value is a function of fault current. If it is a ribbon-element fuse, the voltage is a function of applied voltage across the fuse.
3. *I^2t clearing:* Maximum allowed by the current-limiting fuse. This measures the energy-limiting effect of the fuse.

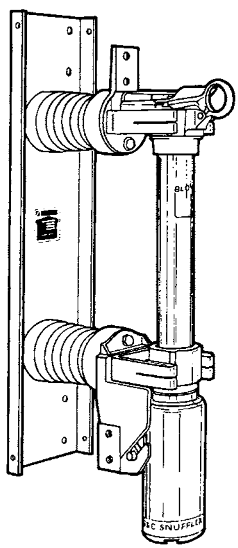
Care in application of current-limiting fuses according to voltage rating must be maintained. In general, these fuses should not be applied to circuits with a voltage less than 50% of the fuse-voltage rating to avoid excessive peak arc voltages.

It is equally important that fuses not be exposed to system recovery voltages in excess of their rating.

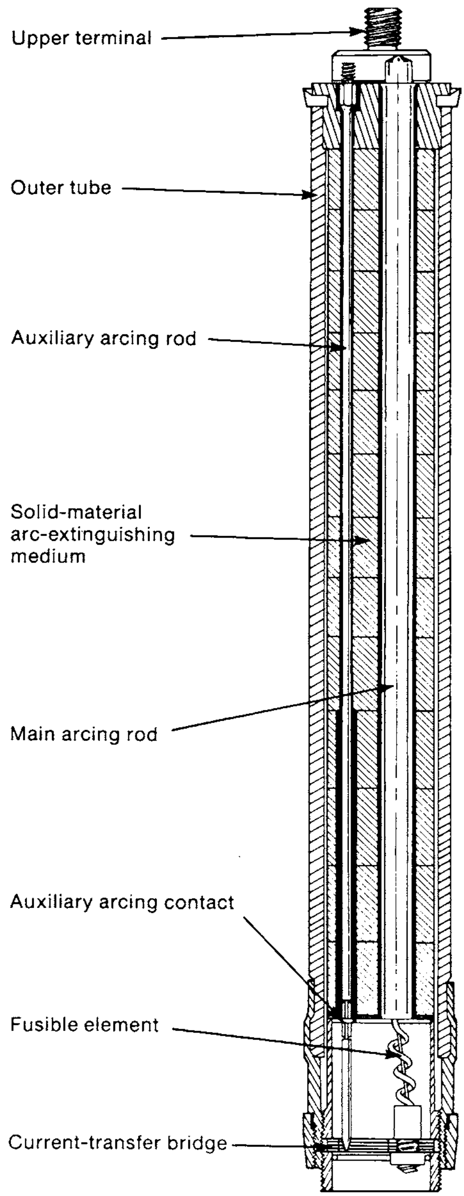
Fuses in Enclosures. High-voltage fuses may be mounted in enclosures for several applications: industrial service entrance switchgear, pad-mounted switchgear or transformers for underground circuits, or in enclosures for subsurface applications. Most fuses will require special adaptation. Power fuses are fitted with a muffler to reduce the intensity of the exhaust gases when used in enclosures. Current-limiting fuses are supplied with special seals to prevent the ingress of fluid when applied under oil such as in transformers. Fuse cutouts are not recommended for use in enclosures or vaults.

Derating of fuses in enclosures may have to be considered because of restricted heat transfer. Consult the manufacturer.

Electronically Controlled Protective Devices. Electronically controlled protective devices offer greater flexibility and accuracy through the use of state-of-the-art electronics. An electronic power



(a)



(b)

FIGURE 10-124 (*a*) Indoor-type power fuse; (*b*) cross-sectional view of power-fuse refill unit. *(S&C Electric Company.)*

fuse and an electronic sectionalizer for use at distribution voltage levels are two examples of this technology.

The electronic power fuse utilizes an electronic control module to provide current sensing, time-current characteristics, and control power for the fuse. High-speed interruption of fault currents to 40,000 A is provided by an interrupting module. The devices are completely self-contained (nonventing) and

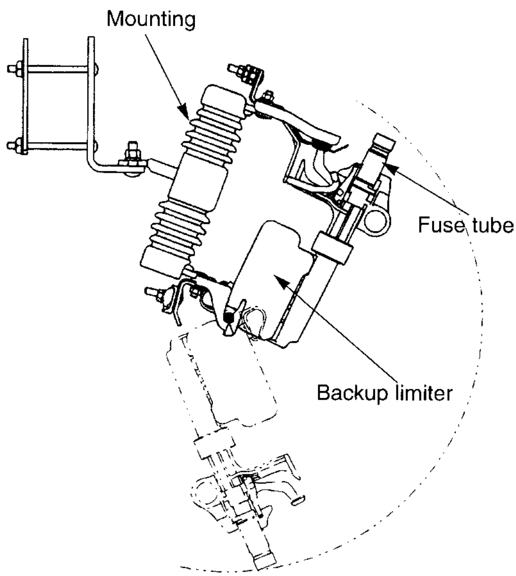


FIGURE 10-125 Fuse limiter. *(S&C Electric Company.)*

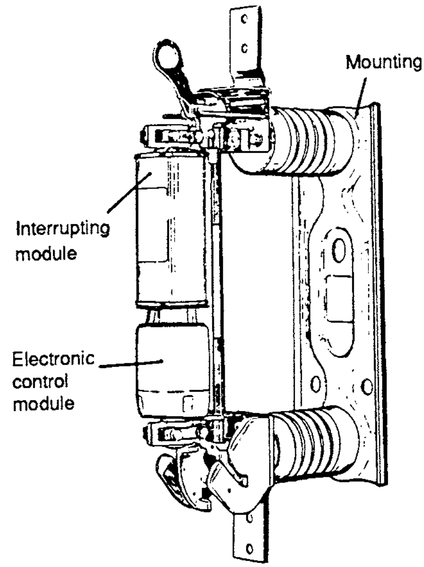

FIGURE 10-126 Electronic power fuse. *(S&C Electric Company.)*

require no external power source. These power fuses are used in metal-enclosed switchgear, pad-mounted switchgear, and metal-enclosed fuse gear. They are available to 600 A continuous current and 4.16 through 25 kV. Three families of time-current characteristics are available. Figure 10-126 shows an electronic power fuse.

The electronic sectionalizer consists of an electronic module which fits into the mounting of a standard open-type cutout. The sectionalizer counts the number of fault current pulses allowed by an upstream recloser and operates to an open position during the recloser's open time. The sectionalizer has no time-current characteristics. It is generally used to replace a fuse at the distribution lateral where fuse coordination is difficult or impossible. Sectionalizers have no fault-interrupting capability and must be used in conjunction with an upstream recloser. Sectionalizers are available in continuous current ratings to 200 A; count settings of 1, 2, or 3; and distribution voltage ratings from 15 to 38 kV. The electronic modules require no external power source. An electronic sectionalizer is shown in Fig. 10-127.

10.6.2 Switches

Disconnecting switches are used primarily for isolation of equipment such as buses or other live apparatus. They are used for sectionalizing electric circuits such as buses or lateral circuits or even portions of main feeders for special purposes such as testing and maintenance. Standards pertaining to disconnect switches are listed in Table 10-16. Generally, these devices are not rated to break load current except when equipped with specific auxiliary devices. Interruption of load currents, magnetizing currents, or capacitive currents without other aiding devices may not be successful. While not recommended, disconnect switches without loadbreak capability have been used to interrupt limited values of load, charging, and magnetizing current. Their performance depends not only on the magnitude of the current but also on the speed of operation, wind direction, velocity, and clearance to other energized or grounded components. The principal concern is that the arc which is created may establish a high-current fault. Arc reach may approach tens of feet or more depending upon system voltage and the current being interrupted. However, these switches must be designed to carry

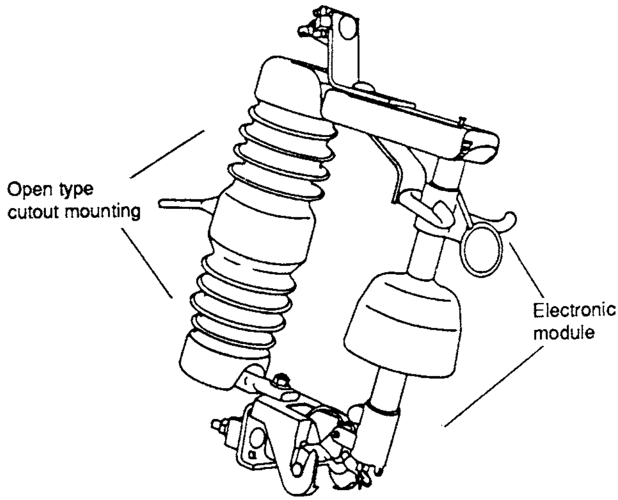

FIGURE 10-127 Electronic sectionalizer. *(S&C Electric Company.)*

expected load currents and remain closed for momentary current flow such as fault currents. Fault currents in excess of a specific rating may cause the switch to be blown open by the magnetic forces due to the short-circuit current.

There are three classes of disconnect switches:

1. Station
2. Transmission
3. Distribution

Switches can be further categorized as gang- or hookstick-operated and loadbreak or nonloadbreak types.

The basic insulation level (BIL) of station-class equipment is normally higher than for transmission or distribution equipment. Station equipment ranges from 2.4 to 765 kV at present. Disconnect switches rated up through 3000 A are available. Manual or automatic switching can be provided.

The design of disconnecting switches demands considerable attention to the contact surfaces. Consideration must be given to the rigors of extreme environments.

High-pressure contacts are generally the form used to provide the current transfer. Current densities of 100,000 A/in^2 are not uncommon when using silver for contact points. Contact pressures as high as 500,000 lb/in^2 ensure that good cleaning action is achieved and keeps the current transfer points free from contamination.

Transmission disconnecting switches are generally used as load-management tools. Increasing needs for transmission lines and decreasing availability of right-of-way makes automatic switching of transmission load desirable.

Load management is achieved during "dead time" by switching the proper disconnects automatically through sensing loss of voltage. These systems are available through 161 kV, 1200 A.

The objective of load management is to minimize outage time and allow for more efficient utilization of substation capacity at the distribution level. There is a growing interest in automating distribution class switches to achieve load-management objectives.

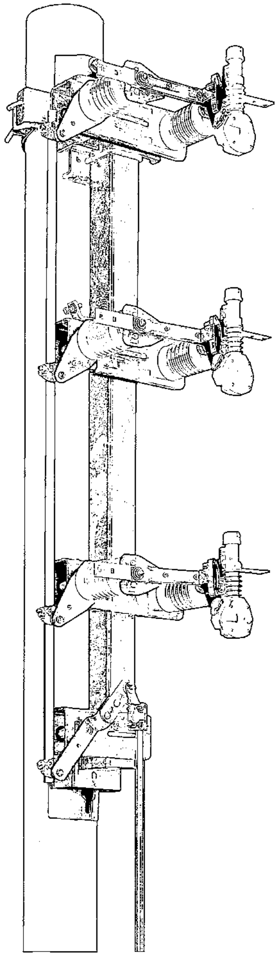

FIGURE 10-128 Gang-operated, phase-over, distribution loadbreak switch. *(S&C Electric Company.)*

Distribution disconnecting switches are becoming the method of providing for both single- and 3-phase sectionalizing. As distribution voltage grows to higher levels, the utility must provide more sectionalizing or switching capability or suffer large and longer outages during faults. Hence, at 34.5 kV one may find some switching capability every 2000 to 3000 ft of overhead conductor. Figure 10-128 shows a typical gang-operated distribution loadbreak switch.

Single-phase disconnect switching with load-interrupter capability can be applied where ferroresonance is not a problem. This type of switching is found on single-phase circuits. Single-phase switching of a heavily loaded 3-phase circuit is not desirable.

Gang-operated switches with loadbreak capability interrupt these loads without concern for ferroresonance problems. In application, these 3-phase switches can be mounted in either horizontal or vertical configurations. To ensure proper operation, the mounting should be as rigid as possible. Care must be exercised in proper alignment of blades and clips. Attention to these matters allows proper operation without overstressing porcelain insulators or distortion of contact surfaces and operational handles.

Load-Interrupter Devices. Load-interrupter devices, when combined with disconnecting switches, provide the desired capability of switching load currents without circuit breakers. Generally, these interrupters are auxiliary devices and are not continuous-duty in terms of carrying load. This load interruption can be achieved by

1. Insertion of a resistor in the circuit following opening of the main switch contact and interruption of the current drawn between arcing horns in the air.
2. Use of a blast of air or other gas to effectively lengthen the arc resulting from the main contacts opening.
3. Use of an interrupter paralleling the main contacts just prior to opening and interrupting in this auxiliary chamber after the main contacts open. This is typically accomplished with an expulsion-type device or vacuum switch.

Figure 10-129 shows an expulsion-type load interrupter used on distribution disconnecting switches to assist in interrupting load current.

Switches for Underground Circuits. The continuing trend toward underground distribution circuits increases the need for pad-mounted switchgear. These are available in both live- and dead-front configurations, with the latter growing in popularity.

Live-front switchgear is typically air-insulated and utilizes in-air switches for loadbreak operation and power fuses for fault interruption. All components are directly accessible and operable.

Dead-front switchgear is typically air-, oil-, or gas-insulated. Air-insulated dead-front switchgear is similar to live-front switchgear except that components are isolated within grounded compartments and are not accessible when energized.

Oil-insulated dead-front switchgear typically uses in-oil switches or vacuum interrupters for loadbreak operation and current-limiting fuses or vacuum interrupters for fault interruption. These have the advantage of being more compact than air-insulated units. The disadvantage is that the oil insulation can become contaminated following in-oil arc interruption or from external contaminants. SF_6-insulated switchgear uses components similar to those used in oil-insulated switchgear. Contamination of SF_6 is less of a concern, although SF_6-insulated gear must be more carefully designed and constructed to ensure gas integrity.

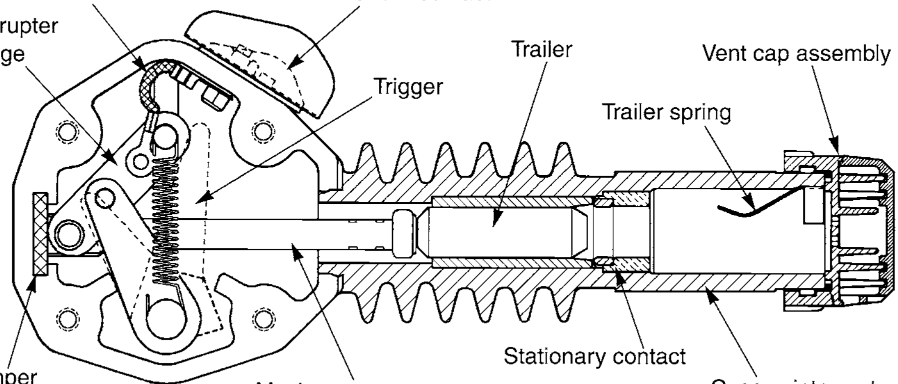

FIGURE 10-129 Load interrupter, expulsion type, used in distribution systems. *(S&C Electric Company.)*

Dead-front designs generally provide increased isolation from energized components, but at the expense of operating simplicity and visual confirmation. External connections are made by means of separable insulated connectors. These connectors generally must be removed to provide a visible break when working on cable or equipment. Some more recent dead-front designs allow visual confirmation of internal visible breaks on both switches and fault interrupters, and some provide integral grounding of cables. This eliminates the need to move elbows and provides isolation from energized components, while also offering the visual confirmation provided in live-front switchgear.

In addition, recent designs have become available either with provisions for motor operation or fully integrated with motor operation and controls for use with SCADA systems.

Oil-insulated and SF_6-insulated switchgear can also be submersible and thus used in subsurface applications where space is at a premium or aesthetics are critical, such as in metropolitan areas. Refer to ANSI C37.72 for standards governing dead-front pad-mounted switchgear, and ANSI/IEEE C37.71 for subsurface load-interrupting switches.

10.7 CIRCUIT SWITCHERS

BY JON HILGENKAMP

Circuit switchers are mechanical switching devices suitable for frequent operation; not necessarily capable of high-speed reclosing; capable of making, carrying, and breaking currents under normal circuit conditions; capable of making, and carrying for a specified time, currents under specified abnormal conditions; and capable of breaking currents under certain other specified abnormal circuit conditions. They may include an integral isolating device. Circuit switchers available today use SF_6 as an interrupting medium and may be equipped with a trip device connected to a relay to open the circuit switcher automatically under specified abnormal conditions, such as overcurrent or faults.

A circuit switcher, like a circuit breaker, must carry normal load currents within a specified temperature range to prevent damage to key components such as contacts, linkage, terminals, and isolating device parts. Principal designating parameters of a circuit switcher are maximum operating voltage, BIL, rated load current, interrupting current, whether an isolator is required, whether a trip device is required, and whether manual or motorized operation is required.

A circuit switcher essentially combines the functions of a circuit breaker (without reclosing capability) and a disconnecting switch (by providing visible isolation, but not necessarily meeting the safety requirements of all users). A circuit switcher provides a cost-effective alternative means of transformer protection and switching, line and loop switching, capacitor or reactor switching, and load management, with protection in most instances.

Evolution of the circuit switcher concept provides a more in-depth understanding of its application versatility and its limitations.

10.7.1 History of Circuit-Switcher Development

After World War II, the drive to electrify the remaining rural and sparsely populated areas of the United States was renewed. Providing fully rated circuit breakers for switching loaded circuits was frequently beyond budget limitations. This created a need for new transmission and subtransmission voltage circuit-switching devices. One such device could be described as a load interrupter. It appeared in a wide variety of forms. Most were attachments to disconnect switches.

Initially, most of these devices used low-volume oil as an interrupting medium. Ablative gas-generating devices and later vacuum displaced oil. With rare exceptions, these devices had deficiencies.

In the mid-1950s, SF_6 was first employed as an interrupting medium. The application was an interrupter attachment for disconnect switches.

Whereas ablative devices and vacuum bottles are limited to approximately 30-kV recovery voltage per gap, this single-gap SF_6 device was readily applied on 138-kV systems for up to 600 A loadswitching. Most of these vacuum, ablative, and SF_6 devices were shunted into the circuit during the disconnect switch opening process. As the 1960s approached, the circuit switcher was born. It appeared as an in-line device. While the first version employed a number of ablative devices in series, it soon evolved into the use of SF_6 as a medium. Because of the unfavorable experience with the earlier devices, the general acceptance of the circuit switcher took much effort and considerable time. A typical installation is shown in Fig. 10-130.

Applications for circuit switchers have been primarily for transformer protection. The circuit switcher provides load-switching capability and mainly protection for faults that originate on the secondary side of the substation transformer. The zone of protection for circuit switchers in this

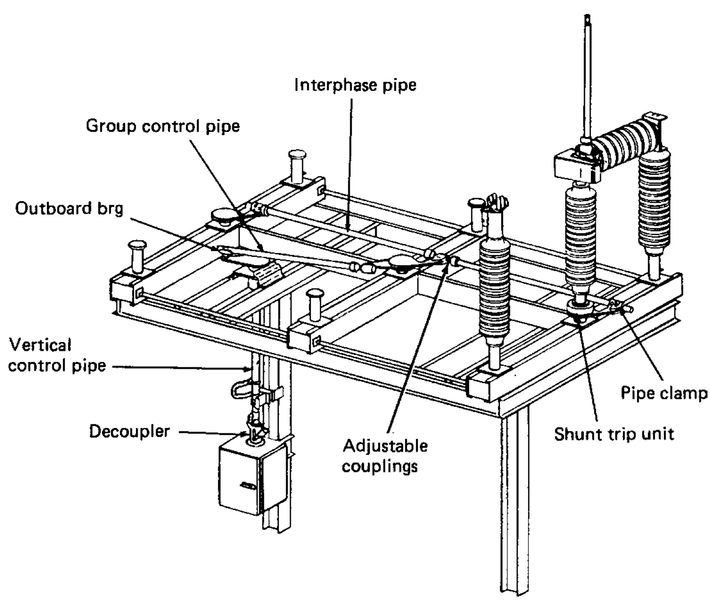

FIGURE 10-130 Schematic of typical 3-pole arrangement. Two poles have been deleted to clarify mechanical drive-train arrangement.

location is typically from the current transformers inside the transformer on the high-voltage bushings to the secondary feeder breakers. There is generally shorter strike distance on the secondary bus and more exposure to flashover from wildlife and other causes. Therefore, circuit switchers are specifically tested to interrupt the higher transient recovery voltages (TRVs) associated with faults initiated on the secondary of the transformer and cleared by the high-side protective device. For application where the available high-side short-circuit current exceeds the device's capability, blocking relays can be used. However, in most applications this is not necessary.

10.7.2 General Construction

Live-tank SF_6 gas puffer-type interrupters are utilized by most circuit switchers today. In the closed position, the contacts are surrounded by a flow guide and piston assembly which is ready to mechanically generate a "puff" of SF_6 to cool and deionize the arc that is established prior to circuit interruption. The moving cylinder attached to the contact assembly is driven by the main opening spring, causing the gas to be pressurized by the stationary piston. The stationary contact "follows" the moving contact as the piston assembly achieves the prepressurized gas condition. When the contacts (which are hollow tubes) part, an arc is established and the gas flow divides into two parts and flows down the stationary and moving contact tubes. The alternating nature of the arc current waveform results in two current zeros every cycle. As long as the arc is sufficiently "hot" or conductive through the SF_6 dielectric medium, the current will reestablish. At the first current zero where the SF_6 density is sufficient to stop the arc from reestablishing itself and to provide necessary dielectric strength, the arc is interrupted. This entire process from trip signal initiation to current interruption requires from 3 to 8 cycles or 50 to 133 ms in modern circuit switchers.

Figure 10-131 illustrates a typical "blade-disconnect model" circuit switcher with the interrupter and blade connected in series. For opening, the trip device, called a "shunt trip," receives a trip signal when the relay system detects an abnormal condition within the specified range or when the operator desires a high-speed circuit opening. By discharging its operating spring, the shunt trip rotates the insulator above it at high speed, thus tripping and discharging the opening spring in the driver mechanism. This actuates the interrupter to open the circuit. If the insulator above the shunt trip continues to rotate, by motor or manual actuation of the drivetrain controls, the blade opens to achieve visible isolation. The blade-hinge mechanism is actuated directly by the rotating insulator through the driver mechanism. Continued rotation of the insulator after the blade is open will "toggle" the drivetrain controls to lock the blade in its open position.

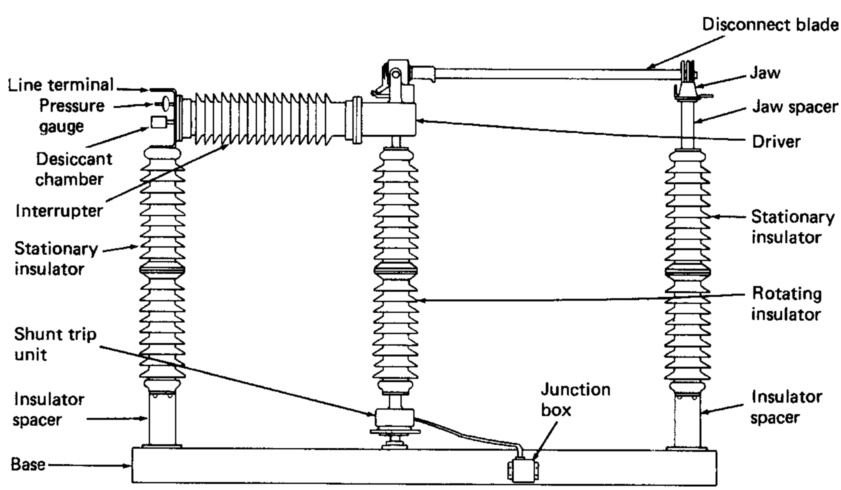

FIGURE 10-131 Single pole of blade-type circuit switcher.

For closing, the reverse rotation of the insulator first releases drivetrain toggle and allows the blade to begin closing. The shunt-trip units have already recharged during the opening operation. As the blade closes, the closing springs are charged in the driver. The last few degrees of closing rotation lock the blade in position and release the closing springs in the driver, thus closing the interrupter. The opening springs are charged as the closing springs discharge. If the unit has closed into a circuit condition that provides a trip signal to the shunt trip units, the opening process may immediately proceed since all springs are charged and all controls are ready.

The closing operation may be achieved in other designs by closing the interrupter during the opening stroke of the blade. When a close operation is called for, all that is necessary is to close the blade, because the interrupter is already closed. Because of the arc established in air for this type of closing, high-speed operation of the blade is necessary to minimize damage to contacts and prevent flashovers. Both methods of closing are proven over many years of field use.

Bladeless circuit switchers operate exactly the same as blade models, except that on opening, the insulator rotation is used only for driver and interrupter actuation. Models that depend on high-speed blade operation for closing are available in bladeless nondisconnect configuration, but circuit closing must be accomplished by other means.

For models without shunt trip, opening is accomplished by rotating the insulator to the point where the driver opening spring would normally be tripped by the shunt trip's rotation. This configuration is used where protection duty is not a function of the circuit switcher.

Transformer Protective Devices. Recently, a new transformer protective device has entered the market specifically for application on the high-side of substation transformers from 69 to 138 kV. These devices offer a 3-cycle 31,500 A interrupting rating with electronically linked pole units. They have been tested for interrupting the high TRVs from secondary-side faults and provide an economical alternative to other protective devices. They are supplied in conjunction with a separate or integrated disconnecting device on the high-voltage side of the protective device. Figure 10-132 shows a typical substation transformer protective device.

FIGURE 10-132 Substation transformer protective device. *(S&C Electric Company.)*

10.7.3 Ratings

Short-Circuit Current. Circuit switchers are "specific-duty" or "medium-fault" interrupting devices and generally fulfill a requirement between high-power fuses and circuit breakers in a transmission or distribution system. Circuit-switcher designs to date do not encompass instantaneous reclosing capability since their most common application of transformer protection precludes this requirement.

Typical short-circuit current ratings are from 4 to 40 kA on a symmetric current basis, depending on type of interrupting duty and voltage rating. The symmetric current is the highest value of the ac component in rms amperes measured at the instant of contact part.

When interruption occurs, a TRV is imposed in microseconds across the interrupting device as a result of system adjustments to the new state before a steady-state condition is achieved known as the normal-frequency recovery voltage. TRV attempts to reestablish the arc by either thermal reignitions or dielectric breakdown of the interrupting gap. Refer to ANSI C37.04 and C37.06 for TRV definitions and ratings. The TRV seen by the highside interrupting device after clearing a fault that initiated on the secondary of the transformer is high because of the characteristics of transformer.

Continuous Current. A continuous current rating is the designated limit of current in rms amperes that can be carried continuously under usual service conditions and in an ambient temperature not in excess of 40°C without exceeding temperature limits assigned to the various materials comprising the current-carrying parts or that are in contact with these parts. For further information refer to ANSI C37.04, C37.30, and IEC 694.

Circuit-switcher continuous current ratings are 1200, 1600, and 2000 A.

Short-Time Current. This is a dual rating to verify the capability of the circuit switcher to carry abnormally high currents in the closed position for short periods of time

1. Rated momentary current is the total current in asymmetric rms amperes (ac and dc components) carried for 10 cycles on a 60-Hz basis. These ratings can approach 50 times the continuous current ratings and assure the device will withstand the high electromagnetic forces from initial transient conditions of a short circuit tending to bring about mechanical damage or contact separation.
2. Rated 3-s current is 62.5% of the rated momentary current and verifies that the current-carrying parts will withstand the heating effect without excessive annealing or contact welding. Common circuit switcher momentary ratings are 61, 70, and 80 kA.

Close-and-Latch Current. For those circuit switchers that make the circuit in the interrupting device, a close-and-latch rating is required as is a close rating for the type that closes the circuit on a disconnect switch blade. This rating verifies the capability of the contact structure and operating mechanism to withstand the forces developed by closing in on a fault. Close-and-latch ratings are 30 and 40 kA. Limited-duty close ratings for the blade type are of the same magnitudes.

Rated Voltage. Rated voltages for circuit switchers are generally stated in terms of maximum system design voltages that indicate the upper limit at which the device is designed to operate. Circuit switchers are most commonly applied at 72.5 through 242 kV but are also available for special applications at 362 kV.

In order to provide safe insulation levels to ground and across the device when in the open position, the circuit switcher must withstand certain specified magnitudes and waveshapes of test voltages without flashover or puncture of any of its insulation systems. This is the rated dielectric strength and consists of

1. One-minute dry and 10-s wet low-frequency (60-Hz) withstand voltage.
2. Dry lightning-impulse (1.2×50 μs waveshape) withstand voltage. It is the positive-polarity withstand level that is the basic-insulation-level rating (BIL in kilovolts).
3. Dry and wet switching-impulse (250×2500 μs) withstand voltage. This rating applies only at 362 kV and above.
4. Dry chopped-wave impulse withstand voltage. The requirement for this rating has yet to be determined for a circuit switcher but is a standard rating for a circuit breaker. If applicable, this rating would apply to a bladeless model circuit switcher having graded gaps in series per pole.

Interrupting Time. The rated interrupting time is the maximum permissible interval between energizing the shunt trip coils at rated control voltage and the interruption of the main circuit in all poles when interrupting a current within the required interrupting capabilities. This interrupting time may be modified under certain asymmetrical current conditions as detailed in ANSI C37.04. Circuit switchers are available from 3- to 8-cycle interrupting times.

Duty Cycle. Operating duty is the short-circuit current to be interrupted, closed upon, etc. The duty cycle is a stated sequence of closing and opening operations. Various types of circuit switchers will have different duty cycles. An example is O-17s-CO where the first operation is an open followed by 17 s to permit the operating mechanism and blade to recycle in order to perform the close-open cycle.

Corona-RIV. A corona-free rating is commonly established to prevent radio and television interference. This is referred to as the radio influence voltage (RIV) and should be less than 500 μV as determined by a test circuit per NEMA Publication No. 107. As a general rule, a circuit switcher that produces no visible corona under dark conditions at 105% of rated voltage will have a negligible RIV level.

10.7.4 Selection and Application

The versatility of circuit switchers and related circuit-interrupting devices requires careful selection of the ratings, components, and accessories to be specified for a given protection and/or switching duty. The following criteria must be considered:

1. System data
   - ***a.*** Nominal service voltage
   - ***b.*** Maximum continuous current
   - ***c.*** Through-fault current withstand
   - ***d.*** TBasic impulse (insulation) level
2. Circuit-protection duty
   - ***a.*** Present and future available fault currents
   - ***b.*** Length of overhead lines or underground cables
   - ***c.*** Transformer ratings, impedance, and connections
   - ***d.*** Transient recovery voltage
   - ***e.*** Interrupting time, maximum
3. Switching duty
   - ***a.*** Inductive currents (unloaded transformers)
   - ***b.*** Small capacitive currents (unloaded lines and cables)
   - ***c.*** Inductive/capacitive currents (choke coils, capacitors, grounded or ungrounded)
   - ***d.*** Closing on fault
   - ***e.*** Closing of long lines

Approximately 80% of all circuit switchers are applied on the primary or high-voltage side of a transformer for switching and fault-protection duty. By means of protective relaying, faults which occur within the protection zone of the transformer can be detected to bring about tripping of the primary-side circuit switcher. Should the fault occur on the secondary side, which is most frequently the case, the magnitude of fault current at the circuit-switcher location is limited by the transformer impedance and is less than the available primary-fault current. Hence, the use of the term "inherent secondary-fault current," and for some circuit switchers, a dual short-circuit current rating for primary or secondary faults.

Associated with these reflected secondary faults are the inherent capacitance and inductance of the transformer windings, which generally produce higher TRVs than is the case with a primary fault. These higher TRVs can increase the difficulty of the interruption process, while conversely, the impedance-limited fault current is easier to interrupt. Circuit switchers are tested for this condition as defined in the nearly completed ANSI C37.016 which is the new standard for circuit switchers. This test standard defines secondary fault test with a TRV that is more severe than the circuit breaker test standard. Therefore, the circuit switchers demonstrate interrupting capability for this specific duty.

Primary-fault currents in excess of the switcher rating can often be cleared by source-side circuit breakers having interrupting times shorter than those of a circuit switcher. It is also common to block tripping of the circuit switcher when the fault current is in excess of its rating and pass this duty on to the source-side breaker.

Circuit switchers and interrupters are generally available in mounting arrangements similar to isolating air-disconnect switches. Since they are not freestanding, their application and that of the supporting structure design and/or optional freestanding pedestal is influenced by phase spacings desired, terminal height, altitude, atmospheric elements, seismic conditions, and wind, ice, and terminal pad loadings.

The phase spacing recommended in the ANSI C37.32 differentiates between the minimums for vertical-break disconnect switches (also applying to bus supports) and the increased spacings required for horn gap switches (switching devices utilizing arcing in air as an operating mode). From a safety viewpoint, it is important to consider the method of operation in addition to the duty applications of the particular device as a determination in selecting the phase spacing.

Elevation of the installation site, in addition to the temperature, humidity, and air-contamination characteristics, significantly affects the dielectric strength and coordination of these circuit-interrupting devices. The guidelines established in ANSI C37.30 for site elevations coupled with a further analysis of these other factors may dictate the use of higher-voltage-rated units or extra-leakage-distance porcelain standoff insulators.

Seismic, wind, ice, and terminal pad loadings must also be considered in the design of the supporting structure.

Testing. Industry standards specifically for circuit switchers have yet to be fully implemented. There is a draft standard, ANSI C37.016, which is close to being adopted. Accordingly, up to this point applicable sections of existing standards for circuit breakers and disconnect switches have been used as a guide in establishing definitions, ratings, capabilities, and test procedures for circuit switchers (see ANSI C37.09 and C37.34). In addition, specific testing for secondary fault currents and the associated higher TRVs has been completed by some circuit switcher manufacturers.

Tests can be considered to consist of four different groupings:

1. Type or design tests are for the purpose of proving the capability of the switcher to meet the specified ratings.
2. Reliability tests are part of a quality assurance program to demonstrate that the circuit-switcher design has achieved a specified mechanical reliability. They consist of growth or prototype tests to improve on the established design reliability, demonstration, or pilot run tests to assure the reliability requirements have been met, and acceptance or production tests to verify that production units comply with the demonstrated design reliability.
3. Routine or production tests are done to ensure that the production is in accordance with established procedures. This includes testing of individual components and subassemblies.
4. Installation testing to assure that the circuit switcher will perform its intended function in the system.

Accessories and Maintenance. As discussed in a preceding section, circuit-switcher manufacturers offer optional freestanding support pedestals in addition to many other accessories, some of which

10.8 AUTOMATED FEEDER SWITCHING SYSTEMS

The method known as SCADA has long been used to control transmission systems, providing the operational flexibility and speed required for efficient and reliable performance. The use of SCADA in the distribution system is becoming increasingly important as utilities move into a deregulated, competitive environment. The acronym *SCADA* is being replaced by the generic term *distribution automation* (DA), which incorporates the principle of computers operating switching and other control devices automatically in response to preprogrammed events in the system. Automated switching of distribution feeder circuits provides significant improvements in reliability, enhances operational flexibility, and increases productivity of both utility personnel and distribution lines.

Automated feeder switching systems utilize controls, sophisticated algorithms, and data communications to go beyond the reliability benefits of more traditional reclosers and automatic sectionalizers. An automated switching system can be programmed to not only reduce outage times, but do so without subjecting unfaulted circuits to "bumps" caused by intentional closing into faults required by fault-detection or troubleshooting schemes. Further, an integrated fault-isolation and restoration system can incorporate real-time evaluation of prefault loads into the algorithm to prevent overloading of a backup circuit when transferring load from a faulted circuit. This allows the utility planner more flexibility in circuit design by increasing the amount of load that can normally be carried by a given circuit.

Such systems, with current and voltage monitoring, also provide the utility with a convenient way to monitor distribution feeder circuits, thus enabling the utility to take immediate action in the event of current or voltage excursions exceeding normal operating limits. This, in turn, results in improved power quality and service for the customer.

Automated feeder switching systems can also provide the means to optimize feeder and substation loading by enabling the shifting of load from one feeder to another in a very short time frame. This same capability can yield hard-dollar cost savings associated with deferment of capital projects when coupled with planning practices that take advantage of the new technologies.

With the increasing power of computers and improving communications, it is certain that automated feeder switching systems will provide benefits that have yet to be considered in the electric utility industry.

Examples of Automated Feeder Switching Systems. A large investor-owned electric utility in New York needed to dramatically improve reliability in response to a challenge from the New York public utility commission. After analyzing its system as well as the nature and locations of faults, it was decided that an automated feeder switching system would provide the quickest route to needed improvements in electric service reliability.

A typical MES feeder "loop" is shown in Fig. 10-133. It consists of two circuits joined by a normally open tie switch. In turn, each feeder circuit will have a normally closed automated switch installed at the electrical half-way point on the circuit. All switches are equipped with voltage and current monitoring as well as communication and control units (CCUs) housing the switch controls,

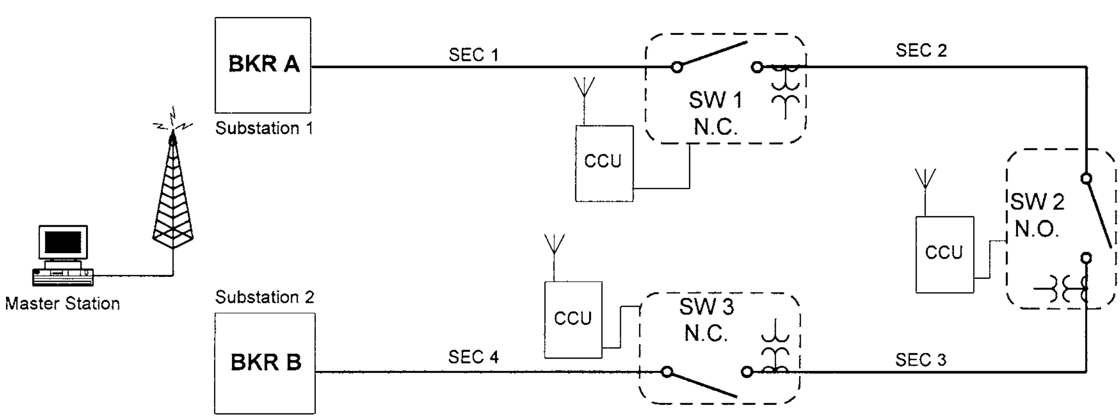

FIGURE 10-133 Typical automated feeder circuit loop.

power supplies, remote-terminal units (RTUs) and radios for establishing communication with the master station.

Faults occurring in Sec. 2 will result in a trip of substation breaker BKR A. The control at switch SW1 will sense the passage of fault current and the subsequent loss of voltage precipitated by the opening of BKR A. A sectionalizing algorithm will initiate and open the switch after a predetermined time delay set to coordinate with the recloser interval of BKR A. The station breaker is reclosed to determine if the fault condition is temporary or permanent. A typical reclosing breaker may reclose up to 3 times on some systems. Once SW1 is open and the fault is isolated, BKR A will reclose, restoring service to the customers in Sec. 1. At this point, the crew can proceed directly to SW1 and commence the search for the fault from there, further reducing the amount of time for fault location.

Faults occurring in Section 1 will result in a lockout of substation BKR A. At this point, SW1 will see a loss of voltage and transmit an alarm to the master station. The master will then interrogate SW1 and find that it saw loss of voltage, but no overcurrent. This condition indicates a section 1 fault. The master station will then initiate the section 1 fault algorithm and interrogate SW1 to determine the load in section 2 just prior to the fault. The master then interrogates SW3 for load information. If the addition of section 2 load to the current load on section 3 will not result in an overload condition, then the master station will instruct SW2 to close, restoring service to section 2.

The MES system can be operated in three modes. The first is traditional SCADA, where the dispatcher must identify and analyze circuit conditions before deciding on restoration procedures, which must then be sent to the field devices individually. In the second mode, the master station computer will identify and analyze the circuit condition and make an operational recommendation to the dispatcher, who can then choose to accept the recommendation and execute a simple acknowledge command which will automatically issue appropriate commands to field devices. The third mode identifies and analyzes circuit conditions and automatically issues commands to field devices to isolate faulted sections and restore service to unfaulted sections. It should be noted that the system can utilize up to seven switching devices on a given circuit loop similar to that shown in Fig. 10-133. The figure was simplified for clarity in this example.

A large metropolitan utility serving customers in and around Chicago wanted to improve electric service. However, they did not have a SCADA master station at the beginning of the project and needed a way to improve service without installing one. In this case, the utility installed a system which utilizes distributed intelligence in the switch controllers to do all analysis as well as fault isolation and circuit restoration. Such a system operates in much the same way as described in the example above. The key difference is that this system does not utilize the first two modes of operation: traditional SCADA and suggesting operational recommendations. The advantage is the ability to install the system without the need for a communications network or SCADA master station. This system does its work automatically without human intervention—or the need for a communication system. It should be noted that the system can be easily disabled in the field for line work if desired and can be upgraded to work with a master control station.

10.8.1 Automated Switches

A key part of an automated feeder switching system is the automated switch. The term “automated” in this context means the switch is designed for use on an automated or SCADA system. In order to be automated, existing switches may be retrofitted with motor operators, current and voltage sensors, RTUs and communication devices to allow the remote operation necessary to realize the benefits available with automated feeder switching systems. However, switches designed for occasional, manual operation may not be entirely suitable for operation on an automated distribution circuit feeder. Manual switches are typically not designed to be operated the hundreds of times required by a fully automated system over the life of a typical switch. Nor are they ordinarily designed for duty-cycle fault-closing to allow the system operator to inadvertently close into a fault from the SCADA master station—and still leave the switch in an operable condition.

More recently, switches designed specifically for automation have appeared in the market (Fig. 10-134). Such switches incorporate design features that make them particularly applicable for use in an automated feeder switching system:

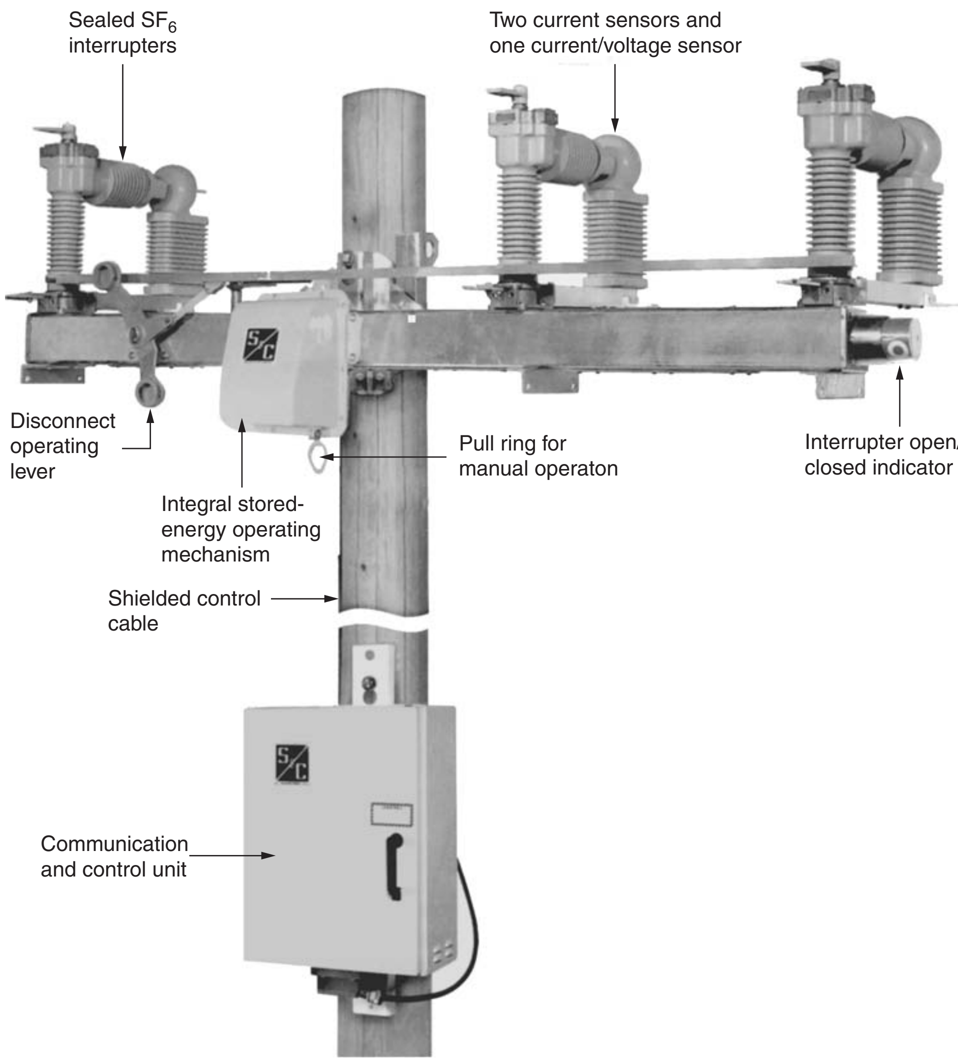

FIGURE 10-134 Scada-Mate switching system. *(S&C Electric Company.)*

1. *Duty-cycle fault-closing* allows the switch to be closed into a typical fault several times before experiencing damage severe enough to render the switch inoperable.
2. *Integrated voltage and current sensors* provide the ability to monitor voltages, currents, and loads that are in turn used as inputs to algorithms to effect automated switching for fault isolation and restoration and for shifting loads for circuit optimization.
3. *Integrated operating mechanisms* enable the switches to be operated remotely via computer commands. Integration with the switch ensures optimum operation without the need for cumbersome ground-to-switch linkages.
4. *Integrated load interrupters* should be designed to allow operation under any weather conditions since it will not be possible to visibly inspect the switch for ice or other problems prior to operation.

5. *Integrated control power sources* eliminate the need to rely on locally available control power sources—or to install such power sources.
6. *Integrated visible air-gap isolation* provides the visible air gap when needed for certain types of line work.

In addition, an associated control package should include switch-operating controls, a local/remote switch, backup power for dead-line SCADA operation, a remote-terminal unit, and data-communication devices. The entire package should be assembled and tested for proper operation by a single supplier to eliminate the need for the utility to perform the integration. The control box should be separately located from the switch to allow access by technicians who are not qualified in high-voltage operations. In underground switchgear applications, the control should be isolated from the high-voltage compartments of the switchgear.

CONTENTS

11.1 TRADITIONAL ENERGY SOURCES

BY RAMESH BANSAL

Electricity has been generated for the purpose of powering human needs for more than 120 years from various energy sources. The importance of dependable electricity generation was revealed when it became apparent that electricity was useful for providing heat, light, and power for human activities. Today, traditional (conventional) sources of power generation are fossil fuels (coal, petroleum, natural gas), hydro and nuclear power systems.

11.1.1 Coal

The primary sources for coal are China, the United States, and the former USSR. These countries have 75% of the coal reserves. Coal was the first fossil fuel used for producing electricity. Electricity is produced at a coal-fired fossil plant by the process of heating water in a boiler to about 540°C to produce steam. The steam, under tremendous pressure of about 130 Kg/cm^2, flows into a turbine, which spins a generator to produce electricity. Many environmental problems are associated with the use of coal including nitrous oxides, sulfur oxides, CO_2, as well as particulate matter is released when coal is burned. Nitrous oxides and sulfur oxides cause acid rain and CO_2 is responsible for global warming.

11.1.2 Crude Oil (Petroleum)

The use of oil started after the 1860s. Oil is liquid hydrocarbon. There are three main products of oil: kerosene, fuel oil, and gasoline. About 75% of the oil production is controlled by OPEC (Organization of Petroleum Exporting Countries), which was formed in 1973. OPEC can negotiate as a block to sell their oil, and thus are able to set higher prices. The advantages of oil are easy to handle, store, and transport. Also, it is used for things other than energy: productions of plastic, lubrication, etc. While oil burns cleaner than coal, the same pollutants are produced and the same environmental problems are associated with oil production, transport, and combustion.

11.1.3 Natural Gas

Natural gas is available in three types: methane, propane, and butane. Natural gas is often found in association with crude oil. The largest reserves are found in the Persian Gulf countries. Advantages of natural gas are that it burns cleaner than the other fossil fuels, less nitrous oxides and sulfur oxides are produced, and less particulate matter, but CO_2 is still produced. Combustion turbines can run on natural gas or low-sulfur fuel oil and are designed to start quickly to meet the demand for electricity during peak operating periods. Air enters at the front of the unit and is compressed, mixed with natural gas or oil, and ignited. The hot gas then expands through turbine blades to turn the generator and produce electricity.

11.1.4 Hydro

Hydroelectric power is a form of power that utilizes the energy released by water falling on the turbine blades that rotates the generator to produce electricity. Hydroelectricity is a renewable energy source, since the water that flows in rivers has come from precipitation such as rain or snow. The energy that may be extracted from water depends not only on the volume but also on head (the difference in height between the water crest [or source] and the water outflow).

TABLE 11-1 Installed Hydroelectric Capacity

Country	Hydroelectric installed capacity (MW)
United States	79,511
Canada	66,954
China	65,000
Brazil	57,517
Russia	44,000
Norway	27,528

Hydroelectric power supplies about 20% of the world's electricity. Norway produces virtually all of its electricity from hydro, while Iceland and Austria produce 83% and 67%, respectively, of their electricity from hydro. Countries with their hydroelectric installed capacities are shown in Table 11-1.

The world's largest hydroelectric power stations in operation are at Itaipu, Brazil with an installed capacity of 12,600 MW and Three Gorges Dam, China with installed capacity of 18,200 MW, which is scheduled to be completed by 2009.

The chief advantage of hydro systems is elimination of the cost of fuel. Hydroelectric plants are immune to price increases for fossil fuels and do not require imported fuel. Hydroelectric plants tend to have longer lives than fossil-fuel-fired generation, with life spans of 50 to 100 years. Operation and maintenance costs also tend to be low since plants are generally heavily automated and have fewer personnel on-site during normal operation. Hydroelectric plants are pollution free. Since the generating units can be started and stopped quickly, they can follow system loads efficiently, and may be able to reshape water flows to more closely match daily and seasonal system energy demands. Concerns have been raised by environmentalists that large hydroelectric projects might be disruptive to surrounding aquatic ecosystems. Another disadvantage of hydroelectric dams is the need to relocate the people living where the reservoirs are planned.

11.1.5 Nuclear Fuel

The first commercial nuclear power stations started operation in the 1950s. There are now some 440 commercial nuclear power reactors operating in 31 countries, with over 364,000 MW of total capacity. Main countries producing electricity from nuclear power are the United States, France, and

Japan, having installed capacities of 97,585, 63,474, and 46,343 MW, respectively, as of May 2005. Nuclear fission, or the splitting of atoms of ^{235}U, releases energy, which is used to heat water and produce steam, which drives turbines to produce electricity.

Although uranium is mined, very little of it is needed compared to coal or oil, so the mining itself is not as big an environmental concern as it is for the fossil fuels. Advantages of nuclear power include the lack of pollution-causing emissions. There are great dangers associated with nuclear power production, however, since a by-product of the process, plutonium, can be used to make nuclear weapons. In addition, there are problems associated with how to dispose off nuclear waste and how to deal with decommissioning old power plants that are no longer productive.

The two most common types of nuclear power plants are boiling water reactor (BWR) and pressurized water reactor (PWR), both using water as coolant. In BWR plants, the water is allowed to boil in the reactor core, the steam is then passed through the turbine, which runs the generator to produce electricity. In PWR plants, there are two more cycles linked by the heat exchanger. In PWR, fuel rods are placed in the reactor vessel to make up the core—the part of the plant that produces heat. When a uranium atom splits in the process called nuclear fission, it gives off energy in the form of heat. To regulate the heat-producing process, control rods and borated water are used. The borated water speeds up or slows down the fission process, and the control rods shut down the reaction when they are inserted between the fuel rods. A nuclear plant works in much the same way that a dam or fossil fuel plant does, in which large turbine blades are used to run a generator to produce electricity. At a hydroelectric dam, the force of the falling water spins the turbine blades, while at a coal-fired or nuclear plant, the force of steam spins the blades. A nuclear plant, however, uses uranium instead of coal as a fuel to make steam.

11.2 RENEWABLE ENERGY TECHNOLOGIES

BY RAMESH BANSAL

The energy crisis, which began in 1973, caused petroleum supplies to decrease and prices to rise exorbitantly. This crisis forced developing countries to reduce or postpone important development programs, so they could purchase petroleum to keep their economies operating. It created the urgent necessity to find and develop alternative energy sources, as other fossil fuels (coal, oil, and natural gas), nuclear energy, and renewable energy resources.

There are concerns about nuclear energy because of the associated accident risks; waste disposal difficulties, nuclear terrorism, and nuclear weapon proliferation are dangerous in themselves. Acquiring nuclear energy from the industrialized world could, moreover, result in greater technological and economic dependence on developed countries. World's proved fossil fuel resources might be exhausted in about 100 years, thus making situation alarming. A more feasible alternative to petroleum, coal, and nuclear reactors in developing countries is the *direct* and *indirect* use of solar energy, which is renewable, abundant, decentralized, and nonpolluting.

Each day, the sun sends to earth many thousands of times more energy than we attain from other sources (the equivalent of 200 times the energy consumed by the United States in 1 year). This energy can be captured *directly* as radiation or—even more significantly—*indirectly* in waterfalls, wind, and green plants. Taking into account that the technology needed for exploiting renewable energy resources is simple and relatively economical, it is important from a strategic point of view that energy planning in Third World countries, particularly in the humid tropics, be oriented to developing the solar alternative. It offers them one of the few opportunities to develop independently of the industrialized countries. This section briefly describes various renewable energy sources, that is, solar, wind, small hydro, biomass, geothermal, tidal, magnetohydrodynamic (MHD), and ocean thermal energy conversion (OTEC).

11.2.1 Solar Energy

Solar power describes a number of methods of harnessing energy from the light of the sun. It is already in widespread use where other supplies of power are absent such as in remote locations and in space. As the earth orbits the sun, it receives approximately 1,020 W/m^2 at sea level.

Solar power may be classified as direct and indirect. Direct solar power involves only one transformation into a usable form, for example, sunlight hits a photovoltaic cell to create electricity and warms the surface or heats the water when the light is converted to heat by interacting with matter. Indirect solar power involves more than one transformation to reach a usable form. Many other types of power generation are indirectly solar-powered, for example, (i) vegetation use photosynthesis to convert solar energy to chemical energy, which can later be burned as fuel to generate electricity; (ii) energy obtained from oil, coal, and peat originated as solar energy captured by vegetation in the remote geological past and fossilised; (iii) hydroelectric dams and wind turbines are indirectly powered by solar energy through its interaction with the earth's atmosphere and the resulting weather phenomena; (iv) energy obtained from methane (natural gas) may be derived from solar energy either as a biofuel or fossil fuel; (v) ocean thermal energy production uses the thermal and gradients that are present across ocean depths to generate power.

Solar power can also be classified as passive or active. *Passive solar systems* are systems that do not involve the input of any other forms of energy apart from the incoming sunlight. *Active solar systems* are those that use additional mechanisms such as circulation pumps, air blowers, or automatic systems that aim collectors at the sun. Effective use of solar radiation often requires the radiation (light) to be focused to give a higher intensity beam, that is, parabolic dish, parabolic trough, etc., are used to concentrate light at a point or a line. At the focus, high-concentration photovoltaic cells (solar cells) or a thermal energy "receiver" may be placed. Most of the solar energy used today is harnessed as heat or electricity. Solar design aims the use of architectural features to replace the use of grid electricity and fossil fuels with the use of solar energy and decrease the energy needed in a home or building with insulation and efficient lighting and appliances. Following are the main applications of solar energy:

Photovoltaic systems: Solar cells, also known as photovoltaic cells, use the photovoltaic effect of semiconductors to generate electricity directly from the sunlight. Because of high manufacturing costs, their use has been in limited until recently. One cost-effective use has been in very low-power devices such as calculators with LCDs. Another use has been in remote applications such as roadside emergency telephones, remote sensing, cathodic protection of pipelines, and limited to isolated home power applications. A third use has been to power orbiting satellites and other spacecraft. However, the continual decline of manufacturing costs (dropping at 3% to 5% a year in recent years) is expanding the range of cost-effective uses.

Solar heating: Solar hot water systems are quite common in some countries where a small flat panel collector is mounted on the roof and is able to meet most of a household's hot water needs. Cheaper flat panel collectors are also often used to heat swimming pools, thereby extending the swimming season. There are some new applications of thermal hot water, like air cooling, currently under development.

Solar cooker: Taps the sun's power in an insulated box, which has been successfully used for cooking. Solar cooking is helping many developing countries both by reducing the demands for local firewood and maintaining a cleaner environment for the cooks.

11.2.2 Wind Energy

Among the renewable sources of energy available today for generation of electrical power, wind energy stands foremost because of the no pollution, relatively low capital cost involved and the short gestation period required. Wind-powered systems have been widely used since the tenth century for water pumping, grinding grain, and other low-power applications. There were several early attempts to build large-scale wind-powered systems to generate electricity. Recently, wind turbine of 4.5 MW and rotor diameter of more than 112.8 m has been in operation.

Today, wind energy is the fastest growing energy source. Presently, wind power meets the electricity needs of more than 35 million people. Globally, the wind power industry employs around 70,000 people and is worth more than $5 billion. According to Global Wind Energy Council (GWEC), global wind power capacity has increased from 7,600 MW at the end of 1997 to 47,337 MW by February 2005. Main countries producing electricity from wind are Germany, Spain, the United States, Denmark, and India, having their installed capacities 16,629, 8,263, 6,470, 3,117, and 3,000 MW, respectively, by February 2005. Today, wind power accounts for about 0.4% of the world's electricity demand. An analysis by the European Wind Energy Association (EWEA) shows that there are no technical, economic, or resource limitations that prevent wind power from developing to nearly 12% of the world's electricity supply by 2020, but with strong political commitment worldwide, the wind energy industry could install an estimated 1200,000 MW by 2020.

The total wind power P_w that is available to a wind turbine is given by

$$P_w = (\rho A V^3)/2 \tag{11-1}$$

where ρ is the density of the air in kg/m^3, A is the exposed area in m^2, and V is the velocity in m/s. The maximum power that can be realized from a wind system is 59.3% of the total wind power. The power in the wind is converted to mechanical power with an efficiency (coefficient of performance) c_p, which is transmitted to the generator through a mechanical transmission with efficiency n_m, and is converted to electricity with an efficiency n_g. The electrical power output is then

$$P_e = c_p\, n_m\, n_g\, P_w \tag{11-2}$$

For a given system, P_w and P_e will vary with wind speed. As the wind increases from a low value, the turbine is able to overcome all mechanical and electrical losses and start delivering electrical power to the load at cut-in speed V_C. The rated power output of the generator is reached at rated wind speed V_R. Above V_R, some wind power is spilled to maintain constant power output. At the furling speed V_F, the machine is shut down to protect it from high winds. Seasonal and diurnal variation has significant effect on wind. Other factor, which affects power from wind, is height of wind turbine. Wind speed increases with the height because of friction at the earth's surface.

There are a number of ways of classifying wind systems, for example, according to size of power output, rotational speed of wind turbines, orientation of wind turbines, etc. According to the size of power output, wind systems may be classified, for example, as small, medium, and large.

According to the rotational speed, wind turbines are classified as fixed speed and adjustable speed generators. In fixed speed generators, the rotor is held constant by continuously adjusting the blade pitch and/or generator characteristics. For synchronous generators, the requirement of constant speed is very rigid and only minor fluctuations of about 1% for short durations could be allowed. As the wind fluctuates, a control mechanism becomes necessary to vary the pitch of the rotor so that the power derived from the wind system is held fairly constant. Induction generators with small negative slip can also be considered as constant speed. Induction generators are simpler than synchronous generators. They are easier to operate, control and maintain, have no synchronization problem, and are economical. Modern high-power wind turbines are capable of adjustable speed operation. Key advantages of adjustable speed generators compared to fixed speed generators are that they are cost effective, provide simple pitch control, and yield higher output for both low and high wind speeds.

According to the orientation of turbines, wind turbines are classified as horizontal and vertical axis machines. In horizontal axis wind turbines (HAWT), the axis of rotation is parallel to the direction of the wind. Depending upon the number of blades these may be classified as single-bladed, double-bladed, three-bladed, multibladed, and bicycle-bladed. In vertical axis wind turbines (VAWT), the axis of rotation is perpendicular to the direction of wind. These machines are also called *crosswind axis machines*. Main designs of vertical axis machines are Savonious and Darrieus rotors. The principal advantages of VAWT over conventional HAWT are that VAWT are omnidirectional, that is, they accept the wind from any direction. The vertical axis rotation also permits mounting the generator and gear at the ground level. On the negative side VAWT requires guy wires attached to the top for the support, which may limit its application particularly for the offshore sites.

Wind speeds over the open ocean average 30% to 50% higher than on land, while turbulence is reduced because of the absence of surface obstructions such as hills, trees, and buildings. Since power increases as the cube of the wind speed, the substantial increases in output that can be achieved in offshore wind power systems can more than offset the increased cost of sitting wind turbine in water. Offshore designs are therefore made to meet different requirements. Wind machines must have marine grade components, seals, and coatings to protect them from corrosion. In Europe, offshore projects are now springing up off the coasts of Denmark, Sweden, the United Kingdom, France, Germany, Belgium, Irelands, the Netherlands, and Scotland.

11.2.3 Small Hydropower

Although this technology is not new, its wide application to small waterfalls and other potential sites is new. It is best suited to high falls with low volume, such as occur in high valleys in the mountains. It is the application of hydroelectric power on a commercial scale serving a small community. These plants are classified by power and size of waterfall. A generating capacity of up to 10 MW is becoming generally accepted as the upper limit of small hydro, although this may be stretched up to 30 MW in some countries. Small hydro can be further subdivided into mini-hydro, usually defined as less than 1,000 kW, and micro-hydro which is less than 100 kW.

Hydroelectric power is the technology of generating electric power from the movement of water through rivers, streams, and tides. Water is fed via a channel to a turbine where it strikes the turbine blades and causes the shaft to rotate. To generate electricity, the rotating shaft is connected to a generator which converts the motion of the shaft into electrical energy. Small hydro is often developed using existing dams or through development of new dams whose primary purpose is river and lake water-level control, or irrigation. A small-scale hydroelectric facility requires a sizeable flow of water and a reasonable height of fall of water, called the *head*. Another advantage of using water resources is that hydraulic works can be made simple, and large constructions, such as dams, are not usually required. When dams are necessary, they affect less area than in lower zones because of the steepness of the terrain. Dams, which exploit the kinetic energy of water by raising small quantities of water to heights through the use of regulated pressure valves, can provide water for domestic uses and for agriculture in areas that are moderately higher than adjacent water courses. Another interesting possibility is the utilization of induction generators for supplementing small hydroelectric plants, which require lower initial costs and have technical operation advantages over synchronous generators.

11.2.4 Biomass Energy

Biomass contributes 14% of the world's primary energy demands, and in developing countries it constitutes 35% of the primary energy supply. Biomass is an energy carrier that can be used in solid, liquid, and gaseous forms, and is a versatile source of energy that can produce electricity, heat, transport fuel, and can be stored conveniently. Energy production of biomass units ranges from small scale to multi-megawatt size. The main biomass conversion technologies are biomass gasifiers and biogas generation.

Biomass is organic nonfossil material. In other words, biomass is all plant, trees, and animal matter on the earth's surface. Humans, domestic animals, and crops comprise somewhere between 40% to 60% of the earth's biomass. In many ways biomass can be considered as a form of stored solar energy. The energy of the sun is "captured" through the process of photosynthesis in growing plants. Biomass is sometimes burned as fuel for cooking and to produce electricity and heat. Methanol and ethanol are popular sources of alternative energy produced by the fermentation of organic matter, such as manure, under anaerobic conditions. The use of biogas is encouraged because methane burns with a clean flame and produces little pollution. Digestion of manure occurs in a digester, which must be strong enough to withstand the buildup of pressure and must provide anaerobic conditions for the bacteria inside.

11.2.5 Geothermal Energy

Electricity from geothermal energy is generated by utilizing naturally occurring geological heat sources. Geothermal-generated electricity was first produced at Larderello, Italy, in 1904. Since then, the use of geothermal energy for electricity has grown worldwide to about 8,000 MW of which the United States produces 2,700 MW. The largest dry steam field in the world is The Geysers, about 90 miles north of San Francisco, began in 1960, which produces 2,000 MW. Geothermal power is generated in over 20 countries around the world including Iceland (producing 17% of its electricity from geothermal sources), the United States, Italy, France, New Zealand, Mexico, Philippines, Indonesia, and Japan.

Large scale electrical generation is possible in areas near geysers or hot springs by utilizing naturally occurring steam, superheated ground water, or using geothermal heat to heat a heat-transfer fluid. Experiments are in progress to make deep wells into hot dry rocks (HDR), which can be economically used to heat water pumped down from the surface. Geothermal areas without steam are called HDR. HDR programs are currently being developed in Australia, France, Switzerland, and Germany. Magma (molten rock) resources offer extremely high-temperature geothermal opportunities, but existing technology does not allow recovery of heat from these resources.

Although geothermal sites are capable of providing heat for many decades, eventually they are depleted as the ground cools. It can be said that the geothermal resource is not strictly renewable in the same sense as the hydro resource. Currently, there are few geothermal resource areas capable of generating electricity at a cost competitive with other energy sources, such as natural gas and coal. Some do not have a high enough temperature to produce steam and others don't have the water to produce steam, which is necessary for current plant designs. Also, instead of producing electricity, lower temperature areas can provide space and process heating.

11.2.6 Tidal Energy

Tidal power is a means of electricity generation achieved by capturing the energy contained in moving water mass due to tides. Two types of tidal energy can be extracted: kinetic energy of currents due to the tides and potential energy from the difference in height (or *head*) between high and low tides. The extraction of potential energy involves building a barrage. The barrage traps a water level inside a basin. Head is created when the water level outside of the basin changes relative to the water level inside. The head is used to drive turbines. In any design this leads to a decrease of tidal range inside the basin, implying a reduced transfer of water between the basin and the sea. This reduced transfer of water accounts for the energy produced by the scheme.

Tidal power is classified as a renewable energy source, because tides are caused by the orbital mechanics of the solar system and are considered inexhaustible within a human time frame. The root source of the energy comes from the slow deceleration of the earth's rotation. The moon gains energy from this interaction and is slowly receding from the earth. Tidal power has great potential for future power and electricity generation because of the total amount of energy contained in this rotation. The efficiency of tidal power generation largely depends on the amplitude of the tidal swell, which can be up to 10 m where the periodic tidal waves funnel into rivers and fjords. Selection of location is critical for a tidal power generator. The potential energy contained in a volume of water is

$$E = xMg \tag{11-3}$$

where x is the height of the tide, M is the mass of water, and g is the acceleration due to gravity. Therefore, a tidal energy generator must be placed in a location with very high-amplitude tides. Suitable locations have been found in the former USSR, the United States, Canada, Australia, Korea, the United Kingdom and in many other countries.

11.2.7 Magnetohydrodynamic Generation

MHD power generation is a method of direct conversion of heat into electrical energy. Kinetic energy of the fluid is converted into electrical power by the interaction of the electrical conducting fluid under the influence of magnetic field. In thermal generation of electric energy, the heat released by the fuel is converted to rotational mechanical energy by means of a thermocycle. The mechanical energy is then used to rotate the electric generator. Thus, two stages of energy conversion are involved in which the heat to mechanical energy conversion has inherently low efficiency. Also, the rotating machine has its associated losses and maintenance problems. In MHD technology, the hot gases produced by the combustion of fuel without the need for mechanical moving parts directly generate electric energy.

The fluid conductor is typically an ionized flue gas resulting from combustion of coal or other fossil fuels. The conductive fluid flows through the magnetic field, inducing an electric field by the Faraday effect. The electric field is orthogonal to both the fluid velocity and magnetic field vectors. As a result, potential difference is developed between the two walls of the duct. The direct current generated is converted to alternating current by a solid-state inverter. A typical MHD plant requires combustion gases of about 2,650ºC and a pressure of 500 to 1,000 kPa. Commercial scale MHD plants will use superconducting magnets. To achieve superconducting properties, the magnets must be cooled to around 4K. The MHD technology is in the relatively early development stage, although test data indicate that there are no fundamental barriers for commercialization of MHD technology. Several prototype units are being tested in the United States.

11.2.8 Ocean Thermal Energy

OTEC is an energy technology that converts solar radiation to electrical power. OTEC systems use the ocean's natural thermal gradient—the fact that the ocean's layers of water have different temperatures to drive a power-producing cycle. As long as the temperature between the warm surface water and the cold deep water differs by about 20°C, an OTEC system can produce a significant amount of power. The oceans are thus a vast renewable resource, with the potential to help us produce billions of watts of electrical power. The potential is estimated to be about 10^{13} W of base load power generation. The cold, deep seawater used in the OTEC process is also rich in nutrients, and it can be used to culture both marine organisms and plant life near the shore or on land.

The main advantages of OTEC are that (i) it uses clean, renewable, and natural resources, (ii) warm surface seawater and cold water from the ocean depths replace fossil fuels to produce electricity, (iii) suitably designed OTEC plants produce negligible pollution, and (iv) it can produce freshwater as well as electricity, which is a significant advantage in island areas where freshwater is limited. The disadvantages of OTEC are (i) OTEC-produced electricity at present costs more than the electricity generated from fossil fuels at their current costs, (ii) plants must be located where a difference of about 20ºC occurs year-round, (iii) ocean depths must be available fairly close to shore-based facilities for economic operation, and (iv) no energy company may put money in this project because it only had been tested in a very small scale.

OTEC covers 71% of the earth's surface and acts as a natural collector and store of solar energy. On an average day, 60 million km^2 of tropical seas absorb an amount of solar radiation equivalent in heat content to about 245 billion bbl of oil. The main countries in which OTEC plants exist are the United States with installed capacity of 100 MW, the United Kingdom, the Netherlands, Japan, and Taiwan with capacity of about 10 MW. By 2010, about 1,000 OTEC plants are expected to be installed in the range 1 to 100 MW to generate about 50,000 MW.

11.3 SOLAR ENERGY

By AHMED ZOBAA, CAIRO (Egypt) University

The sun's energy arrives on earth in the primary form of heat and light. Other aspects of solar radiation are less easily perceived and their detection often requires sophisticated equipment. All solar radiation travels through space in waves, and it is the length of these waves (the shortest is less than a millionth of an inch, the longest more than a thousand yards) by which all solar radiation is classified. The aggregate of all radiation aspects of the sun is called the *solar spectrum*.

There are two important facets about the solar spectrum:

1. While the sun emits radiation in all wavelengths, it is the short wavelength radiation that accounts for the majority of energy in the solar spectrum. For example, the portion of the spectrum perceived as the visible light is a relatively small segment compared to the variety of spectrum wavelengths, yet accounts for 46% of the energy radiating from the sun. Another 49%, which is perceived as heat, is derived from the infrared band of the spectrum.
2. The proportion of different wavelengths in the solar spectrum does not change and therefore the energy output of the sun remains constant. A measurement of this phenomenon is known as the *solar constant*, defined as the amount of heat energy delivered by solar radiation to a square foot of material set perpendicular to the sun's rays for 1 h at the outer edge of the earth's atmosphere. The solar constant measurement is about 429.2 Btu with minimal changes over the year. The energy measured as the solar constant is not a measure of the amount of solar energy that actually reaches the earth's surface, since as much as 35% of all the solar radiation intercepted by the earth and its surrounding atmosphere is reflected back into space. Additionally, water vapor and atmospheric gases absorb another 15%. As a global average only about 35% to 40% of the solar radiation entering the atmosphere actually reaches the earth's surface.

11.3.1 Solar Constant

The solar constant is the amount of energy received at the top of the earth's atmosphere on a surface oriented perpendicular to the sun's rays (at the mean distance of the earth from the sun). The generally accepted solar constant of 1,368 W/m^2 is a satellite measured yearly average.

In order to calculate the solar constant, the following equation is used:

$$S = E\,(\text{sun}) \times (R\,(\text{sun})/r)^2 \tag{11-4}$$

where S = solar constant
E = surface irradiance of the sun
R = 6.96 × 105 km = radius of the sun
r = 1.5 × 108 km = average sun-earth distance

The solar constant is not really constant; this is due to the variation of the intensity of the sun due to sunspots. *Sunspots* are convective activity in the upper layer of the sun. Their number varies in cycles of 22 years and influences solar luminosity. Another reason why S varies is because of changes in the average distance earth-sun "eccentricity." The eccentricity varies regularly with periods of about 100,000 and 400,000 years. The maximum change in S associated with variation in eccentricity is about 0.1%. The angle of tilt of the earth's axis of rotation varies between 22° and 24.5° with a periodicity of about 40,000 years.

Table 11-2 presents some values of solar constants in kWh/m^2/day for different countries in the world.

11.3.2 Radiation Received at Earth's Surface

The earth gets only 2 billionths of the sun's energy, but that is still a lot. However, life (through photosynthesis) uses only 0.023% of the energy that reaches the surface of the earth (Fig. 11-1).

- Thirty-four percent of the sun's energy is reflected back into space by snow and clouds. This reflective quality of a planet is called its *albedo*.
- Fourty-two percent of the energy goes to warm the land and water. The warmth of the earth is constantly being radiated into space, and the sun's energy replenishes this warmth.
- The water cycle—evaporation and precipitation—uses 23% of the solar energy.
- Winds and ocean currents use 1%.

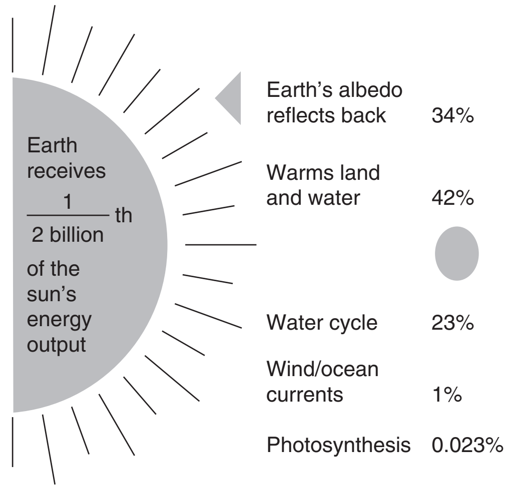

FIGURE 11-1 Percent of the sun's energy on the surface of the earth.

11.3.3 Flat-Plate Collector

A typical *flat-plate collector* (Fig. 11-2) is an insulated metal box with a glass or plastic cover, called the glazing, and a dark-colored absorber plate. Low-iron glass is a common glazing material for flat-plate as it gets high percentage of the total available solar energy. Simultaneously, only very little of the heat emitted by the absorber escapes the cover (greenhouse effect).

In addition, the transparent cover prevents wind and breezes from carrying the collected heat away (convection). Together with the frame, the cover protects the absorber from adverse weather conditions. Typical frame materials include aluminum and galvanized steel; sometimes fiberglass-reinforced plastic is used.

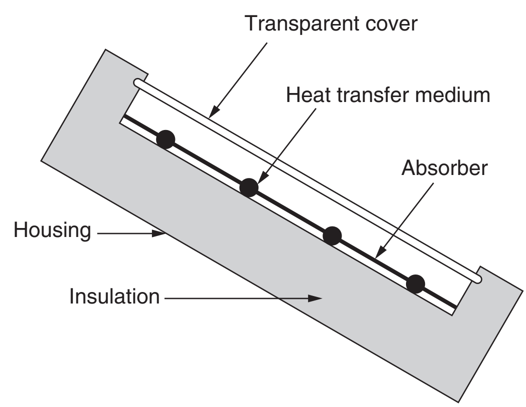

FIGURE 11-2 Elements of the basic flat-plate collector.

The insulation on the back of the absorber and on the sidewalls lessens the heat loss through conduction. Insulation is usually of polyurethane foam or mineral wool, though sometimes mineral fiber insulating materials like glass wool, rock wool, glass fiber, or fiberglass are used.

Flat-plate collectors fall into two basic categories: air and liquid. Both types can be either glazed or unglazed (according to the previously mentioned classification).

11.3.4 Collector Efficiency

The collector performance is evaluated in terms of collector efficiency, the ratio of the energy collected to that incident on the collector, usually expressed as a percentage. At a fixed rate of solar insulation, the collector efficiency of a given collector decreases with temperature difference between the collector and the surrounding air. Thus, there is a trade-off between temperature of collection and amount of energy collected. If high collection temperatures are desired, a larger amount of collector surface is needed than would be required to gather the same amount of energy at a lower collection temperature. Since the major cost of most solar energy systems is in the collectors, it is important to keep both the unit cost of the collectors and the total amount of collector surface as small as possible.

TABLE 11-3 Collection Efficiencies for Flat-Plate Collectors

Type	Day-long efficiency
Plastic tube type	25%
Bare plate	30%
Covered plate	35%
Suspended plate	40%
2-cover suspended plate	45%

Ordinarily, a surface that is a good absorber is also a good emitter. Collector efficiency can be improved by the use of a selective surface, one which has a high absorption for sunlight but a low radiation emittance. Selective surfaces are usually prepared by a plating on deposition process. At a fixed collector temperature, collector efficiency may be more than doubled over that of an ordinary surface when selective surfaces are utilized. Selective surfaces also permit the collection of energy at a higher than normal temperature without as large a decrease in collector efficiency as would occur for a nonselective absorber surface.

Table 11-3 presents collection efficiencies for flat-plate collectors.

11.3.5 Heating with Solar Energy

Today, we are able to harness to power of the sun in numerous ways, including using it for water heating, space heating, and space cooling in buildings. Many buildings are now designed to take full advantage of the sun's warmth, and incorporating solar heating in a building will begin to return on the investment immediately. Solar heating can be fully integrated into a building during the design phase or an existing building can be retrofitted to take advantage of solar heating. Solar heating can be used to provide hot water or heat the air in a building (space heating). Solar heating can be either passive, such as simply using large windows to let in more light and warmth, or active, where specially designed mechanical systems increase the heat gained from the sunlight.

Passive Solar Heating. Just as the name implies, passive solar heating allows the sun to do all the work. That is, there is no additional mechanical assistance. When referring to space heating, passive solar design takes advantage of the sun's warmth through such design features as large, south-facing windows and materials in the floors or walls that will absorb warmth during the day and release that warmth at night, when the heat is most needed because the south side of a building always receives the most sunlight. Passive solar water heating refers to a hot water system that is not aided by heat pumps. These systems will include a solar collector to heat the water and a storage tank to store the hot water.

Active Solar Heating. Active solar heating uses concepts similar to passive solar heating. However, active solar takes the power of the sun and amplifies it. Using specially designed mechanical systems, active solar heating can generate much more heat for space heating and hot water than passive solar alone. There are two basic types of active solar heating systems, depending on whether air or a liquid is heated in the solar collector. A liquid-based system heats water or an antifreeze solution in a "hydronic" collector, and an air-based system heats air in an "air" collector. Both of these systems collect and absorb solar radiation, then transfer the solar heat directly to the interior space or to a storage system; an auxiliary or backup system provides the additional heat.

The technical potential for residential applications of solar heating systems is 0.5 to 1.0 m^2 of solar collector/inhabitant. "Solar countries" such as Israel, Greece, and Cyprus already have high "solar water heating penetration" (Israel has about 0.95 m^2 per inhabitant), whereas some of the best IEA (International Energy Agency) countries, such as Greece and Austria, have a penetration of between 0.2 and 0.25 m^2 per inhabitant. The average solar penetration in IEA countries is roughly 0.04 m^2 per inhabitant; this would suggest that a strong growth of solar heating installations could be expected in the future. Driving forces for market development will be reduced costs and the desire to reduce greenhouse gas emissions. A number of studies carried out by the IEA and the European Commission in several countries reach a common conclusion: the market for solar water heaters is huge and—taken as a whole—is steadily growing, although the market growth will differ widely from country to country. Currently, the most important solar application is for residential water heating. Today, systems for hot water production in single-family houses are dominant; although, in the future, solar heating systems will be used in all types of housing. In countries with centralized heating systems, such as district heating, large-scale solar energy systems will feed heat to the distribution network. Such systems have been successfully demonstrated in Scandinavia and Germany. Swimming pool solar systems, common in some countries, also present a large market.

11.3.6 Solar Thermal-Conversion Plants

The thermal energy collected from a solar collector can be converted into work or mechanical energy by the use of a heat engine, which can then be used to generate electricity. The three types of thermodynamic cycles which seem to be practical with solar systems are the Rankine cycle, the Brayton cycle, and the Sterling cycle. The *Rankine cycle* is a vapor power cycle that is used with modifications in most large-sized electric generating plants. The *Brayton cycle* is a gas power cycle used as the basis of most gas-turbine power plants. The *Sterling cycle* is a high-efficiency cycle used as the basis for an external combustion gas engine with relatively low pollution and noise characteristics. A schematic flow diagram for a solar power plant operating on the Rankine cycle is shown in Fig. 11-3.

The limitations imposed by the second law of thermodynamics apply to any solar thermal power cycle. This limitation is best expressed in terms of the Carnot principle, which says that it is impossible to construct an engine that operates between two given heat reservoirs and which has a higher thermal efficiency than a Carnot engine operating between the same reservoirs. The *Carnot engine* is an idealized heat engine that is thermodynamically reversible and receives heat from a high-temperature reservoir (the source) and rejects heat to a lower-temperature reservoir (the sink). The useful work done per cycle is the difference between the heat added and the heat rejected during the cycle.

The thermal efficiency, the ratio of useful work done to the heat supplied, is expressed for the Carnot cycle in terms of the temperature of the reservoirs with which it is exchanging heat.

$$\eta = 1 - \frac{T_L}{T_H} \tag{11-5}$$

where η = thermal efficiency of the Carnot cycle
T_L = absolute temperature (degrees Celsius + 273.15°C) of sink
T_H = absolute temperature of source

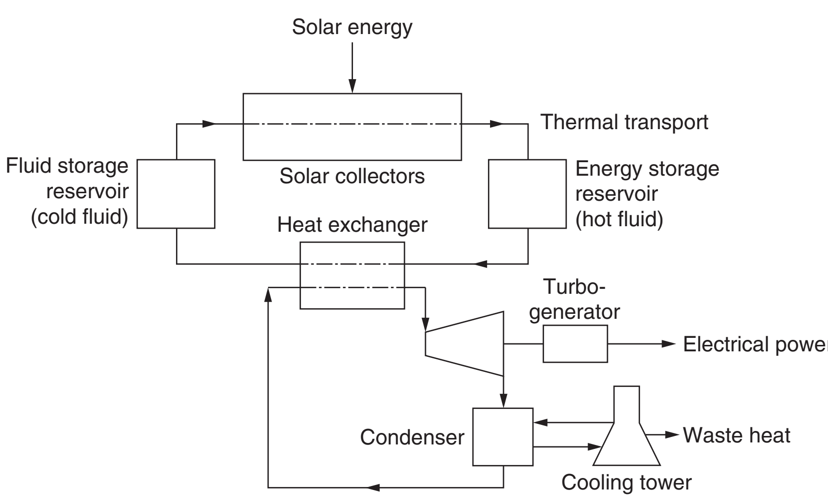

FIGURE 11-3 Schematic diagram of a solar power plant operating on the Rankine cycle.

For a solar energy system collecting heat at 121.1°C (250°F), the maximum thermal efficiency for any heat engine using that heat and rejecting heat to the atmosphere at 10°C (50°F) would be

$$\eta = 1 - \frac{273.15 + 10}{273.15 + 121.1} = 0.282 \qquad (11\text{-}6)$$

In other words, even an ideal heat engine would convert only 28% of the solar energy collected if the collector exit temperature were 121.1°C (250°F). A real engine would convert considerably less.

The White Paper of the European Commission for a community strategy and action plan on renewable energies of 1997 foresees at least 1 GWe of those systems implemented in Europe by the year 2010. This objective can be achieved by a scenario of a number of 25 to 30 commercial solar thermal power plants with 30 to 50 MWe unit size each and distributed along the south of Europe.

India, Egypt, Morocco, and Mexico have now applied within the GEF (Global Environment Facility) Operational Programme for about U.S. $50 million GEF grant for each project to cover their incremental costs of solar thermal power projects.

With positive experiences in construction and operation of the first European demonstration power plant projects being under development (50 MWe THESEUS on the Crete island in Greece; 10 MWe Planta Solar [PS 10] in Southern Spain), other projects are expected to follow. Until the year 2015, the market potential for solar thermal power plants is estimated at least with 7 GWe in Southern Europe, representing a CO_2 reduction potential of up to 12 million tons per year.

11.3.7 Concentrating Collectors

Flat-plate collectors have very poor collector efficiencies at temperatures above 93.3°C (200°F), and therefore are not suitable for use in solar thermal power plants. Collectors that concentrate the sun's rays can give higher collector efficiencies and much higher outlet temperatures than flat-plate collectors.

Concentrating collectors use mirrored surfaces to concentrate the sun's energy on an absorber called a *receiver*. The mirrored surface focuses sunlight collected over a large area onto a smaller absorber area to achieve high temperatures.

These collectors reach much higher temperatures than flat-plate collectors. However, concentrators can only focus on direct solar radiation, so their performance is poor on hazy or cloudy days. Concentrators are most practical in areas of high exposure to the sun's rays.

Concentrators are used mostly in commercial applications because they are expensive. Some residential solar energy systems use parabolic-trough concentrating systems. These installations can provide hot water, space heating, and water purification.

11.3.8 Central and Distributed Systems

Solar thermal power plants may be classified as central receiver systems or as distributed systems. In the central receiver system, solar energy is transferred optically from the individual collectors to a single receiver, for example, a boiler for a Rankine-cycle-type power plant. The most common approach for this type of plant is to locate the boiler at the top of a tall tower and to surround the tower with hundreds of mirrors which can reflect the sun's rays to the top of the tower. Systems have been proposed that would generate superheated steam at about 537.7°C (1,000°F) to reach thermal efficiencies comparable with conventional fossil-fueled power plants. The turbine generator would be located on the ground near the base of the tower.

In a distributed system, energy is transported from individual solar collectors by heated fluid flowing through pipes to a central boiler. The collectors are normally of the concentrating type such as parabolic, troughs, or paraboloidal dishes. Flat-plate collectors could be used, but the relatively low temperatures which they can produce lead to low thermal efficiencies. The resulting low overall plant efficiencies would require some rather large areas if flat-plate collectors were used. This is balanced to some degree by the lower cost per unit area of flat-plate collectors as compared with concentrating collectors.

Because of the intermittent nature of the sun, a solar power plant should be operated as an energy-displacement system, in connection with a conventional power system, which is employed whenever sufficient solar energy is not available because of clouds or night. Another approach is to have fossil fuel available to the solar system to furnish the required heat as needed. A third approach is to store thermal energy collected by the solar system for use during the periods of inadequate solar insulation. In a solar power plant this would involve the storage of a liquid at high temperature. A suitable storage medium should be low in cost and have high heat capacity, high temperature capability, and a lower vapor pressure. It also should be noncorrosive, nontoxic, and have a high thermal conductivity so that heat can be stored or removed at the desired rate without excess heat-transfer surface. If the fluid is to circulate through the solar collectors, it is also desirable that it does not freeze at the temperatures that might be encountered at night. Thermal insulation of the storage tanks is necessary, since storage will be at high temperatures and for reasonably long periods of time. Energy storage also could be accomplished by generating electricity and then using the electricity for pumped storage, electrolysis of hydrogen, charging of batteries, or flywheels.

11.3.9 Solar Energy Facts

In the United States. The position taken by the U.S. government in the current National Energy Review and the ability for the solar industry to structure long-term contracts will be key factors influencing the period over which solar energy takes to become economically self-sustaining. Proposals for a 10% federal tax credit up to $2,000 per solar system are under review.

Around 1.2 million solar thermal systems have been installed in the United States. Over 80% of these have been to residential users.

On June 10, 2001, Governor George Pataki of New York mandated that state facilities purchase at least 10% of their power needs from renewable sources by 2005, and 20% of those needs by 2010.

On May 16, 2001, the California Energy Commission increased the rebate on solar energy systems to the lesser of 50% off the purchase price or $4,500 per kilowatt (peak). Previous rebates based on levels as high as $3,000 per kilowatt (peak).

In Japan. For the fiscal year 2001, the Japanese solar rooftop program received applications for 114 MW of solar from 29,389 households.

Nearly 45% of the world's solar cell production is manufactured in Japan. Japan and the United States are the two biggest exporters of photovoltaic (PV) cells and modules.

Solar capacity is expected to increase nearly tenfold by 2010, which would then account for 30% of renewable energy supply. The national target is 5,000 MW of installed PV systems by the fiscal year 2010.

In Germany. The "Feed-in Law" in Germany permits customers to receive up to 45.7 eurocents per kilowatt hour for solar generated electricity. The program now calls for a total of 1,000 MW to be installed. By the end of 2001, the Kreditanstalt fur Wiederaufbau (KfW) Bank, which administers the 100,000 Roof Program in Germany, had approved loans for over 126 MW of PV systems. Bavaria tops the list of states in Germany with over 50 MW of systems approved.

The Feed-in Law fixes tariffs for approved renewable energy projects for a 20-year period from the plant commissioning and will apply incremental price cuts. Initial prices were set at 47.7 cents per kilowatt hour for solar energy, 8.6 cents per kilowatt hour for wind, from 9.6 to 8.2 cents per kilowatt hour for biomass, 8.4 to 6.7 cents per kilowatt hour for geothermal, and 7.2 to 6.3 cents per kilowatt hour for hydropower, waste, and sewage gas.

Some 20,000 solar electricity systems yielding an output of about 77 MW were installed in 2001, almost twice as many as the previous year. With these additions, the total solar electricity capacity in Germany is now estimated at over 170 MW.

According to current estimates, the German solar market reached a volume of about 1.5 billion marks in the year 2000. By the end of the decade, the market volume should increase to almost 7 billion marks.

In Australia. Renewable energy consumed as a percentage of the total energy consumed fell slightly between 1977 to 1978 and 1997 to 1998 (from 7% to 6% of primary energy consumed). Of this 0.9% was solar.

Worldwide. Solar energy accounts for less than 0.1% of the total global primary energy demand. Solar energy demand has grown at about 25% per annum over the past 15 years. (Hydrocarbon energy demand typically grows between 0% and 2% per annum.)

Japan, Germany, and the United States constituted 71% of the world market, unchanged on the previous year. In Japan and Germany, grid-connected applications accounted for over 95% of the market.

For the fiscal year 2002, the Japanese solar rooftop program received applications from 42,838 households.

Over 45% of the world's solar cell production is manufactured in Japan. Europe is second with 25% and the United States with 19%. Around 70% of the U.S. production is exported. However, this percentage will decline over the medium term.

Four companies account for over 50% of solar cell production: Sharp, Kyocera, BP Solar, and Shell Solar.

A residential solar energy system typically costs about $8 to $10 per watt. Where government incentive programs exist, together with lower prices secured through volume purchases, installed costs as low as $3 to $4 per watt or some 10 to 12 cents per kilowatt hour can be achieved. Without incentive programs, solar energy costs (in an average sunny climate) range between 22 and 40 cents per kilowatt hour for very large PV systems.

Japan overtook Switzerland in 2001 in terms of the proportion of solar cells installed per person in the country.

11.4 PHOTOVOLTAICS

BY AHMED ZOBAA

Solar electric or PV systems convert some of the energy in sunlight directly into electricity. PV cells are made primarily of silicon, the second most abundant element in the earth's crust and the same semiconductor material used for computers. When the silicon is combined with one or more other materials, it exhibits unique electrical properties in the presence of sunlight. Electrons are excited by the light and move through the silicon. This is known as the *photovoltaic effect* and results in dc electricity. PV modules have no moving parts, are virtually maintenance-free, and have a working life of 20 to 30 years.

There are three basic categories of PV systems with several types in each category. Crystalline silicon flat-plate collectors are the most developed and prevalent type in use today. These include single-crystal silicon and polycrystalline silicon, which are either grown or cast from molten silicon and later sliced into their cell size. They are then assembled onto a flat surface; no lenses are used. Thin-film systems are inherently cheaper to produce than crystalline silicon but are not as efficient. They are produced by depositing a thin layer of PV material to a substrate such as glass or metal. This group includes amorphous silicon, like the kind found in calculators and watches. Concentrators use much less of a specialized PV material and employ a lens or reflectors to concentrate sunlight on the PV cell and increase its output. They can be produced more cheaply than either of the other type due to the reduced amount of expensive PV material. However, they can use only direct sun, so they must track the sun precisely and do not work when it is cloudy.

11.4.1 Photovoltaic System Terms

PV system terms progress from small to large as follows:

- PV cells, the smallest unit of a PV system, are wired together to form modules.
- *Modules* are usually a sealed or encapsulated unit of convenient size for handling.
- Modules are wired together to form panels.
- Groups of panels form arrays.

- A number of arrays form an array field.
- The total system includes the arrays and any other equipment, such as charge controllers, storage (batteries), tracking, and monitoring equipment, collectively called *balance of system (BOS) components*.

11.4.2 History of Photovoltaics

The history of photovoltaics dates back to 1839, and major developments evolved as follows:

- In 1839, Edmund Becquerel, a French physicist, observed the photovoltaic effect.
- In the 1880s, selenium PV cells were built that converted light in the visible spectrum into electricity and were 1% to 2% efficient. Light sensors for cameras are still made from selenium today.
- In the early 1950s, the Czochralski meter was developed for producing highly pure crystalline silicon.
- In 1954, Bell Telephone Laboratories produced a silicon PV cell with a 4 % efficiency and later achieved 11% efficiency.
- In 1958, the U.S. Vanguard space satellite used a small (less than 1-W) array to power its radio.
- The space program has played an important role in the development of photovoltaic ever since.
- During the 1973 to 1974 oil embargo, the U.S. Department of Energy funded the Federal Photovoltaic Utilization Program, resulting in the installation and testing of over 3,100 PV systems, many of which are still in operation today.
- The 1970s through the 1990s have seen a relative disinterest in solar power, with majority ownership of many U.S. PV manufacturers being transferred to German and Japanese interests.
- The Gulf War of 1990 again sparked America's interest in non-fossil fuel energy alternatives.

11.4.3 The PV Power Market

PV systems traditionally have been economical in remote applications. Most common examples include wireless and cellular communications systems, off-grid homes, recreational vehicles and boats, power for offshore oil rigs, and highway sign lighting and call boxes. Water pumping, vaccine refrigeration, and water purification have all been important roles for photovoltaics in developing countries.

Market forces seem to have a hold of the PV market, since sales in 1995 rose 20%. Most U.S. manufacturers are increasing production significantly, and costs are expected to fall with the new volumes.

Current estimates of worldwide production of solar photovoltaic cells and modules for 1998 are about 120 MW, up steadily and dramatically from only 40 MW in 1990. Worldwide sales have been increasing at an average rate of about 15% every year during the last decade, although that growth rate has been slower in some markets and regions but faster in others. We believe that there is a realistic possibility for the market to continue to grow at about a 15% rate into the next decade. At this rate, the world production capacity would be 1,000 MW by 2010, and photovoltaics could be a $5 billion industry. These are realistic benchmarks, and show the solar business to be a very exciting market opportunity in the near term.

Developing countries today are the largest and fastest growing segment of the PV market. For the 2,000 million people in the developing world who currently have no access to basic electrical services, PV presents the opportunity for a giant leap forward and a much needed improvement in living standards. For the PV services industry, the developing world represents an enormous new business opportunity.

Photovoltaic prices are continuing a downward trend as manufacturers increase production. Cost decreases, combined with national and state incentive and subsidy programs, and renewable energy capacity mandates, have led to the emergence of a steadily growing market for bulk photovoltaic installations (greater than 100 kW capacity). Merchant PV plants are being built in places where favorable feed-in tariffs make projects profitable. Bulk installations significantly decrease the installed cost of PV power at individual sites, while simultaneously driving market demand for PV equipment. The major players and PV technologies in each market are identified along with the mounting modes (roofing tiles, weather skins, carport shading, window walls, and so on) that are prominent. The potential impact of mass production of promising emerging PV technologies is examined. Market forecasts are provided for capacity, new projects, and annual revenue for the 2002 to 2008 time frame. The forecasts cover national, regional, and world markets for both single-site bulk PV installations and bulk purchases for national village power supplies and large residential projects. Project revenue is growing at over 40% per year, and will likely reach $1 billion annually by 2010.

International Activity. U.S. PV exports increased in capacity from 14.814 million ft^2 in 1993 to 17.714 million ft^2 in 1994, an increase of 19.6%. U.S. PV imports increased from 1.767 million ft^2 in 1993 to 1.98 million ft^2 in 1994, an increase of 12%. U.S. module production is leading world growth as well. In 1993, the United States produced 21 MW of PV, of which 14.8 MW was exported. By 1997, global demand led to a record breaking PV production year with a 42% leap in worldwide production. The United States produced 46.4 MW with $175 million in sales and exported 33.8 MW (73% of production) overseas. India is boosting production and becoming a major world producer of PV modules. The Indian government plans to power 100,000 villages with renewable energy, primarily PV modules, and install solar-powered telephones in each of the nation's 500,000 villages. Mexico planed to electrify 60,000 villages using photovoltaics by the year 2000. Hospital Bulape (serving 50,000 outpatients per year in Zaire) and several other major hospitals in Zaire depend totally on solar power for everything from x-ray equipment to air conditioning. In Morocco, solar panels are sold in bazaars and open markets, next to carpets and tinware. In San Buenaventura, Guatemala, a local utility has installed PV panels on 42 of the community's 86 homes at one-third the cost of extending power lines into the village. Malta-Solar Power, Ltd. has begun construction of a new PV plant with a maximum production capacity of 3 MW per year. At full production, this plant will be able to produce 40% of all 1995's module production capacity for all developing countries. South African companies are building a PV manufacturing plant near Alexandra township that will serve to electrify 10,000 homes, 600 clinics, and 1,000 schools with solar power. Kenya has electrified 20,000 homes using photovoltaics in the last few years, compared with 17,000 new homes that were hooked up to the central power grid. Siemens Solar in 1995 sold just over 40% of its output in North and South America, nearly 40% to Europe and Africa, and "just under" 20% went to Asia. 5SI President Gernot Oswald expects the biggest growth in the next few years to come from Asia. There are over 500,000 homes using PV today in villages around the world for electricity. In Kenya, more rural households receive electricity from PV than from the conventional power grid. The single largest market sector for PV is village power at about 45% of worldwide sales. This is mostly comprised of small home lighting systems and water pumping. Remote industrial applications such as communications are the second largest market segment.

11.4.4 Global PV Market

The fast growing world market for PV greatly reflects the growing rural electrification demand of less developed countries around the world. The global PV market has grown at an average rate of 16% per year over the decade with village power driving demand. The total worldwide PV production in 1980 was only 6.5 MW, and by 1997 this had increased to 126.7 MW.

For many applications, especially remote site and small power applications, PV power is the most cost-effective option available, not to mention its environmental benefits. New PV modules generally retail for about $5 per peak watt, depending on quantities purchased. Batteries, inverters, and other balance of system components can raise the overall price of a PV system to over $10 to $15 per installed watt. PV modules on the market today are guaranteed by manufacturers from 10 to 20 years, while many of these should provide over 30 years of useful life. It is important when designing PV systems to be realistic and flexible, and not to overdesign the system or overestimate energy requirements (e.g., overestimating water-pumping requirements) so as not to have to spend more money than needed. PV conversion efficiencies and manufacturing processes will continue to improve, causing prices to gradually decrease.

PV conversion efficiencies have increased with commercially available modules that are from 12% to 17% efficient, and research laboratory cells demonstrate efficiencies above 34%. A well-designed PV system will operate unattended and requires minimum periodic maintenance, which can result in significant labor savings. PV modules on the market today are guaranteed by the manufacturer from 10 to 25 years and should last well over 30 years. PV conversion efficiencies and manufacturing processes will continue to improve, causing prices to gradually decrease; however, no dramatic overnight price breakthroughs are expected.

11.4.5 Common Photovoltaic Applications

PV is best suited for remote site applications that have small to moderate power requirements, or small power consuming applications even where the grid is in existence. A few power companies are also promoting limited grid-connected PV systems, but the large market for this technology is for stand-alone (off-grid) applications. Some common PV applications are as follows:

Water Pumping. Pumping water is one of the most competitive arenas for PV power since it is simple, reliable, and requires almost no maintenance. Agricultural watering needs are usually greatest during sunnier periods when more water can be pumped with a solar system. PV-powered pumping systems are excellent for small to medium scale pumping needs (e.g., livestock tanks) and rarely exceed applications requiring more than a 2 hp motor. There are thousands of agricultural PV water pumping systems in the field today throughout Texas. PV pumping systems' main advantages are that no fuel is required and little maintenance is needed.

A PV-powered water pumping system is similar to any other pumping system, only the power source is solar energy; PV pumping systems have, as a minimum, a PV array, a motor, and a pump. PV water pumping arrays are fixed mounted or sometimes placed on passive trackers (which use no motors) to increase pumping time and volume. AC and dc motors with centrifugal or displacement pumps are used with PV pumping systems. The most inexpensive PV pumpers cost less than $1,500, while the large systems can run over $20,000. Most PV water pumpers rarely exceed 2 hp in size. Well installed quality PV water pumping systems can provide over 20 years of reliable and continuous service.

Gate Openers. Commercially available PV-powered electric gate openers use wireless remote controls that start a motorized actuator that releases a gate latch, opens the gate, and closes the gate behind the vehicle. Gates are designed to stop if resistance is met as a safety mechanism. Units are available that can be used on gates up to 16 ft wide and weighing up to 250 lb. Batteries are charged by small PV modules of only a few watts. Digital keypads are available to allow access with an entry code for persons without a transmitter. Solar-powered gate-opening assemblies with a PV module and transmitter sell for about $700.

Electric Fences. P-power can be used to electrify fences for livestock and animals. Commercially available packaged units have maintenance free 6 or 12-V sealed gel cell batteries (never need to add water) for day and night operation. These units deliver safe (non-burning) power spikes (shocks) typically in the 8,000 to 12,000 V range. Commercial units are UL (Underwriters Laboratories) rated and can effectively electrify about 25 to 30 miles of fencing. Commercially packaged units are available from about $150 to $300, depending on voltage and other features.

Water Tank Deicers. For the north plains of Texas in the winter, PV power can be used to melt ice for livestock tanks, which frees a rancher from going out to the tank with an ax to break the surface ice so the cows can drink the water. The PV module provides power to a small compressor on the tank bottom that generates air bubbles underwater, which rise to the surface of the tank. This movement of the water with the air bubbles melts the tank's surface ice. Commercially available units are recommended for tanks 10 ft in diameter or greater, and can also be used with ponds. Performance is best for tanks that are sheltered, bermed, or insulated. Installation is not recommended for small, unsheltered tanks in extremely cold and windy sites. Approximate cost for a complete owner-installed system, including a PV module, compressor, and mounting pole, is about $450.

Commercial Lighting. PV-powered lighting systems are reliable and a low-cost alternative widely used throughout the United States. Security, billboard sign, area, and outdoor lighting are all viable applications for PV. It's often cheaper to put in a PV lighting system as opposed to installing a grid lighting system that requires a new transformer, trenching across parking lots, etc. Most stand-alone PV lighting systems operate at 12 or 24 V dc. Efficient fluorescent or sodium lamps are recommended for their high efficiency of lumens per watt. Batteries are required for PV lighting systems. Deep cycle batteries specifically designed for PV applications should be used for energy storage for lighting systems. Batteries should be located in protective enclosures, and manufacturer's installation and maintenance instructions should be followed. Batteries should be regulated with a quality charge controller. Lighting system prices vary depending on the size; average systems cost from $600 to $1,500.

Residential Power. Over 500,000 homes worldwide use PV power as their only source of electricity. In Texas, a residence located more than a mile from the electric grid can install a PV system more inexpensively than extending the electric grid. A Texas residence opting to go solar requires about a 2 kW PV array to meet its energy needs, at a cost of about $15,000. The first rule with PV is always energy efficiency. A PV system can provide enough power for an energy-efficient refrigerator, lights, television, stereo, and other common household appliances.

A great number of PV installations for homes have taken place in Mexico. The experience of PV electrification varies widely across Mexico and is demonstrative of the potential pitfalls of haphazard installations. Over 40,000 PV home lighting systems have been installed in Mexico, mostly through government programs (Foster 1998). However, nearly half of these systems are not functioning today, mostly due to poor balance of systems hardware (i.e., the PV modules work fine), where improper batteries and poor quality charge controllers are used. It is important for any PV user to use quality equipment and install PV systems in accordance with local electric codes. This greatly reduces the potential for future problems.

Evaporative Cooling. PV-powered packaged evaporative cooling units are commercially available and take advantage of the natural relation that when maximum cooling is required is when maximum solar energy is available. These units are most appropriate for comfort cooling in the dry climate of West Texas where performance is best. Direct evaporative coolers save 70% of the energy over refrigerated units. Battery storage is obviously required if cooler operation is desired at night. Array size would vary with the power requirements of the cooler motor. A linear current booster (LCB) is useful between the PV modules and the cooler's dc motor if the cooler is coupled directly to the PV array. Packaged PV evaporative cooling systems for residences generally run from $500 to $1,500, depending on size.

Telecommunications. This was one of the early important markets for PV technologies, and continues to be an important market. Isolated mountaintops and other rural areas are ideal for stand-alone PV systems where maintenance and power accessibility make PV the ideal technology. These are often large systems, sometimes placed in hybrid applications with propane or other type of generators.

Consumer Electronics. Consumer electronics that have low power requirements are one of the most common uses for PV technologies today. Solar-powered watches, calculators, and cameras are all everyday applications for PV technologies. Typically, these applications use amorphous PV technologies that work well even in artificial light environments such as offices and classrooms.

11.4.6 Glossary of Solar and Photovoltaic Terms

Cell Efficiency. The ratio of the electrical energy produced by a PV cell (under full sun conditions or 1 kW/m^2) to the energy from sunlight falling on the cell.

Charge Controller. A component that controls the flow of current to and from the battery subsystem to protect the batteries from overcharge and overdischarge. The charge controller also may monitor system performance and provide system protection.

Diffuse Radiation. Sunlight received indirectly as a result of scattering due to clouds, fog, haze, dust, or other substances in the atmosphere.

Direct Radiation. Light that has traveled in a straight path from the sun (also referred to as beam radiation). An object in the path of direct radiation casts a shadow on a clear day.

Flat-Plate Array. A photovoltaic array in which the incident solar radiation strikes a flat surface and no concentration of sunlight is involved.

Fresnel Lens. A concentrating lens positioned above and concave to a PV material to concentrate light on the material.

Grid-Connected. Referring to an energy-producing system connected to the utility transmission grid (also called utility interactive).

Hybrid System. A power system consisting of two or more power-generating subsystems (e.g., the combination of a wind turbine and a PV system).

Insolation. The amount of sunlight reaching an area usually expressed in watts per day.

Load. Electrical power being consumed at any given moment. The load that an electrical generating system supplies varies greatly with time of day and to some extend season of year. Also in an electrical circuit, the load is any device or appliance that uses power.

Parallel-Connected. Referring to a method of connection in which positive terminals are connected together and negative terminals are connected together. Current output adds and voltage remains the same. (See also series-connected.)

Photovoltaic Cell. The semiconductor device that converts light into dc electricity. The building block of PV modules.

Series-Connected. Referring to a method of connection in which the positive terminal of one device is connected to the negative terminal of another. The voltages add and the current is limited to the least of any device in the string. (See also parallel-connected.)

Solar Constant. The rate at which energy is received from the sun just outside the earth's atmosphere on a surface perpendicular to the sun's rays. Approximately equal to 1.36 kW/m^2.

Thick Cells. Conventional cells, such as crystalline silicon cells, which are typically from 4 to 17 mil thick. In contrast thin-film cells are several micrometers thick.

Thin-Film Cells. PV cells made from a number of layers of photosensitive materials. These layers are typically applied using a chemical vapor deposition process in the presence of an electric field.

Voltage Regulator. A device that controls the operating voltage of a PV array.

11.5 WIND POWER

BY PALMER CARLIN

11.5.1 Introduction

In order to present the current status of wind energy technology concisely but still include important related issues, the following material is divided into four sections: the first section provides a quick survey of contemporary activity in wind energy. The second section presents the basic physics and technology of wind energy conversion together with a description of turbine features. The third section includes issues that arise in the application of wind machines, and the fourth and final section contains conclusions and references.

11.5.2 Contemporary Activity in the Wind Energy Field

With the onset of the energy crisis in 1976, interest in renewable energy sources suddenly intensified. As a result, both private and government agencies became involved. As an example of private activity, the American Wind Energy Association (AWEA) was founded with provision for both corporate and individual memberships. Typical corporate members are electric utilities and wind turbine manufacturers, while typical individual members are wind consultants, university personnel, wind turbine owners, and private citizens. A directory of its membership is available on the Internet.[1]

The U. S. Department of Energy (DOE), working through the National Wind Technology Center (NWTC) of the National Renewable Energy Laboratory (NREL) in Golden, Colo., supports a comprehensive wind energy program. Sandia National Laboratories (SNL) in Albuquerque, New Mexico, participates in the national program as well. One part of the program offers cost-shared contracts to private industry on a competitive basis for the development of advanced wind technology. Other parts of the program support wind research within the government laboratories, and the testing facilities at the NWTC can be made available for qualifying private companies.

In anticipation of the rising global importance of wind energy, in 1977 the International Energy Agency launched the Implementing Agreement for Co-operation in the Research and Development of Wind Turbine Systems.[2] Since then, 19 nations have joined this group by becoming members of its executive committee, which meets semiannually to exchange information about wind energy developments. The location of the meeting rotates among member nations, and the hosting nation includes visits to its wind installations. As wind technology progresses and new challenges arise, the committee creates suborganizations called *annexes* to which member countries contribute expert delegates. The operating agent of each annex reports to the executive committee at its semiannual meetings until the annex completes its task. In their 2004 Annual Report, the executive committee stated that the world's wind generation capacity exceeded 47 GW and was expected to continue growing at a rate of 28% per year.

11.5.3 Wind Turbine Analysis and Description

Wind Turbine Power Calculation. Good engineering models for predicting wind turbine performance can be obtained from some simple assumptions plus a few equations from elementary physics. By considering energy, momentum, and mass conservation laws, aerodynamicists in the mid-nineteenth century established the "axial momentum" theory for analysis of airplane propellers. One of the results is the expression for the flux of kinetic energy of the wind or any other fluid through an area normal to that fluid flow, which is

$$P_w = {}^1/_2\, \rho\, A\, V_w^{\,3} \tag{11-7}$$

where P_w is total wind power in watts, ρ is air density in kilograms per cubic meter, A is a mathematical area in square meters normal to the wind, and V_w is the wind speed passing through that area in meters per second. The cubed velocity is plausible because each air mass element carries kinetic energy proportional to velocity squared, and the rate of passage of each element being directly proportional to velocity yields the third velocity factor.

Because the extractable energy of the wind exists only as macroscopic kinetic energy, no practical machine can remove all of that energy, as there is no way to dispose of the resulting stationary air. Two aeronautical engineers independently examined this limitation in the 1920s. Lanchester[3] and Betz[4] separately used the ideal model in Fig. 11-4. It assumes that the perfectly inviscid fluid passes through an "actuator disc," which represents a wind machine rotor. An *actuator disc* is a mathematical convenience commonly used in wind turbine (as well as aircraft propeller) analysis. This porous disc extracts

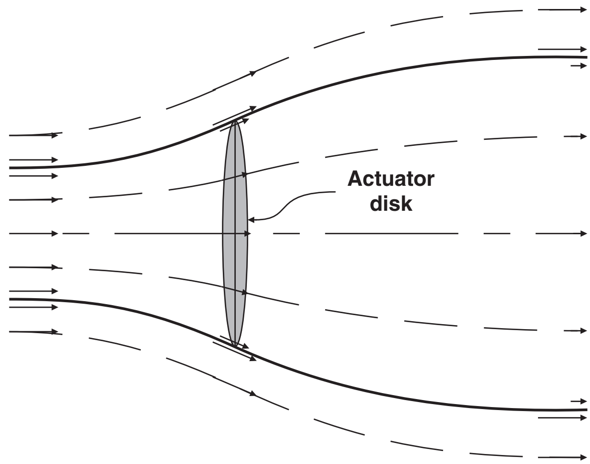

FIGURE 11-4 Idealized inviscid fluid flows through an actuator disc.

mechanical energy from the flow by causing a pressure drop. On the upstream side, the pressure has been raised above atmospheric by the slowing airstream, while on the downstream side pressure is lower. Ambient atmospheric pressure in the flow will be recovered downstream by further slowing. By extending axial momentum theory to this model, they showed that the maximum fraction of the above wind power that can be captured is $^{16}/_{27}$ or about 59%. This is known as the *Lanchester/Betz Limit* or more commonly the *Betz Limit*. Mathematical results derived using this model are assumed to apply as an upper limit to any device that extracts kinetic energy from a free fluid stream.

To account for this fundamental limit as well as additional imperfections introduced by practical wind turbines, wind engineers define the dimensionless power coefficient, C_p, for a wind turbine as follows

$$P = {}^1/_2\rho A C_p V_w^{\ 3} \qquad \text{watts} \tag{11-8}$$

where P is now the useful extracted power. One can see that this coefficient for a particular machine is the fraction of the total wind power that the wind machine can reclaim in a wind of V_w. Depending on the context this power may or may not include the losses in the power train of the turbine. Because of the Betz limit this fraction can never exceed 0.59. Measured values of power coefficient for real turbines range from 0.25 to more than 0.45.

There are a few important additional observations to be made in Fig. 11-4. First, note that the wind speed in the tube of air that will impinge on the disc (bounded by solid lines) begins to slow before it arrives there and it continues to slow after it leaves. As this fluid is assumed ideal, it has no viscosity, so the surrounding air slides past the subject tube and neither speed is affected by the other.

Second, for the mass flow to remain constant at any cross section, the declining fluid speed requires the tube cross section to expand. The velocity reduction and, therefore, the change in flow cross section proceeding from left to right, depends on the amount of energy being removed from the tube. Note that these results are independent of the type of device that is extracting energy from the flow. In the limit of no removal, the fluid tube cross section remains constant and equal to that of the actuator disc, and there would be no reduction of wind speed.

Finally, the velocity vectors shown represent the optimal case of the Betz limit. For this case, the impinging wind speed has been reduced to two-third of its original value as it reaches the turbine disc, and ultimately declines to one-third of the original value downstream. In this ideal case, the velocity reduction for this tube of fluid is permanent as mentioned above. In real cases of viscous flow in the atmosphere, this wake is dissipated and reenergized downstream by the surrounding unretarded wind. This wake process is very important to the design of a wind power plant with many successive rows of turbines. Turbines positioned farther into the center of a wind power plant are subjected to much greater turbulent buffeting that results in blade fatigue and up to 15% loss of annual energy compared to the most upwind turbines.

Obviously, current engineering analyses that account for the rotating blades and the effect of material fatigue are much more refined. For an excellent account of these approaches, consult Ref. 5.

11.5.4 Wind Turbine Classes

Based on the method of extracting energy from the airstream, two fundamental classes of wind machines can be defined. "Lift type" machines use airfoils that create lift at right angles to the airflow like an airplane wing. On the other hand, if a machine extracts energy by depending on the wind to push a specially shaped object directly downwind, it is a member of the other and much older class of wind machines called "drag machines."

In the lift class of machines, it is convenient to divide turbines into two main classes based on the orientation of their axis of rotation. The rotor axis of the horizontal axis wind turbine (HAWT) is parallel to the flow of the wind, while the rotor axis of the vertical axis wind turbine (VAWT) is transverse to the wind. At this writing, the latter constitutes less than 3% of commercial wind machine installations.

Horizontal Axis Wind Turbine. Usually, the designer of a new wind machine will select the power rating and the axis orientation first. For a HAWT at least four other important choices follow:

Rotor Orientation. In an upwind HAWT, the wind passes through the rotor before passing the tower, so that the blades are never shielded from the direct wind. However, special mechanical drives with control systems and direction sensors must be provided to move (yaw) and maintain the rotor in this upwind position. Conversely, a downwind machine can depend on the natural tendency of the wind to blow the rotor to the opposite side of the tower, and thus preclude the need for the special mechanical drive and sensors. The cost, however, is that each blade must pass through the turbulent wind region behind the tower, and thereby experience mechanical impulses that can shorten the rotor's fatigue life and create additional noise.

Blade Count. Although multiple-bladed turbines exist, economic factors at least for the present, have determined that either two- or three-bladed rotors are the most practical. It should be mentioned that the moment of inertia of a three-bladed rotor about its yaw axis is independent of the rotor's position, while this quantity varies from a maximum to a minimum as a two-bladed rotor rotates from horizontal to vertical orientation. During high yawing rates, this means that the gyroscopic moment on the main shaft is fluctuating wildly for a two-bladed rotor (See Hub Type).

Hub Type. The simplest and most obvious case of blade attachment is the rigid hub in which there is no relative motion of the rotor blades with respect to the supporting shaft. This is the usual case for smaller three-bladed rotors and is often used for two blades. Alternatively, suppose the wind machine rotor uses only two blades built as a long rigid beam, and suppose these blades are attached to the wind machine's main drive shaft by a single pin transverse to both this shaft and the blades. If this pin acts as a hinge allowing a small amount of movement, then this is a "teetering rotor." This feature eliminates bending at the end of the main rotor shaft in a turbulent wind and allows the plane of rotation of the blades to be somewhat misaligned with the main rotor shaft of the turbine for a few moments if necessary.

Aerodynamic Control. In considering aerodynamic control, we must distinguish between the control of power flow and the need to stop rotation in case of equipment failure or excessive wind. Although the speed of a wind turbine is normally controlled by the load torque of its electric generator, excess wind, loss of utility power, breakdown of the generator, or loss of the mechanical transmission would allow the turbine rotor to spin out of control. For this reason, all wind machines need some form of aerodynamic control.

The two most common hardware approaches to meeting this problem are (1) stall control and (2) pitchable blades. If stall control is chosen, the turbine will be designed such that when the wind exceeds the speed that fully loads the generator, the resulting large angle of attack of the wind on the blade airfoil causes the blades to stall thereby reducing mechanical power to the generator shaft.

In this case, the wind machine rotor blades are mounted permanently at a fixed pitch angle. The appeal of this method is its simplicity and consequent lower cost.

Alternatively, the existence of pitch control on propeller driven aircraft suggests full-span pitch control for wind machines, in which each blade can be rotated around its own longitudinal axis. When the rotation is sufficient to present the leading edge directly into the wind (i.e., approximately 90°), the average wind torque on the rotor will go to zero. Thus, positive control is achieved at the expense of rotating blade root attachments and complicated mechanical hub linkages, but enjoys the advantage (over stall control) of being able to reduce wind torque to zero on average.

Many stall-controlled turbines have additional aerodynamic control for emergencies in the form of tip flaps. These are flat plates mounted at the tip of the wind machine blades and normal to the blade's longitudinal axis. During normal machine operation they are in the stowed position where they present their edge to the slipstream and consequently offer low drag resistance. In case of incipient loss of control, these tip flaps can be deployed either by centrifugal force or by electrical trigger. They then pivot outward, presenting their entire surface broadside to the slipstream. This tangential drag force dramatically reduces rotor speed, though it does not stop the rotor completely. A mechanical brake is provided for that purpose.

Vertical axis wind turbine. The Darrieus or vertical axis wind turbine, which is sometimes called the "eggbeater" type machine, has several important advantages. It will operate with the wind approaching from any direction, the generator can be mounted in the base of the machine, and the primary mechanical loads on the blades are tension. Measured power coefficients are similar to those for HAWT machines. Some disadvantages are that aerodynamic torque only occurs as the blade moves across the wind, which results in torque pulsation, and the turbine is not self-starting. However, the primary problem is that the long slender blades are subject to many different modes of vibration with the resulting loss of fatigue life.

11.5.5 Wind Turbine Performance

Probably the most important quantitative information about a wind turbine is its power curve. A typical example is shown in Fig. 11-5 in which the rotor is assumed to be turning at a constant speed. The ordinate shows the power that a machine will produce if it is being driven by the steady wind shown on the abscissa. This example machine reaches its rated speed and power at about 17 m/s, and its furling or cutout wind speed at 23 m/s at which point its control system will automatically shut it off.

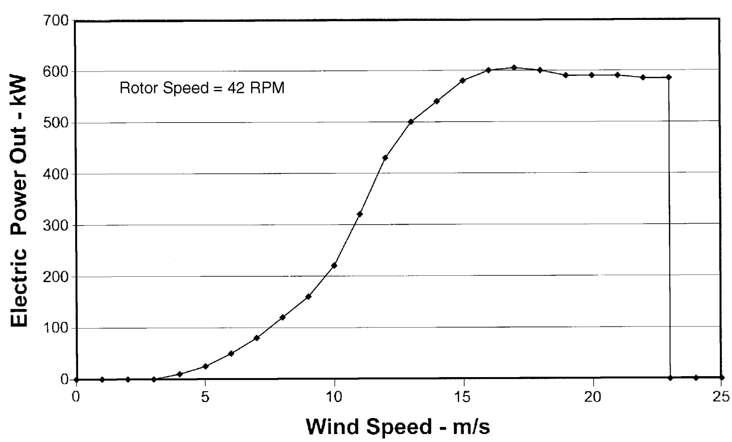

FIGURE 11-5 A typical power curve for a constant speed turbine (rotor speed = 42 rpm).

Although the previous power expression shows that power should be proportional to the cube of the wind speed, typical wind machine power rises more slowly and levels off at higher wind speed. This is because the power coefficient, C_p, is not a constant. To account for the effect of rotor speed on the power coefficient, it is useful to define a dimensionless quantity called "tip-speed ratio" sometimes abbreviated TSR or lambda (λ).

$$\lambda = R\omega/V_w \tag{11-9}$$

where R is the radius of the circle swept by the rotor, ω is the rotor angular speed in radians per second, and V_w is the wind speed. Note that the TSR can be thought of as the linear speed of a rotor blade tip measured in units of the existing wind speed. Thus, for a TSR of 7, the blade tip is traveling 7 times faster than the wind at that instant.

For a wide range of rotor and wind speeds it can be shown that the power coefficient is a function of TSR as is seen in Fig. 11-6. It is therefore possible, by knowing rotor speed and wind speed, to calculate the power produced by the given wind turbine using the expression

$$P = {}^1/_2\rho A C_p(\lambda) V_w^{\,3} \tag{11-10}$$

where C_p is obtained from Fig. 11-6. By finding the TSR for maximum C_p, we can calculate the rotor speed for a given wind speed that will give best performance for this machine. It will therefore mark the wind speed neighborhood in which we should strive to operate the machine.

This is discussed further in Sec. 11.5.8.

Figure 11-6 also shows that the power coefficient curve drops to zero for high TSRs. This can be interpreted as the TSR that would be obtained if no load were placed on the wind machine rotor, and the TSR at that point allows us to calculate the "runaway" rotor speed for any given wind. Although this speed is finite, most large machines are not designed to operate at such high speeds and would be damaged or destroyed if they were allowed to do so. On the other hand, for TSRs less than about 3, the power coefficient can be seen to be low and usually not well-known, because most fixed-pitch turbine airfoils will be stalled at this angle of attack.

While the information in Fig. 11-6 is sufficient to approximate the performance of fixed-pitch, constant-speed machines, if blade pitch is available as another control variable, then more information

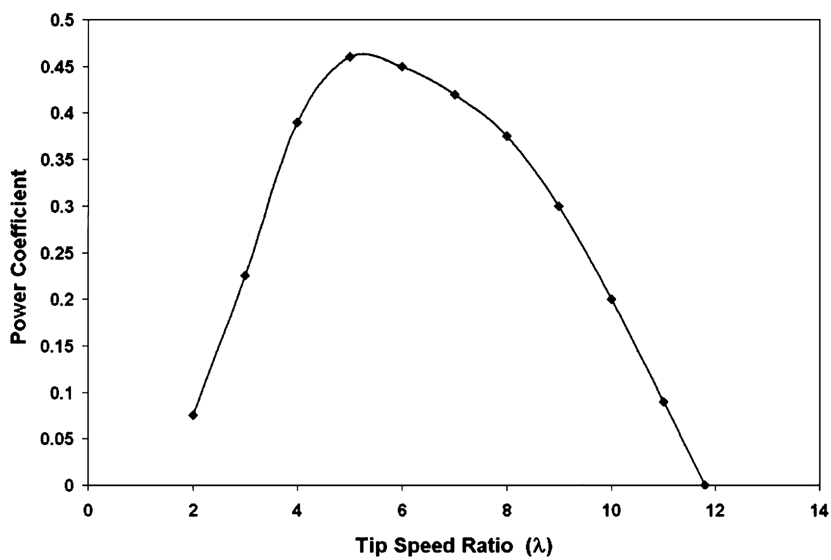

FIGURE 11-6 Example of a power coefficient vs. tip-speed ratio curve.

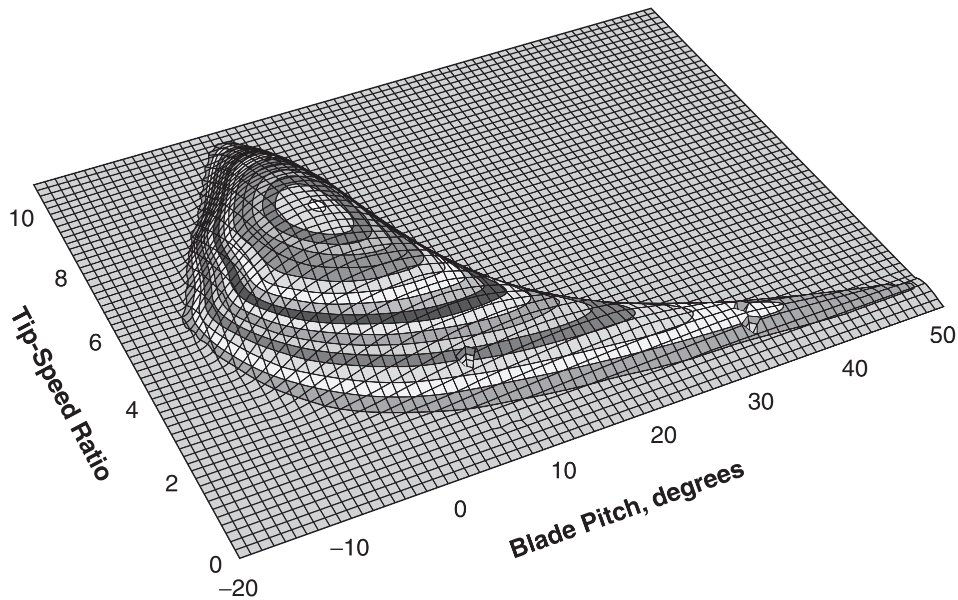

FIGURE 11-7 Power coefficient surface of a typical wind turbine.

is needed. Recall that blade-pitch angle is the angle between a blade chord line and the plane of rotation of the wind machine rotor, and for most high-speed turbines, it is in the range of 0° to 6°.

To account for this new variable, we must resort to a mathematical surface in three-dimensional space. In Fig. 11-7, the power coefficient is shown as a function of both TSR and blade-pitch angle. The fact that this surface has a single C_p maximum near zero degrees pitch and a TSR of 6 shows that maximum performance for this turbine can be had at really only one blade-pitch angle and at one TSR. Thus, ideal performance will occur only if the rotor blade tips are moving about 6 times faster than the existing wind speed and the blades are pitched to approximately zero. Of course, if a wind machine's electrical or mechanical capacities are being exceeded, pitch can be used to reduce power.

Other aerodynamic control techniques that have been tested include pitchable blade tips, ailerons, spoilers, and generator torque.

All of the preceding material applies only to devices that use airfoils that extract energy through the use of aerodynamic lift. The older wind machines that use the drag phenomenon exist in many forms, such as the ubiquitous cup anemometer. Although the latter is useful for accurate wind speed measurement, it is not efficient in the collection of raw energy. Machines using this technology are usually robust and can be fabricated using unsophisticated equipment. However, per unit of active collection area, they tend to require much more material than a lifting machine. But more important is that the maximum theoretical power coefficient for this technology ($Cp = {}^{4}/_{27}$) is exactly one-fourth that of the lifting class of wind machine ($Cp = {}^{16}/_{27}$). This is the reason that drag machines are never found in commercial wind power plants.

The purpose of this hardware section was limited to a discussion of wind machine energy conversion performance. The complete detailed design of a commercial wind machine would also include an extensive structural loads and fatigue analysis.

11.5.6 The Wind Resource

As indicated in the previous discussion, the wind turbine's energy source, the wind, must be well-known to accurately site turbines and predict performance. The Pacific Northwest National Laboratory (PNNL), at the request of DOE, began studying the wind resource in the United States and its territories in 1979 to identify practical locations for wind energy exploitation. Today, wind resource activities take place at NREL. In the wind maps developed by PNNL and NREL, the results are presented in terms of wind classes. Class 1 is least energetic while class 7 is the most energetic. An annual average wind resource map for the United States is shown in Fig. 11-8. In the atlas developed by PNNL[6], wind resource data are sorted in various ways such as by seasonal average, by annual average, by elevation above the terrain, or by land topography. State wind resource maps recently produced by NREL show much greater detail than the national map shown in Fig. 11-8.

The fact that the atmosphere has viscosity and that the lowest layers of the wind are being slowed by contact with the earth's surface means that the wind speed will change according to the altitude above the earth's surface. Although this wind shear depends on many local variables, the commonly accepted empirical expression for this change below about 300 m is a power law:

$$v_2/v_1 = (h_2/h_1)^{\alpha} \tag{11-11}$$

where α = about a one-seventh average, v_n = wind speeds at vertical locations 1 and 2, and h_n = elevations above a reference plane for 1 and 2.

Although the wind by its nature is stochastic, for a given geographical location, it is possible to assign a characteristic wind speed probability density curve. Such curves, together with power curves for a particular model of wind machine, can be used for good estimations of the annual energy that can be captured and therefore a good estimation of annual revenue from a proposed wind power plant. Because the power that can be extracted from the wind varies as the cube of the instantaneous wind speed, a region having, for example, a 2% higher annual mean wind compared to another region will be expected to yield 6% more energy than the second region, all other things being equal. This difference can be financially important for a wind farm operator.

Many probability expressions have been examined, but present usage has evolved to just a few. For example, a Gaussian curve will usually give a very good fit to a 10-min wind speed data set. However, the Weibull expression is more widely accepted for annual records. Two parameters, c and k, give the Weibull curve its flexibility to more nearly fit experimental data. The c parameter adjusts the numerical scale on the abscissa or independent variable axis. The shape factor, k, adjusts the relative width of the peak of the curve:

$$f(v) = \frac{k}{c}\left(\frac{v}{c}\right)^{(k-1)} e^{-\left(\frac{v}{c}\right)^k} \tag{11-12}$$

Examples of the Weibull function are given in Fig. 11-9 for $k = 2$ and $k = 3$.

Good energy sites for wind machine installations very often can be fit with a shape factor of $k = 2$. This special case of the Weibull expression is the well-known Rayleigh function. A useful theoretical model can be made by postulating a perfect wind machine that can operate in all winds at the Betz limit of power coefficient, namely $0.593 = {}^{16}/_{27}$. Assume this machine is placed in a region where the wind statistics exactly fit a Rayleigh probability density function. Calculations based on this model can be used to set upper limits to the amount of annual energy that can be captured by any real machine in a similar location. In particular, if inertia effects are ignored, and the product of this ideal Betz power curve and the Rayleigh function is integrated over all winds, the result will be the mean annual power of a "Rayleigh-Betz" wind machine. It can be reduced to the following expression[5]:

$$P_{av} = \rho\,({}^2/_3\,D)^2\,V_{av}{}^3 \tag{11-13}$$

where ρ is air density, D is the diameter of the swept area, and V_{av} is the mean annual wind. The implied annual energy that this ideal model will collect will therefore be the product of the hours in a year with this average power. For example, if a wind machine with a 15-m rotor diameter is operated at sea level for a year in an ideal Rayleigh wind regime of mean value 5 m/s, then the energy captured could not exceed

$$\begin{aligned} W &= 8{,}760 \text{ h/year} \times 1.2 \text{ kg/m}^3 \times ({}^2/_3 \times 15 \text{ m})^2 \times (5 \text{ m/s})^3 \\ &= 131.4 \times 10^6 \text{ watthours} = 131.4 \text{ megawatthours} \end{aligned}$$

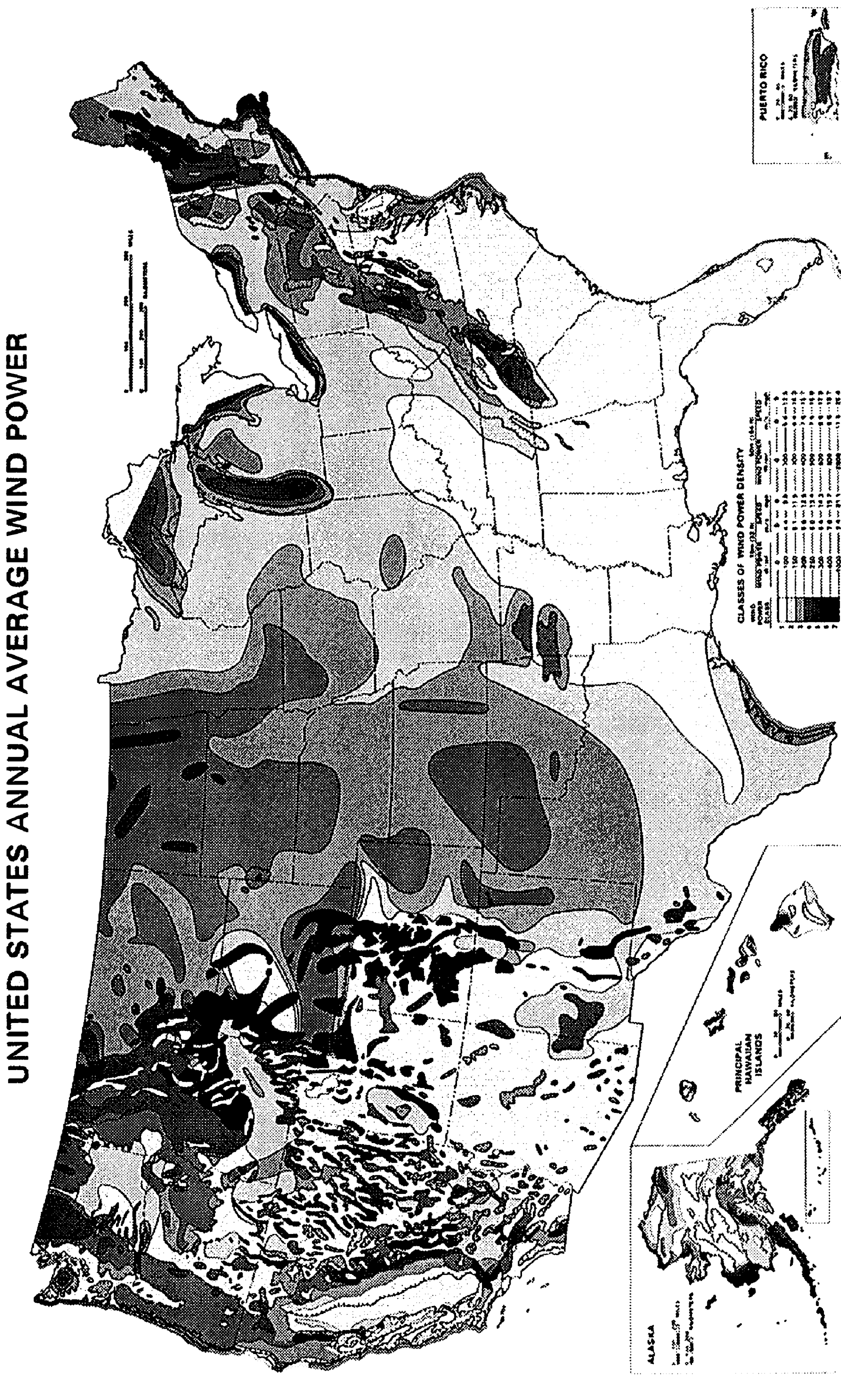

FIGURE 11-8 Wind energy resource map of the United States.

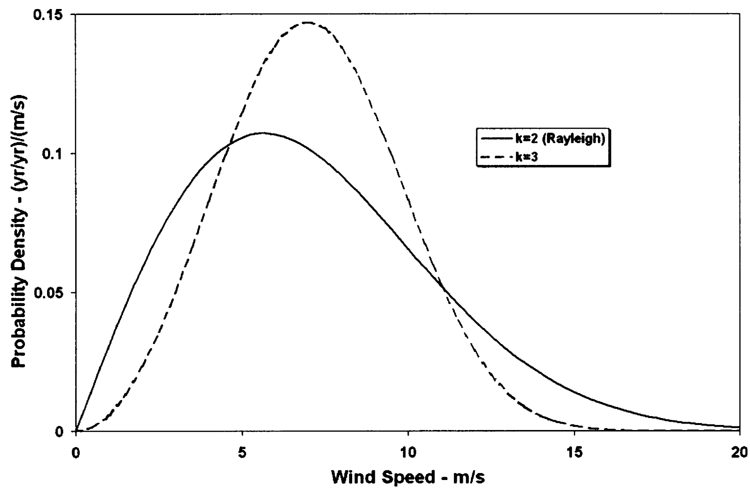

FIGURE 11-9 Weibull probability densities for scale factor $c = 8$ m/s.

Note that average air density has an important influence on calculated wind turbine power, as shown in this example: The sea level air density of 1.2 kg/m^3 falls off to 1.0 kg/m^3 at about 1,500 m above sea level. This of course means a power reduction back to 83% of sea level power for the same wind speed. If seasonal changes in temperature and barometric pressure are known, corrections to annual calculated power can be made.

Being able to estimate annual average wind speeds and annual output is useful for planning purposes, but being able to forecast the wind accurately for one or two days could provide a significant economic benefit, allowing utility engineers to plan ahead for wind generation to replace fossil-fueled generation. Various methods have been developed, and are continuing to be developed, to accurately forecast wind power one to two days ahead. Several commercial companies offer this wind forecasting service.

11.5.7 Wind Turbine Electric Systems

Generators. During the rapid development of wind power plants in the late 1980s and early 1990s, nearly all grid-connected wind turbine generators were of the induction type. Induction generators are much less expensive than the synchronous type, but their primary flaw is their need to draw lagging current from the grid to supply their excitation. This apparent disadvantage is sometimes useful for a utility in that if the utility to which they are paralleled goes down, induction generators loose their reactive excitation from the utility grid and automatically cease producing power. Presumably, aerodynamic controls on the wind turbine rotor will limit its speed if it loses its load in this manner.

It has become commonplace for electric utilities to require induction generator owners to provide power factor correction capacitors that will supply nearly all of the required lagging current. The flaw of this solution is that if the interconnected utility were to have a forced outage, there is the possibility for self-excitation of the remaining online wind generators. Thus, if this isolated subsystem happens to have generation approximately equal to its load, then the system could sustain itself long enough to cause considerable damage. At present, this scenario is essentially impossible because of the wind turbine's control system, which halts the turbine if either frequency or voltage stray beyond given narrow limits.

At present, a growing electric generator technology receiving consideration for wind systems is the permanent magnet (PM) type. Certain small wind turbine systems in the range of less than 10 kw have employed such generators for many years. Progress in the development of rare earth permanent magnets and other types of permanent magnets has made the use of PM generators more feasible for larger-sized wind systems. The advantages of PMs over conventional synchronous generators are simplicity of construction and no energy loss in the field winding. These advantages are achieved at the price of no adjustment of field strength and the high cost of permanent magnets. The loss of flexibility in the PM generator can be largely compensated for with semiconductor power processing.

Power Electronics. The continuing progress in the development of larger and less expensive semiconductor devices has opened the way to variable-speed, constant-frequency wind energy systems. The rapid growth of the use of adjustable speed drives for motors in manufacturing production lines illustrates the present high reliability of power electronics. The two most frequent methods of using this technology for generation are (1) conversion of the entire variable-voltage, variable-frequency output of a wind machine (sometimes called "wild ac") to direct current, then reconverting it to utility quality ac power; and (2) alternatively, when a wound rotor, variable-speed induction machine is fed with an appropriate variable frequency current from a power semiconductor system, the stator will supply constant voltage, constant frequency power to the interconnected utility bus. This arrangement is usually called the doubly fed induction generator and offers the advantage of a smaller power rating for the power electronics equipment.

11.5.8 Controls and Control Algorithms

The prime movers for conventional utility grid generators, having been developed along with their companion generators, are capable of very precise speed and power control. These levels are totally under the control of the utility dispatcher.

Wind turbines, however, must exploit whatever wind presents itself at a particular instant. Anemergonic (wind energy) engineers have agreed on a taxonomy to describe the three successive operating regions that a wind turbine progresses through as the ambient wind increases from calm to maximum. Region one is that region preceding startup and below cut-in. Cut-in is the point at which there is just sufficient wind to produce measurable energy. For most machines this is in the range of 4.5 to 5 m/s.

Region two identifies operation between cut-in and rated power operation; it is where the electrical power output uniformly increases as wind speed rises from cut-in speed. For constant-speed wind turbines in this region, rotor speeds are selected such that the maximum power coefficient will occur when the most productive wind exists. The most productive wind is that speed, which if a wind turbine were allowed to operate only in a narrow band centered on this speed, would capture more energy than being centered on any other narrow band of wind speed. This wind speed exists because of the opposing effects of exploitable energy rising with the cube of wind speed and the decline in frequency of occurrence of such winds for increasing speeds. For the special case of a wind regime governed by the Rayleigh probability density, this wind speed occurs at 159% of the annual average wind and at exactly twice the most probable wind speed. The range of possible values for the wind speed that defines the upper edge of region two is quite broad and is machine dependent. It is usually the least wind that will yield the maximum continuous power output for that turbine.

Variable-speed wind turbines in region two attempt constantly to adjust their speed to hold their TSR at the maximum power coefficient point. This flexibility is purported to make it possible to collect theoretically up to 20% more annual energy than the same machine constrained to operate at constant speed. The obvious consideration is to balance this gain with the expense and power losses in any auxiliary equipment such as power electronics modules that are needed to provide the variable-speed feature.

As steady-state operation in wind speeds beyond rated speed would overheat the generator, means must be taken to limit wind power input. This identifies the upper edge of region two, which is the lower edge of operating region three. It is the region where the control algorithm must change from attempting to maximize energy capture to minimizing equipment damage. Although in principle, generator torque can be used to continuously limit wind machine speed to its specified maximum value, the well-designed wind machine always has an additional means of aerodynamic control to prevent a utility failure from allowing the wind turbine to accelerate out of control. Although it is at the cost of appreciable mechanical complication of the rotor hub, the most common and effective aerodynamic control is that of continuous control of pitch angle of the wind machine rotor blades.

Even though there is only one best angle for a particular wind machine to operate at as can be seen from the surface in Fig. 11-7, the figure also shows that increasing blade pitch can rapidly reduce power coefficient and therefore output power from the rotor. In fact, at 90° pitch the rotor should, in principle, come to rest. In real applications, especially in larger machines, there is the practical problem of pitching speed and whether blades can be pitched quickly enough to achieve the appropriate power or mechanical load reduction.

Design and testing of control algorithms that minimize fatigue damage of a wind turbine drive train and blades without lessening energy capture continues to be an important area of research.

11.5.9 Computer Simulation

Having reviewed energy collection, electrical generation, and dynamic control of wind turbines, it is not surprising that there are in general three families of computer simulation programs that provide insight into some of these areas.

There are the performance programs that simulate energy capture for hybrid electric systems. A *hybrid system* in an energy production system that combines two or more energy sources such as wind, solar, and diesel. Using either typical time history wind samples or a wind probability density curve together with a typical electrical load history, these programs will forecast the energy from the wind turbines together with the run time of any associated engine generator set. Time periods of interest are not less than months.

The next class of simulation is focused on aerodynamics, mechanical dynamics, and structures. Solutions yielded include such things as static and varying loads on structures, predicted power curves, normal vibration modes of machine components, and control system responses. Time scales treated are from seconds to minutes.

The last category includes the electrical simulations of the transients in generators and power electronics. Simulation results can warn of possible self-excitation of induction generators, overvoltages due to harmonic resonances from power electronic modules, or excess starting transient currents. Time scales used could be from microseconds to a few seconds.

Figure 11.10 illustrates three types of investigations that require different time scales. Electrical short circuits and resulting transients occur in a few seconds, while voltage regulation occurs over minutes and load following up to a day.

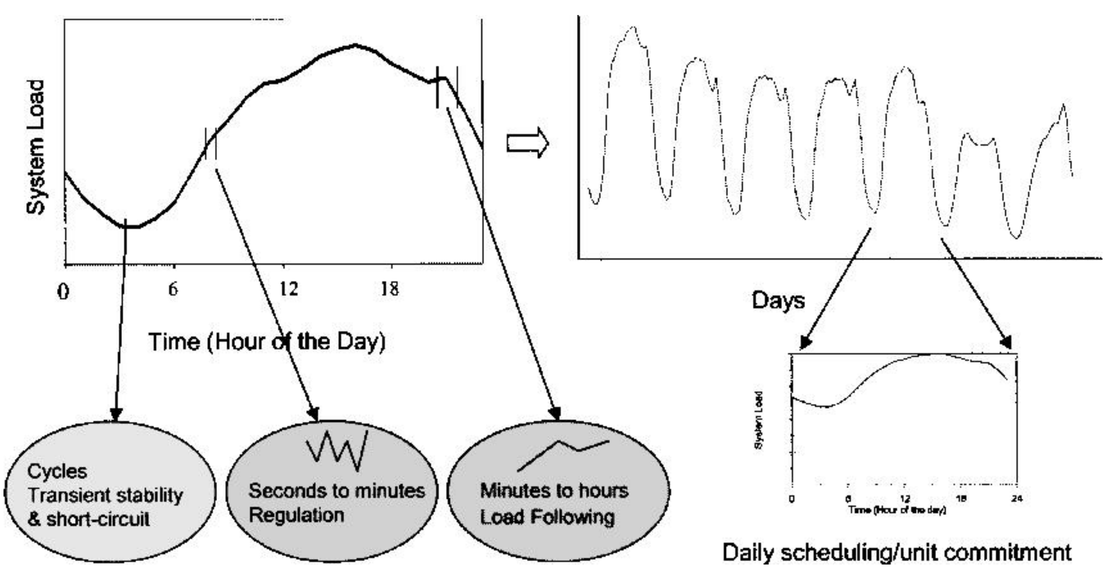

FIGURE 11-10 Three Simulation Regimes.

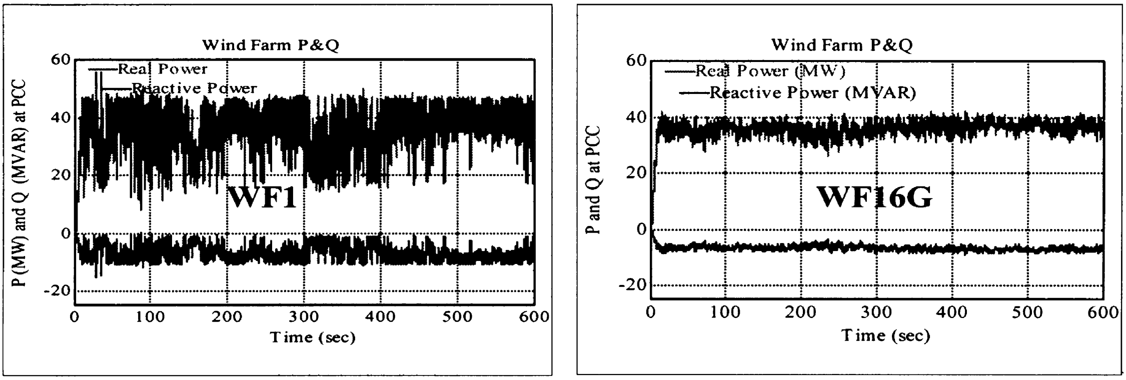

FIGURE 11-11 Real and reactive power output of a wind power plant with different aggregations.

Wind power plant designers have rightfully designed turbine controllers and safety features to disconnect and stop a turbine if it detects a fault such as a short circuit in the connection to the utility. Unfortunately, in practice, when this occurs at a wind farm of up to 50 turbines, they usually will all shut down even if the fault clears instantaneously. Each turbine must then be individually restarted. This interesting problem is called *low voltage ride through* (LVRT), and is used to describe the wind turbine's ability to stay connected during such a disturbance. The solution to this situation must be a balance between safety and inconvenience.

Figure 11-11 is an example of simulation that shows the effect of spatial diversity in a wind plant and how it naturally smoothes the power delivered.

Figure 11-11 shows a simulation of the real and reactive power of a wind farm of 200 turbines with a total rated output of 45 MW. This figure compares two methods of aggregation. The left graph shows the output of the simulation when we assume that the entire wind farm is represented by identical wind turbines, all turbines are located at the same spot and each one of them is driven by the same wind speed. Thus, the collective output of individual turbine is reflected as the output of the entire wind farm at the point of interconnection. In the right graph, the wind farm simulation groups the wind turbines into 16 different groups to simulate the diversity of a wind farm. Each group has a different number of wind turbines and is driven by a time series wind speed. Each series is time shifted with respect to other wind speed files driving different groups of wind turbines. The time shift approximates the time delay of the wind reaching different groups of wind turbines caused by differences in geographical location among the groups. Although this method is not perfect, it is closer to the reality of a wind farm. It clearly shows that the power fluctuations at the point of interconnection are significantly reduced when we consider the aggregation for 16 groups of turbines because of cancellation of the power fluctuations among the groups.

11.5.10 Issues Related to Wind Turbine Use

By Charles Butterfield, Michael Millian, Eduard Muljadi

Classes of Usage for Modern Wind Turbines. Commercially available wind turbines for electric power range in size from less than 100 W to a several megawatts. Although today wind turbines are employed in many ways, a few important classes of applications can be identified. The most publicized and largest in terms of aggregate power is, of course, the wind power plant application. Modern wind power plants can be as large as 300 MW and are often located within a short distance of each other. These wind power plants feed the same utility line. Although there are some significant policy drivers that have influenced the development of wind power plants, today wind is often economically competitive with conventional generation. It is therefore likely that significant new wind generating capacity will be developed in the next several years.

Another class called "wind-hybrid" denotes one or more midsized turbines operating in conjunction with other power sources such as a diesel generator, a photovoltaic system, and other sources of power that are all managed by a common control system. Wind-hybrid systems provide a means to reduce the costs of electric power in outlying regions where conventional fuel is expensive and difficult to transport. Remote villages in developing countries and polar regions are the usual applications of this class.

Small turbines comprise the third class of wind turbine. They usually are privately owned for use on ranches, farms, vacation cabins, and remote communication repeater stations.

The remainder of this section is a collection of several unrelated topics that nevertheless affect the employment and acceptance of wind energy.

Certification. As in many other areas of technology, prospective buyers need to have confidence in the claims of a manufacturer. This leads to the concept of certification such as those that exists in the field of electrical appliances. The United States is participating in the development of International Electrotechnical Commission (IEC) standards for wind turbines through the American Wind Energy Association (AWEA) and the American National Standards Institute (ANSI) memberships in IEC. The IEC 61400-XX series covers design requirements, testing requirements, and certification guidelines. At present there are two dominant international certification bodies active in the European wind turbine industry: Germanischer Lloyd[7] and Det Norske Veritas (DNV). Each certification body has developed its own rules and requirements for type certification, but they generally have the same goal: to review the design documentation and ensure that the turbine has been designed with engineering discipline in accordance with recognized industry standards, and that it will function reliably throughout its specified life. Most turbines installed in Europe must be certified by one of these bodies as a national requirement. Although the United States does not require such certifications, yet to alleviate financial risks, most commercial-scale turbines are certified.

These international certifications do not satisfy utility interconnection requirements in the United States. Interconnection requirements are usually set by individual utilities for large-scale turbines. However, the Federal Energy Regulatory Commission (FERC) is attempting to set general interconnection rules such as FERC Order 661, Interconnection of Wind Turbines. For small turbines, IEEE 1547 defines interconnection requirements that can be certified by Underwriters Laboratories (UL) and other certification bodies and are usually accepted by local electrical inspectors.

Over the past 5 years, the European community has encouraged harmonization of the different certification rules to facilitate trade within Europe. This has resulted in active standards development programs on the international level, primarily IEC.

The Wind Turbine Research Program conducted for DOE by NREL employs a comprehensive engineering development process that includes regular design, testing, and documentation reviews throughout the process. This process follows accepted international procedures, including the International Standards Organization—ISO 9001.

Grid Integration and Operational Impacts. Wind power plants have an impact on power system operations. Generally, these impacts can be divided into timescales that correspond to utility operational practice (see. Fig. 10). The regulation timescale is from a few seconds to several minutes. In the regulation, timescale generation responds to small, fast fluctuations in the load, primarily via automatic generation control (AGC) computers. These fast fluctuations are generally uncorrelated.

The next load following timescale spans several minutes to several hours. Load fluctuations in this timescale are managed by generating units that are economically dispatched. Changes in load over this timescale are more highly correlated than in the regulation timescale and fluctuate over a wider range. *Unit commitment* is the process of determining which of the slow-start (thermal) units will be needed for the day-ahead schedule and ensuring those units are available when needed. Wind power plants generally increase the need for regulation and load following service and can complicate the unit commitment process. Over the planning horizon, considerations of system adequacy can be evaluated using reliability models. System adequacy is often measured by loss of load probability or a related metric. The contribution of wind power plants to system adequacy is often measured as the effective load carrying capability (ELCC) of the wind power plant. Because of the intermittent nature of the wind, ELCC as a percent of rated capacity is generally low and often falls in the range of 10% to 40% of rated capacity. Several power pools, regional transmission organizations, and other entities have developed simple approaches to calculating wind capacity value. These are detailed in Ref. 8.

TABLE 11-4 Some Samples of Integration Costs to Utilities of Wind Power Plants

Study	Relative Wind Penetration (%)	Regulation ($/MWh)	Load Following ($/MWh)	Unit Commitment ($/MWh)	Total ($/MWh)

Several detailed studies have been performed to analyze the impact of wind power on system operations. The Utility Wind Interest Group (UWIG) is an organization that serves as a clearinghouse for challenges and solutions related to wind energy, and UWIG was the sponsor of one of the early studies. The general approach of the recent wind integration studies is to perform a full system analysis using standard software tools, recognizing that wind contributes an additional source of variability into an already variable system. Because the system needs to be balanced in aggregate, it is not necessary to balance each movement in wind one-for-one by a counter move of a conventional generator, and the standard simulation tools perform a system optimization that observes the requirements for balancing loads and resources. One summary of studies performed in the United States appears in Ref. 7. To analyze the impact that wind has in the regulation timescale, a method developed at the Oak Ridge National Laboratory is often used[9]. This approach allocates the regulation burden to variable loads and resources, and has been applied to wind in several analyses. Table 11-4 has been updated to reflect PacifiCorp's 2004 Integrated Resource Plan[10]. The table shows the range of integration costs from recent studies of wind's impact on power system operation and economics.

11.5.11 System Operation with Wind Power

By Yih-Huel Wan

When a wind power plant is connected to the grid, power and voltage fluctuations are concerns for system operators. Modern wind turbines can provide very good voltage regulations, but the power from the wind power plant is not controlled by its operators. However, actual wind power plant output data show that although wind power fluctuations are stochastic in nature, they are not completely random. Because of wind speed persistency, the magnitudes and rates of power level changes from wind power plants are seldom extreme. Wind speed does not change instantaneously, nor does power from wind power plants.

Short-time step changes of wind power are small. For example, the average magnitude (absolute value) of second-to-second step changes is less than 0.2% of the nameplate capacity for small wind power plants (with tens of turbines) and 0.1% for large wind power plants (with hundreds of wind turbines). The average magnitude of minute-to-minute step changes ranges from about 1.2% of the nameplate capacity for small wind power plants to about 0.3% of the capacity for large wind power plants. Power from large wind power plants is less variable than power from small wind power plants because of spatial variation of wind speeds. Physical separations and differences of local terrains cause wind speeds to vary. Even adjacent wind turbines within the same wind power plant do not experience the same wind conditions during short time frames and their instantaneous outputs are not likely to be synchronized (e.g., outputs from some turbines are increasing while others are decreasing). Such spatial variation in wind speeds makes the combined outputs from more turbines less volatile, especially in short time frames.

Wind power can experience bigger changes during longer periods, but average magnitudes of wind power changes for longer time steps are still relatively small. Average magnitudes of 10-min step changes range from 3% of the nameplate capacity for small wind power plants to 2% of the nameplate capacity for large wind power plants, while average magnitude of hourly step changes ranges from 7% to about 5% of the nameplate capacity.

In addition to small average magnitude of wind power step changes, the standard deviation values of wind power step changes are also small. This indicates that most of the wind power step changes are of small values and large step changes are relatively rare. As an example, Fig. 11-12 shows the distribution of 10-min wind power step changes for 1 year from a large wind power plant with a nameplate generating capacity of 100 MW. Over 98% of all 10-min step changes are within $\pm 3\sigma$ (or $\pm$11 MW or $\pm$11% of the power plant's nameplate capacity in this case). Large swings of wind power do occur, but those infrequent large changes are almost always related to well-defined weather events such as storms and weather fronts. Most of these weather events can be accurately predicted in advance to allow system operators time to take remedial actions.

Step change statistics define the outer boundary of the wind power fluctuations. The rate of change of wind power levels in a given time interval (e.g., 10 min or 1 h) is another indicator of wind power plant behavior. Power levels from a wind power plant fluctuate continuously because the wind speed changes continuously as it moves through the wind power plant. For example, in a 1-s wind power data series, the average duration for wind power increases or decreases is only 2.2 s (with a standard deviation of 4.4 s). With 1-min data series, the average duration of the increases and decreases is 2.4 min (with a standard deviation 8.4 min). Consequently, wind power plant ramping rates are also very modest. Table 11-5 lists the wind power 10-min ramping statistics.

As shown in the table, average ramping rates are less than 0.5% of the power plant's nameplate capacity per minute. The maximum ramping rates can be large, especially for the negative ramping (rapid wind power decreases). However, such big changes occur infrequently. The distribution of ramping rates of three wind power plants for 1 year is shown in Table 11-6. It shows that wind power plant ramping rates seldom exceed 5% of the nameplate capacity per minute.

Further examination of the data indicates that not all of those very large ramping rates are the result of wind speed changes. Again, most of these large ramping rates are related to well-defined weather events that can be forecasted.

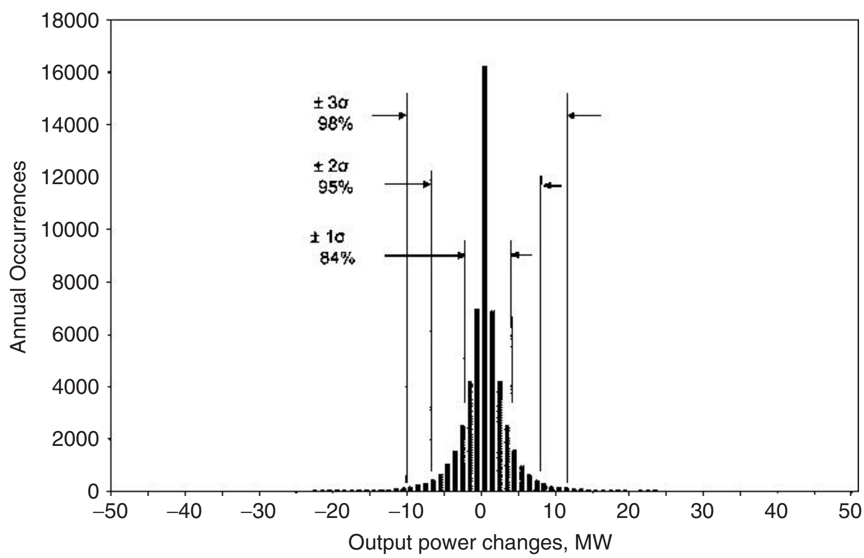

FIGURE 11-12 Wind plant power output changer during 10-min interval.

TABLE 11.5 Wind Power 10-min Ramping Characteristics

	Average (kW/min)	Average (%/min)	Standard deviation (kW/min)	Standard deviation (%/min)	Max (+) (MW/min)	Max(−) (MW/min)
10 MW Plant	47	0.45%	78	0.74%	1.2	–1.4
100 MW Plant	269	0.26%	465	0.45%	7.0	–12.2
220 MW Plant	438	0.18%	811	0.34%	11.3	–29.0

Actual operations experience suggests that most control areas will have few problems integrating wind power at relatively low penetration levels. Utilities in several Midwestern and western states have had wind power supplying from 6% to 14% of their online loads during high wind periods. Recent studies also concluded that impacts of wind power on system operations are minor.

11.5.12 Wind Turbine Acoustic Noise

The importance of sounds emanating from a wind turbine obviously depends on its surroundings. In remote locations of the deserts of California or Texas or in offshore installations worldwide, the relatively low-level sound emitted by a group of wind machines is unimportant. In northwestern Europe, where a single machine may stand near a cluster of houses, even low-level sounds, especially at night, can be annoying. Wind turbine noise can be divided into two classes: mechanical and aerodynamic. Mechanical noise includes transmission gear tones and generator whine. These are common machinery problems and can be ameliorated by the usual methods of gear selection and soundproof insulation.

Aerodynamic noise, in turn, can be divided into impulsive and broadband noise. Impulsive noise essentially always comes from a downwind rotor blade passing behind its tower; it is caused by the sudden change in wind flow across the rotor blade. This can be modified by spiral strakes and other shapes attached to the tubular tower or changing the blade-to-tower distance. For lattice towers, the effect is somewhat less but is still present. VAWTs also have a shadow due to the central supporting column, but it is somewhat less pronounced than for HAWTs.

Broadband noise is the swishing noise of the air interacting with the turbine blades and is generated in varying degrees by all turbines. There are obviously many sources for this sound, but three important ones are blade tip vortex, blunt trailing edge airfoil, and turbulence in the wind itself. At the present writing, designers agree that broadband noise decreases with decreasing linear tip speed.

For more information on wind turbine acoustics, refer to Ref. 11.

11.5.13. Wildlife Considerations

By karin Sinclair

As wind turbines are installed across the country, concerns over possible wildlife impacts have expanded. Throughout the 1990s, the principal concern was for avian impacts. In 1992, primarily because of possible negative impacts caused by wind power development on golden eagles (Aguila chrysaetos) in the Altamont Pass Wind Resource Area in California, DOE and NREL, working

TABLE 11-6 Distribution of Ramping Rates

	$< \pm1\sigma$ (78 kW/min)	$< \pm2\sigma$ (156 kW/min)	$< \pm3\sigma$ (234 kW/min)	$< \pm4\sigma$ (312 kW/min)	$< \pm5\sigma$ (390 kW/min)	> 5%/min (525 kW/min)

collaboratively with stakeholders including utilities, environmental groups, consumer advocates, utility regulators, government officials, the wind industry, and the National Wind Coordinating Committee's (NWCC) Avian Subcommittee, formed an active avian-wind power research program.

Avian concerns fall within two main areas: the effect of avian mortality on bird populations, and possible litigation over the killing of even one bird if it is protected by the U.S. Migratory Bird Treaty Act or the U.S. Endangered Species Act or both. After a decade of research, focused predominantly on developing solutions to reduce or avoid avian mortality caused by wind energy development throughout the United States, the DOE/NREL research task came to an end. A list of the reports generated from these research projects can be found at http://www.nrel.gov/wind/avian_reports.html.

In 1999, the Avian Subcommittee of the NWCC published guidelines for conducting avian research (Studying Wind Energy/Bird Interactions: A Guidance Document). These guidelines contain metrics and methods that should be applied to all current avian research projects. It was anticipated that the use of a standardized set of metrics and methods would help facilitate comparability among research sites.

Since DOE/NREL ended its research on issues related to avian impacts, concerns for other wildlife issues have emerged. For example, impacts on bats have become a concern as a result of high bat fatalities found at two newer wind power plants in the northeast (the Mountaineer Wind Energy Center in Tucker County, West Virginia, and the Meyersdale Wind Energy Center in Somerset County, Pennsylvania). In 2003, bat carcasses were found while conducting traditional post-construction avian fatality surveys. Although bat carcasses have been found at other wind power plants across the country, the number of fatalities found at these two sites far exceeds anything found to date. Bat-specific fatality searches have now begun at other U.S. wind power plants.

Two other issues, potential impacts on nocturnal species and grassland/shrub steppe species, have been identified by the NWCC's Wildlife Workgroup (previously known as the Avian Subcommittee). To begin addressing these issues, the Wildlife Workgroup will develop a companion document to the Guidance document, focusing on nocturnal issues such as nocturnal behavior of birds and bats. A literature review of wind power impacts on grassland/shrub steppe habitats will also be produced.

11.5.14 Summary

Over the past 30 years, wind energy has passed through its infancy and childhood and is now achieving a measure of maturity as is evidenced by the turning of researcher efforts from physics and performance of wind turbines to how energy derived from wind can better interface with today's technology and be accepted for what it can contribute. For example, the committee on wind energy within the International Energy Association now supports special groups studying *integration of wind and hydropower, wind energy in cold climates,* and *dynamic models of wind power plants for power system studies*.

By January 2006, the world had an installed capacity of 56 GW, and growth is expected to continue at 28% per year for a few years. In some countries, wind energy is supplying up to 20% of that nation's electrical power.

According to the IEA Annual Report, traditional technologies average electrical generation costs are in the range $25 to $45 per megawatthour. Levelized wind generation ranges from $35 to $95 per megawatthour.

Conferences

Two major wind energy conferences are held every year: Windpower and the Wind Energy Symposium. Windpower is sponsored by AWEA; the Wind Energy Symposium is held in conjunction with the AIAA Aerospace Sciences Meeting & Exhibit. Both conferences publish proceedings.

11.6 GEOTHERMAL POWER

BY RAYMOND FORTUNA

The outer crust of the earth contains a very large reservoir of energy present as sensible heat. This resource is between one and two orders of magnitude larger than the recoverable energy from uranium and thorium in the same volume of rocks. If 1% of the thermal energy contained within the uppermost 10 km of the earth could be tapped, the amount of heat would be 500 times that contained in all oil and gas resources of the world. The only natural fuel system that represents a larger energy resource on the earth is the fusion energy of deuterium.

11.6.1 Origin and Types of Geothermal Energy

Large quantities of heat that are economically extractable tend to be concentrated in places where hot or even molten rock *(magma)* exists at relatively shallow depths in the earth's outermost layer (the crust). Such hot zones generally are near the boundaries of the dozen or so slabs of rigid rock (called *plates*) that form the earth's lithosphere, which is composed of the earth's crust and the uppermost, solid part of the underlying denser, hotter layer (the *mantle*).

According to the theory of plate tectonics, these large, rigid lithospheric plates move relative to one another, at average rates of several centimeters per year, above hotter, mobile mantle material (the asthenosphere). High heat flow also is associated with the earth's hot spots, whose origins are somehow related to the narrowly focused upward flow of extremely hot mantle material from very deep within the earth. Hot spots can occur at plate boundaries (e.g., in Iceland) or in plate interiors thousands of kilometers from the nearest boundary (e.g., the Hawaiian hot spot in the middle of the Pacific plate). Regions of stretched and fault-broken rocks (rift valleys) within plates, like those in

East Africa and along the Rio Grande River in Colorado and New Mexico, also are favorable target areas for high concentrations of the earth's heat at relatively shallow depths.

Zones of high heat flow near plate boundaries are also where most volcanic eruptions and earthquakes occur. The magma that feeds volcanoes originates in the mantle, and considerable heat accompanies the rising magma as it intrudes into volcanoes. Much of this intruding magma remains in the crust, beneath volcanoes, and constitutes an intense, high-temperature geothermal heat source for periods of thousands to millions of years, depending on the depth, volume, and frequency of intrusion. In addition, frequent earthquakes, produced as the tectonic plates grind against each other, fracture rocks, thus allowing water to circulate at depth and to transport heat toward the earth's surface through these fractures. Together the rise of magma from the mantle and the circulation of hot water (hydrothermal convection) maintain the high heat flow that is prevalent along plate boundaries. Accordingly, the plate-boundary zones and hot-spot regions are prime target areas for the discovery and development of high-temperature hydrothermal-convection systems capable of producing steam that can drive turbines to generate electricity (Duffield and Sass 2003).

Water circulates freely through hydrothermal resources. For magma and hot, dry rock resources, much less water is present. The magma resource is at the highest temperature and is relatively water poor. Magmas range in temperature from about 650 to 1300°C, depending on chemical composition. The hot, dry rock resource is characterized by hot, solid rock that contains little or no water because it has few pore spaces or fractures to store and transmit water. The geopressured-geothermal resource consists of hot water saturated with methane and trapped typically in sandstones in young sedimentary basins. In the United States, this resource is abundant along the Gulf Coast in Texas and Louisiana. At present, only hydrothermal resources are used to generate electricity commercially.

11.6.2 Utilization of Geothermal Energy

Geothermal energy has been used for electricity production since 1904 in Italy, and since that time, there has been a steady expansion of this resource on a worldwide basis, with 8000 MW of installed capacity in 2004. High-grade geothermal resources are cost-effective, and in light of their environmentally benign character, the worldwide expansion is expected to continue.

Geothermal energy is immune to daily and seasonal fluctuations and therefore is a reliable power source with a high plant capacity factor. California obtained 5% of its electricity from geothermal plants in 2005. U.S. geothermal plants produce 15 to 16 billion kWh of electricity annually at costs of 4.0 to 8.0 cents per kilowatthour, which is competitive with other energy sources. Seventy plants, totaling 2600 MW of installed capacity, produce electricity in Nevada, Utah, Hawaii, and California. The first resource to be developed in the United States was the steam field at The Geysers, about 90 miles north of San Francisco. The Geysers steam field has produced electricity since 1960 and is the largest geothermal power plant development in the world.

Commercial production of electricity from geothermal resources has been carried out for 40 years in New Zealand and for over 30 years in Japan. Power production is currently under way in Australia, China, Costa Rica, El Salvador, Ethiopia, France (Guadeloupe), Guatemala, Iceland, Indonesia, Italy, Japan, Kenya, Mexico, New Zealand, Nicaragua, Philippines, Portugal (Azores), Romania, Russia, Thailand, and Turkey.

For steam-dominated resources, naturally occurring dry steam can be used directly in a fairly standard, low-pressure steam turbine to generate electricity. The steam is produced via geothermal wells and fed to the turbine through insulated pipes. Power plant developments at The Geysers, California, and Larderello, Italy, use dry steam.

Liquid-dominated geothermal resources are more common than steam-dominated resources. If resource temperatures are sufficiently high (>171°C), the liquid can be flashed partially to steam for use in a steam turbine using a single-flash or double-flash process. If the geothermal reservoir fluid is in a compressed liquid state, it partially flashes to steam in the wellbore as it rises to the surface. Additional steam is separated in surface flash tanks and fed to the turbine. The remaining liquid is injected back into the reservoir. If the resource temperature is high enough, the fluid can be flashed twice. Flashing occurs in the well and in a first separator at the surface. The high-pressure steam is fed to the high-pressure stages of the turbine. The liquid fraction from the first separator is flashed

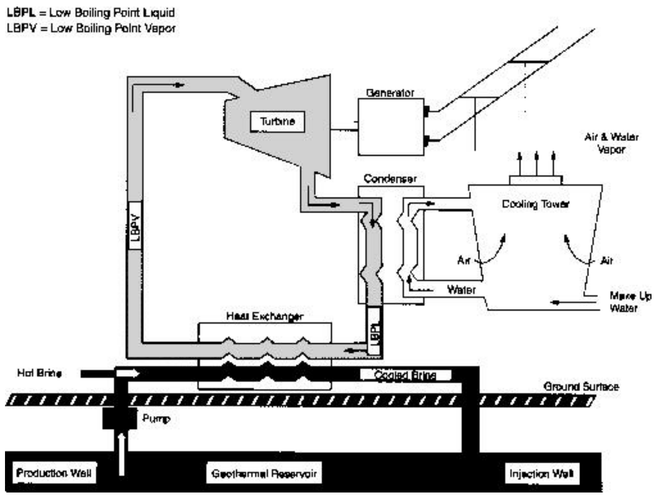

FIGURE 11-13 Schematic diagram of a binary geothermal power plant. (*U.S. Department of Energy*)

again in a second, low-pressure separator. The additional steam is fed to the low-pressure stages of the turbine. The addition of a second flash increases plant efficiency by about 20% compared with single-flash systems.

For liquid-dominated geothermal resources at resource temperatures not sufficiently high enough for flash systems, a binary cycle (organic Rankine cycle) is used (Fig. 11-13). The geothermal fluid is used to heat a working fluid with a low boiling point, such as refrigerants, isobutane, or propane. The heat of the geothermal brine is transferred to the pressurized working fluid in heat exchangers. The working fluid is vaporized and expanded through a turbine to produce power and then condensed and recycled through the heat exchangers in a closed cycle. The cooled brine is injected into the reservoir. Flash and binary cycles are combined sometimes to maximize the efficiency of extracting energy from a single stream of geothermal fluids. Typically, the binary cycle operates in a "bottoming" mode, using the outflow from a flash plant as its input.

In sizing large geothermal power plants, it is important to note that (1) the cost of fluid collection and injection increases as more wells are required, and (2) the relative cost of piping and the amount of heat lost in fluid transmission both increase as the distance between the resource wells and the plant increases. With increased system size, beneficial economies of scale of larger turbine-generators are traded off against the increased cost of the brine-gathering system. Geothermal power costs are sensitive to wellhead temperatures, well flow rates, and well costs. These three parameters determine to a large extent the economic value of a geothermal resource. The thermodynamic efficiency of the conversion process increases with higher resource temperatures. The size and cost of many power plant components vary inversely with temperature and directly with total fluid flow through the plant. Power plant costs increase as resource temperatures decrease because thermodynamic efficiency declines, and the heat content of the geothermal fluid is also less, requiring more mass per kilowatt. At some reservoirs, however, shallow, low-temperature wells can be inexpensive and very productive. Therefore, in some cases, low-temperature geothermal resources still may provide cost-effective power (DOE/EE-0044).

11.6.3 Exploration for Geothermal Energy

Exploration identifies geothermal resources, estimates resource potential, and establishes resource size, depth, and potential production. Refinements of exploration techniques evolved from those used in the petroleum and mining industries. Geothermal exploration of unmapped regions typically proceeds in two basic phases: (1) reconnaissance, or delineation of one or more geothermal provinces; and (2) detailed exploration for exploitable reservoirs within the provinces.

During the first phase, reconnaissance, regional geology and fracture systems are studied, such as young volcanic features, tectonically active fault zones, and overt or subtle geothermal manifestations. To design specific exploration programs, information is collected from various sources, including regional geologic and geophysical maps, satellite imagery, geochemical sampling of thermal and nonthermal waters and gases, analysis of surface rocks and soils, aerial photography, and measurement of thermal gradients in existing wells. If the reconnaissance phase proves satisfactory, the second phase of detailed exploration focuses on individual prospects. The first step in detailed exploration is geologic mapping on scales of about 1:6000. The objective is to understand the broad distribution of rock types, alteration zones, faults, fractures, and thermal features. Geochemical studies also are undertaken, and the collected information is integrated to produce a preliminary model of the area. Geophysical surveys are used to refine the preliminary model. If the model is encouraging, thermal-gradient wells are drilled to depths of 100 to 600 m. These wells provide the first strong direct evidence of the location and intensity of thermal energy. If indications of a hot resource are strong, the first deep hole, a "wildcat well," is drilled. If the wildcat is successful, it is followed by additional production-sized wells to confirm and assess the resource (DOE/EE-0044).

11.6.4 Drilling for Geothermal Energy

Power-generation systems require deep production and injection wells to produce and dispose of the geothermal fluids. The predominant method for drilling these deep wells is rotary drilling, adapted from the oil and gas industry. There are major differences between geothermal well drilling and oil and gas well drilling. Temperatures of geothermal fluids may reach 400°C compared with 200°C for deep oil and gas basins. These high temperatures cause rapid degradation of ordinary drilling equipment and drilling fluids. Production pressures for geothermal reservoirs are usually very low, in many cases subhydrostatic. The underpressured reservoirs can become plugged if ordinary high-density drilling muds are used. To overcome this situation, compressed air, aerated fluids, or foam is used. Geothermal formation rocks are usually more abrasive and harder than petroleum formation rocks. These formations severely degrade bits and tubular materials, especially when air is used as the drilling fluid. High temperatures also cause elongation of the wellhead and casing. Tolerance for casing motions must be accommodated when designing the wellhead, and geothermal wells are cemented from top to bottom to control the effects of casing elongation.

Drilling is one of the most expensive activities in any geothermal power development project. Each well can cost $1 to $3 million, and an average geothermal field consists of 10 to 100 or more wells. Drilling costs account for one-third to one-half of the total cost of a geothermal project.

11.6.5 Geothermal Reservoir Engineering

Reservoir engineering involves (1) formation evaluation, (2) reservoir modeling to forecast productivity and longevity, (3) well field management, and (4) analysis of production trends. Information derived from these activities is used to formulate a production strategy that balances the cost of delivered power or fluid with reservoir longevity.

Formation Evaluation. A number of techniques are used prior to production to evaluate the properties and flow parameters of the reservoir rock, to identify major fluid-bearing fractures and permeable rocks, and to understand reservoir-well interactions. Some of these techniques are analysis of well logs, drill cuttings, and drill cores to derive reservoir parameters such as permeability, porosity, and fracture characteristics; analysis of injected tracer return patterns to define the movement of fluids in the reservoir; pressure-transient well tests to determine the controlling flow and storage capacity of the formation and to delineate reservoir boundaries and heterogeneity; laboratory analyses of reservoir rocks and fluid samples; borehole televiewer, caliper, and spinner (flowmeter) surveys to locate fractures downhole; large-scale seismic arrays to record the pattern of seismic events in the reservoir; magnetotelluric analysis of the reservoir structure; and experimental geophysical and geochemical techniques to locate and map fractures and other geologic features.

Reservoir Modeling. An initial conceptual model of the reservoir, used to estimate its production capacity, is generated in the early stages of production and is updated continuously. The early reservoir model is then expanded from a conceptual model to a complex two- or three-dimensional numerical model. A variety of techniques can be used, including conceptual geologic modeling to define the geometry and physical properties, numerical simulation of reservoir behavior under production and injection conditions, geochemical modeling to analyze changes in reservoir fluids and rocks and to predict the movement of chemical fronts, analysis of well test data to determine key reservoir parameters, and wellbore simulation to analyze fluid flow and heat transfer inside the wellbore.

Well Field Management. Well field management optimizes production strategies. Well field management begins with the initial production stage and continues through the entire production period. Techniques include well field design optimization considering appropriate variations in well locations and depths, production rates and methods, fluid injection locations and rates, and production and injection control strategy; cost-benefit studies of energy extraction rates versus the cost of flashing flow or pumped production; improved injection techniques and injection well replacement strategies to increase production through heat sweep from the reservoir rocks; monitoring subsurface fluid movement using high-precision gravimeters; studies of water-rock interactions, sources of corrosion, and corrosion mitigation; use of liquid-phase and vapor-phase tracers to understand fluid movement within the reservoir; and monitoring microseismic activity to understand the stress vectors in the reservoir and the distribution of productive and/or receptive fractures. Microseismic monitoring also can reduce any environmental concerns that the production or injection of fluids may cause significant seismic activity.

Determination of Reservoir Production Trends. The monitoring of long-term production histories helps to understand reservoir production trends, reservoir–power plant system performance, and reservoir longevity. Recent advances in computer technology facilitate data storage and analysis and enhance the use of reservoir simulators. Methods used are long-term monitoring through geophysical measurements and geochemical sampling to detect fluid depletion and recharge ratios, microseismic monitoring of injected fluid to trace flow patterns and associated fracturing, numerical simulation of nonisothermal flows of multicomponent, multiphase fluids in porous and fractured media, and numerical simulation of multiphase, multicomponent aqueous species and noncondensible gases to model phase partitioning of components, conductive and convective heat flow, relative permeability effects, capillary pressure, and flow in fractured media.

11.6.6 Research and Development

Geothermal research and development activities are continuing worldwide. Improvements in the following areas are expected to have significant impacts: (1) techniques to identify and locate geothermal resources, (2) improved equipment and methods for well drilling and completion, (3) improvements in reservoir engineering, modeling, and management techniques, (4) advanced materials and improved power conversion cycles, and (5) permeability enhancement methods. Exploration techniques being refined include seismic imaging, spontaneous potential, three-dimensional magnetotelluric, gravity, electrical resistance tomography, transient electromagnetic, hyperspectral and satellite imaging, fracture and strain detection, and geochemical surveys. Drilling research and development (R&D) includes high temperature electronics and batteries, polycrystalline diamond compact (PDC) bits, mudjet augmented bits, downhole fiber optics, diagnostics-while-drilling, phosphate and sodium silicate-based well cements, and lost circulation control. For reservoir management, research areas include new chemical tracers, reservoir-wellbore simulators, and injection techniques. Power plant R&D includes innovative power cycles, hybrid wet-dry cooling, noncondensible gas removal, enhanced air-cooled condensers, coatings to prevent corrosion, hydrogen sulfide abatement, and silica recovery from geothermal fluids.

Three hot, dry rock pilot projects are active: the Soultz project in France, the Bad Urach project in Germany and the Cooper Basin project in Australia. These projects involve fracturing rocks of low permeability and conducting water circulation tests to extract heat from the human-made reservoirs. Other hot, dry rock experiments have been conducted at the Fenton Hill site in New Mexico, the Rosemanowes site in Cornwall, England, and the Fjallbacka site in western Sweden.

Techniques to increase permeability in marginally productive natural *hydrothermal* systems are being tried at sites in the western United States. These experiments are being conducted at the margins of productive geothermal fields and are referred to as *enhanced geothermal systems*.

Geothermal heat pump (also called *ground-source heat pump*) technology is making significant strides. The geothermal heat pump uses the earth as a heat source for heating or as a heat sink for cooling. A water and antifreeze mixture circulates through a pipe (usually polyethylene) buried in the ground (vertically or horizontally) and transfers thermal energy to a heat exchanger in the heat pump. The heat exchanger is a water-to-refrigerant loop. The ground-loop heat exchanger rejects heat from the condenser or delivers heat to the evaporator, depending on the mode of operation. Instead of a ground loop, groundwater can be used as the heat source and sink where groundwater is available and disposal of groundwater is acceptable. Geothermal heat pumps offer the advantage of a more stable source/sink temperature when compared with air-source heat pumps and can reduce electricity consumption by up to 30%. Researchers are reducing the cost of ground-loop installations, examining the practicality of adding supplemental heat rejection devices, and developing in situ tests and software to estimate the thermal conductivity of the soil and rock.

Low- to moderate-temperature resources ($<150°C$) are used increasingly for space heating, aquaculture, crop drying, and industrial processes. A well brings hot water to the surface, and a system of piping and heat exchangers delivers the heat to the space or process. A disposal system either injects the cooled water underground or disposes of it on the surface. Worldwide, geothermal direct use installed capacity totals more than 12,000 MWt, with 600 MWt in the United States.

11.6.7 Economics

For 5-MW and larger power plants using high temperature resources, the capital costs for the exploration, wells, and power plant range from $1,150 to $2,100 per kilowatthour. For 5-MW and larger power plants using moderate temperature resources, the capital costs range from $1,350 to $2,500 per kilowatthour. O&M cost range from 0.4 to 0.8 cents per kilowatthour for these plants. These costs are based on World Bank data, and future costs are expected to decline based on technology improvements. DOE/EPRI document EPRI/TR-109496 summarizes additional cost data for flash and binary power plants.

Competition from low-cost electricity from natural gas has strongly affected the development of geothermal power plants in the western United States. Approximately 900 MW of geothermal power plants were installed in the western United States between 1980 and 1990. However, since about 1990, the advent of cheaper electricity from natural gas–fueled systems and low load growth rates have slowed the pace of development. In 1990, geothermal power developers expected to compete against power at 6 to 7 cents per kilowatthour in 1996. By 1993, however, the developers were competing against power at 2.5 to 3.5 cents per kilowatthour in western states. However, strong overseas markets for these systems continue to provide a strong base for ongoing technology improvements and new federd tax credit and . . . increase in the United States are expected to . . . future development.

11.7 ENERGY STORAGE

BY MOHAN V. AWARE

Introduction

Energy is manifested in mechanical, electrical, chemical, and thermal forms—the latter being a special form of mechanical energy. Energy may be converted from any of these forms to any other form by one or more intermediate processes. Energy is stored in order to match energy supply with demand and/or to contain it for transport to a point where it can be used. Energy can be stored mechanically, electrically, chemically, or thermally. An energy-storage system generally comprises a converter to alter the energy from the type available to the type best stored, a storage subsystem which contains and stores the energy, and a reconverted subsystem to transform the stored energy to the type needed. The motivation for building and using storage is economics, since storage systems would displace generation equipment fired with premium fuels.

In this section, review of the various types of electrical energy-storage systems that store energy in a variety of forms but whose input and output are electrically presented. The review will include a brief description of the theory underlying the operation, a discussion of engineering concepts including conversion and reconversion methods, and an outline of the specifications and applications for each storage system.

All energy-storage devices have a fixed quantity of usable energy. Once the energy has been consumed, the device will have to be refilled or charged. The quantity of energy or hours of storage of an energy-storage device are determined largely by its intended application and by the incremental cost for the storage subsystem. In the deregulated environment of electrical energy systems, the cost-effectiveness of these storages is having special importance. Research and development is ongoing for all areas of energy storage. Some of the primary energy storage development goals include

- Lower costs
- Longer life
- Higher efficiency

Over the years, a lot of energy storage systems for electrical energy were developed. The most frequently used systems are shown in the Fig. 11-14. When energy is produced in the form of electricity,

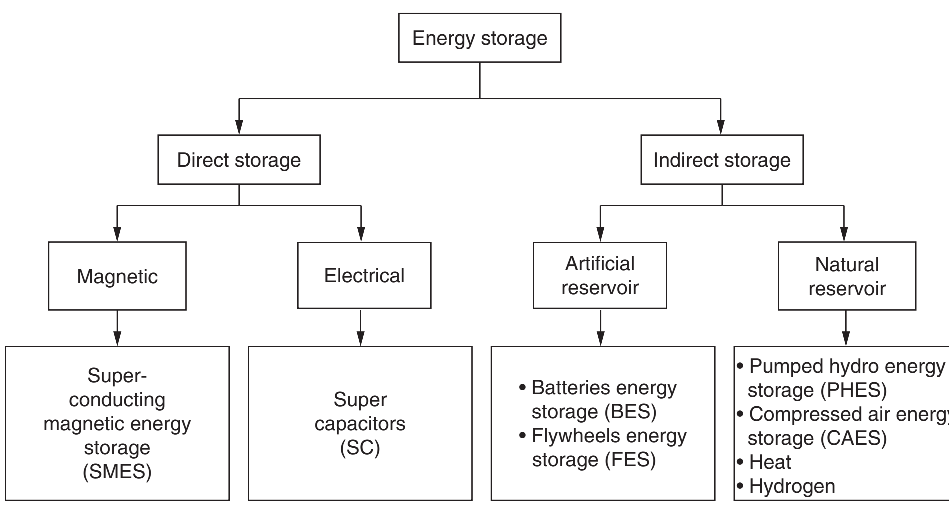

FIGURE 11-14 Energy storage system.

it has to match the load demand. There is no facility to allow the storage of electricity to facilitate the generation interdependently of the load demand. This needs intermittent energy storage devices. The application of these devices in sustainable energy systems is presented with their interface to main system in following sections.

11.7.1 Electrochemical Energy Storage

Batteries. The most traditional of all energy storage for power system is the electrochemical energy storage (EES). The major classification can be made in three categories. They are primary batteries, secondary batteries, and fuel cells. The common feature of these devices is primarily that stored chemical energy is converted into electrical energy. Although the input and output energy of a battery is electrical, the storage is in the chemical form. The most widely known device is the conventional lead-acid battery. The technology is mature and the costs are fairly well-known. The battery life is fairly long, perhaps 10 years or more when properly maintained, but the initial cost is high if one wishes to store enough energy for significant use. In some cases, however, it is the only thing available. In such circumstances, it may be used to operate few lights, television sets, and similar low-demand devices. More effective use of batteries for energy storage awaits the development of more efficient and less costly batteries.

Electrolysis of water represents another technique for storing energy in chemical form. The stored product of hydrogen can be used as fuel. To minimize storage requirements, it must be stored at relatively high pressures, and even so the energy density is fairly low. Greater energy densities could be achieved by liquefaction, but the mechanical and cryogenic technologies required are expensive. One of the major attractions of this approach is that the basic raw material is distilled water, and it is possible to develop similar devices to run on hydrogen directly. These include simple heaters and internal-combustion engines. The former could be used for space heat, grain drying, cooking, etc., and the latter could be adapted to small range vehicles such as mini-tractors and mini-trucks. In certain rural situations, these devices could be useful and would not require imported fuel.

Lead-Acid Batteries. One of the oldest and best-known devices used to store energy is the lead-acid battery. The technology is based on the reduction of lead dioxide to lead sulfate at the positive electrode and the simultaneous oxidation of the lead to lead sulfate at negative electrode. The electrolyte, sulfuric acid, is consumed and energy is discharged during this process. Energy is stored by reversing these reactions, that is, charging the battery.

The energy stored is proportional to the voltage (2.08 V per cell) and to the amount of lead. Lead has a high molecular weight, is an inherently inefficient chemical for battery energy storage, and is used for carrying current in cell. As a result, the amount of lead required per kilowatthour of storage is 50 to 100 lb, which unfavorably affects both the weight and cost of the storage system. A serious drawback of this battery is therefore its low energy density (i.e., energy stored per unit weight of battery), which is about 10 to 25 Wh/lb depending also on design and operation. Under suitable operating conditions, a well-designed and manufactured lead-acid battery can achieve 2000 cycles and last for 10 years. However, life is substantially sacrificed to achieve higher energy densities required for certain application, such as electric vehicles.

A lead-acid battery system comprises individual cells that have capacity range from a few tenths of a kilowatthour to a few kilowatthours. A large submarine cell can have a capacity of 10 kWh and weigh 1,000 lb. Lead-acid cells are often arranged in series strings to achieve the desired dc voltage for conversion or for the application intended. The number of strings will depend on the energy requirements. Energy conversion is often achieved by solid-state converter/rectifier systems. Lead-acid batteries are used in submarines, forklift trucks, uninterrupted power supplies, electric vehicles, and short-term emergency power systems for several applications including telephones, computers, and nuclear power stations. Lead-acid batteries are also being considered for electric utility application. West Berlin's utility (BEWAG) installed a 8.6 MW/9.3 MWh lead-acid battery system in 1987 to meet a part of its system regulation (maintaining frequency stability) and spinning reserve needs (supplying short-term emergency power).

Nickel-Cadmium and Other Commercial Batteries. The nickel-cadmium battery is the only other commonly employed rechargeable battery besides lead-acid. The chemical reaction involves reduction of nickel oxide to nickel hydroxide and oxidation of cadmium to cadmium hydroxide in an alkaline electrolyte (20% to 35% potassium hydroxide). The voltage of this couple (1.3 V) is less than that of lead-acid, and the energy density (about 20 Wh/lb) is slightly better. Due to the high costs for nickel and cadmium, this battery is expensive and is only used when extremely long life or lighter weight is required. Major applications are satellites, portable equipment and tools, and various military applications. Other secondary (rechargeable) batteries considered for these and their specialized application are silver-zinc, nickel-iron, and nickel-hydrogen. These systems are all expensive and are less environmentally friendly, but they are durable and have very long lives. Compared to lead-acid battery, the higher reliability of individual cell is offset by the larger number of cells required.

Advanced Batteries. Over the past two decades, a number of advanced batteries have been investigated. The aim of the research programs has been to lower the costs while maintaining the desirable specifications (durability and performance) of the lead-acid and nickel-cadmium batteries. A secondary objective is to achieve improved energy densities. The advanced battery systems closest to commercialization are zinc-chloride, zinc-bromide, and beta (sodium-sulfur) batteries. These are compared in Table 11-7. In contrast to the lead-acid and nickel-cadmium systems, these advanced batteries use low-cost, readily available active materials and enjoy simple electromechanical reactions, which should lead to excellent durability.

These advanced batteries either operate at higher temperature (Na-S) or employ flowing electrolytes (Zinc-halogen). The additional subsystems for such batteries to maintain flow or temperature add to overall system complexity, which in turn, affects their reliability. However, these subsystems normally will be built within the battery system and will have the same modular character of the lead-acid battery. As a result of these additional subsystems, optimal economics will not occur until module sizes are in the 100- to 400-kWh range, a factor of 10 larger than the largest lead-acid battery modules. The size of module will have application only where there are fairly sizable energy storage requirements, such as electric utility and commercial or industrial applications, which require a capacity of few hundred kilowatts to several megawatts. While there is hope that these advanced batteries can be used for electric-vehicle application, their economic optimal size and complexity suggest that the economic goals for this application will be difficult to achieve. An electric-vehicle battery has to be inherently simple from both the design and engineering standpoint to meet owner expectations.

The advanced batteries are not yet commercially available at affordable costs. Engineering prototypes of the zinc-chloride system at a size of 500 kWh began independent testing in early 1984. Similar-sized prototypes of the other advanced batteries were tested in 1991. Limited commercial availability of these systems can occur within a few years of successful independent testing. However, acceptable costs may occur for yet an additional 3 to 5 years, and only with a reasonable market.

Fuel Cells. A *fuel cell* is an electrochemical device wherein the chemical energy of a fuel is converted directly into electric power. The main difference between a conventional battery and a fuel cell is that, unlike a battery, a fuel cell is supplied with external reactants; as a result whereas a battery is discharged, a fuel cell never faces such a problem as long as supply of fuel is provided. Fuel cells, distinguished from other secondary batteries by their external fuel store, have an even longer history than the lead-acid battery. The first hydrogen-oxygen fuel cell was demonstrated in principle by English lawyer W. R. Grove in 1989, although the bulk of fuel cell's development has been in the

TABLE 11-7 Advanced Battery Systems

System	Positive electrode	Negative electrode	Cell voltage	Temperature, °C	Achievable energy densities, Wh/lb
Na–S	S	Na	2.1	300–350	45–55
Zn–Cl	Cl	Zn	2.1	20–50	30–40
Zn–Br	Br	Zn	1.8–1.9	20–50	20–30

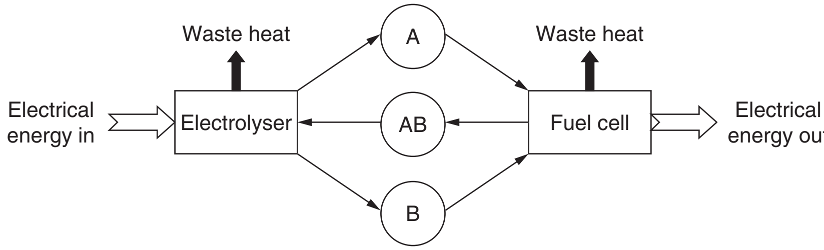

FIGURE 11-15 Schematic diagram of an electrochemical fuel cell.

last 40 years and the major application has been in the space industry. Major research activity in secondary batteries worldwide is concerned with material research for advanced batteries, in particular, materials for solid solution electrodes and for solid electrolytes. It should be noted that solid electrolytes are equally applicable to an electrochemical fuel cells. The processing functions of an electrochemical fuel cell are presented in Fig. 11-15.

Essential functions of the fuel cell are

1. The charging (or electrolyser) function in which the chemical AB is electrochemically decomposed to A and B.
2. The storage function in which A and B are held apart.
3. The discharge (or fuel cell) function in which A and B are reunited with simultaneous generation of electricity.

Fuel cells are generally characterized by the type of electrolyte that they use. Main fuel cell systems under development for practical applications are phosphoric acid (PA), proton exchange membrane (PEM), molten carbonate (MC), solid oxide (SO), direct methanol (DM), and alkaline fuel cell.

The different types of the fuel cells are having their respective properties and applications. A typical fuel cell-based power processing system showing the major plant processes is shown in the Fig. 11-16 . There are three major steps involved in the generation of the power from a fuel cell. The first and foremost step is achieved purity of the available hydrogen gas. This is done with the help of a fuel processor. A carbonaceous fuel is fed to the fuel processor, which in turn, produces a hydrogen rich gas at its output. This hydrogen rich gas is then fed to the anode electrode of the fuel cell. The second step involves the fuel cell operation itself. The fuel cell is fed with the hydrogen rich gas at its anode and supply of air to the cathode. The hydrogen atoms at the anode gets split up into positive protons and negative electrons. These electrons follow an external path on their way to the cathode, thus supplying power to an external load in the process.

The third step is the power conditioning step, which includes power electronic converters. Power electronic converters add more flexibility to the operation of the system.

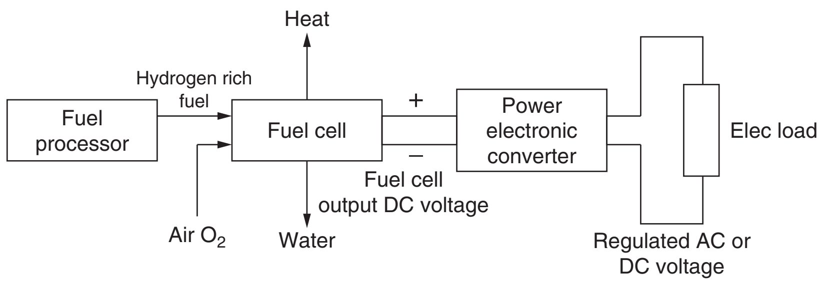

FIGURE 11-16 Typical fuel cell-based power processing system.

11.7.2 Mechanical energy storages

Flywheels. Mechanical energy may be stored in the form of kinetic or potential energy. A flywheel, in essence, is a mechanical battery—simply mass rotating about an axis. Although the use of the flywheel as a kinetic energy storage device is well-known, it has not, until recently, been considered practical to build flywheels that could store energy for several hours or days. They take an electrical input to accelerate the rotor up to speed by using the built-in motor, and return the electrical energy by using this same motor as a generator. Steel flywheels have been used to power certain types of vehicles, such as buses and trucks, for very short runs, but the energy-storage periods have at the best been for a few minutes.

The basic problems of flywheels are as follows. First, the stress in any rotating structure is proportional to the first power of the diameter and second power of the angular velocity. With steel structures, the limiting stresses are exceeded before any significant amount of usable energy can be stored. Second, even if the flywheel could store significant energy, it would soon be dissipated by bearing friction and windage losses. It has been pointed out by Post and Rabenhorst that one or two orders of magnitude improvement over conventional flywheel technology could be achieved by

(*a*) Using fiberglass resins and polymer materials, which have a much higher strength-weight ratio than steel.

(*b*) Running the flywheel in a vacuum.

(*c*) Using air-or magnetic-suspension bearing technology developed in recent years.

If the projections of Post and Rabenhorst are supported by experimental evidence, it appears that flywheel could become practical for storing significant amount of energy efficiently for several hours. This could make flywheel practical for electrical peaking and short-run vehicular transportation.

Flywheels involve the storage of kinetic energy in a rotating object. The stored energy is proportional to the object's moment of inertia times the square of its angular velocity. In order to optimize the energy-to-mass ratio, the flywheel needs to spin at the maximum possible speed. For a flat disk, the moment of inertia is proportional to its mass times the square of its radius. Therefore, the energy stored is proportional to its mass and the square of angular velocity. Rapidly rotating objects are subject to centrifugal forces that can rip them apart. Thus, while dense material can store more energy, it is also subject to higher centrifugal force and thus fails at lower rotational speeds than low-density materials. Therefore, tensile strength is more important than the density of the material. Two approaches to flywheel energy storage are generally pursued. The commonly used approach is to use a heavy material, like steel, and operate at a moderate speed. The other approach, the so-called advanced flywheel, uses lighter high-strength materials like glass or carbon fibers and operates at high speed. Recent advances in composite materials technology may allow nearly an order of magnitude advantage in specific strength of composite when compared to even the best engineering metals. The result of this continuous research in composite has been a flywheel that operates at rotational speed in excess of 100,000 rpm with tip speeds in excess of 1000 m/s.

Flywheels have smoothed our energy sources in such historic applications as the potter's wheel, the grain mill, and the water wheel. Today, its best use is in engines of various types. For large-scale electric storage, economics would dictate the use of lighter-weight high-speed (30,000 r/min) wheels operating in a vacuum and using magnetic bearings to reduce friction. Under these conditions, energy efficiencies of about 80% are achievable. Since the speed of the wheel will change as energy is added or withdrawn, the motor-generator will have to accommodate variable speeds. Several approaches to variable-speed generation have been investigated for wind application, although today's wind machines use fixed speed generators. Conservation measures have encouraged the use of variable-speed motors, and several manufactures now have this technology available in large sizes, for such applications as thermal power plant fans and pumps. The flywheel itself is an expensive way to store energy, with costs probably twice that of the lead-acid battery. However, it has several advantages over chemical energy storage, like energy density and better capability to exchange energy.

However, for application such as utility system regulation, where there are high-power and low-energy requirements, flywheels would be suitable if integrity and reliability can be demonstrated. The ideal use for today's flywheels is still to absorb and dissipate mechanical energy to smooth the

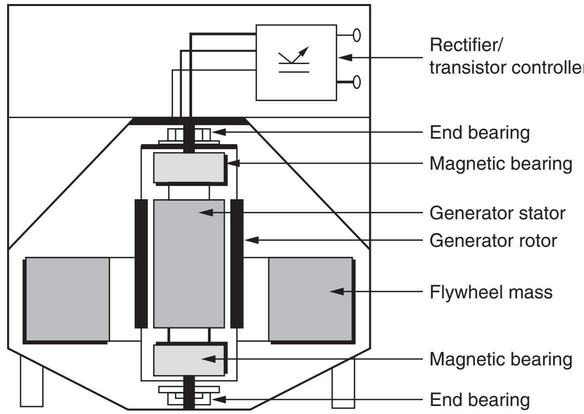

FIGURE 11-17 Flywheel storage system.

operation of rotating machinery. The ultrahigh rotational speed required to store significant kinetic energy in these systems virtually rules out the use of conventional mechanical bearings. Instead most systems run on magnetic bearings. These relatively recent innovations use magnetic forces to leviate a rotor, eliminating the frictional losses inherent in rolling element and fluid film bearing. Unfortunately, aerodynamic drag losses force most high speed flywheels to operate in a partial vacuum. A modern high-speed flywheel system is shown in Fig. 11-17.

Pumped Storages. Mechanical energy may be stored in the form of potential energy by pumping water to a reservoir at a higher level and allowing it to flow down to a lower reservoir whenever the energy is required. In this pump-back system, the kinetic energy of the flowing water is usually converted to electrical energy, although it can be used directly as mechanical energy. The energy can be extracted from the hydro power plant depending on both the volume of the water available and the head of the water that can be exploited. The pump storage will provide the most efficient and cheapest operation when it can be provided a high head between the two reservoirs. This will allow greatest amount of energy to be stored in the smallest volume of water resulting in a smaller pump and turbine, reducing capital costs. Pumped hydro storage usually comprises the upper reservoir, waterways, a pump, a turbine, a motor, a generator, and lower reservoir as shown schematically in the Fig. 11-18.

A difficulty of the pump-back storage system is that relatively large reservoirs are required. Most pump-back systems are built where there is a large natural basin for an upper reservoir located near an existing lake or river, the latter serving as the lower reservoir. With current technology in pump-back systems, generally about two-thirds of the energy is available for utilization after storage.

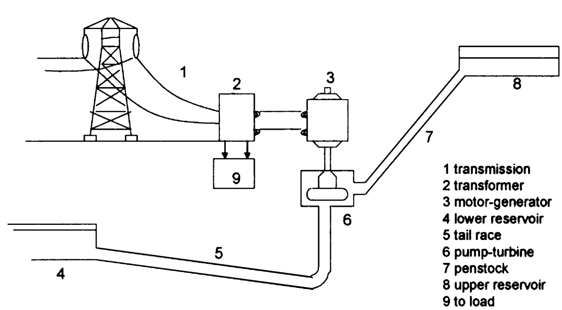

FIGURE 11-18 Pumped hydroelectric energy storage.

Hydraulic turbines have a maximum efficiency of around 95% and pumps are less efficient operating around 90%. Therefore, pump storage plants will have maximum efficiency of around 85%.

Pumped hydro or pumped storage, as it is often called, has been used in electric utility systems for over 50 years. Electricity is used to operate a motor-generator combination to pump water to an elevated reservoir. When energy is required, water is allowed to flow down to a lower reservoir through a turbine-generator combination, much like the turbine generators in conventional hydroelectric plants. The energy stored is proportional to the head (height differential between the upper and lower reservoir) times the stored volume of water. For head of 1200 ft, 36 ft of water is required for generation of 1 kWh. For a head of 120 ft, 360 ft of water is required to generate 1 kWh.

In areas where topographic or ecological considerations rule out pumped-hydro plants, utilities now may choose to go underground. A modification of pumped hydro, underground pumped hydro (UPH) would have its lower reservoir located about a mile below the earth's surface in a competent hard-rock cavern. A UPH plant therefore can be sited in flat terrain and should have only a minimal effect on the surrounding environment. The most significant drawback of UPH is that the plants must be in huge sizes (2,000 MW/20,000 kWh) to be economically attractive.

Both pumped hydro and UPH, like conventional hydro, have very fast response characteristics (emergency full-power capability is 10 s) and very high efficiencies (72% to 75%). These factors, along with low capital costs, have led to the construction and operation of 18,000 MW of pumped hydro in the United States. Another 16,000 MW is planned or under construction. Pumped hydro typically will be the storage alternative of choice for electric utilities having favorable topography. Main barriers for the future growth in pumped-hydro capacity are the availability of suitable sites and large environmental impact of these schemes.

Compressed Air. Another method for storing mechanical energy is through compressed air. Two basic methods are of interest: direct compression and isothermal compression. Direct compression, to be practical, requires the availability of natural or man-made underground caverns, which can be sealed off and pressurized to hydrostatic pressure or below. Utilization of the stored energy requires the availability of low-pressure turbines or piston engines similar to the old-style steam engines. Generally, such systems provide a relatively low overall efficiency. About one-third of initial energy can finally be utilized. This figure can be improved considerably when compressed-air system is combined with gas turbine cycles or with refrigeration cycles, because the energy required to compress the turbine inlet air need not be charged against turbine fuel efficiency if the air is already compressed.

Of increasing interest is isothermal hydraulic compression. In this process (which is at least 3,000 years old), a vertical tube is placed in front of a dam which is creating a head of water (typically 5 to 10 m). Water flowing into the inlet entraps air bubbles, which are carried with water. The water then passes through the bottom of a sealed tank or cavern, where the air bubbles rise. Ultimately, the air in the tank or cavern is compressed to a pressure slightly under the hydraulic head of the vertical (venturi) tube. That compressed air can then be used in a simple turbine or other suitable expander to obtain usable mechanical energy. Such isothermal hydraulic compressors were used from ancient times until the later part of the nineteenth century, when they were gradually replaced by electrical, steam, or internal-combustion devices. Because the compression is isothermal, the apparent efficiency of such systems can be very high, and with the rising cost of fuel, interest in this storage system is rapidly rising. A typical air-storage gas-turbine power plant with a constant pressure reservoir is shown in Fig. 11-19.

CAES involves the compression of air into an underground cavern or reservoir (excavated rock, solution-mined salt, or aquifer) where it is stored. Favorable geologies exist in about 75% of the United States. Geologic considerations generally dedicate that most of the heat of compression be removed (and used or stored, if possible) before the air is stored underground. During generation, the air is expanded through a turbine to drive a generator. Economics dictates that heat be added to the air from a thermal store or through combustion of fuel prior to the expansion-generation phase.

CAES technology recently has become commercialized for electric utility application. The commercial units incorporate modified combustion turbines wherein the compressor and expander are physically separated by clutches and motor-generator. For the expansion-generation phase, the technology uses oils or gas, although other fuels can be used. When a heat exchanger is incorporated to use exhaust heat to raise the temperature of the pressurized air, the overall energy balance involves approximately

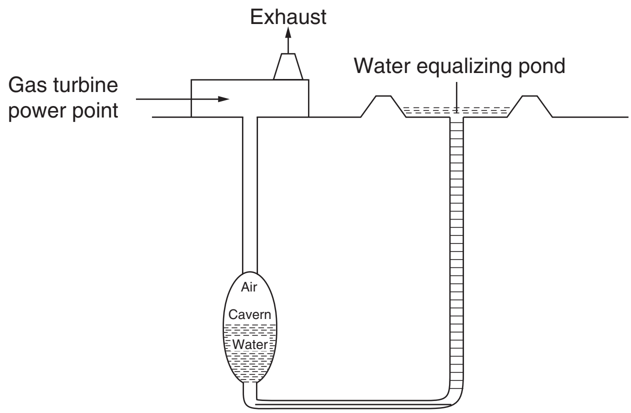

FIGURE 11-19 Air-storage gas-turbine power plant with a constant pressure reservoir.

4,000 Btu of oil or gas (during the generation phase) and 0.775 kWh of electricity (for the compression step) to produce 1 kWh of plant output. Typical energy-storage efficiencies cannot be calculated because a mixture of fuels is used. However, overall energy use is about 11,500 Btu/kWh, assuming the electricity for compression was generated at 10,000 Btu/kWh. A storage device using only electricity would have an efficiency of 87% to achieve an overall fuel use of 11,500 Btu/kWh, again assuming charging electricity is generated at 10,000 Btu/kWh. CAES system can be used on very large scales. Unlike other systems considered, large-scale CAES is ready to be used with entire power plants. Apart from the hydro pump, no other storage method has a storage capacity as high as CAES. Typical capacities for a CAES system are around 50 to 300 MW. The storage period is also the longest due to the fact that its losses are very small. A CAES system can be used to store energy for more than a year. The main drawback of CAES is probably the geological structured reliance.

11.7.3 Thermal Energy Storage

Energy can be stored as heat in appropriate materials, provided that suitable thermal insulation surrounds the storage substances. Hot rocks and fireplace bricks have served as primitive heat storage devices from ancient times. Water, rocks, and materials of high heat capacity, which are generally available, are commonly used as a storage media. Sources of energy such as solar heaters or wind generator can be used. The major difficulty is that the energy can be reutilized only as heat. Reconverting the heat energy to electrical or mechanical energy involves significant losses because of fundamental thermodynamics limitations. Storage temperature generally would be low, of course, and maximum reconversion efficiency (to mechanical or electrical form) would be on the order of few percent. Nevertheless, direct reutilization as heat can be practical, and this is done in some places. While thermal and cool storage has many applications, including thermal storage of off-peak energy in many European homes, it is not economically viable with electricity being both the energy source and the final product. The poor efficiency of converting heat to electricity is prohibitive. Thermal storage is generally only economically attractive when the energy required is heat. Thermal energy storage is ideally suited for applications such as space heating, where low quality, low temperature energy is required, but it is also possible to use thermal energy storage with conventional coal and nuclear-fired power plants, which dominates installed capacity of electricity utilities and is likely to continue to do so for the near future. Site-specific applications where heat is stored as steam and hot water at power plants have proven economic. However, retrofits of such technology into existing power plants have proven economic, but it would be difficult and costly since thermal and cool storage do not involve electricity and effectively store the thermal energy. Small water tanks are widely used for solar heat storage systems as shown in the Fig. 11-20.

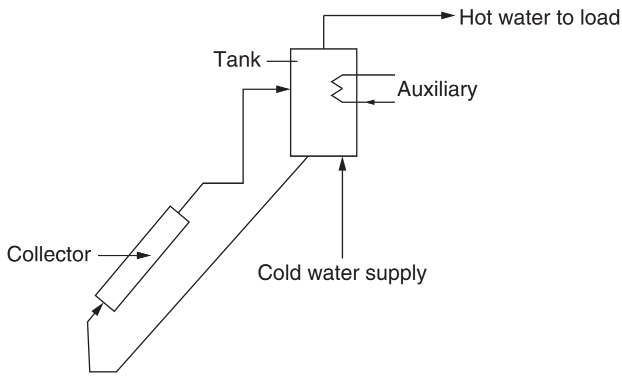

FIGURE 11-20 Hot water panel system with natural circulation.

11.7.4 Electrical Energy Storage

Superconducting Magnetic Energy Storage. Electricity (dc) can be stored in magnetic fields, wherein the energy stored is proportional to the inductance times the square of the current. An energy storage system based on magnetic would involve an ac-dc-ac converter system (like batteries) and a large coil of a superconductor (e.g., a niobium-titanium alloy). To achieve superconductivity, the conductor is maintained in a bath of liquid helium at about 1.8 K. Since there are no moving parts in the coil and electrical resistance is near zero, efficiencies can be above 90%. Energy losses occur in the converter and refrigeration system, although both can be designed to achieve high efficiency. The cost per unit of stored energy of superconducting magnetic energy storage (SMES) varies with the minus one-third power of stored energy. In other words, cost per unit of stored energy decreases by 21% for each doubling of storage capacity. In practice, therefore, very large sizes of several thousand megawatthours are required for SMES to be cost-competitive.

The basic operation of a complete SMES system is very simple and its setup is shown in Fig. 11-21. The transmission voltage from ac network is first stepped down from a few kilowatts to several hundred volts using a step-down transformer. This is then converted into dc, which is fed into the superconducting coil.

When power flows from system to coil, the dc voltage will charge up the superconducting coil and energy is stored in the coil. When ac network requires power boost, say when there are sags, spikes, and voltage and frequency instabilities, coil discharges and acts as a source of energy. The dc voltage is converted back into ac voltage through the converter.

The maximum energy stored depends on the design of the device. SMES systems are able to store upto 10 MW. However, some research believe an SMES can potentially store up to 2,000 MW. Theoretically, a coil of around 150 to 500 m radius would be able to support a load of 5000 MWh at 100 MW depending on the peak field and ratio of the coil's height and diameter.

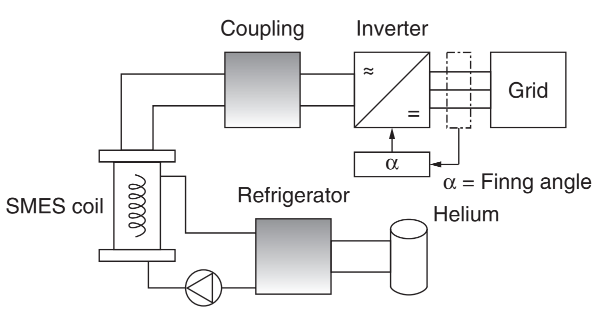

FIGURE 11-21 Basic setup of a SMES unit.

SMES is, however, attractive for applications where high power is required for very short periods. For example, a small 10- MW, 3-s experimental system was built to inhibit subsynchronous resonance in a high-voltage ac line from the state of Washington to California. Through R&D, SMES costs might be reduced sufficiently to become competitive for bulk-storage application. Ongoing research is directed to improving conductor current density and developing innovative design concepts that lower conductor support requirements. High Temperature Superconductor (HTS) coils of Ag-clad $(Bi, Pb)_2 Sr_2 Ca_2 Cu_3 O_{10+x}$ material, which can be operated with liquid nitrogen are commercially available. With successful research, issues involving the effects of magnetic fields, land use, and quality control suggest that the practical systems are commercially available and operational. A typical bidirectional converter with cryogenic arrangement is shown in Fig. 11-22.

Ultracapacitor. Capacitors are some of the most essential building blocks of electronic circuits to hold dc voltages. Based on the same principle, but on a much larger scale, it is conceivable that capacitors could be used to store energy for extended periods of time. Until some time ago, however, capacitors only managed to hold very little energy compared to a regular battery. In 1997, researchers from CSIRO developed the first supercapacitor. This is basically a capacitor which is able to hold significantly more charge using thin film polymers for the dielectric layer. The electrodes are made of carbon nanotubes. The energy density of a normal capacitor is only 0.5 Wh/kg. PET super capacitors can store 4 times more energy compared to the normal capacitor. Carbon nanotubes and polymers are practical for supercapacitors. Carbon nanotubes have excellent nanoporosity properties allowing the polymer tiny spaces to sit in the tube and act as a dielectric. Polymers have redox (reduction-oxidation) storage mechanism along with a high surface area. There are researches going on to replace carbon nanotubes with ceramics for their superconducting properties. These promising technologies introduce potential to improve the energy storage and represent a new generation of electrochemical components with very high capacitance for energy storage. A capacitor storage system with grid interface is shown in Fig. 11-23.

Supercapacitors are well suited to replace batteries in many applications. This is because at the moment their scale is comparable to that of batteries, from small ones used in cellular phones to large ones that can be found in cars. Even though supercapacitors have a lower energy density compared to batteries, they avoid many of the battery's disadvantages.

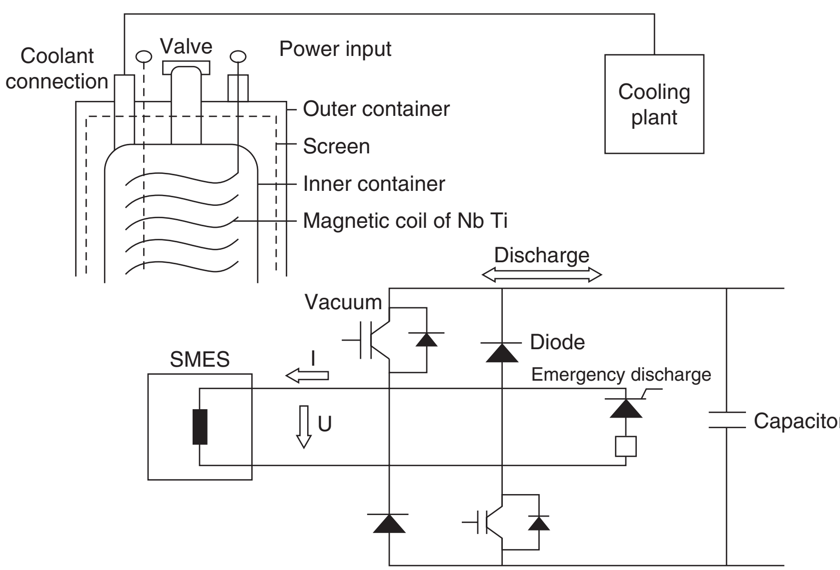

FIGURE 11-22 SMES high-temperatures system (HTS).

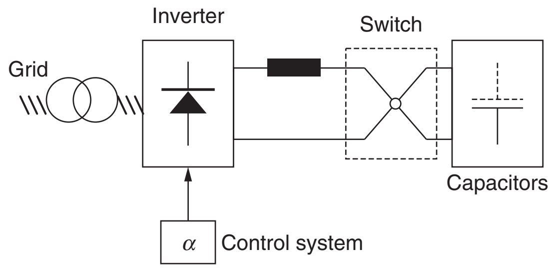

FIGURE 11-23 Capacitor storage system with grid connectivity.

Batteries have a limited number of charge/discharge cycles and take time to charge and discharge because the process involves chemical reactions with noninstantaneous rates. These chemical reactions have parasitic thermal release that causes the battery to heat up. Batteries have a limited life cycle with a degrading performance and acidic batteries are hazardous to the environment. Super capacitors can be charged and discharged almost an unlimited number of times. They can discharge in matters of milliseconds and are capable of producing enormous currents. Hence, they are very useful in load levelling applications and fields where a sudden boost of power is needed in a fraction of a second. They do not release any thermal heat during discharge. Supercapacitors have a very long lifetime, which reduces maintenance costs. They do not release any hazardous substances that can damage the environment. Their performance does not degrade with time. Supercapacitors are extremely safe for storage as they are easily discharged. They have low internal resistances, even if many of them are coupled together. Even though they have a lower energy density, are bulkier and heavier than an equivalent battery, they have already replaced batteries in many applications due to their readiness in releasing power. Supercapacitors were initially used by the U. S. military to start the engines of tanks and submarines. Most applications nowadays are in the field of hybrid vehicles and handheld electronic devices.

In most hybrid vehicles, 42 V supercapacitors are used. General Motors has developed a pickup truck with a V8 engine that uses the supercapacitor to replace the battery. The efficiency of the engine rose by 14%. The supercapacitor supplies energy to the alternator. In rural areas, where there are voltage sags in the power grid, supercapacitors can be used to reduce the effect of fluctuations. The supercapacitor has become available to the public. A commercial supercapacitor can hold 2,500 F, release 300 A of peak current with a peak voltage handling of about 400 V. The life cycle of this supercapacitor is more than 1×10^6 charge/recharge cycles.

11.7.5 Economics of the Energy Storage Media

There is a diversity of storage technologies to store electrical energy. They are somewhat more complex to analyze than that of conventional generation systems because the number of hours of operation will dictate capital costs and its use. It is important to note that the total cost of storage system ($/kW) is the sum of power-related costs expressed in $/kW and the storage-related costs ($/kW) times the required hours of storage. Thus, if long periods of storage are required, it is critical to have an inexpensive storage subsystem. On the other hand, for high-power applications with short discharge periods, low conversion cost and fast response are the key requirements. Table 11-8 outlines relative economics for the various storage systems discussed. For electric utility systems, a combination of storage systems might be optimal because of the relative costs. For example, batteries could be used for peaking (less than 5 h of storage) and CAES for intermediate duty cycle (more than 8 h of storage).

Besides economics, there are several other considerations that should be addressed before a storage system is selected for a particular application: siting restrictions, environmental impact, response time, unit size, lead time, commercial availability, and operational experience. A relative comparison of specific energy and specific power for various storages and their backup times are shown in Fig. 11-24 *a* and *b,* respectively.

TABLE 11-8 Relative Economics for Energy Storage System

Storage technology	Conversion cost, $/kW	Storage cost, $/kW
Lead-acid battery	Low	High
Nickel-cadmium battery	Low	Very high
Advanced battery	Low	Moderate
Pumped hydro	Moderate	Low
Underground pumped hydro	Moderate	Low to moderate
Compressed air	Moderate	Low
Superconducting magnet	Low	Very high
Flywheel	Low to moderate	Very high

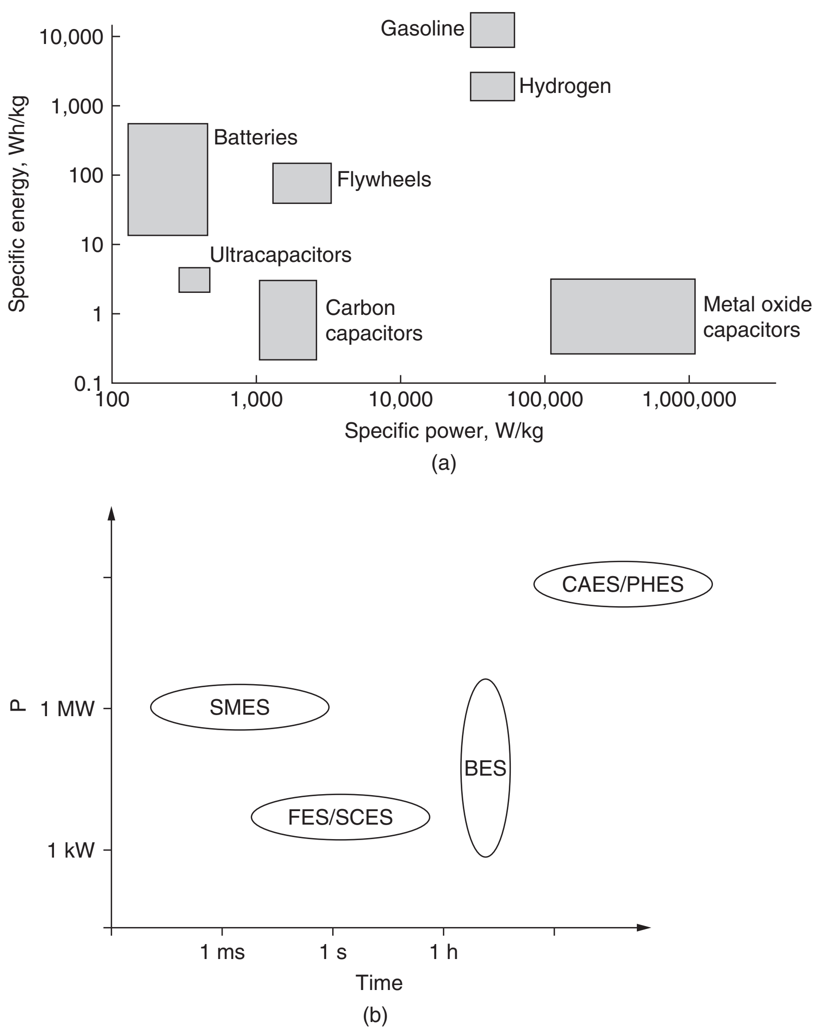

FIGURE 11-24 Electrical power and energy storage comparison: (a) comparison of specific energy and specific power in various energy storages; (*b*) storage technology with its backup times.

TABLE 11-9 Performance and Cost Comparison of Energy Storage

	Batteries	Flywheel	Pumped hydro	CAES	GAS	Micro SMES	SMES	Capacitors
Efficiency	~75%	~90%	~75%	~70% + fuel	~60% + fuel	~95% + refrigeration	~95% + refrigeration	~95%
Energy Capital Cost	200 $/kWh + replacement	800 $/kWh	16.8 $/kWh	10 $/kWh	250 $/kWh	~300 $/kJ	Depends on size	3600 $/kJ
Power Capital Cost $/kW	300	220	600	425	1000	500	300	300
Fixed O & M $/kW/yr	1.55	7.5	4.3	1.35	2.8	8	1	5% of capital
Variable O & M $/kWh	0.5	0.4	0.43	0.1	0.1	0.5	0.1	-

Only after these entire factors are considered then the storage system be selected for any particular application. Once selected, storage systems often will be very competitive with generation technologies, provided low-cost charging energy is available.

Table 11-9 presents the most commonly used and emerging storage systems' comparison with their operating hours and efficiencies. Most storage systems have greater size and operational flexibility than the competing generation schemes and therefore should be seriously considered in any utility expansion plan and for certain utility customers.

11.8 BATTERIES

BY ROBERT D. WEAVER AND PAUL BUTLER

11.8.1 Principles of Operation

Electrochemical Principles and Reactions. A *battery* is a device that converts the chemical energy contained in its active materials directly into electrical energy by means of oxidation-reduction electrochemical reactions. These types of reactions involve the transfer of electrons from one material to another. In a battery (Fig.11-25), the negative electrode or anode is the component capable of giving up electrons, that is, being oxidized during the reaction. It is separated from the positive electrode or cathode, that is, the component capable of accepting electrons and being reduced. The transfer of electrons takes place in the external electric circuit, connecting the two materials. Transfer of charge is completed within the electrolyte by movement of ions (anions and cations), not by electron flow.

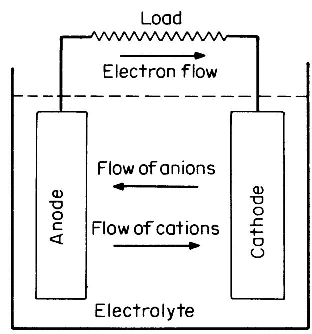

FIGURE 11-25 Electrochemical operation of a battery.

The operation of a fuel cell is similar to that of a battery except that one or both of the reactants are not contained in the electrochemical cell but are fed into it from an external supply when power is desired. The fuels are usually gaseous or liquid (compared with the metal anodes generally used in batteries), and oxygen or air is the oxidant.

Components of Batteries. The basic unit of the battery is the cell. A battery consists of one or more cells, connected in series or parallel depending on the desired output voltage and capacity. The cell consists of three major components: the anode (the reducing agent or fuel), the cathode or oxidizing agent, and the electrolyte which provides the necessary internal ionic conductivity. Electrolytes are usually liquid, but some batteries employ solid electrolytes which are ionic conductors at battery operating temperatures. In addition, practical cell design requires a separator material (which serves to separate the anode and cathode electrodes mechanically), electrically conducting grid structures or materials added to each electrode to reduce internal resistance, and suitable containers.

Theoretical Cell Voltage and Capacity. The theoretical capacity (amperehours) of a battery system is determined by its active materials. The maximum electrical energy (watthours) corresponds to the free-energy change of the reaction. The theoretical voltage and specific energy ratings of a number of electrochemical systems are given in Table 11-10. The voltage is determined by the active materials selected, while the amperehour capacity is determined by the amount (weight) of available reactants. One gram-equivalent weight of material will supply 96,480 c, or 26.805 Ah, of electrical charge.

Factors Influencing Battery Voltage and Capacity. In practice, only a small fraction of a battery's theoretical specific energy is realized. As a rule of thumb, a secondary (rechargeable) battery will not attain much more than 25% of the theoretical value; claims of specific energy values significantly greater than 25% of theoretical should be viewed with appropriate caution. Refer to Table 11-10

TABLE 11-10 Characteristics of Some Battery Systems

Battery type—common name	Chemical reactant		Theoretical battery		Practical battery	
	Negative electrode	Positive electrode	Voltage, V	Specific Energy, Wh/kg	Nominal voltage, V	Nominal specific energy,[a] Wh/kg
Primary						
Leclanche	Zn	MnO_2	1.5	260	1.2	80

for representative voltages and specific energies for practical batteries. There are many reasons for the reduction. The weights of nonreactive components (e.g., containers, separators, electrolyte) will degrade the specific energy and performance of any battery system. There may be other, less obvious, factors as well. Consider a "room temperature" system as an example. If, as is so often the case, its performance, because of self-discharge, is degraded significantly by a modest increase in temperature, and if the application is one involving high power, such as use in an electric vehicle, a major weight penalty must be added for the heat-exchange system required to keep temperature below a practical limit. There may well be other temperature-related considerations; an inability to produce required power when below room temperature may require heating prior to use with attendant delays and weight penalties. Other factors influencing the voltage and capacity of a battery are as follows:

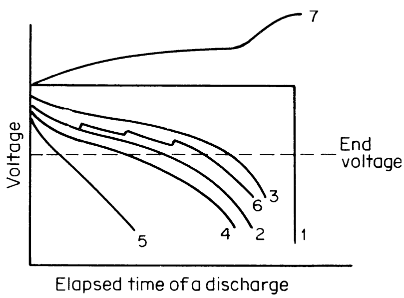

FIGURE 11-26 Battery-discharge characteristics.

Voltage Level. When a battery is discharged, its voltage is lower than the theoretical voltage. The difference is caused by *IR* losses due to cell resistance and by polarization of the active materials during discharge. This is illustrated in Fig. 11-26. The theoretical discharge curve of a battery is shown as curve 1. In this case, the discharge of the battery proceeds at the theoretical voltage until the active materials are consumed and the capacity fully utilized. The voltage then drops to zero. Under actual conditions, a typical discharge curve is similar to curve 2. The initial voltage is lower than theoretical, and it drops off as the discharge progresses.

The Current Drain of the Discharge. As the current drain of the battery is increased, the *IR* loss increases, the discharge is at a lower voltage, and the discharge duration is usually reduced (curve 5). At extremely low current drains, it is possible to approach the theoretical capacities (in the direction of curve 3). In a very long discharge period, the chemical degradation during the discharge becomes a factor and causes a reduction of capacity.

Voltage Regulation. The voltage regulation required by the equipment is most important. As is apparent by the curves in Fig. 11-26, design of equipment to operate to the lowest possible end voltage results in the highest capacity and longest service life. Similarly, the upper voltage limit of the equipment should be established to take full advantage of the battery characteristics. In some applications, where only a narrow voltage range can be tolerated, voltage regulators may have to be employed to take full advantage of the battery's capacity. If a secondary battery is used in conjunction with another energy source, which is permanently connected in the operating circuit, allowances must be made for the voltage required to charge the battery, as illustrated in curve 7, Fig. 11-26. The maximum voltage available from the charger must exceed the maximum battery charge voltage.

11.8.2 Primary Batteries

General. A number of different types of primary (nonrechargeable) batteries are used widely in civilian, industrial, and military applications. They are a convenient, usually relatively inexpensive, lightweight source of power for portable electric devices. The general advantages of primary batteries are reasonably good shelf life, high energy densities at low to moderate rates, little, if any, maintenance, and ease of use. Typical characteristics and applications of these batteries are shown in Tables 11-11 and 11-12.

Leclanche Cell ($Zn\text{-}MnO_2$). The Leclanche or carbon-zinc dry cell, known for over 100 years, is still the most widely used of all the dry-cell batteries because of its low cost, reliable performance, and ready availability. Cells and batteries of many sizes and characteristics have been manufactured to meet the requirements of a wide variety of applications. Characteristics of typical cells are given in Table 11-12.

Composition. The Leclanche cell uses a zinc anode, a manganese dioxide cathode, and an electrolyte of ammonium chloride and zinc chloride dissolved in water. Powdered carbon (acetylene

TABLE 11-11 Major Characteristics and Applications of Primary Batteries

System	Characteristics	Applications
Zinc-carbon (Leclanche) ($Zn\text{-}MnO_2$)	Popular common low-cost primary battery, available in variety of sizes	Flashlight, portable radios and electronics, toys, novelties, instruments, etc.
Magnesium ($Mg\text{-}MnO_2$)	High-capacity primary battery, long shelf life	Military receiver-transmitters, aircraft emergency transmitters
Mercury (Zn-HgO)	Highest capacity (by volume) of conventional types, flat discharge, good shelf life	Hearing aids, medical (heart pacers), photography, detectors, receiver-transmitters, military sensor and detection equipment
Alkaline (Zn-alkaline electrolyte-MnO_2)	Good low-temperature and high-rate performance, moderate cost	Cassettes and tape recorders, calculators, radio, and TV—popular for high-drain primary-battery application
Silver-zinc (Zn-AgO)	Highest capacity (by weight) of conventional types, flat discharge, good shelf life	Hearing aids, photography, electric watches, missiles and space application (larger sizes)
Lithium (lithium-SO_2)	New battery system—recent development; highest-performance primary battery, excellent low-temperature performance, long shelf life	Will have wide, general-purpose application when available; first uses will be military and special civilian applications needing high-capacity and low-temperature performance
Solid electrolyte	Extremely long shelf life, low-power battery	Medical electronics, memory circuits, fusing

black) is mixed with the depolarizer to improve conductivity and retain moisture. As the cell is discharged, the zinc is oxidized and the manganese dioxide reduced. The overall cell reaction is

$$Zn + MnO_2 \rightarrow ZnO + Mn_2O_3$$

Construction. The Leclanche cell is made in many shapes and designs, but in two basic constructions: cylindrical and flat. Similar chemical ingredients are used in both constructions. In the common cylindrical cell (Fig. 11-27) a zinc can serves as the cell container and anode. The manganese dioxide is mixed with acetylene black and solid ammonium chloride, wet with a zinc chloride–ammonium chloride electrolyte, and shaped in the form of a bobbin. A carbon rod is inserted into the bobbin. The rod serves as a current collector and is porous enough to permit the escape of gases, which accumulate in the cell, without allowing leakage of electrolyte. The separator is a cereal paste, also wet with electrolyte, which physically separates the two electrodes and provides the means for ion transfer through the electrode. In the newer "paper-lined" cell, an absorbent kraft paper is used as the separator. This provides thinner separator spacing and lower internal resistance.

Another cyclindrical cell is the "inside-out" construction shown in Fig. 11-28. In this cell, an injection-molded, impervious, inert carbon wall serves as the container of the cell and as the current collector. The zinc anode, formed in the shape of vanes to increase its surface area, is located inside the cell and surrounded by the cathode mix. This ensures efficient zinc consumption and, since zinc is not used as a container, a high degree of leakage resistance.

The flat-cell construction is illustrated in Fig. 11-29. In this cell, carbon is coated on a zinc plate to form a duplex electrode—a combination of the zinc of one cell and the carbon of the adjacent one. The flat cell has a higher energy-to-volume ratio, since the rectangular shape utilizes the available volume better than does the cylindrical cell.

Zinc Chloride Cell. A modification of the Leclanche cell is the zinc chloride electrolyte cell. The construction is similar to the conventional carbon-zinc cell, but the electrolyte contains only zinc

chloride, without the saturated solution of ammonium chloride. The zinc chloride cell is a high-performance cell with improved high-rate and low-temperature performance, and a reduced incidence of leakage. A comparison of the performance of the zinc chloride cell with the conventional cell is presented in Fig. 11-30.

Magnesium Dry Cells (Mg-MnO_2). A magnesium dry cell has two main advantages over the zinc-carbon cell: twice the capacity or service life of an equivalently sized zinc cell and the ability to retain this capacity during storage, even at elevated temperatures (Fig. 11-31). The construction of the magnesium dry cell is similar to the cylindrical carbon-zinc cell except that a magnesium alloy is used instead of zinc. The cathode consists of an extruded mix of manganese dioxide, acetylene black (to provide conductivity and moisture absorbency), magnesium perchlorate electrolyte, barium and lithium chromate as corrosion inhibitors, and magnesium hydroxide as a buffering agent to improve storage life. The degree of "wetness", or amount of water, is critical because water participates in the anode reaction and is consumed during discharge. A carbon rod serves as the cathode current collector. The separator is an absorbent kraft paper as in the paper-lined structure. Sealing of the magnesium cell is critical, since it must be tight to retain cell moisture during storage and also provides a means for the

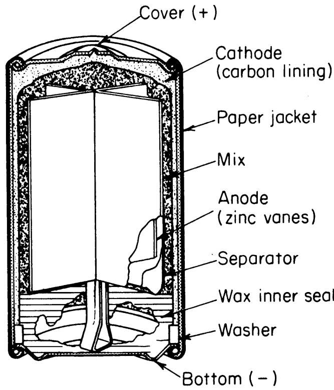

FIGURE 11-28 Cross section of a Leclanche "inside-out" cell.

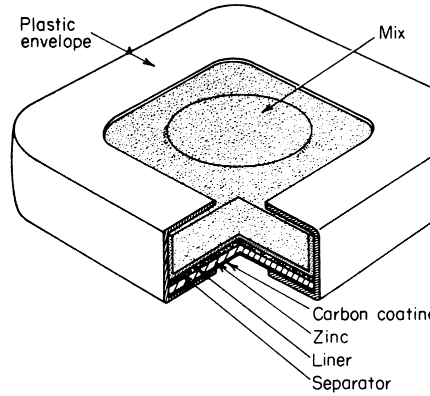

FIGURE 11-29 Leclanche flat cell.

escape of hydrogen gas which forms as the result of a parasitic reaction during the discharge of the battery. This is accomplished by a mechanical vent—a small hole in the plastic top seal washer under a retainer ring, which is deformed under pressure, releasing the excess gas. Magnesium batteries have not been fabricated successfully in flat-cell designs.

The overall reaction of the Mg-MnO_2 cell is

$$Mg + 2MnO_2 + H_2O \rightarrow Mn_2O_3 + Mg(OH)_2$$

At the same time, hydrogen is generated as the result of the parasitic magnesium corrosion reaction:

$$Mg + 2H_2O \rightarrow Mg(OH)_2 + H_2$$

The efficiency of the magnesium anode during a typical discharge is about 70%. Considerable heat is generated during the discharge of a magnesium battery owing to the exothermic side reaction and the *IR* loss resulting from the difference between the theoretical and operating voltages. This heat can be used to advantage at low ambient temperatures to maintain the battery at a warmer temperature.

The good shelf life of the magnesium cell results from a protective film that forms on the inside of the magnesium can, preventing corrosion. This film, however, is responsible for a voltage "delay"—a delay in the cell's ability to deliver full output voltage after it has been placed under load (Fig. 11-32).

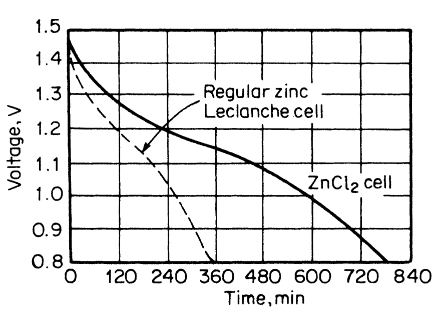

FIGURE 11-30 Comparative performance of zinc chloride and Leclanche cells.

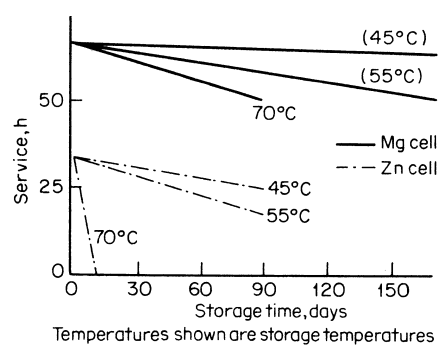

FIGURE 11-31 Comparison of service life vs. storage time of magnesium and Leclanche cells.

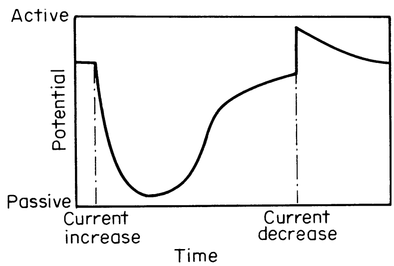

FIGURE 11-32 Voltage delay characteristics of magnesium cells.

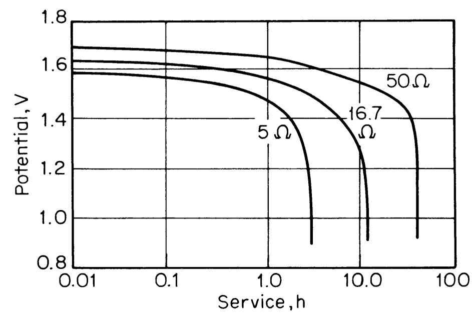

FIGURE 11-33 Discharge curves of magnesium cells (A size, 20°C).

This delay is usually less than 0.3 s, but is longer for discharges at low temperatures and high current drains and after prolonged storage at high temperatures.

Typical discharge curves are given in Fig. 11-33. The magnesium battery is less sensitive to discharge rate than the carbon-zinc cell. The performance of the magnesium cell for various discharge rates and temperatures is shown in Fig. 11-34.

While successful in military use, the magnesium battery has not found wide commercial use. This is due to the fact that the magnesium battery loses its excellent storageability after being partially discharged, and hence is unsatisfactory for long-term intermittent use. Other influencing factors are the higher unit cell voltage and the evolution of hydrogen and heat on discharge which present a potential safety hazard.

Zinc–Mercuric Oxide Cells (Zn-HgO). The zinc alkaline–mercuric oxide battery is noted for its high capacity per unit volume, a relatively constant output voltage during its discharge, and good storage characteristics.

Composition. The zinc–mercuric oxide cell uses amalgamated zinc as the anode, mercuric oxide (mixed with 5% to 10% graphite) as the cathode, and potassium hydroxide as the electrolyte. A saturated solution of zinc oxide is added to the electrolyte to retard the corrosion of zinc, minimize the production of hydrogen, and improve the stability of the cell.

The overall chemical reaction during discharge is

$$Zn + HgO \rightarrow ZnO + Hg$$

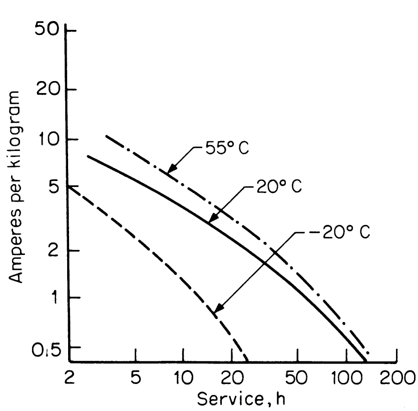

FIGURE 11-34 Service capacity of magnesium cell.

The amperehour capacities of the mercuric oxide cathode and the zinc anode are equalized or balanced, and on completion of the cell's discharge, no residual unoxidized zinc remains. Without this feature, the zinc would continue to react, generating hydrogen gas in the cell.

Construction. The zinc–mercuric oxide cell is manufactured in three basic structures: the wound-anode type, the flat-pressed powdered cathode and anode type, and the cylindrical pressed powdered electrode type.

The three types of structures are shown in Fig. 11-35. All constructions use a steel can, which does not take part in the electrochemical reaction and is not consumable, for the cell container. In the wound-anode type, the anode is composed of a corrugated zinc strip with an absorbent paper wound in an offset manner so

FIGURE 11-35 Zinc-mercuric oxide cell structures (*left*) and characteristics (*right*).

that it protrudes at one end and the zinc protrudes at the other end. The zinc is amalgamated with 10% mercury and the paper impregnated with the electrolyte, which causes it to swell and produce a positive contact pressure. The cathode is a pellet made of powdered mercuric oxide and graphite which is pressed into the steel can. An absorbent KOH-resistant separator is placed between the two electrodes. The cell has a crimped seal; the can is separated from the top by an insulating neoprene or plastic grommet.

In the pressed-powder cells, the zinc powder is amalgamated and pressed into a pellet with sufficient porosity to allow electrolyte impregnation. A double-can structure is used in the larger-sized cells as a safeguard. Under excessive gas pressures, the compression of the upper part of the grommet by internal pressure allows the gas to escape into the space between the two cases. A paper tube surrounds the inner can so that any liquid carried by the discharging gas will be absorbed, maintaining a leak-resistant structure. Release of the excess gas pressure reseals the cell.

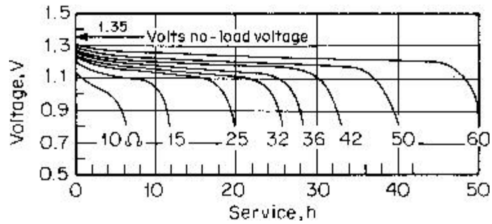

FIGURE 11-36 Discharge curves of zinc–mercuric oxide cells.

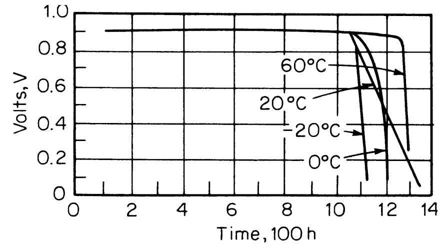

FIGURE 11-37 Discharge curves of cadmium-mercuric oxide cells.

The cylindrical and button cells are variations of the pellet design. The button cell uses a gelled electrolyte to reduce electrolyte leakage further. The mechanical and electrical specifications of representative cells of each of the three constructions are given in Fig. 11-35.

Voltage. The open-circuit voltage of the mercury cell is 1.35 V and is reproducible within 0.001 V. On discharge, the cell is characterized by a very flat discharge as shown in Fig. 11-36. The cutoff voltage usually is 0.9 to 1.0 V per cell.

Cadmium–Mercuric Oxide Cell (Cd-HgO). The substitution of cadmium for zinc results in a very stable system with a predicted shelf life of up to 10 years, as well as performance at low temperatures (Fig. 11-37). The watthour capacity of this cell, because of its lower voltage, is about 60% of zinc–mercuric oxide cell capacity. In design, the cadmium–mercuric oxide cell is similar to the zinc–mercuric oxide cell. These mercuric-oxide systems (Zn and Cd) are being evaluated because of environmental concerns.

Zinc–Silver Oxide Cell (Zn-AgO). The primary zinc alkaline–silver oxide cell is similar in design to the small zinc–mercuric oxide button cell but uses silver oxide in place of mercuric oxide. Cells range in capacity up to 200 mAh for use at 50-h and lighter loads. The silver oxide cell has an open-circuit voltage of 1.6 V and operates about 0.2 V higher than the mercuric oxide cell. Typical discharge curves for this cell are given in Fig. 11-38. The silver oxide cell has a higher energy density (on a weight basis) and is less sensitive to a reduction in ambient temperature than the mercuric oxide cell. At the design loads, the cell will deliver about 70% of its 20°C performance at 0°C and 35% at –20°C. These characteristics make this battery desirable for use in hearing aids, photographic applications, and electronic watches.

Alkaline–MnO_2 Cell (Zn-MnO_2). The zinc alkaline–MnO_2 cell uses the same electrochemically active materials, zinc and manganese dioxide, as the Leclanche cell, but differs in construction and in the use of highly conductive potassium hydroxide electrolyte which results in a lower internal resistance. The advantage on low-rate or intermittent discharge is marginal, but on high- and continuous-drain conditions, the alkaline cell can deliver from 2 to 10 times the amperehour capacity of the Leclanche cell. Its performance at low temperatures is superior to other commercially available dry batteries.

$$Zn + 2MnO_2 \rightarrow Mn_2O_3 + ZnO$$

The electrolyte undergoes no change during the discharge, maintaining its high conductivity throughout the cell's life. It thus differs from the Leclanche cell, whose resistance increases during the discharge.

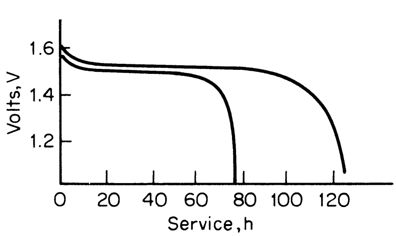

FIGURE 11-38 Discharge curves of zinc–silver oxide cells.

Construction. The principal features of the Zn-MnO_2 cell are the manganese dioxide cathode of high density, a zinc anode of high surface area, and the highly conductive potassium hydroxide electrolyte. As illustrated in Fig. 11-39, the MnO_2, mixed with graphite or carbon black, is pressed against the inner surface of the can, which serves as the cathode current collector. The anode is centrally located and consists of a mixture of granular or powdered zinc, which is amalgamated to reduce hydrogen evolution, and the electrolyte. In some designs, a gelling agent is used to immobilize the electrolyte and minimize leakage. A highly absorbent, chemically inert material separates the electrodes.

Voltage. The open-circuit voltage of the alkaline-MnO_2 cell is 1.5 V. Its discharge is similar to the Leclanche cell, but it is superior at the heavier discharge loads. Typical discharge curves are given in Fig. 11-40.

Service Life. At light loads, the service life of the alkaline cell is about the same as the Leclanche. However, its service capacity remains relatively constant with increasing load and is much superior to the Leclanche at higher current drains. The performance of the alkaline cell for various discharge rates and temperatures is shown in Fig. 11-41.

Effect of Temperature. The alkaline-MnO_2 cell performs well at low temperatures, excelling over the best Leclanche cells. The cell operates to temperatures as low as –40°C.

Shelf Life. The shelf life of the alkaline-MnO_2 cell is moderately superior to the Leclanche cell. Capacity retention is about 90% after 1 year of storage at 20°C.

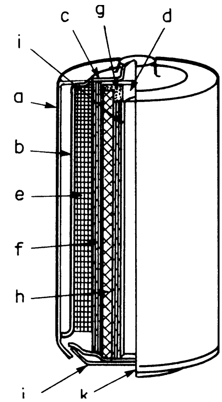

FIGURE 11-39 Construction of alkaline-MnO_2 cells: (*a*) outer nickel-plated can; (*b*) tube adapter; (*c*) inner gold-plated can; (*d*) insulator disk; (*e*) depolarizer; (*f*) outer absorbent with barrier; (*g*) insulating ring; (*h*) anodes; (*i*) inner absorbent; (*j*) molded double top; (*k*) clear plastic dielectric jacket. Electrolyte not shown. (*Duracell.*)

Lithium Primary Batteries. The lithium battery has a number of advantages over other primary-battery systems. Lithium is an attractive anode because of its reactivity, light weight, and high voltage; cell voltages range between 2 and 3.6 V, depending on the cathode material.

The advantages of the lithium battery include high specific energy and energy density, on the order of 250 Wh/kg and 400 Wh/dm^3, respectively; high power density; flat discharge characteristics; excellent service over a wide temperature range, down to –40°C or below; and good shelf life (up to 5 years without refrigeration is anticipated).

Nonaqueous solvents must be used as the electrolyte because of the reactivity of lithium with aqueous solutions. Organic solvents, such as acetonitrile and propylene carbonate, and inorganic solvents, such as thionyl chloride, are typical. A compatible solute is added to provide the necessary

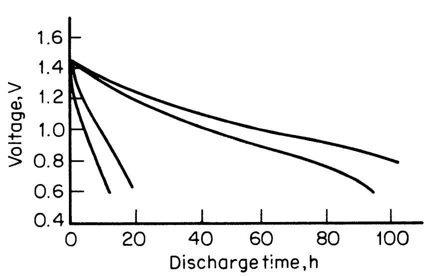

FIGURE 11-40 Discharge curves of an alkaline-MnO_2 cell at 20° C.

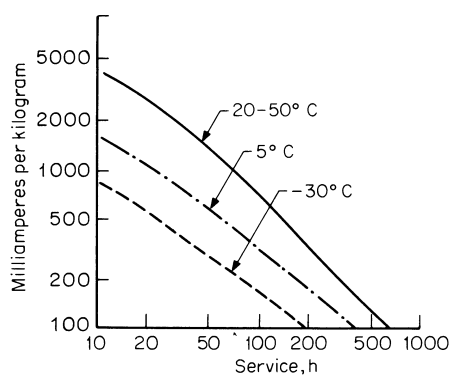

FIGURE 11-41 Service capacity of an alkaline-MnO_2 cell.

electrolyte conductivity. A number of different materials—sulfur dioxide, carbon monofluoride, vanadium pentoxide, and copper sulfide—are used as the active cathodes.

Lithium–Sulfur Dioxide Cell. One advanced lithium primary cell uses sulfur dioxide for the cathode material and an electrolyte consisting of acetonitrile and lithium bromide. The cell reaction is

$$2Li + 2SO_2 \rightarrow Li_2S_2O_4 \text{ (lithium dithionite)}$$

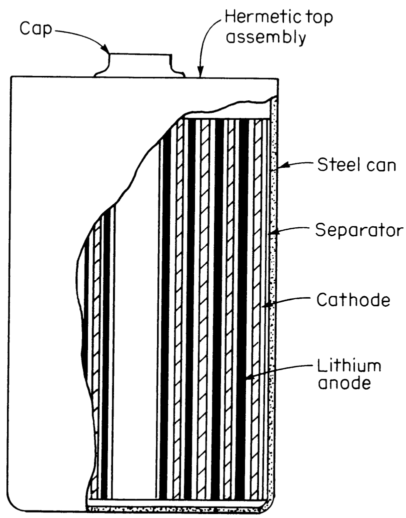

FIGURE 11-42 Cross section of a cylindrically wound Li-SO_2 cell.

The cell is typically fabricated in a cylindrical structure as shown in Fig. 11-42. A "jellyroll" construction is used, made by spirally winding strips of lithium ribbon, a polypropylene separator, and the cathode electrode (a Teflon-carbon mix pressed on an aluminum screen). This design provides the high surface area and low cell resistance necessary to obtain high-current and low-temperature performance. The roll is inserted in a steel container which is electrically connected to the anode. The cathode, in turn, is connected to its terminal and the cell hermetically sealed. The electrolyte-depolarizer mixture (70% SO_2) is added through a temporary opening in the cell to an SO_2 pressure of about 4 atm. The critical manufacturing operations are carried out in dry rooms or dry boxes to minimize the moisture content of the cell.

The good shelf life of the lithium-SO_2 cell is attributed to the protective film formed by the initial reaction of lithium and SO_2, which prevents further reaction or loss of capacity during stand. During discharge, the SO_2 is depleted and the cell pressure reduced. The discharge is generally terminated by the deactivation of the carbon electrode by blocking the active area from precipitation of the discharge product.

The performance characteristics of the Li-SO_2 cell are given in Figs. 11-43 through 11-46. Figure 11-43 shows typical discharge curves for the cell at various discharge loads. The high cell voltages and flat discharge curves shown are characteristic of this cell.

Figure 11-44 presents the performance of the Li-SO_2 cell at various temperatures and discharge rates. The superior low-temperature performance (over 60% of the normal-temperature performance available at –30°C) is noteworthy. Figure 11-45 illustrates the shelf life of the lithium cell. Although

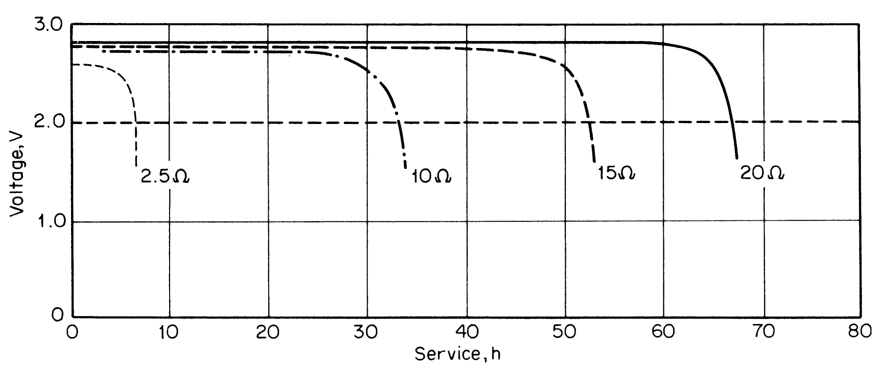

FIGURE 11-43 Typical discharge curves of Li-SO_2 cell at 20°C at various loads.

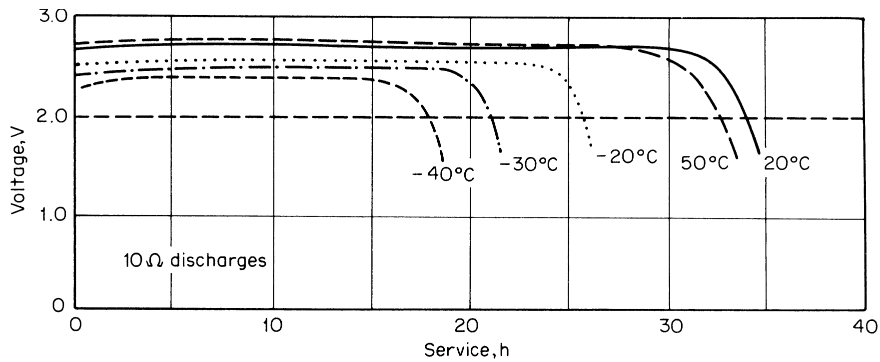

FIGURE 11-44 Effect of temperature on performance of Li-SO_2 cells (D size).

very long-term storage has not been demonstrated experimentally, the data suggest a long-shelf-life capability even at high temperatures, particularly with newer cell designs.

Special attention must be given to the design and use of the lithium battery, since it contains materials that are potentially flammable and toxic. Properly designed cells are equipped with safety vents which release SO_2 when the cells reach high temperatures and pressures, thus preventing explosive damage.

The lithium battery can deliver unusually high current. Since high internal temperatures can develop from continuous high current drain, short circuiting, or inadvertent internal cell shorts, such use must be avoided. It is advisable to equip batteries with fuses to protect against short circuiting.

Charging lithium-SO_2 cells may result in explosion of cells (even those which are equipped with safety vents) and should not be attempted. Similarly, cells or groups of cells should not be connected in parallel without diode protection to prevent one group of

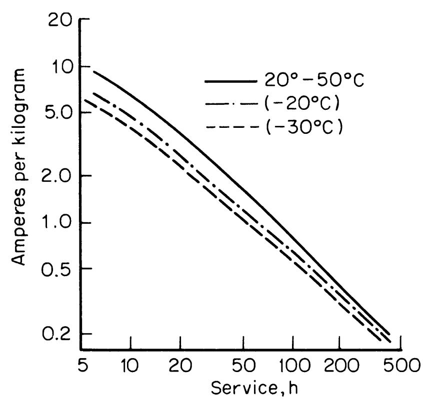

FIGURE 11-45 Service capacity of Li-SO_2 cells at various temperatures.

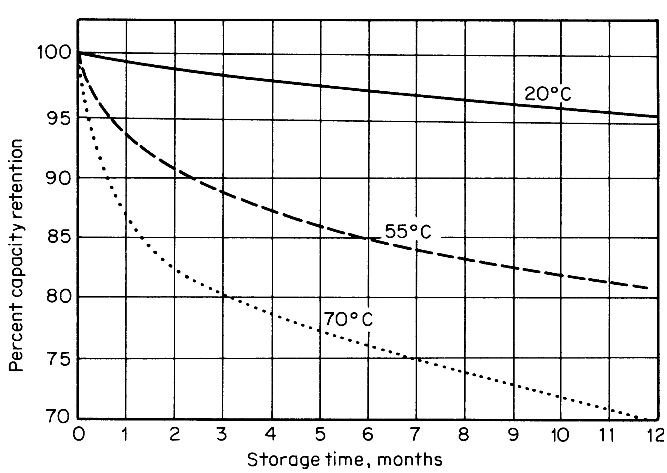

FIGURE 11-46 Shelf life of Li-SO_2 cell at different storage temperatures.

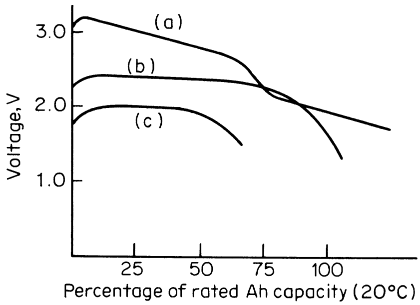

FIGURE 11-47 Typical discharge curves of lithium–solid cathode cells: (*a*) vanadium pentoxide, 8-h rate, 20° C; (*b*) carbon monofluoride, 20-h rate, 20°C; (*c*) carbon monofluoride, 20-h rate –20°C.

cells from charging the other. Forced discharging, which could occur with cells that are connected in series or to an external power supply, also may result in venting and/or explosion. Currently, special procedures govern the transportion, shipment, and disposal of lithium batteries. While it requires special handling and design, the many advantages of the lithium cell result in increasing use of this battery in military and civilian areas.

Other Lithium–Organic Electrolyte Cells. A number of other cathode materials, mostly solid, have been developed for lithium primary cells. Cells using these solid cathodes have the advantage of being nonpressurized but do not have the high current capability of the SO_2 system. Some cells are specifically designed for low-rate applications, using "bobbin"-type constructions. These cells deliver higher energy outputs and should provide safe operation, since they are self-limiting in energy and current output. Typical discharge curves for the carbon monofluoride and vanadium pentoxide cells are shown in Fig. 11-47.

Inorganic Electrolyte Cells. Certain nonaqueous inorganic liquids, such as thionyl chloride ($SOCl_2$) and sulfuryl chloride (SO_2Cl_2), also are capable of forming a passivating film on the lithium anode, similar to that in SO_2, and can be used both as the electrolyte solvent and as the active cathode material. A commonly used solute is $LiAlCl_4$. Cells made with these components are similar in construction to the Li-SO_2 cell but are not pressurized at room temperature because of the lower vapor pressure of the thionyl chloride. The Li-$SOCl_2$ cells also operate at approximately 0.5 V higher than the comparable Li-SO_2 cell. Figure 11-48 compares the discharge curves of the two batteries and illustrates the higher voltage and energy output of the thionyl chloride cell. The cells exhibit good shelf life, but the passivating protective film that forms, particularly at high-temperature storage, is not readily penetrated, and excessively long voltage delays occur, especially at high-rate and low-temperature discharges. Lithium–thionyl chloride cells are available in a range of capacities from 1.4 to 8,000 Ah. Corresponding specific energy ranges from 240 to 450 Wh/kg at

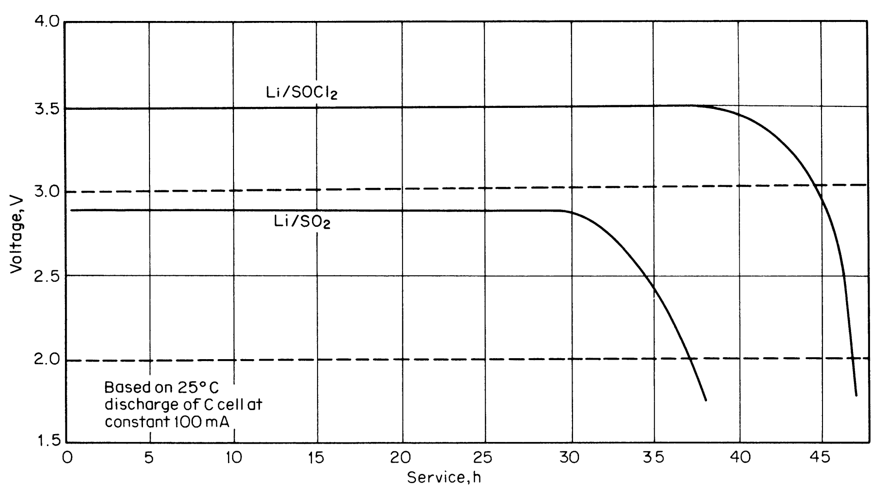

FIGURE 11-48 Discharge curves of Li-$SOCl_2$ and Li-SO_2 cells.

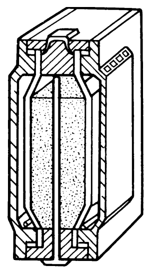

FIGURE 11-49 Construction of primary zinc-air cell. (*Duracell.*)

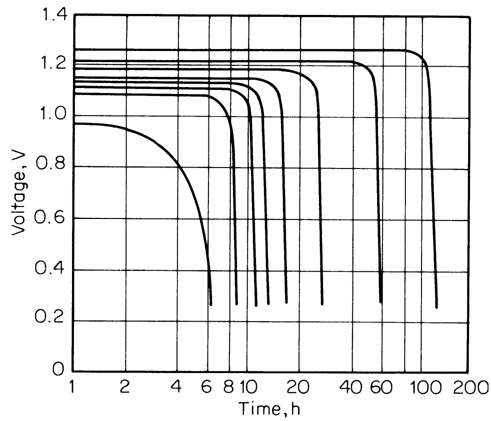

FIGURE 11-50 Typical discharge curves of zinc-air primary cells. (*Duracell.*)

rates of about 10 days. The cells display safety characteristics that reflect engineering to accommodate the high-energy nature of the reactants. A representative cell reaction is

$$2Li + SOCl_2 \rightarrow 2LiCl + {}^1/_2S + {}^1/_2SO_2$$

Zinc-Air Cells. Primary batteries using air as the depolarizer can deliver high energy densities, since they do not contain active cathode material. Zinc-air batteries, using bulky zinc anodes, a carbon-air cathode, and potassium hydroxide electrolyte, constructed in heavy-glass or hard-rubber containers, had been used successfully for many years in railway signals and similar applications. They were noted for their high energy densities but low power output capability. Lower-capacity zinc-air batteries, up to the 20-Ah size, are now being developed, using thin Teflon-coated fuel cell-type electrodes. These new structures have high specific energy, on the order of 220 Wh/kg, and are capable of moderately high current drains.

Construction. A typical construction of the primary zinc-air cell is shown in Fig. 11-49. It consists of a high-surface-area, gelled zinc anode, fabricated by pressing zinc granules with a gelled potassium hydroxide electrolyte, and a teflonated air cathode made of a low-cost, non-noble-metal catalyst. Cylindrical-shaped and button cells also have been designed. Effective sealing is essential in this construction to prevent electrolyte leakage. The cells are stacked to form a battery; space must be left between each cell for air circulation.

Performance Characteristics. The zinc-air battery is best suited for continuous, moderate-drain discharges at temperatures between –20 and +35°C. Intermittent operation usually results in a loss of capacity due to the drying out of the cell. Since the cell depends on oxygen from the air for its operation, differences in performance occur with variation in air circulation. Figure 11-50 shows typical curves for continuous discharge at 20°C. The flat discharge is characteristic of this cell. Figure 11-51 shows the energy output of the zinc-air battery at various temperatures. In addition to the reduction of service life, the average voltage decreases with decreasing discharge temperature.

Primary zinc-air cells must be stored in sealed bags after manufacture to maximize storage life. Limits of storage as well as the integrity and leak resistance of the cell seal

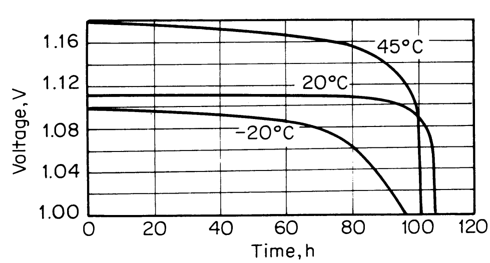

FIGURE 11-51 Voltage vs. time curve of zinc-air cell at various temperatures. (*Duracell.*)

TABLE 11-13 Characteristics of Solid Electrolyte Cells

System	Cell voltage, V	At 100-h rate Wh/dm^3	At 100-h rate Wh/kg
$Ag/RbAg_4I_5/I_2$	0.66	40–80	15–25
$Li/LiI(Al_2O_3)/PbI_2$, Pb	1.9	100–200	35–70
$Li/LiI(Al_2O_3)/PbI_2$,PbS,Pb	1.9	300–500	75–150
$Li/LiI/I_2$ (poly-2-vinylpyridine)	2.8	250–500	120–180

have yet to be determined. Once the packaging has been removed, the battery should be put into service shortly thereafter, since moisture loss results in dry-out and reduced capacity.

Solid Electrolyte Batteries. Most batteries depend on the ionic conductivity of liquid electrolytes for their operation. The solid electrolyte batteries depend on the ionic conductivity of an electronically nonconductive salt in the solid state as, for example, Ag^+ ion mobility in silver iodide. Cells using these solid electrolytes are low-power (microwatt) devices but have an extremely long shelf life and the capability of operating over a wide temperature range. The absence of liquid eliminates corrosion and gassing and permits the use of a hermetically sealed cell. The solid electrolyte batteries are used in medical electronics (in devices such as heart pacemakers), for memory circuits, and for fusing and other such applications requiring a long-life, low-power battery.

Several types of solid electrolyte batteries are being marketed using different solid electrolytes and active materials. The characteristics of several of the available types are summarized in Table 11-13. Of special significance are the high energy densities (5 to 10 Wh/in^3) achieved with the Li-anode solid electrolyte battery. Typical construction of solid electrolyte cells is shown in Fig. 11-52. The design features a sealed structure to exclude moisture and maintain a high-density, void-free package.

The discharge curves for various solid electrolyte cells at 25°C are given in Fig. 11-53. Since the batteries are designed primarily for low current drain, continuous discharge at high rates is not practical. The energy density and power density also are dependent on the operating temperature. A significant characteristic of the solid electrolyte battery is its long shelf life. Projections based on limited tests (1 to 2 years) predict a shelf life exceeding 15 years at 20°C. Figure 11-54 shows the projected capacity retention at various storage temperatures.

Other Primary Batteries. Many other electrochemical systems have been used as primary batteries to obtain special performance characteristics. The more prominent ones are listed in Table 11-14.

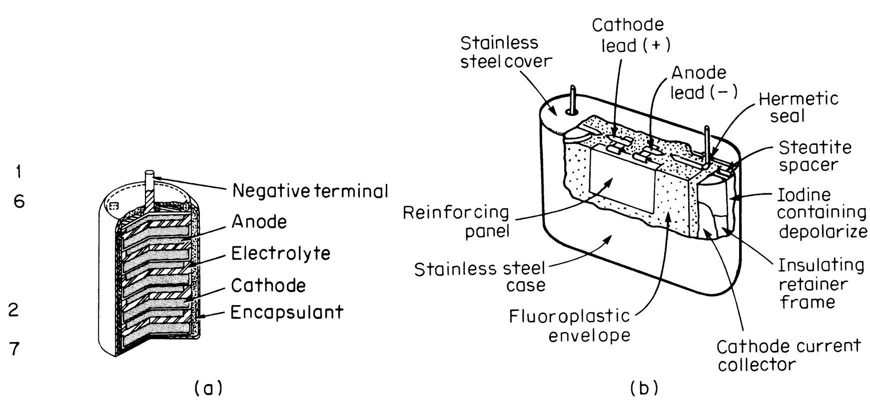

FIGURE 11-52 Construction of solid electrolyte cells: (*a*) silver iodide cell; (*b*) lithium iodide cell.

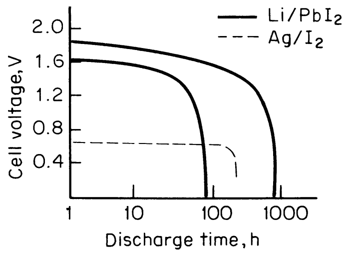

FIGURE 11-53 Typical discharge curves of solid dielectric electrolyte cells.

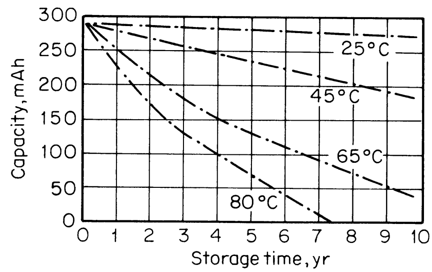

FIGURE 11-54 Capacity retention vs. temperature of solid electrolyte cells. (*Sigma Technologies International, Inc.*)

Recharging Primary Batteries. Recharging primary batteries is a practice that should generally be avoided since the cells are not designed for such use. In most instances it is impractical, and it could be hazardous in cells that are tightly sealed and not vented to permit the release of gases that form during charge and discharge. Most primary cells and batteries are labeled with a cautionary notice advising that they should not be recharged.

TABLE 11-14 Major Characteristics and Applications of Secondary Batteries

System	Characteristics	Applications
Lead-acid		
Automotive	Popular, low-cost secondary battery—moderate capacity, high-rate and low-temperature performance	Automobile starting, lighting, ignition (SLI); lawnmowers, tractors, marine, float service
Motive power	Designed for deep 6- to 9-h discharge, cycling service	Industrial trucks, materials handling; special types used for submarine power
Stationary	Designed for standby float service, long stand life	Emergency power—uninterruptible power supplies
Valve-regulated	Low maintenance, moderate cost, good float capability moderate cycle life	Many of the above applications, plu, TV, portable tools, lights and appliances, radios and cassettes and tape players
Nickel-cadmium		
Vented	Good high-rate, low-temperature capability; flat voltage, excellent cycle life	Aircraft batteries, industrial and emergency-power applications, communication equipment
Valve-regulated	Good high-rate, low-temperature performance, excellent cycle life, low maintenance	Photography, portable tools, appliances, standby power
Lithium-ion	Good gravimetric and volumetric energy and power, high cell voltage	Consumer electronics
Nickel-metal hydride	Replacement for nickel-cadmium, slightly higher cost, less robust low-temperature peformance	Same as nickel-cadmium
Zinc–silver oxide	High energy density, good high-rate capability, low cycle life	Lightweight portable radio, TV, and communication equipment; torpedo propulsion, drones, submarines, and other military applications

Some Leclanche zinc-carbon cells can be recharged for several cycles under carefully controlled conditions. For successful recharging, the cell should be placed on charge soon after removal from discharge and at a low rate (about 16 h charge time). The cell voltage on discharge should not be less than 1.0 V when it is removed for charging. The cells must be returned to service soon after recharging, since the shelf life after recharge is poor. Note the recent introduction of Rayovac Renewal "reusable alkaline batteries."

11.8.3 Secondary Batteries

General. Secondary (rechargeable) batteries are widely used in many applications. Most are characterized, in addition to their ability to be recharged, by high power densities, by their capability to be discharged at high rates, by flat discharge curves, and by good low-temperature performance. Their energy densities are usually lower than those of primary batteries. The characteristics of some secondary batteries are listed in Table 11-14.

The applications of secondary batteries fall into two major categories:

1. Those applications where the secondary battery is used essentially as a primary battery, but recharged after use. Secondary batteries are used in this manner for convenience (as in handheld calculators or electronic flash units), for cost savings (as they can be recharged rather than replaced), or for power drains beyond the level of primary batteries.
2. Those applications where the secondary battery is used as an energy-storage device, being charged by a prime energy source and delivering its energy to the load on demand. Examples are automotive and aircraft systems, and emergency and standby power sources.

A summary of some of the major applications of the various types of secondary batteries is given in Table 11-14.

Lead–Acid Battery (Pb-PbO$_2$). The lead-acid battery is the most widely used secondary battery. Its low cost, reliability, and generally favorable performance characteristics account for its acceptance in many different applications. This type of battery is manufactured in many sizes, ranging in capacity from less than 1 Ah (small plastic-encased or sealed portable cells) to several thousand amperehours for stationary and vehicle-propulsion types. Characteristics of typical cells are summarized in Table 11-14.

Composition. The lead-acid battery uses highly reactive sponge lead for the negative electrode, lead dioxide as the active positive material, and a sulfuric acid solution for the electrolyte. As the cell discharges, the active materials of both electrodes are converted into lead sulfate. The sulfuric acid electrolyte also takes part in the reaction producing water. On charge, the reverse reactions take place. The state of charge of the battery can be determined in some cases by measuring the specific gravity of the electrolyte, which decreases on discharge and increases on charge. The discharge and charge reactions of the battery are

$$Pb + PbO_2 + 2H_2SO_4 \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} 2PbSO_4 + 2H_2O$$

At the end of charge, electrolysis of water may occur, producing hydrogen at the negative and oxygen at the positive electrode.

Construction. The most common construction for the lead-acid cell is the pasted-plate design. A cross section of an automotive-type battery using this construction is shown in Fig. 11-55. The active material for each electrode is prepared as a paste by mixing finely divided lead oxides and suitable expander materials with sulfuric acid. The paste is spread onto a lead-alloy grid which provides the necessary electrical conductivity and structure to hold the active materials. The resulting plates are soldered or welded to connecting straps to form positive and negative plate groups which are interleaved. Separators are placed between the electrodes, and the completed element is

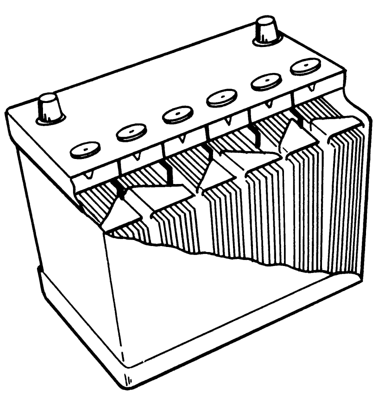

FIGURE 11-55 Cross section of lead-zinc automotive battery. (*GNB, Inc.*)

placed in a container. The container is designed with a sediment space under the element to safely collect any of the active material that is dislodged. Sufficient headroom is provided above the plates to hold excess electrolyte and allow electrode growth. Conventional lead-acid batteries often employ alloy-strengthened grids; calcium and antimony are the common alloying metals. The alloying is necessary to provide adequate strength for the thin grid structure to facilitate casting.

The low maintenance value regulated lead-acid batteries, which became popular in the mid-1970s, use calcium-lead grids, which are more resistant to corrosion and self-discharge. Water loss from gassing during charge is minimized in this design. The battery is filled with an excess of electrolyte and closed to prevent contamination. Other design features are improved separator materials which reduce the possibility of internal shorting, enclosed internal connectors, and lightweight, high-impact-strength polypropylene cases.

Other lead-acid batteries are similar in design to the automotive battery but vary in lead-alloy composition, plate thickness, separators, container, etc., to optimize the performance characteristics for the particular application.

General Performance Characteristics. The general performance characteristics of the lead-acid battery are given in Fig. 11-56.

Voltage. The nominal voltage of the lead-acid cell is 2 V; the voltage on open circuit is a direct function of the specific gravity, ranging from 2.12 V for a cell with 1.28 specific gravity to 2.05 V at 1.21. Figure 11-57 presents typical discharge curves for the lead-acid cell. The end of discharge cutoff voltage is usually about 1.75 V per cell but can be as low as 1.0 V per cell at extremely high rates, as in automotive starting service.

Specific Gravity. The selection of the specific gravity of the electrolyte at the start of discharge depends on the service requirements. The electrolyte concentration must be high enough for good electrical conductivity and to fulfill electrochemical requirements, but not so high as to cause separator deterioration or corrosion of other parts of the cell, which would shorten life and increase self-discharge. A specific gravity of 1.26 to 1.28 is usually used in automotive and high-performance batteries, and one as low as 1.21 for stationary standby batteries. The specific gravity should be reduced in high-temperature climates.

During discharge (Fig. 11-57), the specific gravity decreases about 0.125 to 0.150 points from a fully charged to a fully discharged condition. The change is proportional to the amperehours discharged. The specific gravity is thus an excellent means for checking the state of charge in a flooded battery. One must wait 5 or 10 min after discharging prior to measurement of specific gravity to allow the acid concentration to equilibrate. On charge, the change in specific gravity should similarly be proportional to the amperehour charge accepted by the cell, but there is a lag because complete mixing of the electrolyte does not occur until gassing commences near the end of the charge.

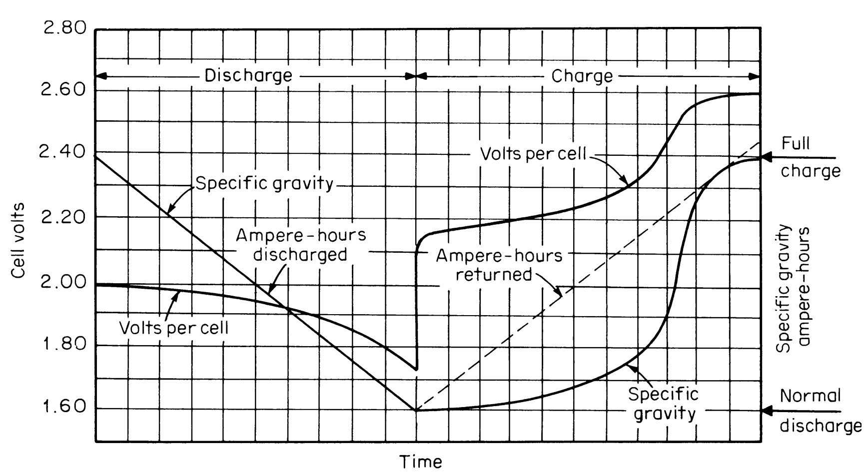

FIGURE 11-56 Performance characteristics of lead-acid cells. (*GNB, Inc.*)

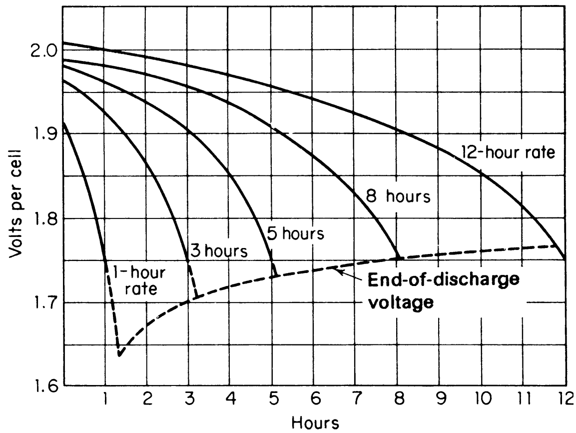

FIGURE 11-57 Discharge curves of lead-acid cells at different hour rates.

Service Life. The service life of a typical automotive-type lead-acid cell is shown in Fig. 11-58 for different discharge rates and temperatures. These curves have been normalized to the 20-h rate at 25°C. A 100-Ah cell, for example, will deliver 20 h of service when discharged at 5 A at 25°C or 1 h of service when discharged at –40°C at 20 A. Typically, higher service capacity is obtained at lower discharge rates and higher temperatures. In general, a battery may be discharged without harm at any rate of current it will deliver, but the discharge should not be continued beyond the point where the cell approaches exhaustion or where the voltage falls below a useful value.

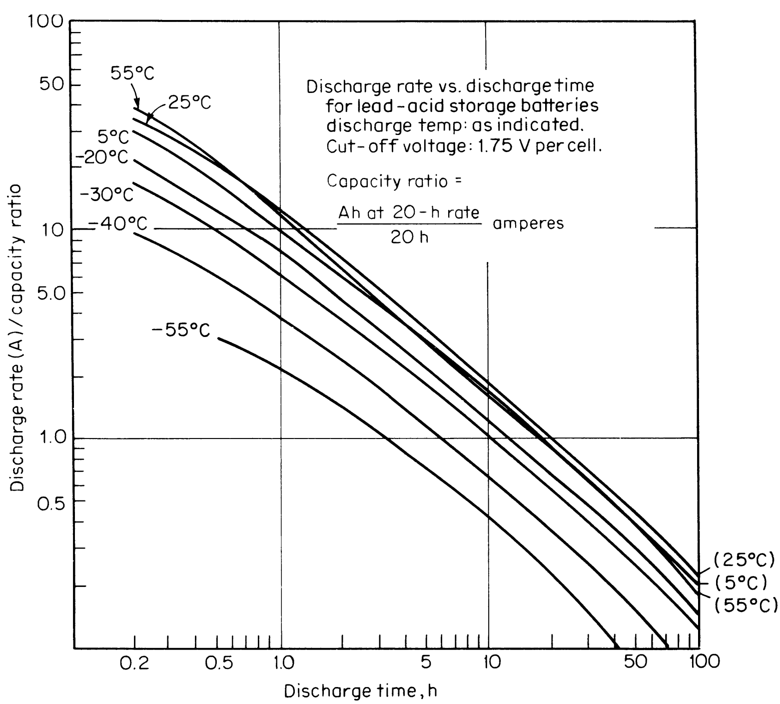

FIGURE 11-58 Service-capacity curves of lead-acid batteries.

Automotive cells are typically made with thinner plates, have a larger surface area, and use a higher concentration of electrolyte than motive-power and stationary batteries, so higher currents can be drawn at higher voltage levels. Hence, the electrical output of stationary batteries, which are designed for long-life service, will be somewhat lower to that indicated in Fig. 11-58.

Temperature. The variation of the performance of the lead-acid cell at different temperatures and loads is given in another form in Fig. 11-59. Although the battery will operate over a wide temperature range, continuous operation at high temperatures may reduce cycle life as a result of the increase in the rate of corrosion.

Self-Discharge. The self-discharge rate (loss of battery capacity during storage) depends on a number of factors, including the type of lead alloy used, the concentration of electrolyte, the age of the battery, and temperature. Self-discharge is caused by local chemical reactions between components of the plate and occurs almost entirely in the negative electrode. The rate of self-discharge is about 15% per month for antimonial-lead batteries at 25°C. Batteries using purer lead grids have substantially lower rates of self-discharge. Capacity lost by self-discharge can be recovered by recharging the battery. For best practice, a battery on stand should be recharged every 3 to 6 months, since prolonged storage and self-discharge can cause irreversible damage and make recharge difficult, owing to sulfation of the plates.

Lead-Calcium Cells. The lead-calcium cell uses a small percentage of calcium to give the lead grid the necessary physical rigidity in place of a larger amount of antimony normally used. Thus, it is closer to a pure-lead grid and has considerably reduced self-discharge due to local chemical action. The calcium alloy cells are best suited for standby float or open-circuit service rather than a cycling type of use. Frequent recharging in cycle use causes the grid in the positive plate to enlarge owing to corrosion of the lead grid and shortens life expectancy. Because of the improved performance, in terms of self-discharge and life, the use of calcium has largely replaced the use of antimony in the storage-battery market.

Nickel-Cadmium Batteries. The major alkaline secondary battery is the nickel-cadmium battery, which is noted for high power capability, long cycle life, good low-temperature performance, ruggedness, and reliability. This battery system is manufactured in many sizes, ranging from the small sealed button and

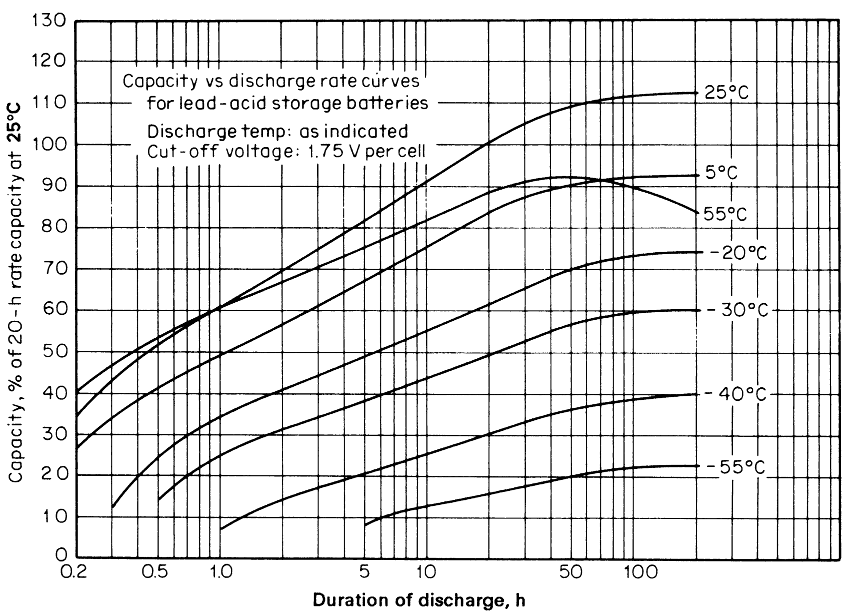

FIGURE 11-59 Performance of lead-acid batteries at various temperatures.

cylindrical cells with capacities as low as 0.020 Ah to larger vented cells for stand by and emergency service with capacities over 1,000 Ah. The nominal voltage of the nickel-cadmium cells is 1.2 V; the open-circuit voltage is 1.4 V. Table 11-14 lists the characteristics of different types of nickel cadmium cells.

Nickel-Metal Hydride. The nickel-metal hydride battery technology has become widely used in the last 10 years for consumer electronics as well as in propulsion and industrial applications. This technology is replacing nickel-cadmium batteries in many applications due to the environmental concerns related to cadmium. Nickel-metal hydride cells use the same nickel electrode as does the nickel-cadmium battery, but the negative electrode consists of hydrogen (generated during charge) absorbed in a metal alloy. This electrochemical couple is well-known in a related technology, nickel-hydrogen batteries, which are used in high value satellite applications. The cost of the metal hydride battery is more than for nickel-cadmium, but still competitive for consumer and industrial products. It also exhibits more capacity per unit mass than does nickel-cadmium, but generally has lower discharge rate capability.

Construction of a typical cylindrical nickel-metal hydride cell for consumer products is shown in Fig. 11-60. The cell contains a safety vent, but is normally sealed to retain the hydrogen that is generated during charge. Cells are also available in button and prismatic configurations. Large, industrial scale cells are also available, and an example is shown in Fig. 11-61.

Typical voltage performance curves for a cylindrical cell are shown in Fig. 11-62. The technology has discharge limitations below about –20°C, but performs reasonably above that temperature. It does exhibit the

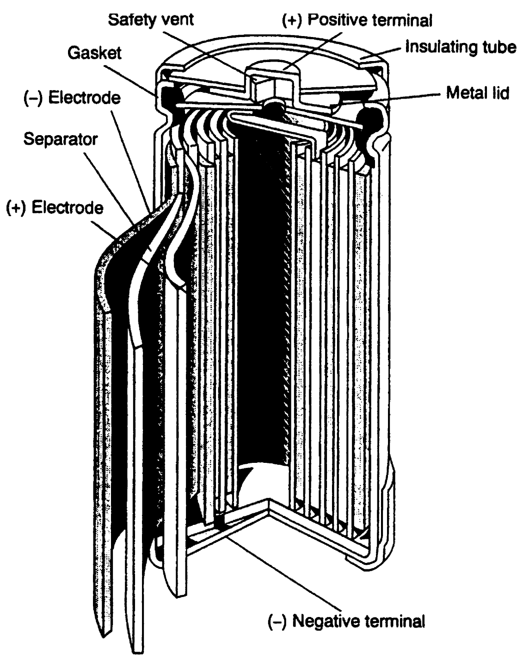

FIGURE 11-60 Construction of a sealed cylindrical nickel-metal hydride battery. (*Courtesy of Duracell Inc.*)

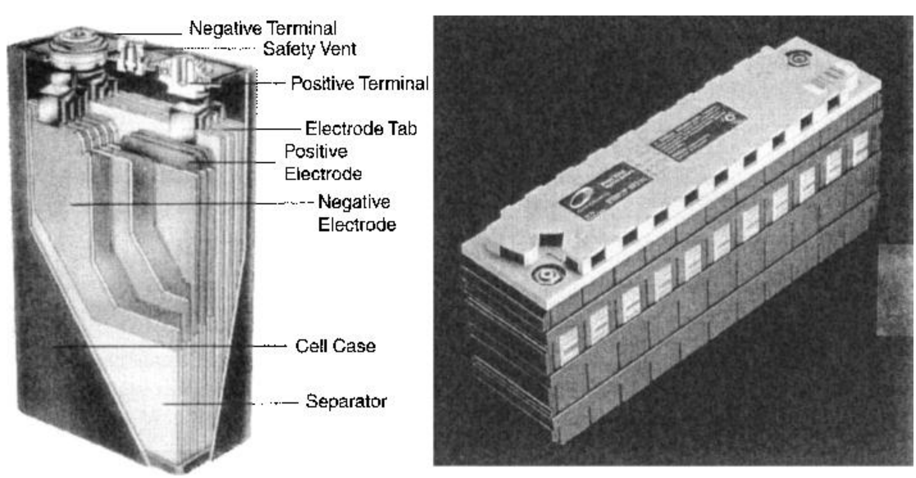

FIGURE 11-61 GM Ovonic 90-Ah prismatic cell and 13-V module.

FIGURE 11-62 (*a*) Discharge capacity vs. ambient temperature for sealed cylindrical nickel-metal hydride batteries at various discharge rates; end voltage 1.0 V/cell. (*b*) Discharge capacity (% of 0.2*C* rate) vs. discharge rate (*C*-rate) for sealed cylindrical nickel-metal hydride batteries at various temperatures: end voltage 1.0 V/cell.

memory effect, similar to nickel-cadmium cells, and this must be accommodated during use of the battery. However, there are several active research and development programs on the nickel-metal hydride technology, and improvements in performance and packaging are ongoing.

Rechargeable Ambient-Temperature Lithium Batteries. A huge range of new battery chemistries and products has become available in the last 5 to 10 years based on lithium. These batteries typically operate at close to room temperature, and provide significant advantages in gravimetric and volumetric energy and power characteristics relative to other rechargeable batteries. Products are available in an almost limitless range of electrochemistries and materials, and are known as lithium-ion, lithium polymer, lithium alloy, and lithium metal. The common material is lithium, but it may be present in metallic or ionic form, and there is a wide range of positive electrodes used, including cobalt oxide, manganese dioxide, and an equally wide range of electrolytes (e.g., organic liquids, gels, polymers), and conductive salts (e.g., lithium hexafluorophospate). It is impossible to generalize when describing this technology, but rather specific types and products must be considered. However, various versions of this technology are being used by the millions of units in many consumer electronics products, and they are being evaluated for larger industrial and propulsion applications.

Cell construction of a typical cylindrical lithium-ion cell is shown in Fig. 11-63. This technology is also available in prismatic and pouch cell designs. Cell capacities range from less than 1 Ah to over 150 Ah. A major advantage of the technology is the high operating voltage per cell, typically in the range of 2.5 to 4.2 V. This translates into fewer cells in series to achieve a given battery voltage. Typical performance data for small cylindrical cells as a function of discharge rate and temperature are shown in Fig. 11-64. Generally, the discharge power capability of this technology is not as good as that for nickel-cadmium batteries. These batteries are generally more expensive than commercial alternatives, but prices have been dropping as production capacity is increased.

It should be kept in mind that the use of rechargeable ambient-temperature lithium batteries must be carefully controlled to maintain battery safety. Many cells and battery packs include a controller which consists of electronics and software to carefully monitor, adjust, or terminate charge and discharge.

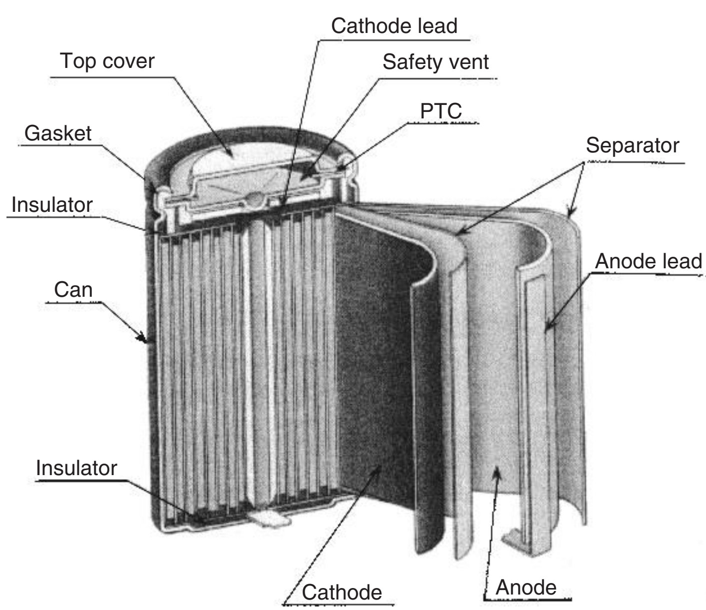

FIGURE 11-63 Cross-sectional view of a cylindrical Li-ion cell. (*Courtesy of the University of South Carolina. Reproduced with permission from the Journal of Power Sources.*)

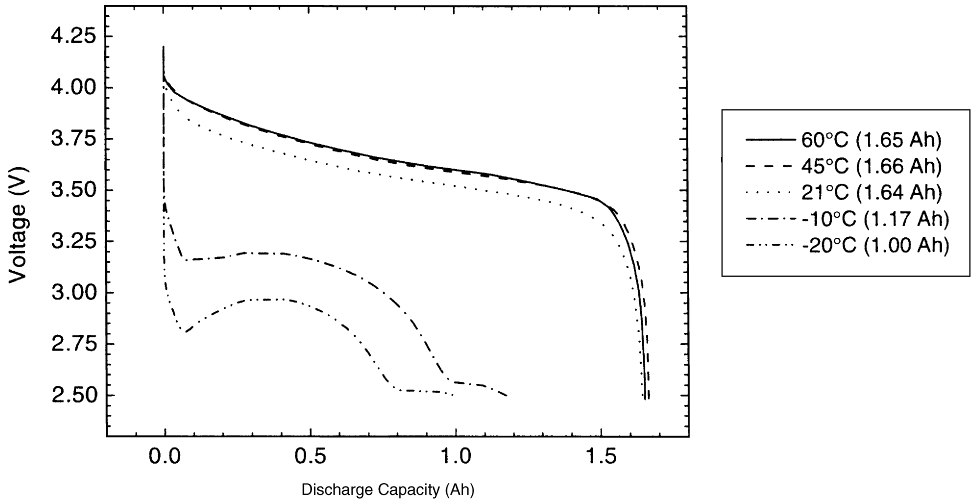

FIGURE 11-64 Approximate *C*-rate discharge of an 18650-type C/$LiCoO_2$ battery at various temperatures when charged in a CCCV regime at 1.65 A to 4.2 V for 2.5 hours, then discharged at 1.5 A. The average voltage at 21°C was 3.6 V, and at –20°C 2.9 V. (*Courtesy of NEC Moli Energy.*)

There have been numerous accidents involving this technology, and there are significant restrictions on transporting large quantities of cells and batteries on commercial aircraft, for example. This technology is also less tolerant to physical abuse than comparable battery chemistries, and care must be taken in harsh environments to avoid battery venting or thermal runaway.

The technology continues to evolve and improve in terms of performance and safety. There are many active research and development programs in progress worldwide to make products more robust, deliver higher discharge rates, and extend cycle life. Improvements in safety are also ongoing. This technology area is poised to continue growing for most small battery applications, and it may also become viable for large industrial and propulsion applications as further improvements in safety and control are realized.

The Battery Field. Readers are referred to an excellent in-depth technical review of batteries: *Modern Battery Technology,* Clive D. S. Tuck (ed.), West Sussex, England, Ellis Horwood Limited, ISBN 0-13-5902665-5. Another comprehensive battery reference is the *Handbook of Batteries,* 3rd ed., David Linden (ed.), New York, McGraw-Hill. This reference includes listings of companies that manufacturing various batteries.

The room-temperature solid electrolyte silver ion conducting devices described in association with Fig. 11-51 are available from Sigma Technologies International, Inc., Tucson, Arizona.

Several other advanced rechargeable battery technologies are being developed worldwide for many diverse applications. They are subject to government and industrial research and development, and the organizations and corporate sponsors/owners change frequently in this dynamic field. The following is a snapshot of the current advanced technologies in development.

- Lithium-alloy/iron sulfide high temperature batteries—Argonne National Laboratory
- Sodium/nickel chloride high temperature batteries (Zebra battery)—MES-DEA SA (Swiss), Beta Research and Development
- Sodium/sulfur high temperature batteries—NGK Insulator
- Vanadium-redox aqueous flowing electrolyte batteries—VRB Power Systems
- Zinc-air batteries—Electric Fuel Battery Corp
- Zinc/bromine flowing electrolyte batteries—ZBB Technologies

11.9 FUEL CELLS

11.9.1 General Concepts

A *fuel cell* is an electrochemical device that continuously converts the chemical energy of a fuel (and oxidant) to electrical energy. The essential difference between a fuel cell and a battery is the continuous nature of the energy supply. The fuel and the oxidant, which is usually oxygen, are supplied continuously to a fuel cell from an external source.

The fuel cell uses liquid or gaseous fuels, such as hydrogen, hydrazine, hydrocarbons, and coal gas. The oxidant in a fuel cell is gaseous oxygen (or air). Fuel cells are close to receiving widespread commercial acceptance in stationary power generation due to improvements in efficiency and reductions in capital cost. Fuel cell-based generating stations typically have operating efficiencies ranging from 40% to 50%. In comparison, many generating stations operate at 30% to 35% efficiency.

A practical fuel cell power plant, depicted in Fig. 11-65, consists of at least three basic subsystems:

1. A power section, which consists of one or more fuel cell stacks–each stack containing many individual fuel cells usually connected in series to produce a stack output ranging from a few to several hundred volts (direct current). This section converts processed fuel and the oxidant into dc power.
2. A fuel subsystem that manages the fuel supply to the power section. This subsystem can range from simple flow controls to a complex fuel-processing facility. This subsystem processes fuel to the type required for use in the fuel cell (power section).
3. A power conditioner that converts the output from the power section to the type of power and quality required by the application. This subsystem could range from a simple voltage control to a sophisticated device that would convert the dc power to an ac power output.

In addition, a fuel cell power plant, depending on size, type, and sophistication, may require an oxidant subsystem as well as thermal and fluid management subsystems.

11.9.2 Operation of Fuel Cells

A simple fuel cell is illustrated in Fig. 11-66. Two catalyzed carbon electrodes are immersed in an electrolyte (acid in this illustration) and separated by a gas barrier. The fuel, in this case hydrogen, is bubbled across the surface of one electrode while the oxidant, in this case oxygen from ambient

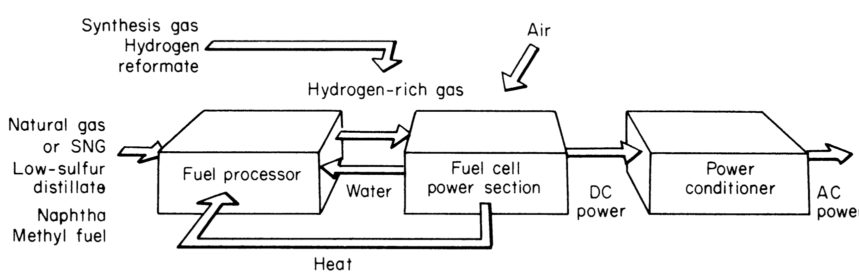

FIGURE 11-65 Generalized schematic diagram of a fuel cell power plant.

air, is bubbled across the other electrode. When the electrodes are electrically connected through an external load, the following events occur:

1. The hydrogen dissociates on the catalytic surface of the fuel electrode, forming hydrogen ions and electrons.
2. The hydrogen ions migrate through the electrolyte (and a gas barrier) to the catalytic surface of the oxygen electrode.
3. Simultaneously, the electrons move through the external circuit to the same catalytic surface.
4. The oxygen, hydrogen ions, and electrons combine on the oxygen electrode's catalytic surface to form water.

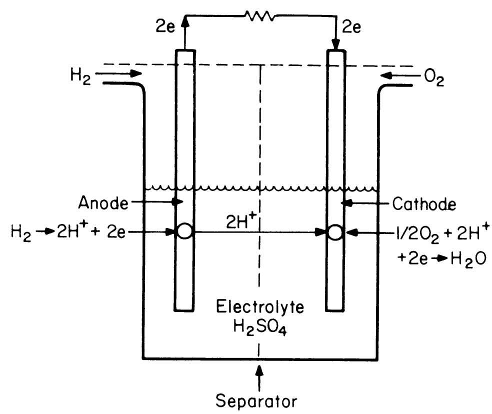

FIGURE 11-66 Operation (reaction mechanism) of the fuel cell.

The reaction mechanisms of this fuel cell, in acid and alkaline electrolytes, are shown in Table 11-15. The major differences, electrochemically, are that the ionic conductor in the acid electrolyte is the hydrogen ion (or, more correctly, the hydronium ion, H_3O^+) and the OH^- or hydroxyl ion in the alkaline electrolyte. Further, in the acid electrolyte the product, water, is produced as the cathode and in the alkaline electrolyte fuel cell at the anode.

The net reaction is that of hydrogen and oxygen producing water and electrical energy. As in the case of batteries, the reaction of one electrochemical equivalent of fuel theoretically will produce 26.8 Ah of dc electricity at a voltage that is a function of the free energy of fuel-oxidant reactions. At ambient conditions, this potential is ideally 1.23 V dc for a hydrogen-oxygen fuel cell.

11.9.3 Major Components of the Fuel Cell

The important components of the individual fuel cell are

1. The *anode* (fuel electrode) must provide a common interface for the fuel and electrolyte, catalyze the fuel oxidation reaction, and conduct electrons from the reaction site to the external circuit (or to a current collector that, in turn, conducts the electrons to the external circuit).
2. The *cathode* (oxygen electrode) must provide a common interface for the oxygen and the electrolyte, catalyze the oxygen reduction reaction, and conduct electrons from the external circuit to the oxygen electrode reaction site.
3. The *electrolyte* must transport one of the ionic species involved in the fuel and oxygen electrode reactions while preventing the conduction of electrons (electron conduction in the electrolyte causes a short circuit). In addition, in practical cells, the role of gas separation is usually provided by the electrolyte system. This is often accomplished by retaining the electrolyte in the pores of a matrix (or inert blotter). The capillary forces of the electrolyte within the pores allow the matrix to separate the gases, even under some pressure differential.

TABLE 11-15 Reaction Mechanisms of the H_2–O_2 Fuel Cell

	Acid electrolyte	Alkaline electrolyte
Anode	$H_2 \rightarrow 2H^+ + 2e$	$H_2 + 2OH^- \rightarrow 2H_2O + 2e$
Cathode	$\frac{1}{2}O_2 + 2H^+ + 2e \rightarrow H_2O$	$\frac{1}{2}O_2 + 2e + H_2O \rightarrow 2OH$
Overall	$H_2 + \frac{1}{2}O_2 \rightarrow H_2O$	$H_2 + \frac{1}{2}O_2 \rightarrow H_2O$

Other components also may be necessary to seal the cell, to provide for gas compartments, and to separate one cell from the next in a fuel cell stack.

11.9.4 General Performance Characteristics

The performance of a fuel cell is represented by the current density versus voltage (or polarization) curve (Fig. 11-67). Whereas ideally a single H_2-O_2 fuel cell could produce 1.23 V dc at ambient conditions, in practice, fuel cells produce useful voltage outputs that are somewhat less than the ideal and decrease with increasing load (current density). The losses or reductions in voltage from the ideal are referred to as *polarization*, as illustrated in Fig. 11-67.

These losses include the following:

1. Activation polarization represents energy losses that are associated with the electrode reactions.
2. Ohmic polarization represents the summation of all the ohmic losses within the cell, including electronic impedances through electrodes, contacts, and current collectors and ionic impedance through the electrolyte. These losses follow Ohm's law.
3. Concentration polarization represents the energy losses associated with mass transport effects. For instance, the performance of an electrode reaction may be inhibited by the inability of reactants to diffuse to or products to diffuse away from the reaction site.

The net result of these polarizations is that practical fuel cells produce between 0.5 and 0.9 V dc at currents of 100 to 400 mA/cm^2 of cell area. Fuel cell performances can be increased by increasing cell temperature and reactant partial pressure. For any fuel cell, the tradeoff always exists between achieving higher performance by operating at higher temperature or pressure and confronting the materials and hardware problems imposed at the more severe conditions.

11.9.5 Fuel Cell Systems

Classification and Types. Fuel cell systems can take a number of different configurations, depending on the combination of type of fuel and oxidant, whether the fueling is direct or indirect, the type

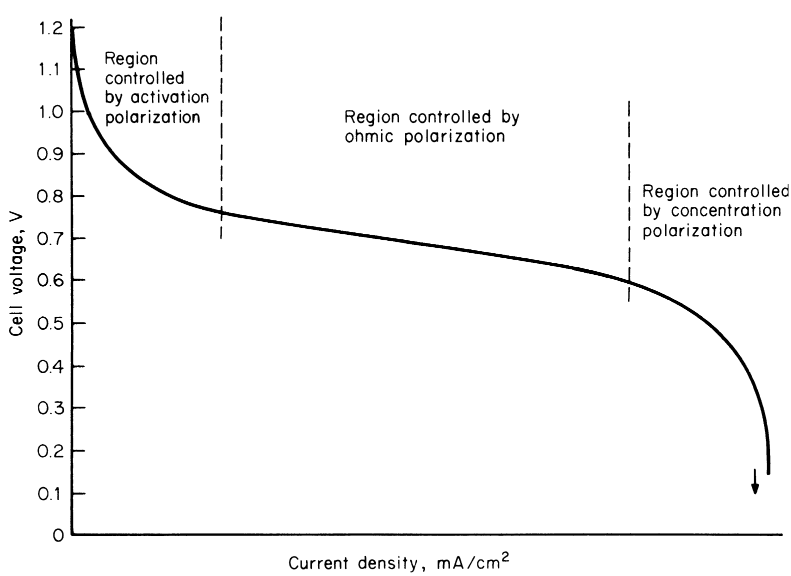

FIGURE 11-67 Fuel cell polarization curve.

of electrolyte, the temperature of operation, etc., although in actual practice, the number of combinations is limited. A listing of the practical fuel cell systems is given in Table 11-16.

Acid Fuel Cells. Table 11-16 lists two types of acid fuel cells (solid polymer electrolyte and phosphoric acid), aqueous alkaline fuel cells, molten carbonate fuel cells, and solid oxide fuel cells. Acid fuel cells are characterized by the following:

Ionic conduction is provided by hydrogen ions [or by hydronium ions (H_3O^+)].

Platinum or platinum alloys (in very small quantity) are the active electrocatalysts.

Carbon (graphite) is an acceptable material of construction for current collectors, gas separators, etc., and is commonly used.

Solid Polymer Electrolyte System. The solid polymer electrolyte (SPE) system uses an ion-exchange membrane as the electrolyte. The advantages of the SPE fuel cell are (1) the electrolyte, being a solid, cannot change, move about, or vaporize from the system; and (2) the only liquid in the fuel cell is water, minimizing corrosion. The disadvantages are (1) the SPE must be hydrated (water-saturated) to perform; consequently, operation must be under conditions where the by-product water does not vaporize into the reaction air stream faster than it is produced; this constrains cell operation to under 60°C at ambient pressure and about 120°C at elevated pressures; and (2) the SPE freezes at about 0°C and undergoes a freeze-drying phenomenon. This constraint is applicable to those where low-temperature capability is not a requirement.

Due to their inability to operate much above 120°C, SPE fuel cells are best suited for use with hydrogen-rich gases that contain little or no carbon monoxide. Carbon monoxide inhibits the fuel cell anode reaction, the degree of inhibition decreasing with increasing temperature. Consequently, SPE fuel cells have found their important applications in the space program operating on pure hydrogen or in military applications operating on hydrogen obtained by the decomposition of a hydride.

TABLE 11-16 Classification of Practical Fuel Cells

Application	Fuel	Oxidant	Electrolyte	Temperature
Remote				
Space	Direct H_2	Liquid O_2	Aqueous alkaline Solid polymer	Low, intermediate Low
Undersea	Direct H_2 Direct hydrazine	Liquid O_2 Hydrogen peroxide	Aqueous alkaline	Low
Military				
Low power, ≤ 100 W	Indirect hydride	Air	Aqueous alkaline Solid polymer	Low
High power, ≥ 500 W	Indirect hydrocarbon Indirect methanol	Air	Phosphoric acid	Intermediate
Commercial power				
Dispersed (or on-site)	Indirect hydrocarbon		Phosphoric acid	Intermediate
	Indirect methanol, ethanol Direct coal gas	Air	Molten carbonate	High
Central station	Indirect coal Direct coal gas	Air	Phosphoric acid Molten carbonate Solid oxide	Intermediate High Very high
Vehicle	Hydrogen Hydride Indirect methanol Indirect hydrocarbon	Air	Phosphoric acid	Intermediate

Phosphoric Acid Electrolyte System. The phosphoric acid electrolyte system operates at 150 to 220°C. At lower temperatures, phosphoric acid is a poor ionic conductor. At higher temperatures, material stability (carbon and platinum) becomes limiting. The advantages of phosphoric acid fuel cells are (1) the electrolyte is very stable, (2) the phosphoric acid can be highly concentrated (~ 100%) where the water vapor pressure is very low and steady-state water removal by the reactant gases will always equal product water rate, and (3) at 150 to 220°C, the anode performance is very good even on fuels containing up to 5% carbon monoxide. The disadvantage of phosphoric acid fuel cells is that the cathode performance is sluggish. In fact, the major technology thrusts in phosphoric acid are toward improvement of the cathode. The phosphoric acid fuel cell is a preferred system for use with fuels containing carbon oxides.

Alkaline Fuel Cells. Although early alkaline fuel cells operated at relatively high temperature (~250°C) with concentrated (85 wt%) potassium hydroxide, systems developed more recently operate at much lower temperatures (<120°C) using less concentrated (35 to 50 wt%) potassium hydroxide. The lower temperature enables the use of matrices to retain the electrolyte and increases the life of other components.

Alkaline fuel cells are characterized by the following:

Ionic conduction is provided by hydroxyl (OH^-) ions.

A wide range of electrocatalysts can be used, including nickel, silver, metal oxides, spinels, and noble metals—although the truly high-performance systems use at least small amounts of noble metal.

Construction materials include carbon, nickel, and stainless steel.

The advantages of alkaline fuel cells are that (1) cathode performance is much better than for acid fuel cells and (2) materials of construction tend to be low in cost. The primary disadvantage is that the electrolyte reacts with carbon oxides to form potassium carbonate. This severely limits the cells' performance. Thus, alkaline fuel cells have only limited application where carbonaceous fuels or air is used as a reactant. The important applications (space and underseas) involve pure hydrogen and oxygen.

Molten Carbonate Fuel Cells. Molten carbonate fuel cells use an alkali metal (Li, K, Na) carbonate as the electrolyte. Since these salts can function as electrolytes only when in the liquid phase, the cells operate at 600 to 700°C, which is above the melting points of the respective carbonates. Molten carbonate cells are characterized by the following:

Ionic conduction is by the carbonate ion; thus, the carbonate ion must be involved in the two electrode reactions:

$$\begin{array}{ll} {}^1/_2\,O_2 + CO_2 + 2e \rightarrow CO_3^{2-} & \text{(cathode)} \\ CO_3^{2-} + H_2 \rightarrow CO_2 + H_2O + 2e & \text{(anode)} \\ \hline {}^1/_2\,O_2 + H_2 \rightarrow H_2O & \text{(net)} \end{array}$$

A consequence of this is that CO_2 must be recycled from the anode to the cathode.

At 600 to 700°C, electrode reactions proceed without highly specific catalysts. Nickel and nickel oxide work quite well; noble metals are not used.

Construction materials include nickel and ceramics.

The advantages of molten carbonate fuel cells are that (1) cell performance is good, activation polarization is small; (2) at 600 to 700°C, any carbon monoxide in the fuel converts to hydrogen on the anode via the water gas shift reaction, that is,

$$CO + H_2O \rightarrow CO_2 + H_2$$

(as a result, fuel gases high in carbon monoxide are readily used); and (3) waste heat from the fuel cell can be available at a relatively high temperature (>500°C), enabling its use in bottoming or industrial heating cycles.

Disadvantages are that (1) the high temperature imposes severe constraints on materials suitable for long lifetimes and (2) a course of carbon dioxide is required to complete the cathode reaction (this is provided by recycling CO_2 from the anode exhaust to the cathode inlet). As a result, molten carbonate fuel cells are best suited for applications that integrate the fuel cell with a carbonaceous fuel processor, that is, a reformer or coal gasifier.

Solid Oxide Fuel Cells. As the name implies, solid oxide fuel cells employ a solid, nonporous metal oxide electrolyte, which allows ionic conductivity by the migration of oxide ions through the lattice of the crystal. Stabilized zirconia is commonly used as the electrolyte. The cells operate at 900 to 1,000°C. Whereas practical cells of the technologies previously discussed are normally packaged into "filter press" or "plate and frame" stack assemblies, solid oxide fuel cells are configured into tubular cell stacks.

Characteristics of the solid oxide fuel cell include the following:

Ionic conduction is provided by oxide ions.

The cathode employs metal oxides, such as praseodymium oxide or indium oxide; the anode uses nickel or nickel cermet.

Because of the high temperature, materials of construction will likely be confined to ceramics or metal oxides.

Solid oxide fuel cells offer advantages similar to those of molten carbonate cells, that is, good performance on fuels containing hydrogen or hydrogen and carbon monoxide, the elimination of noble-metal catalysts, and the availability of high-grade reject heat. In addition, they do not suffer the constraint of molten carbonate cells which require a carbon dioxide recycle to the cathode. The primary disadvantages are the very high temperature of operation and the severe material constraints imposed by the ~1,000°C temperature.

11.9.6 Low-Power Fuel Cell Systems

The advantageous characteristics of fuel cells led to the development of a number of different systems ranging in size from the portable units, 5 W or smaller to kilowatt power levels (where ease of operation, low maintenance, and silence are important), to large stationary plants delivering megawatts of power (where the high efficiency over the range from full to partial load and reduced pollution are significant). The lower-power fuel cells were designed mainly for military or special applications such as the space program. For the space applications and for forward-area military use, the fuel cell offers high energy densities that exceed the performance of batteries when operated over long periods of time.

Portable Fuel Cells. Fuel cells in the power range of up to about 200 W can be an attractive alternative to batteries for long-term operation, with potential reduction in the weight and cost. The size limitation of these portable fuel cell systems is generally too small to permit the use of elaborate fuel conditioning. Hence, easily handled and readily oxidized fuels (e.g., liquid or gaseous fuels such as hydrazine, methanol, and ammonia) and fuels that provide hydrogen through a simple physical or chemical reaction have been used in most fuel cell systems of this size and type. For these ground applications, air-breathing, rather than pure oxygen, systems are used.

While the fuel cell systems in this size and power range potentially have advantageous characteristics, system complexities and the development of new battery systems with higher energy densities have limited the interest and successful use of the low-power fuel cell.

Direct Fuel Cell Systems. Direct-type fuel cells, in which the fuel can be introduced into the fuel cell without requiring conversion to hydrogen, were considered for small fuel cell systems because they eliminated the need for a fuel-conditioning unit, thus saving important space and weight. Methanol (CH_3OH) and hydrazine (N_2H_4) were the main liquid fuels used. Methanol is directly oxidizable, but removal of the carbonate, one of the reaction products of the dissolved methanol fuel cell in alkaline electrolytes, from the electrolyte is extremely difficult. Efforts then shifted to hydrazine. Hydrazine decomposes easily into hydrogen and nitrogen at the electrode surface; in fact, the voltage observed is that of hydrogen.

Major effort was directed toward a silent power source for forward-area military use. A 60-W, 24-V hydrazine-air fuel cell was developed in a configuration similar to the one used later for the metal hydride cell. The fuel cell used a 35% potassium hydroxide electrolyte and a 64% hydrazine monohydrate fuel and operated between 55 and 70°C with a fuel utilization of 600 Wh/kg. A larger 300-W, 24-V power source also was developed for forward-area use. This system weighed 20 kg, with electrolyte and 4 L of fuel and had a volume of 35 dm^3. The fuel was sufficient for 12 h of operation at 300 W. Field tests confirmed the successful electrochemical functioning of the cell, but mechanical deficiencies caused early failure of the system.

Metal Hydride Fuel Cells. The majority of current portable fuel cell developments use a metal hydride as the source of hydrogen fuel. Metal hydrides are attractive because they can store large amounts of hydrogen more conveniently and with a higher energy density (total equivalents of hydrogen per total weight of hydrogen source and container) than hydrogen in a pressurized or liquefied form.

One type of metal hydride produces hydrogen by the reaction with water, for example, calcium hydride (CaH_2):

$$CaH_2 + 2H_2O \rightarrow Ca(OH)_2 + H_2$$

A second type of metal hydride, a reversible hydride, is based on the principle that certain metals or alloys (e.g., iron titanium, lanthanum nickel, and various other rare-earth metal and nickel alloys) have the ability to take up large amounts of hydrogen gas within their crystal structure. A reduction in pressure or an increase in temperature release the hydrogen. These hydrides can deliver hydrogen at about 500 Wh/kg.

$$NaAlH_4 + H_2O \text{ (excess)} \rightarrow Al(OH)_3 + NaOH + 4H_2$$

The hydride, in the form of a solid pellet, delivers in excess of 2000 Wh/kg. Hydrogen for 4 h of operation is supplied to the fuel cell with a single 120-g charge. The Kipp generator delivers hydrogen to the fuel cell on demand; when no hydrogen demand exists, the pressure builds up in the generator, forcing water away from the fuel pellet and stopping the reaction.

A later design used a reversible metal hydride, lanthanum pentanickel hydride, as the source of hydrogen:

$$LaNi_5 + 3H_2 \rightleftharpoons LaNi_5H_4$$

This change, replacing the exothermic sodium aluminum hydride generator with the reversible metal hydride source, which absorbs heat on the release of hydrogen, could reduce the total heat output of the system by 65%. The system was found to operate satisfactorily at 20°C, but higher ambient temperatures still caused problems because of the much higher operating temperature of the fuel cell stack.

SPE Fuel Cell. There is renewed interest in the SPE fuel cell for applications in which mobility is important and power requirements are low. The advantages of the SPE cell are ease of product water removal, simple construction, stable electrode-electrolyte interface, and favorable life characteristics.

The SPE cell is being considered for power levels from a few watts to 500 W, operating in the –40 to 50°C range with no restrictions on humidity. Special designs, including insulation for low temperatures and methods for waste heat disposal, probably will be required to achieve this performance. The cell operates on hydrogen and ambient air. Preferred fuel sources for hydrogen generation

TABLE 11-17 Utility Fuel Cell Power Plant Programs

Role	Size	Fuel	Efficiency, %	Electrolyte
On-site power plants	40–300 kW	Pipeline gas	39–42 or 90 (with reject-heat recovery)	Phosphoric acid
Dispersed (substation) power plants	5–25 MW	Petroleum- or coal-derived gas or liquid	41–47 or 80 (with reject-heat recovery)	Phosphoric acid
Central station power plants	150–600 MW	Coal	45–50	Molten carbonate or phosphoric acid

are magnesium and aluminum, which are reacted with salt water. Bottled hydrogen, hydride-stored hydrogen, or hydrides also may be used. With magnesium, it is expected to obtain energy densities (fuel consumption) of about 220 Wh/kg on a wet basis and 1300 Wh/kg on a dry basis. For longer missions, where a larger system weight can be tolerated, re-formed methanol combined with carbon monoxide absorption is being considered.

Utility Fuel Cell Power Plants. Interest in the fuel cell as a utility power plant results from its efficiency, its environmental acceptability, and its modular construction. The fuel cell may serve utilities in several ways, as summarized in Table 11-17. Relatively small fuel cell power plants (with a capacity ranging from 40 to 300 kW) could be set up in commercial and residential buildings. Such a plant would use natural gas as a fuel. The plant would provide both electric and thermal energy (the latter from the waste heat of the fuel cells), consuming the same amount of fuel ordinarily required for the thermal demand alone. Overall efficiencies approaching 90% have been projected for fuel cell power plants of this type. An advantage of the fuel cell is that the waste heat can be used without altering the power production characteristics. Larger plants, ranging in capacity from 5 to 25 MW, could be dispersed throughout an electric utility system to perform load-following duty efficiently, taking advantage of the higher efficiency of the fuel cell even at reduced loads. In the future, fuel cells could be integrated with coal gasifiers to provide large, central-station, base-load power plants that utilize coal directly. The capacity of such plants would range from 150 to 1,000 MW. A plant of this kind is projected to be more than 45% efficient, on the basis of the heating value of the coal consumed.

Phosphoric Acid Fuel Cells. The basic *cell structure* of the phosphoric acid fuel cell (PAFC) is shown in Fig. 11-68. It consists of

1. *A carbon or graphite separator-current collector plate* that separates hydrogen from the air of the adjacent cell (in a multicell stack) and also provides the electrical series connection between cells.
2. *Anode current collector ribs* that conduct the electrons from the anode to the separator plate. The ribbed configuration provides gas passages for hydrogen distribution to the anode.
3. *An anode* that consists of a porous graphitic substrate with the surface adjacent to the electrolyte treated with a platinum or platinum alloy catalyst.
4. *An electrolyte matrix* that retains the concentrated phosphoric acid.
5. *A cathode* that is similar to the anode but uses a modified noble-metal catalyst and an increased catalyst loading (usually 0.5 mg/cm^2) to enhance the oxygen reduction kinetics.
6. *Cathode current collector ribs* that are also virtually identical to the anode ribs.

These single cells are stacked in series to produce the desired output power and voltage.

Phosphoric acid fuel cell power plants are also being considered for use in central stations. These power plants would utilize integrated coal gasifiers to supply the hydrogen-rich fuel and would provide base load power.

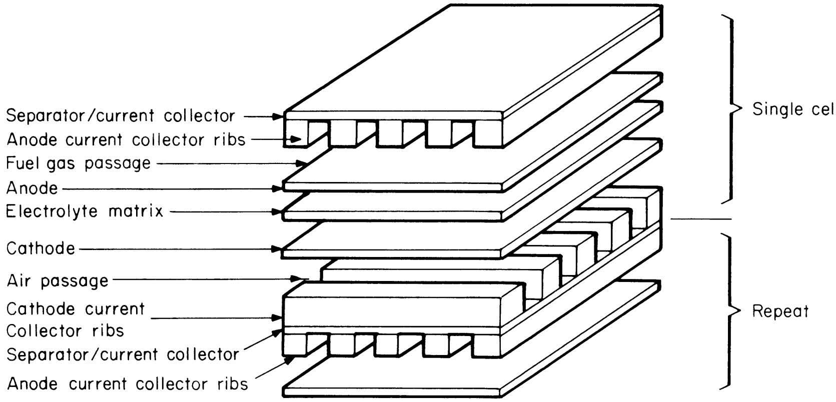

FIGURE 11-68 Basic phosphoric acid electrolyte fuel cell.

Molten Carbonate Fuel Cells. In contrast to the PAFC, molten carbon fuel cell (MCFC) development efforts are focused on large, multimegawatt (~600 MW) central-station power plants integrated with a coal gasifier. This focus is, in part, due to their high operating temperature and the problems inherent in starting (heating) and stopping (cooling) MCFC power plants.

Cell structure for the MCFC is geometrically very similar to that of the PAFC. The materials that are used, however, are very different from those used in the PAFC. The MCFC consists of

1. A *separator and current-collector plate* that separates the fuel gas from the air of the adjacent cell in a multicell stack and also provides the electrical connection between cells. Like its PAFC counterpart, it must be impermeable to hydrogen and oxygen, a good electronic conductor, and stable to fuel and air environments in the presence of 650°C carbonate salts.
2. An *anode current collector* that conducts the electrons from the anode to the separator plate. This current collector also must provide passage for fuel flow. In some configurations, this function is provided by ribbing or folding the separator plate.
3. An *anode* that consists of a porous nickel treated with a refractory oxide to reduce sintering. At the 650°C temperature, no other catalyst is required.
4. An *electrolyte system* comprising a mixture of lithium–potassium carbonate and inert powder (presently a lithium aluminate). This mixture forms a paste when molten and freezes to form a "tile" when cooled. This electrolyte system presents major challenges to MCFC development. It must have minimum ionic resistance while separating the fuel and oxidant gases at pressure differentials in excess of 0.07×10^5 Pa. In addition, it must be electronically insulating.
5. A *cathode* that is similar to the anode except that it uses nickel oxide (doped with lithium to impart electronic conductivity).
6. A *cathode current collector* that has similar requirements and configurational operations as the anode current collector. Since nickel is thermodynamically unstable, material options include lithium-doped nickel oxide and corrosion-resistant stainless steel.

As with the PAFC, individual cells are stacked in series to result in a cell stack of the required power and voltage output.

Molten Carbonate Fuel Cell Power Plants. The thrust of the MCFC program is the development of a central-station power plant, comprising a coal gasifier, gas cleanup system, MCFC

TABLE 11-18 Design Requirements and Goals for a Central Station MCFC Power Plant

Requirements	
Central station plant	
Power level	–675 MW(e)
Fuel specification	Illinois no. 6 coal
Modular construction	
Environmental	Projected 1985 federal requirements
Site characteristics	"Middletown" except for cooling tower heat rejection
Goals	
Base load duty with daily load following capability	
Heat rate	6.8×10^6 J/kWh
Capital installed cost (1982 dollars)	\$1500/kW(e)
Plant availability	85%
Life goals (75% capacity factor)	
Fuel cell stacks	6 years
Balance of plant	30 years
Startup/shutdown	
Startup: Cold startup in 4 to 6 h	
Shutdown: 100% to zero load in 3 h	
Daily load following	
Large-load-change response time of 2 h	
Small-load-change response rate up to 2%/min	
Abnormal conditions	
Complete-load rejection (breakers opening)	
Partial-load rejection (from power system breakup)	
Sustained abnormal voltage or frequency operation	
Limit fault current to 1.1 per unit current (rms basis)	
Other	
Independent var control	

(topping cycle), and gas or steam turbine (bottoming cycle). Design requirements and goals for a 675-MW power plant are described in Table 11-18. A possible power plant configuration would include

600 MCFC stacks (having five hundred 1-m^2 cells each) for a total 450-MW output

15 coal gasifiers capable of handling 3×10^{11} J/h each

10 heat-recovery steam generators

Five 15-MW gas turbines

One 150-MW steam turbine

Although the ultimate application of the MCFC will likely be as a large coal-fueled, central-station power plant, other applications such as that of dispersed or on-site generators with and without reject heat recovery are also being considered. Because of the high operating temperature, the quality of the MCFC's waste heat could be compatible with a variety of industrial heating applications. Also, at 600°C, in situ re-forming of methane or methanol is possible; this could result in a very efficient small power plant.

Direct Fuel Cell Systems. Methanol (CH_3OH) and hydrazine (N_2H_4) are the liquid fuels that have been used in direct fuel cells, since they are more readily oxidized than the fossil fuels. Work is still in the development stage, and no systems were available commercially in the mid-1970s. Effort in recent years has been deemphasized.

Hydrazine has been used in a 60-W and larger configurations. The 60-W hydrazine unit is similar to the hydrogen fuel cell and delivers over 600 Wh/kg but was abandoned in favor of the hydrogen system. Similar experience was obtained with a larger 120-kg, 1.5-kW unit which degraded rapidly after 300 h of service.

A relatively small effort continues on direct hydrocarbon fuel cells, particularly with high-temperature (1,000 to 1,200°C) solid electrolyte fuel cells. The higher temperatures should allow direct reaction of the hydrocarbons with improved kinetics, although the potential benefits may be offset by the problems of high-temperature operation.

11.10 MAGNETOHYDRODYNAMICS

By N.B. MORLEY and M.S. TILLACK

11.10.1 Introduction

The interaction of moving conducting fluids with electric and magnetic fields provides for a rich variety of phenomena associated with electro-fluid-mechanical energy conversion. Effects from such interactions can be observed in liquids, gases, two-phase mixtures, or plasmas. Numerous scientific and technical applications exist, such as heating and flow control in metals processing, power generation from conducting two-phase mixtures or conductor-seeded high-temperature gases, magnetic confinement of high-temperature plasmas—even dynamos that create magnetic fields in planetary bodies. Several terms have been applied to the broad field of electromagnetic effects in conducting fluids, such as *magneto-fluid-mechanics, magneto-gas-dynamics*, and the more common one used here—*magnetohydrodynamics*, or MHD.

Practical MHD devices have been in use since the early part of the twentieth century. For example, an MHD pump prototype was built as early as 1907.[1] More recently, MHD devices have been used for stirring, levitating, and otherwise controlling flows of liquid metals for metallurgical processing and other applications.[2,3] Gas-phase MHD is probably best known in MHD power generation. Since 1959,[4,5] major efforts have been carried out around the world to develop this technology in order to improve electric conversion efficiency, increase reliability by eliminating moving parts, and reduce emissions from coal and gas plants. Closed-cycle liquid metal MHD systems using both single-phase and two-phase flows also have been explored.

Still, more novel applications are in development or on the horizon. For example, recent research has shown the possibility of seawater propulsion using MHD[6] and control of turbulent boundary layers to reduce drag.[7] Extensive worldwide research on magnetic confinement of plasmas has led to attainment of conditions approaching those needed to sustain fusion reactions.[8]

In the following sections, we review the basic equations describing coupled MHD behavior as well as some basic MHD phenomena in liquids, gases, and two-phase mixtures. Much of the underlying physics described is common to many of the applications cited above. Also included are discussions of several of the most important applications, together with their special analysis techniques and examples of equipment involved.

11.10.2 Basic Equations

The Full Set of MHD Equations

The MHD Equations. The complete set of MHD equations for a Newtonian, constant-property fluid flow includes the Navier-Stokes equations of motion (i.e., momentum equation), the equation of mass continuity, Maxwell's equations, and Ohm's law. In differential form, they constitute the following system of equations:

$$\rho\left(\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla)\,\mathbf{u}\right) = -\nabla p + \mathbf{j} \times \mathbf{B} + \mu_f \nabla^2 u + \rho \mathbf{g} \tag{11-14}$$

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{u} = 0 \tag{11-15}$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \tag{11-16}$$

$$\nabla \times \mathbf{B} = \mu_m \mathbf{j} \tag{11-17}$$

$$\mathbf{j} = \sigma(\mathbf{E} + \mathbf{u} \times \mathbf{B}) \tag{11-18}$$

where the MHD body force $\mathbf{j} \times \mathbf{B}$ is included in the Navier-Stokes equation. The displacement current has been neglected from Ampere's law, which is a valid approximation for nonrelativistic phenomena typical of the response of an inertial liquid. Implicit in Eqs. (11-14) to (11-18) are the following additional relations:

$$\nabla \cdot \mathbf{B} = 0 \tag{11-19}$$

$$\nabla \cdot \mathbf{j} = 0 \tag{11-20}$$

This system of equations is a rich one, describing not only all of the phenomena generally associated with low frequency fluid mechanics and electromagnetics, but also new phenomena not seen in either discipline. Simplifications usually are required to obtain solutions to physical systems of interest. For instance, for quasi-steady flow problems where $\partial B/\partial t$ is negligible, the electric field can be represented as the gradient of an electric potential φ, which simplifies the problem by eliminating vector Eq. (11-16).

Magnetic Induction. The magnetic induction equation is derived easily by taking the curl of Ohm's Law:

$$\nabla \times \mathbf{j}/\sigma = \nabla \times \mathbf{E} + \nabla \times (\mathbf{u} \times \mathbf{B}) \tag{11-21}$$

If $\nabla \times \mathbf{E}$ is replaced by Faraday's Law (Eq. 11-16) and $\nabla \times \mathbf{j}$ is replaced by the curl of Ampere's law (Eq. 11-17), then, using the vector identity

$$\nabla \times (\nabla \times \mathbf{B}) = \nabla(\nabla \cdot \mathbf{B}) - \nabla^2 \mathbf{B} \tag{11-22}$$

we obtain

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{u} \times \mathbf{B}) + \frac{1}{\mu_m \sigma} \nabla^2 \mathbf{B} \tag{11-23}$$

Equation (11-23) is known as the induction equation, and suggests that the motion of a conducting liquid in an applied magnetic field, through the generation of electric current, will induce a magnetic field in the medium. The total field is the sum of the applied and induced magnetic fields. The relative strength of the induced field is characterized by the magnetic Reynolds number ($\mathrm{Re}_m = \sigma\mu_m uL$). The neglect of the induced magnetic field is a valid assumption when Re_m is small.

Dimensionless Parameters. Fluid mechanics equations typically are cast in dimensionless form so that the relative strengths of the different terms can be inferred by the size of any multiplying factors. The equation of motion (Eq. 11-14) can be written in dimensionless form by making the substitutions

$$\mathbf{j}^* = \frac{\mathbf{j}}{\sigma u_o B_o} \tag{11-24}$$

$$p^* = \frac{p}{\sigma u_o B_o^2 a} \tag{11-25}$$

$$\nabla^* = \frac{1}{a}\nabla \qquad u^* = u/u_o \qquad B^* = B/B_o \tag{11-26}$$

where a, u_o, and B_o are characteristic values of length, velocity, and applied magnetic field. Characteristic values of the current density and pressure have been selected carefully in order to scale the phenomena of interest; different values could have been selected, leading to different systems of nondimensionalization. Using this system, the equation of motion (excluding gravity) becomes

$$\frac{1}{N}\left(\frac{\partial \mathbf{u}^*}{\partial t} + (\mathbf{u}^* \cdot \nabla)\mathbf{u}^*\right) = -\nabla p^* + \mathbf{j}^* \times \mathbf{B}^* + \frac{1}{Ha^2}\nabla^2\mathbf{u}^* \tag{11-27}$$

The characteristic parameters Re, Ha, and N are the Reynolds number, the Hartmann number (which is an average measure of the ratio of magnetic to viscous force), and the interaction parameter (which is a measure of the ratio of magnetic to inertial forces). They are defined as

$$\mathrm{Re} = \rho u_o a/\mu_f \tag{11-28}$$

$$\mathrm{Ha} = aB_o\sqrt{\sigma_f/\mu_f} \tag{11-29}$$

$$N = \mathrm{Ha}^2/\mathrm{Re} = aB_o^2\sigma_f/\rho u_o \tag{11-30}$$

Table 11-19 gives representative values of these characteristic dimensionless parameters, for example, cases of interest. When the Hartmann number and interaction parameter are both sufficiently large, the momentum equation (Eq. 11-27) throughout the bulk of the fluid is often reduced to the simple form

$$\nabla p = \mathbf{j} \times \mathbf{B} \tag{11.31}$$

Whether this inviscid, intertialess approximation is always valid in cases with high Hartmann number and interaction parameter is still the subject of some debate.

Electrical Equations and Ohm's Law.

The Lorentz Force. Underlying the MHD body force is the fact that free charges, with charge q, moving in a magnetic field experience a "Lorentz" force perpendicular to both their velocity and the magnetic field induction:

$$\mathbf{F}_q = q(\mathbf{v} \times \mathbf{B}) \tag{11-32}$$

TABLE 11-19 Typical Values of Re, Ha, N, and Re_m for Several Materials (Assuming $a = 0.1$ m, $B = 1$ T, $u = 1$ m/s)

	NaK (100°C)	Hg (20°C)	Electrolyte (20°C) 15% KOH	Air (3,000°C) with 2% K
Re	1.6×10^5	9.1×10^5	4.3×10^4	350
Ha	6800	2700	17.5	98
N	290	8.2	7×10^{-3}	27
Re_m	0.30	0.14	1.2×10^{-5}	1.3×10^{-5}

For collisionless particles of mass m, the Lorentz force results in pure harmonic motions in the plane perpendicular to the magnetic field (B_z) with characteristic cyclotron frequency $\omega_c = qB_z/m$:

$$m\dot{v}_y = -qv_xB_z \qquad m\dot{v}_x = qv_yB_z \tag{11-33}$$

$$\ddot{v}_y = -\frac{qB_z}{m}\dot{v}_x = -\left(\frac{qB_z}{m}\right)^2 v_y \qquad \ddot{v}_x = \frac{qB_z}{m}\dot{v}_y = -\left(\frac{qB_z}{m}\right)^2 v_x \tag{11-34}$$

$$v_y = A_1 \cos \omega_c t + A_2 \sin \omega_c t \qquad v_x = A_3 \cos \omega_c t + A_4 \sin \omega_c t \tag{11-35}$$

In contrast, for collisional particles that are forced to follow the fluid velocity **u**, the Lorentz force acts on electrons and ions in a direction perpendicular to the flow, but in opposite directions for positive and negative charges. The net result is charge separation, leading to the generation of electric fields. The open circuit voltage between electrodes spaced a distance d apart in a conducting fluid is

$$V_{oc} = \int_0^d (\mathbf{u} \times \mathbf{B}) \cdot dI \tag{11-36}$$

An electric field $\boldsymbol{\varepsilon}$ arises between the electrodes such that $\boldsymbol{\varepsilon} + \mathbf{u} \times \mathbf{B} = 0$, corresponding to the zero-current condition in Ohm's Law (Eq. 11-18). If current is allowed to flow, as a result of some return current path, then the electric field and electrode voltage are reduced due to the electrical resistance of the fluid:

$$\boldsymbol{\varepsilon} = (\mathbf{u} \times \mathbf{B} - \mathbf{j}/\sigma) \tag{11-37}$$

The Hall Effect. In the regime between collisional and collisionless particles, the Hall effect can be important. Usually, the current induced in the fluid is carried predominantly by electrons, which are considerably more mobile than ions. The electron drift velocity, given by

$$\mathbf{j} = n_e e\, \mathbf{u}_e \tag{11-38}$$

leads to a second component of velocity, and so, according to Eq. (11-32), a secondary force and electric field

$$\varepsilon H = \beta \mathbf{j} \times \mathbf{B} \tag{11-39}$$

where $\beta = 1/n_e e$ is the Hall constant. The current component created by this electric field, that is, the "Hall current," is given by $-\mu_e \mathbf{j} \times \mathbf{B}$, where $\mu_e = \omega\tau/B$ is the electron mobility τ is the electron collision mean-free time. This leads to a more generalized statement of Ohm's Law including the Hall effect:

$$j/\sigma = (\varepsilon + \mathbf{u} \times \mathbf{B}) - \frac{\mu_e}{\sigma}\mathbf{j} \times \mathbf{B} \tag{11-40}$$

A vector diagram of the electric field components from this relation is shown in Fig. 11-69. Further theoretical discussion of the generalized Ohm's Law can be found in Refs. 9–12.

Generalized Ohm's Law. Ohm's Law, cited above, is a constitutive relationship (for instance, analogous to the equation of state for gases) and as such has a limited range of applicability. Various forms of Ohm's Law can be obtained depending on the approximations made in deriving the current-field relationships from the equations of motion and the interactions of the constituent parts of the fluid. For weakly-ionized gases in thermal equilibrium at moderate temperature, Eq. (11-40) has the equivalent tensor form (neglecting ion current):

$$\mathbf{j} = \hat{\boldsymbol{\sigma}} \cdot (\varepsilon + \mathbf{u} \times \mathbf{B}) = \hat{\boldsymbol{\sigma}} \cdot \varepsilon^* \tag{11-41}$$

or

$$j_v = \sum_k \sigma_v^k \varepsilon_k^* \tag{11-42}$$

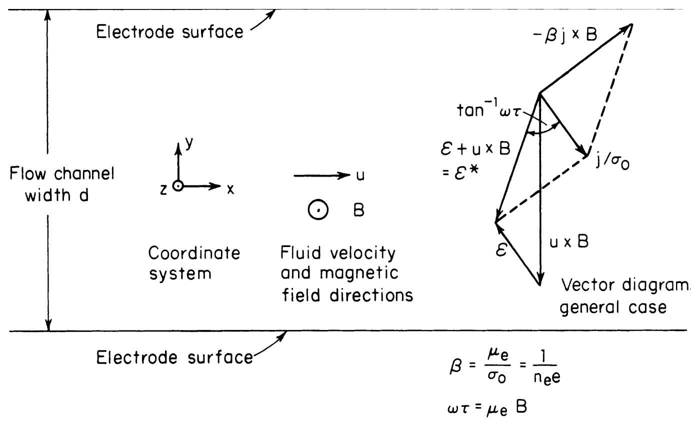

FIGURE 11-69 Vector quantities in the generalized Ohm's Law.

When $\mathbf{B} = z_1 B_z$,

$$\hat{\sigma}/\sigma f = \begin{vmatrix} \frac{1}{1 + \omega^2\tau^2} & \frac{-\omega\tau}{1 + \omega^2\tau^2} & 0 \\ \frac{\omega\tau}{1 + \omega^2\tau^2} & \frac{1}{1 + \omega^2\tau^2} & 0 \\ 0 & 0 & 1 \end{vmatrix} \tag{11-43}$$

where

$$\omega = \frac{eB}{m_e} \qquad \text{electron cyclotron frequency}$$

$$\tau = \frac{\lambda}{c_e} \qquad \text{electron collision mean free time}$$

$$\omega\tau = \mu_e B \qquad \text{Hall parameter}$$

The dimensionless product $\omega\tau$, often called the "Hall parameter," is an important characteristic number in MHD design. The conductivity tensor is anisotropic due to the Hall component unless $\omega\tau << 1$ (typical values for weakly-ionized gases are 1 to 5.) On a microscopic scale, the Hall parameter indicates the average angular travel of electrons between collisions. Typical values are $\lambda \sim 10^{-7}$ m, $c_e \sim 10^5$ m/s, $\tau \sim 10^{-12}$ s, $\omega = 1.76 \times 10^{11}\, B \sim 10^{12}$/s for $B = 6$ T. Since the mean free path is inversely proportional to pressure, lower pressure and higher values of B give larger values of $\omega\tau$.

On a macroscopic scale, the value of $\omega\tau$ indicates the relative importance of the Hall field and Hall current. When $\omega\tau = 1$, the total current is directed 45° to the left of the ε^* vector (see Fig. 11-69), and for large values of $\omega\tau$ the current vector is nearly perpendicular to ε^* (predominantly Hall current). In weakly ionized gases, if both the electron ($\omega\tau$) and ion ($\omega_i\tau_i$) Hall parameters are large simultaneously then the angle is reduced. In this case, the conductivity is reduced due to a phenomenon called "ion slip." Even though τ_i is ordinarily larger than τ_e, ω_i is much smaller than ω_e, such that the product $\omega_i\tau_i$ is usually negligible.

For highly collisional fluids (such as condensed liquids) where $\tau \to 0$, the Hall current is negligible, and the use of Eq. (11-18) without further modification is satisfactory.

Circuits with Conducting Ducts. For MHD flows in electrically conducting ducts with no external load, a return current can exist in the duct walls (Fig. 11-70). For a uniform flow velocity u, the loop voltage equation is written:

$$\oint \varepsilon \cdot dl = 2b\left(uB - \frac{j_y}{\sigma_f}\right) - 2b\frac{j_w}{\sigma_w} = 0 \tag{11-44}$$

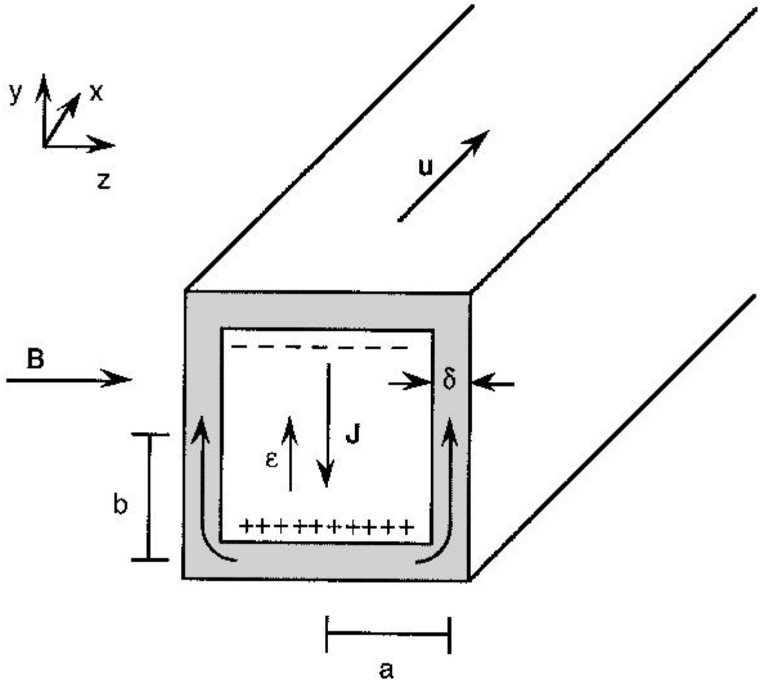

FIGURE 11-70 Current paths in a conducting duct.

where the subscript w denotes values in the wall. Conservation of current dictates:

$$j_y\, a = j_w\, \delta \tag{11-45}$$

so that Eq. (11-44) becomes

$$j_y = \sigma_f u B \frac{\Phi}{1 + \Phi} \tag{11-46}$$

where Φ is the "wall conductance ratio"

$$\Phi = \frac{\sigma_w \delta}{\sigma_f a} \tag{11-47}$$

For this type of uniform flow, Eq. (11-31) can be used to estimate the pressure required to drive a flow at velocity u through the duct.

Basic Flow Characteristics and Power Production

Hartmann Flow. Equation (11-46) predicts zero current when the walls are not electrically conducting; however, the no-slip boundary condition on the fluid at the wall, results in a nonuniform channel velocity and the formation of a boundary layer with a reduced $\mathbf{u} \times \mathbf{B}$ emf, allowing a conducting return-current path through the fluid itself.

For one-dimensional, fully developed (hence inertialess) flow, the momentum equation for $u_x(z)$ becomes

$$\frac{dp}{dx} = j_y B_z + \mu_f \frac{d^2 u_x}{dz^2} \tag{11-48}$$

where dp/dx is constant, and Ohm's Law is

$$j_y = \sigma(\varepsilon - u_x B_z) \tag{11-49}$$

It can be shown that the electric field also is constant, so that one can substitute Ohm's Law into the momentum equation and obtain a simple differential equation for u_x:

$$\mu_f \frac{d^2 u_x}{dz^2} - \sigma_f B^2 u_x = \left(\frac{dp}{dx} - \sigma_f B\varepsilon\right) \tag{11-50}$$

The solution to this equation is

$$\frac{u_x}{u_b} = \frac{\text{Ha}\cosh\text{Ha}}{\text{Ha}\cosh\text{Ha} - \sinh\text{Ha}}\left[1 - \frac{\cosh\text{Ha}\,\frac{z}{a}}{\cosh\text{Ha}}\right] \tag{11-51}$$

where u_b is the bulk average velocity. For large values of the Hartmann number, Eq. (11-51) simplifies to

$$\frac{u_x}{u_b} \approx 1 - \exp\left[\text{Ha}\left(\frac{|z|}{a} - 1\right)\right] \tag{11-52}$$

Equation (11-52) describes a velocity profile that is nearly flat throughout the duct, with thin boundary layers at the walls where viscous drag forces the flow to zero. The thickness of the Hartmann boundary layer scales as a/Ha. The shape of the Hartmann profile is shown in Fig. 11-71 for a range of Hartmann numbers.

Channel Power and Conversion Efficiency. The total electric power generated internally in a channel is equal to the mechanical work against the MHD body force, which is given by the product of the volume flow rate and pressure drop.

For a distributed medium, the Lorentz force leads to the pressure gradient

$$\nabla p = n\mathbf{F}_q = nqv \times \mathbf{B} = \mathbf{j} \times \mathbf{B} \tag{11-53}$$

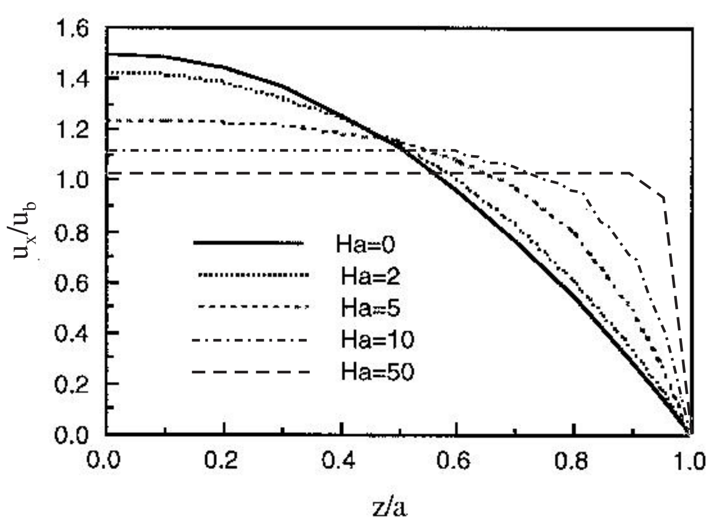

FIGURE 11-71 Normalized Hartmann velocity profiles for Ha = 0, 2, 5, 10, 50.

so that the power density is simply:

$$P_i = \mathbf{u} \cdot \nabla p = \mathbf{u} \cdot (\mathbf{j} \times \mathbf{B}) \tag{11-54}$$

The amount of power delivered to the external load is

$$P_L = \mathbf{j} \cdot \varepsilon \tag{11-55}$$

so that we can write the local electrical efficiency as;

$$\eta_e = \frac{P_i}{P_L} = \frac{j \cdot \varepsilon}{u_x j_y B_z} \tag{11-56}$$

11.10.3 Liquid MHD

Introduction. As seen above, the presence of the **j** × **B** force on the flow of conducting *liquids* can alter the velocity and pressure characteristics of the flow. The interaction with a magnetic field also can significantly affect the onset and character of turbulent fluctuations. These two effects together or individually can dramatically alter the heat-transfer characteristics and fluid drag in closed or open channel liquid flows. Technological applications of such phenomena include cooling systems for magnetic fusion reactors and reduced-drag ship hulls and airplane fuselages.

The MHD force can be applied in such a way that useful work can be done. For example, EM pumps can be designed to precisely control liquid flows, liquid metal flows, in particular, where high temperature and corrosive tendencies prohibit the use of seals in standard mechanical pumps. Such pumps have no moving parts and are extremely reliable. The converse is also possible; MHD generators can produce high currents at low voltages.

This section is concerned with exploring the interaction of the magnetic field with liquid flows both with and without applied electric currents. For incompressible liquids, the equations of Sec. 11.10.2 are valid, with Eq. (11-15) reduced to

$$\nabla \cdot \mathbf{u} = 0 \tag{11-57}$$

A discussion of various applications where such phenomena are encountered is included as well. More comprehensive discussions of many of these subjects can be found in textbooks[3,13–15] as well as the numerous other references provided throughout this section.

Closed Channel Flows

Fully Developed Channel Flow. The term *fully developed,* used to describe Hartmann flow in Sec. 11.10.2, denotes a condition where the velocity profile is no longer changing (zero derivative) in the main flow direction, that is, a flow that has reached a stable steady state driven by a constant pressure gradient, $P = -dp/dx$. The study of fully developed flow with a constant applied magnetic field is useful because the equations can be solved analytically for a variety of cases, and then can be used as benchmark problems for complete numerical algorithms. In addition, the fully developed solutions predict some phenomena of general interest, especially the existence of different boundary layers, which are important for a general understanding of MHD flows. By controlling the amount of current that can flow in the main body of the liquid, these boundary layers and the MHD boundary conditions exert a significant influence on the velocity profile and pressure drop.

Equations and Boundary Conditions for Two-Dimensional Fully Developed Flow. In a rectangular channel (a round pipe is fundamentally the same), we denote the flow direction as x and restrict the applied magnetic field B_o to be constant and aligned with z, as seen in Fig. 11-70. The MHD equations, Eqs. (11-14), (11-16) to (11-18), and (11-57), can be simplified to the following form:

$$\mu_f\left(\frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2}\right) + \frac{B_o}{\mu_m}\frac{\partial B_x}{\partial z} = -P \tag{11-58}$$

$$\frac{1}{\sigma_f \mu_m}\left(\frac{\partial^2 B_x}{\partial y^2} + \frac{\partial^2 B_x}{\partial z^2}\right) + B_o\frac{\partial u}{\partial z} = 0 \tag{11-59}$$

where the velocity vector has only one component in the x-direction, and the magnetic field is the sum of the constant applied field in the z-direction and the small field induced in the x-direction.

$$\mathbf{u} = [u(y, z), 0, 0] \qquad \mathbf{B} = [B(y, z), 0, B_o] \tag{11-60}$$

Terms quadratic in B have been discarded as small, an assumption equivalent to assuming small Re_m, so that B really represents a stream function for the electric current, where

$$\mu_m j_y = \frac{\partial B_x}{\partial x} \qquad \mu_m j_z = -\frac{\partial B_z}{\partial z} \tag{11-61}$$

Walls parallel to the magnetic field (i.e., "side walls") are located at $y = \pm b$, and walls perpendicular to the field (i.e., "Hartmann walls") are located at $z = \pm a$. The boundary condition for the velocity is the standard fluid-mechanical no-slip condition:

$$U = 0 \qquad \text{(at all walls)} \tag{11-62}$$

For certain boundary conditions on the induced field B, analytical solutions exist in the form of infinite series to the system. Much of the classic work in the 1950s and 1960s focused on solving these equations either exactly or approximately by expanding one dimension in an appropriate set of eigenfunctions. Some boundary conditions for the induced field are summarized in Eqs. (11-63) to (11-65). These conditions are derived by considering the behavior of the normal n and tangential s current at the wall, and using Eq. (11-61) to phrase these conditions in terms of the induced magnetic field.

$$B = 0 \qquad \text{electrically insulated wall}^{16,17} \tag{11-63}$$

$$\frac{\partial B}{\partial n} = 0 \qquad \text{perfectly conducting wall}^{18} \tag{11-64}$$

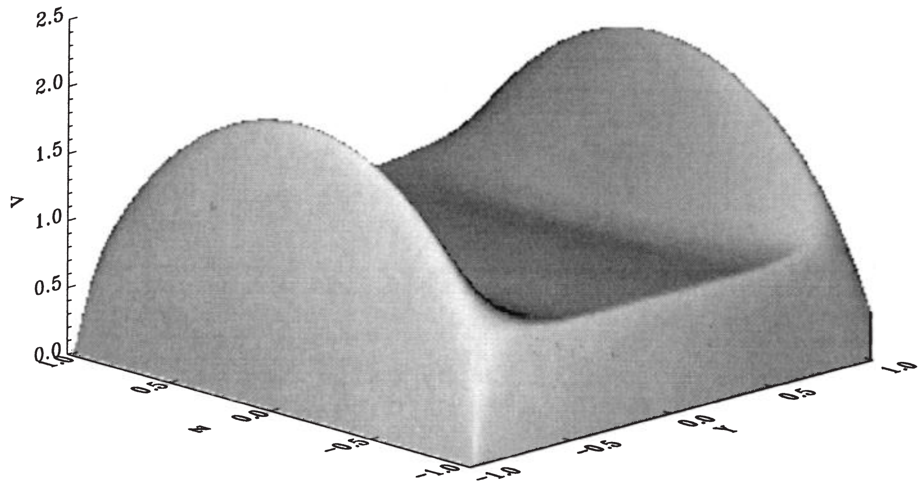
$$a\,\Phi\frac{\partial B}{\partial n} - B = 0 \qquad \text{thin conducting walls}^{19\text{–}21} \tag{11-65}$$

Inviscid Core Flow and Boundary Layers. When Ha is large, the infinite series solutions cited above show (see Fig. 11-72) the existence of a flat, inviscid core region in the central section of the duct, bordered by different types of viscous boundary layers near the Hartmann walls and side walls[22]. In this core region, the driving force of pressure is balanced entirely by the MHD force, $\nabla p = \mathbf{j} \times \mathbf{B}$. The curl of this equation implies that $(\mathbf{B} \cdot \nabla)\mathbf{j} = 0$, indicating that the current density is constant along (applied) field lines in the core. A constant pressure and a constant current produce a flat constant velocity in the core region.

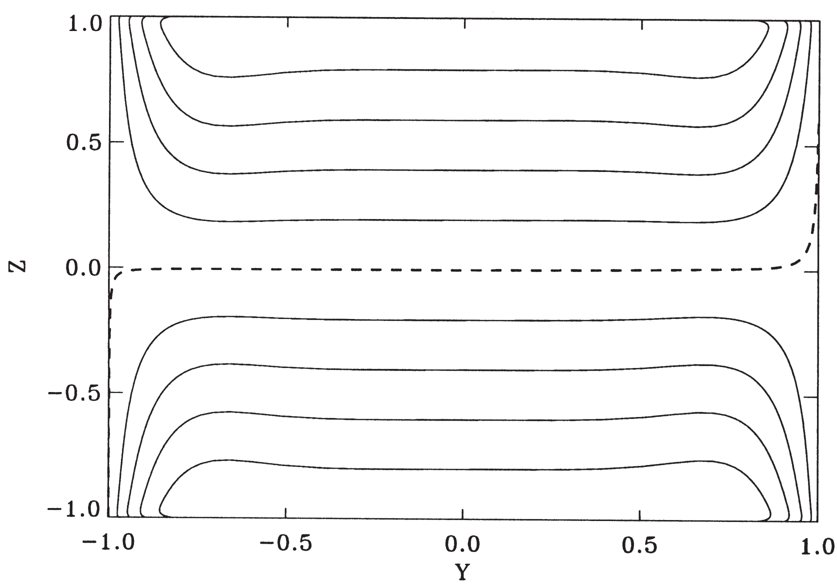
On the Hartmann walls at $z = \pm 1$, a Hartmann layer forms (similar to that seen in the one-dimensional example of "Basic Flow Characteristics and Power Production" under Sec. 11.10.2), as shown in Fig. 11-72. Hartmann layers have thickness of a/Ha, and join smoothly to the core value of the velocity. The Hartmann layer serves as a region where electric currents induced in the core flow in the y-direction can return and complete the current loop. This role as current return path makes the Hartmann layer an active boundary layer, one whose properties control the amount of flow possible in the core region. If the Hartmann wall is electrically conducting, the electric current will flow in the wall as well, and the influence of the Hartmann layer on the core flow will be accordingly reduced.

In most cases, it is the combined conductivity of the Hartmann layer and Hartmann wall that determines the MHD resistance to the fluid flow in the core, and so governs the pressure gradient P (i.e., the pressure gradient required to drive the flow at a given average velocity). In an electrically insulated channel with laminar flow, the increase in P is due to increased shear friction at the walls as a result of the modification of the parabolic laminar velocity profile. The average electromagnetic force in this case is zero since all the current induced in the flow closes through boundary layers in the fluid itself. For large Ha with insulated walls, P increases linearly with Ha. For electrically conducting channels, the net electromagnetic force is no longer zero, but can in fact be quite large. For a perfectly conducting channel with large Ha, P increases proportionally with Ha^2.

On the side walls at $y = \pm 1$, one observes the formation of a different type of boundary layer, alternately known as a "side layer," shear layer," or "Shercliff layer." The interpretation of these layers



(a)



(b)

FIGURE 11-72 Flow profiles in a square ($\beta = 1$) duct with Ha = *75*, insulated side walls, and Hartmann walls with $\Phi = 0.1$: (*a*) velocity profile; (*b*) electric current paths.

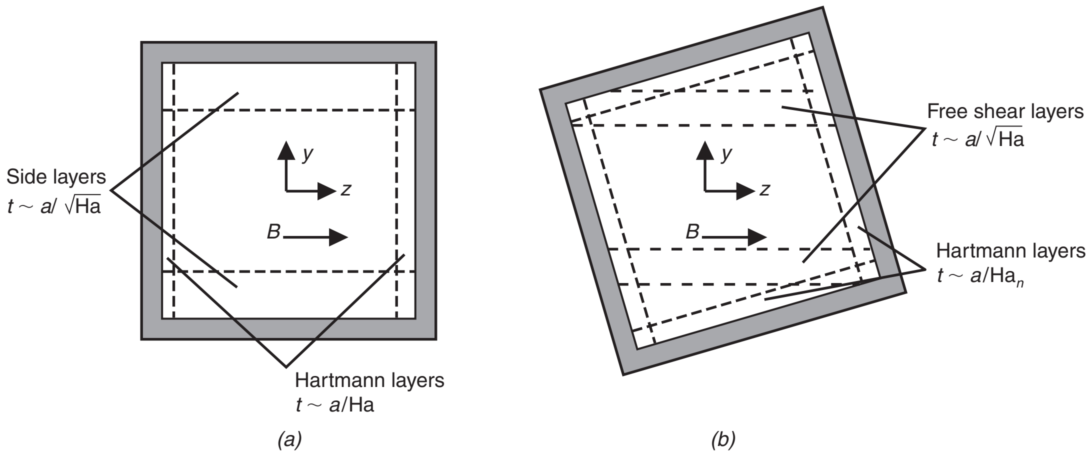


FIGURE 11-73 Boundary layers in a rectangular duct (*a*) aligned with and (*b*) oblique to an applied magnetic field.

is a region where mismatched electric potentials equalize, sometimes with a significant jet of liquid when the Hartmann walls are electrically conducting. (This is the case pictured in Fig. 11-73). These jets can carry an appreciable portion of the net mass flux under certain cases. The thickness of side layers is of order $a/\mathrm{Ha}^{1/2}$, which is much greater than that of the Hartmann layer. Thus, in most cases (except when the Hartmann walls are highly conducting but the sidewalls are not), the electrical resistance of the side layers does not add significantly to the total resistance of the return current path, and so does not influence the core velocity. For larger Hartmann numbers on the order of 10^3 or 10^4, the flow in the core region drops almost to zero, and the velocity jets can be up to a factor of Ha times the core flow velocity. Obviously, such velocity structures can be very important in determining heat transfer in liquid metal coolant pipes, as well as affecting corrosion, mass diffusion, and other important physical processes.

Hartmann layers will form on any wall that has a normal component of B_o, but shear layers form only along the magnetic field lines. Thus, if the channel is not perfectly aligned with B_o, then all walls will have Hartmann layers, and the shear layers will detach from the wall and form about the magnetic field line that intersects the corner of the duct (see Fig. 11-73*b*). Shear layers that extend into the fluid are known as *free shear layers*.[23]

Developing Flows, Variable Fields, Variable Duct Sizes, and Entrance Effects. Few practical MHD flows are fully developed over their entire length. Developing flows are inherently three-dimensional since the motion, electric currents, and magnetic field and its gradients invariably are oriented in different directions. Sudden expansion and other change in the magnetic field, channel shape, or channel electrical conductivity can result in significant changes in velocity profiles and additional three-dimensional pressure drops. Even local regions of reversed flow are possible in different MHD duct flow configurations, as in the case of a locally conducting crack in a pipe wall covered with an electrical insulator coating.

Only when the flow has advanced sufficiently far from these disturbances will it again become fully developed and assume the characteristic velocity profiles and pressure drops discussed above. A rigorous treatment of the effects of changes in field and geometry possible in MHD machines are available in the literature.[3,13,14] One example of practical interest is the entrance of a rectangular duct into a magnetic field (typical of MHD conduction pumps discussed later), and the so-called M-shaped velocity profile. Use of the core flow approximation, described in more detail below, is a powerful tool for analyzing these MHD phenomena at large Ha.

Duct Flows in Varying Magnetic Fields. Consider a rectangular duct with the orientation shown in Fig. 11-70, but assuming that at $x = 0$, the magnetic field changes abruptly from zero to some

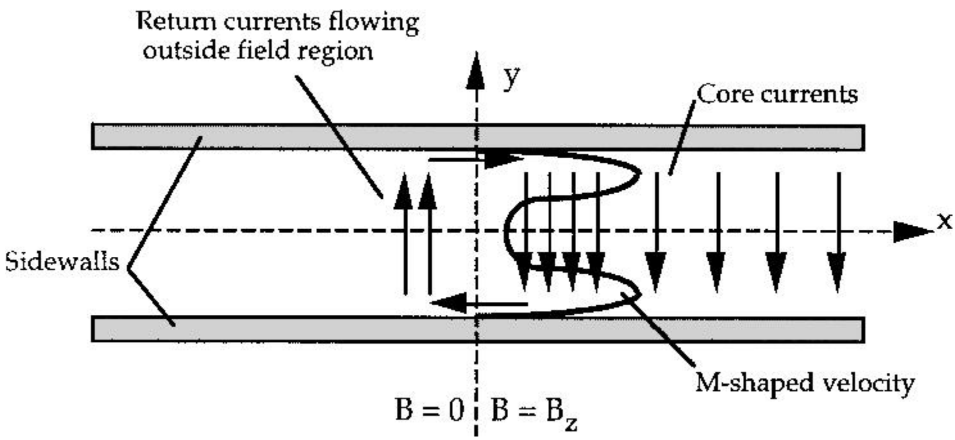

FIGURE 11-74 Simplified current paths and velocity profile for duct in a variable magnetic field.

value B_z. (The case of a more gradual transition does not fundamentally change the description.) As in the fully developed case, the $\mathbf{u} \times \mathbf{B}$ emf induces a current in the negative *y*-direction. At the sidewalls, the current can turn into the *z*-direction and then flow to the Hartmann walls, but now it can also turn (more easily) into the *x*-direction and return to the other sidewall through the region of no field directly adjacent to the region of high field (see Fig. 11-74). The same electric field set up by the charge separation that drives return current through the Hartmann layers (walls) will drive this current in the no-field region. Thus, an additional current closure path exists, and so more core current can flow in the high field region as compared to the corresponding fully developed flow in a region of constant B_z. This additional current results in a greater pressure drop, usually denoted Δp_{3D}.

The current in the *x*-direction near the sidewalls also causes a distortion of the velocity profile near the region of changing B_z. The j_x current, which is positive in the upper part of the channel ($y > 0$), will induce a force in the negative *y*-direction near the sidewall. This force will essentially pressurize the sidelayer, and cause a velocity jet to form in the sidelayer. A similar result occurs in the lower half ($y < 0$) plane. The result is a velocity profile called "M-shaped," where the velocity is reduced in the core due to increased $\mathbf{j} \times \mathbf{B}$ forces, but increased in the sidelayers. This looks very similar to the sidelayer jets that can occur in fully-developed flow when the Hartmann walls are electrically conducting, but the M-shaped profile forms in the developing region even when the entire channel is nonconducting. Like the fully developed sidelayer jets, the M-shaped velocity profile is shorted out when the sidewalls are highly conducting, since the j_x current preferentially flows in the walls in this case, and no force is induced in the liquid itself. The same effect occurs at the exit of a magnetic field, and even if the field is more gradually varied.

Mathematically, the formation of the M-shaped velocity profile can be understood by taking the curl of the steady invicid equation of motion:

$$\nabla \times \{\rho(\mathbf{u} \cdot \nabla)\mathbf{u} = -\nabla p + \mathbf{j} \times \mathbf{B}\} \tag{11-66}$$

and considering the *z* component of vorticity:

$$\rho u \frac{\partial \omega_z}{\partial x} \cong -j_x \frac{\partial B_z}{\partial x} - B_z \frac{\partial j_y}{\partial y} \tag{11-67}$$

Both terms on the right hand side of Eq. (11-67) will be negative in the upper right quadrant of Fig. 11-74, and positive in the lower right quadrant. These sources of *z*-directed vorticity can be thought of as swirling motion that decelerates the center and shifts fluid to the sidelayers, causing the formation of the velocity jets. It is easily seen that the formation of sidelayer jets in fully developed flow is also governed by the last term in the above equation, which is present in regions of constant B_z as well.

General Core Flow Equations. For high conductivity liquids like liquid metals, calculations at high Ha can become very difficult unless simplifying approximations are made. One such approximation indicated by the above discusion is the so-called core flow approximation, where the momentum equation is simplified to

$$\nabla p = \mathbf{j} \times \mathbf{B} \tag{11-68}$$

In 1968, Kulikovskii[24] showed that the core equations (Eqs. 11-18, 11-20, 11-57, and 11-73) could be manipulated in such a way as to reduce the solution for any flow geometry without sidewalls or internal shear layers to, at most, 4 two-dimensional partial differential equations. In addition, the magnetic field is assumed to be externally applied ($\mathrm{Re}_m = 0$). The unique features of these equations allow us to separate components of velocity and current into components parallel and perpendicular to the magnetic field:

$$\mathbf{j}_\perp = \frac{B}{B^2} \times \nabla p \tag{11-69}$$

$$j_\parallel = \int \left(\mathbf{B} \times \nabla \frac{1}{B^2}\right) \cdot \nabla p \, dl + A_1 \tag{11-70}$$

$$\mathbf{u}_\perp = -\frac{1}{\sigma B^2} \nabla p + \frac{\mathbf{B}}{B^2} \times \nabla \varphi \tag{11-71}$$

$$u_\parallel = \int \left[\left(\mathbf{B} \times \nabla \frac{1}{B^2}\right) \cdot \nabla \varphi + \left(\nabla p \cdot \nabla \frac{1}{\sigma B^2}\right) + \frac{\nabla^2 p}{\sigma B^2}\right] dl + A_2 \tag{11-72}$$

$\mathbf{j}_\perp$ is obtained by taking the cross-product of $\mathbf{B}$ with the momentum equation (Eq. 11-68). Similarly, $\mathbf{u}_\perp$ is obtained by taking the cross-product of $\mathbf{B}$ with Ohm's Law [Eq. 11-18]. $j_\parallel$ and $u_\parallel$ are obtained by integrating the conservation laws (Eqs. 11-20 and 11-57 along the magnetic field direction, dl, defined by $\nabla_\parallel = d/dl$.

Finally, the electric potential can be related to the parallel current:

$$\sigma \frac{\partial \varphi}{\partial l} = j_\parallel \tag{11-73}$$

$$\sigma \varphi = \iint \left(\mathbf{B} \times \nabla \frac{1}{B^2}\right) \cdot \nabla p \, dl' dl + A_1 l + A_3 \tag{11-74}$$

The boundary conditions at the walls completely determine the unknown functions (A_1, A_2, p, and ϕ). There are four boundary conditions. Zero mass flux into the walls and conservation of current are applied twice for each field line: once where the field line enters the fluid and once where it exits.

$$\mathbf{u} \cdot \hat{n} = 0 \tag{11-75}$$

$$\Phi \nabla^2 \varphi = \mathbf{j} \cdot \hat{n} \quad \text{for conducting ducts} \tag{11-76}$$

$$\frac{1}{Ha} (\nabla \times u) \cdot \hat{n} = \mathbf{j} \cdot \hat{n} \quad \text{for nonconducting ducts} \tag{11-77}$$

This method has been successfully applied to the solution of a number of basic geometries in Ref. 25. and formulated in a very general fashion in Ref. 26. For symmetric problems, the constants A_1 and A_2 can be eliminated. The constant A_3 can be replaced by the evaluation of φ at any location along l. (For example, A_3 can be replaced by φ_w, the potential at one wall.) In this case, only two partial differential equations remain for p and φ_w.

The resulting set of linear partial differential equations can be solved using any appropriate numerical technique. A finite difference representation was applied and SOR was used to solve the resulting system of algebraic equations.[25] Corrections for sidelayers and internal shear layers also have been developed.[27]

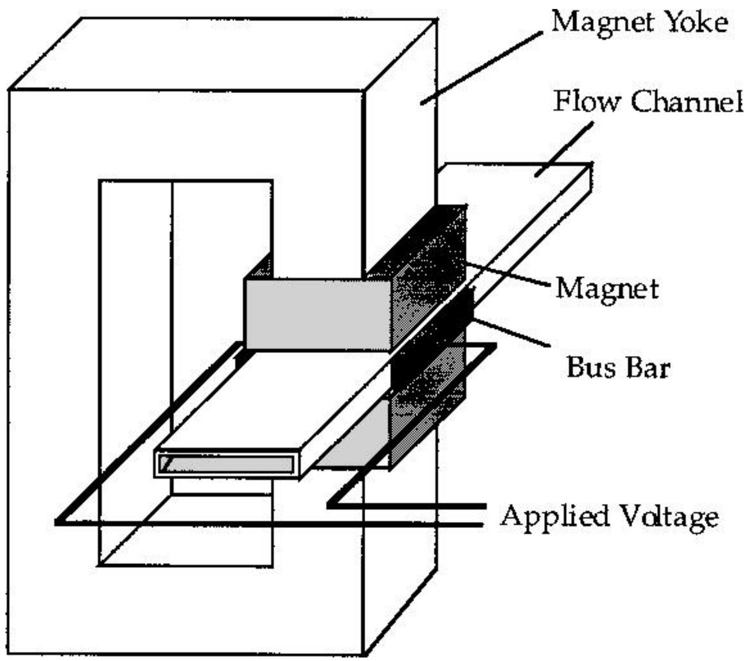

FIGURE 11-75 Generic dc conduction pump with rectangular channel.

EM Pumps and Flowmeters. One of the more practical uses of the MHD force is in pumping systems, where electrical energy is converted directly into force on the working liquid. EM pumps (as they are commonly known) have been in existence for many years, and many different designs have been successfully developed and employed. A generic conduction style pump is shown in Fig. 11-75. Another common MHD device is the EM flowmeter, where the potential induced by fluid motion is measured and used to infer the average flow rate.

These devices can be constructed with no moving parts and no direct contact with the working liquid. This is a distinct advantage if high temperature and/or corrosive liquids must be handled. The absence of seals or moving parts leads to a highly reliable system. In addition, EM pumps are typically controllable, and even reversible, by varying the magnitude and direction of the applied current.

MHD Flowmeters. Equation (11-36) suggests that the voltage induced by the $u \times B$ emf would provide an ideal method by which one could measure the average flowrate of a conducting liquid. However, it is impossible to achieve a completely open-circuit configuration as described by Eq. (11-36), as return current will flow in pipe walls and boundary layers of all finite size channels. Some accounting for these return currents must be included when determining a relation for the voltage signal as a function of the flow velocity. Ohm's Law, as written in Eq. (11-37), shows the effect of return currents on the measured voltage signal in a rectangular channel like that in Fig. 11-69:

$$-\varepsilon = \varphi/2b = uB - j/\sigma \tag{11-78}$$

where φ is the voltage signal. Any core current allowed to flow, then, reduces the measured voltage signal by some amount. Using the result of Eq. (11-46) for the core current density, we see that the voltage signal is

$$\varphi = \frac{2buB}{1 + \Phi} = \frac{QB}{2a(1 + \Phi)} \tag{11-79}$$

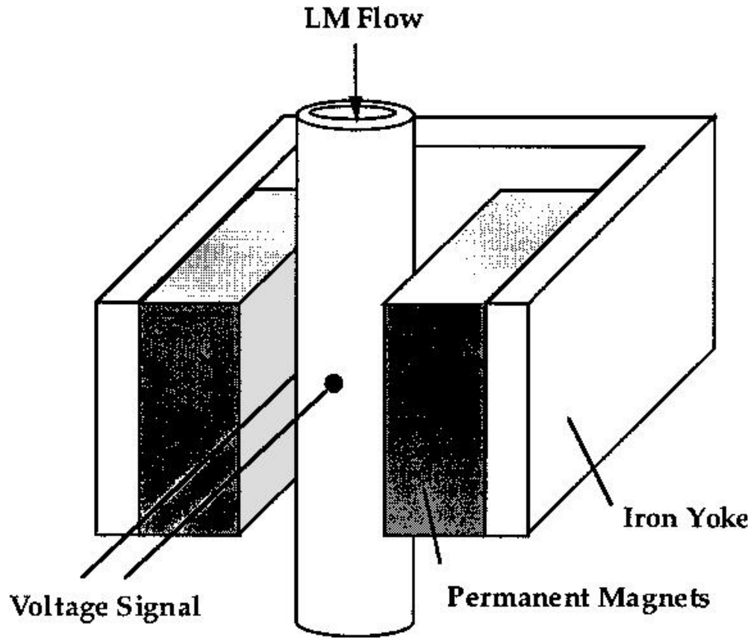

FIGURE 11-76 Generic dc EM flowmeter.

which is independent of the electrical conductivity of the liquid, except as it appears in the wall conductance ratio Φ. This means that many moderately conducting liquids can also be measured by this method, especially when an electrically insulated channel can be used. (For insulated channels, substitute Ha^{-1} for Φ in Eq. 11-79.) For common laboratory and industrial values of the flow rate Q, magnetic field induction, and duct dimensions, the measured voltage is typically in the range of hundreds of microvolts to several millivolts.

Most MHD flowmeters do not use rectangular channels, but instead use round pipes that can fit easily into standard piping systems, like that shown in Fig. 11-76. Reference 28 suggests the following relation for the volumetric flowrate in a pipe made of an electrically conducting material:

$$Q = 3162 \frac{k_4}{k_1 k_2 k_3} \frac{d\varphi}{B} \tag{11-80}$$

where Q is in units of gpm, B is in Gauss, the inside pipe diameter d is in inches, and the electric leads to measure φ are attached to the outside of the pipe wall.

Equation (11-80) takes into account, in the form of semiempirical multiplicative constants k_{1-4}, several nonideal effects that were ignored in Eq. (11-78). k_1 is the pipe-wall current shunting correction factor defined as

$$k_1 = \frac{2dD}{D^2 + d^2 + \dfrac{\sigma_w}{\sigma_f}(D^2 - d^2)} \tag{11-81}$$

where D is the outside pipe diameter, also in inches.

Poorly conducting liquids tend to have a k_1 correction factor that deviates significantly from unity, meaning that the electrical signal is lower for the same flowrate and so more difficult to measure accurately. k_2 is the magnetic field end-effect correction factor. It is empirically obtained as a function of the magnet pole piece length L. Typical values are given in Table 11-20. k_3 is the magnetic material temperature correction factor, which accounts for changes in the magnetic field as a function of temperature of the permanent magnetic material or electromagnet windings. The manufacturer of such materials typically provides the appropriate temperature correction factors. k_4 is the pipe thermal expansion correction factor, which accounts for changing pipe sizes as a function of temperature and can be expressed as $k_4 = 1 + \gamma\,(T - T_o)$, where γ is the thermal expansion coefficient for the pipe material. For 304 stainless steel, the value of γ is 9.6 μ-in/in F.

TABLE 11-20 Magnetic Field End Effect Correction Factors[28]

L/D	k_2
1.5	0.91
1.9	0.96
2.4	0.98
3.0	0.99

The idea behind these simple dc flowmeters has evolved into more complicated implementations where pulsed dc or pulsed ac electromagnets are used to sample the flowrate at some pulse rate. The pulsed electromagnet devices have lower power consumption and lower heat generation in the electric coils. These devices are available commercially[29] with all manner of pipe materials and sizes and can be inserted easily into existing piping configurations. Small units ($d \approx 1$ in) have accuracies of around 1% at full scale. The accuracy tends to improve as pipe sizes become larger.

Conduction Pumps. Liquid metal conduction pumps, or "Faraday" pumps, consist of a rectangular channel in the gap of a magnet (either a permanent or electromagnet) where an electric current is passed through the conducting liquid perpendicular to the field. The resulting $\mathbf{j} \times \mathbf{B}$ force drives the flow. This type of pump is a conceptually simple extension of the rectangular duct flows discussed above with sidewalls replaced by electric bus bars connected to an outside voltage source, which drives current in the direction opposite to the $\mathbf{v} \times \mathbf{B}$ emf.

To understand the pressure and flowrate behavior of a simplified conduction pump, pictured in Fig. 11-75, it is helpful to represent the pump by an equivalent electrical network Fig. 11-77. Here, R_{LM} is the effective resistance of the liquid in the channel, R_{Loss} is the resistance of any loss paths such as the channel walls and fringing paths outside the magnetic field area, and E_i is the voltage induced in the flow, which works against the applied current I_a. Assuming slug flow of flow rate Q in a rectangular pumping channel of flow length L within the field, with walls of thickness δ_w and electrical conductivity σ_w, the following approximations can be applied:

$$R_{LM} = \frac{b}{La\sigma_f} \qquad R_{\mathrm{Loss}} = \frac{b}{L\delta_w\sigma_w} \tag{11-82}$$

$$I_{LM} = \frac{2a\Delta p}{B} \qquad E_i = 2buB = \frac{QB}{2a} \tag{11-83}$$

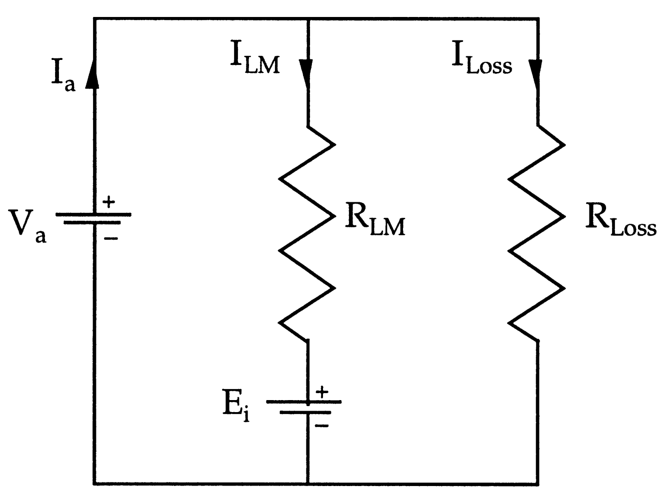

FIGURE 11-77 Circuit network equivalent of a conduction pump.

The duct geometry used is the same as in Fig. 11-70, and the R_{loss} term only takes into account current losses through conducting Hartmann walls for simplicity. The circuit then can be solved to give the following linear relationship between pressure and flow rate:

$$\Delta p = \frac{BAI_a/2a - B^2LQ\Phi\sigma_f}{A(1 + \Phi)} \tag{11-84}$$

where $A = 4ab$ is the flow cross-sectional area, and Φ is the wall conductance ratio defined in the usual way as in Eq. (11-47). This relationship is plotted in Fig. 11-78 for a small conduction pump with various values of Φ. We see the obvious need for thin and/or low conductivity walls in the pumping channel structure in order to maximize the pumping power. In the case of $\Phi = 0.1$, at flowrates above 7.51/s, all of the applied current is simply shunted through the walls, as the induced emf is larger than the applied voltage. Current flow in the core is reversed, and MHD drag, instead of pumping, results.

The applied voltage for this particular pump, assuming $Q = 10$ l/s and $\Phi = 0.01$, is only 213 mV. The inherently low voltage and high current of conduction pumps is one of their disadvantages, since they require special power supplies capable of coupling efficiently to such a load. Possible power supplies that are more efficient than standard transformer-rectifier systems include homopolar and unipolar generators, which can be up to 80% efficient. To increase the voltage of the load somewhat, it is common to run the field coil windings of the electromagnet in series with the LM section, so that only one supply (albeit at a greater power level) is needed.

The power dissipated in the conduction pump system for our example above is

$$P_a = 0.215 \text{ V} \cdot 1500 \text{ A} = 322 \text{ W} \tag{11-85}$$

The power delivered to the fluid ($Q \cdot \Delta p$) is $P_f = 0.01 \text{ m}^3/\text{s} \cdot 25.7 \text{ kPa} = 257$ W. This gives an efficiency of 81%. A formula for the electrical efficiency in the general case is easily constructed in terms of either the applied voltage or the applied current:

$$\eta_e = \frac{Q\Delta p}{V_a I_a} = \frac{BQ}{2aV_a\left(1 + \dfrac{\Phi}{1 - BQ/2aV_a}\right)} = \frac{2bI_a - BLQ\sigma_f\Phi}{2bI_a\left(1 + \dfrac{2bI_a}{BLQ\sigma_f}\right)} \tag{11-86}$$

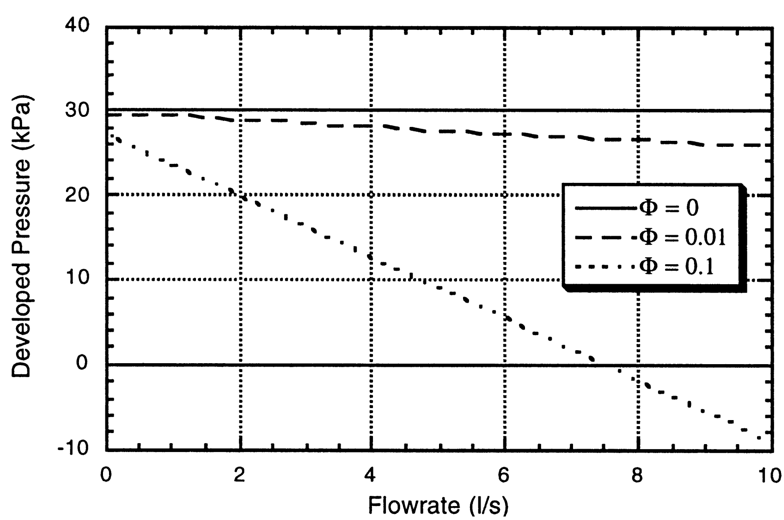

FIGURE 11-78 Pressure head of a conduction pump for various wall conductance ratios and the following parameters: $a = 5$ cm, $b = 15$ cm, $L = 30$ cm, $B = 2\ T$ (iron core electromagnet), $I_a = 1{,}500$ A, and $\sigma_f = 10^6\ \Omega$ m.

However, the losses in the wall included in this simple calculation are not the only losses the conduction pump experiences. Applied current usually fringes outside the area of the applied magnetic field where it induces no $\boldsymbol{j} \times \boldsymbol{B}$ force. Energy is lost to the damping of turbulence and restructuring of the average velocity profile as the liquid enters the magnetic field area. Energy losses occur due to friction of the flow on the channel walls and the applied magnetic field is altered by the field induced by the applied current itself. All of these effects decrease the net efficiency of conduction pumps to the order of 15% to 20% for small pumps, and 40% to 50% for larger pumps. Including losses in generators and field windings, the bus bar efficiency for liquid metal conduction pumps varies from 10% to 40%, increasing with pump size.[30]

As seen from Eq. (11-86), even in the absence of losses other than the resistance of the LM itself, the electrical efficiency of the system is equal to $\eta_e = \eta_{\text{ind}} = 2buB/V_a$, which is the induction efficiency, that is, the ratio of induced voltage due to the $\boldsymbol{u} \times \mathbf{B}$ emf to the applied voltage V_a.

Induction Pumps. An alternative to the conduction pump is the induction pump, where electric currents are induced in the liquid metal by means of a time-varying magnetic field, producing a $\boldsymbol{j} \times \boldsymbol{B}$ force with the instantaneous field to drive the flow. Many types of induction pumps are possible. Here we focus on the flat linear induction pump and the annular linear induction pump. The advantage of induction pumps is that they can be driven easily by single-phase or 3-phase ac power sources, possibly with a variable transformer for control of the flow rate. Typical disadvantages are greater power losses and the need for electrical insulation at high temperatures close to the working liquid.

The flat linear induction pump, or FLIP is conceptually similar to an ac induction motor. The 3-ϕ winding, however, produces a sliding, rather than rotating magnetic field, which tends to pull the fluid along. The action of this class of pump is easily pictured by contemplating the simplified induction pump shown in Fig. 11-79. If the peak vertical magnetic field is sliding to the right, leaving behind a slightly reduced magnetic field, a current loop will be induced. This induced current tries to maintain the field at its original strength. The induced current into the page will be in a region of stronger magnetic field than the current coming out of the page, since the field peak is propagating to the right, so the net $\boldsymbol{j} \times \boldsymbol{B}$ force will be to the right.

The disadvantage to these systems is that in order to have a relatively wide channel for liquid flow, the gap between the stators must be larger than that in induction motors, and the field losses are

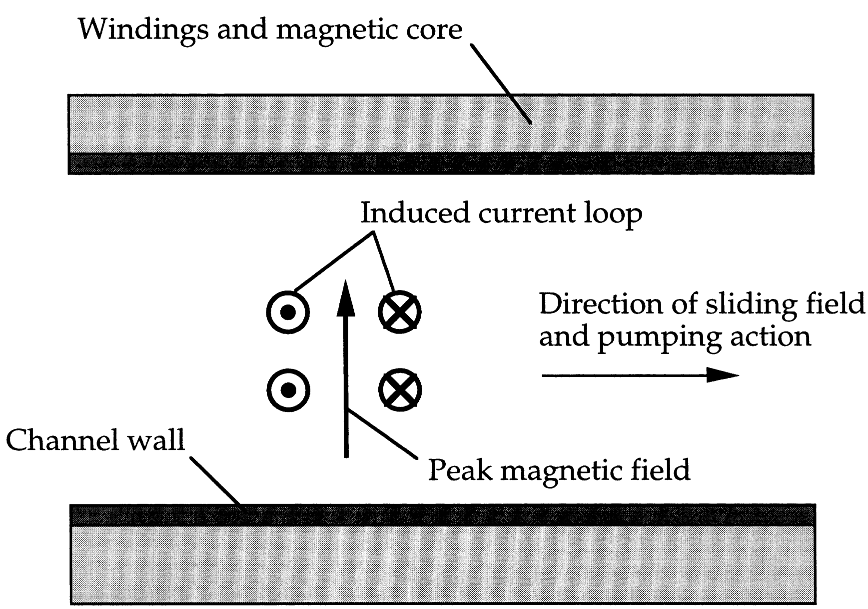

FIGURE 11-79 Operation of an induction pump.

relatively higher. In addition, field fringing occurs at the boundaries of the wide, flat channel where the magnetic core stops. One-sided stator induction pumps are also possible, but losses will be even higher. Such systems have uses as EM stirrers and for ship propulsion, as will be discussed later.

The annular linear induction pump (ALIP), sometimes called an Einstein-Szilard pump, is a modification of the FLIP so that end effects do not cause additional field losses. The ALIP consists of an annular flow region with an internal magnetic core. Induced currents flow in a continuous loop through the liquid, and no core edge exists off which magnetic fields fringe. In essence, an ALIP is like a FLIP that has been bent around until the free ends are joined.

Design guidelines and photographs of various styles of EM induction pumps are available in Ref.[31].

MHD Ship Propulsion. Another potential use of EM pumping technology is MHD thrusters for ship propulsion. Seawater has a moderate electrical conductivity, of the order of 5 $(\Omega \cdot \text{m})^{-1}$, and under the appropriate set of conditions can be pumped by the Lorentz force. Care must be taken to avoid large losses in conducting walls in this application, but this is more easily done when the working fluid is seawater rather than high temperature liquid metals.

Conduction pump thrusters[32] are more commonly envisioned for MHD ship propulsion because of the difficulty inducing large currents in poorly conducting water. Using the above equations for the conduction pump, we find that the ideal conduction pump thruster will deliver a power to the liquid equal to

$$P_w = F_{\text{EM}}u = (1 - \eta_e)\eta_e \frac{\sigma_f V_a La}{b} \tag{11-87}$$

For a given size channel (usually limited by the size of the craft under consideration), a given applied voltage (usually limited by the power supply aboard the craft, e.g., a battery), and a given liquid (seawater), the mechanical power is maximized at $\eta_e = 50\%$. This means one-half of the electrical power supplied is lost as Ohmic heating. Thruster designers must decide whether their goal is to maximize mechanical power or to minimize energy consumption.

For a moderately sized submarine (10-m diameter, 83-m length) using four conduction thrusters with length $L = 55$ m, $b = 5$ cm, and $a = 15$ cm, a 5-T field is sufficient to generate reasonable thrust and efficiency. At a speed of 36 knots, the thrusters will consume about 66 MW of electric power, requiring a 200 MW thermal nuclear plant with a typical thermal conversion efficiency (excluding power needed for other boat systems). This level of power is not unreasonable for a submarine of this size. Superconducting magnets are necessary for this field strength and core size, since the Ohmic losses in resistive magnets would be unacceptable.

At least one design using an induction pump thruster has been advanced. The "ripple motor" described by Mitchell and Gubser[33] utilizes a 3-ϕ ac solenoidal winding around a core of seawater. An annulus of liquid sodium or other liquid metal serves as an intermediate layer separated from the seawater by a flexible membrane. The thickness of the sodium layer is matched to the skin depth of the ac field. The traveling magnetic field sets up a traveling pressure wave in the sodium and thus a traveling wave on the flexible membrane. This wave pushes along the seawater and eventually ejects it out of the trailing end of the thruster, providing the thrust.

Turbulence in Liquid MHD Flow. MHD forces can have a large effect on the turbulence structure of liquid flows. Not only does the induction of a current density result in Ohmic dissipation of energy, a new energy loss mechanism that augments the viscous dissipation, but the field also changes the average velocity profiles as discussed in previous sections, resulting in new turbulence-creation scenarios as compared to non-MHD flows. The magnetic field is typically thought to *laminarize* already turbulent flows or to prevent the transition to turbulence in laminar flows. In electrically conducting channels,[13] core velocity fluctuations are damped for values of Ha/Re $>$ 0.008. Near the sidelayer jets, though, turbulent fluctuations increase, indicating that the strong velocity jets, like those depicted in Fig. 11-71, are unstable and periodically break down. For Ha/Re $>$ 0.02, these fluctuations are also damped (or at least unresolved due to boundary layer thinning), and the liquid flow becomes effectively laminar.

Electrically insulating channels exhibit a change, as the field is applied, from standard turbulence to a quasi-two-dimensional turbulence, where the vorticity of the turbulent fluctuations is predominantly aligned with the direction of the field. Turbulence fluctuations of this type can be quite long-lived and probably result from the reorganization of the flow as it enters into a magnetic field. The formation of M-shaped velocity structures, which then decay into rotating vortices, is the source of such fluctuations. In an infinitely long, electrically insulated channel, all turbulence fluctuations are eventually damped when Ha/Re > 0.008.

Control of turbulence near the wall of a ship or submarine can in theory reduce the overall drag on the structure. Early work on MHD channel flows[34] showed that the pressure drop in an initially turbulent LM duct flow could be reduced by the judicious application of a magnetic field. (Too strong a field will result in increased MHD drag, as discussed above.) For the control of turbulence near ships, one must contend with the fact that seawater is a poor electrical conductor, and that induced currents alone will not dissipate enough energy to stabilize a turbulent boundary layer. Instead, currents must be generated by an applied voltage.

One such scheme to reduce drag on, and radiated noise from, a flat plate is to construct the surface with alternating north and south pole magnets interspersed between positive and negative electrodes (see Fig. 11-80). The crossing lines of magnetic field and current induce a $\boldsymbol{j} \times \boldsymbol{B}$ force in the streamwise direction, acting as a sort of one-sided conduction pump. Preliminary experiments[35] have shown that turbulent fluctuations can be reduced over much of the boundary layer when the modified interaction parameter ($N^* = j_o B_o \theta / 0.5 \rho u_\tau^2$, where j_o, B_o are the current, field at the electrode, magnet surface, and θ and u_τ are the standard momentum thickness and friction velocity of the boundary layer, respectively) is order one or larger. The boundary layer is found to approach an asymptotic value, rather than growing indefinitely and breaking down due to instability. Work in this area by a number of researchers is continuing.

Open Channel Flows. Open channel flows of liquids in magnetic fields are of interest for metallurgical and welding applications where melts and melt layers are influenced by electric currents and applied magnetic fields. There is also interest in open channel MHD flows in magnetic fusion energy reactors where it might be advantageous to have high heat flux surfaces facing the burning plasma be covered with a flowing liquid metal layer.[36] When the problem of open channel MHD flows is examined closely, one finds that the complicated motion of closed-channel duct flows described above becomes even more complicated when the liquid interface (free surface) is allowed to move in response to MHD forces.

The interfacial boundary condition for open-channel flows requires that the tangential component of the viscous stress must be continuous. The term "free surface" implies the less general case where the liquid surface is unhampered by friction with a gas phase outside the liquid region, and so the tangential component of the stress vanishes. However, this condition is changed in MHD flows

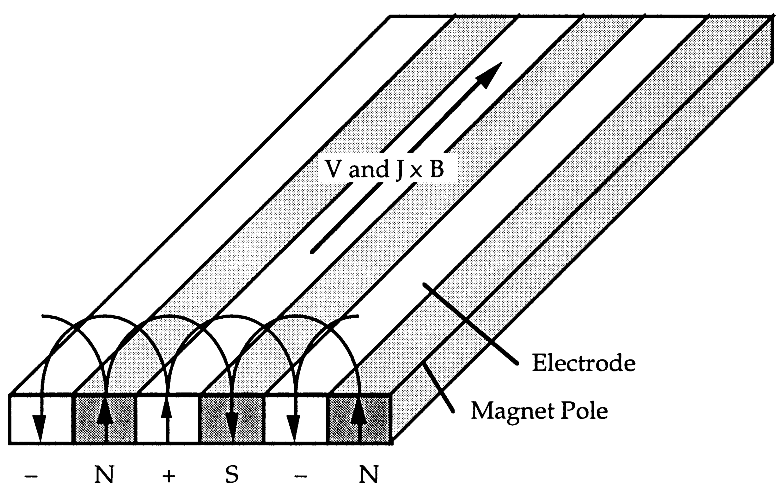

FIGURE 11-80 Turbulence reduction technique for seawater: alternating magnets and electrodes.

where the total stress, the sum of the tangential viscous and magnetic stresses, must be continuous. The magnetic stress is represented by the Maxwell stress tensor (found elsewhere in this handbook), and can exist in vacuum as well as in conducting media. This EM stress vanishes for temporally and spatially uniform magnetic fields, but needs to be considered in the general case.

Some simple cases of flow down an inclined plate are analyzed by Alpher,[37] Aitov,[38] Morley[39] and others. It is seen that for a magnetic field normal to the surface of a very wide, long plate, a half-Hartmann velocity profile forms in the surface normal direction. The flow is essentially that shown in Fig. 11-70 split open, where $z = 0$ is the free surface and $z = 1$ is the back plate. The Hartmann layer on the plate is exactly the same as one would expect in channel flow, and provides a return-current path for currents generated in the core. Also similar to flow in ducts, the modification of the velocity profile and the unbalanced $\boldsymbol{j} \times \boldsymbol{B}$ force can cause an increase in drag. For flow down an inclined plate, where there can be no applied pressure driving the flow, this results in a thickening and slowing down of the flow. More complicated magnetic field and flow geometries are considered in Ref. 40 where the effects of magnetic field gradients are especially emphasized.

Similar to the effect of magnetic fields on turbulence is the stabilizing effect of magnetic fields at the free surface. It has been shown both theoretically and experimentally that a constant strong magnetic field can stabilize an otherwise wavy free surface, resulting in a smooth flow. For the flow described in the preceding paragraph, Hsieh[41] found that for high Ha, the surface is stable to long wavelengths provided that

$$\text{Re} < \frac{\exp(2\text{Ha})}{4} \cot\theta \qquad (11\text{-}88)$$

where Re is the Reynolds number of the flow and θ is the angle of inclination of the plate to gravity. This is a much greater range of Reynolds number than the classical non-MHD result of Re $<$ 5/4 cot θ.

Applications in Metals Processing. Metals processing requires the handling of large amount of liquified metals in a controlled manner. Certainly the MHD devices discussed above, for example, pumps and flowmeters, will have manifold applications in this industry. But it is also possible to actively control the shape of a free surface by use of high-frequency ac magnetic fields.

A high-frequency magnetic field in the region around an electrical conductor, like a liquid metal, takes a finite time to penetrate into the conductor. It is easily seen from Eq. (11-23) in the limit of slow motion of the liquid $\boldsymbol{u}$ as compared to the sinusoidal oscillation frequency ω, that:

$$\frac{B}{\tau} \cong \frac{1}{\sigma_f \mu_m} \frac{B}{\delta^2} \qquad (11\text{-}89)$$

If the characteristic time τ is taken as $2\omega^{-1}$, then the skin depth $\delta \cong (2/\sigma_f \mu_m \omega)^{1/2}$. This means that if δ is small, the field cannot penetrate far into the conducting medium during the oscillation period of the ac field. In reality, currents induced in the skin region act to nullify the applied field variation. The resulting $\boldsymbol{j} \times \boldsymbol{B}$ force can have both a pressure-like component and a tangential stress component. The pressure component can be applied to the free surface in such a way to deflect and shape jets of liquids issuing from a nozzle and even levitate an entire melt. The tangential stress components can be used to induce motion and stir the melt as desired. The induced currents can also provide significant Joule heating in the skin region.

Using a combination of all these effects, it is possible to design various MHD devices like levitating, self-stirred, induction furnaces where the LM never comes in contact with a solid crucible surfaces, and MHD granulators where free LM jets or sheets decay into droplets that then solidify into powders. The interested reader is referred to Davidson,[3] Moreau,[13] and Kolesnichenko[2] for more detailed mathematical descriptions of these problems with more complete bibliographies.

11.10.4 Gaseous MHD

Introduction. Since 1959, substantial effort has been devoted to exploring the conditions under which a conducting gas moving through a magnetic field might generate useful electrical power. The primary motivation for the development and use of MHD generators in central-station power plants is the production of power at lower cost through reduced fuel costs per unit of energy produced, traded off against additional capital and operating costs. Operation at high thermal conversion efficiency provides the added benefit of reduced thermal discharge from the plant, thus reducing thermal pollution as compared with conventional steam plants with $\eta \sim 40\%$ or nuclear plants with efficiency as low as 30%.

As originally envisioned, the MHD generator was a "topping" unit on an otherwise conventional steam turbine-generator station. In this case, electric power is generated in the MHD unit, and its exhaust heat, with temperature as high as 2,200 K, is used to generate steam. The limiting Carnot efficiency for such a station might be raised from a maximum of about 65% ($T_1 = 850$ K, $T_2 = 300$ K) upward toward 85% ($T_1 = 2{,}600$ K, $T_2 = 420$ K). The net efficiency of the combined cycle can be expressed as $\eta_1 + \eta_2(1 - \eta_1)$, where η_1 is the efficiency of the MHD generator and η_2 is the efficiency of the "bottom" steam plant. Typical values are $\eta_1 = 0.25$ and $\eta_2 = 0.4$, for an overall efficiency of 0.55.

Perhaps the greatest importance of the MHD steam plant, as now envisioned, is its potential for very low air pollution while burning high-sulfur coal.[42] The SO_2, NO_2, and particulate emissions are all reduced to very low levels by their interaction with the MHD "seed" material. In pilot plant tests, 2.2 wt.% sulfur coal was burned in a cyclone furnace at 2,200°C with seed concentration of 1 g · mole K_2CO_3/kg coal with 99.8% removal of SO_2, leaving only 5 ppm SO_2 in the gaseous effluent. This occurs because of an affinity that the potassium seed material has for SO_2. So seed recovery in the MHD system, which is necessary for economic reasons, also removes the SO_2. The seed removal costs are calculated as approximately one-fifth of the SO_2 removal costs in a conventional coal-fired plant. In the same tests, through the use of 2-stage combustion, NO_x emissions were reduced below 150 ppm, and complete combustion of CO was achieved.[42,43]

Table 11-21 summarizes the main features of both open and closed cycle systems which remain the subject of both theoretical and experimental investigation. Generally, practical designs have dc output taken from electrodes at the sides of the MHD channel. Ac power is obtained using electronic inverters.

In the remainder of this section, we first review the main generator configurations used in MHD power generation, together with their governing electrical equations. Flow behavior is described for an example case, using the segmented-electrode Faraday type of generator. Following this, properties of seeded gases are given, and finally the major engineering issues for electrodes and magnets are summarized.

Generator Configurations. Figure 11-81 depicts the basic elements of a generic MHD generator, having quasi-one-dimensional flow of partially ionized gas channeled through a perpendicular, static magnetic field. For this geometry, $\mathbf{u} = \hat{\mathbf{x}}\, u_x$ and $\mathbf{B} = \hat{\mathbf{z}} B_z$. In the general case, the components of Ohm's Law (Eq. 11-22) are

$$j_x = \sigma\varepsilon_x - \mu_e j_y B_z \tag{11-90}$$

$$j_y = \sigma\varepsilon_y - \sigma u_x B_z + \mu_e j_x B_z \tag{11-91}$$

$$j_z = \varepsilon_z = 0 \tag{11-92}$$

TABLE 11-21 Gaseous MHD Power Generating System Features

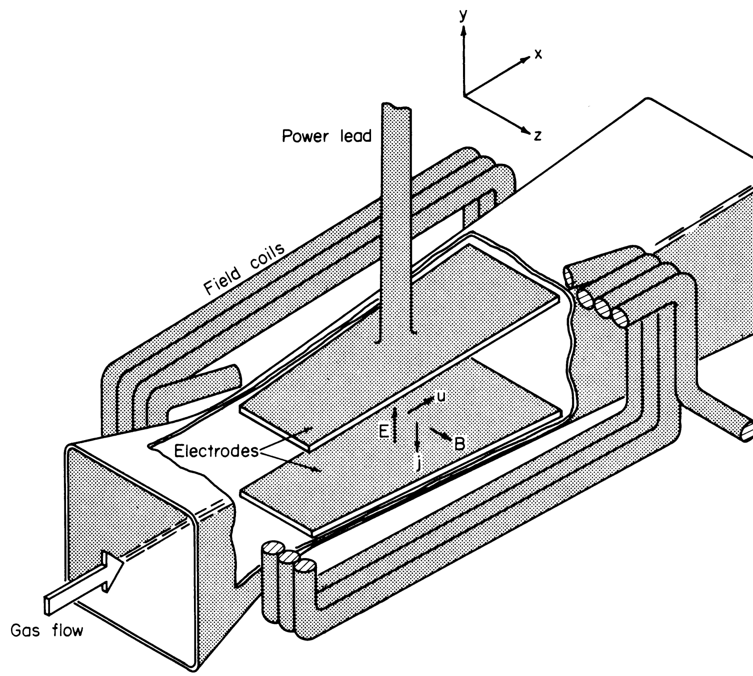

FIGURE 11-81 Basic elements of a magnetohydrodynamic generator.

Four alternative generator configurations are considered here and depicted in Fig. 11-82:

(*a*) Segmented-electrode Faraday generator
(*b*) Continuous-electrode Faraday generator
(*c*) Hall generator
(*d*) Diagonally connected generator

(a) Segmented-electrode Faraday generator. Configurations in which the circuit for j_y is completed through the external load are called *Faraday generator* configurations. If the electrodes are segmented along the *x*-direction in order to electrically isolate each pair, then the Hall current is suppressed ($j_x \approx 0$).

Assuming uniform conditions across the channel, the open circuit voltage ($j_y = 0$) is given by Eq. (11-91):

$$V_{oc} = -\int_o^d \varepsilon_y \, dy = -\int_o^d u_x B_z \, dy = -u_x B_z d \tag{11-93}$$

and the load power generated is

$$P_L = j_y \varepsilon_y = -\sigma(u_x B_z - \varepsilon_y)\varepsilon_y = -\sigma u_x^2 B_z^2 (1 - K)K \tag{11-94}$$

where the dimensionless loading parameter K is defined by $K = \varepsilon_y / u_x B_z$. Using Eq. 11-56, we find that the conversion efficiency is

$$\eta_e = \frac{j_y \varepsilon_y}{u_x j_y B_z} = \frac{\varepsilon_y}{u_x B_z} = K \tag{11-95}$$

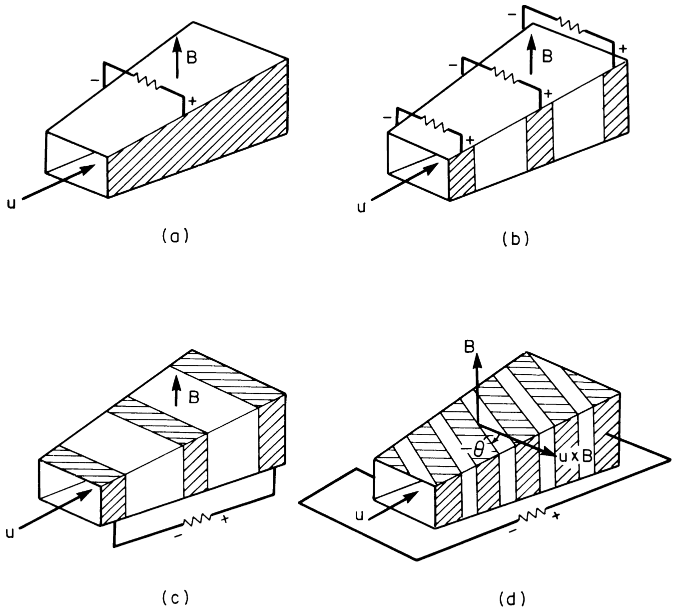

FIGURE 11-82 Generator configurations: (*a*) segmented-electrode Faraday generator; (*b*) continuous-electrode Faraday generator; (*c*) Hall generator; and (*d*) diagonally-connected generator.

(b) Continuous-electrode Faraday generator. In a continuous-electrode generator, $\varepsilon_x = 0$ and the Hall current is finite, $j_x \neq 0$. The *x*-component of current (in the direction of the fluid flow) has its circuit completed through the electrode walls. The j_y component is reduced due to this effect:

$$j_x = -\mu_e j_y B_z$$

$$j_y = \frac{\sigma}{1 + \omega^2\tau^2}(\varepsilon_y - u_x B_z) = \frac{\sigma u_x B_z}{1 + \omega^2\tau^2}(1 - K) \qquad (11\text{-}96)$$

The load power is:

$$P_L = j_y \varepsilon_y = \frac{\sigma}{1 + \omega^2\tau^2}(\varepsilon_y - u_x B_z)\varepsilon_y = -\frac{\sigma u_x^2 B_z^2}{1 + \omega^2\tau^2}(1 - K)K \qquad (11\text{-}97)$$

The open-circuit terminal voltage is the same for both types of Faraday generator, as is the local electrical efficiency, $\eta_e = K$. However, the power density is reduced by $1 + \omega^2\tau^2$ when the electrodes are continuous.

(c) Hall generator. In the Hall generator configuration, opposing electrode pairs are short circuited ($\varepsilon_y = 0$), and the circuit for j_x is completed through the external load. In this case, the current components derived from Eqs. (11-90) to (11-92) are

$$j_x = \frac{\sigma}{1 + \omega^2\tau^2}(\varepsilon_x + \omega\tau u_x B_z) \qquad (11\text{-}98)$$

$$j_y = \frac{\sigma}{1 + \omega^2\tau^2}(\omega\tau\varepsilon_x - u_x B_z) \qquad (11\text{-}99)$$

The open circuit voltage ($j_x = 0$) across the full channel length is given by

$$V_{oc} = -\int_o^L \varepsilon_x \, dy = \int_o^L \omega\tau u_x B_z \, dx = \omega\tau u_x B_z L \tag{11-100}$$

In this case, the Hall loading parameter is written $K_H = -\varepsilon_x/\omega\tau u_x B_z$, so that the load power generated is

$$P_L = j_x \varepsilon_x = \frac{\sigma}{1 + \omega^2\tau^2}(\varepsilon_x + \omega\tau u_x B_z)\ \varepsilon_x = \frac{\sigma\omega^2\tau^2 u_x^2 B_z^2}{1 + \omega^2\tau^2}(1 - K_H)K_H \tag{11-101}$$

The conversion efficiency is

$$\eta_e = \frac{j_x \varepsilon_x}{u_x j_y B_z} = \frac{(1 - K_H)K_H}{K_H + 1/\omega^2\tau^2} \tag{11-102}$$

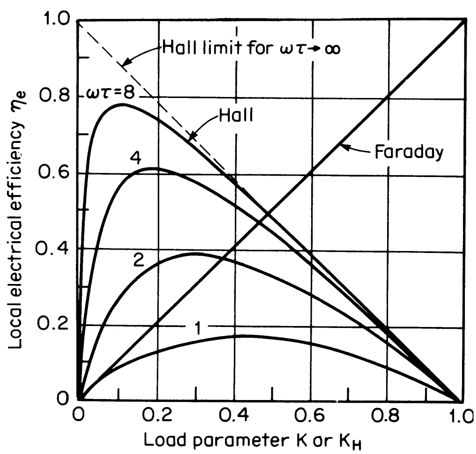

FIGURE 11-83 Comparison of local electrical efficiencies of Faraday and Hall generators.

A comparison between Faraday and Hall generator efficiencies is given in Fig. 11-83. Good efficiency in a Hall generator requires high $\omega\tau$ and a small loading parameter, whereas the Faraday generator efficiency is independent of $\omega\tau$ and improves with higher values of the loading parameter.

(d) Diagonally-connected generator. A configuration that has been favored recently is diagonal connection of electrodes along equipotential surfaces at the angle $\theta = \tan^{-1}\varepsilon_y/\varepsilon_x$ with respect to the vector $\mathbf{u} \times \mathbf{B}$. Ideally, with this configuration, the Hall current is zero, and the electrode voltage between opposite pairs is the same as for the Faraday generator. With the diagonal connections, the overall circuit is a series connection of multiple Faraday-generator electrodes. The output, at comparatively high voltage, is taken between the first and last electrodes in the series.

The characteristics of the diagonally connected generator are intermediate between those of the Hall and Faraday generators. Allowing for a finite Hall current, the current components in their most general form are

$$j_x = \frac{\sigma}{1 + \omega^2\tau^2}[\varepsilon_x - \omega\tau(\varepsilon_y - u_x B_z)] = \frac{\sigma u_x B_z}{1 + \omega^2\tau^2}\omega\tau\,(1 - K) - \frac{K}{\tan\theta} \tag{11-103}$$

$$j_y = \frac{\sigma}{1 + \omega^2\tau^2}(\omega\tau\varepsilon_x + \varepsilon_y - u_x B_z) = -\frac{\sigma u_x B_z}{1 + \omega^2\tau^2}\left(1 - K + \frac{\omega\tau K}{\tan\theta}\right) \tag{11-104}$$

The condition $j_x = 0$ is satisfied if

$$K = \frac{\omega\tau\tan\theta}{1 + \omega\tau\tan\theta} \tag{11-105}$$

In this case, the local electrical efficiency is $\eta = K$.

Energy Extraction and Flow Relations. In general, numerical solutions are needed to solve the complete set of equations governing power generation and flow. The simple case of a quasi-one-dimensional constant-velocity ideal gas flow is examined here in closed form in order to provide insight into the flow behavior. The velocity is maintained constant as the gas expands by adjusting the flow area Ac such that mass conservation leads to

$$\frac{d}{dx}(\rho A_c) = 0 \tag{11-106}$$

A Faraday generator configuration with segmented electrodes is assumed. In this case, the Hall current vanishes and Ohm's Law can be written as

$$j = \sigma(\varepsilon - uB) = -\sigma uB(1 - K) \tag{11-107}$$

The pressure variation is linear for a constant field:

$$\frac{dp}{dx} = jB = -\sigma uB^2(1 - K) \tag{11-108}$$

The solution can be written in terms of the pressure at the inlet ($x = 0$):

$$\frac{p}{p_o} = 1 - \frac{x}{L_i} \tag{11-109}$$

$$L_i = \frac{1}{1 - K}\frac{p_o}{\sigma uB^2} \tag{11-110}$$

where L_i is the "interaction length,"[44] which is an approximate measure of the channel length required to extract an appreciable amount of the gas energy.

The energy equation can be used to determine the temperature variation along the duct. The total fluid enthalphy (per unit mass) is the sum of the kinetic energy, internal energy, and static pressure:

$$H = u^2/2 + e + p/\rho \tag{11-111}$$

Conservation of energy equates the rate of change of fluid energy with the electric power dissipated:

$$\rho\frac{dH}{dt} = \mathbf{j} \cdot \varepsilon \tag{11-112}$$

With constant velocity, we can replace H by the static enthalpy h:

$$h = H - u^2/2 \tag{11-113}$$

For an ideal gas, $h = C_pT$, so that the energy equation becomes:

$$\rho C_p u\frac{dT}{dx} = j\epsilon \tag{11-114}$$

We can replace the current density and electric field in Eq. (11-114) using Eq. (11-31) and the definition of the loading parameter, $K = \varepsilon/uB$:

$$\rho C_p u\frac{dT}{dx} = \frac{1}{B}\frac{dp}{dx} \cdot uBK \tag{11-115}$$

Solving for K,

$$K = \rho C_p\frac{dT}{dp} \tag{11-116}$$

For an ideal gas, the temperature and pressure are related by

$$C_pT = \frac{\gamma}{\gamma - 1}\frac{p}{\rho} \tag{11-117}$$

If we use Eq. (11-116) to replace ρ in Eq. (11-117), we find

$$\frac{dT}{T} = K\left(\frac{\gamma - 1}{\gamma}\right)\frac{dp}{p} \tag{11-118}$$

This can be integrated to give the relation between p and T:

$$\frac{T}{T_o} = \left(\frac{p}{p_o}\right)^{K(\gamma-1)/\gamma} \tag{11-119}$$

The pressure, temperature, flow area, and Mach number are plotted in Fig. 11-84. The Mach number is

$$M \equiv \frac{u}{c_s} = \frac{u}{\sqrt{\gamma P/\rho}} = \frac{u}{\sqrt{\gamma RT/W_m}} \tag{11-120}$$

where c_s is the local speed of sound, R is the universal gas constant, and W_m is the molecular weight of the gas. For constant velocity:

$$\frac{M}{M_o} = \left(\frac{T}{T_o}\right)^{1/2} = \left(\frac{p}{p_o}\right)^{K(\sigma-1)/2\sigma} \tag{11-121}$$

Working Fluid Conductivity. Conductivity of the working fluid is a critical parameter in a gaseous MHD topping unit. The conductivity is obtained by summing the contributions from each species. However, electrons contribute most of the conductivity due to their higher mobility.

$$\sigma = n_e e \mu_e = \frac{n_e e}{m_e \nu} \tag{11-122}$$

At low ionization states, the electron mobility is inversely related to the collision frequency with neutral particles. As the degree of ionization increases, the mobility is reduced by electron-ion and

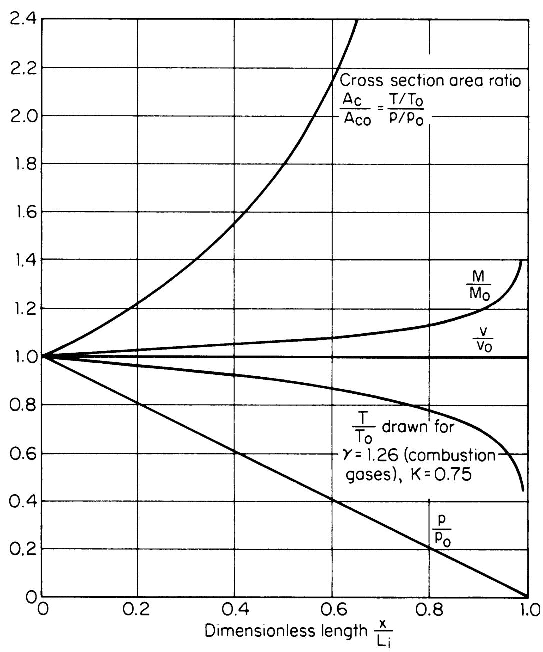

FIGURE 11-84 Dimensionless ratios vs. normalized length (x/L_i) in an ideal, constant-velocity channel.

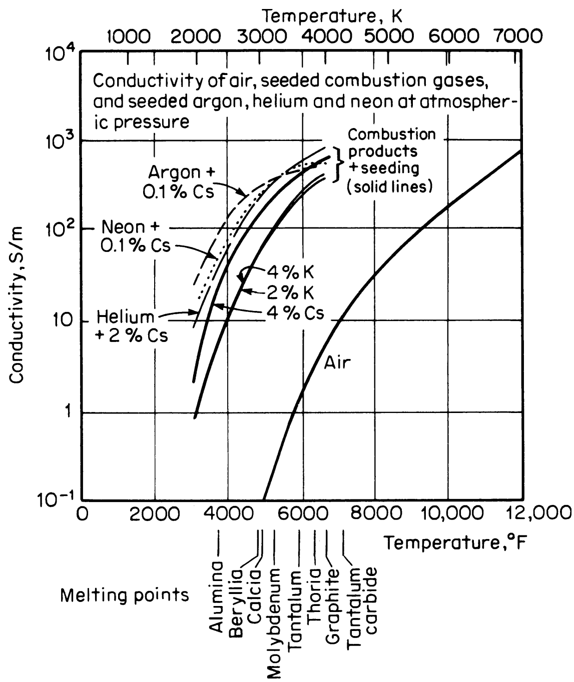

FIGURE 11-85 Conductivity of air, seeded combustion gases and seeded argon, helium, and neon at atmospheric pressure. (All curves, except for air, are from Ref. 46.)

electron-electron collisions, which have higher cross sections. At only 1% ionization, already this effect becomes significant. Therefore, a high degree of ionization is not necessary to achieve an appreciable fraction of the fully ionized conductivity.

Temperatures for fossil-fuel combustion are in the range of 2,500 to 3,000 K. At these temperatures, thermal ionization of air, combustion product gases, or inert gases is so low that the electron density is orders of magnitude below that is necessary to obtain suitable conductivity (see Fig. 11-85). One might obtain marginally acceptable conductivity by reducing the gas pressure, however, this also would result in larger duct and heat-exchanger sizes.

Fortunately, a large increase in conductivity can be obtained by seeding the gas with a small percentage of materials with much lower ionization potential. The ionization potential of the outermost electron in air is ~14 V, and that of inert gases is even higher. Alkali metals make exceptional seed materials, with ionization potential of 3.89 V for cesium, 4.34 V for potassium, and 5.4 V for lithium. Some calculated conductivities of seeded gases are shown in Fig. 11-86 as a function of temperature and pressure. In general, these curves are in close agreement with measured values (e.g. Ref.[45])

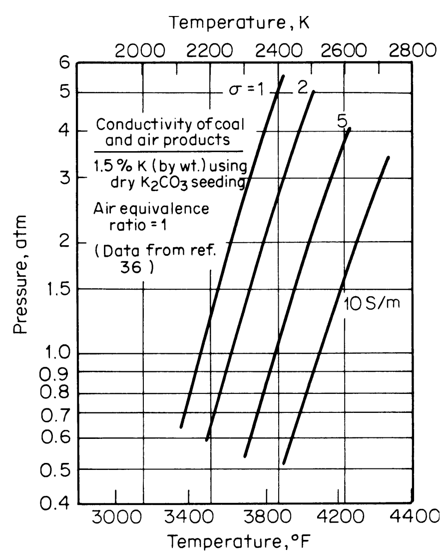

FIGURE 11-86 Conductivity vs. temperature and pressure for seeded coal products and air using 1.5 wt.% K, obtained using dry K_2CO_3. (Adapted from Ref. 46.)

Unfortunately, alkali metals also carry a relatively high collision cross section, such that an increasing percentage of seed atoms not only increases the electron density but also decreases the mobility. An optimal seeding percentage is reached at about 0.1% for cesium and potassium in argon and about 0.3% in neon.[46]

11.10.5 2-Phase MHD

Flow Characteristics. MHD of conducting 2-phase mixtures, consisting of liquid and gas phases, raises new phenomena providing the potential for unique applications. 2-Phase mixtures may arise from boiling or from mixing of distinct gas and liquid phases—for example, helium mixed with a liquid metal. Here we summarize the basic flow characteristics of 2-phase mixtures and the application to liquid metal MHD (LMMHD) for power conversion.

Much of the early progress studying 2-phase flows was based on empirical results,[47–50] since the underlying flow structures can be very complex. Similar to single-phase flows, the effect of the magnetic field is to suppress turbulence and to alter the velocity profiles. In addition, modifications in the interface configuration and slip between phases occur, and the transition between flow regimes can be shifted.

Typical 2-phase flow patterns are depicted in Fig. 11-87. As in ordinary 2-phase flow, increasing superficial gas velocity causes the flow to transition from bubbly, to churn, to slug, and finally to annular mist flow regimes.[51] However, observable differences between MHD and non-MHD behavior occur, as summarized in Fig. 11-87.

MHD Generators and Power Conversion. Liquid metal MHD power conversion using 2-phase mixtures was contemplated as early as the 1960s.[52] In the 1970s, an extensive program was conducted at Argonne National Laboratory (ANL),[50,53–56] culminating in the development of a constant-velocity dc Faraday generator using N_2 with Na or NaK. Following this early work, a rather extensive program was initiated at Ben-Gurion University, where a variety of power conversion systems have been analyzed and/or tested.[55]

The use of liquid metals for power conversion avoids the very high temperatures required to maintain an ionized gas in the conducting state. In that case, practically any heat source can be used, including solar, geothermal, nuclear, or even coal combustors. In addition, the higher conductivity of liquid metals makes possible higher power density with moderate magnetic fields, so that relatively small sized generators are possible. For example, liquid metals offer conductivities of the order of 10^6 to 10^7 $(\Omega \cdot m)^{-1}$ at low temperature, as compared with 10 $(\Omega \cdot m)^{-1}$ for the case of He seeded with 0.45% Cs at 2,000 K. Considerable support has been obtained for research on space-based power supplies, due in part to these advantages.[56]

In general, a thermodynamic cycle requires a working medium (or "thermodynamic medium") that can expand and contract with temperature, for example, gas or steam. For MHD power conversion, the thermodynamic fluid is mixed with an electrodynamic fluid (the liquid metal) to allow MHD generation.

Because the heat capacity of the liquid phase significantly exceeds the gas phase, 2-phase flow expansion (and compression) occurs nearly isothermally. This results in potentially higher thermal conversion efficiency, approaching that of the ideal Carnot cycle. For example, Fig. 11-88 compares a standard gas Brayton cycle *T-s* diagram with a modified cycle using a LMMHD generator.

Several classes of thermodynamic cycles are possible, depending on the types of coolant (e.g., gas, liquid, and/or 2-phase fluid), the use of evaporation or gas mixing, and the use of bottom cycles. These are summarized in Table 11-22.

In the "homogeneous cycle," the thermodynamic and electrodynamic fluids remain mixed throughout the cycle (Fig. 11-89). The heat source causes the working fluid to evaporate, which drives expansion through the 2-phase generator.

In an Ericsson cycle, a mixer/separator combination provides the ability to operate over wider temperature ranges. The main steps are depicted in Fig. 11-90. In this example, the top cycle has four main steps: (1) the liquid metal is heated by a heat source; (2) a mixer combines the thermodynamic fluid with the liquid metal; (3) the mixture is expanded through a generator; and (4) the two phases

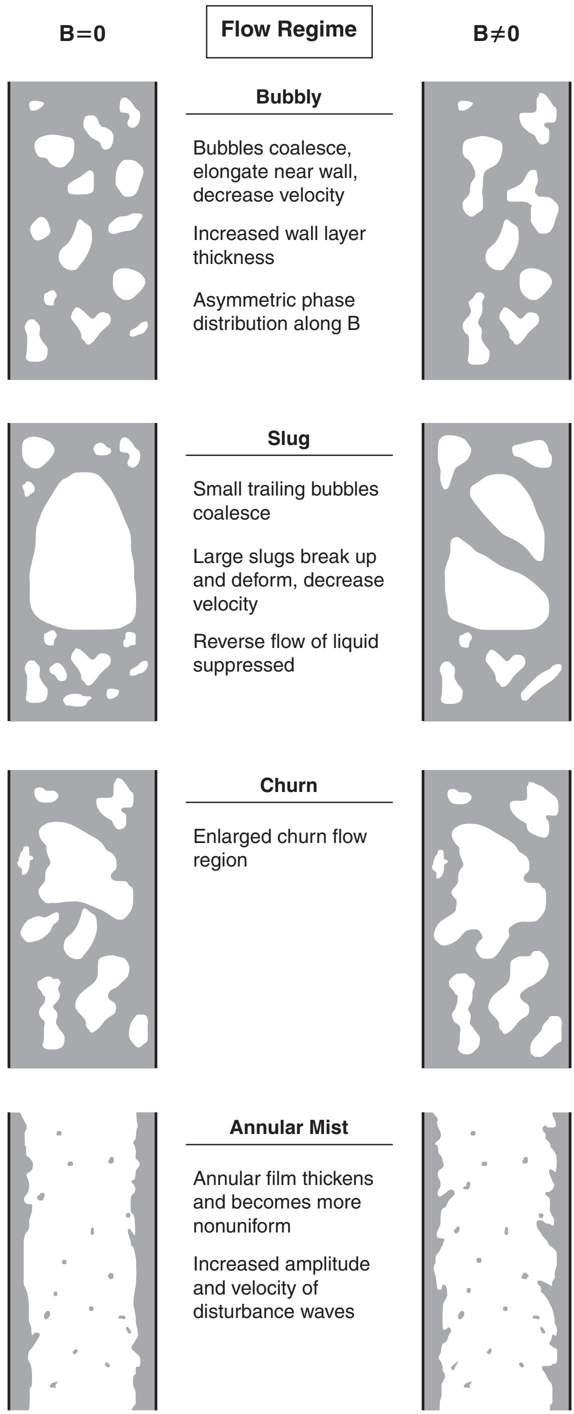

FIGURE 11-87 Effect of magnetic field on 2-phase flow regimes.

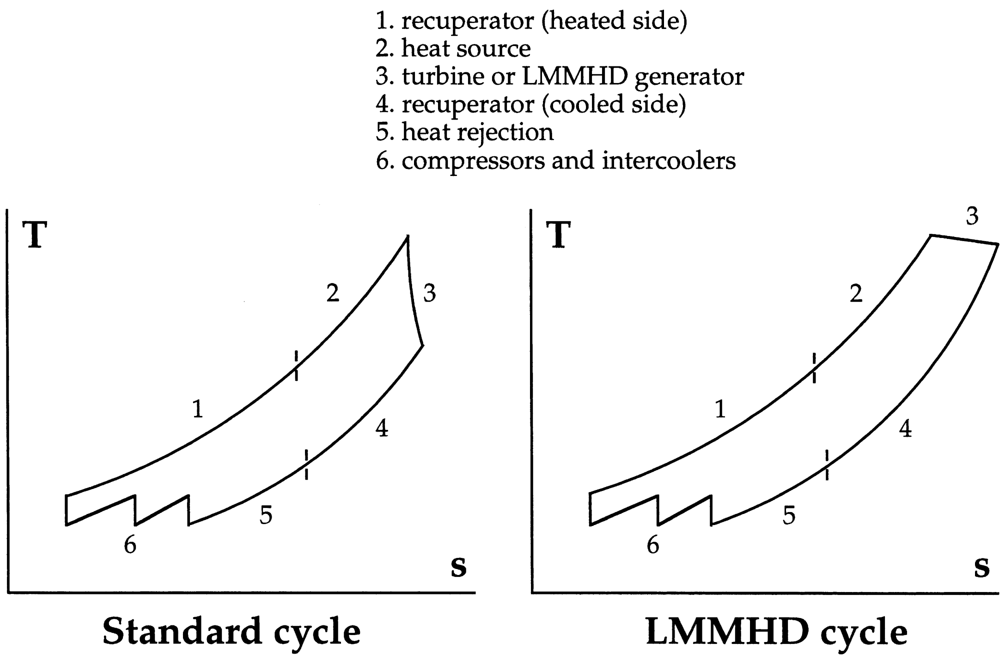

FIGURE 11-88 Standard Brayton cycle compared with MHD Brayton cycle.

are separated. The gas side of the cycle may itself take advantage of the useful heat by expansion through a Brayton cycle turbine, or it could utilize a 2-phase MHD compressor.

In the Rankine cycle, typically water is injected into a chemically compatible liquid metal (such as a lead-alloy). A steam turbine and/or 2-phase generator is used for electric generation.

11.10.6 Nomenclature

- a channel half-width parallel to B
- b channel half-width perpendicular to B
- B magnetic field intensity
- B_o characteristic field strength, used to nondimensionalize equations
- c_e RMS electron thermal velocity in a Maxwellian distribution, $(3kT_e/m_e)^{1/2}$
- c_s speed of sound
- e charge on an electron

TABLE 11-22 LMMHD Cycles and Possible Working Fluids[55]

Cycle type	Working fluids
Homogeneous cycles	Na, K, Cs, etc.
Ericsson cycle with LMMHD compressor or Brayton gas turbine/compressor	Na/He, Li/He
Rankine cycles with or without steam turbine	Pb-alloy/steam
Binary cycles (e.g., homogeneous top plus Rankine bottom)	

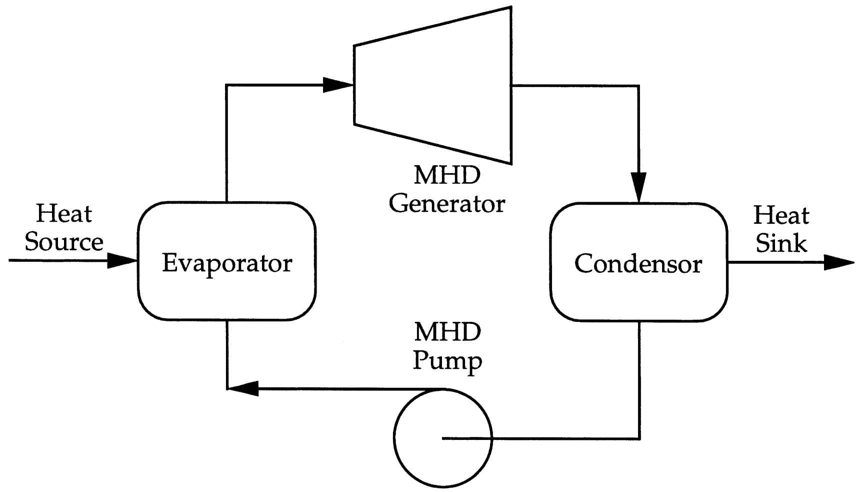

FIGURE 11-89 Homogeneous LMMHD cycle.

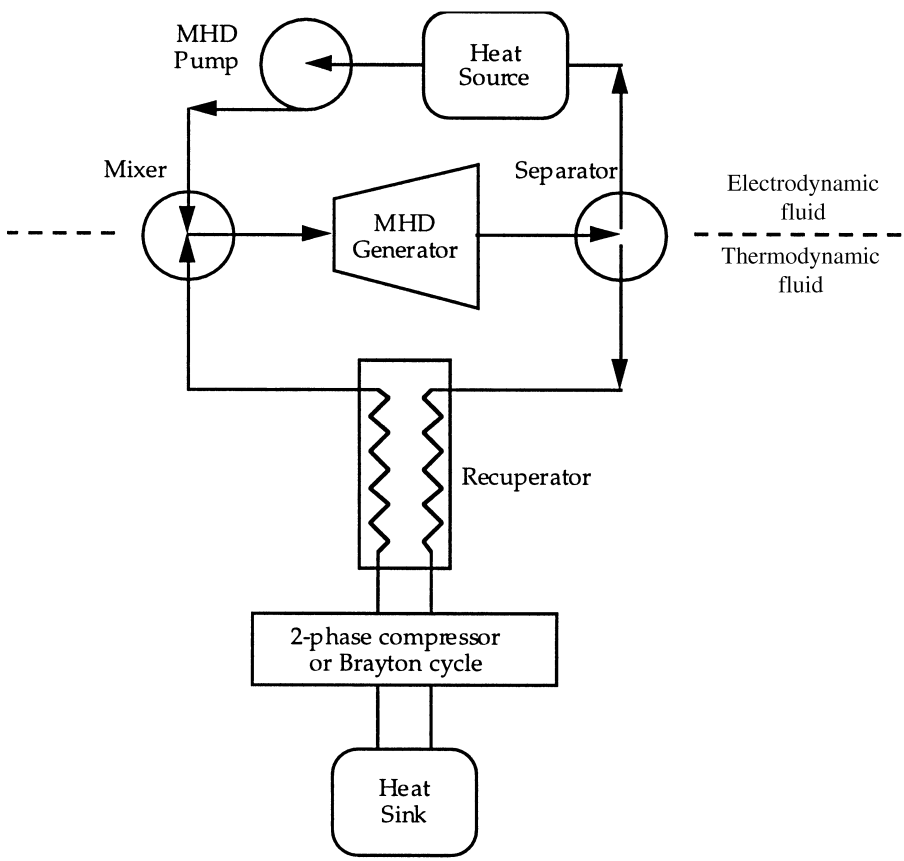

FIGURE 11-90 Modified Ericsson cycle with LM heating.

Ha	Hartmann number, $aB\sqrt{\sigma/\mu_f}$
j	current density
j_f	current density in fluid
j_w	current density in wall
k	Boltzmann constant
K	loading parameter
K_H	Hall loading parameter
l	length
m	mass
m_e	electron mass
n_e	number density of free electrons
p	fluid pressure
P	pressure gradient
q	electric charge
Re_m	magnetic Reynolds number, $\sigma\mu$vl
R_L	load resistance
T_e	electron temperature
u	fluid velocity
$\mathbf{u}_e$	drift velocity of electrons
v	particle velocity
v_b	bulk average velocity
v_o	characteristic velocity, used to non-dimensionalize equations
V	nondimensional velocity
V_{oc}	open circuit voltage
W_m	molecular weight
X	non-dimensional x coordinate
Y	non-dimensional y coordinate
β	rectangular channel aspect ratio
δ	wall thickness or skin depth
ε	electric field
λ	electron mean free path
μ_e	electron mobility, $\omega\tau/B$
μ_f	fluid dynamic viscosity
μ_m	magnetic permeability
ν	electron-atom collision frequency
ν_f	kinematic viscosity, μ_f/ρ
ρ	fluid density
σ	electrical conductivity
σ_f	electrical conductivity of fluid
σ_w	electrical conductivity of wall
τ	electron mean collision time, λ/C
φ	electric scalar potential
Φ	wall conductance ratio
ω_e	electron cyclotron frequency, $eB/m_e = \mu_e B/\tau$
ω_c	cyclotron frequency

CONTENTS

12.1 INTRODUCTION

The long-range trend for electric supply, demand, and costs are rising erratically and are very volatile as of this writing. The supply is changing due to recent energy deregulation legislation and also due to the rising demands for energy in a global economy of rising fuel prices. The electric demand within the United States is expected to increase dramatically.

The increase is due in part to an expected shift to hybrid or electric cars based on fuel cells, and mass transportation to replace the present fossil fuel based transportation. The need for biofuels and hydrogen fuels in diverse geographic locations will result in new and upgraded electric transmission lines for reliability and transportation of energy.

Fuel	Coal	Oil	Natural Gas	Water	Wind Bio-fuels
Transportation	Train Boat Barge Truck	Ship Pipeline	Pipeline LNG—Ship CNG—Ship, train, truck	Water Shed System—River	
Conversion	Electric Generation Plant	Electric Generation Plant	Electric Generation Plant	Electric Generation Plant	Electric Generation Plant
Transportation	Transmission Distribution		Transmission Distribution	Transmission Distribution	Distribution
Customer	Conversion to Heat, Motion, Information				

FIGURE 12-1 Leontief model of the energy industry.

A strategic infrastructure for the production and distribution of energy is essential for industrialized nations. The oil crisis of the 1970s, the first oil crisis, demonstrated the dramatic increases in the price of oil and the resulting impact on modern economies of the western nations. The recent dramatic increase in the energy demands of the Asian countries will accelerate and acerbate these crises.

A Leontief model of the energy industry is shown in Fig. 12-1. Coal was the fuel that industrialized the western countries. Oil and, now, natural gas are sustaining the western economies. Conversion of natural gas to liquid natural gas (LNG) and compressed natural gas (CNG) increases the economy of gas shipment. Hydrogen fuel will most likely start to impact the energy infrastructure in a similar way that LNG has altered the shipment of energy across the oceans. Hydrogen gas will most likely be created and used locally for the most part due to containment problems. Production of hydrogen gas by fuel cells or as a biofuel (bacteria based) is most likely to be a local or distributed process, another distributed generation plant. Hydrogen as a fuel is not yet firmly defined.

Electricity competes with direct use of fuel, such as oil and natural gas, as well as distributed generation based on wind and biofuel–based units. Energy is transported to the point of consumption either directly or primarily by pipeline, or indirectly as electricity.

An electric supply chain model is shown in Fig. 12-2. A traditional natural gas supply chain is shown in Fig. 12-3. An LNG supply chain is depicted in Fig. 12-4. Similar supply chains can be

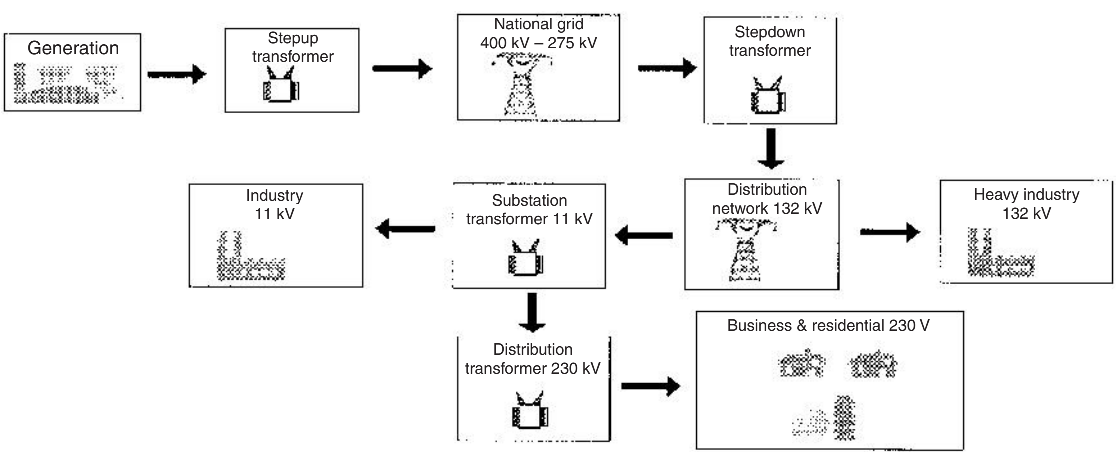

FIGURE 12-2 Electric supply chain model.

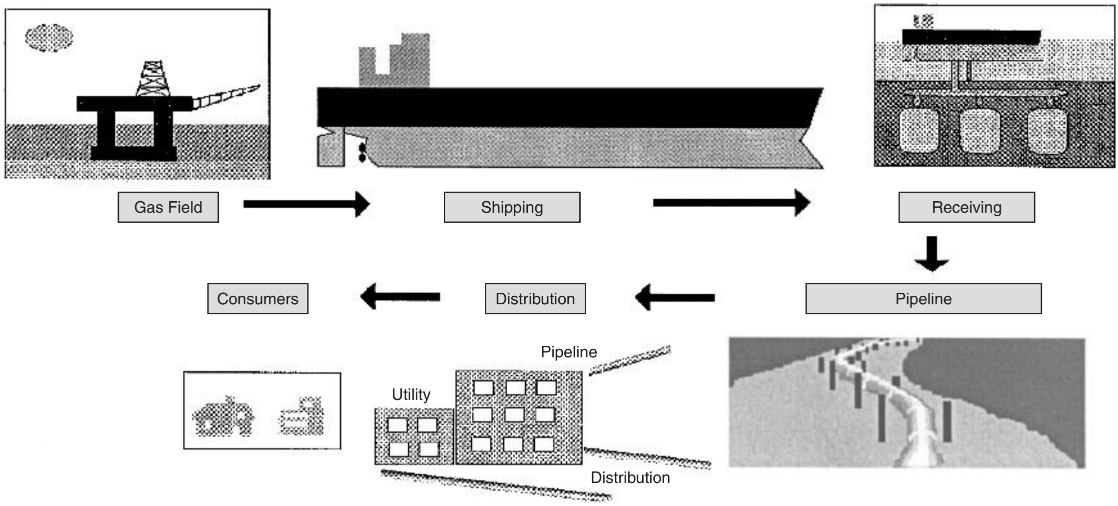

FIGURE 12-3 Natural gas supply chain.

used to depict the use of each type of fuel. Coal, for example, would include track networks for train transportation, river networks for barge transportation, and highway networks for truck transportation.

There is always the comparison of locating a generating plant near a fuel supply and transmitting the power versus locating the generation plant near the load and transporting the fuel. This is the traditional planning problem of comparing the cost of transportation by wire, train, barge, truck, or pipeline. The traditional electric system planning problem was to resolve the more economic and reliable manner of transporting fuel, such as coal, from the mine to the customer. The typical question

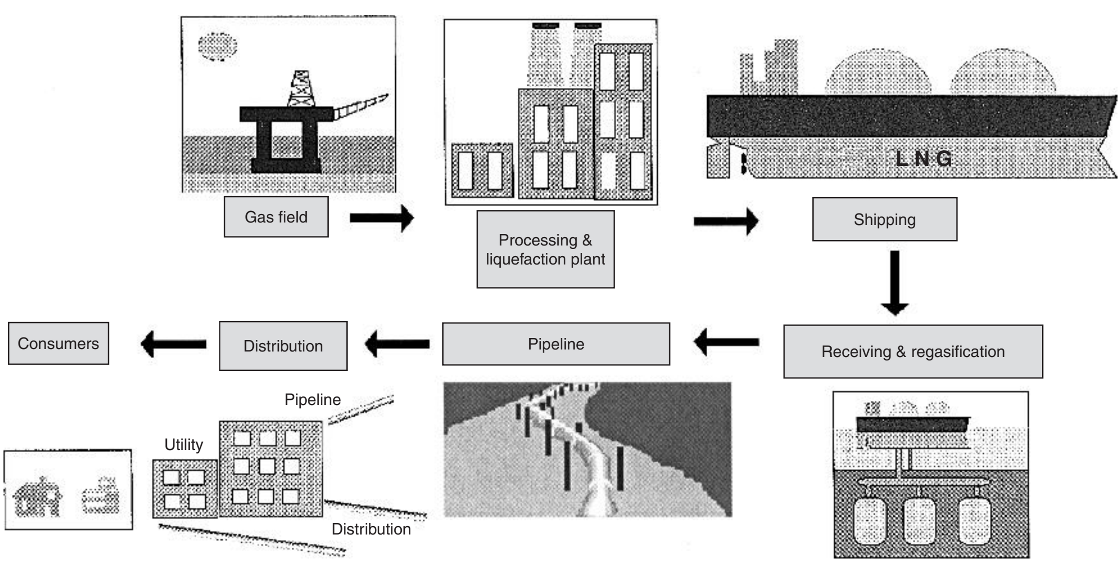

FIGURE 12-4 Liquid natural gas supply chain.

was if the *unit train* of 110 coal cars was more efficient and reliable due to the storage possibilities of coal, than an electric network, highvoltage alternating current (HVAC) or highvoltage direct current (HVDC) systems, to move the energy from the source to the customer.

The expansion of the train network for coal capacity is presently recognized as a constraint on electric system planning as this means of transportation is often congested, and suffers from restricted flows. The same question was posed in the use of oil and natural gas. The expansion of the pipeline networks has leveled the price of oil and natural gas between industrial centers. Thus, there are multiple transportation networks that are operated, maintained, and expanded to move energy from the source to the customer. Each of these networks is an energy grid.

Distributed generation has a compounding impact on the electric transmission system. Distributed generation is composed of natural gas–fired combustion turbines, biofuel–fired combustion turbines, wind generation, solar cells, and recently, gas-fired combined-cycle units consisting of combustion turbines connected directly to boilers, either solely for secondary heat conversion or for additional fuel combustion. Such distributed generation, often called renewable sources, decreases the need for the electric transmission system for basic energy delivery. Instead, the transmission system shifts to a role of providing an alternate energy source when the local distributed generation is not available to provide the desired level of reliability.

The interaction between transmission and distributed generation is complicated by the details of ownership and of interrelated operational responsibility. Many alternative or renewable energy-conversion forms are not expected to be connected to the electric grid but they do considerably alter the use of the energy grids by shifting the demand pattern. Essentially, the interrelationship of alternative resources alters the demand as the customer selects between the competing supply chains.

As a regulated industry, technological improvements reduced the cost of electricity, when all other cost factors were increasing rapidly. The cost of electric energy consists of the total delivered cost from fuel mining, fuel transportation, generation, transmission, and distribution through the supply chain. The generation cost can be broken down into three major components: fuel, equipment, and wages. The relative magnitude of these various components changes primarily in response to fuel cost changes (global economic) and environmental factors, especially due to the environmental impacts, especially as addressed by the Kyoto protocol.

By the late 1980s, the share of the total electric energy cost allocated to fuel costs had increased to 42%. This is equal to the share representing all equipment costs (i.e., generation, transmission, and distribution) at that time. This trend, however, is not expected to continue because of reduced utility dependence on oil as a primary fuel source, and as the LNG supplies increase.

Generating equipment costs have increased more than other equipment costs. In the late 1960s, annual expenditures on construction of generating equipment represented 50% of all utility construction expenditures. This share decreased to 40% by 1989. Generating equipment costs are expected to continue to increase more than other equipment costs, because of the additional costs added to power plants to accommodate environmental and other regulatory requirements. Plant costs have been rising in recent years. Table 12-1 shows average operating expenses from 1992 through 2003.

Distribution costs are determined principally by the population density of the load being served and the geographic characteristics. The shift to buried cable has significantly increased distribution costs in many countries.

Transmission was primarily needed to transport power in a regulated environment. A secondary need was to interconnect for increased reliability. In a competitive environment, more transmission is needed to remove monopoly threats and price manipulation. Transmission costs have always entered into economic comparisons of alternative generation siting. Transmission availability is a major factor when considering alternative–generation contracts in a competitive environment. Transmission limitations and costs have rendered some competitive generation sources beyond the reach of some customers.

Wages represented 26% of the total cost of electric energy in 1968. These costs decreased, compared with other costs during the 1970s. The share represented by the cost attributed to wages was about 18% in the early 1980s. The share today is decreasing as mergers and acquisitions, along with benefit reforms, such as pensions, have reduced the impact of wages for most companies.

TABLE 12-1 Average Operating Expenses for Major U.S. Investor-Owned Electric Utilities

(Miles per Kilowatthour)

Plant Type	2003	2002	2001	2000	1999	1998	1997	1996	1995	1994	1993	1992

Two principal economic factors of bulk energy supply are the cost of the equipment and the cost of the fuel. Many combinations of these two have significant energy price impacts. Decisions between existing available and new assets can only be made after estimating all costs, including capital costs, fuel costs, wages, and maintenance costs that occur periodically.

Financial calculations are used to compare the various future scenarios of supplier and buyer interactions. Other environmental and end-use requirements, such as recreation, aesthetics, and health values, have to be included in all economic evaluations.

12.2 PRIMARY SOURCES OF ELECTRIC POWER

12.2.1 General

The primary energy sources for the production of electricity have been based on the combustion of fossil fuels (coal, oil, and natural gas) to produce steam to drive turbines. Alternatively, rivers are impounded to provide water to drive hydraulic turbines. A third principal source is the heat of nuclear reaction by uranium to produce steam to drive steam turbines.

12.2.2 Fossil Fuel Resources

During the early stages of the industrial revolution, most energy was generated by burning wood or coal in a boiler to produce steam to drive reciprocating steam engines, which, in turn, drove machinery by a system of belts and pulleys or was connected to drive wheels for locomotive use. Early electric power generation used the same process except that the belts and pulleys were connected to a generator to produce electricity. A significant advance was the development of the steam turbines.

Multiple units are generally located in one plant in order to achieve economies of scale, as common equipment can then serve more than a single unit. Common equipment includes fuel- and ash-handling equipment, water treatment, support buildings, and computer equipment, electrical equipment inventory for replacement parts, operating and maintenance staff, and transmission-line substation equipment.

Bituminous, subbituminous, and lignite are classifications given to coals to indicate the amount of heat content per measure of weight. Transportation costs are significant and thus lignite, which has the lowest heat content, is often burned only in plants located at the fuel source. Experiments to convert coal to gases have been conducted to reduce the cost of coal transportation and have been implemented with limited success.

Part of the sulfur found in coal is converted to sulfur oxides, which are considered pollutants when discharged into the atmosphere. Most of the eastern and all the midwestern coals have high sulfur content, which requires some form of sulfur-removal equipment. Such equipment significantly increases plant capital costs and reduces plant efficiency. Coals with lower sulfur content are located in some western states. Transportation costs to bring this coal to the East and Middle West add significantly to its cost.

Presently, it is not financially feasible to convert coal to gaseous or liquid fuel, but it is an area of increased research and development. These procedures are attractive because they offer the possibilities of sulfur removal before combustion and of providing fuel for combustion turbines as well as steam boilers.

Boilers and precipitators are designed for the specific heat content, and so and so other physical and chemical properties (like sulfur content) of the fuel need to be used. Rising fuel costs have justified the conversion of many units to the use of multiple fuels.

Biofuels are quickly coming to the forefront as the price of oil escalates. Bio-fuels include ethanol, soy diesel, and gases produced from agricultural sources and animal and human wastes. Recent advances in waste processing have led to the building of power plants in conjunction with waste treatment, especially the waste from animal herds. Plans have been announced to convert human wastes into gases in the near future, partly as a response to reduce the environmental impact of waste-water treatment.

Solid waste is currently being used as a fuel and as an additive to coal in conventional power plants. Such combination fuel burning was in response to landfill limitations, but the increasing cost of oil is starting to justify the active use of waste resources.

Combustion turbines use gaseous and liquid fossil fuels that are burned, such that the hot gases can be used to drive a turbine directly. These combustion turbines eliminate the conversion of energy to steam and subsequent conversion to electricity, and thus have lower costs due to this system reduction. Such combustion turbines are less efficient and require more expensive fuels and more maintenance. The net economic impact is higher operating costs. Recent developments have increased their efficiencies significantly by using the exhaust output of several units as input to a boiler system to create steam as a traditional unit performs. The output of a combustion turbine is a high heat content exhaust gas. Not only is this gas at a high temperature, but it also contains a considerable amount of unburned fuel. It is economically possible to use the exhaust gas to generate steam either directly in a waste-heat recovery boiler or as preheated combustion air into a conventional boiler with the addition of other fuels. The steam produced can then drive a steam turbine-generator.

This arrangement is called a *combined-cycle plant*. Internal combustion engines are used to drive electric generators at distributed sites for reliability of supply. Hospitals, airports, emergency facilities, communication facilities, and other infrastructure needs require distributed generation to achieve significantly increased reliability requirements. Due to the operating costs of such facilities, they do not represent a significant part of total power generation at this time.

Residual fuel oil is a significant source of energy for power production. This oil contains the heavier components of crude oil that remain after gasoline and other light hydrocarbons have been removed. Oil-fired steam power plants are less expensive to build and operate than coal-fired plants. Combustion turbines use lighter oils as fuel.

Natural gas was traditionally a fuel for steam power plants located near oil fields where the gas is produced. The clean burning properties of gas have lead to gas firing in coal or oil boilers in other parts of the country as natural gas pipeline capacity is available. As there is a high value of natural gas for chemical and space-heating uses, its future use as an energy source for electric generation is limited. Natural gas is a significant fuel for distributed generation, especially if the heat can be used locally. Such generation includes combustion turbines that readily use natural gas as a fuel, especially when combined with an additional heat recovery system, called a combined–cycle plant.

12.2.3 Nuclear Fuel

Nuclear reactors were developed as economical electric power production when the long–term storage of the spent nuclear fuel was considered inexpensive. Subsequent studies have led to a mixed conclusion as to whether or not spent fuel can be stored economically over the lifetime of the radioactivity.

No new nuclear units have been built recently in the United States due to the concerns of long–term storage and potential run-away reactions. Many other countries have continued to develop nuclear energy, given the increasing shortage of fossil fuels. The long–term storage of spent fuel continues to be an unsolved problem. Several existing facilities have presently reached the maximum local storage of spent fuel. Additionally, many existing units in the United States are approaching the end of their useful life cycles.

Natural uranium is the basic fuel for all heavy-water fission reactors. It must be enriched (the content of fissionable uranium increased from the natural value of about 0.7% to about 3%) to be usable. This increase is accomplished by passing the natural product through filters or centrifuges that increase the concentration of fissionable material in part of the output while reducing it in the remainder, which is then unusable as fuel. A breeder reactor converts this depleted uranium back into usable fuel, thereby greatly extending the amount of usable uranium.

Plutonium is a fissionable by-product of nuclear reactor operation. It can be mixed into natural or enriched uranium to recover the energy available in the plutonium.

Fusion reactors are expected to use deuterium as fuel. This material exists in large quantities in water but would have to be extracted and converted into a usable form as is presently under investigation as a multinational experiment.

12.2.4 Hydroelectric Power

Natural precipitation as rain or snow provides a continuous source of water at elevations higher than sea level. The flow of water back to lower elevations provides a source of energy by converting the potential energy into kinetic energy using waterwheels. Impoundment of rivers by dams provides a steady energy source and a larger elevation difference to localize the potential energy. The higher elevation of water locally is measured as effective water head. The natural elevation differential Niagara Falls was used for the motive power for the first commercial alternating current (ac) central station.

Hydropower is a renewable fuel resource. However, the traditional harnessing of hydropower is complicated by the need to dedicate a significant part of a river course to form a lake large enough to provide a steady water source. Initial costs for the dam and other construction work are significantly higher than for other types of generation. This higher first cost must be offset by long-time fuel cost savings. Therefore, the justification of hydropower is very sensitive to the replacement of other fuels and the scheduling procedures. Often the cost of a project is divided between multiple uses of water, such as power, navigation, irrigation, recreation, and flood control. These competing uses greatly restrict the availability (and thus the relative cost) of the power.

The use of tidal movement of water to generate power has been proposed in some coastal locations where there are large tides. Because of the relatively low water head provided by tidal action, it was originally thought necessary to impound huge quantities of water. The cost of the impounding structures has been found to be prohibitive. The structures also probably would have a significant environmental impact owing to their great size. A new alternative is to use wind generators to harness the energy in tidal, river, and ocean currents. Such water generators resemble wind generators but are inverted, suspended from the surface, restricted to locational movement by anchors, and spin as the current flows across the blades, roughly at the speed of a revolving door. While navigational use of that immediate area is restricted, the impact is considerably different from conventional hydro facilities. It is expected that the low cost of such systems may revitalize many of the abandoned hydro facilities with low head capability.

Efforts are being made to develop power from ocean-wave action, but these are experimental and have a significant impact on the aesthetic shoreline use.

12.2.5 Geothermal Steam

At several locations in the world, natural steam is close enough to the surface of the earth that is accessible by using conventional drilling methods to pipe it to the surface. These locations are too few to be of any overall significance to most countries. The expansion of the use of geothermal steam to areas where the heat is not near the surface will require major progress in the development of very deep–well drilling technology. There is a considerable cost to the maintenance of such units as the steam has significant quantities of corrosive and solid materials that reduce the life-expectancy of heat transfer equipment. However, the availability of such steam in several locations could be harnessed to generate hydrogen within the near future for export to energy–dependent regions.

12.2.6 Fuel Cells

Fuel cells generate low-level direct-current (dc) power as a result of a chemical reaction between a hydrocarbon fuel and oxygen. Development has progressed to the point where practical devices are available, even with the use of natural gas and other biogases. However, the costs have not yet been reduced to the point where fuel cells can be considered as competitive with other conventional power sources except in special applications where highly reliable power sources are required or in remote locations.

12.2.7 Primary Batteries

Primary batteries use a chemical reaction between two components of the battery to produce dc power. The battery components are depleted up in the process. At present, the cost is prohibitive for large-scale applications.

12.2.8 Solar Electric Power

Electric power can be developed from the sun's rays in two ways: solar cells that produce low levels of dc power as a result of the sun's rays striking certain materials and solar boilers that consist of a system of mirrors that concentrate the rays from a large area onto a vessel containing water. Practical use of solar electric power must overcome two fundamental problems: (1) the sun's energy is so diffuse that very large earth surface areas must be covered by the mechanism used to collect and convert the energy; and (2) practical energy output is limited to part of the daylight hours on cloudless days. The practical locations in the United States are in the southwestern deserts, which are relatively far from power-consuming areas as to require major transmission lines to deliver the power.

The diffuse nature of the sunlight can be harvested by the use of many photovoltaic solar cells located on all homes within a regional area. Several home owners in the southwest part of the United States have invested in such systems as the price of oil has risen significantly. Presently, such installation cost in the range of $15,000 to $20,000. The net profit from such installations was demonstrated as $200 to $300 per month in 2005. Home owners were pleased with this return on investment while reducing the dependency of the country on oil.

The use of solar collectors to power a conventional boiler have been constructed and demonstrated. Maintenance costs are high as the reflective surfaces are easily contaminated and abraded in such environments. Research into more resistant materials may soon render it possible to justify the conversion of solar energy to steam, solely on the basis of the fuel that is not consumed.

12.2.9 Wind Power

It is practical to generate power from propeller-driven generators. Recent developments in the capability of equipment and the advanced controls to cope with the variable nature of the wind and demand have lead to a major shift to use wind as a primary source of electricity. The European Union and several U.S. investors have committed to major wind development investments. Several European countries have shifted to a high penetration of wind generation, as high as 61% in the Netherlands, due to expected scarcity of fossil fuels in their regions. Costs have been significantly reduced, while the equipment reliability has been dramatically improved. The use of wind generation is easily justified for remote areas.

12.2.10 Distributed Generation

There are two generic types of distributed generation. Distributed generation is inherent when renewable resources are the fuel, such as biofuels, solar, and wind. Distributed generation is also justified when heat or steam can serve other uses.

Several companies have developed small gas-fired generating units that are intended to be located in small groups scattered throughout the distribution system. The first units were designed to be 50 kW in size. Such systems have been installed and justified when the heat is also used for environmental heating or manufacturing processes. In remote locations where electrical systems do not exist, it is expected that one or two extra units can be installed if biofuels are available. Such systems are used extensively as backup and for unplanned expansion. Many of these are operated as stand-alone systems.

It is necessary to have alternative power sources to supply the load when the sun is not shining, the water flow is reduced in dry season, and the wind is not blowing at the proper speed. These alternative resources include energy storage and demand–side management, as well as the use of conventional power plants. Thus, many of the renewable energy systems (wind, water, biofuels, etc.) require alternative sources, such as conventional power systems, or local storage. Local storage can include heat storage as well as hydrogen–based fuel cells.

There are industrial processes that require large amounts of heat at temperatures and pressures below those at which boilers generate steam. When such combined demands are served by an integrated power plant, it is possible to obtain low–cost power by generating steam at a higher temperature and pressure and running it through a turbine, subsequently exhausting the steam in the condition required by the industrial process. This arrangement for multiple uses is called a cogeneration unit (traditionally called a topping unit) as such a joint service capability provides economical energy for the following reasons:

1. The additional construction cost for the higher-temperature and higher-pressure boiler plant is not significantly higher than the cost of a boiler plant built to supply the industrial process demand only.
2. The required additional fuel generating higher-temperature and higher-pressure steam is less than the fuel cost for generating steam for industrial demand only. One principal reason for this is that for a conventional generating unit, the steam must be condensed back into water to obtain good overall efficiency. The condenser used for this purpose must be supplied with cooling water that absorbs most of the heat in the steam exhausted from the turbine. This heat is then dissipates to the atmosphere. There is far less condenser heat loss because the exhaust steam is used for process heat.
3. Cogeneration units are installed in many facilities requiring high reliability for industrial processes.

Another method of producing by-product power is the use of an extraction turbine, which has openings at one or more points to allow steam to be removed after it has passed partway through the turbine. This steam is at a lower temperature and pressure than the inlet steam and can be used as process steam. As with a topping unit, the extraction steam does not lose heat to a condenser; therefore, its generation efficiency is very high.

12.3 ENERGY STORAGE SYSTEMS

12.3.1 General Aspects

Electric power is a highly perishable commodity. There is no means of storing it directly in an electrical form. Thus, sufficient generating capacity must be constructed to meet the peak load. This expensive capacity is underused during off-peak periods. Energy-storage systems can reduce the overall cost of power by reducing the amount of generating capacity required. The storage system absorbs energy during off-peak periods and delivers it to the load during peak periods. To be economically effective, the storage system's construction cost must be low and its efficiency high.

12.3.2 Pumped-Storage Hydro

Storing energy can be accomplished by using an electric motor-driven pump to raise water from a lower pool to an upper reservoir when the electric load demand is low (at night or on weekends) or when excess generating capacity is available. Later, the same motor pump can be operated in reverse as a turbine-generator using the water in the upper reservoir as an energy source.

For a pumped-storage system to be economically justified, the power-source fuel cost must be very low (hydro, nuclear, high-efficiency fossil, solar), and the construction cost of the pumped-storage plant must be lower than alternative generating capacity. Low construction costs per unit of power require a very large capacity plant and a large elevation difference between the upper and lower pools (doubling the water head cuts the required storage volume in half). There are not many locations where the topography is suitable for this type of installation.

12.3.3 Hydrogen Fuel Cycle

A scheme that has been proposed to store the energy output of low-fuel-cost plants when they are not required to supply load is the hydrogen fuel cycle. The surplus generating capacity would be used to obtain hydrogen from water by electrolysis. The hydrogen would then be stored or transported for use as a fuel in another generating unit. Much development work will be required to determine the overall costs for this system.

12.3.4 Storage Batteries

Practical storage-battery systems are available to store surplus electrical energy in chemical form for use at a later time. However, at the present time, overall cost benefits have not been sufficient to justify the large-scale trial installations that are needed to verify costs and reliability. Research has instead been conducted on fuel cells that serve the equivalent purpose.

12.3.5 Cryogenic Storage Magnets

Research has been conducted on large cryogenic (supercold) magnets that have the capability of storing large amounts of energy in their magnetic field for long periods of time because of the very low electrical losses in the magnet conductors. Much additional research and development are required before the relative economics of this device can be determined.

12.3.6 Flywheels

The use of mechanical flywheels has been proposed for energy storage. Major development of strong materials will have to be made and pilot plants built to demonstrate the reliability and costs for this type of storage before it can be justified. Funding for this research has been reduced.

12.4 DEVELOPMENT OF ELECTRIC POWER SYSTEMS

12.4.1 Need for Fuel, Demand, and Price Forecast

The process of deregulating the electric industry is still very much ongoing. There are still many questions that haven't been answered regarding how the markets should operate and what is an appropriate market design. The instability of some electric markets has affected other industries, such as the fuel industry. As previously stated, the national load decreased after the 1973 oil crisis. With these industries so closely tied together, it has become harder to provide an accurate forecast on load growth. With the fuel markets seeing record high prices, will demand respond to the price hike and drop? To what extend would it drop? Would the drop be temporary? Could this actually

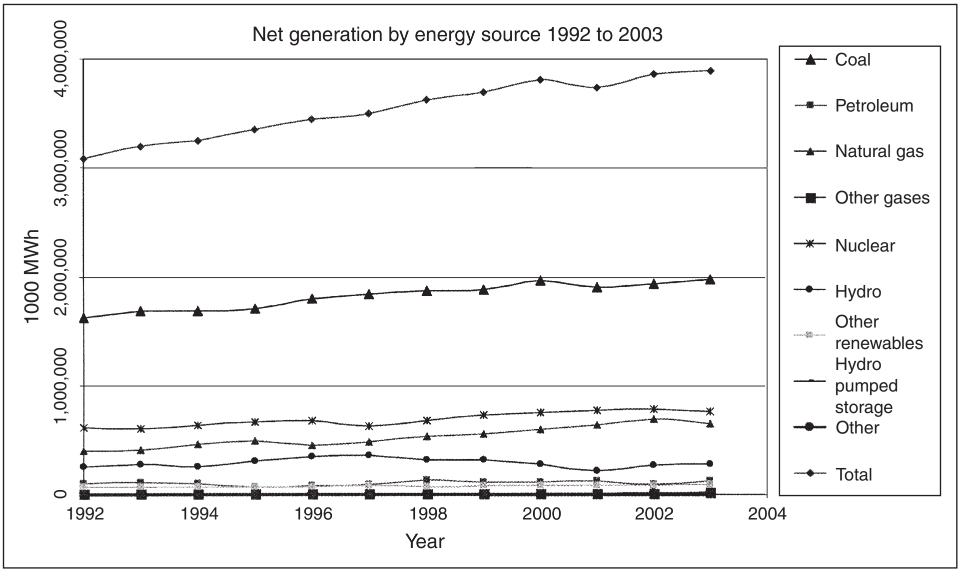

FIGURE 12-5 Net generation by energy source in the U.S.

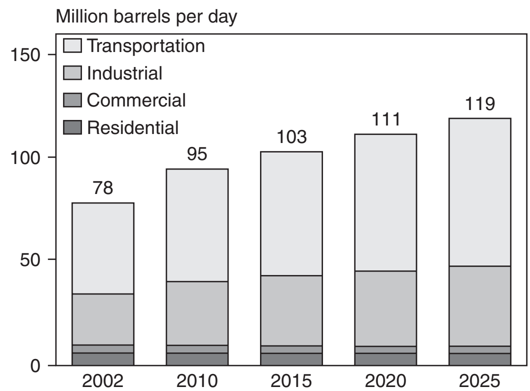
cause a spike in load growth due to products being switched from fuels to electric loads as we are seeing with hybrid cars? These are all important to understand.

Figure 12-5 shows the net generation in United States from 1992 to 2003 by energy source. The top line is the total generation. Notice that the only decrease in total generation was right after the California market crisis, though the decrease was temporary.

The total net generation has grown just over 2% a year. The fuel types that have the largest growth is natural gas and other (i.e., wind, solar, etc.) with growth rates over 4%. The high growth rate in other, which is mainly renewables like wind and solar, describes the market's concern over the dependency on oil as well as environmental implications. These sources are also becoming more economically justifiable when compared to fossil fuels due to the increase in fossil fuel costs. This concern to invest in energy sources that are more expensive is a sign of how the buyers are beginning to affect the deregulated markets now. Under regulation, there would be no high–price spikes, so assuming the demand to be inelastic was considered not to be an issue.

With the deregulated markets and the frequent market prices, this assumption is becoming more invalid. Though buyers still do not have a direct choice on who they can buy their energy from yet, it is still apparent that the views of the buyers are affecting the markets based on the large growth in renewables. As of right now, the buying side of the electric industry is not deregulated but many support such an idea. If and when that happens, people's preferences as to how their electricity is generated (i.e., environmental impacts) will come into play and those doing the forecasts right now have never dealt with this before; thus, predicting what will happen is a challenge. There is also the suggested market setup where buyers who want better reliability can pay for such and those less dependent on having a reliable connection can pay less. The markets are essentially including more of the buyers' preferences and this will only complicate the forecasting.

Right now most car dealerships have a waiting list for hybrids since they are so popular and this has caused a high demand spike in the industries that create the battery packs. In return, the efficiency in the battery packs is improving due to investment possibilities as well as the costs are decreasing. Figure 12-6 shows the distribution of oil consumption by the different sectors. With transportation being the largest sector and having the highest growth rate, it is easy to understand how even a small conversion from oil to electrical loads can cause predictions to be off.



Sources: History: Energy information administration (EIA), *International Energy Annual 2002*, DOE/EIA-0219(2002) (Washington, DC, March 2004), website www.eia.doe.gov/iea/. Projections: EIA, system for the analysis of global energy markets (2005).

FIGURE 12-6 World oil production by end-use sector.

With the growth of load very dependent on fuel costs, another issue that is arising comes from the emerging economies like China that are greatly increasing their fuel and energy consumption and thus causing a large growth in demand for the entire world. This factor is probably the most influential with regard to load–growth forecasts since predicting what will happen with these foreign countries complicates it immensely instead of just focusing on what is happening within the United States.

It is predicted that the oil consumption in emerging Asia will double between 2002 and 2025. With such strong changes in an industry as this, forecasting becomes very difficult.

Likewise, updating a forecast to be able to account for the exercise of market power is extremely difficult. The Organization of the Petroleum Exporting Countries (OPEC) share of the world oil production market is predicted to increase. Thus, their market power will increase as well. The mature economies are predicted to have very low growth in coal consumption. This reflects the demand side pressure for fuels that are less harmful to the environment.

The cost of fuel is dependent on a lot of variables: supply, demand, market power, etc. There is expected to be a large jump in the petroleum and natural gas markets while the cost of coal is relatively unchanged. The main reason is, though the cost of coal is cheaper, the United States is not investing a lot in coal due to political, environmental impacts, etc.

The demand for oil will increase; however, the price of oil will be more dependent on political, economical, and environmental concerns. These concerns will be the driving forces in determining whether prices will be high or not, since it is predicted that there will not be a problematic scarcity of oil through 2025. These concerns range from the influence governments have on those controlling the markets like OPEC to future environmental laws that might be enacted.

12.4.2 Basic Market Economic Concepts

The major change of industry restructuring is the use of markets to connect the information needs between each link in the supply chain instead of a separate company in a power geographic area. Several markets are implemented to properly price the necessary services to produce and to transport electric energy at an acceptable level of availability. The spot market is for immediate delivery of the commodity. The forward market is for the near–term delivery of the commodity. The future markets are for the financial hedging of the commodity. The bilateral markets include all contracts not traded but executed and committed for commodity delivery. The contingent markets are for potential trades of a commodity under unusual operating conditions, such as spinning reserves. The option markets include buyer selection contracts that give the right but not the requirement to execute a commodity–exchange contract. Energy balancing and load following markets are used to match the periodic (hourly) energy contracts with the actual instantaneous demand.

A market's basic purpose is to enable buyers and sellers to determine the best allocation of resources which investment is optimal, and so on. Additional commodities, originally organized by the U.S. government, are emission rights that can be traded. Such trading has been a core component of the Kyoto Agreement that is yet to be implemented but has been signed by most of the world governments.

12.4.3 Capital Budgeting Financial Economics

The basic criterion generally used in regulated electric power economic analyses is that the alternative requiring least revenue from the customer is the proper economic choice (Jeynes, 1968). The basis for re-regulated economic analysis is financial analysis as applied to any financial instrument or commodity. The essential process is to determine the costs of investment, costs of operation and of maintenance, and then to compare these costs to the expected revenue over a time horizon. The demand and supply forecasts are discussed in the previous section.

The cost of capital is the major fixed charge associated with an investment, as it is necessary to determine the total payments needed to pay the bonds, financial instruments (mortgage), and stock dividends associated with the investment cost of that equipment. Labor and material cost, including overhead and profit of the supplier (direct construction cost), is easier to track as the facilities are installed. The use of activity–based costs (ABC Accounting) is used extensively to track expenses per task for proper assignment of cost factors.

The cost of fuel includes the price of removing the raw material at the mine or well, processing costs, and the cost of the transportation system (railroad, pipeline, shipping, etc.). Usually, the cost of fuel is reduced to a single figure expressed in dollars per million British thermal units (Btus) as demonstrated by the NYMEX futures contracts. The expense to process and deliver the material is the next cost component to be included. The cost of fuel is priced, based on other fuel market prices due to value of energy selected by the consumer. Increases in the cost of production due to environmental regulations, increases in labor costs, and increases in transportation costs are the components with the largest increases as of this writing.

The amount of fuel in inventory is usually the amount required for 2 or 3 month's operation for each plant. For nuclear fuel, the carrying charges are very high as costs for expended fuel maintenance is increasing as storage costs are clouded by political uncertainty. Generating unit efficiency is stated in terms of the heat content (Btus) required from fuel to produce electric energy (kilowatthour). This conversion curve shows the quantity of fuel energy converted to electric energy (Btu/kWh) is called the *heat rate.* The net cost of fuel (dollars/kWh) is the product of the raw-fuel cost (dollars/million Btus) and unit heat rate (Btu/kWh).

Operation and maintenance costs consist of the labor expenses, including overheads for the plant operating and maintenance personnel, and maintenance and operating materials (other than fuel). These costs are modeled as a fixed component (dollars per year) and a variable component that varies with the amount of power produced (dollars/MWh). Since the total of the two is a smaller value compared with ownership and fuel costs, it is common to average the two components into a single figure. A figure of about $15/kW per year is the median value, with many plants within $\pm 50\%$ of this value and a few beyond that range. Within this wide range there is no correlation with unit size, type (coal, oil, nuclear), or number of units in the plant as the financial economics demonstrate that costs beyond that range are not viable projects.

12.4.4 Financial Engineering Methods of Analysis

Comparison of alternative means of providing power requires combining costs that occur at different times. The cost for constructing a plant occurs over a several-year period prior to initial operation of the facility. Financial analysis is based on the general concepts of capital asset pricing theory, alternatively, arbitrage–pricing theory. Once the future costs of fuel, construction, operation, and maintenance are forecast, then the demand is forecasted to determine the probabilistic revenue that could be obtained by those assets. The basic consideration is that the expected profit has to be sufficient to pay the risk premium for the expected relative corporate risk.

CONTENTS

13.1 BOTTOM-LINE ECONOMIC MEASUREMENTS

This primer is intended to give a quick introduction to the financial considerations that drive the decisions to start or abandon a project. The *bottom line* on any project is that it is either better or worse than alternative investments. Money is the usual medium for measuring "better" because all the other factors like risk, reputation, and enjoyment, often can be translated into a monetary equivalent.

The decision to start a project, and the selection of the method to finance it, may involve many interrelated factors. Chief among these factors are the values of project costs and receipts, interest rates, possible returns from other projects, tax regulations, and available financing. The remainder of this primer briefly discusses these items and illustrates the economic differences resulting from three different methods of financing a project: (1) 100% financing by the owner, (2) 50% owner's equity and 50% borrowed debt, and (3) leasing from another owner.

The illustrations herein are intended to convey the certain knowledge that taking shortcuts on economic analysis may lead to an inappropriate decision. This is particularly true when a long-term project, like a new energy production system, is being evaluated against a short-term project, like purchasing specialty machinery for producing a product which has a limited sales life. The correct decision is the one which yields the greatest total value to the owner.

13.2 THE VALUE OF MONEY

Money has no value of its own; its value is proportional only to the goods and services it provides. The amount of goods and services money can provide in a given year relates directly to the relative value of money at that one point in time. If inflation did not reduce the value of money over time, a specified amount of dollars could buy the same set of goods and services in one time as in another. Because of inflation, however, the value of that specific amount of dollars decreases over time; the same amount of money is worth fewer goods and services in later periods. As a result, the decision to start a project should consider both the *amounts* of expenditures and receipts associated with the project and the *timing* of those cash flows.

TABLE 13-1 Relationship of Nominal Dollars to Real Dollars

	Dollars in year of receipt					
	Year 1	Year 2	Year 3	Year 4	Year 5	Total
Nominal value (actual dollars)	100.00	100.00	100.00	100.00	100.00	500.00
Real value (1984 buying power)	100.00	90.91	82.64	75.13	68.30	416.98
Nominal value (actual dollars)	100.00	110.00	121.00	133.10	146.41	610.51
Real value (1984 buying power)	100.00	100.00	100.00	100.00	100.00	500.00

The terms used to express the effect of time on the value of money are (1) *real dollars* and (2) *nominal-year dollars* or *nominal dollars*. Nominal dollars refer to the amount of dollars received or spent in a given year. Because of inflation, a dollar received in year *X* will be worth more or less than a dollar received in year *Y*. In order to compare the two, the real purchasing power of a year *X* dollar must be compared against the real purchasing power of a year *Y* dollar. It makes no difference whether (1) year *X* dollars are converted into the number of year *Y* dollars that have the same real purchasing power, or (2) year *Y* dollars are converted into year *X* dollars. If more convenient, both can be converted into equivalent dollars of some other nominal year.

In order to consider the effects of inflation on a project, all cash flows from each of the various years of the project should be expressed on a directly comparable, common year basis so that their relative values can be considered. To accomplish this, the *nominal-year dollars* of cash flow in each future year are converted to *constant-year dollars* by *discounting* their value back to that of one common year.

If inflation is running at 10% per year, the relative value of $100 in hand in year 1 will be $110 in year 2 or $121 in year 3, etc. Likewise, future values must be discounted to obtain their value today. In other words, the *real value* of $146.41 (nominal-year dollars) received 4 years away is only $100.00 in year 1 dollars. The illustration in Table 13-1 uses such a 10% *discount rate* to calculate the real value (in constant year 1 dollars) of future nominal-year dollars for each year. The first two rows show the decline in real value (the ability to purchase goods and services) of a stream of $100 annual receipts. The second two rows show the increase in annual dollar receipts required to maintain the same real income in each future year.

If a project is to be a success, the sum of its real costs and real returns must be positive enough to overcome any uncertainty about the occurrence of future costs and returns. The *present value* of a future income stream (or cost stream) is the sum of the *real* values of the individual future receipts (or costs). The *net present value* (NPV) of a project is calculated by subtracting the present value of project costs from the present value of expected project returns. The example in Table 13-2 illustrates both the time value of money and the process of calculating the net present value of a project. The nominal dollar values of cash stream A are identical, but in reverse order, to those in cash stream B.

In this illustration, if B is a revenue stream and A is a cost stream, the project makes some money in 5 years; the NPV is a positive value of $30. If only the nominal dollar flows are considered, the project appears to break even; the *nominal return* over the life of the project is zero. However, that

TABLE 13-2 Calculation of Net Present Value

	Yearly cash flow, $								Total cash flow, $	
	Year 1		Year 2		Year 3		Year 4			
Cash stream	Nom.*	NPV†	Nom.	NPV	Nom.	NPV	Nom.	NPV	Nominal value	Present value @ 10% discount rate
A	100	91	150	124	180	135	220	150	650	500
B	220	200	180	149	150	113	100	68	650	530
B – A	120	109	30	25	−30	−22	−120	−82	0	30

*Nom. = nominal value.
†NPV = net present value.

is *not* the case in real terms. Because of the time difference in the cash flows, the project earns a net positive real spendable return.

In this example, the project begins to lose money in year 3. Obviously, if the project can be stopped at the appropriate time, more income will be retained by the owner. If not, the project may still be the best alternative, especially if the scenario of Table 13-2 is the worst expected case and the "best guess" case would return significant profits. Whether this particular project would be started depends on such factors as the relative returns that can be earned from alternative projects, the relative risk of each project, the availability of financing, and the type and usefulness of tax advantages.

Annual Charges. It is desirable to have a convenient method of calculating the annual costs of capital investments made in an alternative scheme. Fortunately, this often can be done realistically by using a level carrying charge which is expressed as a percentage of the original investment.

The total revenue requirements of a piece of equipment are the sum of the annual charges for

1. Return on investment
2. Depreciation
3. Income tax
4. Property taxes
5. Insurance
6. Operating and maintenance expenses

The first five of these charges can conveniently be estimated as a percentage of original investment. The operating and maintenance charges should be estimated separately for each project because they do not relate to capital investment as a percentage.

Level Annual Carrying Charges. The level annual carrying charge is the percentage by which the capital investment can be multiplied to determine its annual cost on a uniform basis. The value of this carrying charge is very much dependent on the expected life of the piece of equipment because depreciation varies in accordance with life expectancy. A method of obtaining the level annual carrying charge is as follows: (1) calculate the sum of the annual charges for return on investment, depreciation, income tax, property tax, and insurance for each year of the expected life of the piece of equipment, (2) use the appropriate present-worth factor with each annual cost to convert the annual cost to a present-worth value; (3) sum up these values to obtain the total present worth of the annual carrying charges; and (4) multiply the total present worth by the capital recovery factor (see Fig. 13-1) to get the equivalent uniform annual charge. Figure 13-2 shows graphically the actual and equivalent carrying charges for a capital investment of a piece of equipment with a 5-year life and an assumed 8% cost of money.

The total carrying charges with 8% cost of money for various service lives are estimated as follows:

Years of life	Level annual total carrying charge in %
5	30.82
10	20.59
15	17.44
20	16.04
25	15.34
30	14.96
35	14.76
40	14.67
45	14.63
50	14.63

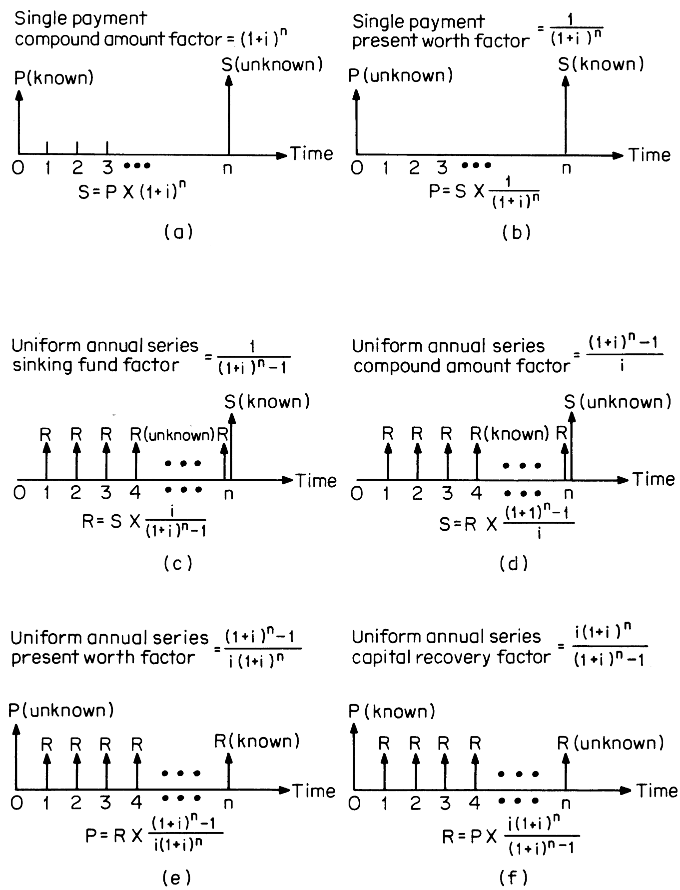

FIGURE 13-1 Graphic interpretations of compound interest factors.

Operating and Maintenance Expenses. This cost component varies with the nature of the project. It is usually not a direct function of the capital invested and may have an inverse tendency. That is, alternatives often exist for higher capital expenditures to reduce operating costs. Therefore, it is *not* expressed as a percent of capital investment in most cases. Nevertheless, it should be included in annual costs.

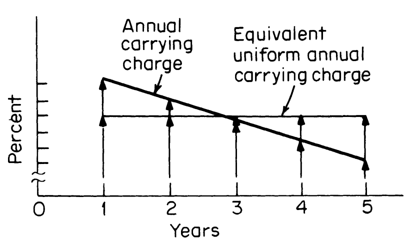

FIGURE 13-2 Representation of carrying charges.

Study Period. When determining the economic comparison of alternatives by comparing the present worth of annual costs, the study period should be taken to the point that the alternatives are equivalent in capability. If this is not practical, the study should be taken so far into the future that the difference in present worth would be insignificant.

Economic Evaluations. A simple example will show a comparison between two alternatives. Let *CC* represent the capital investment multiplied by the level annual carrying charge, operating and maintenance (*O&M*) represent annual operation and maintenance, and *RR* represent the total revenue requirement necessary annually to carry the project. A pad-mounted sectionalizing switch is needed for an underground circuit. The choice is between two manufacturers who can supply the switch but with different characteristics as follows:

	Mfr. A	Mfr. B
Installed cost	\$3600	\$3300
Operating and maintenance	50/year	100/year
Expected life	30 years	20 years

There is no salvage value at end of life. Determine which alternative is less expensive.

The first step is to draw a time diagram like Fig. 13-3. The common point in time for the two alternatives is 60 years, so two cycles of *A* should be compared with three cycles of *B*.

Present-worth analysis:

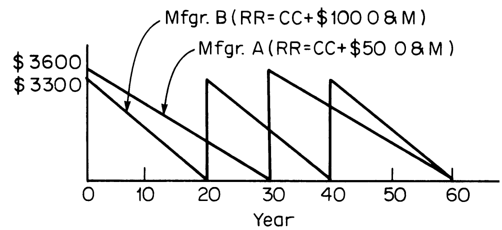

FIGURE 13-3 Time diagram.

$$\begin{aligned}\text{PW Mfr. } A\text{'s alternative} &= 3600 \times 0.1496 \times 11.258 + 50 \times 11.258 \\ &\quad + (3600 \times 0.1496 \times 11.258 + 50 \times 11.258)\, 0.0994 \\ &= 6063.11 + 562.90 + 658.63 \\ &= \underline{\underline{7284.64}}\end{aligned}$$

$$\begin{aligned}\text{PW Mfr. } B\text{'s alternative} &= 3300 \times 0.1604 \times 9.818 + 100 \times 9.818 \\ &\quad + (3300 \times 0.1604 \times 9.818 + 100 \times 9.818)\, 0.2145 \\ &\quad + (3300 \times 0.1604 \times 9.818 + 100 \times 9.818)\, 0.0460 \\ &= 5196.86 + 981.80 + 1325.32 + 284.22 \\ &= \underline{\underline{7788.20}}\end{aligned}$$

where 3600 = installed cost of Mfr. *A*'s switch
0.1496 = level annual carrying charge for 30-year *A* switch
11.258 = 8%, 30-year uniform annual series present-worth factor
50 = *O&M* of *A*'s switch
0.0994 = 8%, 30-year single-payment present-worth factor
3300 = installed cost of Mfr. *B*'s switch
0.1604 = level annual carrying charge for 20-year *B* switch
9.818 = 8%, 20-year uniform annual series present-worth factor
100 = *O&M* of *B*'s switch
0.2145 = 8%, 20-year single payment present-worth factor
0.0460 = 8%, 40-year single payment present-worth factor

Manufacturer *A*'s switch would be the overall lowest cost and would be the better deal provided the capability and reliability of the two switches are equivalent.

13.3 DECISION CRITERIA

There are two measures of the relative worth of projects—the net spendable *amount* of the return (the NPV) and the rate of return on the investment required. The latter measure is the *internal rate of return*. Mathematically, the internal rate of return is the discount rate at which the present value of the cost stream (including both original investments and subsequent costs) equals the present value of the revenue stream. The internal rate of return of the preceding project is obviously greater than 10%, since the NPV is positive at a 10% discount rate. If the NPV had been negative, then it would have been obvious that the internal rate of return was less than 10%.

A decision criterion often used to discriminate between projects is the *payback period,* or *payback*. Mathematically, the payback period is the *cost of the improvement* divided by the *average annual savings*. Although first-year savings are sometimes used as the divisor, the average savings should be used and should include escalations over the life of the project. Using only the first-year savings can yield an incorrect payback.

The following discussion demonstrates that a payback criterion often can lead to the wrong conclusion. If cash stream *A* and cash stream *B* of Table 13-2 were both "savings" streams resulting from the investment of $400 in projects A and B, respectively, the payback would mathematically be the same for each project because they have the same total savings. The average savings (income) is $650 divided by 4 years, or $162.50 per year. The payback for each project is the $400 investment divided by the average annual savings of $162.50, or almost 2.5 years. However, the NPV of each is not equal. The NPV of project A is $100 ($500 to $400); project B's NPV is $130 ($530 to $400). The time value of money causes project B to clearly be the better project; the payback criterion fails to differentiate between the two.

Because of the time-value-of-money problem, a payback criterion actually can indicate that a lesser project is better. For example, if the 1987 savings of project A increased from $220 to $240, the NPV of the project would increase from $100 to $114. Clearly, project B with an NPV of $130 is still better, if the discount rate is 10%. However, the payback period for project A would now decrease from 2.5 to 2.4 years; as a result, the wrong project would be picked if a payback criterion is used.

The type of payback discussed earlier is called a *simple payback* because it uses nominal-year dollars in the calculations. If real (constant-year) dollars are used, it is called the *discounted payback period* or the "breakeven period." In the preceding example, using a discounted payback criterion would have indicated the correct choice in both cases. In Table 13-2, the average discounted savings for projects A and B would be $125 [$500 present value (PV)/4 years] and $132.50, respectively; the discounted paybacks would be 3.2 years ($400/$125/year) and 3 years, respectively. Project B would be chosen because of its shorter payback period.

If the year 4 savings of project A increased to $240, the PV of savings would only increase to $514. Since this would still be less than the PV of $530 for the savings from project B, project A would have lower average discounted savings and a longer discounted payback than project B; the correct relative choice would be made. It is clear that if paybacks are used at all, the discounted payback should be used.

Although the preceding illustration shows the possible folly in looking only at nominal numbers, Table 13-3 and Fig. 13-4 show that folly even better. Both project *X* and project *Y* require a $1000 initial investment. It should be clear from Table 13-3 that project *Y* is the better of the two investments. It would be chosen whether the decision criterion was NPV, internal rate of return, calculated discounted paybacks, or calculated simple paybacks. However, if the first-year savings is used in the payback calculation, or if actual payback time (see the graph) is used, project *X* would be chosen. This shows the problem with using first-year savings instead of average savings; it also brings up another important point. It is *cash flows* which dominate business decisions; both the level and the timing of those flows can be critical. Project *X* could very well be the appropriate project to choose if the timing of its cash flows allowed other projects to be undertaken such that the aggregate benefit of all projects was increased. The final decisions on projects should be made on an overall benefit basis.

Another useful tool for comparing projects is the *benefit-cost ratio,* which is the present value of the benefits (savings) divided by the initial cost. For projects *X* and *Y* of Table 13-3, the benefit-cost

TABLE 13-3 Net Present Value vs. Payback ($1000 original investment, 10% discount rate)

						Project return				
	Net cash returns by year					Nominal $		Discounted $		
Project	1	2	3	4	5	Total	Net	PV	NPV	%IRR*
X	500	500	250	100	50	1400	400	1155	155	18.5
Y	200	300	400	500	600	2000	1000	1444	444	23.3

	Simple payback, year			Discounted paybacks, year	
	Calculated using				
Project	1st-year savings	Average savings	Actual payback	Calculated	Actual
X	2.0	3.6	2.0	4.3	3.5
Y	5.0	2.5	3.2	3.5	3.8

*IRR = internal rate of return.

ratios are 1.155 and 1.444, respectively. When the appropriate discount rate is used, any benefit-cost ratio greater than unity (1.0) indicates that the project is profitable.

Calculating the NPV and the internal rate of return from each alternative project is a rational method of discriminating between projects and ranking them in an investment priority. First, the projects can be ranked in descending order by the internal rates of return. With an unlimited amount of money and management time, a company would be expected to start all projects with an internal rate of return greater than the cost of money to the company. However, in the "real world," this is usually not the case. The firm is usually limited in capital, or in management capability, and must choose a

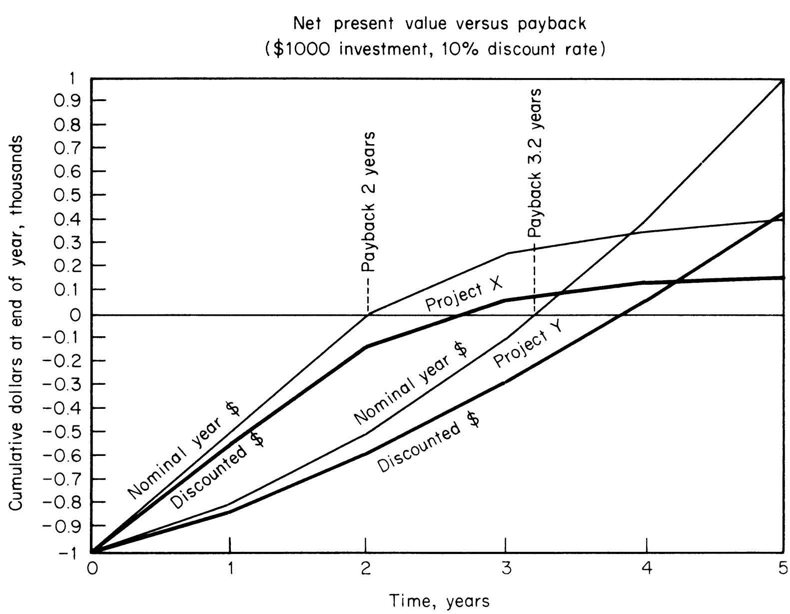

FIGURE 13-4 Graph of net present value vs. payback (values from Table 13-3).

subset of the complete menu of alternative projects. The NPVs of the projects can be used to help match available resources to achieve the greatest total real return.

In addition to the consideration of the real income and the real rates of return from the various projects, the nominal-dollar flows of each project must be considered to ensure that the cash flow of the company will be great enough to provide the capital needed in each time period.

If the total cash outlay required for all projects is greater than the total income during any period, the company must either borrow the shortfall or pay it out of available cash. For many companies, available cash is tight, and expected business conditions are not good or are uncertain. These companies will rarely invest in a set of projects that may put them in financial jeopardy—even if the expected long-term returns are great. It is not unusual for a low-return project to be substituted for a high-return project when the cash requirements of the high-return project coincide with other cash demands and the company cannot economically provide the required funds at that time.

The example in Table 13-3 is simplistic. It incorrectly assumes that (1) the project costs and returns are certain and (2) all proceeds of the project can be retained by the owner. Uncertainty of cash flows should be considered by using "sensitivity analysis" and comparing expected results under both optimistic and pessimistic conditions. The tax consequences of the manner in which a project is financed are discussed in the next sections. Further comments on the characteristics affecting the type and amount of an investment are provided at the end of this primer.

13.4 AFTER-TAX CASH FLOWS

The net amount of cash available for reinvestment in the company or distribution to the owners depends on the tax consequences of a project and its financing. For tax purposes, there are two kinds of project expenditures—expensed and capitalized. Expenditures for short-lived items consumed in making a product or providing a service are generally allowed to be "expensed" in the year they are made. Such expenses are allowed to be deducted from gross income before taxes are computed. Examples are rent, parts, travel expenses, utility bills, raw materials, labor, and advertising.

Capitalized expenditures will continue to give service for several years. The company is allowed to recover those expenses over a number of years by deducting a percentage of the cost each year from the gross income of the company before calculating the taxes. This "depreciation recovery" follows specific rules for the number of years over which the recovery is made and the percentage of the cost allowed as a tax deduction each year.

Typical capitalized expenditures are buildings, machinery, and land. Since buildings and machinery are "consumed" in service, they are considered depreciable property. Land, however, is not consumed and cannot be depreciated except under special circumstances, such as where the usefulness of the land is indeed consumed and a depletion allowance is authorized.

Deductions have no value in themselves; they merely serve to reduce the amount of income that is taxable. As a result, the actual value of an allowed expense or depreciation deduction depends on the *incremental tax rate* of the company. This is the rate charged against the "last" income earned in a year. Since a tax deduction offsets or "shelters" income by reducing the taxable income, the value of a tax deduction is the amount of tax that would have been paid on the income that is sheltered by the deduction. The higher the incremental tax rate, the greater the tax expense avoided by taking the deduction. The reduction in income taxes that *results* from allowed deductions has the same effect as an increase in project revenues; each increases the net revenues of the project. (*Note:* Deductions are not cash items and are not spendable income; their value is that they generate savings in taxes that otherwise would have to be paid.)

Most projects qualify for one or more special tax subsidies called *tax credits*. A tax credit can offset a tax otherwise owed to the government; the actual cash required for paying taxes is thus reduced. Tax credits are usually in the form of a stated percentage of the capitalized project investment and are usually allowed only in the year of the investment. Unlike allowed depreciation, the effect on the company from a tax credit is independent of the incremental tax rate. The tax credit is a direct reduction in the tax liability of the company. If the tax credit is greater than the tax liability in that year, the unused portion can be applied in other years.

TABLE 13-4 Tax Calculation

Gross income
− interest payments
− operating expenses
− allowable amortization and depreciation on equipment
− other tax-deductible expenses
= taxable income (+ or −)
× incremental tax rate
= initial tax liability (+ indicates due, − indicates saved)
− total tax credits (only if tax liability is positive)
= actual tax (+ indicates due, − indicates saved)

Note: Taxable income is the net difference between gross income and allowed deductions. Since taxable income determines the actual tax liability, it is easy to see the effect on after-tax income of increasing or decreasing the allowed deductions.

The net cash flow in spendable dollars yielded by a project depends on the gross income and the cash expenditures which must be made as a result of the project. The tax effects of the investment and the method of financing the investment can sometimes "make or break" a project. Table 13-4 shows the items that must be considered when calculating tax liabilities.

Table 13-5 shows two methods of calculating the effect of taxes on cash flow; both yield the same answer. These methods are presented here to aid in understanding the effect of nondeductible expenses and noncash tax deductions on the cash flow of a given year. Principal payments on loans are not allowed as a tax deduction, but they are cash payments that must be made during the year. On the other hand, depreciation on depreciable assets is allowed as a tax deduction, and therefore reduces taxes, but it is not an out-of-pocket cash expenditure.

TABLE 13-5 Cash Flow Calculations

Method 1
Taxable income
− principal payments on debt
+ allowable amortization and depreciation (these are noncash-deductible expenses and, as such, are not spent but available)
= cash available for taxes
− tax due (or + tax savings)
= after-tax cash income
Method 2
Gross income
− interest payments
− principal payments
− other cash expenses
= cash available for taxes
− tax due (or + tax savings)
= after-tax cash income

Note: These calculations assume that the total income of this project and other projects is great enough for the owner to use all of the benefits earned in this year. Otherwise, some of the benefits may be carried into another tax year—but they will be worth less because of the time value of money.

13.5 FINANCING EFFECTS

The examples in Table 13-6 show the tax benefits that result from changing the method of financing a project. The project requires an initial investment of $4000. If as in line 1 the owner finances the whole project with personal equity funds, without borrowing any funds and going into debt, the only tax deduction allowed over the life of the project is the depreciation expense. Since both the tax credits and the depreciation expense are related only to the cost of the depreciable assets, and not to the method of financing, both are the same in all cases. If the owner has a 50% incremental tax rate, the allowed deductions generate $2000 in tax savings if the project is 100% equity-financed. The resulting tax benefits total 60% of the original equity investment.

If the owner borrows $1000 and invests $3000 of his or her own money, that is, finances the project in a 25:75 debt-equity ratio, the allowed tax deductions rise by the $492 interest deduction, and the tax benefits increase. Financing part of a project with debt funds is called *leveraging* the equity investment. All the benefits of the project continue to flow to the owner, and the tax benefits themselves increase. As a result of the increased benefits and the decreased equity investment, the ratio of tax benefits to equity increases; the rate of return on the investment thus increases, even though the project itself is bringing in the same gross income.

If the project is financed with a 75:25 debt-equity ratio, the tax benefits which accrue to the owner amount to over 3 times its original equity investment. There are no free lunches, however. If the project fails to reach its income objectives, or costs run higher than expected, the owner will still be liable for payment of the principal and interest payments on the money borrowed for the project. The higher the leverage of the investment in the project, the higher is the business risk the owner faces.

Table 13-7 contains the data for the illustrations of financing effects in the remaining tables. The payments for principal and interest are shown for a debt of $1000 to be repaid over 5 years at 15% interest. The depreciation rates allowed under the accelerated cost recovery system (ACRS) are shown along with the annual depreciation and the investment tax credit allowed on a $2000 depreciable investment. The tables in this text were prepared using 1982 regulations and have been retained for simplicity of illustration. Since tax credits and tax deductions change frequently, care should be taken to use the correct allowances.

Table 13-8 shows the calculations of tax effects and cash flows for a $2000 project which the owner finances completely with equity investment. There are no interest deductions included in the tax calculations, since there is no debt to repay. Likewise, there are no principal payments included in the cash flow calculations. The incremental income tax rate of the owner is assumed to be 50%. This method of financing the project yields a nominal return of $4434 over 5 years from an original investment of $2000. The internal rate of return is 32.6%.

Table 13-9 shows the same project, except that it is now financed with 50% equity and 50% debt, with the debt cost assumed at a rate of 15% per year. A 50:50 debt-equity ratio increases the cash outflow required to service the debt; it reduces the overall nominal return over the 5 years to $3187. However, since the owner invested only $1000, the internal rate of return of the project increases to the 55% level. This indicates that if the owner had $2000 to invest, it would be better (other things

Note: The original *owner* investment of $1000 returns over $3000 in 5 years for an *internal rate of return* of 54.5%. *Leveraging* the owner's equity investment 1:1 with debt causes the internal rate of return on the owner's equity investment to rise because the owner invests only half the money but still receives the full tax benefits.

being equal) to invest $1000 each in two such projects. The yield would then be $6374 for a $2000 investment, as compared with $4434 if only one project is completely owner-financed.

Table 13-10 shows that the same project, with a 30% owner tax rate, yields $3982 in income for the $1000 initial investment. (*Note:* All the tax credit could not be used in the first year because the tax liability was reduced by the lower tax rate.)

13.6 LEASING

When a lease arrangement is worked out between two parties, the lessor party owns the installation, and the lessee party pays for its use. Since the lessee must pay enough profit to the lessor for the lessor to be willing to install the property for the lessee's use, this arrangement might not appear advantageous to the lessee. However, leasing can be a great advantage in several situations, particularly when the lessee does not want to or cannot borrow the initial money required. The tax advantages of a lease often make a project *go* with lease financing when it cannot go otherwise. Tables 13-11 to 13-14 examine the cash flows that occur in a leasing situation.

Table 13-11 calculates the revenue required for the lessor to recover its expenses and investment *without* any return, that is, to break even, if it installs the project and leases it to a lessee. In this particular case, the lessor would make no profit and there would be no incentive to install the project. This case is shown only for the purpose of having a clean example to use as a base for leading into the following examples. Table 13-11 shows the effect of the tax deductions on the lessor; it also shows the out-of-pocket expenses of the lessor that must be covered by the lessee if the lessor breaks even. This is essentially the same set of calculations shown in Table 13-9, except that Table 13-11 calculates the breakeven point.

If the lessor breaks even, Table 13-12 shows the return to the lessee from leasing the project from the lessor. In this case, the lessee invests no money in the project and still reaps a handsome reward. One of the mechanisms that makes leasing work is that the lessee can take the entire cost of the lease as a deduction before taxes, *including the cost of the principal payments of the lessor*. If the lessee were to put the project in on its own, as in Table 13-9, it could deduct only depreciation and interest payments. By leasing, the lessee gets, in effect, two bites at the apple; it gets to deduct the entire

Note: With a zero investment by the lessee, the lessor makes a 15% return and the lessee still makes $1695, an infinite return. The long-run economics of leasing would depend upon the terms of the lease and the residual ownership and use of equipment after the initial payoff.

lease payment before taxes. Since the lease payment includes both the principal payments and the tax effects of depreciation allowances, the lessee, in effect, gets to write off the project twice, once at the lessor's incremental tax rate and once at the lessee's incremental tax rate.

Table 13-13 is the same as Table 13-11, except that Table 13-13 calculates the revenue required to produce a 15% return on investment for the lessor, rather than a breakeven return. Required income almost doubles, primarily because of the income taxes that have to be paid on taxable income before the net cash is available to the lessor.

Table 13-14 shows that the effect of allowing the lessor to earn a 15% rate of return is to cut the lessee's after-tax income roughly in half. However, since the lessee still hasn't invested any money in the project, the rate of return of the lessee is infinitely large. When the return of $1695 from leasing is compared with the return of Table 13-9, where an initial investment of $1000 is required, the attractiveness of many leasing schemes is immediately seen. When such schemes are combined with provisions for the lessee to be able to buy the project from the lessor in the future at a reasonable price and at lessee's option, the package can be especially attractive.

In some cases, leasing is used to protect the lessee from buying a set of equipment that may not work well for its application. By leasing, the lessee gets a chance to work with the equipment and see if it performs as expected—before spending large amounts of investment capital on the installation.

13.7 RATE-OF-RETURN REQUIREMENTS

There are three components of *interest rates*. The first is the *liquidity factor*. There is a value in having cash available to use for whatever investment opportunity may appear in the future. Before one person will lend money to another, the interest earned must compensate the lender for the unavailability of its money while the borrower still has it, that is, for the lack of liquidity. Second, just like one neighbor lending another a lawn mower, the lender of money expects to get it back in just as valuable a condition as when it was borrowed. In the case of money, the borrower must increase the interest rate paid to the lender enough to include the expected rate of *inflation*. This allows the lender to recover the same *value* as originally lent, albeit a greater number of dollars. The third item that must be included in the interest rate, before a lender is willing to part with the money, is enough additional interest to offset any *risks* associated with the loan. Obviously, the riskier a loan appears, the higher the interest rate required by the lender will be. All of these factors entail *uncertainty*. The lender is uncertain about what opportunities may come along later, the devaluation of the loan from inflation, the ability of the lender to repay the loan, changes in government regulations, and other factors.

These same factors influence the *minimum expected rate of return,* or the *hurdle rate,* that a company requires a project to meet or exceed before giving it full consideration. If the company must borrow money to finance the project, it will be concerned about its ability to repay the loan without jeopardizing the company. The very financing methods which leverage a company's investment and produce such high possible returns also leverage the company's financial risk. Usually, the more stable the expected earnings from projects, the more leverage the company is willing to risk.

If a hurdle rate is used to screen potential projects, the hurdle rate should appropriately reflect the weighted cost of capital to the firm. Using a hurdle rate that is significantly different from the weighted cost of capital incorrectly rejects and accepts projects.

It is not correct to use either the opportunity cost of using retained earnings or the interest rate on borrowed debt solely as the hurdle rate. If retained earnings are used in one project, they are unavailable for use in others. The opportunity cost of using those funds is the rate of return that could be earned by investing those funds in routine company business opportunities. As such, they are generally both higher cost and less extensive than available debt funds. Using that rate can deny worthwhile projects and choke the expansion of the firm.

Considering a project to be financed entirely by debt is also unrealistic. If funds are borrowed without a complementary equity investment, the debt-equity ratio rises, the debt coverage ratio falls, and the ability to borrow more funds decreases.

As a result of the above and related factors, the appropriate hurdle rate is the weighted cost of capital to the firm.

Hurdle rates are often used both as a threshold of profitability that projects must meet and as a method of discriminating *between* projects. As stated earlier, using a hurdle rate that is significantly different from the actual cost of capital to the firm will undercommit or overcommit the firm. As shown below, it may also lead to an incorrect choice of projects.

If all projects under consideration have positive cash flows in later years, almost any hurdle rate can be used to determine the "best" projects on a relative NPV basis. The higher the hurdle rate used to discount future cash flows, the lower the resulting NPV. The result may be the wrong NPV, but the relative ranking will not change. However, that is *not* the case where one or more of the projects have some later years with negative cash flows, such as when significant investments in maintenance or replacement are required; relative rankings may change.

In effect, the discount rate used as a hurdle is assumed to be a rate that can continue to be earned in other areas by the dollars returned from a project each year. It can be used to pay off debt and "earn" the avoided interest, or it can be put into another income-producing project. In addition, the higher the discount rate, the less value are later revenues. It is these effects which require the hurdle rate to be close to the actual cost of capital. If a firm cannot actually earn the hurdle rate by reinvesting each year's proceeds from a project, the wrong project may be chosen.

13.8 CHARACTERISTICS AFFECTING INVESTMENTS

The preceding discussions have briefly covered some of the factors that drive the decisions people make about new projects and affect the amounts and types of investments. The following is a summary of items that must be considered when any major project is examined:

Ability to borrow money

Cash on hand

Relative risk of the project

Ability to use tax benefits

Existence of tax credits or unusual benefits or constraints

Relative tax rates

Timing of the costs and revenues

Relative permanence of the investment

Ability to shift to another investment if one becomes more attractive

Ability to maintain and operate the project equipment

The ability of a party with money and a party with a project need to find a satisfactory arrangement for (1) financing the project and (2) appropriately sharing the risks and the benefits is almost limitless. Both parties (they may be the same party if the project is primarily owner-financed) must find an acceptable level of risk and reward.

13.9 RISK AND REWARD

To many people, taking a risk is its own reward; to others, very little risk is worth taking. The successful manager will analyze alternative projects and will adjust project parameters and financing methods to yield combinations of risk and expected reward appropriate for all parties.

The successful project analyst will be guided by the TANSTAAFL principle: *There ain't no such thing as a free lunch*. Someone, somewhere pays for everything. The questions are who? how much? and when? Answering these provides the basis for sound decisions.

CONTENTS

14.1 OVERHEAD AC POWER TRANSMISSION

Overhead transmission of electric power remains one of the most important elements of today's electric power system. Transmission systems deliver power from generating plants to industrial sites and to substations from which distribution systems supply residential and commercial service. Those transmission systems also interconnect electric utilities, permitting power exchange when it is of economic advantage and to assist one another when generating plants are out of service because of damage or routine repairs. Total investment in transmission and substations is approximately 10% of the investment in generation.

Since the beginning of the electrical industry, research has been directed toward higher and higher voltages for transmission. As systems have grown, higher-voltage systems have rarely displaced existing systems, but have instead overlayed them. Economics have typically dictated that an overlay voltage should be between 2 and 3 times the voltage of the system it is reinforcing. Thus, it is common to see, for example, one system using lines rated 115, 230, and 500 kilovolts (kV). The highest ac voltage in commercial use is 765 kV although 1100 kV lines have seen limited use in Japan and Russia. Research and test lines have explored voltages as high as 1500 kV, but it is unlikely that, in the foreseeable future, use will be made of voltages higher than those already in service. This plateau in growth is due to a corresponding plateau in the size of generators and power plants, more homogeneity in the geographic pattern of power plants and loads, and adverse public reaction to overhead lines. Recognizing this plateau, some focus has been placed on making intermediate voltage lines more compact. Important advances in design of transmission structures as well as in the components used in line construction, particularly insulators, were made during the mid-1980s to mid-1990s. Current research promises some further improvements in lines of existing voltage including uprating and now designs for HVDC.

14.1.1 Transmission Systems

The fundamental purpose of the electric utility transmission system is to transmit power from generating units to the distribution system that ultimately supplies the loads. This objective is served by transmission lines that connect the generators into the transmission network, interconnect various areas of the transmission network, interconnect one electric utility with another, or deliver the

TABLE 14-1 Standard System Voltages, kV

161	169		

electrical power from various areas within the transmission network to the distribution substations. Transmission system design is the selection of the necessary lines and equipment which will deliver the required power and quality of service for the lowest overall average cost over the service life. The system must also be capable of expansion with minimum changes to existing facilities.

Electrical design of ac systems involves (1) power flow requirements; (2) system stability and dynamic performance; (3) selection of voltage level; (4) voltage and reactive power flow control; (5) conductor selection; (6) losses; (7) corona-related performance (radio, audible, and television noise); (8) electromagnetic field effects; (9) insulation and overvoltage design; (10) switching arrangements; (11) circuit-breaker duties; and (12) protective relaying.

Mechanical design includes (1) sag and tension calculations; (2) conductor composition; (3) conductor spacing (minimum spacing to be determined under electrical design); (4) types of insulators; and (5) selection of conductor hardware.

Structural design includes (1) selection of the type of structures to be used; (2) mechanical loading calculations; (3) foundations; and (4) guys and anchors.

Miscellaneous features of transmission-line design are (1) line location; (2) acquisition of right-of-way; (3) profiling; (4) locating structures; (5) inductive coordination (considers line location and electrical calculations); (6) means of communication; and (7) seismic factors.

14.1.2 Voltage Levels

Standard transmission voltages are established in the United States by the American National Standards Institute (ANSI). There is no clear delineation between distribution, subtransmission, and transmission voltage levels. In some systems 69 kV may be a transmission voltage while in other systems it is classified as distribution, depending on function. Table 14-1 shows the standard voltages listed in ANSI Standards C84 and C92.2, all of which are in use at present.

The nominal system voltages of 345, 500, and 765 kV from Table 14-1 are classified as extrahigh voltages (EHV). They are used extensively in the United States and in certain other parts of the world. In addition, 400-kV EHV transmission is used, principally in Europe. EHV is used for the transmission of large blocks of power and for longer distances than would be economically feasible at the lower voltages. EHV may be used also for interconnections between systems or superimposed on large power-system networks to transfer large blocks of power from one area to another.

One voltage level above 800 kV, namely, 1100 kV nominal (1200 kV maximum), is presently standardized. This level is not widely, although sufficient research and development have been completed to prove technical practicability.[*1–3]

14.1.3 Conductor Selection

Considerations in Selection.[4] The choice of a conductor for a transmission line, as with structure type, depends on the specific application. Once the mechanical strength requirement of the conductor

[*]Superscript numbers refer to references listed at the end of this section (*1–3).

is satisfied, the conductor choice considers the total costs associated with the conductor and also the corona-related electrical environmental effects of radio and audible noise. Corona also causes power loss, particularly during wet weather.

The electrical stress on the surface of a conductor is a function of the voltage on the conductor, the size (i.e., surface area) of a conductor, and the spacing between conductors and/or grounded objects.

The equivalent size of a conductor can be increased by using either a larger conductor or several smaller conductors electrically and physically connected together (bundled conductors). While a single, very large conductor would be electrically adequate, several smaller conductors offer practicality of manufacturing and transporting, ease of construction, and minimizing material usage and mechanical stresses on the supporting structures during high winds and/or ice on the conductors.

At voltages of 345 kV and above, the minimum conductor size or the minimum number of conductors and the individual conductor size in a bundle are, in addition to cost considerations, normally determined by the corona-related electrical environmental effects. At voltages below 345 kV (e.g., 69 through 230 kV), the minimum size is normally based only on conductor economics.

The conductor sag in the span between structures will depend on conductor materials, conductor weight, conductor strength, conductor tension, conductor temperature, and ice accumulation on the conductor. Strong conductors can be installed at higher tensions and will sag less.

As the current in a conductor increases, the losses increase with a resultant increase in conductor temperature, causing the sag to increase. If the conductor is carrying heavy electrical load on a hot day, very significant increases in sag can occur. Short spans of 150 to 300 ft may have sags of 2 to 5 ft. Long spans of 1000 to 1500 ft may experience sags of 40 ft or more.

Since a limiting design criterion is minimum conductor height above ground (for safety reasons), the maximum sags during operation can determine structure heights and span lengths. Similarly, in certain areas ice can form on the conductors of sufficient weight to limit the structure heights and span lengths to maintain ground clearance.

Economics. Conductor economic analyses normally use the present worth of revenue required (PWRR) method. This considers the sum of the present worth of levelized annual fixed charges on the total line capital investment, plus annual expenses for line losses:

$$\text{PWRR} = \sum_{n=1}^{\text{NYE}} \left(1 + \frac{i}{100}\right)^{-n} \times \left(\text{CI} \times \frac{F_L}{100} + \text{ADC}_n + \text{AEC}_n\right) \tag{14-1}$$

where PWRR = present worth of revenue required
NYE = number of years to be studied
n = nth year
i = annual discount rate in percent
CI = total per mile capital investment
F_L = line fixed-charge rate in percent
ADC_n = per mile demand charge for line losses for year n
AEC_n = per mile energy charge for line losses for year n

The cost of line losses is based on the cost of generating the losses. Annual demand and energy charges are calculated as shown in the following equations.

Annual demand charge for line losses for year *n:*

$$\text{ADC}_n = \frac{C_{\text{kW}} \times \text{ESC}_n}{10^3} \times \frac{F_g}{100} \times \left[1 + \frac{\text{RES}}{100} \times I_L^2 \times \frac{R}{N_c} \times N_{\text{ckt}} \times N_p\right] \tag{14-2}$$

where ADC_n = annual demand charge for year n
C_{kW} = installed generation cost in dollars per kilowatt
ESC_n = escalation cost factor for year n
F_g = generation fixed-charge rate in percent
RES = required generation reserve in percent

I_L = demand phase current in amperes per circuit
R = single conductor resistance in ohms per mile
N_c = number of conductors per phase
N_{ckt} = number of circuits
N_p = number of phases

Annual energy charge for line losses for year *n:*

$$\text{AEC}_n = \frac{C_{\text{MWh}} \times \text{ESC}_n}{10^6} \times 8760 \times \frac{L_f}{100} \times I_L^2 \times \frac{R}{N_c} \times N_{\text{ckt}} \times N_p \tag{14-3}$$

where AEC_n = annual energy charges for year n
C_{MWh} = cost of generating energy in dollars per megawatthour
ESC_n = escalation cost factor for year n
L_f = loss factor for determining energy losses in percent
I_L = demand phase current in amperes per circuit
R = single conductor resistance in ohms per mile
N_c = number of conductors per phase
N_{ckt} = number of circuits
N_p = number of phases

As the conductor size increases, the installed cost increases, because of both the increased conductor cost and the stronger structures necessary to support the larger, heavier conductor and the attendant mechanical loading. The larger conductor cross section, however, results in lower resistance and therefore lower losses. If corona losses are considered, these are also reduced for larger conductors, assuming other dimensions (e.g., phase spacing) remain constant. Therefore, there will be an overall minimum cost at a specific conductor size, where installed cost forces the PWRR higher for large conductors and the cost of losses forces the PWRR higher for smaller conductors. This is conceptualized in Fig. 14-1. In most practical analyses, there is a relatively flat "minimum" total cost (PWRR) region such that the line designer can temper the economic choice with other factors. Various conductor designs and configurations, such as number of conductors per bundle and size of conductors in a bundle, are examples of areas of designer preference. The higher cost of energy, primarily due to increased fuel costs, has increased the significance of cost of losses in the economic analysis, skewing the economics toward larger conductors with lower losses.

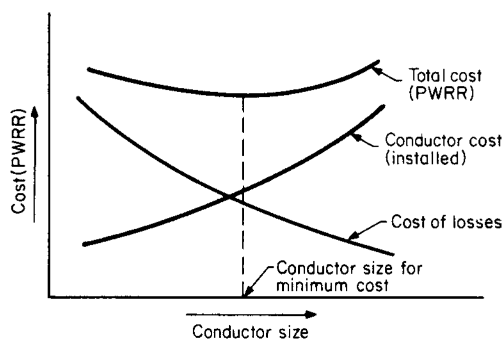

FIGURE 14-1 Conductor economic concept.

Beside the cost of electrical losses, the choice of conductor is an important factor in determining the maximum allowable power flow through the line. For long lines, maximum allowable power flow may be determined by limits on electrical phase shift or voltage drop. For shorter lines, the maximum conductor temperature (thermal rating) may limit the maximum allowable power flow. High thermal capacity can be accomplished either by using a large diameter conductor with relatively low electrical resistance or by using a conductor of relatively smaller diameter tolerant to high operating temperatures, such as ACSS conductors, which can operate continuously at 200°C with no changes in their mechanical properties. For example, consider the following thermal ratings calculated for a transmission line located in an environment with air temperature of 40°C, full sun, and a perpendicular wind speed of 2 ft/s.

Conductor name	Aluminum area (kcmil)	Maximum temperature (°C)	Thermal rating (amperes)
Ibis	397.5	100	640
Drake	795	100	995
Falcon	1590	100	1520
Drake/ACSS	795	200	1600

Calculations leading to optimization plots such as shown in Fig. 14-1 are usually done assuming a relatively simple line model consisting of a conductor in catenary between structures at a typical spacing.[4] In this "typical span" model, the line is approximated as a series of structures that have the same height and spacing so that the conductor between them has the same sag and tension in all spans. Typical numbers of angle and dead-end structures are assumed per mile of line. Structure height is just sufficient to meet ground clearance, and structure cost is estimated based on this height, on phase spacing, and on typical transverse, vertical, and longitudinal loads for this span. Such a simple typical span model yields exact electrical losses, approximate structure costs, and is adequate for the exact calculation of radio noise, audible noise, and electric and magnetic fields.

Having used the "typical span" model to determine the range of conductor sizes which yield minimum total present worth cost of electrical losses and construction costs and adequately low environmental effects, the transmission-line design can be further optimized by considering a more realistic "terrain optimized" model of the line on actual or typical terrain. In such a study, the designer utilizes the availability of fast, efficient tower spotting algorithms to provide more exact structure cost estimates. Such studies have been described in Refs. 5 and 6.

Optimization of transmission designs using modern computer-based techniques allows the designer to consider variations in standard design constraints by modeling alternate designs having various design constraints on the same terrain. For example, transmission-line designs normally assume a standard unloaded conductor tension. Optimization studies might include evaluation of higher than standard conductor tensions in order to reduce conductor sag at high temperature. A "typical span" model may be used to evaluate the savings in structure height due to reduced sag and the increased cost of angle structures due to higher tension levels. A "terrain optimized" model will provide a more realistic estimate of the savings in structure height and the increased cost of angle structures and dead ends and will also identify costs related to uplift of structures at minimum temperature.

In addition to conductor tension, a "terrain optimized" model of the proposed line allows the designer to estimate costs for variations in

Available structure classes (e.g., fewer tangent types, an added light angle structure)

Conductor type (e.g., percentage of steel area in ACSR, self-damping conductor)

Available structure heights (e.g., fewer available heights, taller structures)

Optimization studies involve the consideration of nonstandard conductors and structures. This is typically justified only by large-scale design and construction projects or during the development of new standard transmission designs to meet changes in environmental effect constraints. Reuse of existing "standard" structure designs or conductors is often preferred due to considerations such as spare parts, tools and training, maintenance, known reliability, externally imposed factors such as hot line maintenance clearances, and short or highly constrained construction.

A highly variable component of transmission line costs is getting permits and rights-of-way. In some extreme situations this may be so great as to counter balance the normally much higher cost of underground cables.

14.1.4 Electrical Properties of Conductors

Positive-Sequence Resistance and Reactances. The conductors most commonly used for transmission lines have been aluminum conductor steel-reinforced (ACSR), all-aluminum conductor (AAC), all-aluminum alloy conductor (AAAC), and aluminum conductor alloy-reinforced (ACAR), but conductors able to operate at higher temperatures such as ACSS are available for a modest price premium and are becoming more common. Research is progressing on new high temperature ceramic-cored conductors. Tables of the electrical characteristics of the most commonly used ACSR conductors are in Sec. 4. Characteristics of other conductors can be found in conductor handbooks or manufacturers' literature and web sites.

The per mile resistance, inductive reactance, and capacitive reactance can be determined from the data in the tables of Sec. 4 and the spacing factors X_d and X_d.

The positive-sequence resistance is listed as the 60-Hz value at 50°C. The expression for inductive reactance per mile is

$$X_L = 0.004657f \log \frac{D}{\text{GMR}} \tag{14-4}$$

where D = equivalent spacing in feet, GMR = geometric mean radius in feet as given in the conductor tables of Sec. 4, and f = frequency in hertz. GMR for ACSR conductor is given at 60 Hz. However, 60-Hz values of GMR can be used at other commercial power-system frequencies with small error. X_L also can be expressed as

$$X_L = X_a + X_d = 0.004657f \log \frac{1}{\text{GMR}} + 0.004657f \log D \tag{14-5}$$

When the spacing is 1 ft, X_d becomes zero. Thus X_d is frequently called the "one-foot" inductive reactance. The expression for capacitive shunt reactance per mile is:

$$X_c = \frac{4.099 \times 10^6}{f} \log \frac{D}{r_c} \tag{14-6}$$

where r_c = conductor radius in feet, which can also be expressed as

$$X_c = X'_a + X'_d$$

where

$$X'_a = \frac{4.099 \times 10^6}{f} \log \frac{1}{r_c} \tag{14-7}$$

and

$$X'_d = \frac{4.099 \times 10^6}{f} \log D \tag{14-8}$$

Bundle conductors consist of two or more conductors per phase mechanically and electrically connected and supported by an insulator assembly. The positive-sequence resistance is, to a first approximation, the 60-Hz, 50°C values in the Sec. 4 tables divided by the number of conductors per phase. General formulas for the inductance and capacitance of bundle conductors are

$$L_\phi = \frac{1}{n}\left[0.74113 \log \frac{r_c}{\text{GMR}} + 0.74113 \log \frac{24(S_{gm})^n}{d(M_{gm})^{n-1}}\right] \quad \text{mH/mi} \tag{14-9}$$

From Eq. (14-9) inductive reactance is found to be

$$X_L = \frac{1}{n}\left[K + 0.004657f \log \frac{24(S_{gm})^n}{d(M_{gm})^{n-1}}\right] \quad \Omega\text{/mi at 60 Hz} \tag{14-10}$$

and the capacitance is

$$C_\phi = \frac{0.03883n}{\log[24(S_{gm})^n/d(M_{gm})^{n-1}]} \quad \mu\text{F/mi} \tag{14-11}$$

In the above, n = number of conductors per phase (bundle); d = diameter of conductor in inches; S_{gm} = geometric mean distance between conductors of different phases in feet, found by taking the mean distance from all conductors of one phase to all conductors of the other phases; M_{gm} = geometric mean distance in feet between the n conductors of one phase; K = internal conductor reactance defined as

$$K = 0.004657 f \log \frac{r_c}{\text{GMR}} \qquad \Omega/\text{mi} \tag{14-12}$$

TABLE 14-2 Equivalent Reactances

Bundle	X_{aeq}	X'_{aeq}
2 conductors	$^1/_2(X_a - X_s)$	$^1/_2(X'_a - X'_s)$
3 conductors	$^1/_3(X_a - 2X_s)$	$^1/_3(X'_a - 2X'_s)$
4 conductors	$^1/_4(X_a - 3X_s)$	$^1/_4(X'_a - 3X'_s)$

The inductive series reactance and capacitive shunt reactances for bundled conductors can also be found by using the $X_a + X_d$ method, by determining the equivalent X_a and X'_a of the conductor bundle. The expressions for the equivalents are given in Table 14-2. These expressions are for three-conductor bundles on equilateral spacing and for four-conductor bundles on square spacing. The subscript s indicates the spacing of the conductors within the bundle in feet. Values for X_a and X'_a are in the conductor tables in Sec. 4. Values for X_s and X'_s are from the same formulas as X_d and X'_d.

$$X_s = 0.004657 f \log s \tag{14-13}$$

$$X'_s = \frac{4.099 \times 10^8}{f} \log s \tag{14-14}$$

where s is in feet and f is frequency in hertz. Equation (14-14) is correct for a ratio of spacing s to conductor radius r of 5 or more.

The value of X_{aeq} is added to X_d (the spacing factor, which is determined for the mean spacing between the conductors of the different phases). X'_{aeq} and X'_d are handled in a like manner.

Zero-Sequence Impedances. When earth-return currents due to faults or other causes are to be calculated, negative- and zero-sequence impedances must be determined in addition to positive-sequence quantities. Negative-sequence quantities are the same as the positive-sequence values for transmission lines. Precise determination of the zero-sequence quantities is difficult because of the variability of the earth-return path.

Calculation of zero-sequence impedance parameters is far more complex than for positive-sequence quantities, being a function of conductor size, spacing, relative position of conductors with respect to overhead ground wires, electrical characteristics of overhead ground wires, and the resistivity of the earth-return circuit. Reference 7 includes a detailed analysis of zero-sequence parameters, which are normally calculated using digital computer programs.

Table 14-3 lists representative values of positive- and zero-sequence impedances for different voltage transmission lines with shield wires. Zero-sequence reactance increases for unshielded lines.

TABLE 14-3 Typical Transmission-Line Impedance*

Voltage, kV	R_1	X_{L1}	X_{C1}	R_0	X_{L0}	X_{C0}	X_0/X_1
69	0.280	0.709	0.166	0.687	2.74	0.315	3.86
115	0.119	0.723	0.169	0.625	2.45	0.265	3.39
230	0.100	0.777	0.182	0.591	2.26	0.275	2.91
345	0.060	0.590	0.138	0.551	1.99	0.208	3.37
500	0.028	0.543	0.127	0.463	1.90	0.198	3.50
765	0.019	0.548	0.128	0.428	1.77	0.185	3.23

*R_1, X_{L1}, R_0, X_{L0} are in ohms per mile; X_{C0}, X_{C1} are in megohm-miles.
Note: 1 mi = 1.61 km.

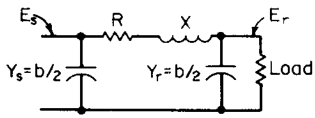

FIGURE 14-2 Nominal-π line.

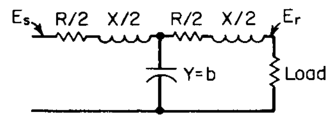

FIGURE 14-3 Nominal-*T* line.

Nominal-π Representation. Transmission lines can be represented by nominal π as in Fig. 14-2, in which half the capacitive susceptance, in siemens, is connected at each end of the line. The nominal-π representation is used in digital computer studies involving lines of moderate length (usually under 100 mi).

Nominal-T Representation. The nominal-T representation of a transmission line is shown in Fig. 14-3. The total line susceptance b, in siemens, is concentrated at A, the midpoint of the line.

ABCD Parameters. These line parameters (general circuit constants) are defined by the equations

$$E_s = AE_r - BI_r \tag{14-15}$$

$$I_s = CE_r - DI_r \tag{14-16}$$

For a short line (under 100 mi) if $Z_1 = R + j\omega L$ and $Z_2 = 2/jb$ (refer to the nominal-π line of Fig. 14-2)

$$A = D = \frac{Z_1 + Z_2}{Z_2} \tag{14-17}$$

$$B = Z_1 l \tag{14-18}$$

$$C = \left(\frac{Z_1 + 2Z_2}{Z_2^2}\right)/l \tag{14-19}$$

For longer lines where l is the length of the line

$$A = D = \cosh(\gamma l) \tag{14-20}$$

$$B = Z_c \sinh(\gamma l) \tag{14-21}$$

$$C = \frac{\sinh(\gamma l)}{Z_c} \tag{14-22}$$

where

$$\gamma = \sqrt{(R + j\omega L)(j\omega C)} \tag{14-23}$$

and

$$Z_c = \sqrt{\frac{R + j\omega L}{j\omega C}} \tag{14-24}$$

and R, L, and C are line resistance, inductance, and capacitance per mile.

Formulas for *ABCD* constants for various circuit configurations are given in Table 14-4.

Surge Impedance Loading. The surge impedance of a transmission line is the characteristic impedance with resistance set equal to zero (i.e., R is assumed small compared to $j\omega L$ of Eq. 14-24).

$$Z_s = \sqrt{\frac{L}{C}} \tag{14-25}$$

TABLE 14-4 Formulas for Generalized Circuit Constants

			Equivalent constants			
No.	Type of network		A_t	B_t	C_E	D_t
1	Series impedance		1	Z	O	1
2	Shunt admittance		1	O	Y	1
3	Uniform line		A	B	C	A
4	Two uniform lines		$A_1A_2 + C_1B_2$	$B_1A_2 + A_1B_2$	$A_1C_2 + A_2C_1$	$A_1A_2 + B_1C_2$
5	Two nonuniform lines or networks		$A_1A_2 + C_1B_2$	$B_1A_2 + D_1B_2$	$A_1C_2 + D_2C_1$	$D_1D_2 + B_1C_2$
6	General network and sending transformer impedance		$A + CZ_{TS}$	$B + DZ_{TS}$	C	D
7	General network and receiving transformer impedance		A	$B + AZ_{TR}$	C	$D + CZ_{TR}$
8	Two networks in parallel		$\frac{A_1B_2 + A_2B_1}{B_1 + B_2}$	$\frac{B_1B_2}{B_1 + B_2}$	$C_1 + C_2 + \frac{(A_1 - A_2)(D_2 - D_1)}{B_1 + B_2}$	$\frac{D_1B_2 + D_2B_1}{B_1 + B_2}$

Note: All constants in this table are complex quantities; $A = a_1 + ja_2$ and $D = d_1 + jd_2$ are numerical values, $B = b_1 + jb_2$ = ohms, and $C = c_1 + jc_2$ = siemens. As a check on calculations of *ABCD* constants, note that $AD - BC = 1$.

The power which flows in a lossless transmission line terminated in a resistive load equal to the line's surge impedance is denoted as the surge impedance loading (SIL) of the line. Under these conditions, the receiving end voltage E_R equals the sending end voltage E_S in the magnitude, but lags E_S by an angle δ corresponding to the travel time of the line. For a 3-phase line

$$\text{SIL} = \frac{(E_{L\text{–}L})^2}{Z_S} \tag{14-26}$$

Since Z_s has no reactive component, there is no reactive power in the line, $Q_S = Q_R = 0$. This indicates that for SIL the reactive losses in the line inductance are exactly offset by reactive power supplied by the shunt capacitance or $I^2\omega L = E^2\omega C$.

SIL is a useful measure of transmission-line capability even for practical lines with resistance, as it indicates a loading where the line's reactive requirements are small. For power transfer significantly above SIL, shunt capacitors may be needed to minimize voltage drop along the line, while for transfer significantly below SIL, shunt reactors may be needed.

SILs for typical transmission lines are given in Table 14-5. Cables normally have current ratings (ampacity) considerably below SIL, while overhead line current ratings may be either greater than or less than SIL. Figure 14-4 presents illustrative overhead line loadability as a function of line length and SIL.

Although Fig. 14-4 is illustrative only of loading limits, it is a useful estimating tool. Long lines tend to be stability-limited and have a lower loading limit than shorter lines, which tend to be voltage-drop- or conductor-ampacity-limited.

TABLE 14-5 SIL of Typical Transmission Lines

System kV	Z_s, Ω	SIL, MW
	Overhead lines	
230	367	144

1200	250	5760
	Cables	
230	38	1390
345	25	4760

14.1.5 Electrical Environmental Effects

Corona and Field Effects. There are two categories of electrical environmental effects of power transmission lines. Corona effects are those caused by electrical stresses at the conductor surface which result in air ionization ("corona") and include radio, television, and audible noise. Field effects are those caused by induction to objects in proximity to the line. While the generic term is electromagnetic effects, within the electric power industry the fields are divided into two types: electric-field effects and magnetic-field effects. Electric fields, related to the voltage of the line, are the primary cause of induction to vehicles, buildings, and objects of comparable size. Magnetic fields, related to the currents in the line, are the primary cause of induction to long objects, such as fences and pipelines.

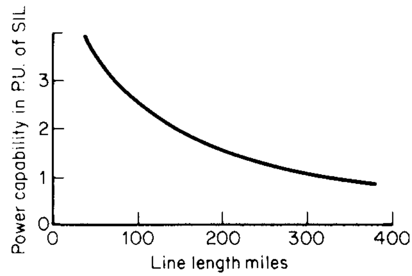

FIGURE 14-4 Overhead line loading in terms of SIL.

Assessment Criteria. In an electrical environmental analysis, it is important to determine the proper criteria for assessment of the impact. For example, the audible noise criterion in a commercial or industrial area would be inappropriate in a quiet residential neighborhood.[8] Likewise, ground-level electric field criteria on a parking lot would be different from that in terrain inaccessible by motor vehicles. For audible noise, the only concern is annoyance, but for electric fields, safety, annoyance, and perception levels all may have to be considered.

Probability of exposure is also an important criterion. The impact of radio noise in arid locations is different from that in places with considerable rainfall. Since different people have different perception and annoyance thresholds, statistical evaluations are necessary, recognizing that some percentage of people will find a generally accepted noise level annoying. Because of the combination of worst-case events which are normally assumed in an electrical environmental analysis, the overall probability of annoyance is usually considerably smaller than initially presumed.

A predictive model is necessary to calculate the expected effect. Depending on the specific effect, it may be an empirical formula or may be quite sophisticated. However, it is only by calculating the effect and comparing it with specified criteria that the overall impact can be assessed. This is illustrated by Fig. 14-5,[9] which is a flowchart of the analysis procedure for an example case of electric-field-induced shock.

Audible Noise. Corona-produced audible noise during foul weather, particularly during or following rain, can be an important design parameter for high-voltage ac transmission lines. Audible noise has two components, a random noise component and a low-frequency hum, each produced by different physical mechanisms. While the hum component is closely correlated with corona loss on the line, the random noise is not. Of these two, the most frequent cause of annoyance is the random noise, and it is this which is calculated and compared with acceptance criteria.

Analyses to predict levels of audible noise consider A-weighted sound level [dB(A)] during rain, including

L_{50}, which is the level exceeded 50% of the time during rain (considering all rain storms over a period of time, usually 1 year).

L_5, which is the level exceeded 5% of the time during rain.

Average, which is the average level of noise expected during rain. (This is usually close to the L_{50} value and is sometimes called "wet-conductor" noise.)

Heavy rain, which is the level expected during heavy rain. (This usually is representative of laboratory artificial rain tests but is assumed representative of the L_5 level.)

Reference 10 compares audible noise formulas, which have been developed throughout the world. One formula for both L_5 and L_{50} values is given by

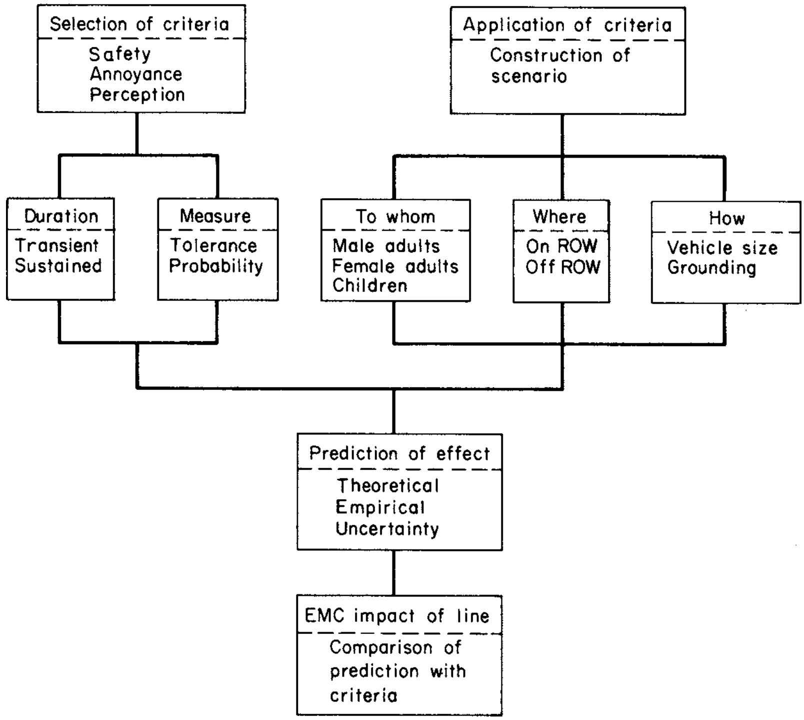

FIGURE 14-5 Factors affecting transmission line EMC for shock effects.

g = Average-maximum surface gradient of conductor or conductor bundle, kV/cm

n = Number of subconductors in a phase (or pole) bundle

d = Diameter of subconductors, cm

D = Distance from line to point at which noise level is to be calculated, m

SL = A-weighted sound level of the noise produced by the line, dB(*A*)

N_p = number of phases

AN = A-weighted sound level of the noise produced by one phase of the line, dB(*A*)

AN_0 = A reference *A*-weighted sound level, dB(*A*)

K_1, K_2, K_3, K_4 = Constant coefficients

Application = All line geometries

Noise measure = L_5 rain and L_{50} rain

Range of validity = 230–1500 kV, $1 \leqslant n \leqslant 16$, $2 \leqslant d \leqslant 6$

For each phase, the L_5 noise level is given by

$$AN_5 = \frac{-665}{g} + 20 \log n + 44 \log d - 10 \log D - 0.02\, D + \text{AN}_0 + K_1 + K_2 \qquad \text{(14-27)}$$

with

$$\begin{aligned} \text{AN}_0 &= 75.2 && \text{for } n < 3 \\ &= 67.9 && \text{for } n \geq 3 \\ K_1 &= 7.5 && \text{for } n = 1 \\ &= 2.6 && \text{for } n = 2 \end{aligned}$$

$$K_2 \begin{aligned} &= 0 && \text{for } n \geq 3 \\ &= 0 && \text{for } n < 3 \\ &= 22.9(n-1)\frac{d}{B} && \text{for } n \geq 3 \end{aligned}$$

where B is the bundle diameter, cm.

The L_{50} level for each phase is obtained from

$$\mathrm{AN}_{50} = \mathrm{AN}_5 - \Delta A \tag{14-28}$$

where

$$\begin{aligned} \Delta A &= 14.2\frac{g_c}{g} - 8.2 && \text{for } n < 3 \\ &= 14.2\frac{g_c}{g} - 10.4 - 8\left[(n-1)\frac{d}{B}\right] && \text{for } n > 3 \end{aligned}$$

and

$$\begin{aligned} g_c &= 24.4\,(d^{-0.24}) && \text{for } n \leq 8 \\ &= 24.4\,(d^{-0.24}) - 0.25\,(n-8) && \text{for } n > 8 \end{aligned}$$

$$\mathrm{SL} = 10 \log \sum_{i=1}^{Np} 10^{AN_i/10} \tag{14-29}$$

Figure 14-6 illustrates a typical presentation of audible noise calculations. The profile, in this case for a representative 500-kV line and wet conductors, quantifies the level of noise in dB(A) greater than 0.002 μbar as a function of distance from the centerline of the structure. From this method of presentation, analysis of maximum levels as well as effect on width of right-of-way can be analyzed. Similarly, design variables such as conductor size, spacing, and configuration; height of conductors; and weather variations can be considered.

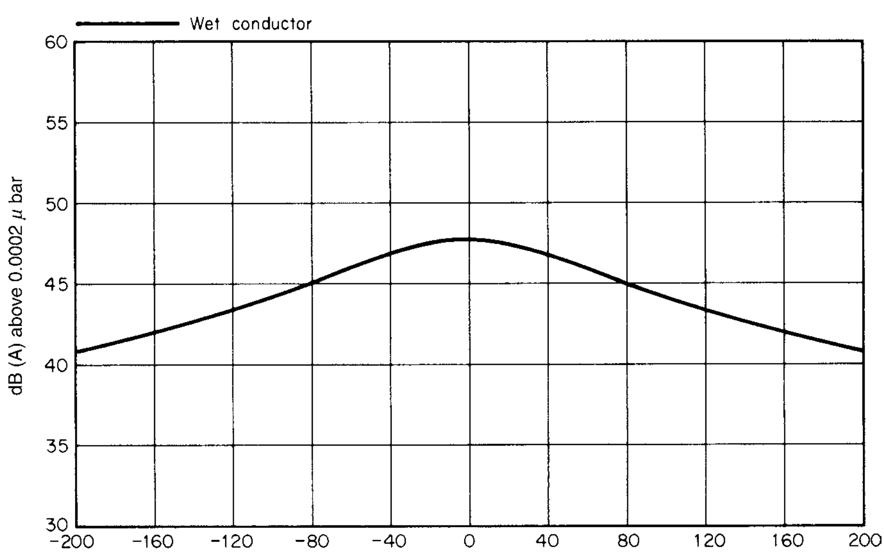

FIGURE 14-6 Audible noise profile at ground level for a transmission line.

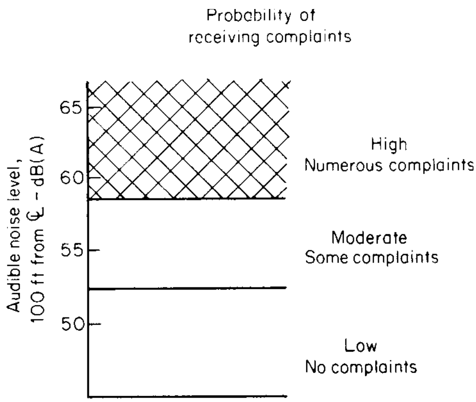

FIGURE 14-7 Audible noise compliance guidelines.

Figure 14-7[3,11] quantifies experience with transmission-line audible noise complaints. These occur mostly during wet-conductor conditions and low ambient noise, such as after rain or during fog. During heavy-rain conditions, the noise of the rain masks the line noise. Other factors during heavy rain, such as closed windows, combine to make this condition less likely to result in complaints even though the noise is louder. In the absence of local noise regulations, comparison of calculated L_{50} or average audible noise with Fig. 14-7 gives a reasonable preliminary evaluation of the possibility of audible noise annoyance. When measurements are to be taken to confirm ambient noise or line noise, care must be taken to follow proper procedures.[12]

Radio and Television Noise. Electromagnetic interference from overhead power lines is caused by two phenomena: complete electrical discharges across small gaps (microsparks) and partial electrical discharges (corona). Gap-type sources occur at insulators, line hardware, and defective equipment and are a construction and maintenance problem rather than a design consideration. They are responsible for about 90% of radio noise complaints and can be located and eliminated as they occur.[13] Conductor and hardware corona is considered during the design phase. On a properly designed line, conductor corona noise rarely results in television interference complaints except perhaps in weak signal fringe areas.

The specification of "corona-free" hardware is important to eliminate electromagnetic interference from conductor support hardware, and is especially important as lines are constructed with closer spacings and resulting higher electric fields on the hardware. Conductor clamps and other fittings, which were formerly acceptable at traditional phase spacings, may not be adequate for compact lines.

For ac lines, radio and television noise are functions of the weather. Fair-weather noise may be significant and varies with the season, wind velocity, and barometric pressure.

Two families of computation methods are available for radio noise: those based on conductor laboratory tests and analytical propagation theory (semianalytical methods) and those based on an empirical formula using data from long-term tests on operating lines (comparative methods).

The comparison method[14] is useful for conventional geometries and designs:

$$\mathrm{RI} = -150.4 + 120 \log g + 40 \log d + 20 \log \frac{h}{D^2} + 10\,[1 - (\log 10 f)^2] \qquad (14\text{-}30)$$

where g = average maximum surface gradient of conductor or conductor-bundle, kV peak/cm
d = subconductor diameter, mm
h = height of phase, m
D = radial distance to observer, m
f = frequency, MHz
RI = fair-weather radio noise, dB

RI is calculated for each phase and the maximum value is used as the RI of the line. Average foul-weather RI levels are assumed to be 17 dB above fair weather, and heavy-rain RI 24 dB above fair weather. Other methods are described in Ref. 3.

As with audible noise, the most useful data presentation is the level of radio noise as a function of distance from the centerline of the structure. An illustrative example for a specific 500-kV line is shown in Fig. 14-8.

There are no generally accepted RI limits in the United States, because of the impossibility of setting universal criteria for all land use and local conditions.[15] A Canadian standard exists for RI limits and is a useful guide.[16]

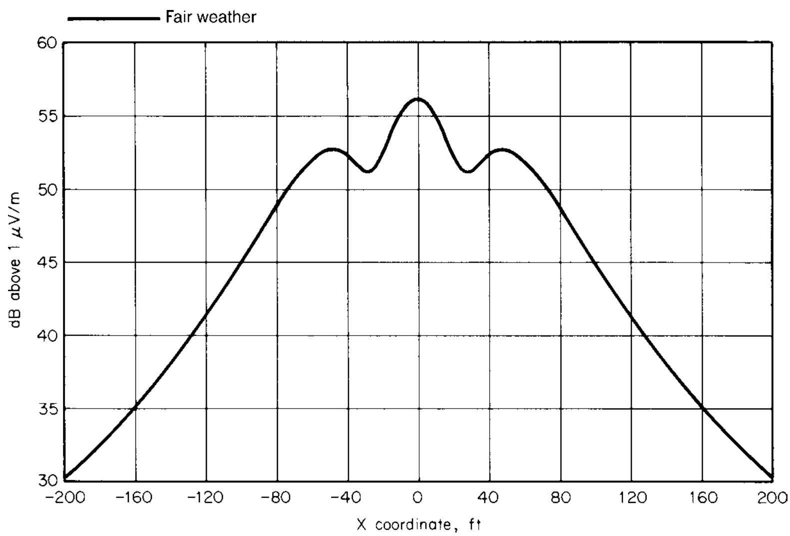

FIGURE 14-8 Radio noise profile at ground level for transmission line.

Two quantities are required to set criteria for evaluation of radio noise. These are the level of signal strength in the line vicinity and an appropriate signal/noise ratio. This latter ratio is typically assumed to be 24 to 26 dB at the edge of the right-of-way. Primary signal strengths may be 54 dB above 1 μV (0.5 mV/m) in rural areas to 88 dB or more in cities.

Prediction of television noise is not as advanced as that of radio noise, primarily because of the limited number of actual cases of conductor corona television interference. As with radio noise, most television interference complaints result from microsparks which can be located and eliminated as they occur. These are not generally a design consideration. In the few cases where corona-caused television noise has occurred in foul weather, it has often been possible to remedy the situation by an improvement in the receiving antennas rather than changes to the transmission-line design. References 3 and 17 contain recent work on prediction and evaluation of TVI.

***Gaseous Oxidants*.** Gaseous oxidants can be produced by corona activity in air and, in sufficient concentrations, may produce adverse effects on flora and fauna. The most important oxidants are ozone (O_3) and oxides of nitrogen (mainly NO and NO_2), where ozone is the major constituent.

Federal standards limit photochemical oxidants to 0.12 part per million for a maximum of 1-h concentration not to be exceeded more than once per year. Some states have more restrictive regulation; for example, the Minnesota Pollution Control Agency standards are for 0.07 ppm by volume (130 μg/m^3). Ozone can be detected by smell at minimum concentrations of 0.01 to 0.15 ppm.

Analytic studies and field measurements have been conducted on both operating and test lines.[18–25] The highest calculated value for 1-mi/h wind parallel to the line was 0.019 ppm maximum ground-level concentration. Measurements have indicated that transmission-line contribution to gaseous oxidants cannot be detected within statistical limits of significance and accuracy. With instrumentation capable of detecting 0.002 ppm, the transmission-line contribution was indistinguishable from ambient.

Thus, gaseous oxidants are not a concern with respect to electric power transmission lines.

Ground-Level Electric Fields. Ground-level electric field effects of overhead power transmission lines relate to the possibility of exposure to electric discharges from objects in the field of the line. These may be steady currents or spark discharges. Other areas which have received attention are the possibility of fuel ignition and interference with wearers of prosthetic devices (e.g., pacemakers).[26]

It is appropriate to consider unlikely conditions when setting and applying electric-field safety criteria because of possible consequences; thus statistical considerations are necessary. Annoyance

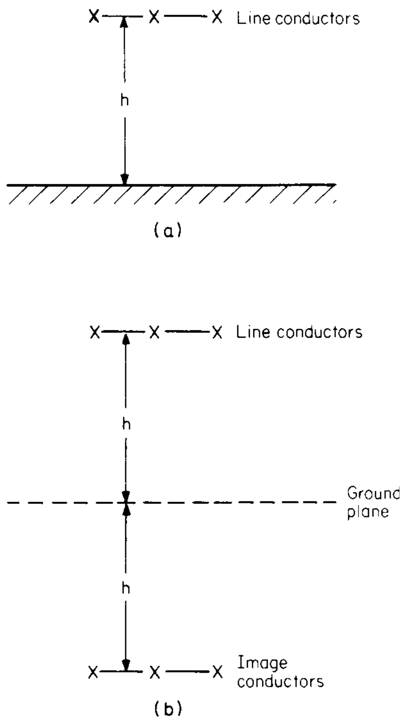

FIGURE 14-9 Representation of conducting earth: (*a*) earth; (*b*) image.

criteria need not be as stringent and mitigating factors can be considered.

Electric-Field Calculations. The resultant electric fields in proximity to a transmission line are the superposition of the fields due to the three-phase conductors. The conducting earth must be represented by image charges located below the conductors at a depth equal to the conductor height.

For example, consider the three-conductor line of Fig. 14-9. The effect of earth can be represented by replacing the earth with image conductors as shown in Fig. 14-9. At 60 Hz and for typical values of earth resistivity, the relaxation time of the earth (the time required for charges to redistribute themselves due to an externally applied field) is so small compared to the power frequency wave that for each instant of time the charge is distributed on the earth's surface as in the static condition (i.e., the earth appears to be a perfect conductor).

The electric fields surrounding the transmission line are a function of the instantaneous charges on the line. Usually, however, the charges are not known, but the voltages to ground of the different conductors are. Since the charge Q on each conductor is a function of the voltage on all conductors, an $n \times n$ capacitance matrix results, where n is the number of conductors, according to the formula

$$[Q] = [C][V] \tag{14-31}$$

which, for a three-conductor configuration (ignoring shield wires), is

$$Q_1 = C_{11} V_1 + C_{12}V_2 + C_{13}V_3 \tag{14-32}$$

$$Q_2 = C_{21} V_1 + C_{22}V_2 + C_{23}V_3 \tag{14-33}$$

$$Q_3 = C_{31} V_1 + C_{32}V_2 + C_{33}V_3 \tag{14-34}$$

The off-diagonal (mutual) capacitance terms significantly affect the final results. The individual terms of the capacitance matrix are computed by

$$C_{nm} = \left.\frac{Q_n}{V_m}\right| \quad \text{all other voltages} = 0 \tag{14-35}$$

where n and m are conductors.

The potential coefficient matrix is, however, more amenable to computation and is defined by

$$[V] = [P][Q] \tag{14-36}$$

whose individual terms are given by

$$P_{nm} = \left.\frac{V_n}{Q_m}\right| \quad \text{all other charges} = 0 \tag{14-37}$$

This is an open-circuit matrix where the individual terms can be computed by assuming a charge at one conductor and calculating the voltage at the prescribed location assuming all the other conductors nonexistent (open-circuited). For a single conductor of radius r and a height h above the earth, the self-potential coefficient is given by

$$P_{nm} = \frac{1}{2\pi\epsilon_o} \ln \frac{2h}{r} \tag{14-38}$$

For two conductors n and m where d_{nm} is the distance between them, and $d_{nm'}$ is the distance between conductor n and the image of conductor m, the mutual potential coefficient is given by

$$P_{nm} = \frac{1}{2\pi\epsilon_o} \ln \frac{d_{nm'}}{d_{nm}} \tag{14-39}$$

This potential coefficient matrix can be calculated and inverted to yield the capacitance matrix:

$$[C] = [P]^{-1} \tag{14-40}$$

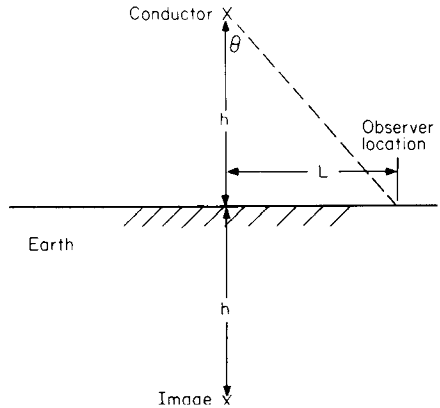

FIGURE 14-10 Single conductor.

This capacitance matrix allows the calculation of the charges on the individual conductors for the given initial voltage distribution according to Eqs. (14-32) through (14-34). Once these charges are obtained, the desired electric fields can be determined.

For the single conductor and observer location of Fig. 14-10, the ground-level electric field is determined from

$$E = \frac{Q_l}{2\pi\epsilon_o r} \tag{14-41}$$

The distance from the conductor to the observer is

$$r = \sqrt{h^2 + L^2} \tag{14-42}$$

Thus

$$E = \frac{Q_l}{2\pi\epsilon_o\sqrt{h^2 + L^2}} \tag{14-43}$$

Q must be determined from $[Q] = [C]\,[V]$. For a single conductor this equation reduces to

$$Q_l = P^{-1}V = \frac{1}{\frac{1}{(2\pi\epsilon_o)}\ln(2h/r)}V \tag{14-44}$$

For a multiconductor configuration, Q would come from the full matrix calculation.

E is radially directed from the line charge. The vertical component is

$$|E|\cos\theta = \frac{Q_l}{2\pi\epsilon_o\sqrt{h^2 + L^2}}\frac{h}{\sqrt{h^2 + L^2}} = \frac{Q_l}{2\pi\epsilon_o}\frac{h}{h^2 + L^2} \tag{14-45}$$

The vertical component of the electric field at ground level because of the image is equal to the field from the conductor, since the image is the geometric mirror image and has the opposite sign charge. Thus, the total ground-level field is given by

$$E = \frac{Q_l}{\pi\epsilon_o}\frac{h}{h^2 + L^2} \tag{14-46}$$

At ground level, the horizontal components of the electric fields of the conductor and its image cancel and the resultant field is purely vertical.

For a 3-phase line, the fields of the three conductors and their images are computed separately and added.

For fields extremely close to the line conductors, care must be taken to represent the local effects properly. For example, the surface field around the conductor is not uniform. For a bundled conductor, it is more nearly represented by a sinusoid. Farther from the conductors, a GMR representation will suffice.

For a bundle of diameter D with n conductors of radius r, the GMR is given by

$$\text{GMR} = \frac{D}{2}\sqrt[n]{\frac{2nr}{D}} \tag{14-47}$$

Replacing the conductor radius with the bundle GMR gives the appropriate representation.

Figure 14-11 illustrates a representative electric-field profile, in kV rms per meter, from the centerline of the structure. This presentation clearly illustrates the maximum field, the location of the maximum, and the effect on right-of-way width considerations. Sensitivity to various parameters can also be quickly evaluated.

Criteria for Evaluation. The effects of electromagnetic fields on humans is due to discharges from objects insulated from ground; typically vehicles, buildings, and fences which become electrically charged by induction from the line. Table 14-6 summarizes effects on humans, ranging from no perception through severe shock and possible ventricular fibrillation.[27]

Criteria for spark discharges are expressed in terms of stored charge or stored energy on the charged object. Levels for perception in adult males are of the order of 0.12 mJ, while experience indicates that approximately 2 mJ results in an annoying spark. Safety is seldom of concern, since approximately 25 J is required for injury, a value beyond that expected on objects beneath transmission lines.

Deno's work, using test data, relates short-circuit current to the undisturbed electric field for objects insulated from ground.[26] Initial calculations assume the worst possible combination of circumstances; no leakage path to ground exists for the object, complete grounding of the person involved, steady contact, and orientation of the vehicle parallel to the line. Table 14-7 lists sample criteria and electric fields needed to meet them for three sample vehicles.

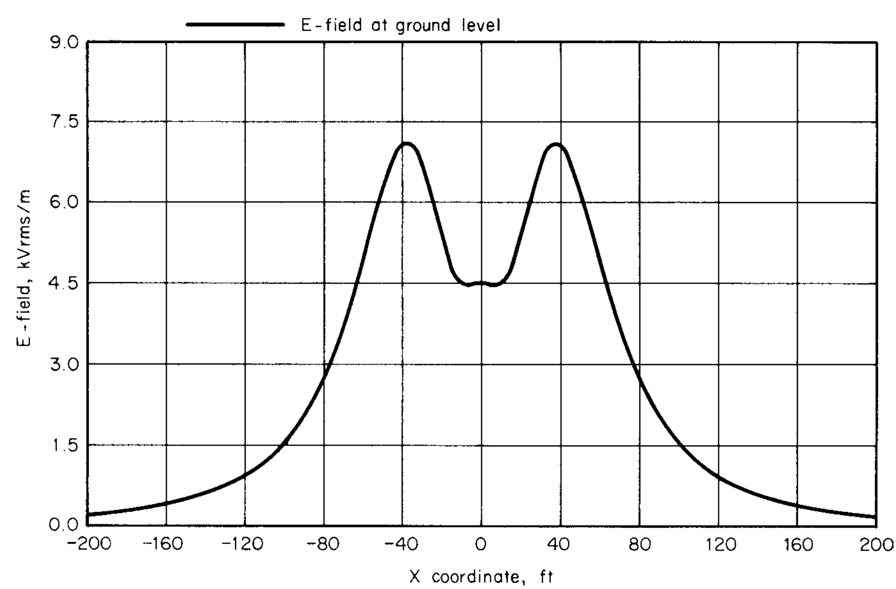

FIGURE 14-11 Electric-field profile at ground level for transmission line.

TABLE 14-6 Threshold Levels for 60-Hz Contact Currents

rms current, mA	Threshold reaction and/or sensation
	Perception
0.09	Touch perception for 1% of women
0.13	Touch perception for 1% of men
0.24	Touch perception for 50% of women
0.33	Grip perception for 1% of women
0.36	Touch perception for 50% of men
0.49	Grip perception for 1% of men
0.73	Grip perception for 50% of women
1.10	Grip perception for 50% of men

TABLE 14-8 Likely Range of Maximum Vertical Electric Field for Various Voltage Transmission Lines

Line voltage, kV	Near-ground vertical electric field, kV/m
765	8–13
500	5–9
345	4–6
230	2–3.5
161	2–3
138	2–3
115	1–2
69	1–1.5

High voltages may develop due to electric-field coupling, but the available short-circuit current is small (i.e., high-impedance source); thus calculations are based on a Norton equivalent and the short-circuit current. A relatively high resistance ground is sufficient to reduce electric-field-coupled voltage.

Table 14-8 lists maximum electric fields on the right-of-way under lines of different voltage classes. The fields attenuate rapidly with distance from the line and are usually much lower at the right-of-way edge.

Fuel Ignition. Theoretical calculations indicate that if several unlikely conditions exist simultaneously, a spark could release sufficient energy to ignite gasoline vapors. These conditions include a perfectly grounded person refueling a car perfectly insulated from ground with a metal can while the car is parked directly under a line. The spark would have to occur in the precise location of optimum fuel-air mixture. Research[3,28] confirms the low probability of accidental fuel ignition under actual conditions.

No confirmed cases of accidental ignition under transmission lines exist, confirming the low probability of these factors occurring simultaneously. Because of the consequences of a gasoline fire, some electric utilities advise that gasoline-fueled vehicles not be refueled near a line of 500 kV or above. If refueling were necessary, the vehicle could be grounded or the can connected to the vehicle to prevent sparks.

Ground-Level Magnetic Fields. Magnetic-field coupling affects objects which parallel the line for a distance, such as fences and pipelines, and is generally negligible for vehicle- or building-sized objects. As opposed to electric-field coupling, magnetic-field coupling is a low-voltage, low-impedance source with relatively high short-circuit currents. Single grounds are ineffective in preventing magnetically coupled voltages and multiple low-resistance grounds are needed. The resistance of the person touching a fence or pipeline is the dominant current-limiting impedance in the equivalent electrical circuit.[29] Calculations are based on a "longitudinal electromotive force" approach and are described in Refs. 30 to 32.

A consideration in the calculation of magnetic fields, which is different from the electric-field calculation, concerns the images. A perfectly conducting earth can be assumed for the electric-field problem, even for realistic values of earth resistivity. The assumption of a transmission line in free space (no earth at all) gives a closer approximation to the ground-level magnetic fields than does the assumption of a perfectly conducting earth for measurements near the line. At distances beyond 100 m, the effect of earth becomes increasingly more significant. The effect of conducting earth is frequently treated by use of an image conductor located at a greater depth in the earth than the conductors are above the earth. Distances of several hundred meters are commonly used for this image depth, according to the relation $D = 660\sqrt{\rho/f}$ meters where ρ is the earth resistivity in ohm-meters and f is the frequency. Magnetic-field calculations are given in Ref. 12, including the use of Carson's terms to evaluate the effects of imperfectly conducting earth.

It is normally adequate to consider conductors in free space without images. For the conductor of Fig. 14-8 without its image

$$B = \frac{\mu_o I}{2\pi r} = \frac{\mu_o I}{2\pi\sqrt{h^2 + L^2}} \tag{14-48}$$

This is then separated into vertical and horizontal components by multiplying by $\sin\theta$ and $\cos\theta$. In general, both components must be retained. For a 3-phase line, all conductors must be computed. Horizontal and vertical components of B from the three conductors must then be combined individually as phasors, considering the angles of the different currents. The combined horizontal and vertical components in general have different angles, causing their resultant to trace an ellipse in time. Single-axis magnetic-field meters with the sensing coil oriented for a maximum reading give the magnitude of the major axis of the field ellipse. A three-axis meter of the type presently used for data logging responds to the square root of the sum of the squares of the three field components (the "resultant" field). The resultant field can be as much as 41% greater than the major axis of the field ellipse for circularly polarized fields of the type which result from symmetrical conductor configurations.[33]

In the same manner, image currents at some assumed depth can be computed and their fields included. The use of matrix calculations allows inclusion of ground wires and bundled conductors as is the case of electric fields.

With both electric and magnetic fields it is essential to follow proper measurement procedures[33] for comparison with calculations.

For electric fields it is important that the field not be perturbed by the presence of the operator or other nearby objects. For both electric and magnetic fields, it is necessary to accurately know the conductor positions, the conductor height, the distance to the observer, and the line operating conditions (voltage and current). Magnetic-field measurements frequently differ from calculations for a number of reasons beyond errors in distance and clearance measurement:

1. Line current is continually varying, so in general it is not as well known as line voltage. In addition to uncertainty concerning the current magnitude at the time of the field measurement, line current unbalance in both magnitude and phase angle can be important. Unbalance has an increasingly significant effect on the magnetic field, the farther one moves from the line. Spot measurements, especially in homes and near distribution lines, are of limited usefulness to characterize exposure. For this reason, it is often advisable to statistically characterize the magnetic field. A statistical description of the field over time can be developed from measurements or calculations which assume balanced currents. It is also sometimes useful to develop a statistical distribution for a specific current level and an assumed maximum unbalance.
2. Related to current unbalance is circulating current in the shield wires, return currents in the earth, and currents in nearby pipes. These currents may cause significant differences between calculation and measurement.
3. The difference between single- and three-axis instruments has been described above. Two operators with different instruments can determine different answers based on the principles of measurement.
4. In nonuniform fields, such as around appliances, the size of the sensing coil and presence or absence of ferromagnetic core material will affect the reading of instruments equally well calibrated in a uniform field. Calibration must be made in a calibrating coil sufficiently large that the field is uniform over the area of the sensing coil, yet not so large that other nearby currents do not affect the field.
5. Harmonic currents have different effects depending on the frequency response of the instrument. Some instruments have a response linearly increasing with frequency, some are flat with frequency, and others have bandpass filters of different waveshapes.

14.1.6 Line Insulation

Requirements. The electrical operating performance of a transmission line depends primarily on the insulation. An insulator not only must have sufficient mechanical strength to support the greatest loads of ice and wind that may be reasonably expected, with an ample margin, but must be so designed as to withstand severe mechanical abuse, lightning, and power arcs without mechanically failing. It must prevent a flashover for practically any power-frequency operating condition and many transient voltage conditions, under any conditions of humidity, temperature, rain, or snow, and with such accumulations of dirt, salt, and other contaminants that are not periodically washed off by rains.[34]

Insulator Materials. The majority of present insulators are made of glazed porcelain. Porcelain is a ceramic product obtained by the high-temperature vitrification of clay, finely ground feldspar, and

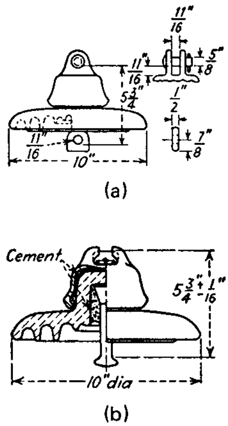

FIGURE 14-12 Typical porcelain disk insulator: (*a*) clevis type; (*b*) ball-and-socket type. (*Locke Insulators Inc.*)

silica. Insulators of high-grade electrical porcelain of the proper chemical composition free from laminations, holes, and cooling stresses have been available for many years.

The insulator glaze seals the porcelain surface and is usually dark brown, but other colors such as gray and blue are used. Porcelain insulators for transmission may be disks, posts, or long-rod types.

Porcelain insulators have been used at all transmission line voltages and, if correctly manufactured and applied, have high reliability.

A typical porcelain disk insulator is shown in Fig. 14-12.

Glass insulators have been used on a significant proportion of transmission lines. These are made from toughened glass, and are usually clear and colorless or light green. For transmission voltages they are available only as disk types. Most glass disk insulators will shatter when damaged, but without mechanically releasing the conductor. This provides a simple method of inspection.

Synthetic insulators, originally pioneered by the General Electric Company in 1963 for high-voltage transmission lines,[35] and more recently introduced by several manufacturers, are finding increasing acceptance. Most consist of a fiberglass rod covered by weather sheds of skirts of polymer (silicon rubber, polytetrafluoroethylene, cycloaliphatic resin, etc.)[36] as shown in Fig. 14-13. Other types include a cast polymer concrete called Polysil R[37] and a coreless type with alternating metal and insulating sections.[38]

Improvements in design and manufacture in recent years have made synthetic insulators increasingly attractive since their strength-to-weight ratio is significantly higher than that of porcelain and can result in reduced tower costs, especially on EHV and UHV transmission lines.

These insulators are usually manufactured as long-rod or post types. The light weight of most designs and resistance to damage aids construction. In addition, their performance under contaminated conditions may be significantly better than that of porcelain.[39]

Use of synthetic insulators on transmission lines is relatively recent and a few questions are still under study, in particular the lifetime behavior of insulating shed materials under contaminated conditions. It has been found necessary to use grading rings on some types at higher voltages to prevent damage to the sheds, and a very small number of insulators have experienced "brittle fractures," in which the fiberglass core breaks close to an end fitting. Despite these problems it appears that reliable synthetic insulators are presently available.

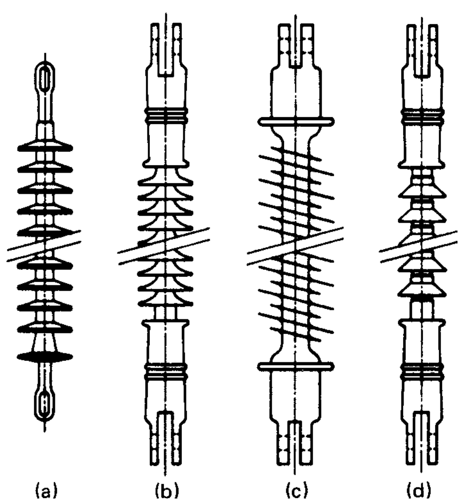

FIGURE 14-13 Typical nonceramic insulators.

Insulator Design. Transmission insulators may be strings of disks (either cap and pin or ball and socket), long-rods, or line posts. Posts are only infrequently applied above 230 kV.

Present suspension insulators conform to ANSI Standard C29.2, and standards have been established for 15,000-, 25,000-, 36,000-, and 50,000-lb ratings. It is common practice to use a factor of safety of 2 for the maximum mechanical stress applied to porcelain or glass insulators. For fiberglass-core insulators it is more common for the manufacturer to supply a recommended maximum working load.

Each manufacturer supplies catalogs which provide a physical description of the insulator's mechanical characteristics, wet and dry 60-Hz flashover strength, and positive- and negative-impulse (1.2×50 μs) critical (50%) flashover strength. Switching surge performance (250×3000 μs) is usually not supplied. In clean conditions most insulators of equivalent dimensions have very similar performance.

Suspension insulator strings, that is insulators used to support the conductor weight at a suspension or tangent structure, may be in I (vertical) or V configurations. The V configuration is used to prevent conductor movement and resultant clearance reductions at the structure. At dead-end or tension structures the insulators must also support the conductor tension, and it is not uncommon for these tension strings to be given a slightly higher flashover strength (e.g., by adding disks) to reduce the likelihood of a flashover that might lead to insulator string mechanical failure. Two or more strings of insulators in parallel can be used on suspension and tension strings to provide higher mechanical strength if required.

The electrical strength of line insulation may be determined by power frequency, switching surge, or lightning performance requirements. At different line voltages, different parameters tend to dominate. Table 14-9 shows typical line insulation levels and the controlling parameter. In compacted or uprated designs, considerably fewer insulators than these have been successfully used.[40,41]

Detailed descriptions of insulation design for electrical performance for different conditions, line voltages, and line types are available[42–44] from a number of studies.

Insulator Standards. The NEMA Publication *High Voltage Insulator Standards,* and AIEE Standard 41 have been combined in ANSI C29.1 through C29.9. Standard C29.1 covers all electrical and mechanical tests for all types of insulators. The standards for the various insulators covering flashover voltages; wet, dry, and impulse; radio influence; leakage distance; standard dimensions; and mechanical-strength characteristics are as follows: C29.2, suspension; C29.3, spool; C29.4, strain; C29.5, low- and medium-voltage pin; C29.6, high-voltage pin; C29.7, high-voltage line post; C29.8, apparatus pin; C29.9, apparatus post. These standards should be consulted when specifying or purchasing insulators.

Line Insulation Design. *Power-Frequency Design.* The criteria for power-frequency design is usually that flashover shall not occur for normal operating conditions, including reduced clearances to the structure from high wind. A typical wind-design limit is the 50- or 100-year return period wind, that is, a wind velocity which occurs only once in 50 or 100 years. This velocity is obtained from local wind records and may be typically 80 to 100 mi/h. Maximum operating voltages are designed by ANSI C84 and C92 standards and are 5% or 10% above the nominal value.

In clean conditions, power-frequency voltage is not a controlling parameter for insulator design (as distinct from air-gap clearance). However, even in quite lightly contaminated conditions it may become so.

Design for contamination is usually expressed as inches of creepage per kilovolt, where the creepage distance is the length of the shortest path for a current over the insulator surface and ranges up to 2 in/kV or more for heavy contamination. Standard insulator disks ($10 \times 5^3/_4$ in) have a typical creepage length of 11.5 in per disk. To avoid very long insulator strings for contamination, disks with additional creepage distance are made. The creepage can be extended by use of lengthened skirts and deeper grooves in the underside. Fog-type disks have up to 21.5 in of creepage per $13^1/_2 \times 8$-in units. A typical fog-type insulator is illustrated in Fig. 14-14.

TABLE 14-9 Typical Line Insulation

Line voltage, kV	No. of standard disks	Controlling parameter (typical)
115	7–9	Lightning or contamination
138	7–10	Lightning or contamination
230	11–12	Lightning or contamination
345	16–18	Lightning, switching surge, or contamination
500	24–26	Lightning, switching surge, or contamination
765	30–37	Switching surge or contamination

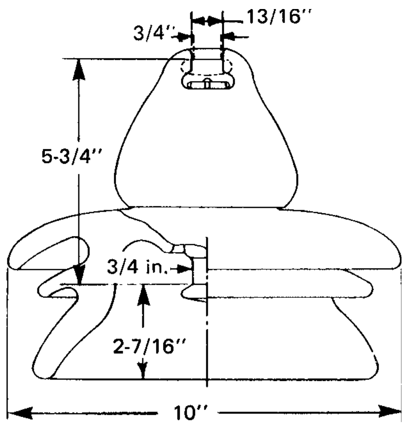

FIGURE 14-14 Typical fog-type disk insulator.

In extremely contaminated conditions, insulation with extended creepage may not be enough. In these cases insulator washing or the use of a silicone or petroleum grease coating (replaced at regular intervals) may be used.

Table 14-10 provides a simplified indication of creepage distance as a function of contamination,[42] and Fig. 14-15 shows guidelines from the IEEE application guide.[43]

For nonceramic insulation the same approach is used, except that subject to manufacturer's recommendations, a reduction in creepage distance up to 30% may be possible. This is due to the physical behavior of the nonceramic insulating material in moist conditions.

Another approach that has sometimes been used to combat contamination effects is the semiconductive glaze insulator. The semiconducting glaze allows a small but definite power-frequency current to flow over the surface. The insulator does not improve the standard test values, such as wet and dry power-frequency flashover and short-time impulse flashover, although it may have some value under switching surge conditions.

The glaze has a surface resistivity of about 10 MΩ per square. This is achieved by special formulations of materials involving, at the present stage of development, the use of tin-antimony additive to a more normal glaze composition. The presence of this small leakage current, of the order of 1 to 2 mA for suspension insulators, but which can be several times that value for large porcelains (such as are used in high-voltage bushings) has three effects:

1. Linearization of the voltage distribution over the insulator or string of insulators. This aids greatly in improving the performance of the insulator with respect to corona disturbance and RIV performance, plus having some benefits under dry and clean conditions.

TABLE 14-10 Insulation Requirements for Contamination: Provisional EHV Line Insulation Design Table for Various Contamination Conditions
Standard 5^5/34 × 10-in vertical insulator units

Contamination		Equivalent amount NaCl, mg/cm^2	Provisional design values		
			Leakage distance in/kV rms line to ground	Average kV rms	
Class	Types			Per in axial length	Per unit
A	Clean atmosphere—rural and forest regions; no industrial contamination	0–0.03	Insulation requirements not set by contamination		
B	Slight atmospheric contamination; suburbs of large industrial regions; railways; frequent washing rains	0.04	1.04	2.0	11.5
C	Moderate contamination containing soluble salts up to 5%; furnaces, dust from metallurgical plants, mine dust, fly ash, fertilizer dust in small quantities	0.06	1.31	1.6	9.1
D	Severe contamination containing 15% or more of soluble salts; dust from aluminum and chemical works, cement plants, heavy agricultural fertilizing, fly ash with high salt or sulfur content	0.12	1.74	1.2	6.9
E	Salt precipitation—seaside regions, salt marshes	0.30	2.11	1.0	5.7

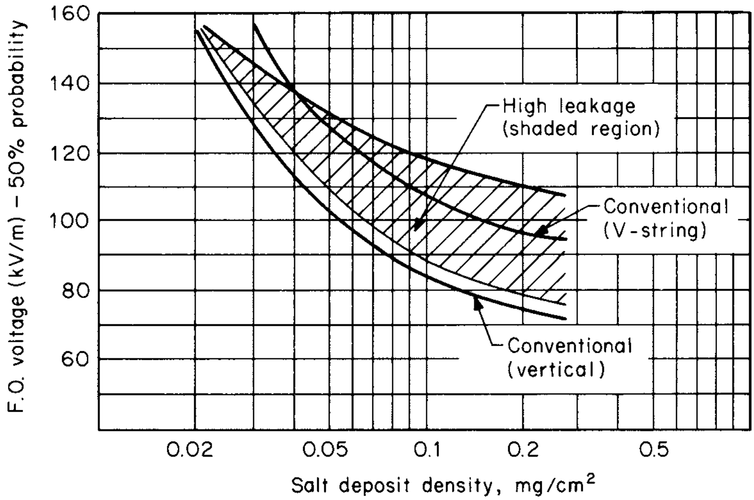

FIGURE 14-15 Power frequency withstand voltage of contaminated suspension insulators in fog expressed in kV/m of connection length (spacing).

2. Heating of the insulator. This occurs because of the power loss associated with the leakage current flow to a temperature which is usually about 5°C over the ambient air conditions. The heating effect enables the insulator to remain dry during conditions of fog or mist. This eliminates the majority of contaminated-insulator flashovers which occur when accumulated contamination becomes damp. This damp contamination condition is the most usual cause for contaminated-insulator flashover because most contaminants are more electrically conducting when damp or wet.

3. The elimination of “dry banding,” which is recognized as another major cause of flashover of standard insulators when contaminated. This occurs when the insulator has been thoroughly wetted, such as in a rain storm which wets but does not thoroughly clean the contamination from the insulator’s surface. Under these conditions dry bands will form as the standard insulator dries, and arcs strike across the dry-band area. These arcs can progress until flashover of the entire insulator occurs. With a semiconducting insulator, the relatively low resistance of the glaze shunts the dry-band area as the insulator dries and prevents the striking of the small power-frequency arcs.

The improved performance possible with semiconducting insulators has been proved in the laboratory and field,[45–49] but, because of the energy losses associated with the inherent leakage current, they are not widely used.

In some severe contamination areas, the problem has been effectively attacked by the use of silicone grease coatings. The unique amoebic action of a thick layer of silicone grease on an insulating surface is such as to envelop conducting solid particles which are said to “load” up the silicone grease to the saturation point, at which time the “used” silicone grease is removed and replaced with new silicone grease. In severe contamination areas, the greasing and degreasing cycles may be required every few months; in less severe contamination areas the cycle may be a year or more depending on experience acquired. In this manner, the time between insulator cleanings can be greatly extended, thus making for substantial savings. Once the silicone coating is used, the coatings must usually be wiped off and replaced manually, as necessary. Among the manufacturers of silicone grease are the General Electric Company and the Dow-Corning Corporation.

For the cleaning operation to remove contamination from the insulator surface, many contaminants such as salt deposits and water-soluble conducting liquids can be successfully removed by hot-line washing, using high-pressure water and insulated nozzles and hoses. Another method is "dry cleaning" by the use of an abrasive powder such as a limestone mixture or biodegradable plastic pellets, discharged at high pressure through hose and nozzle on the insulating surface. In many cases either hot-line washing or dry cleaning alone is sufficient to cope with the rate of accumulation encountered with the particular contaminant. An exception is substantially conducting materials, which take a chemical "set" after exposure to water, such as cement dust, some forms of gypsum, or asbestos, which often must first be manually chipped off or scrubbed off the insulating surface and then covered with silicone grease as previously described.

It should be emphasized that these problems may be very severe or even nonexistent, due to the variability of contamination exposure, which in turn depends on the chemical and electrical nature of the contaminant, prevailing wind direction, persistence of fog, smog, or other weather factors.

To monitor buildup of contaminants, some utilities collect data at the site to warn operating departments of an impending flashover, so as to promptly implement contamination-combative procedures.

Switching Surge Design. Operation of a circuit breaker on a transmission line can cause transient overvoltages, although flashovers due to such switching surges are rare in lines below 500 kV. If the breaker is opening, this may be due to restrikes across the breaker contacts as they separate, although restriking has been nearly eliminated with present breaker technology. If the breaker is closing, the cause may be unequal voltages on each side of the breaker, including the effect of residual charge on the line from a recent deenergization. The crest magnitudes of switching surges are normally defined in per unit of nominal power-frequency-crest phase-to-ground voltage. For example, on a 138-kV line (145 kV maximum), the per unit value is 118 kV. Typical switching surges range from 1 to as high as 4 or 5 per unit, and the varying characteristics of breaker operations provide a distribution of surge magnitudes which is often modeled as a truncated gaussian distribution.

The criterion for switching surge design is usually that flashover shall not occur for most or all switching events. Several design methods have been used, including

1. The maximum expected surge is determined, for example, from a transient network analyzer (TNA) or digital study, and the line insulation is designed to withstand that surge.
2. Rather than the maximum surge, a surge value corresponding to a statistical level is used, typically the 2% value (i.e., the crest value determined from the statistical distribution of surge crests, such that the level will be exceeded by only 2% of all surges).
3. Rather than design insulation to withstand a maximum surge, a statistical approach is used to design for a low number of flashovers per switching event. Typical levels are one flashover per 100 or 1000 breaker operations. This often results in a more economical design than either of the withstand approaches above.
4. By modeling the statistical distribution of switching surge crests, the distribution of insulator flashover with voltage, and the statistical distribution of weather that can be obtained from local weather stations, a probabilistic design can be prepared using a relatively simple computer program based on the allowable flashover rate. Typical procedures, data, and examples for such calculations are provided in several publications.[50,51]

Impulse Surge Design. Impulse surges on a line are caused by lightning strokes to or near the line. At transmission insulation levels, only strokes that directly intercept the line are capable of causing flashovers.

A number of methods of calculating transmission-line lightning performance have been published, and are summarized in the references to Chap. 12 of Ref. 3, together with a simplified calculation method. A computer program for this simplified calculation method is available from the *IEEE WG on Transmission Line Lightning Performance,* and more sophisticated programs for evaluation of multicircuit lines are available from a number of sources.

It is unusual for line insulation to be determined by lightning performance alone. More typically, insulation is determined by other requirements and the lightning performance is then verified. If this performance is unsatisfactory, it is often more efficient to change other design parameters such as shield wires or grounding than to add insulation.

Other methods of improving lightning performance have included addition of surge arresters at relatively frequent intervals along a line, and on double-circuit lines the use of unbalanced insulation so one circuit will flash over first and protect the other. Use of line arresters is most beneficial in regions of high ground resistance. Use of unbalanced insulation can improve the performance of the circuit with the highest insulation, but at the detriment of overall line performance.

Phase-to-Phase Insulation. The controlling paths for flashovers on most presently installed transmission lines are phase-to-ground, since there are usually grounded structure components between phases. However, for some new designs, such as the Chainette,[52] and compact lines the controlling path may be phase-to-phase air gaps or even phase-to-phase insulators.

Design methods for phase-to-phase insulation are essentially the same as for phase-to-ground insulation. Until recently, there was lack of knowledge of conductor clearance at midspan under various dynamic loading conditions, and lack of phase-to-phase switching surge data. Research studies sponsored by EPRI have now provided adequate design information on both topics.[44,50,52]

Protective and Grading Devices. Damage to insulators from heavy arcs was a serious maintenance problem in the past, and several devices were developed to ensure that an arc would stay clear of the insulator string. Subsequent improvements in the use of overhead ground wires and fast relaying have reduced the likelihood of insulator damage to the point that arc protection devices are now rarely used in the United States.

Earlier protective measures consisted of attaching small horns to the clamp, but it was found that horns with a large spread both at the top of the insulator and at the clamp were required to be effective. Under lightning impulse the arc tends to cascade the string, and tests show that the gap between horns should be considerably less than the length of the insulator string. Protection by arcing horns thus resulted in either a reduced flashover voltage or an increase in the number of units and length of the string. In any event, flashover persisted as a power arc until the line tripped out. For these reasons arcing horns have not been used in the United States for many years, although they are fairly common in Europe.

The arcing ring or grading shield is mainly for the purpose of improving the voltage distribution over the insulator string, and its effectiveness is due to the more uniform field. Protection of the insulator is not, therefore, dependent on simply providing a shorter arcing path, as is the case with horns. Efficient rings are rather large in diameter and, for suspension strings, clearances to the structure should be at least as great as from ring to ring. These considerations have made this device generally unattractive for modern construction. Grading rings are now used only at very high voltages for special applications, or with nonceramic insulators. Corona shields help improve the voltage distribution at the line ends of insulator strings.

14.1.7 Line and Structure Location

Preparation for Construction. The cost of preparing for transmission-line construction is a considerable part of the total costs—under some conditions as much as 25%. Right-of-way and clearing are more or less fixed by local conditions, but the cost of surveys, accompanying maps, profiles, and engineering layout is to some extent governed by judgment. Many times in the past the overall costs have been increased by right-of-way difficulties and by delays in receiving proper materials because of inadequate preparations. The engineering work, properly carried out, makes it possible to obtain the right-of-way and complete the clearing well in advance of construction and to purchase every item of material and deliver it to the correct location.

The work of locating and laying out a line does not require great refinement, but careful planning is essential. With inexperienced surveyors or drafters, it must be assumed that errors will be made, and every possible device must be used to discover these errors before construction is started.

Location. The general character of the line location should be determined because it has a definite bearing on the type of design. In extreme cases, such as difficult mountainous sections or in highly developed areas near cities, this may be a determining factor in the selection of the conductor and type of structures.

On heavy trunk lines, minor repairs and replacements are not an important item, and accessibility may often be rightly sacrificed to obtain the economy of a more direct route. Light wood lines must, however, be readily accessible for inspection and repairs. Line location is a matter of judgment and requires a person of wide general experience capable of correctly weighing the divergent requirements for inexpensive and available right-of-way, low construction costs, and convenience in maintenance. In mountainous country or in thickly populated areas, it is generally not advisable to attempt a direct route or try to locate on long tangents. Small angles of a few degrees cost little more and add little to the length of line. Most designs provide suspension structures for line angles of 5° to 15° which are not excessively costly. High, exposed ridges should be avoided, to afford protection against both wind and lightning.

Following a general reconnaissance by ground and air, for which 10 to 20 days per 100 mi should be allowed, and the assembling of all available maps and information, control points can be established for a general route or areas selected for more detailed study which may prove to be determining factors in the location of the line.

With this preliminary work completed, the major difficulties should have been determined. The policy as to such matters as right-of-way condemnation, electrical environmental assessments, telephone coordination, navigable-stream crossing, air routes, airports, and crossings with other utilities must be decided as definitely as possible.

Preliminary specifications should be issued before the final survey is started. These should include (1) outline drawings of the various structures with the important dimensions; (2) conductor sag curves and a sag template; (3) the maximum spans and angles for each type of structure; and (4) the requirements for right-of-way and clearing. Estimated costs are valuable, especially comparative costs of the various types of structure. With this information the field engineer can often, in a difficult section, choose the location best suited to the design.

Aerial maps can often be secured at much less cost than preliminary surveys, and in highly developed areas may be used to advantage for completely laying out the line without sending surveyors into the area until after the right-of-way has been secured.

Photographs taken at approximately 1/2 mi to the inch give sufficient detail for most work. Such maps can be photographically enlarged about four times for special detail. With a 1/2-mi-to-the-inch scale, the route of the line can be determined within a width of about 3 mi and sufficient landmarks located on a fairly accurate map to serve as a guide for flying the line.

Location Survey. The actual survey party can typically be divided into four divisions, each of which can complete at least a mile a day in average weather and country. Their operations may be carried out separately or nearly concurrently by allowing a full week's separation between successive operations and transferring personnel as needed.

The work falls naturally into the following: (1) an alignment party, choosing the exact location and cutting out the line; (2) a staking party, driving stakes at 100-ft stations and locating all obstructions; (3) a level party, taking elevations and side slopes; and (4) a property and topography party, locating property lines.

A field drafting force located at a convenient point for receiving field notes can complete the final plan and profile drawings as fast as the survey can be made.

The method of procedure and size of survey organization depend on the character of the country, the length and type of line, the experienced personnel available, and the schedule which must be maintained. In level, sparsely populated country, satisfactory but incomplete property surveys and profiles have been made during an open dry winter for a wood H-frame line 50 mi in length in approximately 4 months' time, with the personnel averaging a crew of eight and an engineer.

On a development involving the construction of several hundred miles of steel-tower line, the survey for a 65-mi line in rather difficult country, including 25 mi of inaccessible mountainous country, was completed with property maps and profiles in the form for permanent records in 2 months' time with a crew of about 20 and a locating engineer.

Purchase. Generally, right-of-way is not purchased in fee, but a perpetual easement is secured in which the owner grants the necessary rights to construct and operate the line but retains ownership and use of the land. The width of the right-of-way may be stated as a definite width or in general terms, but the easement must provide for (1) a means of access to each structure; (2) permission to erect all structures and guys; (3) all trees and brush to be cleared over a specified width for erection; (4) the removal of trees, which would not safely clear the conductor if the conductor were to swing out under maximum wind or which would not safely clear the conductor if they were to fall; and (5) the removal of buildings, lumber piles, haystacks, etc., which constitute a fire hazard. One of the major causes of serious line outages is the neglect to adhere strictly to conservative rules for clearing.

Tower Spotting. The efficient location of structures on the profile is an important component of line design. Structures of appropriate height and strength must be located to provide adequate conductor ground clearance and minimum cost. In the past, most tower spotting has been done manually, using templates, but several computer programs have been available for a number of years for the same purpose.

Manual Tower Spotting. A celluloid template, shaped to the form of the suspended conductor, is used to scale the distance from the conductor to the ground and to adjust structure locations and heights to (1) provide proper clearance to the ground; (2) equalize spans; and (3) grade the line (Fig. 14-16).

The template is cut as a parabola on the maximum sag (usually at 49°C) of the ruling span and should be extended by computing the sag as proportional to the square of the span for spans both shorter and longer than the ruling span. By extending the template to a span of several thousand feet, clearances may be scaled on steep hillsides. The form of the template is based on the fact that, at the time when the conductor is erected, the horizontal tensions must be equal in all spans of every length, both level and inclined, if the insulators hang plumb. This is still very nearly true at the maximum temperature. The template, therefore, must be cut to a catenary or, approximately, a parabola. The parabola is accurate to within about one-half of 1% for sags up to 5% of the span, which is well within the necessary refinement.

Since vertical ground clearances are being established, the 49°C no-wind curve is used in the template. Special conditions may call for clearance checks. For example, if it is known that a line will have high temperature rise because of load current, conductor clearance should be checked for the estimated maximum conductor temperature. One crossing over a navigable stream was designed for 88°C at high water. Ice and wet snow many times cause weights several times that of the 1/2-in radial ice loading, and conductors have been known to sag to within reach of the ground. Such occurrences are not normally considered in line design, and when they occur, the line is taken out of service until the ice or snow drops. Checks made afterward have nearly always shown no permanent deformation.

The template must be used subject to a "creep" correction for aluminum conductors. Creep is a nonelastic conductor stretch which continues for the life of the line, with the rate of elongation decreasing with time. For example, the creep elongation during the first 6 months is equal to that of the next 9 1/2 years. All conductors of all materials are subject to creep, but to date only aluminum conductors have had intensive study. Creep is not substantial in other conductors, but the conductor manufacturers should be consulted. The IEEE Committee Report, "Limitations on Stringing and Sagging Conductors," in the December 1964 *Transactions of the IEEE Power Group* discusses creep, and the reader should examine that report.[53]

Creep causes a continuous slow increase in the sag of the line which must be estimated and allowed for. The aluminum-conductor manufacturers will furnish creep-estimating curves, and most sag-tension computer programs now available are capable of calculating sags with and without creep. These curves are at approximately constant temperatures, around 15.5 to 21°C, and plot stress against elongation, one curve for each period of time, 1 h, 1 day, 1 month, 1 year, 10 years, etc. The values are integrated values for the period and are considered to be reasonable estimates. The temperature used is a reasonable average of the year's temperature across the center of the United States.

Precise values for creep are impossible to determine, since they vary with both temperature and tension, which are continuously varying during the life of the line. From Fig. 3 of the committee report in Ref. 53, it is found that a 1000-ft span of 954,000-cmil 48/7 ACSR when subjected to a constant tension of approximately 18% of its ultimate strength at a temperature of 15.5°C will have a sag increase in 1 day of approximately 5.5 in; in 10 days, 13 in; in 1 year, 27 in; in 10 years, 44 in; and in 30 years, 52 in.

Unless it is known that the line will have a life of less than 10 years, not less than 10 years' creep should be allowed for. Creep has come into consideration in transmission-line design only during the past 35 years, and to date no standards have been established for handling it. Probably the simplest approach is to check all close clearance points on the profile with a template made with no creep allowance and to specify higher structures at these points if the addition of liberal creep sag infringes on the required clearances. It is possible to prestress the creep out of small conductors, but for large conductors this requires time and special tensioning facilities not normally available. Also the time lost in constructing an EHV line will more than pay for the extra structure height required to compensate for the creep. Prestressing changes the modulus of elasticity, and this new modulus should be used in the design.

The vertical weight supported at any structure is the weight of the length of conductor between low points of the sag in the two adjacent spans. For bare-conductor weights, this distance between low points can be scaled by using a template of the sag at any desired temperature. The maximum weight under loaded conditions should be scaled from a template made for the loaded sags. For most problems, the horizontal distance may be taken as equal to the conductor length. Distances to the low point of the sag may be computed by Eq. (14-65).

Uplift. On steep inclined spans the low point may fall beyond the lower support; this indicates that the conductor in the uphill span exerts a negative or upward pull on the lower tower. The amount of this upward pull is equal to the weight of the conductor from the lower tower to the low point in the sag. Should the upward pull of the uphill span be greater than the downward load of the next adjacent span, actual uplift would be caused, and the conductor would tend to swing clear of the tower.

It is important that abrupt changes in elevation of the structures should not occur, so that the conductor will not tend to swing clear of any structure even at low temperatures. This condition would be indicated if the 0°F curve of the template can be adjusted to hang free of the center support and just touch the adjacent supports on either side. In northern states it would be well to add a curve to the template for the below-zero temperatures experienced.

Insulator Swing. The uplift condition should not even be approached in laying out suspension insulator construction; that is, each tower should carry a considerable weight of conductor. The minimum weight that should be allowed on any structure may be logically determined by finding the transverse angle to which the insulator string may swing without reducing the clearance from the conductor to the structure too greatly. Also, the ratio of vertical weight to horizontal wind load should be limited to avoid insulator swing beyond this angle. The maximum wind is usually assumed at a temperature of 60°F. The wind pressure, measured in pounds per square foot, to be used in swing calculations is a matter of judgment and depends on local conditions. Under high-wind conditions it is reasonable to require somewhat less than normal clearances. Generally a clearance corresponding to about 75% of the flashover value of the insulator is adequate. The insulator will swing in the direction of the resultant of the vertical and horizontal forces acting on the insulator string as shown in Fig. 14-16.

Long Spans. Rough country may necessitate spans considerably longer than contemplated in the design and may involve a number of factors including (1) proper clearance between conductors, (2) excessive tensions under maximum load, and (3) structures adequate to carry the additional loads.

Safe horizontal clearance between conductors is often based on the National Electrical Safety Code (NESC) formula, in which the spacing a in inches is given as proportional to the square root of sag; s is in inches.

$$a = 0.3\ \text{in/kV} + 8\sqrt{\frac{s}{12}} \tag{14-49}$$

This relation was developed for, and is useful on, comparatively short span lines of the smaller conductors and for voltages up to 69 kV; but for very long spans and heavy conductors, the formula results in spacings considerably larger than have proved satisfactory. It also results in spacings that are questionably small for very light conductors on long spans. Percy H. Thomas proposed an empirical formula which takes into account the weight of the conductor and its diameter, requiring less spacing for heavy conductors and a greater spacing for small conductors by the ratio of diameter D in inches to weight w in pounds per foot (D/w) as a means of determining the required conductor

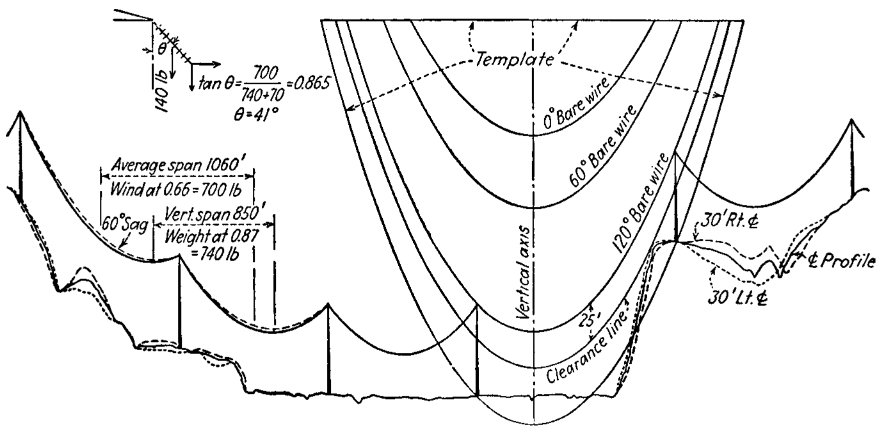

FIGURE 14-16 Sag template determines clearances of a suspended conductor from the ground.

spacing for the average span of the line. The factor C in Eq. (14-81) includes an allowance to permit the standard spacing to be used on somewhat longer spans than average construction. The same formula, however, may be used to examine the spacings which have been successfully used on maximum spans and a value for C selected from experience for determining the safe spacing required for an occasional unusually long span.

Excessive tensions on very long spans may be avoided by dead-ending at both ends and computing such a stringing sag as will result in the same maximum tension as elsewhere in the line. Such a span will be found to have considerably greater stringing sag and lower stringing tension than the normal span. Sag curves or charts are often prepared giving the sag for dead-end spans of various lengths such that the maximum tension under loaded conditions will be the same.

Dead-end construction is costly, and consideration should be given to avoiding this additional expense. It is common practice to permit spans up to double the average span without dead ends, although spans of this length may require additional spacing between wires. A careful examination of some trial figures on the sags and tensions developed in a long span will often indicate how great a span may be carried on suspension structures. The maximum loaded tension which would occur in a long span, if this span were dead-ended and sagged to the same stringing tension as the rest of the line, compared with the maximum tension for normal span lengths, is a good indication of the necessity for dead-end construction.

In case a number of long spans are encountered in a line or section of line, it may prove more economical to reduce the tension in the entire section to the long-span values and accept an increase in sag and corresponding reduction in span length in order to avoid dead ends.

Computerized Tower Spotting.[54–56] In a line of any significant length there are a very large number of possible tower location sequences which meet the requirement for minimum electrical clearances yet also meet the maximum load limits of the chosen structure family. With considerable design experience, it is possible to select a reasonably economical tower spotting solution, but no manual tower spotting method can explore all the possibilities nor find the lowest-cost solution.

In recent years, computer programs have become available to explore nearly all possible tower spotting solutions, selecting those having the lowest cost. In addition to exploring minimum-cost tower spotting solutions for new lines, these computer programs also allow the user to explore uprating alternatives including reconductoring, adding structures, raising attachment points, and retensioning the existing conductors. With the advent of more and more powerful personal computers and easier-to-use graphical interfaces, these programs can be applied even to relatively small line designs. Such programs are particularly attractive when modern digital methods of obtaining terrain data or existing line structure locations, heights, and catenaries can be used to collect the vast amount of input data required.

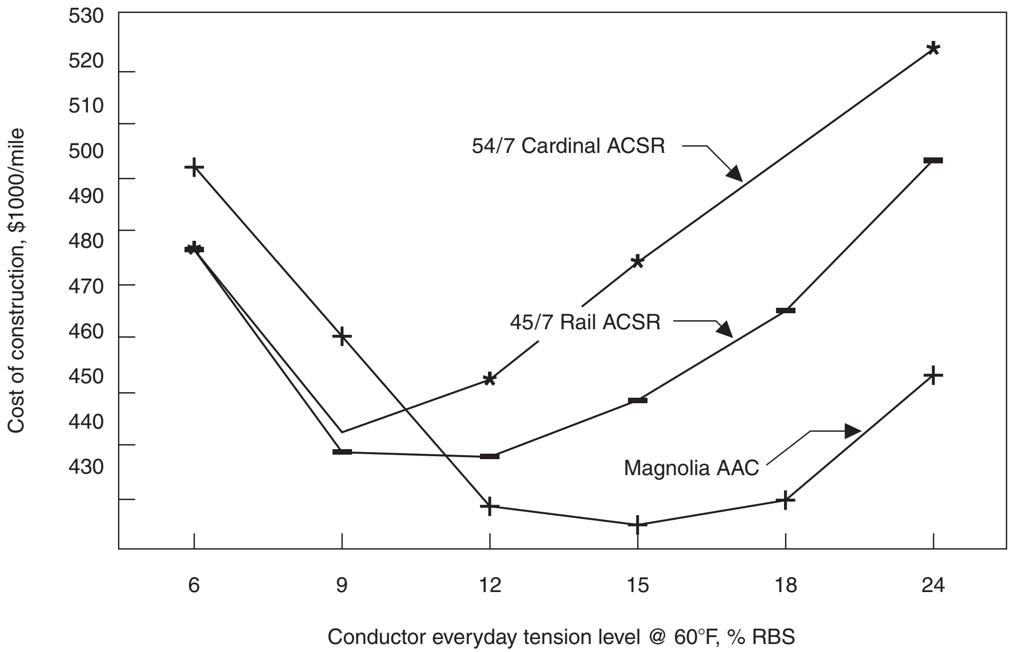

FIGURE 14-17 Cost of construction versus conductor tensions for 1200-ft (366 m) wind span.

Digital data collection and analysis allows the line designer to explore a number of design aspects that were simply impossible just a short time ago. For example, Fig. 14-17 shows the result of a series of lowest-cost numerical tower spotting calculations made to explore the effects of conductor type (all-aluminum conductor, low-steel 45/7 ACSR, and high-steel 54/7 ACSR) and conductor stringing tension expressed as a percent of rated breaking strength (RBS). Each data point represents a optimized tower spotting calculation. It's interesting to note that the lowest-cost solution is the weakest conductor at a modest tension level.

14.1.8 Mechanical Design of Overhead Spans

Conductor and Structure Loads. The span design consists of determining the sag at which the conductor shall be erected so that heavy winds, accumulations of ice or snow, and low temperatures, even if sustained for several days, will not stress the conductor beyond the elastic limit, cause a serious permanent stretch, or result in fatigue failures from continued vibrations.

Unit wind and ice loadings for conductors are found by the following formulas:

$$\text{Wind load (lb/ft)} = p \times \left(\frac{D}{12}\right) \tag{14-50}$$

$$\text{Ice load (lb/ft)} = 1.244 \times (Dr + r^2) \tag{14-51}$$

where p is the wind pressure in pounds per square foot, D is the diameter of the conductor in inches, and r is the radial thickness of the ice in inches. The ice is assumed to be glaze ice with a unit weight of 57 lb/ft^3.

The dead weight of the conductor and the weight of the accumulated ice act vertically; the wind load is assumed to act horizontally and at right angles to the span; the resultant is the vectorial sum.

Under combined vertical and horizontal loading, the conductor swings out into an inclined plane whose angle with the vertical is the angle between the direction of the vertical force and the resultant force. The resulting deflection is measured in this inclined plane.

The following procedures for calculating extreme loadings on transmission line conductors and structures are based on a reliability-based design (RBD) methodology described in ASCE Manual 74.[57] These represent the minimum loading levels for which transmission lines in the United States should be designed. For critical or important lines, more stringent requirements than those given below should be specified to provide improved reliability of the lines. Detailed procedures for designing for higher levels of line reliability are given in Manual 74.

Extreme Wind Loading. The wind pressure p at height z above ground level, in pounds per square foot, is given by the following formula:[57]

$$p = 0.00256(Z_v V)^2 G C_f \tag{14-52}$$

where V = the basic wind speed, in miles per hour, determined from the wind-speed contour map in Fig. 14-18
C_f = the force coefficient given in Table 14-11 or 14-12
Z_v = the terrain factor given in Table 14-13
G = the gust response factor given in Fig. 14-19*a* through *d*

The exposure categories required for the determination of p_z are defined in Table 14-14. These exposure categories and the basic wind-speed map in Fig. 14-18 are not applicable to sections of transmission lines that cross high mountain ridges, large river valleys, or other topographic features where localized wind speed-up effects may occur. In these cases, special meteorological studies should be conducted to establish the appropriate wind loadings.

The basic wind-speed contour map in Fig. 14-18 is taken from ASCE Standard 7-88.[58] Wind speeds from this map represent the 50-year return period fastest-mile speeds at 33 ft above ground for exposure category C.

The effective height z for determining the terrain factor and gust response factor is the distance above ground level to the center of pressure of the conductor or structure. For conductors, it can be approximated as the average height above ground of the conductor attachment points to the structure minus one-third the sum of the insulator length (for suspension insulators only) and the sag of the conductors. For support structures with total heights of 200 ft or less, the effective height can be approximated as two-thirds the total height of the structure. For structures taller than 200 ft, the terrain factor should be varied over the height of the structure to represent the increase in the wind speed with height above ground.

Extreme Ice Loading. The radial ice thickness r for the extreme ice loading condition can be determined from the ice map in Fig. 14-20.[57] This map gives estimates of the average 50-year return period glaze ice thicknesses for five regions of the United States. Since this map was developed from limited observations of icing on overhead lines, it should be used only if statistical data on extreme ice loadings for the region of the transmission line are not available.

Combined Ice and Wind Loading. For combined ice and wind loading conditions, the glaze ice thickness determined from Fig. 14-20 should be combined with a wind speed equal to 0.4 times the wind speed from the wind contour map in Fig. 14-18. The basis for this reduced wind speed is described in ASCE Manual 74.[57] In cases where statistical data on wind speeds during icing conditions are available, those data should be used in lieu of this wind-speed reduction.

Wire Tensions. The wire tensions for the extreme wind loading case should be based on the temperature that is most likely to occur at the time of the extreme wind events. For example, it could be the average of the minimum daily temperatures

TABLE 14-11 Force Coefficients for Cylindrical Surfaces

Description of surface	C_f
Stranded cables (conductors, ground wires, guy wires)	1.0
Smooth circular cylinder	0.9
Rough circular cylinder	1.2
16-sided polygon	0.9
12-sided polygon	1.0
Octagon	1.4

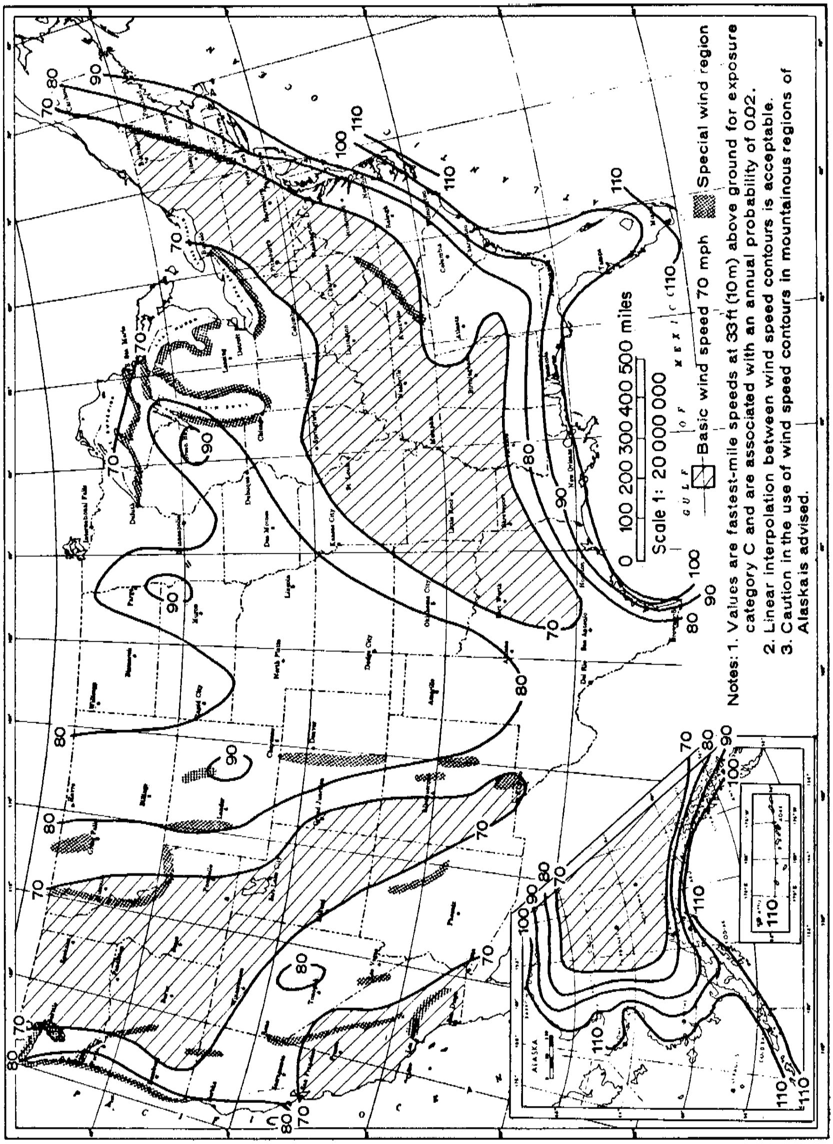

FIGURE 14-18 Basic wind speed, mi/h.

TABLE 14-12 Force Coefficients for Lattice Towers, C_f

ϵ	C_f	
	Square towers	Triangular towers
<0.025	4.0	3.6
0.025−0.44	$4.1-5.2\epsilon$	$3.7-4.5\epsilon$
0.45−0.69	1.8	1.7
0.7−1.0	$1.3+0.7\epsilon$	$1.0+\epsilon$

Notes: ϵ is the ratio of solid area to gross area of tower face.

Force coefficients are given for towers with structural angles or similar flat-sided members.

For towers with rounded members, the design wind force shall be determined using the values in this table multiplied by the following factors:

$\epsilon \leq 0.29$ factor = 0.67
$0.3 \leq \epsilon \leq 0.79$ factor = $0.67\epsilon + 0.47$
$0.8 \leq \epsilon \leq 1.0$ factor = 1.0

For triangular-section towers, the design wind forces shall be assumed to act normal to a tower face.

For square-section towers, the design wind forces shall be assumed to act normal to a tower face. To allow for the maximum horizontal wind load, which occurs when the wind is oblique to the faces, the wind load acting normal to a tower face shall be multiplied by the factor $1.0 + 0.75\epsilon$ for $\epsilon < 0.5$ and shall be assumed to act along a diagonal.

for the strong-wind season. A wire temperature of 15°F is recommended for computing the wire tensions for the combined ice and wind loading case. Although ice accretion typically occurs at temperatures somewhat greater than this, the 15°F temperature accounts for a possible cold front passing after the icing event.

Catenary Calculations for Stranded Conductors. The energized conductors of transmission and distribution lines must be placed in a manner that totally eliminates the possibility of injury to people. Overhead conductors, however, elongate with time, temperature, and tension, thereby changing their original positions after installation. Despite the effects of weather and loading on a line, the conductors must remain at safe distances from buildings, objects, and people or vehicles passing

TABLE 14-13 Terrain Factor, Z_v

Height above ground level, z ft	Z_v		
	Exposure B	Exposure C	Exposure D
0–33	0.72	1.00	1.18
40	0.75	1.03	1.21
50	0.78	1.06	1.23
60	0.82	1.09	1.26
70	0.85	1.11	1.28
80	0.88	1.14	1.29
90	0.91	1.16	1.31
100	0.93	1.17	1.32
120	0.96	1.20	1.35
140	0.99	1.23	1.37
160	1.02	1.26	1.39
180	1.05	1.28	1.40
200	1.08	1.30	1.42

Notes: Linear interpolation for intermediate values of height z is acceptable. Exposure categories are defined in Table 14-1.

TABLE 14-14 Description of Exposure Categories

Exposure category	Description
B	Suburban areas, wooded areas, or other terrain with numerous closely spaced obstructions having the size of single-family dwellings or larger
C	Open terrain with scattered obstructions having heights generally less than 30 ft, e.g., cultivated fields and grasslands
D	Flat, unobstructed coastal areas directly exposed to wind flowing over large bodies of water

beneath the line at all times. To ensure this safety, the shape of the terrain along the right-of-way, the height and lateral position of the conductor between support points, and the position of the conductor between support points under all wind, ice, and temperature conditions must be known.

Bare overhead transmission or distribution conductors are typically flexible and uniform in weight along their lengths. Because of these characteristics, they take the form of a catenary between support points. The shape of the catenary[59,60] changes with conductor temperature, ice and wind loading, and time. To ensure adequate vertical and horizontal clearance under all weather and electrical loadings, and to ensure that the breaking strength of the conductor is not exceeded, the behavior of the conductor catenary under all conditions must be incorporated into the line design. The required prediction of the future behavior of the conductor are determined through calculations commonly referred to as *sag-tension calculations,* which predict the behavior of conductors according to recommended tension limits under varying loading conditions. These tension limits specify certain percentages of the conductor's rated breaking strength that is not to be exceeded on installation or during the life of the line. These conditions, along with the elastic and permanent elongation properties of the conductor, provide the basis for determining the amount of resulting sag during installation and long-term operation of the line.

Accurately determined initial sag limits are essential in the line design process. Final sags and tensions depend on initial installed sags and tensions and on proper handling during installation. The final sag shape of conductors is used to select support point heights and span lengths so that the minimum clearances will be maintained over the life of the line. If the conductor is damaged or the initial sags are incorrect, the line clearances may be violated or the conductor may break during heavy ice or wind loadings.

Sag and Tension in Level Spans. A bare stranded overhead conductor is normally held clear of objects, people, and other conductors by periodic attachment to insulators. The elevation differences between the supporting structures affect the shape of the conductor catenary. The catenary's shape has a distinct effect on the sag and tension of the conductor, which can be determined using well-defined mathematical equations.

The shape of a catenary is a function of the conductor weight per unit length w, the horizontal component of tension, H, the span length S, and the sag of the conductor D. Conductor sag and span length are illustrated in Fig. 14-21 for a level span.

The exact catenary equation uses hyperbolic functions. Relative to the low point of the catenary curve shown in Fig. 14-21, the height of the conductor $y(x)$ above this low point is given by the following equation:

$$y(x) = \frac{H}{w}\left[\cosh\left(\frac{wx}{H}\right) - 1\right] \cong \frac{wx^2}{2H} \tag{14-53}$$

Note that x is positive in either direction from the low point of the catenary. The expression to the right is an approximate parabolic equation based on a MacLaurin series expansion of the hyperbolic cosine.

For a level span, the low point is in the center and the sag D is found by substituting $x = S/2$ in the preceding equations. The exact catenary and approximate parabolic equations for sag become the following:

$$D = \frac{H}{w}\left[\cosh\left(\frac{wS}{2H}\right) - 1\right] \cong \frac{wS^2}{8H} \tag{14-54}$$

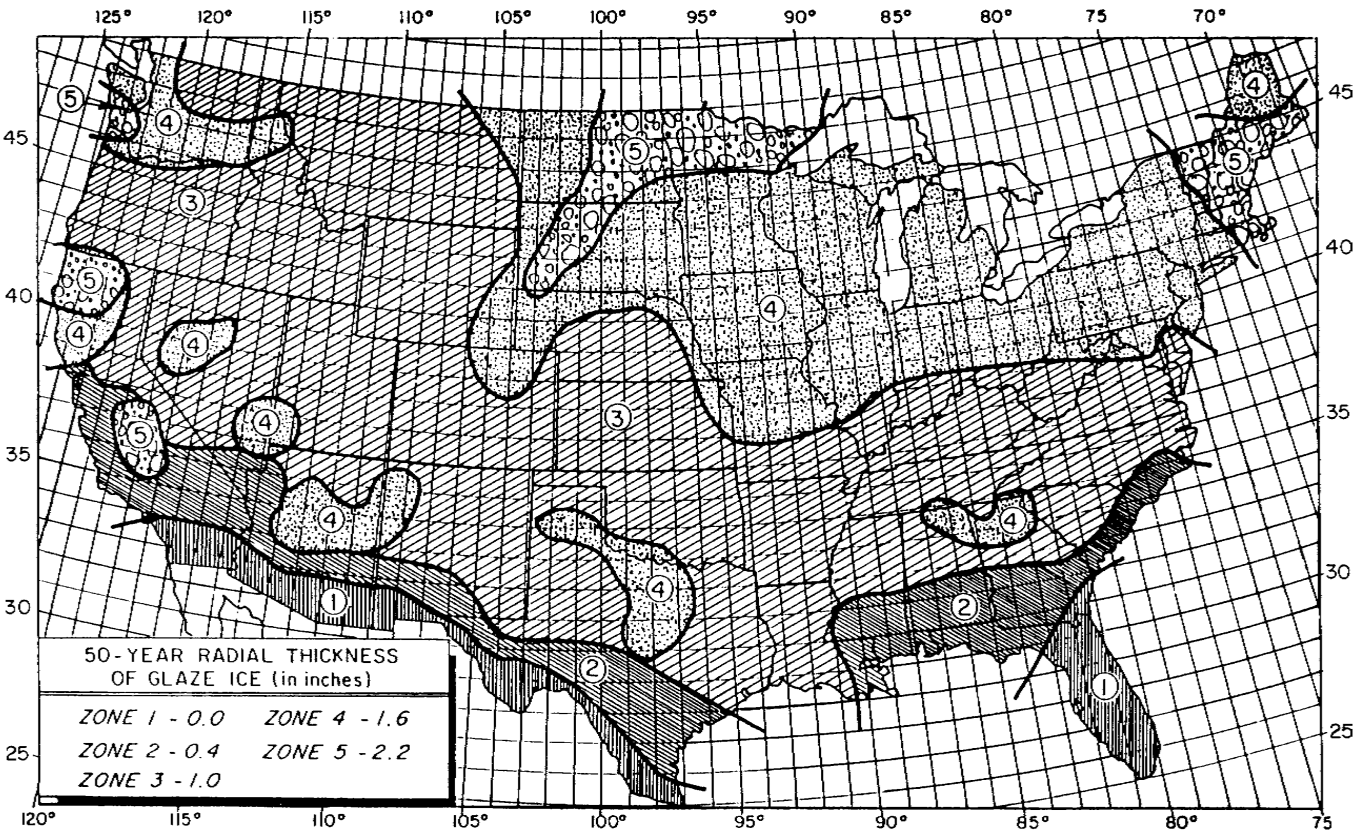

FIGURE 14-20 Extreme radial thickness of glaze ice having a 50-year return period.

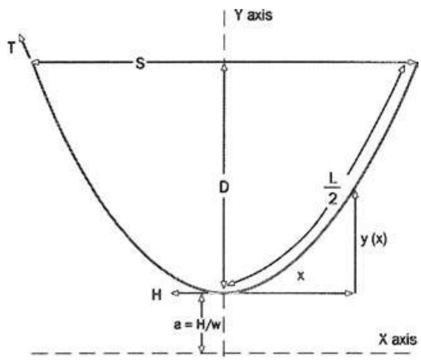

FIGURE 14-21 The catenary curve for level spans.

The ratio H/w which appears in all of the preceding equations is commonly referred to as the *catenary constant*. An increase in the catenary constant causes the catenary curve to become shallower and the sag to decrease. Although it varies with conductor temperature, ice and wind loading, and time, the catenary constant typically has a value in the range of several thousand feet for most transmission-line catenaries.

The approximate, or parabolic, expression is sufficiently accurate as long as the sag is less than 5% of the span length. As an example, consider a 1000-ft (304.5-m) span of Drake ACSR conductor with a per unit weight of 1.096 lb/ft (15.99 N/m) installed at a tension of 4500 lb (20.016 kN). The catenary constant H/w is 4106 ft (1251.8 m). The calculated sag is 30.48 ft (9.293 m) and 30.44 ft (9.280 m) using the hyperbolic and approximate parabolic equations, respectively. For this case where the sag-to-span ratio is 3.4%, the difference in calculated sag between the hyperbolic and parabolic equations is 0.48 in (1.3 cm).

The horizontal component of tension H is equal to the conductor tension at the point in the catenary where the conductor slope is horizontal. For a level span, this is the midpoint of the span. At the ends of the level span, the conductor tension T is equal to the horizontal component plus the conductor weight per unit length w multiplied by the sag D, as shown in the following:

$$T = H + wD \tag{14-55}$$

Given the conditions in the preceding example calculation for a 1000-ft (304.8-m) level span of ACSR Drake, the tension at the attachment points T exceeds the 4500-lb (20.016-N) horizontal component of tension H by only 36 lb (162 N), a difference of only 0.8%.

This shows that the use of horizontal tension H and parabolic equations for the catenary are adequate for typical transmission spans and sags. However, there is little reason to use either approximation in numerical methods.

Conductor Length. Application of calculus to the catenary equation allows the calculation of the conductor length $L(x)$ measured along the conductor from the low point of the catenary in either direction.

The equation for catenary length between the supports is

$$L(x) = \frac{H}{w}\sinh\left(\frac{wx}{H}\right) \cong x\left(1 + \frac{x^2w^2}{6H^2}\right) \tag{14-56}$$

For a level span, the conductor length corresponding to $x = S/2$, is half of the total conductor length L; thus

$$L = \left(\frac{2H}{w}\right)\sinh\left(\frac{Sw}{2H}\right) \cong S\left(1 + \frac{S^2w^2}{24H^2}\right) \tag{14-57}$$

The parabolic equation for conductor length can also be expressed as a function of sag D by substitution of the sag parabolic equation [Eq. (14-54)]:

$$L = S + \frac{8D^2}{3S} \tag{14-58}$$

Conductor slack is the difference between the conductor length L and the span length S. The parabolic equations for slack may be found by equating and rearranging the preceding parabolic equations for conductor length L and sag D:

$$L - S \cong S^3\left(\frac{w^2}{24H^2}\right) \cong D^2\left(\frac{8}{3S}\right) \tag{14-59}$$

While slack has units of length, it may also be expressed as a percentage of the span length. In the preceding catenary calculation, the length of the catenary is 1002.471 ft (305.63 m) and the slack is 2.471 ft (0.753 m), which is 2.47% of the span length. According to the ruling-span approximation, which is discussed later, the tension H and the tension to weight per unit length ratio H/w is the same in all suspension spans between strain structures. Therefore the slack in each suspension span is proportional to the cube of the suspension span length and the total slack is determined largely by the longest spans. It is for this reason that the ruling span is closer to the longest span rather than the average span.

Equation (14-58) can be inverted to obtain an equation showing the dependence of sag D on slack $L - S$:

$$D = \sqrt{\frac{3S(L-S)}{8}} \tag{14-60}$$

Given the preceding 1000-ft (304.5-m) level span of Drake ACSR conductor with 2.471 ft (0.753 m) of slack, a reduction of 6 in (15.2 cm) in slack yields a sag reduction of 3.25 ft (0.99 m). As can be seen from the preceding, small changes in slack typically yield large changes in conductor sag and tension, particularly for short spans.

Sag and tension in inclined spans may be analyzed using essentially the same equations that were used for level spans. The catenary equation for the conductor height above the low point in the span is the same. However, the span is considered to consist of two separate sections, one to the right of the low point and the other to the left as shown in Fig. 14-22. The shape of the catenary relative to the low point is unaffected by the difference in suspension point elevation (span inclination). In each direction from the low point, the conductor elevation $y(x)$ relative to the low point is given by Eq. (14-53):

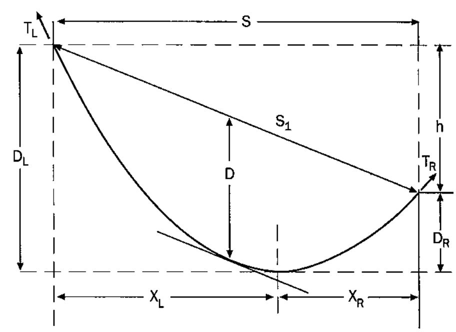

FIGURE 14-22 Inclined catenary span.

$$y(x) = \frac{H}{w}\left[\cosh\left(\frac{wx}{H}\right) - 1\right] = \frac{wx^2}{2H}$$

Note that x is considered positive in either direction from the low point.

The horizontal distance x_L from the left support point to the low point in the catenary is

$$x_L = \frac{S}{2}\left(1 + \frac{h}{4D}\right) \tag{14-61}$$

The horizontal distance x_R from the right support point to the low point of the catenary is

$$x_R = \frac{S}{2}\left(1 - \frac{h}{4D}\right) \tag{14-62}$$

where S = horizontal distance between support points
h = vertical distance between support points
S_1 = straight-line distance between support points
D = sag measured vertically from a line through the points of conductor support to a line tangent to the conductor

(as shown in Fig. 14-22). The midpoint sag D is approximately equal to the sag in a horizontal span, with a length equal to the inclined span S_1.

Knowing the horizontal distance from the low point to the support point in each direction, we can apply the preceding equations for $y(x)$, L, D, and T to each side of the inclined span. The total conductor length L in the inclined span is equal to the sum of the lengths in the x_R and x_L subspan sections:

$$L = S + (x_L^3 + x_R^3)\left(\frac{w^2}{6H^2}\right) \tag{14-63}$$

In each subspan, the sag is relative to the corresponding support point elevation

$$D_R = \frac{Wx_R^2}{2H}, \qquad D_L = \frac{Wx_L^2}{2H} \tag{14-64}$$

or in terms of sag D and the vertical distance between support points

$$D_R = D\left(1 - \frac{h}{4D}\right)^2, \qquad D_L = D\left(1 + \frac{h}{4D}\right)^2 \tag{14-65}$$

and the maximum tension is

$$T_R = H + wD_R, \qquad T_L = H + wD_L \tag{14-66}$$

or in terms of upper and lower support points:

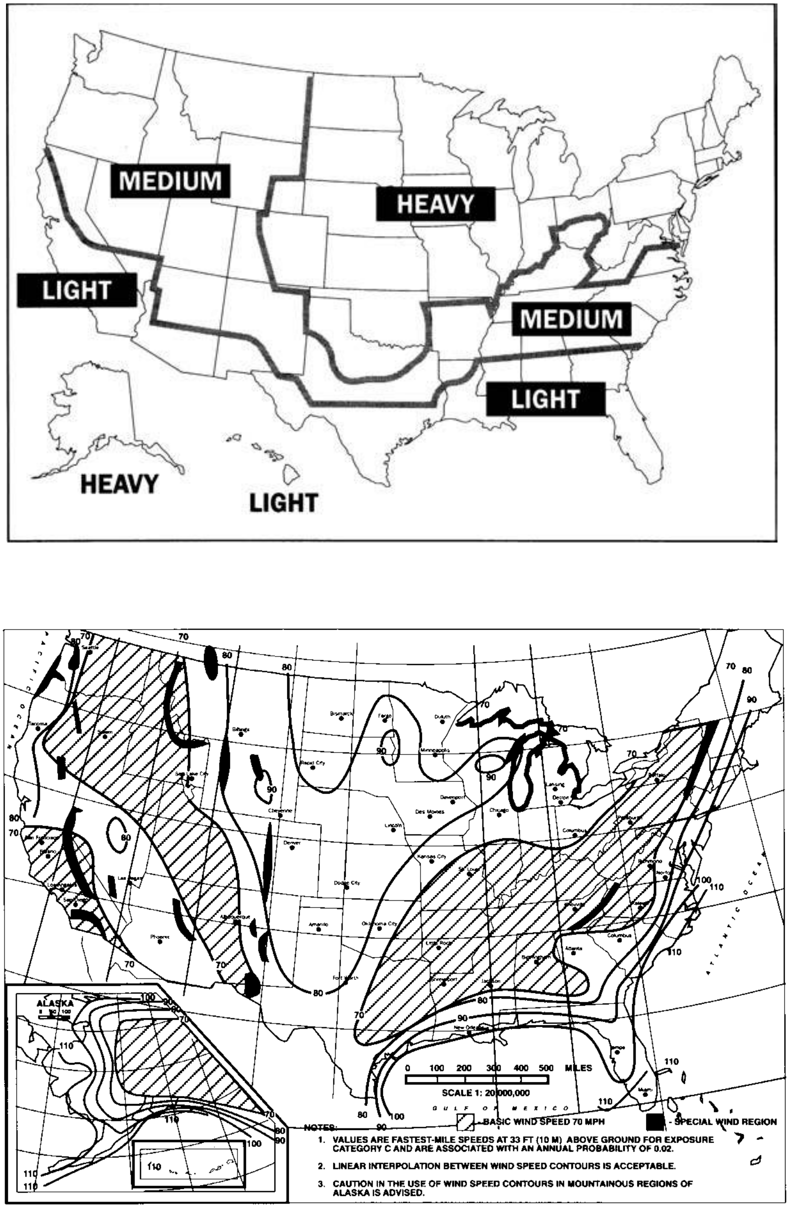
$$T_u = T_1 + wh \tag{14-67}$$

where D_R = sag in right subspan section
D_L = sag in left subspan section
T_R = tension in right subspan section
T_L = tension in left subspan section
T_u = tension in conductor at upper support
T_1 = tension in conductor at lower support

The horizontal conductor tension is equal at both supports. The vertical component of conductor tension is greater at the upper support, and the resultant tension, T_u, is also greater.

Ice and Wind Conductor Loads. When a conductor is covered with ice and/or is exposed to wind, the effective conductor weight per unit length increases. During occasions of heavy ice and/or wind load, the conductor catenary tension increases dramatically along with the loads on angle and dead-end structures. Both the conductor and its supports can fail unless these high-tension conditions are considered in the line design.

The *National Electrical Safety Code* (NESC) suggests certain combinations of ice and wind corresponding to heavy, medium, and light loading regions of the United States. Figure 14-23*a* is a map of the United States indicating those areas. The combinations of ice and wind corresponding to loading region are listed in Table 14-15. The NESC also suggests that increased conductor loads due to high wind loads without ice be considered. Figure 14-23*b* shows the suggested wind pressure as a function of geographic area for the U.S. (NESC).



This figure is reproduced by permission of the American Society of Civil Engineers. [10]

FIGURE 14-23 (*a*) Ice and wind load areas of the United States. (*b*) Wind-pressure design values for the United States. (*American Society of Civil Engineers*).

Certain utilities in very heavy ice areas use glaze ice thickness of as much as 2 in (50 mm) to calculate iced conductor weight. Similarly, utilities in regions where hurricane winds occur may use wind loads as high as 34 lb/ft^2 (1620 Pa). As the NESC indicates, the degree of ice and wind loads varies by region. Some areas may have heavy icing, whereas some areas may have extremely high winds. The loads must be accounted for in the line design process to prevent a detrimental effect on

TABLE 14-15 Ice and Wind Loading For NESC Loading Districts

	Loading districts			
	Heavy	Medium	Light	Extreme wind loading
Radial thickness of ice, in (mm)	0.5 (12.5)	0.25 (6.25)	0	0
Horizontal wind pressure, lb/ft^2 (Pa)	4 (190)	4 (190)	9 (430)	see Fig. 2-4 (NESC)
Temperature, °F (°C)	0 (−20)	+15 (−10)	+30 (−1)	+60 (+15)
Constant to be added to the resultant (all conductors), lb/ft (N/m)	0.30 (4.40)	0.20 (2.50)	0.05 (0.70)	0.0 (0.0)

the line. Some of the effects of both the individual and combined components of ice and wind loads are discussed below:

Ice loading of overhead conductors may take several physical forms (glaze ice, rime ice, or wet snow). The impact of lower-density ice formation is usually considered in the design of line sections at high altitudes.

The formation of ice on overhead conductors has the following influence on line design:

- Ice loads determine the maximum vertical conductor loads that structures and foundations must withstand.
- In combination with simultaneous wind loads, ice loads also determine the maximum transverse loads on structures.
- In regions of heavy ice loads, the maximum sags and the permanent increase in sag with time (difference between initial and final sags) may be due to ice loadings.

Ice loads for use in designing lines are normally derived on the basis of past experience, code requirements, state regulations, and analysis of historical weather data. Mean recurrence intervals for heavy ice loadings are a function of local conditions along various routings. The impact of varying assumptions concerning ice loading can be investigated with line design software.

The calculation of ice loads on conductors is normally done with an assumed glaze ice density of 57 lb/ft^3 (8950 N/m^3). The weight of ice per unit length is calculated with the following equation:

$$w_{\text{ice}} = 0.0281t(D_c + t) \qquad (14\text{-}68)$$

where t = radial thickness of ice, mm
D_c = conductor outside diameter, mm
w_{ice} = resultant weight of ice, N/m

The ratio of iced weight to bare weight depends strongly on conductor diameter. As shown in Table 14-16, for three different conductors covered with 0.5-in radial glaze ice, this ratio ranges from 4.8 for No. 1/0 AWG wire to 1.6 for 1590-kcmil conductors. As a result, small-diameter conductors may need to have a higher elastic modulus and higher tensile strength than do large conductors in heavy ice and wind loading areas to limit sag.

TABLE 14-16 Ratio of Iced to Bare Conductor Weight

ACSR Conductor	D_c, in	W_{bare}, lb/ft	W_{ice}, lb/ft	$\frac{W_{\text{bare}} + W_{\text{ice}}}{W_{\text{bare}}}$
No. 1/0 AWG 6/1 "Raven"	0.398	0.1452	0.559	4.8
477-kcmil 26/7 "Hawk"	0.858	0.6570	0.845	2.3
1590-kcmil 54/19 "Falcon"	1.545	2.044	1.272	1.6

Conductor wind loading influences line design in a number of ways:

- The maximum span between structures may be determined by the need for horizontal clearance to edge of right-of-way during moderate winds.
- The maximum transverse loads for tangent and small-angle suspension structures are often determined by infrequent high-wind-speed loadings.
- Permanent increase in conductor sag may be determined by wind loading in areas of light ice load.

Wind-pressure load on conductors P_w is commonly specified in pounds per square foot (lb/ft^2). The relationship between P_w and wind velocity is given by the following equation:

$$P_w = 0.00256(V_w)^2 \tag{14-69}$$

where V_w is the wind speed in miles per hour.

The wind load per unit length of conductor W_w is equal to the wind-pressure load P_w multiplied by the conductor diameter (including radial ice of thickness t, if any):

$$W_w = P_w \frac{(D_c + 2t)}{12} \tag{14-70}$$

Combined Ice and Wind Loading. If the conductor weight is to include both ice and wind loading, the resultant magnitude of the loads must be determined. The weight of a conductor under both ice and wind loading is given by the following equation:

$$w_{w+i} = \sqrt{(w_b + w_i)^2 + (W_w)^2} \tag{14-71}$$

where w_b = bare conductor weight per unit length, lb/ft (N/m)
w_i = weight of ice per unit length, lb/ft (N/m)
w_w = wind load per unit length, lb/ft (N/m)
w_{w+i} = resultant of ice and wind loads, lb/ft (N/m)

The NESC prescribes a safety factor K in pounds per foot, dependent on loading district, to be added to the resultant ice and wind loading when performing sag and tension calculations. Therefore, the total resultant conductor weight w is

$$w = w_{w+i} + K \tag{14-72}$$

Conductor Tension Limits. The NESC recommends limits on the tension of bare overhead conductor as a percentage of the conductor's rated breaking strength. The tension limits are 60% under maximum ice and wind loading, 35% initial unloaded (when installed) at 60°F, and 25% final unloaded (after maximum loading has occurred), also at 60°F. It is common, however, for lower unloaded tension limits to be used. Except in areas experiencing severe ice loading, it is not unusual to find tension limits of 60% maximum, 25% unloaded initial, and 15% unloaded final. This set of specifications could easily result in an actual maximum tension on the order of only 35% to 40%, an initial tension of 20%, and a final unloaded tension level of 15%. In this case, the 15% tension limit is said to govern.

Transmission-line conductors are seldom covered with ice, and winds on the conductor are usually much lower than those used in maximum load calculations. Under such everyday conditions, tension limits are specified to limit eolian vibration to safe levels. Even with everyday lower tension levels of 15% to 20%, it is assumed that vibration control devices will be used in those sections of the line which are subject to severe vibration. Eolian vibration levels, and thus appropriate unloaded tension limits, vary with the type of conductor, the terrain, the span length, and the use of dampers. Special conductors such as ACSS, SDC, and VR, which exhibit high self-damping properties, may be installed to the full code limits, if desired.

Recent studies by CIGRE Working Group B2/11 led to the development of a guide for choosing suitable installed conductor tension levels. The recommendations are in the form of maximum allowable ratios of tension (*H* in pounds or Newtons) to weight per unit length (*w* in lb/ft or N/m). The primary determinants of the maximum *H/w* ratio include the type of conductor (e.g., ACSR or AAC). The type of terrain (e.g., 4 terrain types, #1 being open, flat, not trees, no obstructions, etc.), and a span parameter *LD/m* where *L* is the span length, *D* is the conductor diameter, and *m* is the mass per unit length of the conductor.

Approximate Sag-Tension Calculations. Sag-tension calculations, using detailed experimental stress-strain and creep elongation laboratory data, are usually performed with the aid of a computer; however, with certain simplifications, these calculations can be made with a handheld calculator. The latter approach allows greater insight into the calculation of sags and tensions than is possible with complex computer programs. Equations suitable for such calculations, as presented in the preceding section, can be applied to the following example:

It is desired to calculate the sag and slack for a 600-ft level span of 795 kcmil-26/7 ACSR Drake conductor. The bare conductor weight per unit length w_b is 1.094 lb/ft. The conductor is installed with a horizontal tension component *H* of 6300 lb, equal to 20% of its rated breaking strength of 31,500 lb. The sag for this level span is

$$D = \frac{1.094(600)^2}{(8)6300} = 7.81 \text{ ft } (2.38 \text{ m})$$

The length of the conductor between the support points is determined from

$$L = 600 + \frac{8(7.81)^2}{3(600)} = 600.27 \text{ ft } (182.96 \text{ m})$$

Note that the conductor length depends solely and directly on span and sag. It is not directly dependent on conductor tension, weight, or temperature. The *conductor slack* is the conductor length minus the span length; in this example, it is 0.27 ft (0.082 m).

Sag Change with Thermal Elongation. The ACSR and AAC conductors elongate with increasing conductor temperature. The rate of linear thermal expansion for the composite ACSR conductor is less than that of the AAC conductor because the steel strands in the ACSR elongate at approximately half the rate of aluminum. The composite coefficient of linear thermal expansion of a nonhomogenous conductor, such as ACSR Drake, may be found from the following equations:[61]

$$\alpha_{AS} = \alpha_{Al}\left(\frac{F_{Al}}{E_{AS}}\right)\left(\frac{A_{Al}}{A_{total}}\right) + \alpha_{St}\left(\frac{E_{St}}{E_{AS}}\right)\left(\frac{A_{St}}{A_{total}}\right) \tag{14-73}$$

$$E_{AS} = E_{Al}\left(\frac{A_{Al}}{A_{total}}\right) + E_{St}\left(\frac{A_{St}}{A_{total}}\right) \tag{14-74}$$

where E_{Al} = modulus of elasticity of aluminum, lb/in^2
E_{St} = modulus of elasticity of steel, lb/in^2
E_{AS} = modulus of elasticity of aluminum-steel composite, lb/in^2
A_{Al} = area of aluminum strands, square units
A_{St} = area of steel strands, square units
A_{total} = total cross-sectional area, square units
α_{Al} = aluminum coefficient of linear thermal expansion, °F^{-1}
α_{St} = steel coefficient of thermal elongation, °F^{-1}
α_{AS} = composite aluminum-steel coefficient of thermal elongation, °F^{-1}

Of course, the modulus of elasticity of an ACSR conductor is not linear. Its elongation is a complex function of both the present stress and prior stress loading over time. Nonetheless, it is informative

to calculate the thermal elongation for approximate elasticity moduli for steel and aluminum strands.
Using elastic moduli of 8 and 28 million lb/in^2 for aluminum and steel, respectively, the elastic modulus for ACSR Drake is

$$E_{AS} = (8.6 \times 10^6)\left(\frac{0.6247}{0.7264}\right) + (27 \times 10^6)\left(\frac{0.1017}{0.7264}\right) = 11.2 \times 10^6 \text{ lb/in}^2$$

and the coefficient of linear thermal expansion is

$$\alpha_{AS} = 12.8 \times 10^{-6}\left(\frac{8.6 \times 10^6}{11.2 \times 10^6}\right)\left(\frac{0.6247}{0.7264}\right) + 6.4 \times 10^{-6}\left(\frac{27 \times 10^6}{11.2 \times 10^6}\right)\left(\frac{0.1017}{0.7264}\right)$$

$$= 10.6 \times 10^{-6}\,°\text{F}^{-1}$$

If the conductor temperature changes from a reference temperature T_{ref} to another temperature T, the conductor length L changes in proportion to the product of the conductor's effective coefficient of linear thermal elongation α_{AS} and the change in temperature $T - T_{ref}$ as follows:

$$L_T = L_{T,ref}[1 + \alpha_{AS}(T - T_{ref})] \tag{14-75}$$

For example, if the temperature of the Drake conductor in the preceding example increases from 60°F (15°C) to 167°F (75°C), then the length increases by 0.68 ft (0.21 m) from 600.27 ft (182.96 m) to 600.95 ft (183.17 m):

$$L(\text{at } 167°\text{F}) = 600.27[1 + (10.6 \times 10^{-6})(167 - 60)] = 600.95 \text{ ft}$$

Ignoring for the moment any change in length due to change in tension, the sag at 167°F (75°C) may be calculated for the conductor length of 600.95 ft (183.17 m) using Eq. (14-60):

$$D = \sqrt{\frac{3(600)(0.95)}{8}} = 14.6 \text{ ft (4.45 m)}$$

Using a rearrangement of Eq. (14-54), this increased sag is found to correspond to a decreased tension of

$$H = \frac{w(S^2)}{8D} = \frac{1.094(600)^2}{8(14.6)} = 3372 \text{ lb (15,100 N)}$$

If the conductor were inextensible, that is, if it had an infinite modulus of elasticity, then these values of sag and tension for a conductor temperature of 167°F would be correct. For any real conductor, however, the elastic modulus of the conductor is finite and changes in tension change the conductor length. Use of the preceding calculation, therefore, will overstate the increase in sag.

Sag Change Due to Combined Thermal and Elastic Effects. With moduli of elasticity around the 10-million-lb/in^2 level, typical bare aluminum and ACSR conductors elongate about 0.01% for every 1000-lb/in^2 change in tension. In the preceding example, the increase in temperature caused an increase in length and sag and a decrease in tension, but the effect of tension change on length was ignored. As discussed later, concentric-lay stranded conductors, particularly nonhomogenous conductors such as ACSR, are not inextensible. Rather, they exhibit quite complex elastic and plastic behavior. Initial loading of conductors results in elongation behavior substantially different from that caused by loading many years later. Also, high-tension levels caused by heavy ice and wind loads cause a permanent increase in conductor length, affecting subsequent elongation under various conditions.

Accounting for such complex stress-strain behavior usually requires a sophisticated, computer-aided approach. For illustration purposes, however, the effect of permanent elongation of the conductor on sag and tension calculations will be ignored, and a simplified elastic conductor assumed. This idealized conductor is assumed to elongate linearly with load and to undergo no permanent increase in length, regardless of loading or temperature. For such a conductor, the relationship between tension and length is

$$L_H = L_{H,\text{ref}}\left[1 + \frac{H - H_{\text{ref}}}{E_C A}\right] \tag{14-76}$$

where L_H = length of conductor under horizontal tension, H
$L_{H,\text{ref}}$ = length of conductor under horizontal reference tension, H_{ref}
E_c = modulus of elasticity of the conductor, lb/in^2
A = cross-sectional area, in^2

In calculating sag and tension for extensible conductors, it is useful to add a step to the preceding calculation of sag and tension for elevated temperature. This added step allows a separation of thermal elongation and elastic elongation effects, and involves the calculation of a zero-tension length (ZTL) at the conductor temperature of interest T_{cdr}. This ZTL (T_{cdr}) is the conductor length attained if the conductor is taken down from its supports and laid on the ground with no tension. By reducing the initial tension in the conductor to zero, the elastic elongation is also reduced to zero, shortening the conductor. It is even possible that for short spans, the zero tension length can be less than the span length.

Consider the preceding example for ACSR Drake in a 600-ft level span. The initial conductor temperature is 60°F, the conductor length is 600.27 ft, and E_{AS} is calculated to be 11.2 × 10^6 lb/in^2. Using Eq. (14-76), the reduction of the initial tension from 6300 lb to zero yields a ZTL at 60°F of

$$\text{ZTL}_{(60°\text{F})} = 600.27\left[1 + \frac{0 - 6300}{(11.2 \times 10^6)\,(0.7264)}\right] = 599.80 \text{ ft (182.82 m)}$$

Keeping the tension zero and increasing the conductor temperature to 167°F yields a purely thermal elongation. The zero tension length at 167°F can be calculated using Eq. (14-75):

$$\text{ZTL}_{(167°\text{F})} = 599.80 \text{ ft } [1 + (10.6 \times 10^{-6})\,(167 - 60)] = 600.48 \text{ ft}$$

According to Eqs. (14-54) and (14-60), this length corresponds to a sag of 10.2 ft and a horizontal tension of 4412 lb. However, this length was calculated for zero tension; it will elongate elastically under tension. The actual conductor sag-tension determination requires a process of iteration as follows:

1. As described above, the conductor's ZTL, calculated at 167°F (75°C), is 600.48 ft; sag is 10.2 ft; and the horizontal tension H is 4412 lb.
2. Because the conductor is elastic, the tension of 4412 lb will increase the conductor length from 600.48 ft to

$$\text{L}_{1(167°\text{F})} = 600.48\left[1 + \frac{4412 - 0}{(0.7264)(11.2 \times 10^6)}\right] = 600.80 \text{ ft (183.12 m)}$$

3. The sag D_1(167°F) corresponding to this length is calculated using Eq. (14-60):

$$\text{D}_{1(167°\text{F})} = \sqrt{\frac{3(600)(0.80)}{8}} = 13.4 \text{ ft (4.09 m)}$$

4. Using Eq. (14-54), this sag yields a new horizontal tension H_1(167°F) of

$$H_1 = \frac{1.094(600)^2}{8(13.4)} = 3674 \text{ lb}$$

TABLE 14-17 Iterative Solution for Increased Conductor Temperature

Iteration no.	Length L_n, ft	Sag D_n, ft	Tension H_n, lb	New trial tension, lb
ZTL	600.48	10.2	4412	—
1	600.80	13.4	3674	$\frac{4412 + 3674}{2} = 4043$
2	600.77	13.2	3730	$\frac{3730 + 4043}{2} = 3887$
3	600.76	13.1	3758	$\frac{3758 + 3887}{2} = 3823$
4	600.75	13.0	3787	$\frac{3787 + 3823}{2} = 3805$

A new trial tension is taken as the average of H and H_1, and the process is repeated. The results are described in Table 14-17.

Note that the balance of thermal and elastic elongation of the conductor yields an equilibrium tension of approximately 3800 lb and a sag of 13.0 ft. The calculations of the previous section, which ignored elastic effects, result in lower tension (3372 lb) and a greater sag (14.6 ft).

Slack is equal to the excess of conductor length over span length. Table 14-17 can be replaced by a plot of the catenary and elastic curves on a graph of slack versus tension. The solution occurs at the intersection of the two curves. Figure 14-24 shows the tension-versus-slack curves intersecting at a tension of 3800 lb, which agrees with the preceding calculations.

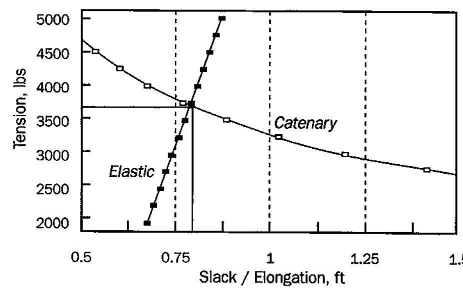


FIGURE 14-24 Sag-tension solution for 600-ft (183-m)

Sag Change Due to Ice Loading. As a final example of sag-tension calculation, calculate the sag and tension for the 600-ft span of Drake with the addition of 0.5 in of radial ice and a drop in a conductor temperature to 0°F. The weight of the conductor increases by

$$w_{\text{ice}} = 1.244t\,(D_c + t) = 1.244(0.5)(1.108 + 0.5)$$
$$= 1.000 \text{ lb/ft } (14.6 \text{ N/m})$$

As in the previous example, the calculation uses the conductor's ZTL at 60°F, which is the same as that found in the previous section, 599.80 ft. The ice loading is specified for a conductor temperature of 0°F, so the ZTL at 0°F, using Eq. (14-75), is

$$\text{ZTL}_{(0°\text{F})} = 599.80[1 + (10.6 \times 10^{-6})(0 - 60)]$$
$$= 599.42 \text{ ft}$$

As in the case of sag and tension at elevated temperatures, the conductor tension is a function of slack and elastic elongation. The conductor tension and the conductor length are found at the point of intersection of the catenary and elastic curves (Fig. 14-25). The intersection of the curves occurs at a horizontal tension component of 12,275 lb, not

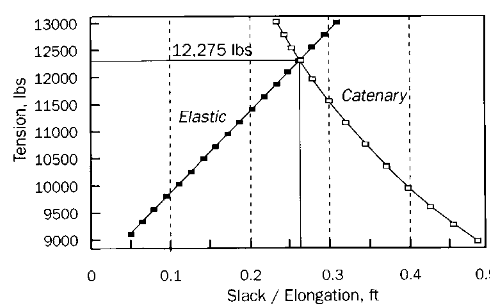

FIGURE 14-25 Sag-tension solution for 600-ft (183-m) span of Drake ACSR at 0°F (−17.8°C) and 0.5-in ice.

very far from the crude initial estimate of 12,050 lb, that ignored elastic effects. The sag corresponding to this tension and the iced conductor weight per unit length is 9.2 ft.

In spite of doubling the conductor weight per unit length by adding 0.5 in of ice, the sag of the conductor is much less than the sag at 167°F. This condition is generally true for transmission conductors where minimum ground clearance is determined by the high temperature rather than the heavy loading condition. Small distribution conductors, such as the 1/0–AWG ACSR in Table14-16, experience a much larger ice-to-conductor weight ratio (4:8), and the conductor sag under maximum wind and ice load may exceed the sag at moderately higher temperatures.

The preceding approximate tension calculations could have been more accurate with the use of actual stress-strain curves and graphic sag-tension solutions, as described in detail in Ref. 62. This method, although accurate, is very slow and has been replaced completely by computational methods.[63]

Experimental Stress-Strain Curves. Sag-tension calculations are normally done numerically and allow the user to enter many different loading and conductor temperature conditions. Both initial and final conditions are calculated, and multiple tension constraints can be specified. The complex stress-strain behavior of ACSR-type conductors can be modeled numerically, including both temperature and elastic and plastic effects.

Stress-strain curves for bare overhead conductors include a minimum of an initial curve and a final curve over a range of elongations from 0% to 0.45%. For conductors consisting of two materials, an initial and final curve for each is included. Creep curves for various lengths of time are typically included as well.

Overhead conductors are not purely elastic. They stretch with tension, but when the tension is reduced to zero, they do not return to their initial length. Thus, conductors are plastic; the change in conductor length cannot be expressed with a simple linear equation, as used in the preceding hand calculations. The permanent length increase that occurs in overhead conductors yields the difference in initial and final sag-tension data found in most computer programs.

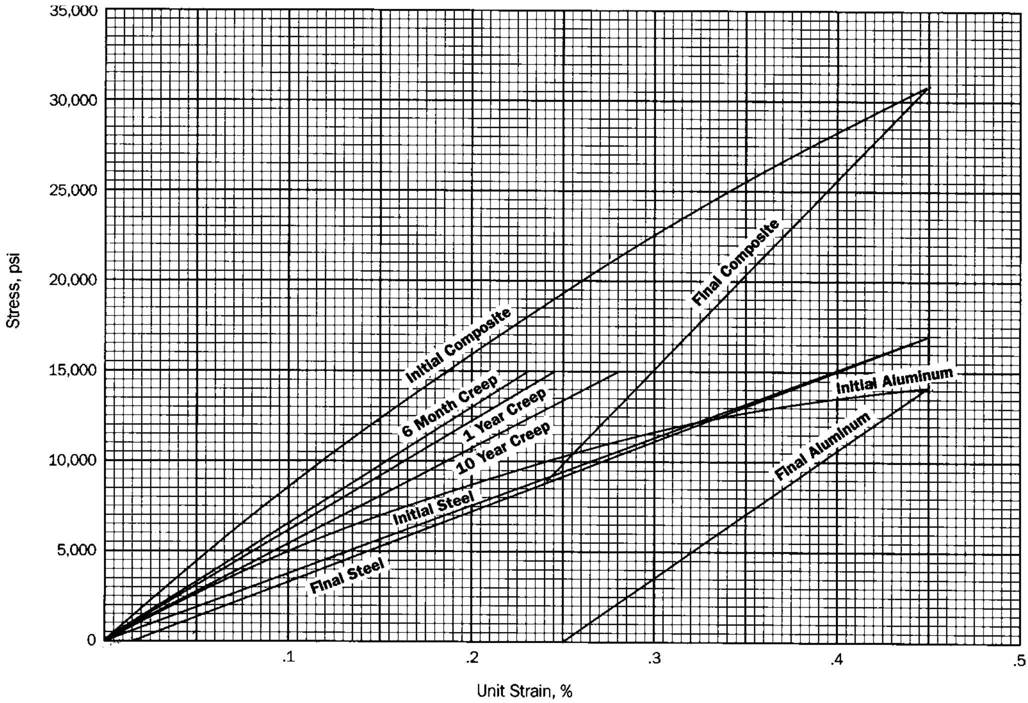
Figure 14-26 shows a typical stress-strain curve[64] for a 26/7 ACSR conductor; the curve is valid for conductor sizes ranging from 266.8 to 795 kcmil. A 795-kcmil 26/7 ACSR Drake conductor has a breaking strength of 31,500 lb (14,000 kg) and an area of 0.7264 in^2 (46.9 mm) so that it fails at an average stress of 43,000 lb/in^2 (30 kg/mm^2). The stress-strain curve illustrates that at a stress equal to 50% of the conductor's breaking strength (21,500 lb/in^2), the elongation is less than 0.3%. This translates to an elongation of 1.8 ft (0.55 m) in a 600-ft (180-m) span.

Note that the component curves for the steel core and the aluminum-stranded outer layers are separated. This separation allows for changes in the relative curve locations as the temperature of the conductor changes.

For the preceding example, with the Drake conductor at a tension of 6300 lb (2860 kg), the length of the conductor in the 600-ft (180-m) span was found to be 0.27 ft longer than the span. This tension corresponds to a stress of 8600 lb/in^2 (6.05 kg/mm^2). From the stress-strain curve in Fig. 14-26, this corresponds to an initial elongation of 0.105% (0.63 ft). As in the preceding hand calculation, if the conductor tension is zero, its unstressed length would be less than the span length.

Figure 14-27 is a stress-strain curve[64] for an all-aluminum 37-strand conductor ranging in size from 250 to 1033.5 kcmil. Because the conductor is made entirely of aluminum, there is only one initial curve and one final curve.

Permanent Conductor Elongation Due to High Tensions. Once a conductor has been installed to an initial tension, it can elongate further. Such elongation results from two phenomena: permanent elongation due to high-tension levels resulting from ice and wind loads and creep elongation under everyday tension levels. These types of conductor elongation are discussed in the following sections. Both Figs. 14-26 and 14-27 indicate that when the conductor is initially installed, it elongates nonlinearly. If the conductor tension increases to a relatively high level under ice and wind loading, the conductor will elongate. When the wind and ice loads abate, the conductor elongation will reduce along a curve parallel to the final curve, but will never return to its original length.



Equations for Curves (X = unit strain in %; Y = stress in psi):

Initial Composite: $X = 4.07 \times 10^{-3} + (1.28 \times 10^{-5})\,Y - (1.18 \times 10^{-10})\,Y^2 + (5.64 \times 10^{-15})\,Y^3$

$Y = -512 + (8.617 \times 10^4)\,X - (1.18 \times 10^4)\,X^2 - (5.76 \times 10^{-4})\,X^3$

Initial Steel: $Y = (37.15 \times 10^3)\,X$

Initial Aluminum: $Y = -512 = (4.902 \times 10^4)\,X - (1.18 \times 10^4)\,X^2 - (5.76 \times 10^4)\,X^3$

Final Composite: $Y = (107.55X - 17.65) \times 10^3$

Final Steel: $Y = (38.60X - 0.65) \times 10^3$

Final Aluminum: $Y = (68.95X - 17.00) \times 10^3$

6 Month Creep: $Y = (64.75 \times 10^3)\,X$

1 Year Creep: $Y = (60.60 \times 10^3)\,X$

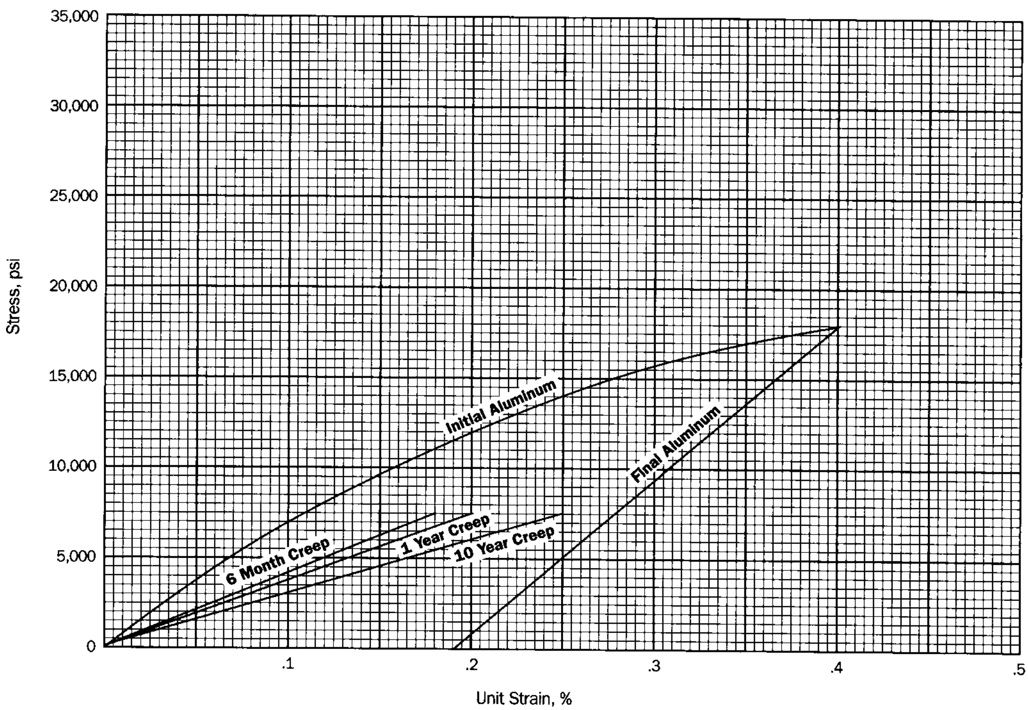
10 Year Creep: $Y = (53.45 \times 10^3)\,X$

Test Temperature 70°F to 75° F

FIGURE 14-26 Stress-strain curves for 26/7-strand ACSR.

For example, refer to Fig. 14-27 and assume that a newly strung 795-kcmil, 37-strand Arbutus AAC has an everyday tension of 2780 lb. The conductor area is 0.6245 in^2, so the everyday stress is 4450 lb/in^2 and the elongation is 0.062%. Following an extremely heavy ice and wind load event, assume that the conductor stress reaches 18000 lb/in^2. When the conductor tension decreases back to everyday levels, the conductor elongation will be permanently increased by more than 0.2%. Also the sag under everyday conditions will be correspondingly greater, and the tension will be less. In most numerical sag-tension methods, final sag-tension values are calculated for such permanent elongation due to heavy loading conditions.

Permanent Elongation at Everyday Tensions (Creep). Conductors permanently elongate under tension even if the tension level never exceeds everyday levels. This permanent elongation caused by everyday tension levels is called *creep*.[64] Creep can be determined by long-term laboratory creep tests.



Equations for Curves (X = unit strain in %; Y = stress in psi):

Initial Aluminum: $X = -5.31 \times 10^{-3} + (1.74 \times 10^{-5})\,Y - (6.17 \times 10^{-10})\,Y^2 + (5.05 \times 10^{-14})\,Y^3$

$Y = 136 + (7.46 \times 10^{4})\,X - (8.51 \times 10^{4})\,X^2 + (2.33 \times 10^{4})\,X^3$

Final Aluminum: $Y = (85.20\,X - 16.14) \times 10^{3}$

6 Month Creep: $Y = (42.30 \times 10^{3})\,X$

1 Year Creep: $Y = (38.20 \times 10^{3})\,X$

10 Year Creep: $Y = (30.60 \times 10^{3})\,X$

Test Temperature 70°F to 75° F

FIGURE 14-27 Stress-strain curves for 37-strand AAC.

The results of the tests are used to generate creep-versus-time curves. On the stress-strain graphs, creep curves are often shown for 6-month, 1-year, and 10-year periods. Figure 14-27 shows these typical creep curves for a 37-strand 250- to 1033.5-kcmil AAC. In Fig. 14-27, assume that the conductor tension remains constant at the initial stress of 4450 lb/in^2. At the intersection of this stress level and the initial elongation curve, 6-month, 1-year, and 10-year creep curves, the conductor elongation from the initial elongation of 0.062% increases to 0.11%, 0.12%, and 0.15%, respectively. Because of creep elongation, the resulting final sags are greater and the conductor tension is less than the initial values.

Creep elongation in aluminum conductors is quite predictable as a function of time and obeys a simple exponential relationship. Thus, the permanent elongation due to creep at everyday tension can be found for any period of time after initial installation. Creep elongation of copper and steel strands is much less and is normally ignored. Permanent increase in conductor length due to heavy load occurrences cannot be predicted at the time a line is built. The reason for this unpredictability is that the occurrence of heavy ice and wind loads is random. A heavy ice storm may occur the day after the line is built or may never occur over the life of the line.

Sag-Tension Tables. To illustrate the result of typical sag-tension calculations, Tables 14-18 to 14-21 present initial and final sag-tension data for 795-kcmil 26/7 ACSR Drake, 795-kcmil, 37-strand AAC

Arbutus, and 795-kcmil Type 16 SDC Drake conductors in NESC light and heavy loading areas for spans of 1000 and 300 ft. Typical tension constraints of 15% final unloaded at 60°F, 25% initial unloaded at 60°F, and 60% initial at maximum loading are used. The calculations in these tables were performed with the Alcoa SAG10™ program, version 1.1.

Initial versus Final Sags and Tensions. Rather than calculated as a function of time, most sag-tension calculations are based on initial and final loading conditions. Initial sags and tensions are simply the sags and tensions at the time the line is built. Final sags and tensions are calculated assuming that (1) the specified ice and wind loading has occurred and (2) the conductor has experienced 10 years of creep elongation at a conductor temperature of 60°F at the user-specified initial tension.

With most sag-tension calculation methods, final sags are calculated for both heavy ice/wind loads and for creep elongation. The final sag-tension values reported to the user are those with the greatest increase in sag.

ACSR Sag-Tension Calculations. Sag-tension calculations for ACSR conductors are more complex than those for AAC, AAAC, or ACAR conductors. The complexity results from the different behavior of steel and aluminum strands in response to tension and temperature. Steel wires exhibit neither creep elongation nor plastic elongation in response to high tensions. Aluminum wires do creep and respond plastically to high stress levels. Also, they elongate twice as much as steel wires do in response to changes in temperature. Table 14-18 presents various initial and final sag-tension values for a 600-ft span of an ACSR Drake conductor under heavy loading conditions. Note that the tensions in the aluminum and steel components are given separately. In particular, some other useful observations are

1. At 60°F, without ice or wind, the tension level in the aluminum strands decreases with time as the strands permanently elongate as a result of creep or heavy loading.
2. Both initially and finally, the tension level in the aluminum strands decreases with increasing temperature (212°F), reaching zero tension at 167°F for initial and final conditions, respectively.
3. At the highest temperature (212°F), where all the tension is in the steel core, the initial and final sag and tension values are nearly the same, illustrating the fact that the steel core does not permanently elongate in response to time or high tension.

† Design condition.

Sag change of ACSR at high temperature

When first installed, the aluminum and steel wire components of ACSR are both under tension and elongate equally. Ignoring for the moment any initial creep of the aluminum strands, the tension division between aluminum and steel in Drake ACSR when initially installed at 20% RBS (6300 lb) at 60°F may be calculated.

If the elastic modulus of the steel core is taken as 27 Mpsi and the steel core area is 0.1017 in^2, then the "spring constant" of the steel core is 2.75 Mlb. If the elastic modulus of the aluminum layers is taken as 8.6 Mpsi and the aluminum strand area is 0.6247 in^2, then the spring constant of the aluminum layers is 5.37 Mpsi. Given the two "springs" in parallel, the tension division can be calculated as follows:

$$H_A = \frac{6300}{\left(1 + \dfrac{2.75}{5.37}\right)} = 4165 \text{ lb}$$

And the tension in the steel core is 2135 lb.

If the temperature of this conductor is increased from 60 to 212°F, the unstressed length of the steel core would increase to 600.38 ft = 599.80 [1 + 6.4e − 6(212 − 60)] and the aluminum strand layers would increase to 600.97 ft = 599.80[1 + 12.8e − 6(212 − 60)]. Clearly the unstressed lengths of the steel core and aluminum layers are now different. Reapplying tension to the composite condutor, the steel core must be preloaded to 2598 lb = (0.59ft/600.38)(26e6 × 0.1017 in^2) before the tension in the aluminum layers beings to increase. The net result of this behavior is that, at high temperature, the conductor tension in the aluminum strands can become zero. This temperature is commonly called the ACSR conductor "kneepoint" temperature. Beyond this "kneepoint" temperature, the thermal elongation of the ACSR conductor is reduced to a level near to that of the steel core alone, though low levels of compression in the aluminum layers must be considered.

Mechanical Interaction of Suspension Spans

Transmission lines are normally designed in line sections with each end of the section terminated by a strain structure that allows no longitudinal movement of the conductor.[60] Structures within each line section are typically suspension structures that support the conductor vertically but allow free movement of the conductor attachment point either longitudinally or transversely.

Tension Differences for Adjacent Dead-End Spans. Table 14-19 contains initial and final sag and tension data for a 700-ft (213-m) and a 1000-ft (305-m) dead-end span with an ACSR Drake conductor that was initially installed with the same 6300-lb tension limits at 60°F. Note that the differences between final tensions at 60°F is 260 lb, which is due entirely to the difference in span length. Even the initial tension (equal at 60°F) differs by approximately 880 lb at –20°F and 610 lb at 167°F.

Tension Equalization by Suspension Insulators. At a typical suspension structure, the conductor is supported vertically by a suspension insulator assembly, but allowed to move freely in the direction of the conductor axis. This conductor movement is possible because of insulator swing along the conductor axis. Changes in conductor tension between spans, caused by changes in temperature, load, and time are normally equalized by insulator swing, eliminating horizontal tension differences across suspension structures.

Ruling-Span Approximation. The sag and tension for a series of suspension spans in a line section can be found using the ruling-span concept.[59,60] The ruling-span (RS) for the line section is defined by the following equation:

$$\text{RS} = \sqrt{\frac{S_1^3 + S_2^3 + \cdots + S_n^3}{S_1 + S_2 + \cdots + S_n}}$$

*Design condition.

where RS = ruling span for the line section containing n suspension spans
S_1 = span length of first suspension span
S_2 = span length of second suspension span
S_n = span length of nth suspension span

Alternatively, a generally satisfactory method for estimating the ruling span is to take the sum of the average suspension span length plus two-thirds of the difference between the maximum span and the average span. However, some judgment must be exercised in using this method because a large difference between the average and maximum span may cause a substantial error in the ruling span value.

As discussed earlier, suspension spans are supported by suspension insulators that are free to move in the direction of the conductor axis. This freedom of movement allows the tension in each suspension span to be equal to that calculated for the ruling span. This assumption is valid for the suspension spans and ruling span under the same conditions of temperature and load, for both initial and final sags. For level spans, sag in each suspension span is given by the parabolic sag equation

$$D_i = \frac{w(S_i^2)}{8H_{\mathrm{RS}}} \tag{14-77}$$

where D_i = sag in the ith span
S_i = span length of the ith span
H_{RS} = horizontal tension from ruling span sag-tension calculations

Suspension spans vary in length, although typically not over a large range. Conductor temperature during sagging varies over a range considerably smaller than that used for line design purposes.

If the sag in any suspension span exceeds approximately 5% of the span length, a correction factor should be added to the sag obtained from Eq. (14-77), or the sag should be calculated using the catenary method presented in Eq. (14-79). This correction factor may be calculated as follows:

$$\text{Correction} = D^2\left(\frac{w}{8H}\right) \tag{14-78}$$

where D = sag obtained from parabolic equation
w = weight of conductor, lb/ft
H = horizontal tension, lb

The catenary equation for calculating the sag in a suspension or stringing span is

$$\text{Sag} = \frac{H}{w}\left[\cosh\frac{Sw}{2H} - 1\right] \tag{14-79}$$

where S = span length, ft
H = horizontal tension, lb
w = resultant weight, lb/ft

Stringing Sag Tables. Conductors are typically installed in line section lengths consisting of multiple spans. The conductor is pulled from the conductor reel at a point near one strain structure, progressing through travelers attached to each suspension structure to a point near the next strain structure. After stringing, the conductor tension is increased until the sag in one or more suspension spans reaches the appropriate stringing sags according to the ruling span for the line section. The calculation of stringing sags is based on the preceding sag equation.

Table 14-21 shows a typical stringing sag table for a 600-ft ruling span of ACSR Drake with suspension spans ranging from 400 to 700 ft and conductor temperatures of 20 to 100°F. All the values in this stringing table have been calculated using the parabolic sag equation with ruling-span initial tensions shown in Table 14-20.

Line Design Sag-Tension Parameters. In laying out a transmission line, the first step is to survey the route and create a plan-profile of the selected right-of-way. The plan-profile drawings serve an important function in linking together the various stages involved in the design and construction of the line. These drawings, based on the route survey, show the location and elevation of all natural

and artificial obstacles to be traversed by, or adjacent to, the proposed line. These plan-profiles are drawn to scale and provide the basis for tower spotting and line design work.

Once the plan-profile is completed, one or more estimated ruling spans for the line may be selected. On the basis of these estimated ruling spans and the maximum design tensions, sag-tension data may be calculated providing initial and final sag values. From these data, sag templates may be constructed to the same scale as the plan-profile for each ruling span, and used to graphically spot structures.

Catenary Constants. The sag in a ruling span is equal to the weight per unit length w times the span length S squared, divided by 8 times the horizontal component of the conductor tension H. The ratio of conductor horizontal tension H to weight per unit length w is the catenary constant H/w. For a ruling-span sag-tension calculation using eight loading conditions, a total of 16 catenary values could be defined, one for initial and one for final tensions under each loading condition.

Catenary constants can be defined for each loading condition of interest and are used in locating structures. Some typical uses of catenary constants are to avoid overloading, ensure that ground clearance is sufficient at all points along the right-of-way, and minimize blowout or uplift under cold-weather conditions. To do this, the following catenary constants are typically found: (1) the maximum line temperature; (2) heavy ice and wind loading; (3) wind blowout; and (4) minimum conductor temperature. Under any of these loading conditions, the catenary constant allows sag calculation at any point within the span.

Wind and Weight Span. The maximum wind span of any structure is equal to the distance measured from center to center of the two adjacent spans supported by the structure. The wind span is used to determine the maximum horizontal force a structure must withstand under high-wind conditions. The wind span is not dependent on conductor sag or tension, only on the horizontal span length.

The weight span of a structure is a measure of the maximum vertical force a structure must withstand. The weight span is equal to conductor weight per unit length times the horizontal distance between the low points of sag of the two adjacent spans. The maximum weight span for a structure is dependent on the design ice and wind loading condition. When the elevations of adjacent structures are the same, the wind and weight spans are equal.

Uplift at Suspension Structures. Conductor uplift, shown in Fig. 14-28, occurs when the weight span of a structure is negative. On steeply inclined spans, the low point of sag may fall beyond the lower support. This indicates that the conductor in the uphill span is exerting a negative, or upward, force on the lower tower. The amount of this upward force is equal to the weight of the conductor from the lower tower to the low point in the sag. If the upward pull of the uphill span is greater than the downward load of the next adjacent span, actual uplift will occur and the conductor will swing free of the tower. This usually occurs under minimum temperature conditions and must be dealt with by adding weights to the insulator suspension string or using a strain structure.

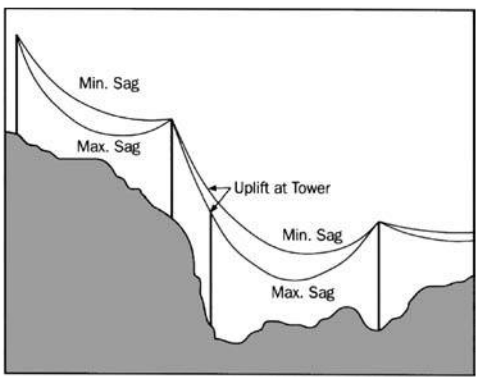

FIGURE 14-28 Illustration of conductor uplift.

Tower Spotting. Given sufficiently detailed plan-profile drawings, structure heights, wind/weight spans, catenary constants, and minimum ground clearances, structure locations can be chosen such that ground clearance is maintained and structure loads are acceptable. Tower spotting can be performed using a sag template, plan-profile drawing, and structure heights, or numerically, by using one of several commercial computer programs. Tower spotting and optimization of line design parameters are discussed in Sec. 14.1.7.

Unbalanced Ice Loads.[65,66] The jump of the conductor resulting from ice dropping off one span of an ice-covered line has been the cause of many serious outages on long-span lines where conductors are arranged in the same vertical plane. The vertical spacing required to prevent "ice-jump" trouble may be estimated by static calculations of the differential sag of two vertically adjacent conductors assuming one conductor has ice and the other has no ice. Normally, sufficient clearance is provided to accommodate this sag difference, including a factor for sag error with a margin for switching surge withstand.

Utility practice, based on historically satisfactory field performance, is typically based on the following criteria for vertical phase-to-phase clearance due to ice:

A maximum sag error of 6 in is assumed.

The upper conductor is assumed to be subject to maximum ice load, typically 1 in for short ruling spans, 0.5 in for unusually long spans.

The lower conductor is assumed to be completely free of ice.

Clearance sufficient to withstand the maximum switching surge is to be provided.

The calculation is performed using normal sag-tension procedures. For certain line designs (e.g., compact lines with post insulators), dynamic techniques are possible.[44,50] However, the trouble has been practically cleared up by horizontally offsetting the conductors from 18 in to 3 ft on medium-voltage lines. The conductor jumps in practically a vertical plane, and this should be true if no wind is blowing, since then all forces and reactions are in a vertical direction.

Wind-Induced Motion of Overhead Conductors. In addition to ordinary "blowout" of overhead conductors (i.e., the swinging motion of the conductor due to the normal component of wind), there are three types of cyclic wind-induced motion that can be a source of damage to structures or conductors or that can result in sufficient reduction in electrical clearance to cause flashover. The categories of wind-induced cyclic motion are eolian vibration, galloping, and wake-induced oscillation.

Eolian vibration can occur when conductors are exposed to a steady low-velocity wind. If the amplitude of such vibration is sufficient, it can result in strand fatigue and/or fatigue of conductor accessories. The amplitude of vibration can be reduced by reducing the conductor tension, adding damping by using dampers (or clamps with damping characteristics), or by the use of special conductors which either provide more damping than standard conductors or are shaped so as to prevent resonance between the tensioned conductor span and the wind-induced vibration force.

Galloping is normally confined to conductors with a coating of glaze ice over at least part of their circumference and thus is not a problem in those areas where ice storms do not occur. It may be controlled by the use of various accessories attached to the conductor in the span to change mechanical and/or damping characteristics. Specially shaped conductors or conductor accessories which alter the iced conductor's aerodynamic characteristics, particularly those that increase aerodynamic damping, are also effective. The amplitude of galloping motions can be reduced by the use of higher conductor tensions and evidence suggests higher tensions can also reduce the possibility of occurrence. Galloping and eolian vibration occur in both single and bundled conductors.

Wake-induced oscillation is limited to lines having bundled conductors and results from aerodynamic forces on the downstream conductor of the bundle as it moves in and out of the wake of the upstream conductor. Wake-induced oscillation is controlled by maintaining sufficiently large conductor spacing in the bundle, unequal subspan lengths, and tilting the bundles.

Eolian Vibration. As wind blows across a conductor, vortices are shed from the top and bottom of the conductor. The vortex shedding is accompanied by a varying pressure on the top and bottom of the conductor that encourages cyclic vibration of the conductor perpendicular to the direction of wind flow. The frequency at which this alternating pressure occurs is given by the expression

$$f = 3.26 \times \frac{U}{d} \tag{14-80}$$

where U = wind speed, mi/h
d = conductor diameter, in
f = frequency, Hz

For a 1.0-in-diameter conductor exposed to a 10-mi/h wind, the vortex shedding force oscillates at 32.6 Hz. To develop significant amplitudes, there must be a resonance between this oscillating wind force and the vibrating catenary (conductor). The fundamental frequency of vibration of the suspended conductor is in the range of 0.1 to 1.0 Hz. Therefore, the eolian vibration force will be unlikely to excite a fundamental span mode. This is verified by actual conductor performance where significant amplitudes are usually observed for frequencies in the range of 10 to 100 Hz. Practical wind speeds cause vortex shedding forces of greater than 10 Hz, eliminating frequencies below this level, and frequencies above 100 Hz are not present because of the rapid increase in conductor self-damping for these higher frequencies.

The maximum alternating stress resulting in strand fatigue normally occurs at the conductor clamp. The stress is related to the amplitude of conductor vibration and is the amplitude normally measured by field recording devices. Stress and amplitude of vibration can be related by analytical means such as the Poffenberger-Swart formula.[67] The amplitude of eolian vibration is fixed by the balance of energy input from the wind-induced vortex shedding forces and the energy loss due to conductor, accessory, and structure damping. The addition of dampers to the conductor has been established as an effective means of control.[68] Special conductors such as SDC and SSAC[69] have also been shown effective in reducing the strand stress levels.

Another effective means of limiting vibration fatigue problems is to increase the self-damping of standard conductors by reducing tension. As a practical approximation, stringing conductors to a final unloaded tension of 15% or less at the minimum seasonal average temperature (usually 0 to 30°F) will prevent vibration fatigue problems. Higher tensions are routinely used in areas where the line is parallel to existing lines and the higher tension on the existing line has not resulted in problems. The use of vibration dampers or special antivibration conductors can also allow the use of higher tension levels.

As with single conductors, bundled conductors are subjected to eolian vibration. However, the interaction of conductors in the bundle due to slightly different tensions and increased damping from spacers results in lower vibration levels for bundles than for single conductors in the same wind exposure.

Galloping. Both bundled and single conductors are subject to galloping during or after glaze ice storms. Galloping oscillations occur at frequencies near the fundamental span mode or its second or third harmonic (0.1 to 1.0 Hz) and exhibit maximum amplitudes as large as the conductor sag. While there has been extensive debate concerning the galloping mechanism, and considerable experimental and analytical study, it appears that there presently exist a number of control methods that are effective in reducing the amplitude and incidence of galloping motion. In-span hardware, such as the "detuning pendulum" developed by EPRI,[70] and the wind damper" developed by Richardson,[71] are effective for existing spans where galloping occurs. The T2 conductor,[72] developed by Kaiser, and several other hardware devices are available to control galloping in new lines.

In contrast, control methods such as sleet melting by use of high current levels appear to be almost totally ineffective in stopping galloping and can result in annealing damage to the conductor.

Wake-Induced Oscillation. Bundled conductors are subject to wake-induced oscillations with amplitudes and frequencies typically between that of eolian vibration and galloping. The frequencies of oscillation are normally in the range of 1 to 10 Hz, and the amplitudes are in the range of 10 conductor diameters. The modes in which such vibration occurs are considerably more complex than the modes exhibited during either galloping or the almost invisible eolian vibrations. The source of wind energy for wake-induced oscillation is, as the name suggests, the wake from the windward conductor of the bundle which causes the motion of the downwind conductor.

There are three basic approaches to the control of wake-induced oscillation.[73] Two involve reducing the input of wind energy, and the third involves detuning the mechanical bundle system to prevent resonance. The methods based on reducing wind energy input to the bundle are bundle tilting and bundle sizing. By tilting the bundle to angles of 20° or more, the downwind conductors are moved to the edge of the upwind conductor's wake and the energy input is reduced. By keeping the subconductor spacing to the order of 20 times the conductor diameter, the wind energy input to the windward conductor is reduced by being moved to a wake region of reduced intensity. The third commonly used method to control or eliminate wake-induced oscillations is to stagger the length or simply to shorten the average subspan length. This method does not control those oscillations where the bundle moves as a rigid body and is somewhat dependent on the mechanical characteristics of the spacers.

In comparison to the damage that can result from eolian vibration or galloping, field reports of wake-induced oscillation damage are usually of a minor nature, primarily conductor abrasion from clashing and spacer breakage, neither of which normally results in system outages.

14.1.9 Supporting Structures

Types of Supporting Structure. Numerous types of structure are used for supporting transmission-line conductors, for example, self-supporting steel towers, guyed steel towers, self-supporting aluminum towers, guyed aluminum towers, self-supporting steel poles, flexible and semiflexible steel towers and poles, rope suspension, wood poles, wood H frames, and concrete poles. The type of supporting structure to use depends on such factors as the location of the line, importance of the line, desired life of the line, money available for initial investment, cost of maintenance, and availability of material. Because of the wide conductor spacing required for electrical clearances and insulation, the high tensile stresses used in conductors and ground cables to pull these cables up to a sag which will keep the heights of the structures within reason, the long spans necessary for crossing ravines in mountainous country, and the reliance to be placed on a major trunk line, lines exceeding 345 kV are frequently built of self-supporting steel towers although guyed and rope-suspension structures are increasingly applied. A line built with self-supporting steel towers is very satisfactory in all respects, as it requires less inspection and has a maximum life with minimum maintenance costs. However, high-strength aluminum-alloy towers are available, and their use is on the increase. They have the advantage of better resistance to corrosive atmospheres than steel.[74] The structural configurations and design details are the same as with steel, with the added problem of greater deflections when stresses are applied owing to the lower modulus of elasticity of aluminum. The effect of long-time creep of aluminum is yet to be determined. Self-supporting steel poles are frequently used in congested districts where right-of-way is limited and short spans are necessary. The advent of EHV has brought a great variety of new structural configurations. Details of some of these have been published. *Electrical World,* Nov.15, 1965, pp. 95–118, contains outline drawings of 35 towers and six wood-pole H-frame structures as applied to EHV, as well as a tabulation of specification items of EHV lines in the United States and Canada. The *Transmission Line Reference Book, 345 kV and Above,* 2d ed., 1982, published by EPRI,[3] contains details of a broad spectrum of 345- through 800-kV structures.

Wood poles are used extensively where they are readily available. Medium- and lower-voltage lines can be built economically with such poles fitted with either steel or wood crossarms. *Wood* H *frames* composed of two poles tied together at the top with wood or steel crossarms have been successfully used for the higher-voltage lines up to 345 kV. To take full advantage of the transverse strength, such poles can be braced internally for at least a portion of their height with wood X bracing.

Concrete poles have been used in some parts of the world where timber is scarce and where the ingredients for making concrete are readily obtainable. Another advantage is that they are impervious to insect damage and other forms of decay prevalent with wood structures in tropical or subtropical climates. They are generally cast in units, by using standard forms, and transported to the site, although they may be manufactured where used. Concrete poles should always have sufficient prestressed steel reinforcement to take care of the bending stresses due to wind loads, pulls from cables, and the like, in addition to being designed as columns under vertical loads. In all structures conductor configuration and the effect of various forces which may act upon them must be taken into account.

Conductor Spacing and Clearances

Horizontal Configuration. The minimum spacing of conductors on structures where post-type or V-string insulators are used on medium-length spans will generally depend on the least separation that can be used at midspan without the conductors approaching too closely under adverse wind- or ice-loading conditions.

With suspension insulators a different problem exists, as the swing of the insulator string has to be considered and clearances to the structure determined. This will generally give conductors a spacing at the supports which will be greater than the required midspan separation. One typical rule is to calculate the swing of the insulator string, both with the wind on the bare conductor and the wind on the ice-coated conductor with the corresponding vertical loads acting at the point of conductor suspension, to determine which condition gives the maximum deflection. The vertical loads should be taken on a length of span which is two-thirds the span for the horizontal loads. This will allow a certain amount of leeway in using a standard height structure at a location where the ground is lower than at the two adjacent structures. After the length of the insulator string has been determined electrically and the angle of insulator swing calculated, a normal electrical clearance is established to the structure from the deflected position of the conductor, which, when applied to the three conductors in their relative positions, will determine the necessary horizontal separation of the phases at the supports. This separation should then be checked to see whether it is sufficient for the midspan separation required. Midspan separations that will not be subject to flashover if the conductors begin to swing out of step are usually inherent on high-voltage lines owing to the clearances required at the structures. On very long spans and on the longer spans of low-voltage lines, these spacings may be insufficient. Thomas[75] proposed a horizontal-spacing formula for the determination of safe midspan spacings in windy territory where gusts and strong eddies might cause wires to start swinging at different periods

$$\delta = \frac{CdD}{w} + A + \frac{L}{2} \tag{14-81}$$

in which δ = horizontal spacing in feet; C = an experience factor discussed later; d = percent sag of the condition to be studied; D = overall diameter of the conductor; w = conductor weight, in pounds per foot, used in calculating d; A = arcing distance of the line voltage (1 ft/110 kV); and L = length, in feet, of the swinging portion of the insulator string. Thomas proposed an experience factor of 4 for copper and 3.5 for ACSR.[75] It has since been found that, in areas not subject to frequent violent winds, values of C as low as 1 will provide safe midspan spacings. Thomas was doubtful whether as to the added $L/2$ distance is necessary, since insulators seldom swing out of step. This doubt seems to have been justified.

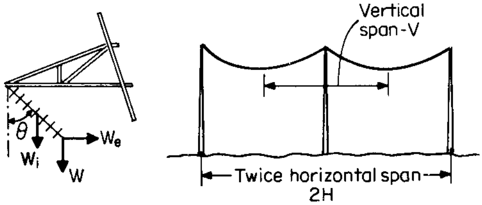

FIGURE 14-29 Determination of suspension insulator swing.

Vertical Configuration. Where the conductors are arranged in vertical configuration, the same electrical clearances will apply for the same voltage as for horizontal configuration, but it may be necessary to increase the vertical separation somewhat to prevent the conductors from coming together or approaching too closely at the center of the span when unequal ice-loading conditions occur or the ice falls off a lower conductor first.

In Fig. 14-29, θ = angle of insulator swing from vertical, H = horizontal span, V = vertical span, w = weight of conductor with or without ice load per lineal foot, and w_i = weight of insulator string including hardware. Then

$$\tan\theta = \frac{Hw_e}{Vw + w_i/2} \tag{14-82}$$

Ground wires, if used, are located above the conductors for lightning protection and in such a position that there is no danger of contact with the conductors at midspan. As ground wires are generally strung with less sag than the conductor cables, ample clearance at midspan is readily obtainable.

These considerations, taken together with the maximum vertical sag to be used and the height required for the conductors above ground level, will determine the height and width of the supporting structure. Extensions can be used where the terrain requires a higher structure than normal.

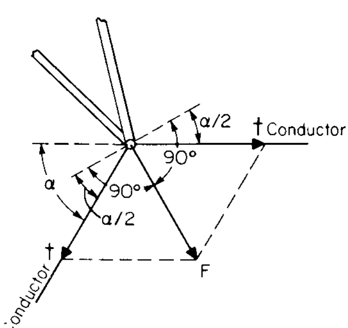

FIGURE 14-30 Determination of transverse forces.

Transverse Forces on Support Structures. Transverse forces acting on towers or poles are due to wind on the conductors and ground cables (and ice coating if in ice districts), wind on the structures, and horizontal components of the tensions in the cables at angle turns in the line (Fig. 14-30).

The stress due to an angle in the line is computed by finding the resultant force produced by the wires in the two adjacent spans. For example, in Fig.14-30, if the change in the direction of the line is the angle a and the stresses t in the adjacent spans are equal to each other, the resultant force

$$F = 2t \sin\frac{a}{2} \tag{14-83}$$

TABLE 14-22 Resultant Force Due to Equal Tensions of 1000 lb in Adjacent Spans

Angle			Angle		
a deg	*a*/2 deg	Resultant *F*, lb	*a* deg	*a*/2 deg	Resultant *F*, lb
10	5	174.4	70	35	1147.2
20	10	347.2	80	40	1285.6
30	15	517.6	90	45	1414.2
40	20	684.0	100	50	1532.0
50	25	845.2	110	55	1638.4
60	30	1000.0	120	60	1732.0

Note: 1 lb = 4.448 N

Table 14-22 gives the resultant force *F* due to a tension *t* of 1000 lb in each conductor of two adjacent spans. The resultant force due to each conductor may be thus computed and the moments about the ground line determined. These moments may be added to those produced by the wind pressure to find the maximum stress.

In applying wind loads to the structure, the appropriate force coefficients, exposure coefficients, and gust response factors should be used.

Longitudinal Forces on Support Structures. Longitudinal forces acting on towers or poles are due mainly to the maximum tension which is assumed to exist in the conductor and ground wires if broken. Ordinarily, especially with suspension insulator strings, these tensions are balanced in the adjacent spans; but if a conductor breaks, a distinct force is produced along the line due to unbalanced tension. If the break occurs on a conductor at the end of a crossarm, there is, in addition to the longitudinal force, a torsional force introduced which must be resisted by the structure. Wind acting in the direction of the line is not ordinarily a factor, as the maximum tension in the conductor is produced when the wind is blowing transverse to the line. As to the reduced stress which occurs in a span from the breaking of a conductor with the suspension insulator string deflecting in the direction of the line, the best practice is to ignore this reduction in tension, as the force due to breaking may cause an impact which more than offsets the reduction in tension. Special release clamps were devised for use on the Plymouth Meeting–Siegfried line of the Philadelphia Electric Company so that, if an insulator string deflected to an angle of 20° in the direction of the line, the clamping mechanism would release the pressure with only the friction in the saddle holding the conductor. This reduced the tension in the conductor considerably; and by assuming a low value for the tension in the conductor due to a break, a more economical structure was obtained.

Vertical Forces on Support Structures. Vertical forces acting on towers or poles are those caused by the weight of that portion of the conductors, plus ice loading if any, which is supported by the structure in question. In addition, there are the weights due to insulators and accessories and the weight of the structure itself. If a structure is located in a valley, there may actually be uplift on it, if the vertical components of the tensions in the conductors exceed the downward loads.

Combined Forces on Support Structures. In determining the maximum forces acting on towers or poles, it is necessary to combine the transverse forces, longitudinal forces (including torsion), and vertical forces so that they act simultaneously. Several different combinations of loading conditions may be desirable, as follows:

1. A condition with all conductors intact and the full transverse and vertical forces acting. These forces should correspond to the appropriate extreme wind and ice loadings and the NESC district loadings. The NESC also specifies overload capacity factors which must be applied to the transverse, vertical, and longitudinal loadings to provide adequate strength of the support structures. These factors depend on the grade of construction and on the type of structure. ASCE Manual 74[57] specifies load factors that can be applied to the extreme wind and ice loading cases to increase the reliability for important or long transmission lines.

2. A condition with all conductors intact, except the number it is desired to assume broken, with the transverse and vertical forces computed for each particular conductor, according to whether it is assumed broken. The longitudinal forces due to broken conductors must be combined with the transverse and vertical forces at all points of support where the conductors are assumed broken. It is customary, when more than one conductor is assumed broken, to consider all breaks in the same span and at the supports which will produce the maximum overturning moment, the maximum torque, or a combination of both.

3. A condition in some localities where extraheavy vertical loads, caused by an unusually large formation of ice on the conductors, may occur. These loads are combined with the weight of the structure.

4. A condition with vertical loads acting upward at the conductor supports.

NOTE: It is not customary to combine transverse and longitudinal loads with the loads specified under items 3 and 4.

Other factors may enter into the determination of the maximum forces acting on supporting structures in special cases, such as the horizontal and vertical components of tensions in guys and the addition of pole-top transformers, switches, and working platforms.[76]

The proper number of conductors to assume broken is a debatable question and depends upon what margin of safety is desired and the amount of money it is desired to invest for this security. Generally speaking, the minimum number of conductors to assume broken for tangent suspension single-circuit towers should be either one ground wire or any one conductor, and for double-circuit towers either one ground wire and one conductor or any two conductors on the same side of the tower and in the same span, by using the different cable supports for application of the forces to determine the maximum stress in each member of the tower. Anchor or dead-end towers should be able to withstand all or any number of conductors and ground wires broken. Generally, the condition of broken conductors and ground wires on one side of the tower will produce greater stresses in the web members than if all the conductors and ground wires are considered broken, owing to the unbalanced torsional forces existing when only the conductors and ground wires on one side of the tower are broken.

Types of Metal Structure. Structures may support single, double, or multiple circuits. The first two types are generally used for transmission lines except in congested areas where right-of-way is very expensive and it is desired to transmit large blocks of power over one line. In such a case three or more circuits may be supported by the structures.

Self-Supporting or Rigid Structures. On both single- and double-circuit tower lines of any considerable length, at least three kinds of towers are required for economic reasons:

1. A tangent suspension tower which can be used for normal spans where no angles in the line occur (Figs. 14-31 and 14-32).

2. An angle suspension tower which can be used for normal spans with a small-angle turn in the line or with longer spans on tangents.

3. An angle tower which can be used for normal spans with a large-angle turn in the line, with extra-long spans on tangent, or as a full dead-end tower for anchoring. Insulators may be either suspended or in the strain position.

Very often it is desirable to introduce a fourth kind of tower with insulators always in the strain position to take care of exceptionally large-angle turns in the line; in extremely long spans on tangent; and also, where required, as a full dead-end tower. When this type of tower is provided, the tower listed in item 3 may be of lighter construction and not used for dead-end purposes.

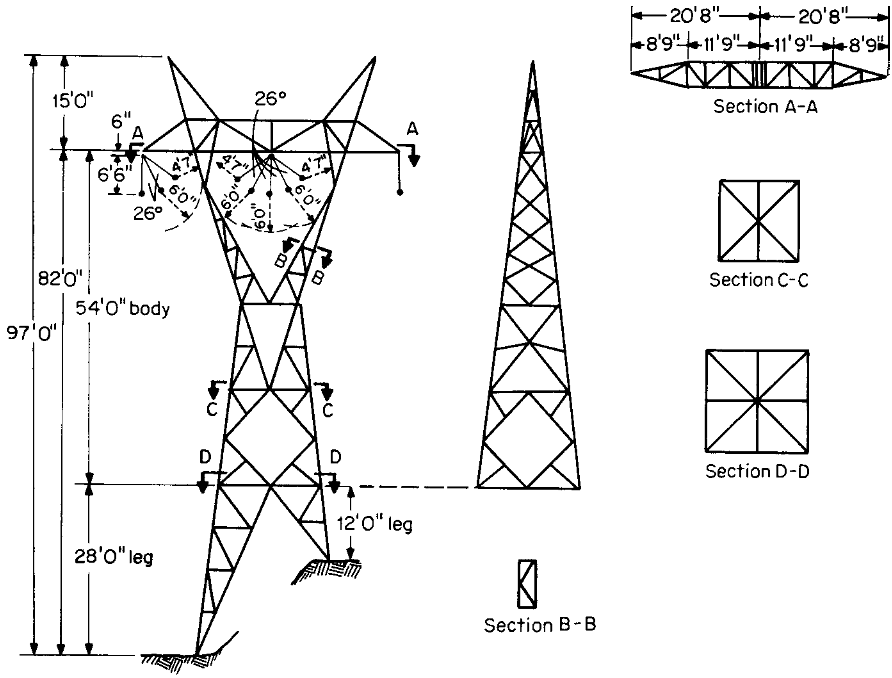

FIGURE 14-31 Tennessee Valley Authority 161-kV single-circuit tangent suspension corset-type tower. (*Designed by Blaw-Knox Co.*)

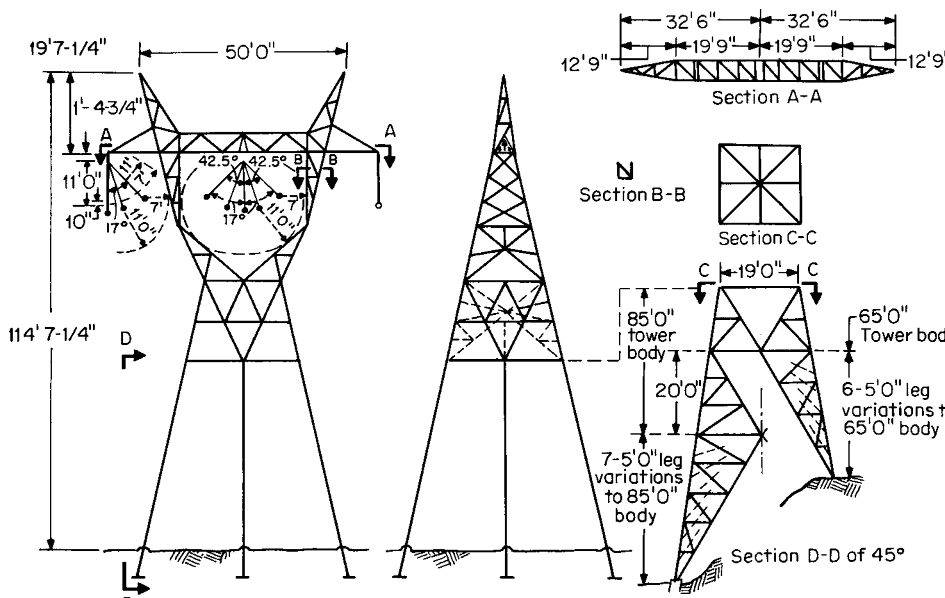

FIGURE 14-32 City of Los Angeles 287-kV tangent suspension rotated-type tower. (*Designed by American Bridge Co.*)

Double-circuit towers with the vertical configuration of conductors, as used on different lines, are very much alike in appearance, generally being square in cross section. It is customary to locate the middle conductors outside the upper and lower conductors.

With single-circuit towers and the conductors arranged in horizontal configuration, a different problem arises which has resulted in the design of special patented structures for the higher-voltage lines with wide conductor spacing. The shape of these towers has been developed with a view to minimizing the weight of steel required in the superstructure and also reducing the size of footings by minimizing the effect of torsion. The more common types are the Blaw-Knox tower (Fig. 14-31), or corseted type, as originally used on the Plymouth Meeting–Conowingo line of the Philadelphia Electric Company; and the American Bridge Company's rotated tower (Fig. 14-32), used on the first Hoover Dam–Los Angeles line (this line has since been uprated to 500 kV) and also by the Bonneville system and on lines of the Tennessee Valley Authority. Either of these types serves the purpose for which it was intended. The theory behind the rotated tower is that the greatest overturning moment is caused by a combination of the transverse forces and longitudinal forces, due to broken conductors, acting simultaneously, which produces a resultant force acting at an angle of approximately 45° with the direction of the line. In this case the whole four tower legs are resisting the overturning moment, thereby reducing foundation loads and consequently costs. Under normal conditions of loading, with only the transverse forces acting, the legs on the diagonal separation will take care of the overturning moment. Obviously the greatest advantage of the rotated type over the nonrotated type is on tangent towers and towers used for small-angle turns in the line when the transverse and longitudinal forces are approximately equal.

Figure 14-33*a* shows a TVA 500-kV conventional-design tangent self-supporting tower for a bundle-conductor line having three 971,600-cmil ACSR conductors per phase. The overhead ground-wire clamps are suspended and insulated from the tower by means of distribution-type guy strain insulators. The overhead ground wires are composed of seven strands of No. 9 Alumoweld and are used for carrier-current communication channels.[77] Each ground-wire insulator is provided with a spill-over gap to protect it during lightning discharges.

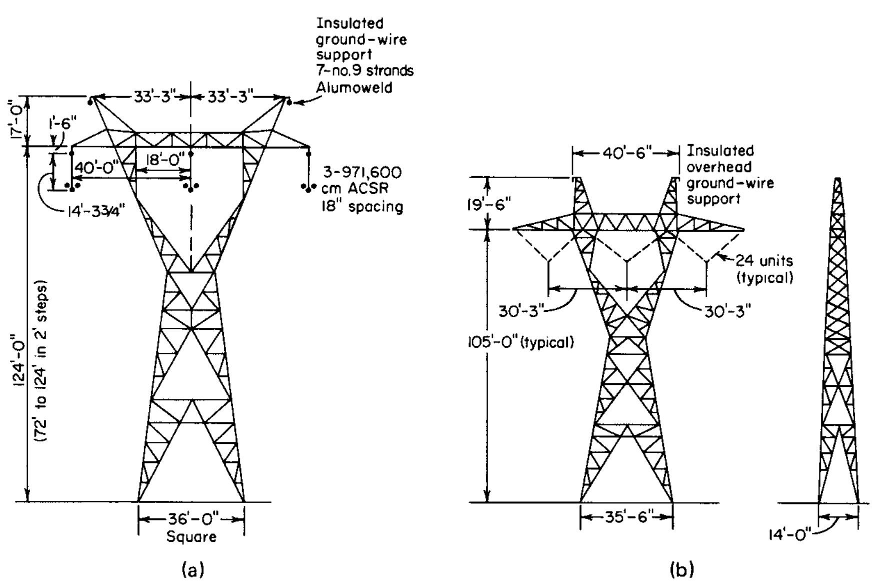

FIGURE 14-33 (*a*) A 500-kV tangent self-supporting tower (Tennessee Valley Authority); (*b*) 500 kV semiflexible steel tangent tower (Arkansas Power & Light Co.).

It is interesting to compare Fig. 14-33*a* and *b*. Both show 500-kV towers, but Fig. 14-33*b* is designed for a narrower right-of-way. The wind side swing of the conductors in a span is half the sag at 30° side swing, and this is common to both towers. Therefore, the saving in right-of-way for Fig. 14-33*b* is 40 ft plus 7 ft, 7 in, less 30 ft, 3 in, or 17 ft, 4 in on each side, or a total of approximately 35 ft.

Figure 14-34 shows a light-suspension 500-kV single-circuit tower typically used by the Bonneville Power Administration (BPA), supporting three 1,192,500-cmil ACSR Bunting conductors per phase and two 7-strand No. 8 Alumoweld overhead ground wires. BPA uses continuous overhead ground wires throughout its entire 500-kV network except on single-circuit lines west of the Cascade Mountains. In the latter case, overhead ground wires extend 1 mi out from the substations. Typically, BPA 500-kV lines are designed to withstand 100-mi/h winds and solid ice coatings up to 1½ in.

A steel suspension self-supporting tower used by Hydro-Quebec for 735-kV Manicouagan lines is shown in Fig. 14-35. Line conductors consist of a four-conductor

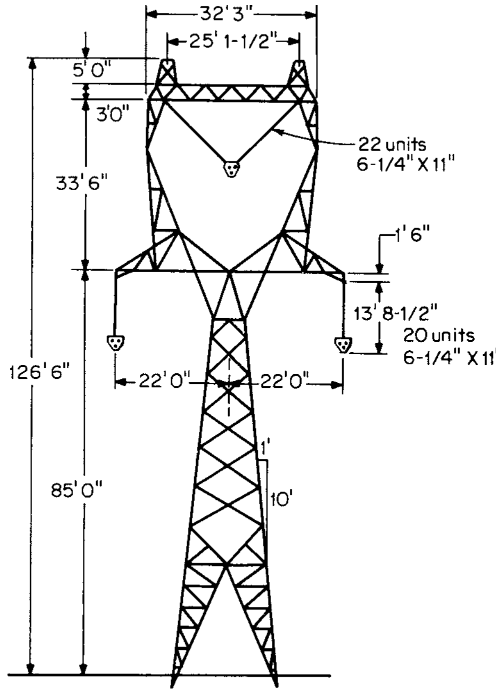

FIGURE 14-34 Suspension-type 500-kV tower. (*Bonneville Power Administration*).

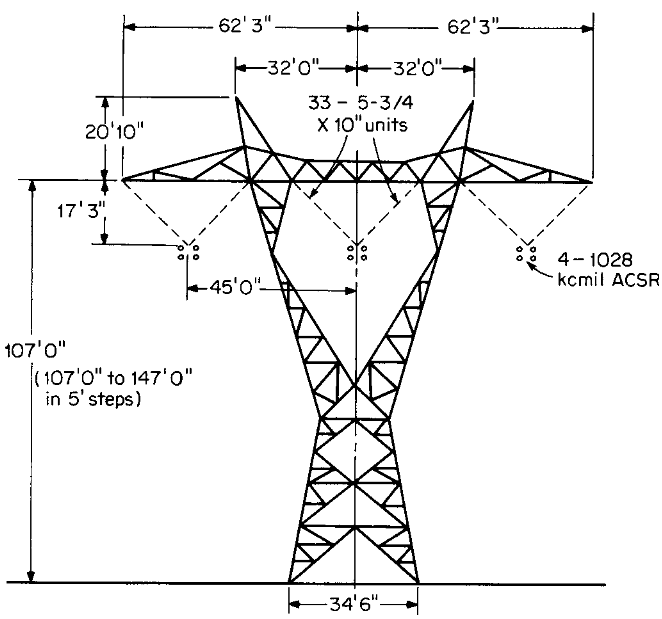

FIGURE 14-35 Steel suspension self-supporting tower for 735-kV Manicouagan lines. (*Hydro-Quebec*.)

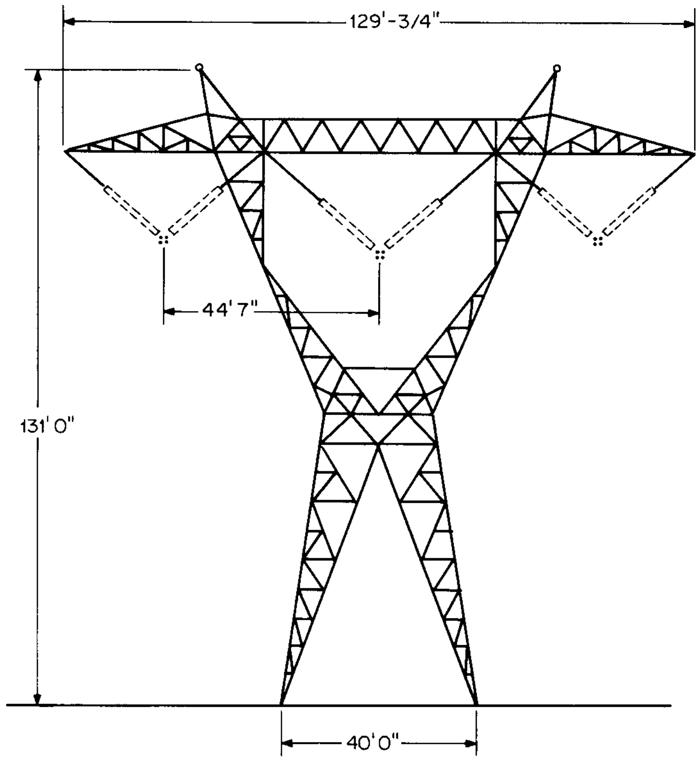

FIGURE 14-36 Steel 765-kV self-supporting suspension tower. (*American Electric Power Co.*)

bundle per phase, where each conductor is a 1,028,000-cmil ACSR insulated with 33 insulator units ($5^3/_4 \times 10$ in) per phase. This type of tower was used on the first stages of the Manicouagan project since September 1965, and in subsequent stages of the same project.

A unique structure is the 765-kV self-supporting steel tower used by American Electric Power Company (Fig. 14-36). This tower, weighing from 44,000 to 66,500 lb, including grillage foundation, was designed by American Bridge Company for erection in parts, if desired, by a Skycrane helicopter. Like AEP's 765-kV V tower shown in Fig. 14-33, there are 30 insulator disks ($5^3/_4 \times 10$ in) per leg of V strings in the outside phases and 32 insulator units in the middle phase. Also, like the tower shown in Fig. 14-33, this tower is designed to meet the same special AEP loading criteria already described. Two overhead ground wires provide a 15° shielding angle to the outside four-conductor bundles.

Semiflexible Structures. Such structures have been used to some extent for the voltages under EHV. This type of tower has a narrow base in the direction of the line. The ground wires are strung tightly to take up unbalanced loads due to broken conductors and form part of the structural system. In case a conductor breaks, the unbalanced load will be taken up by the ground wires and transmitted by them to the next anchor tower.

With the advent of EHV and bundle conductors, semiflexible self-supporting towers are receiving more consideration, and some are being used. With the heavy bundle conductors, the breaking of one conductor is not serious, and the breaking of all conductors of a phase is practically nonexistent. Possible causes are airplanes and tornadoes, which no practical tower could withstand.

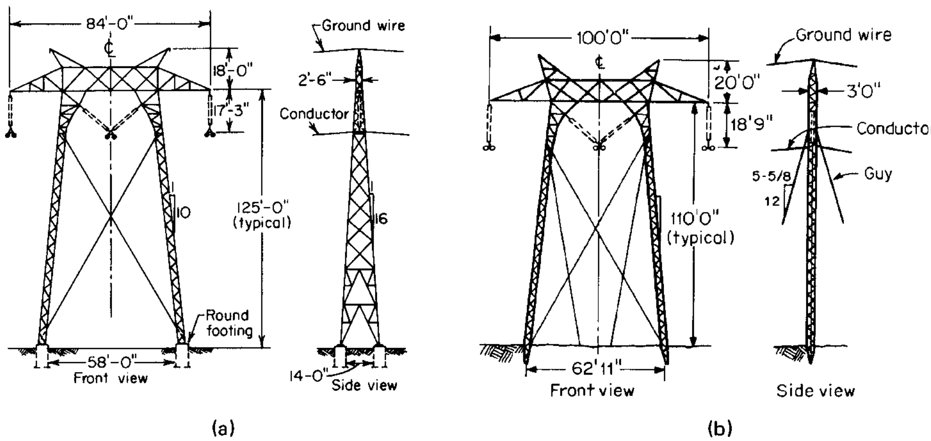

FIGURE 14-37 (*a*) A 500-kV steel tower used in valley areas (*Pacific Gas and Electric Co.*) (*b*) A 500-kV steel tower used in mountainous areas (*Pacific Gas & Electric Co.*)

Figure 14-33*b* shows such a tower as used on the 500-kV system of the Arkansas Power and Light Company. The overhead ground wires are insulated from the towers as they are in Fig. 14-33*a* for communication purposes. Figure 14-37*a* shows a steel-saving semiflexible tower used by the Pacific Gas and Electric Company. Note the X guying used between tower legs to obtain the required lateral strength.

Guyed Towers. Such towers overcome the weakness of semiflexible towers in line with the line. They can be used for single-conductor lines or for any other service. Figure 14-37*b* shows a guyed steel tower used by the Pacific Gas and Electric Company in mountainous country. A feature of the tower is that the legs do not have to be of equal length. This tower has the same internal X guying as the tower of Fig. 14-37*a*. The self-supporting feature of the tower of Fig. 14-37*a* is replaced by four guys in the direction of the line and with an increase in strength.

Figure 14-38 shows a Kaiser aluminum guyed-V 345-kV tower used by the American Electric Power Company. Weighing from 3350 to 5400 lb (1510 to 2450 kg), this tower was erected by using a helicopter to “tilt up” the assembled tower by pivoting about a special hinge at the center foundation. This allows the use of a helicopter with a lifting capacity smaller than the weight of the tower since most of the tower weight is supported by the foundation while it is being tilted up. There are 15 insulator units ($5\frac{3}{4} \times 10$ in) per leg of the V strings on this tower.

Figure 14-39 shows a Kaiser aluminum guyed-V 765-kV tower also used by American Electric Power Company. There are 30 insulator units ($5\frac{3}{4} \times 10$ in) per leg of the V strings in the outside phases and 32 insulator units in the middle phase.

Each of these towers has been designed to withstand special AEP loading criteria which include 100-mi/h winds with no ice, 50-mi/h winds with 1 in of ice, and $1\frac{1}{4}$ in of ice with no wind, in addition to the NESC loading requirements.

Tubular Steel Poles. These poles are being used on city streets and in congested areas where a wide right-of-way cannot be gained. They have been used for voltages up to and including 345 kV. Vertical configuration of conductors is used for all high-voltage lines. Insulators may be side post or suspension[78] on cantilever arms or a combination[79] of the two. Figure 14-40 shows a 230-kV pole used on a line of the Arizona Public Service Company in Phoenix. These poles are of tubular steel in three sections with telescoping joints. The poles are tapered, with a diameter of 24 in at the base and 10.8 in at the top. The mast arms are 8 ft long, of tubular steel, with brackets bolted to the poles with two $\frac{3}{4}$-in through bolts. The poles are spaced approximately 300 ft apart. Insulator side swing is reduced by a 200-lb combined hold-down weight and corona shield. The poles present a pleasing appearance and have elicited no objections even with a line installed on each side of a 60-ft street.

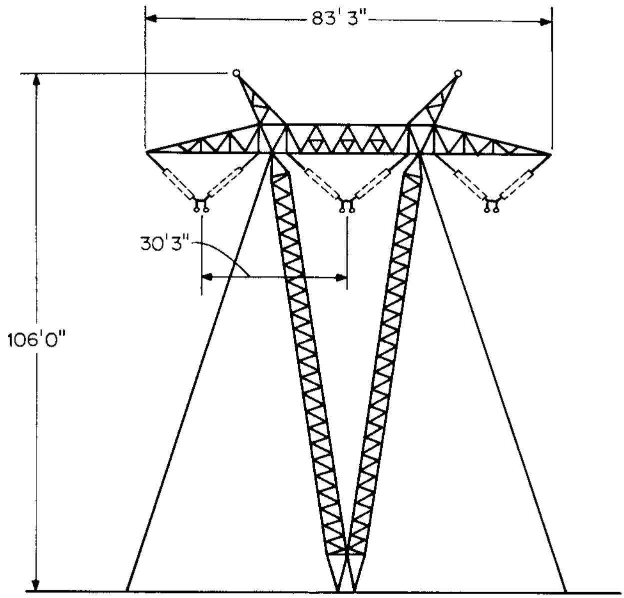

FIGURE 14-38 A 345-kV guyed-V aluminum suspension tower. (*American Electric Power Co.*)

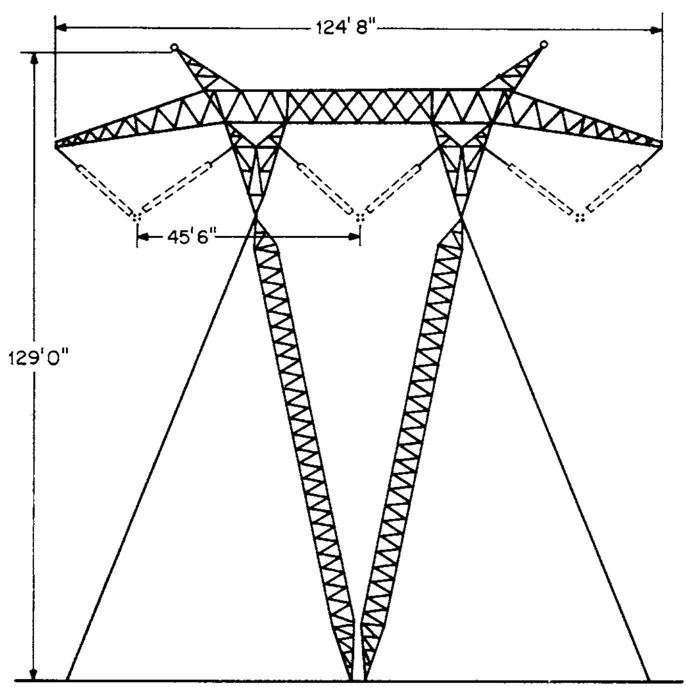

FIGURE 14-39 A 765-kV guyed-V aluminum tower. (*American Electric Power Co.*)

The poles, side arms, and accessories were furnished by the Union Metal Manufacturing Company of Canton, Ohio.

The New Orleans Public Service Company 230-kV line[79] is of similar construction but is designed for hurricane-force winds. The poles are 12-sided, elliptical, high-strength steel, with the short diameter, which is in line with the line, 75% of the long diameter. The insulators are a combination of 12 suspension insulators and a swivel-ended strut (side-post) insulator equal to 12 suspension insulators, to prevent side swing of the suspension insulators. Some poles have side-post 230-kV insulators only. The poles have no base for bolting to a foundation but do have baseplates and are set in concrete in holes 25 ft deep. The holes are made by driving 32-in-diameter steel casings to a depth somewhat deeper than 25 ft and cleaning them out.

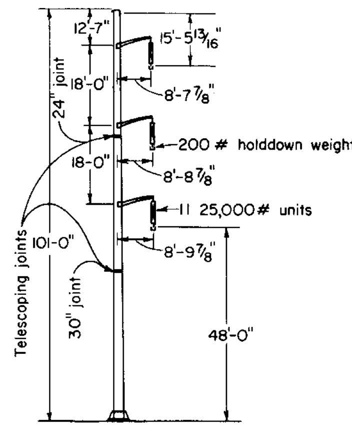

FIGURE 14-40 A 230-kV steel pole. (*Arizona Public Service Co.*)

Special Structures. Transposition towers require special structures where it is not expedient to make the transpositions on a standard tower by the use of special crossarms. Long spans over rivers and bays and crossings over important highways and trunkline railroads frequently require towers which either are much higher than normal or must have a larger factor of safety against collapse. Anchor towers near substations, towers for mounting switches, and towers for turning 90° angles also may come under this classification. Such special structures are designed to suit local requirements and are subject to regulations of the U.S. Army Engineer Corps in the case of navigable-river crossings, to state public-utility commissions or other bodies for highway crossings, and to the particular regulations of railroads which are concerned.

Stresses in Structures—Design. Stresses in towers can be computed analytically by the historic graphic methods or by use of one of the available computer programs for tower analysis and design. Most of the design procedures assume the foundations are rigid. In actual practice, with towers set in the ground, an uneven settlement of the foundations may produce excess stresses which must be considered and taken care of in the overload factor provided against failure. Some flexible lattice-type towers and most pole-type structures will undergo sufficiently large horizontal displacements such that the nonlinear stresses due to the vertical loads acting in conjunction with these displacements (the so-called P-Δ effect) must be considered in the design.

Tension members may be designed for their full net area of section with bolt holes deducted, and compression members may be designed in accordance with the strength formulas given in ASCE Manual 52.[80]

For short panels in narrow-faced towers, it is economical to use a tension and compression system of web bracing without horizontal struts, as the stresses in the corner posts will be reduced considerably, with torsional stresses eliminated entirely. The bracing should make an angle of 30° to 45° with the horizontal, with all web members in any one panel of the same size to divide the loads equally. Where a tension system of diagonal bracing is used with horizontal struts taking the compression, the angle of the bracing may be increased to 50° or more from the horizontal. Long, unsupported lengths of main members can be broken up by the use of redundant members. The lower panels of towers should be so designed that variable-length leg extensions, which are interchangeable, can be employed to take care of sloping ground. Square extensions of any desired length may be used where towers higher than standard are necessary, with variable-length leg extensions fitted to the bottom of the square extensions if required.

Structure Tests. When an important transmission line is built using structures of new design, at least one type of structure (generally the tangent suspension tower or the type which is to be used most frequently) should be tested, first with the working loads as specified for the design of the tower applied, and finally with the ultimate loads which the tower is expected to withstand, applied. Steel poles should always be tested on rigid foundations with the transverse, longitudinal, and vertical loads applied simultaneously to introduce all direct bending and torsional stresses. Crossarms should be tested for the additional torsional stresses introduced, where pin insulators are used, and combined with the longitudinal loads and the heaviest vertical loads specified. Equivalent concentrated loads may be used in some cases to avoid applying a multiplicity of small loads at different points, which would cause delay in shifting loads, but care should be taken to see that all combinations of loads or individual loads which will produce the maximum stress in each member are applied. After the structure has successfully withstood all the specified loads, a destruction test is desirable to determine the overload factor. This can generally be made with the test loads which cause the maximum stresses in the greatest number of members on a tower in place, by increasing the transverse loads indefinitely until failure occurs. After a test is completed, members of a tower should be examined for elongation of bolt holes, straightness, etc.

Towers should be tested with the protective coating which is to be used in service on the steel, and the foundations should be the same as those for which the towers are designed. If it is impossible to test towers on earth foundations, they may be tested on rigid foundations, but a test on rigid foundations will undoubtedly show a greater overload factor than may be expected in service.

Erection of Towers. Towers may be assembled on the ground and then lifted into place by means of self-propelled derrick cranes or latticed-steel gin poles.[81] Very large towers are usually assembled in sections, and the sections are lifted into place by means of cranes or gin poles. Towers in inaccessible locations may be transported and assembled by the use of helicopters. If necessary, the towers can be erected from the ground up by the use of gin poles moved from corner to corner and with the erection crew climbing up on the partly completed structure. This method may be used for small jobs which do not warrant the use of heavy cranes or for very tall towers beyond the reach of cranes, such as those for river crossings.

Insulator and Ground-Wire Attachments. (Fig. 14-41). The method of attaching suspension insulator strings varies. One form of attachment is the U bolt fastened on the underside of the crossarm to which the insulator hardware is attached. This device will give flexibility both longitudinally and transversely. Another attachment is in the form of a bent plate or angle fastened to the underside of the crossarm with a fairly large hole to receive a hook or shackle at the top of the insulator string.

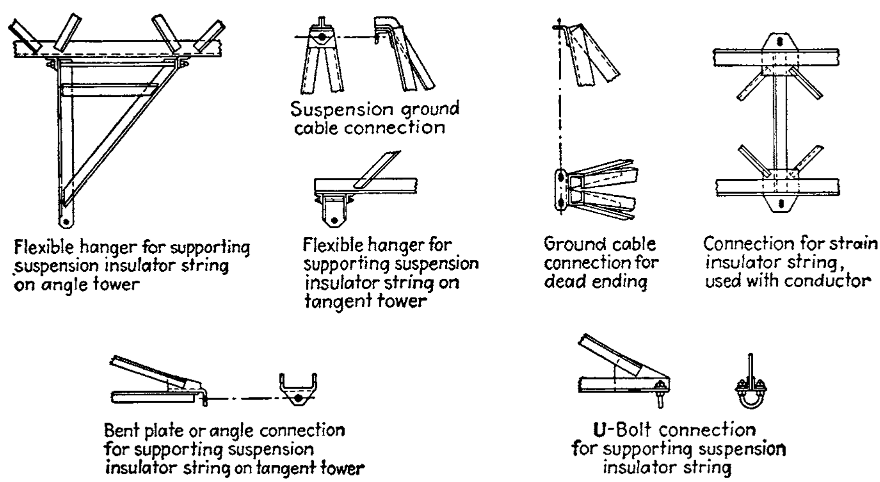

FIGURE 14-41 Insulator and ground-wire attachments.

In order to keep the conductor spacing to a minimum on high-voltage lines and take advantage of clearances to steelwork, the point of attachment of the insulator string may be dropped several inches below the crossarm, in which case flexible hangers are required, that is, hangers which are hinged at the crossarm and free to pivot in the direction of the line. These hangers may be made of plates, shapes, or bent round rods, with suitable connection at the bottom for receiving the insulator string. With suspension-type insulators in the strain position, horizontal pull-off plates are required.

To minimize failure of ground wires due to vibration, they are preferably suspended, and the attachment at the tower consists of an angle or bent plate with a hole to receive the suspension clamp. Patented rigid ground-wire clamps may be obtained if desired, which can be bolted directly to the steel structure. These are generally of the V-groove type.

Ladders and Step Bolts. Ordinary steel towers are provided with step bolts on one corner post for climbing the tower. Special high structures, such as river-crossing towers, should have ladders extending up to the level of the top crossarm. Such ladders should be provided with guard cages supported on the sides of the ladder.

Seismic Effects. This field is complex,[82] involving the various disciplines of the seismologist; the special dynamicist, who understands both structures and equipment and their differences; the vibration test engineer, and the designer who is experienced in the practical aspects of the lines and equipment and their function. There are many subtleties which are rarely appreciated by any one person and, consequently, many authorities must be consulted.

As contrasted with substation equipment, transmission-line structures built to withstand aboveground weather also will generally survive moderate earthquake tremors without noticeable distress. As studies of seismic effects are becoming more sophisticated, investigators have established seismic design criteria in the United States by dividing the country into four zones of seismic probability, the most severe being on the Pacific coast.[83] In such areas periodic review of existing foundations from a seismic standpoint is recommended. Experience in the San Fernando, California, earthquake of February 9, 1971, showed that over the years the foundation strength of a number of towers had been sufficiently reduced by erosion or adjacent excavation that their slopes failed during the earthquake.

One study[84] analyzes the effect of earthquake ground motion on both wood and steel transmission structures. It concludes that, except where damage to foundations and anchors occurs because actual earth fissures or slippage develop, seismic disturbances produce no overstress in transmission structures designed in conformity with the *National Electrical Safety Code.*

Protective Coatings for Steel Structures

Galvanizing. For important transmission lines where long life is desired, it is almost universal practice to galvanize fabricated-steel towers and poles which are field-bolted after the other shop work has been completed, because under such conditions galvanizing is more economical than painting. The method of "hot-dip" galvanizing is also used for bolts and nuts, with the threads rerun for nuts after galvanizing. This has practically superseded the sherardizing, or "dry galvanizing," of bolts and nuts which was in use for a number of years. All galvanizing should be in accordance with the *Standard Specifications for Zinc (Hot Galvanized) Coatings on Structural Steel Shapes, Plates and Bars and Their Products*, as given by ASTM Designation A 123, which calls for an average coating of 2 oz of zinc per square foot of surface.

To test the uniformity in the thickness of the galvanized coating, the Preece test is used. This is described in the *Standard Methods of Determining Weight and Uniformity of Coating* in *Zinc-Coated (Galvanized) Iron or Steel Articles*, as given by ASTM Designation A90.

Structures located near industrial plants, if subjected to sulfuric acid and fumes, should not be galvanized.

Painting. Painting is sometimes resorted to for fabricated-steel towers and poles, and generally shop-riveted, welded, or special steel poles are painted. Towers located near industrial plants in a smoky atmosphere should be painted. The base coat should be a mixture of red lead and raw linseed oil in something like the proportion of 33 lb of dry red lead to a gallon of oil with a little dryer added. The outer coats may be of any good all-weather paint. To keep structures in good condition, painting is necessary every 2 or 3 years. With structures having a larger number of small members, this may make the cost of maintenance very high. On structures having few pieces and large, flat surfaces, painting may be economical.

Where steel structures are buried in the ground, a special problem sometimes arises at the ground level where moisture occurs. At this point, galvanizing may deteriorate after a short interval of time, especially if the soil has a sulfur or acid content. A paint made from asphaltum compounds will often prove useful for protection at these points.

Newly galvanized steel should not be painted until it has a chance to weather for a period of 6 months, and the galvanized surfaces should then be cleaned. Aluminum paint is ordinarily used to paint galvanized towers when the galvanizing has deteriorated.

Weathering, or self-painting, steels have been developed by the major steel companies. These are steels which are not treated with any kind of protective coating, but the chemical composition of which is such that they may be said to "paint" themselves. They are installed completely uncoated but thoroughly cleaned of all mill scale and foreign matter. In a few years, a dense dark-brown oxide with a purplish cast forms which becomes a permanent protective coating to all surfaces exposed to the weather. A slight loss of thickness occurs, which eventually stops, as the corrosion rate is nonprogressive.

Wood Poles. Wood poles are considerably cheaper than steel for many types of construction. The lower cost is due, in part, to the more conservative basis of design normally adopted for steel. Generally, steel structures are designed to support safely one or more broken conductors, whereas wood structures are often not so designed. It is logical that the reasons for choosing the more expensive steel construction should require conservative design throughout and that conditions justifying the cheaper and shorter-lived wood structures would warrant accepting some of the more theoretical hazards.

For voltages of 69 kV and lower, wood is quite generally used.

Wood-pole construction for many years has been used for all voltages up to and including 345 kV. H frames with various modifications have been designed, the most popular using the main crossarm as the bottom member of a truss.

Butt-treated cedar and full-treated pine are used almost exclusively in transmission-line construction; the use of untreated poles has been practically abandoned as uneconomical since the supply of chestnut and northern cedar poles has been exhausted. Treated fir has also been supplied in some quantity from the Northwest.

Cedar poles resist decay, but satisfactory life is not secured unless the butt is treated. The pole is usually treated from the butt to about 2 ft above the ground line. The balance of the pole is not treated. Pine and fir require complete treatment of practically all the sapwood. This treatment is applied under pressure.

No universally effective protection has been devised against woodpecker damage. Some localities are often subject to serious epidemics of woodpecker trouble.

Preservative Treatment. Pole decay is due to a fungus which requires air, moisture, warmth, and food for its subsistence; the wood of the pole constitutes its food. The conditions most favorable to the growth of the fungus are found at the ground line. The preservative has toxic or antiseptic properties which make the wood either poisonous or unfit food for the fungus.

Preservatives and preserving methods conforming to the standards of the American Wood Preservers Association (AWPA)[85] should be used in the treatment of poles. There are many wood preservatives, including those using poisonous salts such as copper, mercury, zinc, and arsenic compounds. However, only two are included in AWPA recommendations for poles, Standard C-4-74-C:

1. Coal-tar creosote, AWPA Standard P1-65
2. A 5% solution of pentachlorophenol in a petroleum distillate, AWPA Standard P8 (commonly called "penta")

By AWPA Standard M1-70, pentachlorophenol is not recommended for use in coastal waters. Coastal waters are defined as salty waters. One other preservative is increasing in popularity. This is

AWPA Standard P11-70, a creosote-pentachlorophenol mixture in which pentachlorophenol is not less than 2% of the mixture. All of these preservatives are applied by the following methods:

1. *The open-tank method*, applied to cedar poles, consists in boiling the butts of the poles in a tank of creosote oil, after which the oil is allowed to cool or the poles are transferred to a cold tank of oil. The duration of the hot and cold treatment, usually 8 h or more, depends on several factors, the most important of which is the degree of seasoning. The treatment is based on the fact that the wood cells expand with heat and on cooling draw the creosote into the wood under atmospheric pressure. The sapwood of unseasoned poles has annular rings of a nearly impervious fiber which prevent penetration of the oil. In seasoning, this fiber dries and breaks open. To ensure penetration of the greater part of the sapwood, which is usually less than 1 in in depth, an incision process has been developed and is almost universally used. Narrow cuts, parallel with the wood fibers, are made to a depth of about 1/2 in at frequent intervals around the circumference of the pole for a distance above and below the ground line. Complete penetration is obtained to a depth somewhat greater than the depth of the incisions even on unseasoned poles.
2. *Pressure treatment* is applied to pine and fir. The poles, on a truck, are run into a steel cylinder and subjected to a steam treatment for a period of several hours at a temperature which will not damage the wood cells, usually specified at not more than 259°F (126°C). The pressure is then removed and a vacuum applied. The steam treatment opens up the wood cells and allows the preservative to penetrate. The length of time required for the steam and vacuum treatment depends on the condition of the wood, the amount of oil that is to be injected, and the depth of penetration desired. From this point in the process, one of two methods may be followed. The *full-cell*, or *Bethel, process* allows all the preservative injected to remain in the wood. This process is generally used for piling and underwater work when it is desired to exclude water from the wood and to resist the attack of marine borers. The *empty-cell process* draws off excess oil and secures protection from decay by the coating of oil left on the walls of the wood cells. The empty-cell process is adequate and preferable for usual structures and is used almost exclusively for poles and arms.

The empty-cell treatment is obtained by either the Rueping or the Lowry process. The Rueping process seems to be in more general use, although the Lowry process is equally successful.

In the *Rueping process*, following the steam treatment, an air pressure is applied. While still under pressure, hot oil is forced into the cylinder. The oil is held under this pressure and maintained at a temperature of about 200°F (93.5°C) by steam coils within the cylinder, for a period of several hours. Upon removing the oil and reducing the pressure, the compressed air within the wood cells forces out the surplus oil. The amount of oil retained depends on the pressures applied and the time of treatment, although it is possible to remove only a part of the oil that has been injected.

The *Lowry process* is similar to the Rueping process except that no compressed air is used. After the preservative has been forced into the wood under pressure, a high vacuum is quickly created, causing a sudden expansion of the air within the wood cells and thus driving out surplus preservative (see also Sec. 4).

Strength Calculations. As used in a line, the pole is a cantelever beam, fixed in the earth at the butt and supporting the transverse wind load from the conductors of a length equal to half the sum of adjacent spans. Computation of the safe load that may be carried is a matter of simple mechanics outlined in Fig. 14-42. Some slight approximations have been introduced for simplicity.

The fact that if the pole were a part of a perfect cone, the maximum fiber stress might occur at a point above the ground line is of more theoretical interest than practical use. The difference between the load carried at the critical section and at the ground line is less than may readily be caused by irregularities in the pole.

Poles are almost universally classified according to the ANSI dimensions (see Sec. 4), which have been arranged so that the nominal ultimate strength is the same for all lengths and species of the same class. Poles are classified as Class 1, 2, 3, etc., and H1, H2, H3, etc., and the minimum circumference 6 ft from the butt is specified for each class and each species to give the desired nominal strength. The nominal ultimate was computed from conservative average ultimate fiber stresses from a very large number of tests.

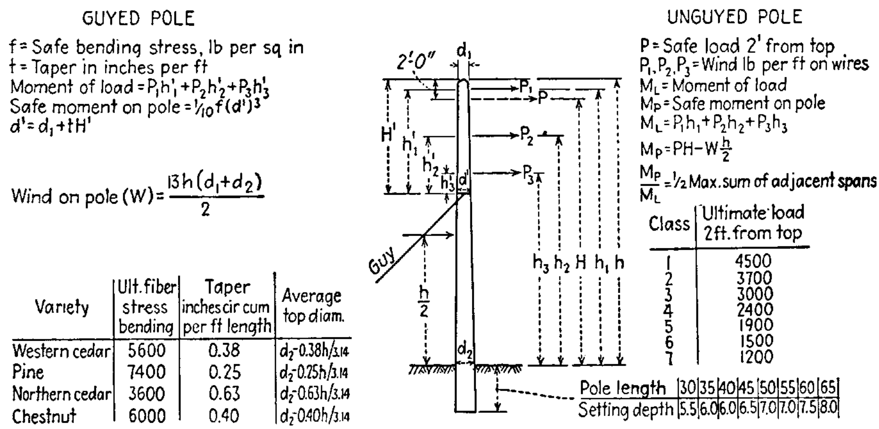

FIGURE 14-42 General pole-strength calculations.

The top diameters are specified but are given only as a minimum and are the same for all species. Actually, the taper of various kinds of timber, although fairly uniform, is quite different for different species, and the average top diameter of ANSI-class poles will be considerably larger than this minimum.

1. *Pole tests.* These give very erratic results, and tests on a few poles should never be given great consideration. Designs should if possible be based on accepted average unit fiber stresses rather than test results unless a considerable number of duplicate tests can be made and averaged.
2. *Factor of safety.* It has been found from experience with heavy transmission-line construction that a safety factor of 2 on the accepted average ultimate is conservative. On light construction, this is sometimes slightly reduced, but a material reduction is usually not justified in view of the deterioration of wood with age. On sustained loads, such as heavy angles, a liberal additional factor of safety is desirable to prevent the pole's warping and giving the appearance of being overloaded. When possible, guys should be attached close to the load to eliminate heavy continued bending.

Setting Depth. The strength of the pole foundation is difficult to reduce to figures and is not of such primary importance to the safety of the structure as in the design of a tower. Failure of the foundation, in the sense that failure is used in the design of steel towers, that is, a considerable movement of the pole in the ground, is of little consequence except for the inconvenience and expense of straightening up the line and retamping the poles. The setting depth for poles of various lengths has been pretty well established by general practice and is almost universally used (see Fig. 14-42). These depths seem somewhat illogical in that no account is taken of the strength of the pole or of the quality of the soil; however, this appears more reasonable when it is considered that the desired result is not to obtain a rigid foundation but to prevent the pole from "kicking" out of the ground.

Wood Crossarms. These are generally manufactured of creosoted yellow pine or untreated Douglas fir. Untreated pine arms of the timber commercially available are not satisfactory. Untreated fir arms are widely used and are apparently giving a life comparable with that of the poles. Arms should be of the highest-quality timber. The smaller arms, up to 5 × 6 in and 10 or 12 ft in length, can generally be supplied on standard crossarm specifications, although structural specifications give very satisfactory arms. Heavy arms for H frames, that is, 6- × 8- and 6- × 10-in timbers and 3- × 8- and

3- × 10-in planks, 20 to 35 ft long, are best purchased as high-grade structural timbers. Structural timbers are furnished under the rigid specifications and inspection of the large timber manufacturers' associations.

Plank Arms. The eccentric connection of large arms to the pole, especially when carrying heavy conductors, is not desirable, and a number of designs make use of two planks, one on each side of the pole attached together at the ends. Generally two 3- × 8-in planks are used in place of a 6- × 8-in timber arm. The plank-arm construction has several advantages in addition to the better connection to the pole, although the end hardware is somewhat complicated, and in many designs the strength of the crossarm against longitudinal loads is somewhat reduced.

Wood versus Steel Arms. Wood crossarms are lower in cost than steel arms of the same strength and, aside from the shorter life, the possibility of being shattered by lightning, and the risk of burning due to leakage current at 345 kV and above, are satisfactory. On wood pole construction, the advantages of steel crossarms—resistance to lightning damage and longer life—are not usually sufficient to offset the insulation strength of wood crossarms. In any event, lightning damage to arms is usually not a major operating problem; and on lines thoroughly shielded with overhead ground wires, crossarm and pole damage is practically eliminated. At higher voltages, crossarms are sometimes equipped with bonding wires to prevent leakage current from burning.

Design of Arms. The design must provide for carrying the vertical load with an ample margin of safety, but often neither the arm nor the connecting hardware is well suited for carrying the full load of a broken conductor as is required of steel towers. Crossarms on single-pole construction have practically no resistance to longitudinal loads. If a heavy conductor breaks, the arm will swing around to very nearly a longitudinal position, restrained only by the attachment of the unbroken conductors. This would be likely to result in badly bent hardware and probably a split and disfigured arm but little serious damage; the major damage would be the broken conductor and not the effects of the break. H-frame construction (see Fig. 14-46*c*) is better adapted to such loads, but the effect of a break is much the same, in that the deflection of the poles and movement of the poles in the ground relieve the greater part of the load and usually result in only some minor damage to the arms and hardware, which is easily repaired.

Double-arm construction can be considered very little, if any, stronger than twice the sufficient bolts and keys to develop the shear. The shear is several times the applied load and makes a very heavy joint necessary.

The common sizes used, 5 × 6 in for lighter single-pole construction and 6 × 8 in for H-frame, allow ample vertical strength for ordinary spans. Conservative unit stresses should be used in vertical load on the arms.

The connecting hardware, as generally used, is not designed as would be necessary in a framed structure, such as a truss, where movement in a joint would cause serious secondary stresses in the main members. Only one 3/4-in bolt is ordinarily employed, even in heavy H-frame construction in types of construction carrying wire heavier than has been general practice, and in very long spans the use of these connections, based entirely on experience, should not be followed without a careful check. The same applies to designs carrying heavy angles on crossarm construction where the entire angle load must be transmitted through the bolts to the pole. For such angles, the 3-pole structure is a more positive arrangement.

Conductor Arrangement and Spacing. In wood construction with short spans over comparatively level terrain, these parameters are determined largely by the line voltage. A wide variety of conductor arrangements is found in past practice. However, with the use of larger conductors and longer spans, the conductor configuration and separation are often a matter of providing the safest arrangement with ample spacing, especially for the occasional longer-than-normal spans encountered in rolling country. The conductor arrangement should provide spacing for these occasional long spans, as it is generally more economical to design a standard structure with spacings suitable for a span about 50% longer than normal rather than to use too many special structures.

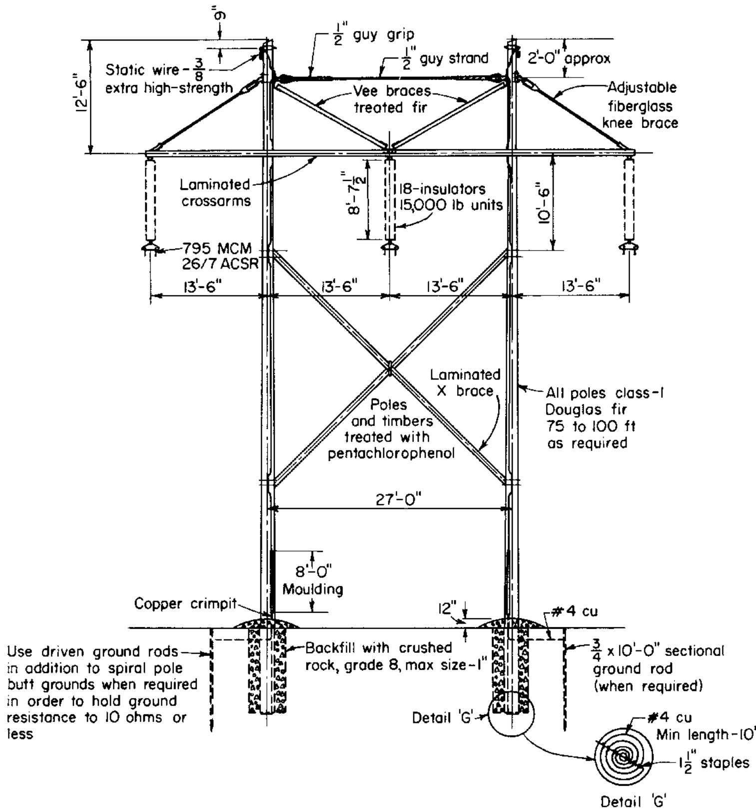

FIGURE 14-43 A 345-kV wood H-frame structure. (*Kansas Gas and Electric Co.*)

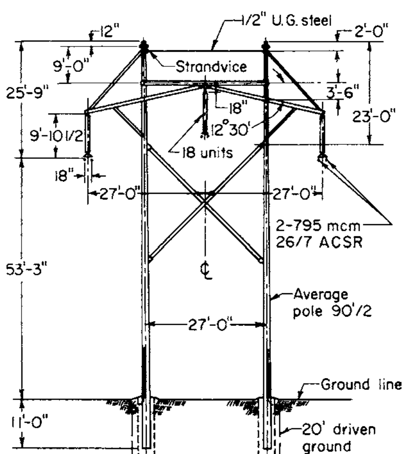

FIGURE 14-44 A 345-kV wood K-frame structure. (*Northern States Power Co.*)

The H-frame design gives one of the best conductor arrangements and mechanical strength for long-span construction and may be used as a special structure for especially long spans in almost any type of line.

Wood-pole H-frame structures are used on EHV lines at an appreciable saving over metal towers. Figure 14-43 shows an H-frame structure with trussed crossarm as used on the Kansas Gas and Electric Company 345-kV lines. This line uses two 795-kcmil ACSR conductors per phase on 18-in bundle spacing and 27-ft phase spacing. The insulator suspension hardware is not grounded, and full advantage is taken of the impulse insulation of the crossarm. Lightning flashovers would be expected to take place between the conductors and the ground wires on the poles and not to follow the insulator string and crossarm. All poles and timbers are penta-treated fir.

Figure 14-44 shows a modified H-frame wood-pole structure, designated a K frame, as used by the Northern States Power Company on its 345-kV system.[86] This

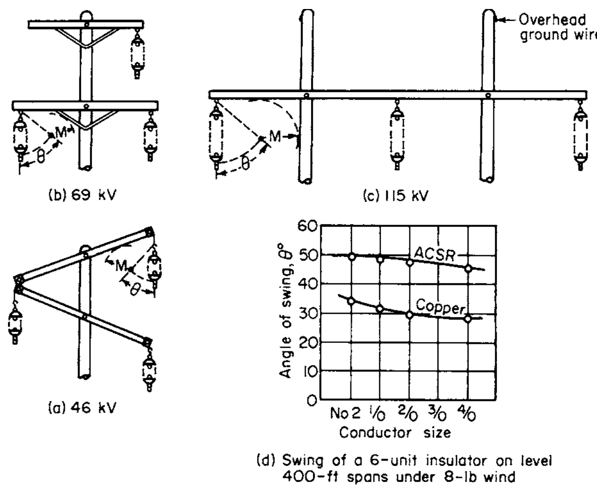

FIGURE 14-45 Typical suspension-insulator arrangements on wood construction.

structure also is designed to carry two 795-kcmil ACSR conductors per phase on 18-in bundle spacing and 27-ft horizontal phase spacing, but the center conductor is approximately 6 ft higher than the outside phases. This structure also takes full advantage of the impulse insulation of the crossarm.

It should be noted that the conductor spacing is primarily a function of the sag and that a conductor arrangement entirely satisfactory for a large or high-strength conductor would be hazardous for a small conductor, with correspondingly greater sags, in the same length of span. Also, a conductor spacing safe for a light loading district should not be used with the heavy sags required for heavy loading conditions. A small or lightweight conductor would require more spacing than a larger or heavier conductor in the same span and with the same sag.

On suspension construction the spacings are usually determined by the clearance required for swing of the suspension insulators as discussed under steel tower design. A detailed layout is required for each conductor, as the size and material have a marked effect on the swing characteristics (Fig. 14-45*c*). A fairly conservative assumption, which results in reasonable design, requires that the clearance from the conductor to a grounded structure shall be at least 0.75 the dry-flashover distance of the insulator or the "tight-string" distance under an 8-lb wind on the bare conductor at a temperature of 60°F. This may be modified in details, and it is common practice to allow somewhat reduced clearances to wood members. Typical layouts are shown in Fig. 14-45.

The swing should be taken for a somewhat more unfavorable case than level spans. The usual range of conditions encountered would be fairly well covered if a vertical span of three-fourths to two-thirds the horizontal span is assumed; that is, the clearances provide for cases where it is necessary to locate a structure somewhat below the elevation of the adjacent supports.

Angle structures in general use are shown in Figs. 14-46 and 14-47. The design is a matter of providing clearance from the conductor to the structure and to the guys under all conditions and at the same time of attaching guys as close to the load as possible to keep bending stresses down to a conservative value. On small angles where the loads are small, the angle pull may be carried as a bending in the pole and arm; but on larger angles, the loads should be carried directly by the guys, insofar as possible.

Figure 14-46*a* shows the usual small-angle construction, illustrating how it may be necessary to offset the arms to give clearance to the inside conductor. Figure 14-46*b* illustrates a similar design for small angles on heavy H-frame construction where the angle is so small that, if the maximum wind should blow from right to left in the illustration, it would cause the insulator to swing somewhat to the left of vertical. Therefore, clearance *M* must be provided, not only to the pole on the right, in the illustration, but also to the pole on the left. In the above designs the guy is attached some

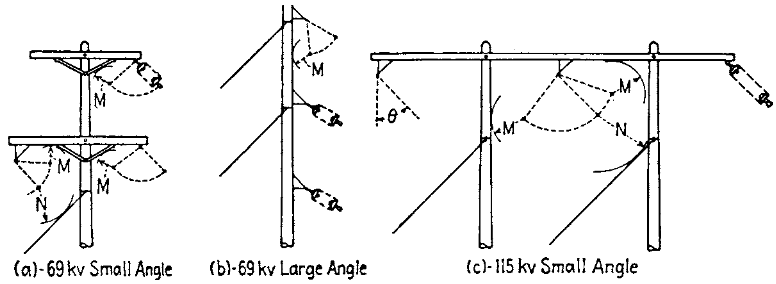

FIGURE 14-46 Suspension-angle structure.

distance below the crossarm in order to give a clearance N from the conductor to the guy, which is somewhat greater than the flashover distance across the insulator. The clearances N and M (Figs. 14-45 and 14-46) indicate the "normal clearance" and "minimum clearance," respectively. The normal clearance should be at least equal to the porcelain insulator.

The bracket on the pole as shown in Fig. 14-45*b* is used for larger angles where the mechanical stresses are too great for crossarm construction but for which the angle pull is not sufficient to swing the insulator string away from the pole under a wind from the right or at locations where a heavy vertical load is encountered on an angle structure. A similar 3-pole design is used for H-frame construction. The position of the insulator may be computed for various combinations of loading as shown below.

The simplest angle structure is illustrated in Fig. 14-46. The fewest pieces of hardware and the most direct transfer of stress to the guy are obtained. However, this design can be used only where the angle load is sufficient to hold the insulator string away from the pole under all conditions.

Angles greater than about 50° are usually dead-ended in a structure similar to Fig. 14-47, as it is not advisable to carry too large an angle on the usual suspension clamp. Erection is difficult on large conductors, and guying becomes complicated for very large angles on suspension construction.

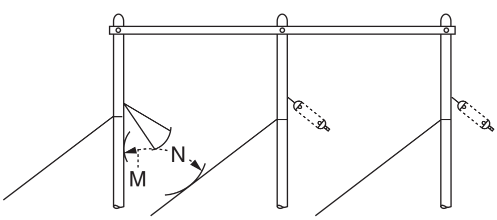

FIGURE 14-47 115-kV large-angle structure.

If grounded guys are used, a ground wire should be carried up the pole; and when the guy is attached close to the insulator, contact should be made with the insulator hardware to avoid the possibility of burning the pole from leakage or splintering from lightning. It is common practice to use one or two additional insulators on such angle structures.

Clearances on angles should be the same as on tangent construction, that is, under normal conditions must be somewhat greater than the flashover distance over the insulator but under maximum wind conditions may be reduced to 0.75 of normal, with some slight further reduction if this clearance is to ungrounded wood (see Table 14-23).

The greatest swing, that is, angle load and wind in same direction, may occur with wind on the bare wire at 0°F, but usually the combined ice and wind load is limiting because of the larger conductor tension. In the case of the wind blowing against the angle, clearances must be computed for a high temperature and resulting low conductor tension. Under normal conditions, for example, 60°F, full clearance should be maintained, equal at least to the dry-flashover distance of the insulator.

The angle load, that is, the transverse component of the conductor tension t at an angle α, is found as follows:

$$\text{Angle load} = 2t \sin\frac{\alpha}{2} \tag{14-84}$$

$$\tan\theta = \frac{(\text{angle load}) \pm (\text{wind load})}{(\text{vertical load}) + (1/2 \text{ weight of insulator})} \tag{14-85}$$

TABLE 14-23 Clearances for Various Lengths of Insulator String

Insulator, $5^3/_4$-in units	Normal clearance, in	Min. clearance 0.75 normal, in
4	$25^1/_4$	19
6	$36^3/_4$	27
8	$48^1/_4$	36
12	$71^1/_4$	50
16	$94^1/_4$	70

Note: 1 in = 25.4 mm.

in which θ = swing of the insulator from the vertical; the vertical load is the weight of the conductor supported by the insulator, or the weight per foot times the distance between the low points of the sag in the adjacent spans; and the horizontal load is the wind load on the spans supported by the insulator.

Pole Ground Wires. Ground wires should be installed on all poles, at all voltages, in lightning areas:

1. To prevent splitting of poles by lightning.
2. To provide a direct connection to ground and prevent pole burning if an insulator breaks down. Since the ground wire on these lines has relatively high resistance to ground, the wire can be small as No. 6 galvanized iron and the ground connection can be several wraps of the wire around the butt of the pole.

14.1.10 Line Accessories (Lines under EHV)

Suspension Clamps. These designs are fairly well standardized for the usual conductors. Simple, light, well-designed clamps in both malleable iron and forged steel are available for almost any conductor. The seat and clamping surfaces should be smooth, without any projections or sharp bends, and should be formed to support the conductor on long, easy curves and at the comparatively sharp bends formed at horizontal and vertical angles. Heavy, complicated clamps, unless very carefully designed, are generally avoided to allow as much freedom as possible at the support. For the same reason care is exercised to avoid rigid connections of any kind.

Trunnion-Type Clamps. These are designed to give an almost completely flexible connection by supporting the clamp on a pivot, approximately on the axis of the conductor (Fig. 14-48). Thus any vibration of the conductor tends to be transmitted through the clamp, eliminating much of the heavy binding stresses caused by a fixed support.

The suspension clamp is intended primarily to support the weight of the conductor and to prevent any longitudinal movement from accidental unequal tensions in adjacent spans. It is generally considered desirable but not always essential that the suspension clamp hold the conductor in case of a break. For large conductors under heavy tensions it is difficult to design a light, flexible connection that will not slip under such a contingency.

Slip, or Releasing, Clamps. Several especially heavy lines have been designed on the proposition that, since suspension clamps could not reasonably be secured that would positively hold the conductor, a clamp should be used that would hold under all ordinary conditions but would slip at something like one-half the maximum conductor tension in case of a break. This arrangement justified a considerable reduction in the exceedingly large longitudinal design loads on the towers and resulted in a considerable saving in tower and foundation costs. Several designs of slip clamps and releasing clamps have been used.

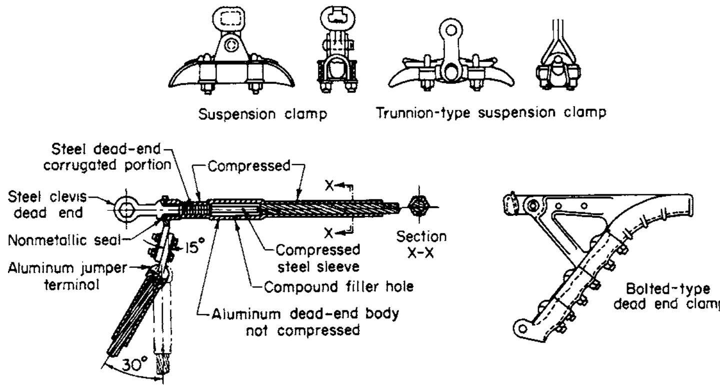

FIGURE 14-48 Conductor clamps.

Dead-End Clamps. These clamps are of the bolted type and are available for practically all copper and aluminum conductors. However, for the larger ACSR conductors the compression-type dead-end clamp is generally used (see Fig. 14-48). This is very similar to the compression splice used on ACSR.

The dead end for the steel core, which may have a clevis or an eye-type end, is pressed on after the aluminum sleeve has been slipped out over the conductor. The aluminum sleeve is then slipped back over the steel sleeve until the aluminum body makes contact with the shoulder of the steel sleeve. The electrical connection tongue on the aluminum body is aligned with the clevis or eye of the steel-core dead end as required, after which the aluminum body is filled with the nonoxidizing compound furnished with the body and the body is compressed. Similar pressed-on dead ends are available for copper, Copperweld, and other conductors. Several manufacturers furnish ACSR dead ends in all sizes required.

Armor Rods. These rods are quite generally used on ACSR lines as a protection against fatigue of the aluminum strands from vibration. Armor rods consist of a bundle of aluminum rods, somewhat larger in diameter than the strands of the conductor, laid parallel to the length of the conductor and arranged to form a complete covering. These are spirally twisted by a tool to lie approximately parallel with the lay of the strands in the cable and are clamped in place at each end. The suspension clamp is attached at the center, with the armor extending 2 or 3 ft on each side. The bending stresses caused by vibration are reduced by the increased diameter and area of metal and distributed over a longer section of conductor.

Vibration Dampers. The Stockbridge damper, as well as several other designs, are devices for damping vibration out of the entire span. Such dampers have been used on ACSR, copper, and steel conductors and ground wires, as illustrated in Fig. 14-49. The cause of conductor vibration and the action of the Stockbridge damper are outlined in the paragraph on wind-inclined motion.

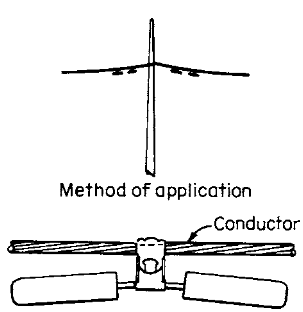

FIGURE 14-49 Vibration damper.

Overhead Ground-Wire Vibration. Overhead ground wires are especially subject to vibration; in fact, most steel ground wires will often be found in rather irregular vibration of small amplitude which generally does not appear to have any ill effects. Ground-wire attachments should be made with at least as great care as given the conductor clamps. Rigid clamps have been almost entirely abandoned in favor of a suspension clamp similar to that used on the conductor and attached by links or shackles so as to give a perfectly flexible connection.

Hardware. Many items of hardware have become fairly well standardized. The dimensions of the eye of eyebolts, the length of thread on various-length bolts, end links, and hardware for suspension insulators are quite uniform. It is usually possible to obtain about identical stock material from a number of manufacturers. Many other items such as shackles, guy clamps, and crossarm braces are furnished in such a wide variety that considerable care is required to choose the most commonly used but suitable stock items. Much expense and confusion in both construction and maintenance are saved by limiting the number of hardware items.

Insulating Braces and Guys. With the use of wood to increase the impulse insulation to decrease the line's sensitivity to lightning flashovers, steel crossarm braces have been replaced with wood on a number of lines. Connections are made by pressed-steel fittings. The use of a 48-in wood brace in place of steel, for additional wood insulation, is roughly the equivalent in lightning-flashover strength of adding one suspension unit to the insulation. The effect on 60-Hz flashover is, however, negligible.

To obtain equal wood insulation at guyed structures to what may be obtained on unguyed construction requires long wood insulators in the guys. These guy insulators are quite efficient because of the high tensile strength of clear wood; an ultimate strength of 6000 lb/in^2 on the net section is conservative. A 2- × 2-in fir insulator will develop the full strength of a 3/8-in Siemens-Martin guy strand. The design of the connection to the pressed-steel fitting requires only that several bolts of insufficient diameter be used to give the necessary bearing area between the wood and the shank of the bolt. The bolts should be placed alternately through the face and side of the stick to prevent splitting.

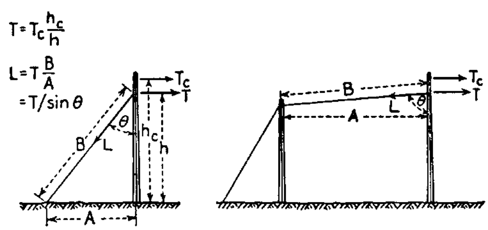
Reinforced fiberglass is receiving increased favor as guy-wire insulators in place of wood, and as crossarm braces in place of wood or steel. Impulse flashover voltages of fiberglass line hardware can be supplied by the manufacturers.

Guys. The various grades of guy strand are almost universally furnished in accordance with ASTM specifications. The ultimate strength for each size and grade is given in Sec. 4. The so-called double-galvanized is generally used. Common guy strand is not ordinarily employed in transmission construction, as the best-quality galvanizing is not furnished in this grade. Siemens-Martin strand is most commonly used for the lighter lines and high-strength strands for heavy construction.

More than one size of guy strand is not economical for a line, and often the same size may be used for several designs. The 3/8-in size, in either Siemens-Martin or high-strength grade, is most generally used both for guys and for overhead ground wires.

In the usual wood-pole construction great refinement is not required in designing guys. Usually it is sufficient to determine the number of guys, of the size and quality to be used on the line, required to support the load, an additional guy being employed for any fractional part. In transmission construction a safety factor of 2 is general for guys, although this may be somewhat reduced.

A common problem in guy design is illustrated in Fig. 14-50. The ratio of the guy load L to the conductor load T is the same as the



DESIGN DATA FOR GUYS

Guy	Ultimate strength, lb	Rod	Net area, sq in.	Ultimate strength, lb
3/8 in. s.m.	6950	5/8 in.	0.202	11,000
3/8 in. h.s.	10,800	3/4 in.	0.302	16,500
7/16 in. s.m.	9350	1 in.	0.551	30,500

ratio of the length of the guy B to the distance A. The length B is readily determined from a sketch drawn to scale.

$$L = T\frac{B}{A} \qquad \text{or} \qquad L = \frac{T}{\sin\theta} \tag{14-86}$$

If the conductor load T_c is above the point of the attachment of the guy, then

$$T = \frac{T_c h_c}{h} \tag{14-87}$$

14.1.11 Conductor and Overhead Ground-Wire Installation

Conductor Stringing. This operation requires an experienced crew, not only to prevent damage to the conductor and overhead ground wire but also to maintain the sags and tensions specified in the design. Correct sags are essential to give the required mechanical safety, but it is equally important that the actual sag in the line correspond to that used in the design, to ensure proper clearances to the ground. More detailed procedures and guidelines are available in an IEEE publication.[87]

Stringing Equipment. All transmission conductors and overhead ground wires should be strung over free-running snatch blocks or rollers made for this purpose. Both conductors and ground wires of any material are easily damaged, and with the long spans and heavy conductors used in modern construction, satisfactory sags cannot be obtained at reasonable cost except by eliminating all possible friction at the supports. Dynamometers for measuring the tension are of value as a means of knowing the tension at all times, but they cannot be relied on to set the sag. The final sag should be adjusted by sighting. Walkie-talkie radios are widely used as standard erection equipment; better and more efficient work is obtained by having direct communication between the reel crew, the pulling crew, and the workers doing the sagging.

Sags are measured by setting sights on the structures at each end of the span at a vertical distance below the conductor support equal to the sag. This method is convenient and well within the necessary accuracy, even for inclined spans. For average inclined spans, the sag is taken as the sag for a level span of the same horizontal length, although the sag for a level span equal to the slope distance is more nearly correct. Except in extreme cases the horizontal and slope distances are practically the same. On long, inclined spans, when the low point of the sag falls below the ground level of the lower tower, it is more convenient to measure the vertical sag below the lower support.

Accuracy of Sagging. Friction in sagging blocks prevents the wire from reaching exactly the same tension at all points. As the wire is pulled up, the sag tends to be greater in spans from the pulling point; and when slacked back somewhat, more sag is thrown into the nearer spans. These effects are usually fairly well eliminated by allowing some time for the tension to equalize and by skillful handling.

Curves of "span versus sag" and "span versus tension" for possible stringing temperatures are used in sagging. The actual conductor temperature in sagging is very important. The IEEE Committee Report on Stringing and Sagging Conductors, *Trans. IEEE Power Group*, December 1964, p. 1235, recommends that the temperatures be obtained by direct measurement at the time of sagging by means of a thermometer placed inside a short length of the conductor and suspended at least 15 ft above the ground. Accurate temperature also is important in making allowance for creep during stringing. Creep elongation starts as soon as the conductor is pulled into the air, and it is important that this elongation be allowed to take place and not to pull the conductor back up to the calculated sag. One way to do this is to use a temperature curve which will indicate the calculated sag plus the additional sag due to creep up to the time of clipping in. The creep sag must be estimated from the manufacturer's curves.

In spans of varying length a greater sag tends to form in the long spans; and on steep grades the sags at the higher elevations tend to be less than at the bottom of the hill. These effects are not of importance except in extreme cases and are due to the fact that the wire is, and must be, supported on rollers in such a way as to be entirely free to travel. Thus the tension in the wire on each side of the roller must be equal irrespective of the slope of the wire away from this support, and the resultant on the support is not vertical but in the direction of the bisector of the angle between the slopes of the wires as they leave the roller on each side. At a support between a short and long span (Fig. 14-51) the wire on the short-span side is more nearly horizontal, *OA*, whereas on the long-span side the wire may have a considerable slope *OB*. The tension on each side must be equal, $OA = OB$, but the horizontal component of the tension is therefore less in the long span *BD* than in the short span *AE*. The resultant *OC* is inclined.

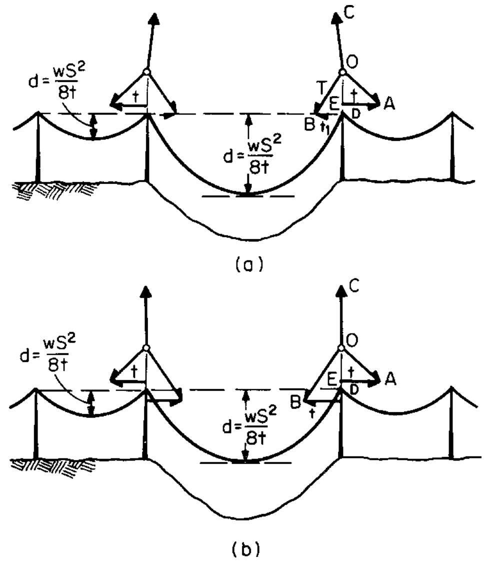

FIGURE 14-51 Diagrams illustrating the change in tension in long spans: (*a*) on rollers; (*b*) clamped in theoretically correct position.

It is theoretically possible, although very difficult practically, to clamp the conductor at the correct position so that the resultant will be vertical and the horizontal tensions equal as in Fig. 14-51. This is the condition assumed in the computations and office location and, for all except extreme cases, is the reasonable assumption.

Similarly, the different slopes of the wire leaving the roller on hillsides with spans of equal length but at different elevations cause the horizontal component of the tension to be less in the wire with the greatest slope (Fig. 14-52). With a series of spans on a slope this effect tends to accumulate, for the horizontal tension t_2 at the upper support must be the same as the horizontal tension t_2 at the lower support, whereas the resultant tension T_2 is less than the tension T_1 because of its smaller slope.

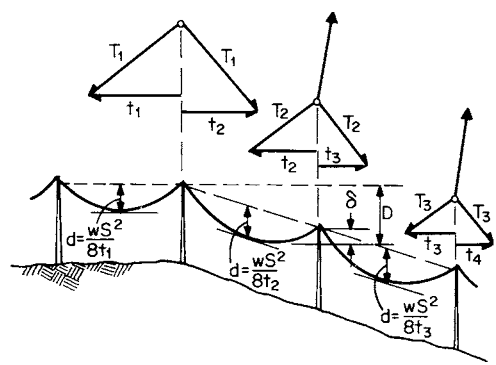

FIGURE 14-52 A much-exaggerated illustration showing the change in tension on hillsides.

The differences in sag are not usually carried from one conductor pull to the next, but each pull is sagged to approximately the correct tension independent of the other; thus when the snubs between pulling sections are removed, differences in tension tend to equalize. For this reason it is best not to clamp in the conductors too close behind the sagging crew. Often skillful sagging reduces these effects by using the friction in the blocks to prevent the conductor from "collecting in the low spots."

These irregularities are of little consequence generally, especially when it is realized that the important consideration is to have equal tensions under maximum load rather than under bare-wire conditions. In extreme cases, provision for the above conditions may be made by special sags, allowing somewhat higher tensions in spans above the normal level of the line and providing extra clearance in low sections so that slightly larger than normal sags may be used. Occasionally special methods must be devised.

Compression Joints. These joints are used with the large ACSR conductors and the large "all-aluminum" conductors, including the high-strength types. As with the compression dead ends, the most widely used joints are those made by Somerset Products Co., a subsidiary of Thomas & Betts Corp., and the Alcoa Conductor Products Co. of the Aluminum Company of America. Cutaway drawings of these joints are shown in Fig. 14-53. They consist of aluminum sleeves and steel sleeves for ACSR. Installation procedures call for the aluminum cable and the insides of the aluminum sleeves to be thoroughly cleaned.

If the conductor is weathered, the strands should be unlayed and all scale removed. The aluminum sleeve is then slipped on the cable and backed out of the way. The aluminum on each cable end is next carefully cut back, care being taken not to nick the steel core, for a distance equal to one-half the length of the steel sleeve plus a distance of 1/2 in or more, depending on the size of the conductor, so that the elongation of the steel sleeve on compression will not interfere with the free lay of the aluminum strands. The conductor ends are then marked by tape or other suitable means to center the sleeve. The steel sleeve is put in place and compressed, working from the center out. The aluminum sleeve is next slipped into place and filled with the nonoxidizing compound furnished with it, the filler holes are plugged, and the joint is ready for compression. The sleeves are compressed by working from the center out. The center section of the aluminum sleeve over the steel sleeve is not compressed. When the compression is completed, the Alcoa sleeve is hexagonal and smooth from overlapping compressions, and the Thomas & Betts sleeve, also hexagonal, has uncompressed ribs between the compressions as shown in Fig. 14-53.

Overhead Ground-Wire Installation. Overhead ground wires should receive no less care in erecting than the conductors because the usual zinc or copper protective coating is very easily destroyed. Ground wires should be sagged in the same way as the conductors except that the important factor in ground-wire sags is to maintain ample clearance to the conductors. Generally, ground wires are sagged to about 80% of the conductor sags, thus ensuring proper clearance even under ice loads. McIntyre joints are frequently used for splicing, but a much more efficient joint can be made with the pressed-steel joint similar to the ACSR joint illustrated in Fig. 14-53.

In addition to wind and ice loads, overhead ground wires are subject to lightning damage and burning at connection points due to power frequency fault currents. Ground wires are sometimes equipped with jumper connectors at tower attachment points to help bypass fault currents. Three-eighths-inch steel ground wire is reasonably resistant to most lightning currents, but positive lightning strokes, or "winter lightning," although relatively rare, can heat the stricken point sufficiently to damage the wire or possibly to cause it to separate.

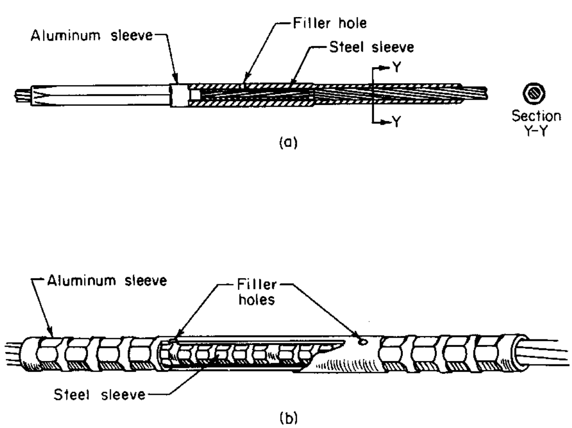

FIGURE 14-53 Compression joints: (*a*) Aluminum Company of America (*b*) Thomas & Betts.

14.1.12 Transpositions

Transpositions[88,89] are made for the purpose of reducing the electrostatic and electromagnetic unbalance among the phases which can result in unequal phase voltages and currents for long lines. Untransposed lines also can cause inductive interference with paralleling wire communication lines. However, communication interference in the past has been largely with overhead long-distance telephone and telegraph lines. Most of these lines are now going underground, and other overhead lines are being replaced by microwave radio.

For some time, transpositions were little used. With the large power-system networks comprising most of the country's transmission lines, the unbalance of an untransposed line is largely smoothed out by the phase-balancing effect of the rotating equipment scattered over the system. The transpositions, however, do enhance the reliability and efficiency of the line in the following respects: (1) they restrain the amount of current which one line will induce in the other, thereby enhancing the reliability of fault arc extinction in the event of a faulty circuit; (2) they serve to reduce transmission power losses; (3) depending on their location, transpositions can serve to reduce the electromagnetic coupling of power-line currents in adjacent telecommunication lines.

14.1.13 Operation and Maintenance

Operation. Effective operation of a system is as essential to good service as is excellent engineering design. In fact, a well-designed system may fall short of its service requirements owing to faulty operation. Aside from switching lines and power units to meet the load conditions of the system, operation consists not only in restoring service promptly after an interruption but also in detecting and removing faulty apparatus, thus actually preventing the development of faults.

A chief system operator should be in absolute control of the system, and if it is a small system, he or she should have direct communication with and direct control over every part of it. If it is a large system, it will not be possible for one person to supervise all switching operations, and area dispatchers must be located at convenient points. These dispatchers will have the same authority over their areas as the chief system operators for small systems. The area dispatchers will call on the chief system operator not only for approval of unusual switching operations, particularly those involving interruptions to important loads. They will, however, make reports each shift, as convenient, on routine switching operations and will report major interruptions as soon as possible, with cause if known. Dummy boards are useful at dispatching centers. These boards should show the one-line diagrams of the circuits at all stations under the dispatcher's supervision, and provision should be made to show whether switches are open or closed. These boards must be kept correct up to the minute, even if it is necessary to do so by temporary means. It is best to anticipate system changes so that the dummy board can show the changes as soon as they are made. During normal operating conditions no switching should be done, including that of generators, without the dispatcher's permission. All dispatching orders should be reported back in order to prevent misunderstandings and should be recorded in log books both by the dispatcher and by the operator who will do the switching. The logs should show a record of all transactions, with particular care about times of receiving orders, of opening and closing switches, and of cases of trouble.

Emergency routines should be set up for all stations and should be followed at times of catastrophic storms when all means of communication with the dispatcher are interrupted. These routines will list the sequence for doing emergency switching on the operator's responsibility in an effort to restore service.

Supervisory control systems make it possible for operators at one transmission substation to operate several nearby substations as well as their own and thereby reduce operating personnel. Supervisory control also makes it possible for one central dispatching office to operate all the transmission substations serving a large metropolitan area. The supervisor may utilize carrier-current, fiber-optic wires, microwave radio, or telephone channels for transmitting information and operating switches.

Sleet or glaze formation on lines is highly undesirable, and some companies prevent it by raising the temperature of the conductors with current. Ice will form on conductors over a small temperature range which is on the order of −3 to +2°C. The current required to prevent ice formation may be found according to Clem[90] from

$$I^2 = \frac{\theta\sqrt{dv}}{8.18 \times R} \times 10^4 \tag{14-88}$$

in which I = current, θ = temperature rise in degrees Celsius above surrounding air, R = conductor resistance in ohms per mile at 20°C, d = diameter of conductor, and v = wind velocity in miles per hour.

With the lines in service, it is usually difficult to obtain sufficient current. However, the necessary current sometimes may be obtained by transferring load from other lines to the line in trouble. Dead lines may be heated by short-circuiting them at one end and sending the necessary current from the other end. The approximate voltage to neutral is $E = I\sqrt{R^2 + X^2}$, where R = resistance per wire and X = reactance per wire.

Melting the ice after it has formed is considerably more difficult and requires more current than is required to prevent formation. Clem's article gives the various formulas required to calculate the melting current.

Maintenance. Periodic inspection is normally maintained over all lines, with the frequency of inspection depending on the country traversed and the importance of the lines. In some densely settled areas, patrols of once a week may be considered necessary, whereas important lines in areas subject to heavy storms or other hazards may not require inspections more than once in 2 months. Patrollers may cover the line on foot, on horseback, by automobile, by all-terrain vehicles (ATVs), or by helicopter, depending on the characteristics of the right-of-way. Close and accurate patrolling is not obtained by one person in an automobile, in general, even when the line follows a highway. Helicopter patrol is by far the best over mountainous and sparsely settled country, and 200 mi a day can be covered readily. The helicopter can fly as slowly and as close to the line as is necessary, and it has the great advantage that the patroller is looking down on the line instead of up against the bright sky as a background. Tower and wood-pole structure numbers should be fastened to the tops of the towers or structures in such a manner that they can be read without trouble by the person in the helicopter. Helicopter patrol cannot be used over urban areas or congested industrial areas because of governmental restrictions on height of flight. Patrols on foot are best in such areas. Horseback patrol is best in cattle-range country, if aerial patrol is not available.

Landslides, washouts, danger timber, or anything else that is a potential danger to the line, such as piles of brush or straw which if burned could cause hot gases to short circuit the line, should be reported. Of course the person on patrol must also be on a close lookout for damaged conductors, insulators, and structures. A pair of field glasses is usually considered indispensable.

Personnel on ground patrols should keep the dispatcher informed as to their whereabouts and should call in from all patrol telephone stations and from substations as they reach them. They should call in not less often than morning, noon, and night. If a storm comes up while patrollers are out on a line, they should call the dispatcher as soon as possible, telling where they can be reached. Patrol cars and helicopters are radio-equipped.

Tree gangs whose sole duty is to remove brush, trim trees, and remove danger timber have been found to be advantageous by large companies. The use of chemical sprays to kill brush along rights-of-way is satisfactory from the standpoint of killing the brush if legally permissible but leaves a potential fire hazard. Care must be taken in spraying that wind does not blow the chemicals over growing crops. This danger has been found to be a disadvantage in helicopter spraying.

Emergency crews are stationed at locations always available by telephone or radio so that every important section of the transmission system can be reached by a crew within a reasonably short time. Small houses containing spare parts, such as insulators, lengths of cables, and clamps should be located at intermediate and accessible points along the line in sparsely settled country. Such houses should be kept locked. Some companies employ concrete construction with iron doors. A routine inspection and checking of materials in such houses is advisable. A light truck, provided with two-way radio and with the necessary tools and materials for making immediate repairs, is used by many companies. In addition to spotlights on the truck, a spotlight operated from a portable storage battery is frequently very useful. Small houses containing spare parts, such as insulators, lengths of cables, and clamps, should be located at intermediate and accessible points along the line in sparsely settled country. Such houses should be kept locked. Some companies employ concrete construction with iron doors. A routine inspection and checking of materials in such houses is advisable.

Line repairs and replacements are accomplished either when the line is energized or deenergized. The line crew should notify the dispatching office when a particular line or section is desired. If deenergized maintenance is desired, the line should then be not merely cleared through the circuit breakers but opened by disconnecting switches as well. If it is to be out of service for an extended period and there is danger of lightning, the line should be grounded out at its terminals to prevent the possibility of flashing over switches or insulators at the terminals. If the line is not equipped with grounding switches, it may be grounded out by equipment such as is used by line crews. Before the line crew is allowed to work, the line should be short-circuited and well grounded on each side of the location where the crew will work, with the grounding equipment in full sight. The grounding equipment should consist of heavy extraflexible copper cables, which should be attached by means of "hot-line" tools and clamps, the line being considered to be "hot" until the grounding equipment is applied. Ground chains are not safe and should not be used. Reliance should not be placed in grounding switches or grounding cables at the ends of the line.

In order to make repairs and replacements without interrupting the service, special "live-line" tools have been devised whereby insulators may be replaced, conductors spliced, etc., on lines of all voltages while the line is hot. Live-line maintenance methods are described in an IEEE Task Group Report[91] of the IEEE Transmission and Distribution Committee (1973). It covers methods and equipment for live-line maintenance. A foundation is presented from which working clearances and methods can be developed for specific needs in particular applications. A bibliography[92] concerning live-line maintenance is available.

Damaged insulators and insulator sections may be detected while they are in service, but suitable precautions should be followed. In general, the methods employed for faulty-insulator detection are based on the measurement of the voltage gradient across the individual units of a string of suspension insulators or across the parts of multipart pin-type insulators. For safety reasons, none of the test methods should be used in wet weather.

Faulty insulators may also be detected by special radio interference locators consisting essentially of a sensitive battery-operated receiver coupled to either a directional loop antenna or a "whip" antenna. The latter type may be attached to a hot-line stick to enable close investigation of the insulator under test. Infrared techniques are also employed.

The Doble method[93] is, in effect, a spark-gap voltmeter which is safe to use and which gives high accuracy in measuring potentials in the field on live transmission-line insulators.

There are two general types of Doble safety tester: the type A single-prong tester for multipart pin-type insulators on either wood or steel construction, and the type B two-prong tester for multiunit suspension-type insulators on either wood or steel construction. The type B is most applicable to transmission lines.

The equipment consists of a micrometer spark gap in series with a capacitor and a special telephone-type headset with which to listen to gap sparkover. The telephone receiver is heard through a rubber hose connected to a highly insulated hollow tube which is long enough so that there is no danger to the operator.

Both sides of the electric circuit of the tester are terminated by exposed metal tips (Fig. 14-54) arranged so as to bridge readily a single insulator disk or section. In the circuit between the two contact tips, a protective insulating capacitor is built into the tester in such a manner as to make the impedance between its terminals greater than the impedance of a single good disk. Thus, in operation, the tester *does not short-circuit* the disk under test. The tester may be considered as a voltmeter which indicates the voltage between the points on the insulator touched by the tips of the tester.

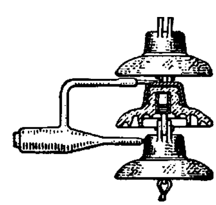

FIGURE 14-54 Doble insulator tester using the principle of a spark-gap voltmeter for suspension insulators.

The degree of defect in the disk under test is indicated by the size of the maximum gap at which a noise is heard in the tester, as compared with the size of a maximum gap for a good disk in the same position in a string; a

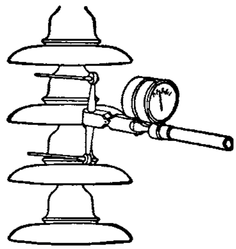

FIGURE 14-55 The I-T-E Imperical Corp. two-prong live-line insulator tester.

totally dead disk gives no sound, irrespective of the gap setting. In practice, one gap length is fixed in advance and used for all units of the string. The operator judges if a unit is defective from the noise heard in the headset. This apparatus is in use for testing insulators on lines at voltages from 11 kV through the medium transmission ranges.

The I-T-E Imperial Corp. live-line insulator tester detects defective insulators, either multipart pin-type or suspension, by comparing the measured voltage distribution over insulators or insulator strings while in service with characteristic curves plotted for good insulators of the same type. It is suitable for use in testing insulator integrity on transmission systems with nominal voltages through 230 kV. The tester employs a single-prong head for multipart pin-type insulators, a small two-prong head (Fig. 14-55) for suspension strings or small one-piece insulators, and a large two-prong head for multipart pedestal insulators. Visual indication is given by means of a meter which shows a deflection in proportions to the voltage gradient. Since relative indications only are required, the meter is calibrated simply in units of deflection. Tests may be made of all shells of multipart pin-type insulators and all units of suspension strings with equal facility. As with the Doble tester, tests should be made only on perfectly dry insulators.

Doble field power-factor test is used (in contrast to that previously described) for testing the insulation of electrical power apparatus *with the apparatus out of service*. Dielectric watts loss and charging current are measured at selected test voltages up to 20 kV, from which power factor, capacitance, ac resistance, and the presence of ionization (corona) can be determined. The specimens to be tested may be in the substation or in the service building.

The test equipment is capable of determining the condition of electrical insulation of bushings, bus supports, cables, capacitors, circuit breakers, insulators, surge arresters, liquid insulation, potheads, rotating machinery, transformers, and voltage regulators. Power-factor measurements with this equipment have been adopted by many companies as a criterion for servicing power-apparatus insulation.

High power factors or sudden increases in power factor from a previous test indicate contaminated or deteriorated insulation which may be an operating hazard. Changes in the watts loss, charging current, ac resistance, and capacitance between tests are also used for indicating operating hazards in apparatus insulation.

A variety of other makes of portable insulation testers, both ac and dc, are available for use in testing line insulation, if desired, when the line is out of service.

14.1.14 Foundations

Lattice-Tower Foundation Loads and Displacement Criteria. Lattice-tower foundation loads consist of vertical tension (uplift) or compression forces and horizontal shear forces. For tangent and small-line-angle towers, the vertical loads on a foundation may be either uplift or compression. For terminal and line angle towers, the foundations on one side may always be loaded in uplift while the other side may always be loaded in compression. The distribution of horizontal forces between the foundations of a lattice tower vary with the bracing of the structure. A typical free-body diagram of foundation loads is shown in Fig. 14-56.

When the foundations of a tower displace and the geometric relationship of the tower to its foundations remains the same, any increase in load due to this displacement will have a minimal effect on the tower and its foundation. However, foundation movements which change the geometric relationship between the tower and its foundations will redistribute the loads in the tower members and foundations. This will usually cause greater reactions on the foundation that moves least relative to the tower, which in turn will tend to equalize this differential displacement.

Presently, the effects of differential foundation movements are normally not included in tower design. Several options are available should the engineer decide to consider differential foundation displacements in the tower design. These options include designing the foundations to satisfy performance criteria which will not cause significant secondary loads on the tower, or design the tower to withstand specified differential foundation movements.

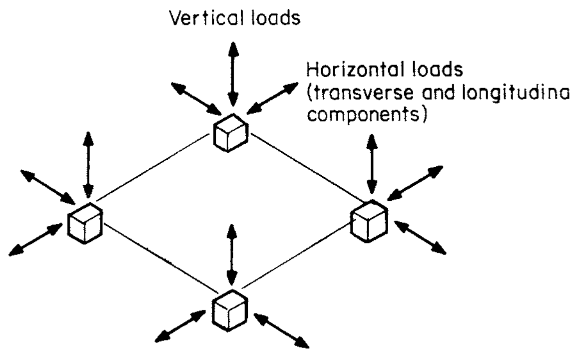

FIGURE 14-56 Typical loads acting on lattice-tower foundations.

Single-Shaft Foundation Loads and Displacement Criteria. Single-pole structures have one foundation so that differential foundation movement is precluded. The foundation reactions consist of a large overturning moment and usually relatively small horizontal, vertical, or torsional loads. Figure 14-57 presents a free-body diagram of the loads.

For single-shaft structures, the foundation movement of concern is the angular rotation of the shaft in the vertical plane and horizontal displacement of the top of the foundation. When these displacements have been determined, the displacement of the conductors can be computed. Under high-wind loading, a corresponding deflection of the conductors perpendicular to the transmission line can be permitted. Accordingly, a large ground-line displacement of the foundation could also be permitted. As a result of foundation rotation, the clearance between the conductors and the structure would be decreased only for structures with single-string insulators. The midspan ground clearance and the change in line angle would also decrease a negligible amount.

In establishing displacement criteria for single-shaft-structure foundations, consideration should be given to how much total, as well as permanent, displacement can be permitted. In some cases, large permanent displacements might be aesthetically unacceptable and replumbing of the structures and/or their foundations may be required. In establishing displacement criteria, the cost of replumbing should be compared to the cost of a foundation that is more resistant to displacement.

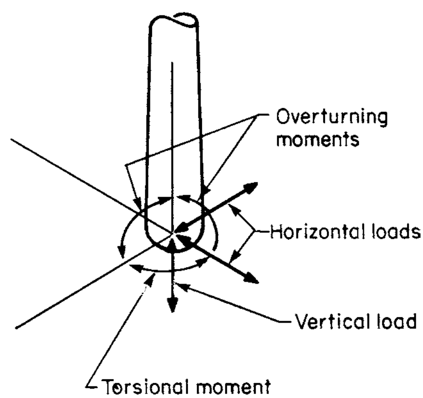

FIGURE 14-57 Typical loads acting on foundations for single-shaft structures.

For terminal and large-line-angle structures, large foundation deflections parallel to the conductor may be intolerable. For these structures, excessive deflections may reduce the conductor-to-ground clearance or affect the load capacity of adjacent structures. There are also problems in the stringing and sagging of conductors if the deflections are excessive. These problems are usually resolved by designing a more deflection-resistant foundation, construction methods, or use of permanent guys.

Framed Structure Foundation Loads and Displacement Criteria. These structures are dependent in part for their stability on one or more of their joints resisting moment. The foundation reactions are dependent on which joints can resist moment and the relative stiffness of the members. Figures 14-58 and 14-59 present free-body diagrams of four- and two-legged framed structures. If the bases of

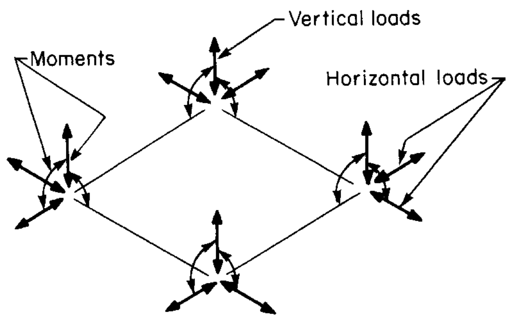

FIGURE 14-58 Typical loads acting on foundations for four-legged framed structures.

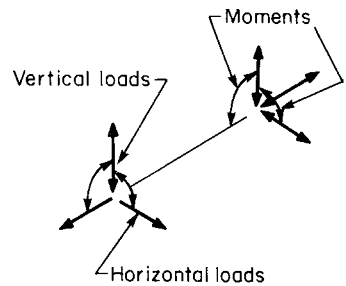

FIGURE 14-59 Typical loads acting on foundations for two-legged framed structures.

structures are assumed as pins or universal joints, then the moments acting on the foundations will theoretically be zero.

Many different types of two-legged, H-framed structures are in use in transmission lines. This has been particularly true since visual impact has become of greater concern.

The H-frame structure is particularly applicable for wood, tubular steel, and concrete poles. The crossarm may be pin-connected to the poles. These structures may be unbraced, braced, or internally guyed as shown in Fig. 14-60.

As with lattice towers, past practice has not usually included the influence of foundation displacement and rotation in H-frame structure design. Significant foundation movements will redistribute the frame and foundation loads. The foundations can be designed to experience movements which will not produce significant secondary stresses, or the structure can be designed to a predetermined maximum allowable foundation displacement and rotation.

Typical HV and EHV Guyed Structures. *Guyed Portal Structures.* The design and utilization of guyed-mast transmission structures (guyed towers) has evolved very rapidly since the mid-1960s or so, and the subject warrants discussion. A high-strength wire stranding used in tension and a latticed mast in compression with limited bending are two of the most efficient structural components, a point not lost on designers of transmission lines in northern Europe during the early days of transmission of electricity.

The most popular form was the guyed portal tower (Fig. 14-61), in which two tripods, each essentially consisting of a mast and two guys, were held apart at the tops by a rigid crossarm. The arrangement permitted the use of two mast footings (compression with a little shear load) and if the structure was not too tall, the four guys could be brought to two anchors, each doing double duty. The structure also offered the possibility of easy ground assembly and erection by one-piece rotation using a gin pole or A frame. Portal tower application was to a large extent limited to flat terrain and relatively short towers (short spans or low voltages) as rough terrain required masts of different lengths, which

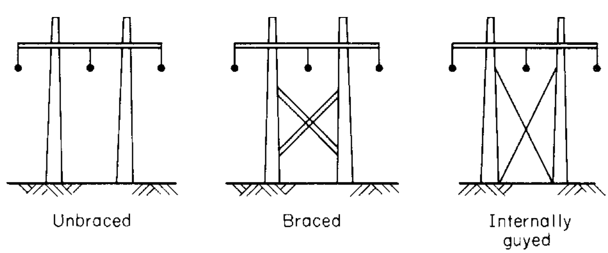

FIGURE 14-60 Typical H-frame structures.

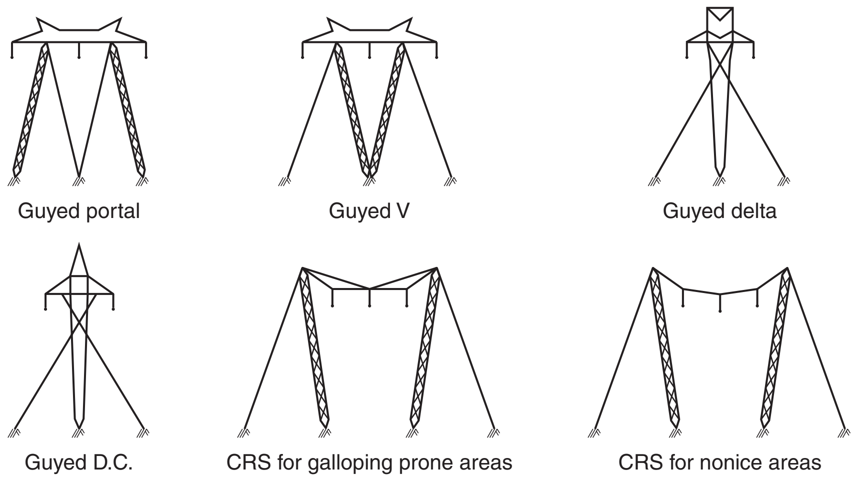

FIGURE 14-61 Typical externally guyed structures.

complicated the usual erection methods and tall structures made common guy anchors an impossibility or else greatly increased the tower stresses under transverse loading.

Guyed-V Tower. In 1957, the guyed V tower was developed[94] so that the guyed-mast principle would be more suitable for rough terrain; the guyed V consisted of the same two tripods moved laterally but was now held together by the crossarm.

Introduction of the guyed V helped promote the initial and serious use of helicopters for line construction for the first guyed-V towers, which were designed in aluminum. The very light weight of both the aluminum material and guyed-mast concept permitted transport and erection of a complete structure with the limited capacity of the helicopters then commercially available. Guyed-V tower use expanded rapidly with thousands of kilometers of lines built at up to the 500-kV level, fabricated in both steel and aluminum as the economies of the V principle were proving to be sufficient to justify use even when helicopter erection was not warranted.

Application expanded into the 750-kV class in the United States, Brazil, and Canada, and nominal spans were consistently in the 450- to 500-m range as the low cost of the extra height of taller towers (two masts and some guy wire) were extending the optimum envelope.

Single-mast guyed towers such as the delta were developed that offered compaction benefits and were also easy to use on rough terrain as they also require only one compression footing; the guy lengths are cut as required to fit the terrain. The guyed-V tower became the most widely used tower at the higher voltages, although all forms of guyed-mast structures were usually restricted to open terrain and areas where widespread guys were not considered to be hazards to the use of large farm equipment or where land occupancy was not a problem.

Cross-Rope Suspension (CRS) or Chainette. The next step in guyed-mast development followed from the failure of a 750-kV class tower due to material defect, a failure in a remote area where construction had been by a large mobile crane that could move only on the frozen winter roads. The replacement guyed-V structure was too heavy for available helicopter lift, and the repair was greatly delayed until crane access came with winter weather.

As voltages increase, all towers tend to become top-heavy, and the guyed-V or guyed-Δ are no exceptions. The urge to dispense with the crossarm led to the development of the *cross-rope suspension* (CRS) tower or *Chainette*, as it is referred to in Quebec, Canada.

The CRS concept was actually derived from the successful CRS system built in the mountains of British Columbia, Canada in 1955[95,96] and uses one or more wire ropes suspended between two guyed masts to replace the crossarm and support the insulator strings. Even at 1000 kV, the individual masts are well within the capacity of modest low cost helicopters, and thus the problems of initial construction and emergency replacement are easily solved, with crane or helicopter. The initial design of the CRS[97,98] made use of the six-part suspension assembly because it was feared that galloping of a single phase might find the support point forces transferred through the rope system to the other phases and thus promote widespread and damaging activity. The CRS found application on the third, fourth, and fifth lines of the 735-kV James Bay system in Quebec and on a section of 500-kV lines in Oregon, in the United States.

The next applications and development have come about in South Africa at 400 kV and in the Argentine at 500 kV, where a single cross rope is used because of the absence of any significant icing and thus no fear of galloping.[96]

All CRS lines must use a special construction or spacer rope extending between the tops of the masts; the initial use is to position the mast tops before the conductors are in place to provide tension to the system and subsequently to provide means of access to the phases by use of a wheeled ladder for both stringing and sagging work and for maintenance.

The CRS type of construction has a few negative aspects as it requires space at the tower sites (an open area that can be farmed), but the positive points are many. Both single- or multiple-rope CRS systems permit reduced phase spacing with increased SIL values and limited only by gradient effects or fear of wind clashing. On the 1150 km of the 500kV line in the Argentine studies showed that clashings were a negligible threat and the reduced phase spacings available by the CRS increased SIL values and reduced compensation costs by many millions of dollars. All wire rope components including the guys are precut to length and can be tested to working loads, and length adjustment is included in only one of the guys. The weight of structural steel in a tower will be about 50% of that of a comparable guyed-V or guyed-Δ tower. With overhead wires attached directly to the tops of the masts, the lightning protection is about as good as possible and the extra relaxation provided by the suspended wire assembly added to the insulator strings ensures that cascading potential is negligible.

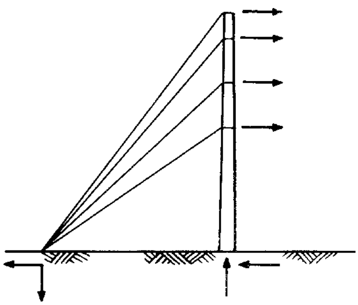

FIGURE 14-62 Single-shaft externally guyed structure.

Guying Rigid Structures. The guyed structures of the preceding section consisted of structural components pivoted or free to rotate at the connections to the foundations. Thus, the guy loads are in all cases determined by simple static analysis. The addition of guys to structures that are fixed or rigidly attached to the foundations (Fig. 14-62) produce arrangements that are indeterminate to varying degrees and for some, the analysis of strength can be quite complex and performance will be dependent on introducing and maintaining precise levels of guy pretension.

The problems arise because of the large strains or stretch that guys develop in order to resist the loads and the varying degrees of rigidity of the structures that they are guying. Guyed-pole structures, as shown in Fig. 14-62, if they are wood and single-pole or the very common H-frame structure, are readily guyed, since the wood components are relatively flexible and allow the guys to develop load before the poles deflect enough to fail.

However, guyed-metal-pole structures that are fixed at their bases become more difficult to assess and analysis is usually needed to confirm both the distribution of loads between the guys and the poles themselves and also to set the pretension needed in the guys to ensure that the deflections or distortions of the components remain within limits. The design engineer must be conscious of the fact that deflections of poles can introduce large additional bending stresses caused by the P-Δ effect—the pole compression acting on the moment arm of the bow of the pole.

The most complex situation arises from attempts to guy rigid lattice structures (Fig. 14-63). In order to resist a load applied to the structure, the guys will normally stretch so much that the rigid structure will already have failed. Successful guying in such a manner requires either oversized guys to limit the stretch of the guys or very precise levels of pretension, set and maintained to distribute the loads in desired manner between the structure and the guys.

There is one condition under which guying of a rigidly framed structure is readily done and that is when the purpose is to restrict the movement of the structure on failure. Longitudinal guying of rigid structures or even of H frames is a method of creating stop towers to limit the movement of slack and thus stop a cascading of structure if one is under way. Transverse guys are sometimes applied outside of heavy angle structures to restrict their failure mode and thus limit the amount of slack that can be introduced into the line system if the tower failure occurs under an extreme ice loading.

Foundation Types. A wide variety of foundation types can be used with self-supporting or guyed lattice, framed, and single-shaft structures. They include the following:

Lattice tower	Framed and single-shaft structures
Steel grillages	Concrete spread foundations
Concrete spread foundation	Drilled shafts
Rock foundation	Direct embedment
Drilled shafts	

Steel Grillages. Figure 14-64 shows three typical types of steel grillages. Figure 14-64*a* is a pyramid arrangement in which the leg stub is connected to four smaller stubs which in turn are connected to the grillage at the base. The advantage of this type of construction is that the pyramid can transfer the horizontal shear load down to the grillage base by truss action. However, the pyramid arrangement does not permit much flexibility for adjusting the assembly, if needed. In addition, it is difficult to compact the backfill inside the pyramid.

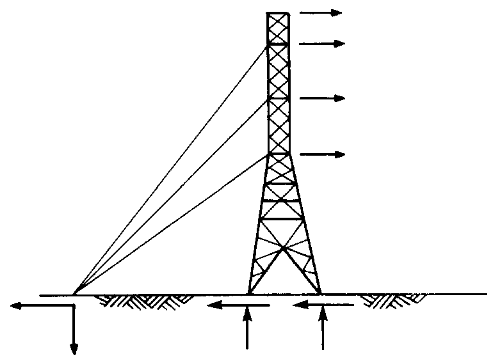

FIGURE 14-63 Externally guyed lattice tower.

Figure 14-64*b* shows a grillage foundation which has the single leg stub carried directly to the grillage base. The horizontal shear is transferred through shear members that engage the passive lateral resistance of the adjacent compacted soil.

Figure 14-64*c* also has the single leg stub carried directly to the grillage base. This type of grillage foundation has a leg reinforcer which increases the area for mobilizing passive soil pressure as well as increasing the leg strength. The shear is transferred to the soil via the leg and reinforcer and resisted by passive soil pressure. The base grillage of these three typical foundations consists of steel beams, angles, or channels which transfer the compressive or uplift load to the soil.

The advantages of steel grillage foundations are that they can be purchased with the tower steel and concrete is not required at the site. The disadvantage is that these foundations usually must be designed before any soil borings are obtained and may have to be enlarged by pouring a concrete base around the grillage if actual soil conditions are not as good as those assumed in the original design. In addition, large grillages are difficult to set with required accuracy. The placement and compaction of the backfill material are critical to the actual load-carrying capacity and load-displacement characteristics of the foundation.

Concrete Spread Foundations. This type of foundation consists of a base mat and a square or round pier. It is constructed of reinforced concrete. There are several variations as indicated in Fig. 14-65. The stub angle can be bent and the pier and mat centered. The mat can be located so that the projection from the stub angle intersects the centroid of the mat or the pier itself can be battered to the tower leg slope.

The stub angle is embedded in the top of the pier so that the upper exposed section can be spliced directly to the main tower leg and diagonals. The stub angle should be of adequate size to resist the

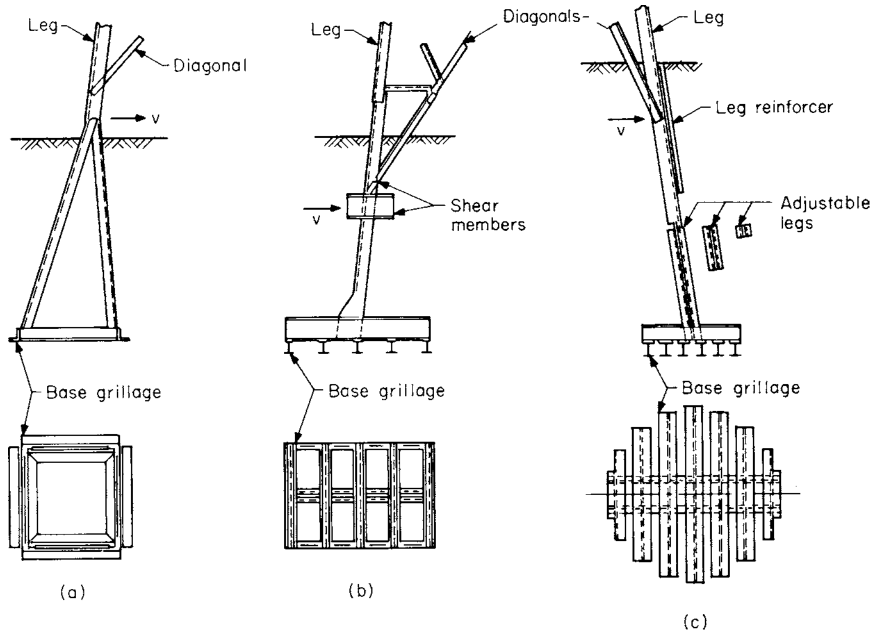

FIGURE 14-64 Typical steel grillage foundations.

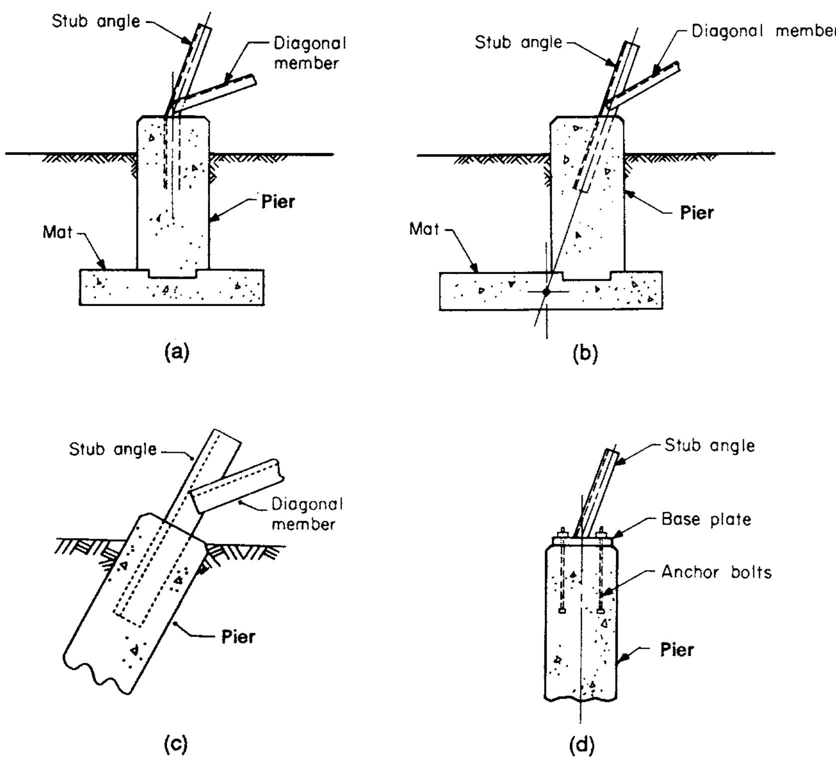

FIGURE 14-65 Typical concrete spread foundations (reinforcing not shown).

axial loads transmitted from the main leg and diagonals plus any secondary bending moment from the horizontal shear, if applicable. The stub angle must be embedded in the concrete to a sufficient length to transmit the load to the concrete. Bolted clip angles or welded stud shear connectors may be added to the lower end of the stub to reduce its length. Anchor bolts can also be used in lieu of the direct embedment stub angle as shown in Fig. 14-65*d*.

Rock Foundations. Many areas of the United States have bedrock either exposed at the ground surface or covered with a thin mantle of soil. Relatively simple, economical, and efficient rock foundations may be installed where this type of terrain is encountered. A rock foundation can be designed to resist both uplift and compression loads plus horizontal shear and, in some structure applications, bending moments. Where suitable bedrock is encountered at the surface or close to the surface, a rock foundation, as shown in Fig. 14-66, can be installed. Bolted clip angles or welded stud shear connectors may be added to the lower end of the stud to reduce its length.

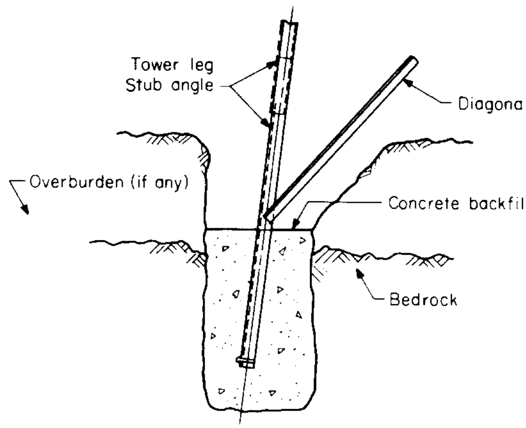

FIGURE 14-66 Rock foundations.

Drilled Shafts. The drilled concrete shaft is the most common type of foundation presently being used to support lattice towers, framed structures, and single shafts. Drilled concrete shafts are constructed by power augering a circular excavation, placing the reinforcing steel and pouring concrete to form a shaft foundation. Lattice towers are attached by embedment of a stub angle or through the use of baseplates and anchor bolts. Framed structures and single shafts are attached through the use of baseplates and anchor bolts.

Drilled shafts can be constructed in a wide variety of soil and rock types. However, the construction of drilled concrete shafts may encounter problems under certain soil conditions. For example, granular soils may collapse into the excavation before concrete can be poured. In soft, cohesive soils, squeezing or shear failure of the soil can occur, producing a reduced diameter or the excavation may become completely obstructed before the concrete is placed. This soil movement in the excavation can result in ground-surface settlement. Thus, casing and/or drilling mud may be required in granular and soft cohesive soils to maintain an open excavation.

Direct Embedment. Direct embedment refers to wood, steel, or concrete pole foundations (both single-shaft and H-framed structures) constructed by power augering a circular excavation in the ground, inserting the pole directly into the excavation, and backfilling the void between the pole and the sides of the excavation. Thus, the pole acts as its own foundation by transferring loads to the in situ soil via the backfill. This technique has been traditionally used for wood-pole foundations and has recently been employed for metal- and concrete-pole foundations.

The quality of backfill, method of placement, and degree of compaction strongly influence the stiffness and strength of a direct embedment foundation. Corrosion of an embedded metal pole is also an important consideration. It should be noted that the presence of granular or soft, cohesive soils may cause the same construction problems for direct embedment foundations as for drilled concrete-shaft foundations.

Subsurface Investigations. The technical requirement of assuring a safe and cost-effective foundation design for transmission structures requires a thorough knowledge of the subsurface conditions along the right-of-way (ROW). The intent of this section is to provide a guide for performing an adequate subsurface investigation for the design of transmission-line structure foundations.

When designing a foundation, the engineer should be concerned with the following factors: (1) the ultimate load-bearing capacity of the subsurface material, and (2) the allowable displacements of the foundation. In the case of grillages and directly embedded poles, the quality of available backfill materials is also a concern. Hence, the objectives of a subsurface investigation are to determine the stratigraphy, physical characteristics, and engineering properties (particularly the strength and deformation characteristics) of the soil or rock underlying a given site.

To determine the most cost-effective foundation, it is necessary to consider the engineering and physical properties of the subsurface materials; construction costs; the construction aspects of a particular foundation type and how they are influenced by such factors as groundwater elevation, safety requirements, contractor capability and experience, and environmental constraints.

The scope of a subsurface investigation will vary depending on foundation loads, type of structure, and probable foundation types, types of subsurface materials, and previous knowledge of subsurface conditions along the line route. It is necessary to use engineering judgment when considering the scope of the subsurface investigation. A detailed outline for developing a cost-effective investigation is given in an EPRI report.[99]

Design of Spread Foundations. Spread foundations are used to support lattice towers. The design of spread foundations for transmission towers must consider both the direction (uplift or compression) and orientation (inclination and eccentricity) of the applied loads. The foundation must be designed to prevent excessive displacement or shear (bearing capacity or uplift) failure of the support soil. A detailed presentation of estimating the uplift and compression capacity of spread foundations is given in an EPRI report.[99]

Design of Drilled Shaft Foundations. Drilled shaft foundations are used to support lattice-tower, framed, and single-shaft structures. This type of foundation supports vertical compression loads through a combination of side shear and end bearing and supports vertical uplift loads by side shear. Lateral loads and overturning moments are supported by lateral resistance of the soil and/or rock in which the shaft is embedded plus the vertical shearing resistance on the perimeter of the shaft, and the horizontal shear on the base and the base moment.

Compression and Uplift Capacity. Methods for computing the compression and uplift capacity of drilled shaft foundations are given in an EPRI report.[100]

Lateral Load Capacity. The response of a drilled shaft to lateral loads is the result of complex interactions between the shaft and the soil and/or rock in which it is embedded. A common method of modeling this interaction is called the subgrade modulus approach. Reference 101 provides a detailed explanation of a method for determining the lateral capacity of drilled shafts. A computer program, MFAD (Moment Foundation Analysis and Design), originally called PADLL, which was developed as part of the EPRI research project eliminates the simplifying assumptions associated with prior models.

Direct Embedment. The response of direct embedment foundations in compression, uplift, and lateral loads is similar to that of drilled concrete shafts. Most of the analytical techniques used in drilled shaft design are relevant to direct embedment design. The principal differences between direct embedment foundations and drilled concrete shaft foundations are: (1) the backfill which intervenes between the pole and the in situ soil, and (2) the stiffness of the embedded structure shaft relative to that of a drilled concrete shaft. Drilled shafts transfer loads directly to the in situ soil. A detailed presentation for the analysis and design of directly embedded poles is given in an EPRI report.[102] Results from 12 full-scale tests on single-pole direct embedment foundations are given in a related report.[103]

Construction Considerations. Factors affecting, and problems associated with, the construction of drilled shaft foundations can be divided into two general areas: (1) geotechnical factors influencing construction, and (2) construction-related problems. A common geotechnical occurrence is the erosion (sloughing, caving in) of loose granular soil layers, mainly below the groundwater level. Another geotechnical factor influencing the overall capacity of the foundation is the release of stresses due to excavation, especially when the hole is left open for a long period of time (say, one or more days, depending on soil conditions). Some construction-related problems are associated with the use of drilling mud (slurry method), which tends to leave an undesirable film (up to various inches of thickness) of soft material adhered to the walls of the hole. Another frequently occurring problem is the perturbance and remolding generated by the use of casing. Also, problems arise when special geometry is requested by the designer for the drilled shaft (under-ream, shear rings, etc.). In all of these cases, in general, good communication is required between field personnel and designers to permit early detection of these conditions.

Design of Anchors and Anchor Foundations. An anchor is a device which will provide resistance to an upward (tensile) force transferred to the anchor by a guy wire or structure leg member. An anchor may be a steel plate, wooden log, or concrete slab buried in the ground, a deformed bar or a steel cable grouted into a hole drilled into either soil or rock, or one of several manufactured anchors which are either drilled or rotated into the ground. Anchorage may also be provided by vertical or battered drilled shafts or piles. Typical types of anchors are shown in Fig. 14-67.

Anchors may be classified as either deadman or prestressed. Deadman anchors are defined as those anchors which are not loaded until the structure is loaded. Prestressed anchors are loaded to specified load levels during installation of the anchor. An advantage of a prestressed anchor is that most of the initial strains of the anchorage system have been removed before the structural load is applied. Therefore, the full capacity of the anchor can be attained at very small deformation (movements in soil of less than $^1/_4$ in are typical). Another advantage of prestressed anchors is that they are proof-loaded to their design load at the time of installation. Disadvantages of prestressed anchors are

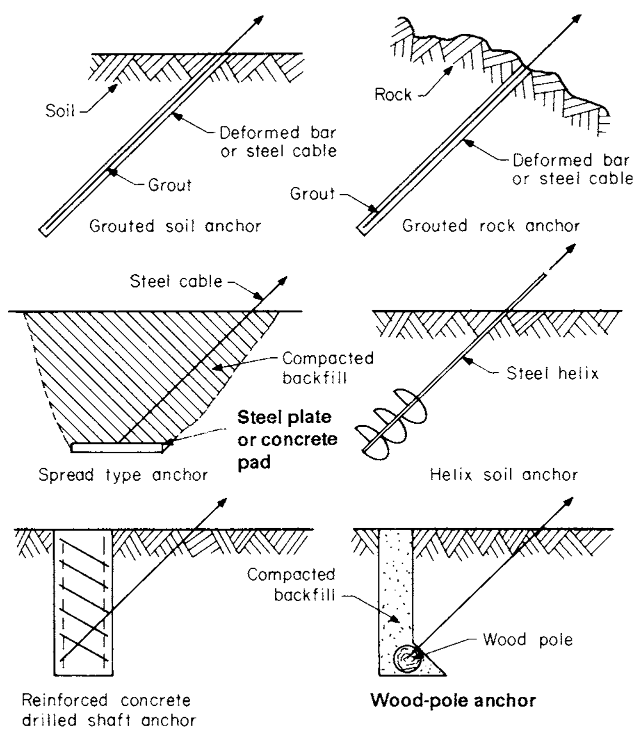

FIGURE 14-67 Typical anchors.

that they are generally more expensive than deadman anchors and they should not be used in compressible soils.

Another advantage of prestressed anchors is that shallow anchors may obtain additional strength by the increased effective stress created by the influence of the bearing plate on the soils adjacent to the anchors.

Deadman anchors may include any of the systems shown in Fig. 14-67. Initial strains in deadman anchors may be reduced by as much as 50% by prestressing them to their design load at the time of installation.

Anchor Application. Anchors are used to permanently support guyed structures, as well as to temporarily support other structure types during erection and stringing. The legs of lattice towers can be anchored directly by rock anchors or helix-type anchors. The uplift capacity of spread foundations may be increased through the use of anchors as shown in Fig. 14-68. Guys and anchors are also extensively used to terminate wire loads on wood structures and to increase wood structure capacity for high transverse loading. At intermediate structure locations, guys and anchors may be utilized to provide additional longitudinal strength. Anchors can be used to increase the load capacity of existing foundations.

Design. The design of an anchor depends on a knowledge of the peak and residual shear strength properties of the soil or rock in which it is embedded. In rock, it is also important to know the degree and depth of any weathering which may have occurred, together with the orientation and spacing of joints and foliation. In addition, an understanding of the load characteristics and the structure deflection tolerance combined with the guy cable elongation is important in selecting and designing the type of anchor. Anchor pullout tests are often conducted to confirm design assumptions where prior experience is lacking.

References 99, 104, and 105 provide detailed information on the design of anchors.

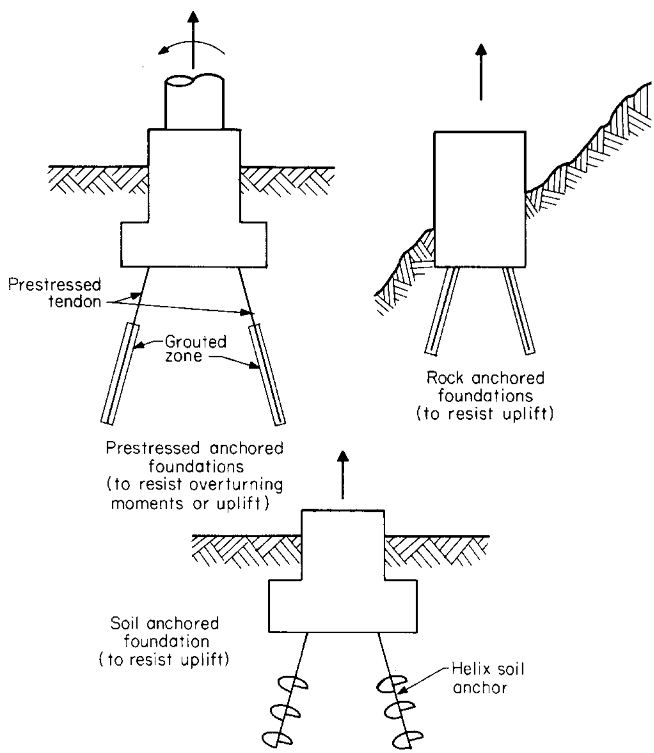

FIGURE 14-68 Typical anchored spread foundations.

14.1.15 Overhead Line Uprating and Upgrading

Performing a transmission line uprating can be very attractive in terms of getting smaller costs and shorter leadtimes when compared to building a new line. Besides that, it can postpone the need of new lines, reduce congestion costs and avoid unnecessary load shedding during contingencies. However, before starting the uprating task, it is important to evaluate some feasibility issues, as well as to choose the most appropriate type of uprating (Thermal Uprating or Voltage Uprating) for a specific transmission line. Each type of uprating requires different kinds of previous analysis and shall be done by its own methods. Sometimes a transmission line uprating also requires a line upgrading. Transmission line upgrading is related to physical modifications to the line.[106,107]

Uprating Feasibility Issues

Technical Feasibility. For this kind of analysis it is important to consider at least the following points:

- *System load requirements*. It is important to evaluate for how long the uprated/upgraded line will satisfy the load requirements.
- *Assessment of current conditions and life expectancy of transmission line materials.* It is important to make this kind of evaluation for the main transmission line components, such as towers, foundations, conductors, insulators, and hardware.
- *Potential margins for uprating/upgrading.* It is important to check electrical clearances, mechanical strengths, ROW width, as well as the possibility of compliance with the requirements of safety codes (e.g., NESC), regulatory bodies and government agencies (e.g., navigable streams, public lands, air lanes).
- *Utility considerations.* Sometimes electric utilities are not authorized to take the transmission line out of service to perform the necessary uprate/upgrade services. In these cases it is important to check if the mentioned services can be done with the line in service.

Economical/Financial Feasibility. For this kind of analysis it is important to consider at least the following points:

- Uprating/upgrading costs vs. new line costs. It is important to remember that technical analysis of old lines usually requires data gathering and this can be very expensive and time consuming. Besides that, it is necessary to estimate what will be the need of the uprated line in terms of additional ROW. Other costs that can be relevant are related to construction (material and labor), maintenance and operation of the uprated line. Environmental costs are usually higher for new lines.
- Uprating/upgrading costs vs. uprating/upgrading benefits.

Environmental Feasibility. For this kind of analysis it is important to consider at least the following points:

- *Environmental considerations.* Usually not so critical when compared to new lines. However, it may be necessary to deal with historical societies, environmental groups, concerned neighbors, and so forth.
- Right-of-way easements. If significant changes will be made to the original line, it is necessary to check the validity of the previous ROW terms of use. It can be difficult to get licensing for the modified line. It is also important to check the existence of ROW encroachments and line crossings that would be unacceptable by the uprated line.

Thermal Uprating

Effectiveness. This kind of uprating can be a good option when the line loading is limited by thermal constraints and the line has margin in terms of maximum allowable conductor temperature.

Previous Analysis to Perform. Before proceeding with a transmission line thermal uprating it is necessary to analyze maximum allowable conductor temperature, conductor-to-ground clearance, magnetic fields, ROW issues, and sometimes structural strengths.

Usual Techniques. Some of the techniques used to perform transmission line thermal uprating are described as follows:

- Performing dynamic thermal rating monitoring
- Raising the thermal limit imposed to the line by some inexpensive substation equipment (e.g., disconnect switches)
- Raising the thermal limit by making similar the thermal limits of all line sections
- Keeping appropriate conductor-to-ground clearances while increasing the maximum allowable conductor temperature
- Bundling the original line conductor with another one, or replacing the line conductor by a more conductive one, to increase the line current-carrying capacity

Some of these techniques have large structural impacts. Performing a transmission line thermal uprating can bring some impact to the substation equipment.

Voltage Uprating. This kind of transmission line uprating can result in a much higher rating increase than thermal uprating. Besides that, transferring the same amount of power in a higher voltage level reduces the line current, and consequently, line losses and voltage drops. However, voltage uprating is typically more expensive than thermal uprating due to the need of also uprating the voltage class of the terminal substations equipment.

Effectiveness. This kind of uprating can be a good option when: the line loading is limited by voltage drop or stability considerations; the line has margins in terms of electrical clearances; the uprating can be done with minimal line modifications or it will be applied to several circuits simultaneously, or the line design criteria can be relaxed.

Previous Analysis to Perform. Before proceeding with a transmission line voltage uprating it is necessary to analyze tower clearances, conductor-to-ground clearance, corona performance, electric fields, ROW issues, and sometimes structural strengths.

Some Usual Voltage Uprating Techniques. Some of the techniques used to perform transmission line voltage uprating are described as follows:

- Addition of insulator units to the transmission line insulator strings
- Replacement of standard insulator units by polymeric or antifog units
- Application of strut insulators (or V strings) to prevent swinging of suspension strings
- Keeping appropriate conductor-to-ground clearances while increasing the transmission line operating voltage
  - Retensioning the existing conductors
  - Performing sag adjustments (cutting out conductor lengths, sliding conductor clamps)
  - Increasing the conductor height at the attachment support (converting suspension strings to pseudo dead-end strings)
  - Increasing the attachment support height
  - Raising towers
  - Moving towers
  - Inserting additional towers
  - Performing terrain contouring (rural areas)
- Bundling the original line conductor with another one, or replacing the line conductor by a bigger one, to assure a good corona performance
- Performing Line Compaction
- Converting a 3-phase double-circuit line to a 6-phase single-circuit line
- Converting a low voltage double-circuit line to a high-voltage single-circuit line
- Converting HVAC lines to HVDC lines

Some of these techniques have large structural impacts.

Voltage Upgrading of Existing Lines. Figure 14-69 illustrates the fact that as transmission voltages increased over the years experience and research has allowed smaller conductor spacings in per unit of the spacing required to withstand power frequency voltage flashover. An observation from Fig. 14-69 is that many lines designed years ago may have clearances sufficient for operation at a higher voltage than the initial operating voltage of the line. Thus, possibilities exist for upgrading the voltage of some older existing transmission lines.

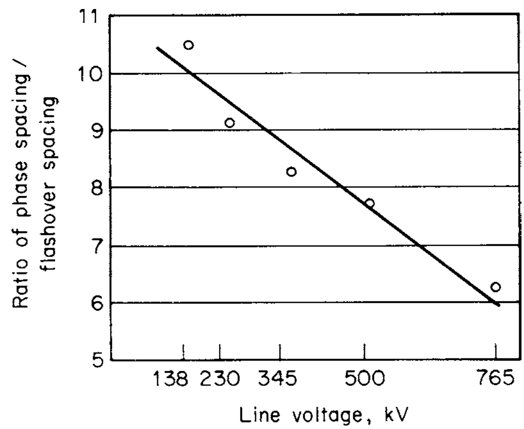

FIGURE 14-69 Phase-spacing ratio versus line voltage.

A voltage upgrading study involves reengineering the line using the best available data. Upgrading differs from new line design because operating experience with the existing line provides a source of data not available to the designer of a new line. It also differs from new line design in that certain reduced design margins may be accepted in order to avoid a complete replacement of structures and conductors.

Voltage upgrading of transmission line ranges from increasing the voltage with minimal modifications to virtual reconstruction of the line. The greater the extent of the modifications, the more mechanical and structural issues become significant. An important part of an upgrading study is careful verification of the existing condition of the line, including conductors, insulators, geometry, structures, and foundations.

Insulation concerns are paramount in a voltage upgrading analysis but trade-offs are frequently necessary between competing requirements. For example, it may not be possible to add insulators of the same type as the original while maintaining the same leakage distance per kilowatt and without adversely impinging on air gap clearances. In such cases several options may be considered, including relaxation of the initial design criteria.

Insulation for power frequency voltage is concerned with contamination performance of insulators and air gaps between energized and grounded line components. An advantage of an upgrading study is the availability of operating experience of the existing line. It is important to carefully review the operating performance of the line at the existing voltage, because problems that may have been previously ignored may become significant with the increased electrical stress at the higher voltage.

Insulator leakage distance required is a function of the degree of insulator contamination at the location of the line. The degree of contamination maybe well known, or if necessary can be determined by laboratory tests. An insulator string can be carefully removed from the existing line so as not to disturb the surface dirt and sent to a laboratory for testing in a fog chamber, or alternatively a sample of the contamination can be taken from insulators on the line and the equivalent salt deposit density determined.

Once the degree of contamination is understood, several options can be considered if there is insufficient space to add conventional insulator units to the strings:

- *Use less leakage distance per kilowatt*. It may be determined that adequate performance can be obtained with less leakage distance than would be customarily be applied to a new line design.
- *Different insulator types*. Additional leakage distance may be possible by application of high leakage or fog-type insulators without excessively lengthening the insulator string length. The hydrophobic properties of polymer insulators may be considered for reducing the leakage distance. Porcelain insulators with semiconducting glaze provide improved contamination performance and may be an option.

Adequate air gap clearances must be maintained under maximum wind swing conditions. Because power frequency voltage is always present, it is necessary to consider insulator swing for the maximum predicted wind speed to maintain adequate clearance for power frequency voltage withstand. It is also necessary to maintain adequate clearances to the edge of the ROW to meet code requirements.

Switching surges have typically not been an issue for the lower transmission voltages. However, in a voltage upgrading, it is necessary to utilize the available space to the maximum degree possible and switching surges can become the dominant effect in limiting voltages. Therefore, a careful switching surge analysis is an important part of a voltage upgrading study. Some transmission lines have been successfully upgraded with proper control of switching surge overvoltages. Control methods may be necessary even at 115 kV and include:

- Use of resistor preinsertion in the circuit breakers
- Application of surge arresters
- Synchronized pole closing circuit breakers

Code and maintenance issues are part of a voltage upgrading study. Control of switching surge overvoltages may allow operation of the line at the new voltage with the same ground clearance that existed previously. The old line may have been designed in compliance with older code editions that are based on a linear relationship between clearance and voltage. Control of switching surge overvoltages may allow use of the alternate clearance calculation and reduced clearances compared to the linear calculation. Likewise, switching surge overvoltages are part of the safety considerations for live line working.

If it is necessary to increase conductor ground clearance to maintain code clearances, retensioning of the conductors may be a possible way of meeting the code requirements. Retensioning conductors increases mechanical forces on dead end and heavy angle structures and necessitates analysis of structure loading. Code ground clearances may also relate to the allowable length of insulator strings. Structures may be modified to increase conductor height. Once structure modifications are considered, structure and foundation loadings must be carefully studied.

Lightning tripout performance is seldom a limiting consideration for a voltage upgrading study. Lengthening the insulator string increases the insulator impulse CFO. Increased voltage adds to the lightning impulse voltage half the time and subtracts half the time depending on the instant of the lightning strike in relation to the power frequency voltage sine wave. The degree of change of line geometry depends on the amount of structural modifications necessary. A lightning performance calculation program can be used to compare the performance before and after the upgrading. Comparison of the calculated performance of the existing line with the line operating record calibrates the program to the line and allows estimation of the change in performance to be expected with the upgrading. Normally the change will be slight. If it is desired to improve the lightning performance with the upgrading, methods such as reducing the structure footing resistance are available.

Corona on energized conductors, hardware, and insulators is a fundamental limitation on the maximum possible voltage on any transmission line. As the voltage is increased, the electric field at the surface of energized components increases. At some point the electric field becomes sufficient to ionize the air and produce excessive corona. Corona manifests itself as electromagnetic interference (EMI—radio noise and television interference), audible noise, and in more extreme cases visible corona and corona power loss. An analysis of corona effects is an essential part of a voltage upgrading study.

Audible noise traditionally has only been a concern for the higher transmission voltages, for example, 500 kV and above. Because corona effects are often the limiting factor for a voltage upgrade, the conductor surface electric field on an upgraded line can be at levels typical of EHV lines, even for 115 kV. Thus, audible noise can become an issue for upgraded lines at voltages where audible noise has traditionally not been a consideration. In any event, it may be necessary to demonstrate adequate audible noise performance to obtain authorization for the upgrade.

Conductor corona caused EMI is the quantity predicted by radio and television noise programs and is the value traditionally used for evaluation of new transmission line designs. The assumption is made that if noise from conductor corona is at an acceptable level, noise from other sources will be insignificant. If EMI limits the voltage below the desired new voltage, mitigation options are reconductoring or adding a second conductor per phase. The second conductor per phase may be added in either a horizontal or vertical configuration. The vertical configuration may be preferred if it impinges less on the air gap clearances to the structure under wind swinging than the horizontal configuration. Reconductoring or adding a second conductor per phase requires a mechanical and structural analysis to ensure the conductors can be properly supported.

While conductor corona EMI is also an essential consideration for voltage upgrading, additional noise sources such as corona on hardware and insulators may become important. "Corona-free" hardware has been used for EHV lines where the electric field on the hardware is greater, while standard hardware has been used for lower voltage lines. The difference for bolted conductor shoes is that standard hardware has the U-bolts arranged so the nuts are on the underside of the shoe, while for corona-free shoes the U-bolts are inverted so the nuts are inside the shoe where they are electrically shielded. Because the electric field on the hardware of an upgraded line may be at levels typically associated with EHV lines, it becomes necessary to change the hardware to corona-free hardware to avoid excessive radio noise.

Under some conditions it may be desired to test hardware or insulators to ensure adequate corona performance. If laboratory tests are performed, care must be taken to properly reproduce the expected electric field at the surface of the hardware or insulators. Traditional laboratory tests have used a voltage above the desired operating voltage and measurement of radio influence voltage (RIV). These tests have been adequate for traditionally designed lines, but may give misleading results for compact or upgraded lines where the surface electric fields are greater than traditional values for the voltage level. Therefore it is necessary to properly characterize the electric field on the device under test.

Experience has indicated that when a transmission line is properly designed for corona-caused EMI, more than 90% to 95% of radio noise complaints and virtually all television interference complaints are a result of spark sources. These spark sources are located and repaired by normal maintenance techniques. Such spark sources include such things as loose bolts or down lead staples on wood poles or films of corrosion between caps and pins of adjacent units in slack strings of suspension insulators. Noise complaint experience for the line considered for upgrading and the physical condition of the line are valuable indicators of the possible presence of spark noise sources. Increasing the line voltage will increase the possibility of spark noise sources and should be considered as part of a voltage upgrading study.

Upgrading voltage might be considered for a line remote from population where audible and EMI noise are deemed of secondary importance. In such a case the possibility of upgrading may be limited by visible corona and corona loss. At some point, as the voltage is increased the power loss in foul weather becomes excessive and increase of voltage becomes impractical.

Voltage upgrading studies are frequently performed in two parts: a preliminary analysis to determine if voltage upgrading of the desired line is feasible, followed by a detailed analysis if the feasibility analysis proves promising. Typical or approximated data may be used to assess feasibility. The scope of the detailed analysis is set by the feasibility study. Not all voltage upgrading studies include all of the same elements. Laboratory tests may be included, in some cases, even construction of a prototype line section for testing. In other cases, some aspects of the detailed study may be of smaller importance because of the degree of margin in the existing design.

Compact Line Design. The most fruitful areas for line compaction are 69- to 230-kV lines, because these designs are generally older, with more generous clearances. Figure 14-70 illustrates a comparison of compact and conventional 230-kV structures. Some compaction is possible, however, at higher transmission voltages by redesign, as shown in Fig. 14-71.

Compact line design techniques may be applied for more efficient use of ROW for new construction, voltage uprating of existing lower-voltage lines, and possible economies. Line compaction is also a tool for reducing electric and magnetic fields at ground level.

A compact transmission-line design analysis consists of the following topics:

Conductor Surface Electric Field and Corona. A given conductor in air has a maximum surface electric field for acceptable levels of corona. EHV lines are typically designed for conductor surface electric fields near this maximum. Compaction of lower-voltage lines raises the conductor surface electric field to EHV levels. Thus conductor and phase spacing/configuration must take corona

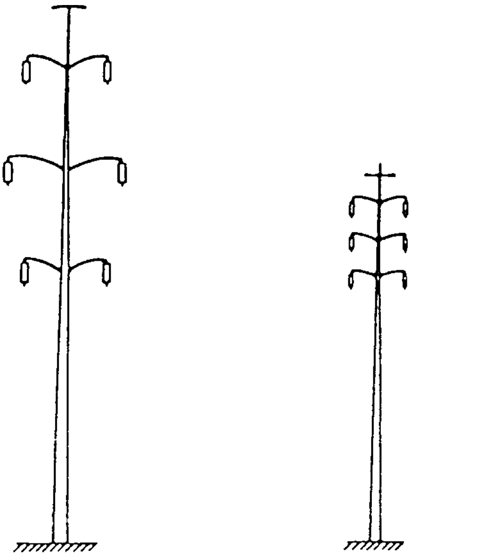

FIGURE 14-70 Comparison of conventional and compact 230-kV lines.

phenomena into account: corona loss, radio noise, and audible noise. Audible noise is not a normal consideration for lower transmission voltages, but should be analyzed for compact lines because of the field levels involved. Because the conductor surface electric field of a compact line is at EHV levels, it is necessary to use EHV-class hardware to limit hardware corona. Laboratory test procedures must be specified in terms of electric field on the conductor surface rather than system voltage.

Insulation Performance. Power frequency voltage (including insulator contamination), switching surge, and lightning performance must be evaluated for the proposed design. Switching surge control can be provided either by surge arresters or resistor preinsertion in the circuit breakers.

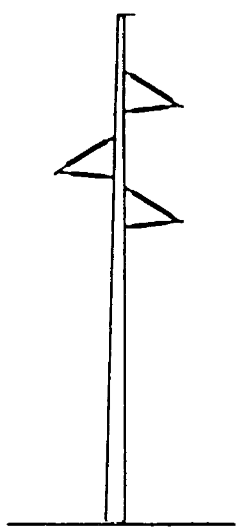

FIGURE 14-71 A 500-kV compact line.

Conductor Motion. The one consideration in design of a compact high-voltage transmission line which differs from EHV practice is mechanical motion of the conductors under wind, ice, and through-fault currents. It is imperative that conductor motion be limited to maintain adequate clearances for power frequency voltage. Differential wind motion, conductor motion under ice release, and ice galloping are extensions of existing practice. A new consideration is motion which results from *through-fault current* (fault current which flows on a line due to a fault somewhere else on the system). Especially with horizontal conductor configurations, magnetic forces from through faults can develop enough conductor motion to cause a line trip.

Because of the need to restrict conductor motion, compact lines are customarily designed with post insulators to restrict conductor motion at the structures. If necessary, inspan insulating spacers can be applied to restrict the conductor motion. Maximum compaction (minimum conductor spacing) is achieved by designs which eliminate grounded supporting structure members in the space between conductors. The spacing reduction is a result of the need for clearances for phase-to-phase voltage between conductors rather than twice the phase-to-ground clearance. Portal structure designs support the conductors from outside the conductor array and are useful for line compaction.

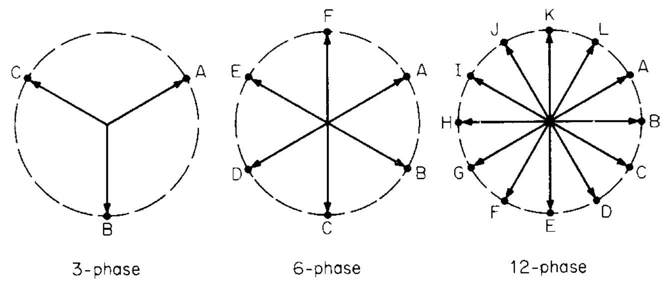

FIGURE 14-72 Illustration of high-phase-order phasor diagrams.

A limitation of compact line design may be a restriction on live-line maintenance because of the reduced clearances. If live-line maintenance is considered in the design phase, it may be possible to develop procedures and to modify the design to allow live-line work while meeting applicable safety codes.[108]

High-Phase-Order Transmission.[109–112]. This is an extension of the principles of line compaction to more than three phases. A general principle can be developed for maximum power transfer in a given amount of space with a given amount of conductor material. The result of this development is that the conductors should be spread symmetrically around the periphery, and energized with the highest possible voltages and phase angles corresponding to the space angle between conductors. The conductor and phase configuration is illustrated for 6- and 12-phase in Fig. 14-72.[111] High-phase-order lines can be constructed smaller than 3-phase lines for equivalent capacity.

An alternative way of looking at high phase order is that conversion of a double-circuit 3-phase line to 6-phase at the same phase-to-ground voltage reduces the conductor surface electric field. This reduced conductor surface electric field can be used either to bring the conductors closer together (compaction) or to increase the phase-to-ground voltage. Thermal loading increases linearly with voltage, and surge impedance loading increases with the square of the voltage. As a result, high phase order holds the potential for voltage uprating of existing double-circuit 3-phase lines by conversion to 6-phase at a higher phase-to-ground voltage.

The benefits and practicality of high phase order have been proved by 3 years' successful operation of a demonstration 6-phase line near Binghamton, New York. An existing double-circuit 115-kV line was converted to 93-kV 6-phase, for a 40% increase in phase-to-ground voltage. A section was converted to compact design, and relay protection was developed and tested. Substation layout proved practical, and economic results are favorable for appropriate applications.[114–118]

14.2 UNDERGROUND POWER TRANSMISSION

By E. C. BASCOM, III and J. A. WILLIAMS

14.2.1 Cable Applications

Traditionally, underground cable systems have been installed in major urban areas where overhead lines are not practical—locations such as airport approaches because of safety issues or water crossings. Cables are generally much more costly than overhead lines from the standpoint of material and installation costs, although recent trends regarding rights-of-way and permitting costs often make the underground alternative more competitive. Increasingly, cables are being selected because existing rights-of-way are too congested or unavailable, or local municipalities will not tolerate a new overhead transmission line. Transmission cables may also be applied for substation getaways, crossings under major overhead line corridors, directionally drilled installations and other installations where technical considerations favor underground cables. Utilities sometimes find it prudent to place short dips in critical areas of overhead circuits, to allow installing overhead lines, which would not otherwise be permitted.[1]

Extruded dielectric (XD)—principally cross-linked polyethylene (XLPE)—cables have become the U.S. standard for voltages up to 230 kV, with short installations up to 345 kV. Over the last 7–8 years, XLPE cables have been used worldwide at 400 and 500 kV. High-pressure fluid-filled pipe-type cables are less commonly installed because of concerns about the dielectric liquids and higher maintenance, but there are a few thousand circuit miles that continue to operate, and several new circuits are installed annually. New self-contained liquid-filled (SCLF) cable installations are being displaced by the availability of XLPE cables at higher voltages. Mass-impregnated nondraining (MIND) paper cables are used for high voltage direct current (HVDC) circuits, although one manufacturer has started supplying polymeric-insulated cable for dc applications. Compressed-gas-insulated transmission systems are uncommon for new installations and used only for special applications—typically short lengths and high-power transfers within substations. In the United States, even though most new installations are extruded dielectric, pipe-type cables account for about 70% of the approximately 6000 circuit miles (10,000 km) in service; XD accounts for 25%, and self-contained liquid-filled accounts for the remainder—with a very small amount of compressed-gas-insulated cables.

14.2.2 Cable System Considerations and Types

Cable Integration into Utility System. Planning and operating considerations for underground cables are different from those for overhead lines.[2] Special attention should be paid to properly represent the cables for utility system analyses, capacitance effects including charging currents, reactor application, system restoration, inductance effects including load sharing, surge impedance loading, insulation coordination, system insulation requirements, and losses. As cables are used at higher voltages—230 kV and above—charging current and reactive compensation should be carefully evaluated. In addition to the effect of cable capacitance on system operation, the current required to charge the capacitor reduces the allowable cable rating. Charging current can be determined from Eq. 14-89, which shows that the charging current increases proportionally with voltage.

$$I_{Charging} = 2\pi f C E_0 = \frac{2\pi f \varepsilon E_0}{18 \ln \frac{D_{INSULATION}}{D_{CONDUCTOR}}} \times 10^{-9} \tag{14-89}$$

In Eq. 14-89, f is the power frequency, C is the capacitance, ε is the insulation dielectric constant (specific inductive capacitance), and E_0 is the line-to-ground voltage in volts.

Table 14.24 lists several characteristics of overhead lines and underground cables.[3] Cables tend to "hog" load compared to overhead lines because of the lower surge impedance as compared to

TABLE 14-24 Typical Electrical Characteristics, 230-kV Overhead Line and Underground Cables

Parameter	Overhead Line	Underground XLPE	Underground HPFF (PPP)
Shunt capacitance, μf/F/mi	0.015	0.30	0.61
Series inductance, mH/mi	2.0	0.95	0.59
Series reactance, ohm/mi	0.77	0.36	0.22
Charging current, A/mi	1.4	15.2	30.3
Dielectric loss, kW/mi	0+	0.2	2.9
Reactive charging power, MVA/mi	0.3	6.1	12.1
Capacitive energy kJ/mi	0.26	2.3	7.6
Surge impedance, ohms	375	26.8	14.6
Surge impedance loading limit, MW	141	1975	3623

overhead lines, although they generally have a lower thermal rating than comparable overhead lines. Since cable ratings are usually lower, potential load flow problems should be investigated when integrating long cable lines in parallel with overhead lines.

14.2.3 Extruded-Dielectric Systems

Extruded-dielectric systems sometimes called solid-dielectric cables provide a simpler, often lower-cost alternative to the paper-insulated cables that have historically been used for transmission cables. Extruded-dielectric cable types have included linear low-density polyethylene (LLDPE), cross-linked polyethylene (XLPE), and ethylene-propylene-rubber (EPR), although XLPE is now the most common insulation type used for transmission cables particularly since the challenges of manufacturing EHV cables with XLPE insulation have been addressed. The absence of dielectric fluid greatly simplifies the ancillary equipment and accessory complexity, and removes concerns about fluid leaks. The XD cables also have lower capacitance than paper-insulated cables, simplifying their integration into the utility system. Although the first XD cables were installed in the United States in the 1960s, they did not find extensive use until the mid 1980s.

Extruded-dielectric cables consist of a copper or aluminum conductor, a conductor semiconducting shield to ensure a smooth electrical profile in the insulation, an extruded polymeric insulation, an extruded insulation shield, outer metallic shielding, and typically a moisture barrier such as a lead sheath or metallic foil laminate, covered with a polymeric (usually polyethylene) jacket (Fig 14-73).

FIGURE 14-73 345-kV extruded-dielectric cables. (Courtesy of LS Cable.)

The "true triple extrusion" method is the state-of-the art method for applying the semiconducting shields and insulation in one pass through the extrusion line to provide sound, void-free interfaces, especially with transmission cables. Extruded-dielectric cable insulation is extremely sensitive to the presence of partial discharge; consequently, this cable must operate under ionization-free conditions.

Exacting manufacturing standards supported by an effective quality assurance system and extensive factory testing are all necessary to provide a high-quality product suitable for application at the highest transmission voltages.

Contrary to initial industry expectations, XD insulation has proven to be sensitive to moisture so transmission cables use moisture barriers to prevent ingress into the insulation. Water blocking is sometimes used on stranded conductors, and water-swellable textile tapes or powder are applied under the metallic sheath. Early cables were steam cured, but most high-voltage extruded-dielectric cables manufactured since the mid-1990s are dry-cured and many are dry cooled (CDCC, continuous dry curing and cooling). Moisture-barrier conductors and swellable tapes under the sheath help maintain the cable free from moisture, particularly when the cable sustains mechanical damage such as from a dig-in. Great improvements in the cables and their accessories in the last decade have led the U.S. utilities to conclude that extruded-dielectric cable reliability is now comparable to paper cables.

Sheath bonding is an important design consideration and requires more careful consideration than at distribution voltage levels. If both ends of the sheath are grounded as is common in distribution, conductor current induces currents in the sheaths, causing heat losses that derate the cable by 10–35%. If the sheath is grounded at one point, the heat losses from circulating currents are eliminated but sheath voltages are induced, equal to approximately 150 V/1000 A/km. Cross bonding, electrically transposing the sheaths, can eliminate sheath circulating currents (although eddy currents still remain) while maintaining acceptable induced voltages.[4]

Extruded-dielectric cables are typically installed individually, either directly buried or in duct. In some cases, the three individual phases are installed at one time in a plastic or steel pipe as part of a “trenchless” installation, in a manner resembling a pipe-type cable installation. Splice spacing ranges from 300 to 1000 m, depending upon the installation mode, reel-shipping lengths, and allowable sheath voltages.

Taped, taped- and field-molded, prefabricated, and premolded splices (Fig. 14-74) have been used; although, premolded splices (joints) are used almost exclusively today.

Terminations have either porcelain or polymer housings, and most designs have a small amount of dielectric liquid (e.g., silicone oil) or gas (SF_6) in the termination.

FIGURE 14-74 “Click-fit” premolded joint. (Courtesy of Prysmian.)

14.2.4 High-Pressure Fluid-Filled (HPFF) Systems

Pipe-type cable had been the U.S. standard because of its ruggedness, and the relative ease of installing pipe in city streets. The first pipe-type cable was a 66-kV circuit installed in Philadelphia in 1932. Many hundreds of miles of 230- and 345-kV pipe-type cables were installed in the 1960s and 1970s. Its use was declined in the late 1980s, as more extruded-dielectric cables were installed and as heavy voltage cable usage generally diminished.

A welded, coated, cathodically protected steel pipe, typically 8.625 or 10.75 in optical density, is pressure and vacuum tested, and the three mass impregnated cables are pulled together into the pipe (Fig 14-75). The cables consist of a copper (occasionally aluminum) conductor, conductor shield, taped insulation, insulation shield, outer shielding, and skid wire to prevent cable damage as they are pulled into the pipe. High-quality kraft paper is typically used at 138 kV and sometimes 230 kV. Introduction of a laminated paper—polypropylene—sometimes referred to as PPP for paper-polypropylene-paper—insulation in the 1980s permitted a lower insulation thickness (0.600 in at 345 kV versus 0.920 in for kraft paper), with lower electrical losses, so this type of insulation is now selected for most new 230 kV and all 345 kV circuits.

FIGURE 14-75 Pipe-type cable.

Splices are typically spaced at 2000–3500 ft intervals. Terminations with porcelain housings make the transition to air insulation and atmospheric pressure.

For a high-pressure liquid-filled (HPLF) system, which has been proven experimentally up to 765 kV though never commercially applied above 345 kV in the United States, the pipe is pressurized to approximately 200 psig (1.4 MPa) with dielectric liquid to suppress ionization. Expansion and contraction of the liquid requires large reservoir tanks and sophisticated pressurizing systems. This provides the possibility of removing the fluid periodically along the length of the line, cooling it (called “forced cooling”), and returning it to the pipe to obtain a 20–50% ampacity increase. Pipe-type cables offer several opportunities for uprating because of the presence of the dielectric liquid.

Nitrogen gas at 200 psig (1.4 MPa) may be used to pressurize the cable at voltages to 138 kV. This high-pressure gas-filled (HPGF) system requires a slightly greater cable insulation thickness because of the poorer insulating qualities of the gas. However, the system greatly reduces environmental concerns because there is limited free dielectric liquid if there is a leak in the pipe, and no external pressurizing equipment is required other than a regulator, nitrogen cylinder, and alarms.

14.2.5 Self-Contained Liquid-Filled (SCLF) Systems

This system was developed in the 1920s, and was a worldwide standard outside the United States through the 1980s. There are many miles in operation at 525 kV, for both land and submarine cables. The cable conductors have a hollow core that provides a longitudinal feeding path for the dielectric liquid. A low-pressure design requires less than 10 psig (70 kPa) pressure to suppress ionization, while a medium-pressure design typically operates at 50–75 psig (350-515 kPa). The 525-kV cables at Grand Coulee dam have a reinforced sheath; the lower end of these cables operates at 400 psig (2.8MPa).[5]

The cables are maintained gas free at a positive pressure from manufacturing through energization and operation because the lower operating pressure (than pipe type) would allow gas ionization, if present. The liquid volume is much lower than that for an HPFF cable. Fluid expansion and contraction is accommodated by bellows-type expansion tanks distributed along the route at spacings

FIGURE 14-76 Self-contained cable. (Courtesy of Prysmian.)

that depend upon sheath construction, core diameter, type of liquid, temperatures, circuit topography, and power transfer. Special fluid stop joints are installed to divide the cable route into a number of hydraulic sections as required because of static pressures (due to route profile) or dynamic pressures (due to fluid volume changes during heating and cooling transients). For very long circuits such as submarine cables, an active pressurizing plant is employed, resembling the plant used for fluid-filled pipe-type cables.

Figure 14-76 shows a self-contained cable. The conductor is most commonly copper, although aluminum has been used. Conductor shields, insulation, and insulation shields are similar to those for pipe-type cables. A lead, reinforced lead, or aluminum sheath maintains pressure, excludes moisture, and provides a fault current path, although submarine cable circuits often include additional copper to support return currents. Aluminum sheaths are usually corrugated to improve flexibility. A polymeric jacket isolates the sheath from ground and provides mechanical and corrosion protection.

Self-contained cables are especially suited for long-distance water crossings because they can be produced in long splice-free lengths, which minimize—or in some cases, eliminate—the number of field splices. Wire armor is provided to aid in cable installation and retrieval, and give a small measure of mechanical protection.

14.2.6 Direct Current Cables

DC cables are used for long water crossings and their shore ends. Charging current and dielectric losses make ac cables unsuitable for lines more than 30–50 mi long (50–80 km), depending upon voltage level and insulation type. Traditional HVDC cables used a mass-impregnated solid-type cable impregnated with a very high-viscosity fluid that had no active fluid pressurizing system (Fig. 14-77). This cable is used for very long (>25 mi, >40km) dc submarine applications. Self-contained liquid-filled or pressurized gas-filled cables have been used for the shorter lengths. Table 14-25 provides a listing of major dc installations. Polymeric insulation materials have recently been developed that are suitable for dc applications, usually combined with IGBT (voltage source) valve converters instead of thyristor valves; these types of HVDC cables can feed smaller loads not connected to large ac systems as was traditionally required.

The insulation for dc cables is especially critical since the insulation is resistively graded instead of capacitively graded as with ac systems. The electrical stress distribution in a dc cable is a function of insulation temperature—electrical stresses can be higher at the outer shielding, whereas for ac cables, the stress is always highest at the conductor shielding. Mass-impregnated cables are generally limited to 50°C-conductor temperatures to avoid temperature distributions that would give too high a stress at the outer shielding.

14.2.7 Gas-Insulated Transmission Lines (GITL)

These "cable" types consist of sulfur hexafluoride (SF_6) gas or a mixtures of SF_6 and nitrogen at pressures from 30–45 psig (200–315kPa) serving as an insulation between a coaxially spaced tubular aluminum conductor and tubular aluminum shield. Insulating spacers maintain separations as shown in Fig. 14-78.

The system is supplied in rigid 40-ft lengths. Large diameters are required because the gas is a poorer insulator than paper-insulated or extruded-dielectric cables—the first 345-kV system had an

18-in enclosure diameter for each of the individual phases. The large diameter enhances heat transfer, conductor sizes are large, and the SF_6 insulation does not have the thermal limitations that other cable types have. Ampacities are therefore very high, usually able to match overhead line capacities with one conductor per phase so these cables often are employed to make high-capacity bus connections within substations. The system is especially suited for short distances, very high currents, and extra-high voltages—the first system was a 600-ft, 2000 A, 345-kV installation.[6]

FIGURE 14-77 HVDC mass-impregnated cable. (Courtesy of Prysmian.)

14.2.8 Superconducting Cables

Superconducting wire has existed for several decades, taking advantage of liquid helium (4 K) temperatures (“low temperature” superconductors) to cool various materials to the point that they show no appreciable electrical resistance. Within the last 5 years, “high temperature” superconductors (HTS) using liquid nitrogen temperatures (80 K) were developed along with methods to make the wire in length suitably long to apply to cables. Two basic types of HTS cable exist; one is the “cold-dielectric” type (Fig. 14-79) where the insulation is at cryogenic temperatures, while the other is a warm dielectric where only the conductor is operating at cold temperatures.

High-temerature superconductors-cable technology offers advantages since the HTS-cable system operates independent of the thermal environment in which it is installed while allowing significant power transfer—using high current densities—with single circuits potentially matching the capacity of overhead lines. HTS cables also offer the possibility of transferring bulk power at what have traditionally been medium voltages by taking advantage of the high current density capability rather than stepping up the voltage as is typically done with conventional “transmission” circuits. One possible application is to retrofit an HTS cable into existing cable pipes or conduits to provide for a significant power transfer increase without the high associated costs of construction and obtaining rights-of-way.

While there has been aggressive research to apply HTS cables at transmission voltages, they have seen only limited use in commercial power systems. Long-term reliability of the cryogenic cooling plants has not been proven, and accessories—joints and terminations—require further development. Cost is also a significant factor in making these systems commercially viable. Materials and installation costs for HTS cable systems are close to 20 times that of a conventional power cable system. Even at this price point, there are certain applications—usually where construction costs, permitting or obtaining rights-of-way are impractical—that HTS cables could see some use. The technology is expected to improve with new generations of superconducting wire becoming available and improved reliability of accessories and cooling plants.

14.2.9 Cable Capacity Ratings: Ampacity

The ampacity (current rating) for underground cables is limited by the maximum conductor temperature that can occur in the insulation with rated current flow through the conductor. The insulation material that is in contact with the conductor shield limits the maximum conductor temperature.

TABLE 14-25 DC Cable Installations

Name of Link	Date	Voltage (kV)	Power (MW)	Length (km)	Cable Type

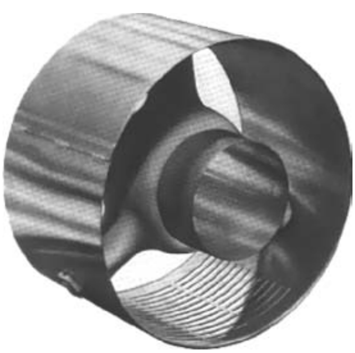

FIGURE 14-78 GITL spacer. (Courtesy of CGIT Westboro.)

The conductor temperature is determined by the heat generated within the cable—electrical losses (I^2R) and dielectric losses (ac cables only)—which passes radially to ambient earth through various thermal resistance layers in the cable, duct (when present), trench, and surrounding soil. The temperature of the conductor can be determined from the following thermal equivalent circuit (this circuit is shown for XD or super conducting final focus [SCFF] cables).

Ampacity can be calculated for XD, SCFF, and HPFF cables by solving the equivalent thermal circuit for conductor temperature based on the type of cable being considered. Figure 14-80 shows an equivalent thermal circuit for an extruded transmission cable installed in conduits. The earth thermal resistance depicted in Fig. 14-80 includes the concrete envelope or other special backfill, if present. Equation 14-90 for the XD cable modeled in Fig. 14-80 is:

$$T_{Conductor} = T_{Ambient} + W_{Dielectric} \times \left(\frac{\overline{R_{Insulation}}}{2} + \overline{R_{Jacket}} + \overline{R_{Jacket-to-Duct}} + \overline{R_{Duct}} + \overline{R_{Earth}}\right) + I^2R_{Conductor} \times \left(\overline{R_{Insulation}} + Qs(\overline{R_{Jacket}} + \overline{R_{Jacket-to-Duct}} + \overline{R_{Duct}} + \overline{R_{Earth}})\right) \tag{14-90}$$

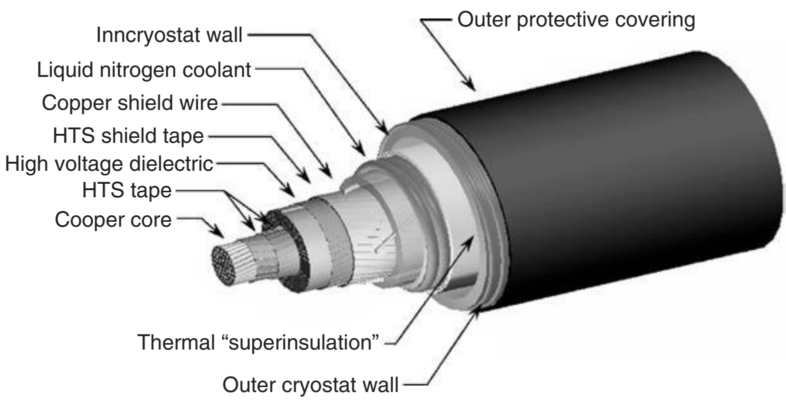

FIGURE 14-79 Cold dielectric HTS superconducting cable. (Courtesy of American Superconductor.)

where the various variables are noted as in Fig. 14-80 with *Qs* being the ratio of losses from the conductor and sheath to the losses only in the conductor.

The earth thermal resistance portion of the equivalent thermal circuit is defined by Eq. 14-91:

$$\overline{R_{earth}} = \frac{\overline{\rho_{backfill}}}{2\pi}\cdot n\cdot\left(ln\left(\frac{D_x}{D_{earth}}\right) + LF\cdot ln\left(\frac{2\cdot L + \sqrt{4\cdot L^2 - D_{earth}^2}}{D_x}\right)\right)$$
$$+\frac{\overline{\rho_{backfill}}}{2\pi} n\cdot LF\cdot ln(F) + \frac{\overline{\rho_{native}} - \overline{\rho_{backfill}}}{2\pi}\cdot n\cdot N\cdot LF\cdot G_b \qquad (14\text{-}91)$$

where $\overline{\rho_{backfill}}$ is the thermal resistivity of the backfill in °C-m/W, *Dx* is the diameter beyond which the average (rather than peak) daily losses are experienced, D_{earth} is the outer diameter of the cable, pipe or conduit, *n* is the number of cables within that earth diameter, *L* is the burial depth to the center of the backfill, *LF* is the daily loss factor (ratio of peak losses to average losses), *F* is a mutual heating effect factor for *N*-1 cables or pipes with *N* being the number of cables/pipes/conduits installed, $\overline{\rho_{native}}$ is the native soil thermal resistivity in °C-m/W and *Gb* is a geometric factor for the backfill envelope.

For ampacity calculations, the dielectric heating is assumed to be constant since the voltage level is generally held to be constant. Also, we can calculate the temperature rise from ac heating as

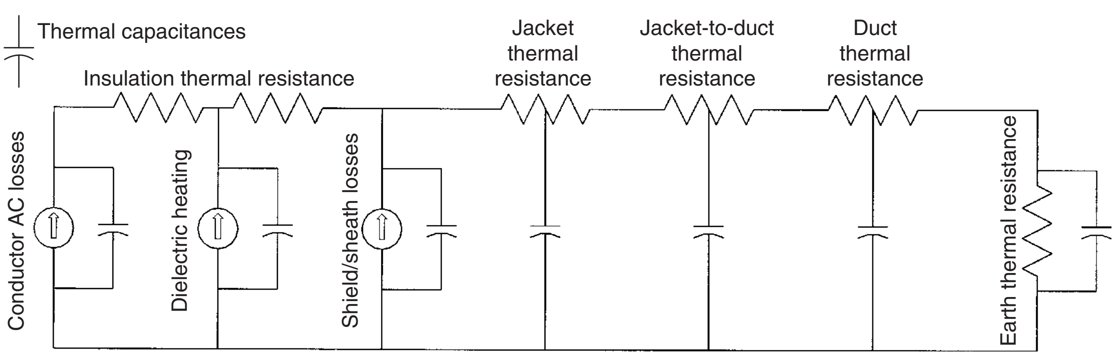

FIGURE 14-80 Equivalent thermal circuit for XD cable installed in conduit.

$I^2 \times (\Sigma R_{AC} \times \overline{R_{Thermal}})$. Then the conductor temperature can be found as $T_{conductor} = T_{Ambient} + \Delta T_{Dielectric} + I^2 R_{AC} \times \overline{R_{Thermal}}$ from which the current for a given conductor temperature can be found:

$$I = \sqrt{\frac{T_{Conductor} - \Delta T_{Dielectric} - T_{Ambient}}{\Sigma R_{AC} \times \overline{R_{Thermal}}}} \tag{14-92}$$

A detailed procedure for calculating ampacity is beyond the scope of this reference. The reader is referred to Refs. 7 and 8 for additional information. The main elements that make up the thermal circuit include the following:

Conductor resistance, is determined based on the cross-sectional area of the conductor, the conductor material (copper or aluminum), the maximum operating temperature, the ac skin, and proximity effects. The maximum operating temperature is defined by the insulation material. Industry-accepted limits for the maximum conductor temperature are 85°C for paper or laminated paper-polypropylene insulations, 75°C for high-density polyethylene insulation, and 90°C for cross-linked polyethylene or ethylene-propylene-rubber insulations. Following the Association of Edison Illuminating Companies (AEIC) practices, these maximum temperatures are reduced by 10°C when the earth thermal parameters are not well defined.

Insulation thermal resistance is expressed in K-m/W (1 K temperature rise occurs when 1 W of heat flows through a thermal resistance of 1 K-m/W). The thermal resistance of the insulation or any cylindrical layer of cable material (i.e., jacket, pipe coating, and conduit) with an inner diameter D_i, outer diameter D_o, and material thermal resistivity of $\overline{\rho}$ can be found as follows:

$$\overline{R_{insulation}} = \frac{\overline{\rho}}{2\pi} ln\left(\frac{D_o}{D_i}\right) \tag{14-93}$$

Typical values for various cable materials are shown in Table 14-26.

Dielectric loss is the heat generated in ac cable insulation as a function of diameters, voltage, insulation temperature (indirectly, as a function of temperature-dependent dissipation factor), specific inductive capacitance, and dissipation factor. Reference 7 should be used to calculate dielectric losses.

Shield/sheath losses are conductor current-dependent losses that result from induced circulating and eddy currents in the cable shield and sheath. Their value depends strongly on the sheath bonding method as described in Sec. 14.2.2.

Earth thermal resistance depends on the cable burial depth, cable phase spacing, cable diameter, native soil thermal resistivity and special backfill thermal resistivity. For a single cable buried in the soil, the thermal resistance can be found from Eq. 14-94:

$$\overline{R_{earth}} = \frac{\overline{\rho_{earth}}}{2\pi} ln\left(\frac{2L + \sqrt{4L^2 - D_e^2}}{D_e}\right) \tag{14-94}$$

L is the burial depth to the center of the cable, and D_e is the diameter to the outside of the cable (for direct buried cables) or the outside diameter of the conduit (for cables in conduit). Transmission circuits generally have one cable for each of the three phases, and some installations

TABLE 14-26 Typical Values for Various Cable Materials

Material	Thermal Resistivity, $\overline{\rho}$ K-m/W
High-density polyethylene (HDPE)	3.5–4.0
Cross-linked polyethylene (XLPE)	3.5
Ethylene propylene rubber (EPR)	4.0–5.5
Oil/paper/laminated paper-polypropylene	5.0–6.0
Polyvinyl chloride (PVC)	4.0–7.0

TABLE 14-27 Typical Values of Soil Thermal Resistivities

Material	Thermal Resistivity, $\bar{\rho}$K-m/W
Fluidized Thermal Backfill (FTB)	0.40–0.75
Concrete	0.30–0.80
Stone screenings	0.40–1.00
Thermal sand	0.50–1.00
Uniform sand	0.70–2.00
Clay	1.00–2.50
Soil with high-organic content	2.00–4.00

include multiple circuits within the same trench. To account for mutual heating that can occur, an additional term must be included in the total earth thermal resistance, as follows:

$$\overline{R_{mutual}} = \frac{\overline{\rho_{earth}}}{2\pi} ln\left(\frac{d_{i1}'}{d_{i1}} \cdot \frac{d_{i2}'}{d_{i2}} \cdot \; \cdots \; \cdot \frac{d_{in}'}{d_{in}}\right) \tag{14-95}$$

where d_{in}' is the distance from cable i to the image of cable n, and d_{in} is the actual distance from cable i to n. For a single 3-phase circuit, $n = 2$. For a double 3-phase circuit (6 cables), $n = 5$. The hottest cable should be used as cable 1.

The soil thermal resistivity varies from 0.5 to 4.0 K°-m/W and is dependent on moisture content, material, mixture, size of particles, and degree of compaction. The earth thermal resistance accounts for up to 75% of the total thermal resistance from conductor to ambient. Although it is not possible to control the native soil thermal resistivity, it is common to backfill the cable trench with special low-resistivity materials such as thermal sand or Fluidized Thermal Backfill (FTB). Most extruded and self-contained liquid-filled systems in duct are encased in a high-strength concrete envelope for mechanical protection and to promote heat transfer. Reference 8 describes the way to model the thermal resistance of this envelope of material. Typical values of soil thermal resistivities are listed in Table 14-27.

Thermal capacitances shown in the thermal circuit are important for calculating the temperature response to load cycle changes or emergency ampacity capability. References [9] and [10] discuss the thermal capacitances of cables in detail. When load changes occur on an underground cable circuit, the temperature of the conductor does not respond instantaneously. A simplified load shape—rectangular load pattern—applied to a previously unloaded extruded-dielectric cable circuit is shown in Fig. 14-81. Note that the hourly fluctuations in the load pattern are in close correlation with the temperature response; these changes reflect the relatively short thermal time constant—a few

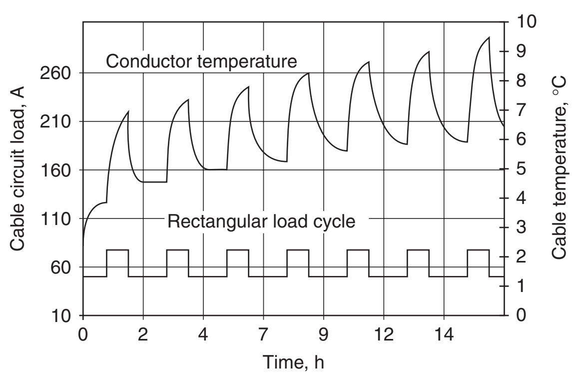

FIGURE 14-81 Temperature response to step load shape.

hours—for cable components. In contrast, the overall average temperature is rising as the duration of the applied load increases; this reflects the relatively long thermal time constant of the earth—approximately 50–150 h—for the mass of soil around the cables.

The impact of the earth thermal capacitance is routinely included in ampacity calculations by using a daily (24 h) "loss factor." The loss factor is essentially the load factor of the losses and is the ratio of the peak losses to the average losses over a day according to Eqs.14-96 and 14-97. Beyond a certain diameter out in the earth, the average effects of heat loss, rather than the peak losses, are experienced. So, the thermal resistances are adjusted accordingly to consider this effect. As the loss factor drops, the ampacity increases. The loss factor concept was initially developed in the Neher-McGrath paper in October, 1957 and is used by many utilities, particularly in North America. International practice (IEC-60287) has been used to calculate ampacities with 100% loss factor (flat load shape), which is generally very conservative since most cable circuits experience at least some load cycling over a 24-h period. Advanced numerical techniques have been applied on a limited basis to consider longer load cycles (several days to several weeks), but the ability to predict load over such long periods limits their applicability.

The mechanics of calculating ampacity are not particularly difficult, but there are many details to be considered. All of the calculations can be done using a hand calculator but are amenable to straightforward computer programming or a computer spread sheet. Ratings for many standard configurations are tabulated in Ref.[11].

High-Pressure Fluid-Filled Cables. Ampacity for HPFF cables may be calculated in a similar manner as for single-core cables. The main difference is that there is an additional element—the cable pipe—that generates heat in the equivalent thermal circuit. The pipe itself heats, and the magnetic pipe causes additional ac losses in the cables. A subtle difference for HPFF cables is that the heat generated by three cables—the three cable phases—must pass through the dielectric fluid in the cable pipe, the pipe coating, and the earth.

Compressed-Gas-Insulated Systems. Heat loss from GITL is by convection and radiation through the air since these systems are almost exclusively installed in air; usually open air but sometimes in enclosed troughs or tunnels. Consequentially, the rating procedure is significantly different from buried cable systems where heat loss is by conduction through the soil. The procedure for calculating ratings is generally an iterative process needed to evaluate the fourth-order relationships—guessing a temperature and rating and then comparing the calculated radiation and convection heat loss to the ohmic (I^2R) heat generated by the bus.

$$W_{radiation} = 5.69 \times 10^{-8}(T_2^4 - T_1^4)\pi D\left(\frac{1}{\frac{1}{e} + \frac{1}{\varepsilon} - 1}\right) \tag{14-96}$$

$$W_{convection} = 8.523\pi D\sqrt{\frac{(T_2 - T_1)^4}{\frac{T_2 - T_1}{2}}} \tag{14-97}$$

With T_2 and T_1 representing the temperature of the GITL surface and ambient air, respectively, D representing the outer diameter of the emitting surface, $e = [1\text{-}D/(6\pi d)]^2$, and ε representing the emissivity of the emitting surface. Details of the calculations can be found in Refs. 12 and 13. For the situation where the GITL is exposed to solar radiation, the methodology used to model solar radiation on overhead transmission lines can be applied.[7, 14, 15]

Transient and Emergency Ratings. Emergency ampacity considers the use of a higher operating temperature for a period combined with the heat storage capacity of the cable and earth environment. The temperature response of a single cable to a given heat output, W, can be found from Eq.14-98:

$$\theta_{Earth}(t) = W_{Cable}\frac{\overline{\rho_s}}{4\pi}\left[-Ei\left(-\frac{D_{earth}^2}{16\delta t}\right) + Ei\left(-\frac{L^2}{\delta t}\right)\right] \tag{14-98}$$

TABLE 14-28 Acceptable Operating Temperature Values

Material	Maximum Temperature (Normal), °C	Maximum Temperature (Emergency), °C
High-density polyethylene (HDPE)	75	90 (<1500 h over cable life)
Cross-linked polyethylene (XLPE)	90	105–130 (<72h)
Ethylene propylene rubber (EPR)	90	130 (<1500 h over cable life)
(Oil/paper/laminated paper Polypropylene	85	100 (<300 h)–105 (<100 h)

In compliance with AEIC specifications, these temperatures must be reduced by 10°C if the thermal environment is not defined for the entire circuit. A thermal route survey, ideally done prior to cable installation, eliminates this requirement. Dielectric fluid circulation in HPFF cables will also help mitigate the effects of localized conditions.

where δ is the earth thermal diffusivity in mm^2/h t is the time of the transient in seconds, L is the burial depth to the center of the cable, conduit, or pipe D_{earth} is the diameter of the cable/conduit/pipe-to-earth interface and ρ_s (needs "overline") is the thermal resistivity of the soil in K°-m/W and *Ei* is a notation to indicate an exponential integral. Further details for calculating emergency ratings may be found in Refs. 10 and 16.

Transient ratings are those in which the heat-storage capacity of the cable system permits short-duration overcurrents without exceeding allowable temperatures. The maximum allowable temperatures and permissible emergency rating durations are defined by cable specifications and agreement with manufacturers. Generally, acceptable operating temperature values are listed in Table 14-28.

A detailed procedure for calculating emergency ratings is available in Refs. 9 and 10.

Forced Cooling. Forced cooling is not very common and is generally considered only for HPFF cables where the dielectric liquid in the steel pipe can be circulated. There are some limited applications where water is circulated through parallel water pipes to provide forced cooling of extruded or self-contained cables. In HPFF cable systems, the dielectric liquid can be removed from the pipe, cooled by various types of heat exchangers, and reintroduced into the pipe at a remote location, generally using a noncabled liquid supply pipe (note that the heat capacity of nitrogen is small so HPGF lines are not forced cooled). The procedure can increase the capacity of the cable circuit by providing a lower-resistance path for the heat generated in the cable to escape to ambient. Figure 14-82 illustrates a typical hydraulic circuit for a forced-cooled cable.

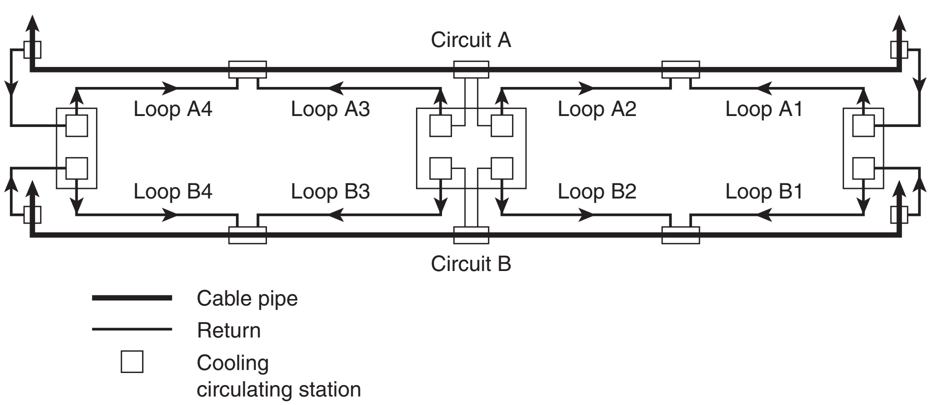

FIGURE 14-82 Hydraulic circuit, typical forced-cooled HPFF cable system.

The major additional components of a forced-cooled HPFF system include a return pipe for the fluid, heat exchangers, circulating pump (800–1600 L/min), lower-viscosity dielectric fluid, and modifications to the cable pipe to prevent cable damage from impinging oil. Reference 17 describes a typical 345 kV forced-cooled system, Ref. 18 describes a procedure for making thermal calculations, and Ref. 19 describes full thermal and hydraulic calculation procedures for pipe-type cables.

The added cost and complexity of forced-cooling equipment, along with potentially high-energy charges for operation of the equipment, have tended to limit forced-cooled installation to areas of very high-installation costs, or to retrofitting on existing HPFF cable lines.

Self-contained and extruded cables can be forced-cooled [18] using parallel water pipes (lateral cooling), conduit water circulation (integral cooling), heat pipes, or internal (core) cooling (Fig. 14-83). One North American utility uses parallel water-cooling pipes to increase the ampacity of a submarine cable as it comes on shore; the shore zone for submarine cables is often limiting, so the cooling system mitigates the ampacity limitation.

Internal cooling for self-contained liquid-filled cables has the advantage of removing dielectric fluid with high heat content from the core of the cable itself. This system requires special joints to periodically remove the line-potential liquid, pass it through heat exchangers, and return it to the cable core.

Lateral and integral cooling have a somewhat lower efficiency, but the simplicity of the cooling system has lead to several commercial installations. Extruded-dielectric cables can make use of either integral or lateral cooling. It is also possible to cool CGIT in the same manner, although there have been no such installations to date.

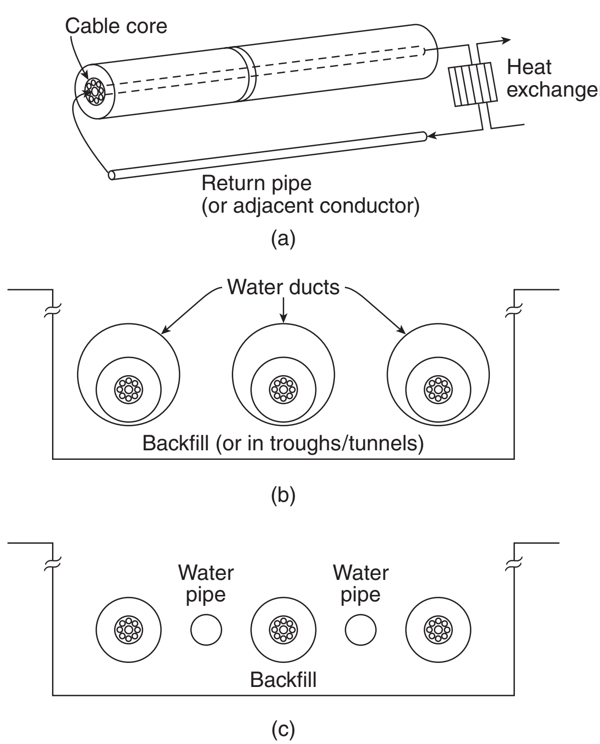

FIGURE 14-83 Alternate methods of cooling single-core cables: (a) internal (core) cooling (SCFF only); (b) integral cooling; (c) lateral cooling.

14.2.10 Cable Uprating and Dynamic Ratings

Cable uprating and upgrading are techniques that are applied to existing cable circuits to get more power through existing infrastructure without building new lines. Many of the basic strategies used for uprating are important to consider for basic ampacity when a new circuit is installed. Utilities frequently need to "uprate" existing circuits; an uprating project can often be implemented quickly to achieve a 10% increase in rating while deferring a multimillion dollar new installation project for several years. In addition, rights-of-way are sometimes difficult to obtain even for underground circuits so getting more capacity through existing lines becomes critically important. Underground cables are especially amenable to uprating, principally because of the very large thermal time constant of the cable/earth system. Also, many older circuits were designed and rated using conservative assumptions; these assumptions may be reviewed carefully, often revealing additional circuit capacity.

Utilities have successfully implemented many approaches for uprating.[20] Typical uprating approaches are summarized below:

- *Characterize the thermal circuit.* In most cases, design engineers properly make conservative assumptions when rating the circuit. A careful audit of route as-built drawings, soil and backfill thermal resistivity, load shape, and so on will provide accurate data and can often permit rerating the circuit 5–10% higher.
- *Perform thermal analysis.* Thermocouples or fiber-optic distributed temperature monitoring cables (Fig. 14-84) can tell the actual cable or pipe temperature at discrete locations or continually along the route. Detailed analysis of loading for the preceding weeks, cable construction data, and trench cross-section information can permit refining the ampacity model, often resulting in significant ampacity increases.[21]
- *Mitigate hot spots.* The thermal analysis may indicate hot spots—a few meters of cable that limit the overall circuit rating—along the route. If the hot spots are localized, they can perhaps be mitigated by

FIGURE 14-84 Distributed temperature system and fiber being used in the field to measure cable temperatures.

removing excess overburden, replacing poor soil with good backfill, recompacting the soil or injecting an additive to reduce thermal resistivity. Sometimes transmission circuits can be upgraded by rerouting nearby distribution circuits or inserting heat pipes to cancel mutual heating effects. Dielectric fluid circulation in HPFF cables can also mitigate localized hot spots.[22] Pipe circuits with only one pipe (no parallel circuit or separate fluid return pipe) can also have some modest circulation using the large fluid reservoir tanks to oscillate fluid in the pipe, mitigating hot spots.

- *Take advantage of load shapes.* Because of its long thermal time constant, the temperature of a cable system today is a result of its loading history for the last several weeks. Utilities typically choose a conservative daily load factor when performing ampacity calculations. Careful calculation of the effects of the actual hourly loads can result in increased ampacities.

- *Fill ducts with a slurry.* The static air space in an XD or SCFF cable duct reduces ampacity by 5–6% or more as compared to a similar direct buried cable. Filling the duct with a removable slurry such as a sand-bentonite mixture can restore that ampacity. Duct ends must be sealed to prevent drying, and it still may be necessary to water jet the slurry if the cable must be removed later. Care must be taken to avoid air pockets, especially if there are dips in the route profile.

- *Reconductor.* Technically called "upgrading," substantial ampacity increases can be achieved for pipe-type cables or XD/SCFF cables in duct by removing the present cable and installing a larger conductor cable, possibly using lower loss insulation (e.g., PPP instead of conventional kraft paper). Utilities sometimes consider allowing a thinner insulation wall on the replacement cable to allow additional space in conduits or pipes for a larger conductor size. Cables with a higher voltage might also be installed, providing a power transfer increase directly proportional with the voltage increase, but this is seldom economical unless the higher voltage already exists in the terminal substations.

- *Add forced cooling.* For HPFF cables, it is possible to remove the liquid from the cable pipe, pass it through a heat exchanger, and send it back into the pipe through a separate liquid line. Although installation and operating costs are high, forced cooling can add 40% to the capacity of an existing cable system. Forced cooling could also be used with XD/SCFF cables using parallel water pipes, but this is uncommon.

- *Dynamic rating.* Cables almost always operate far below their thermal limits, and their conductor temperatures are much lower than allowable values. Therefore, the cables are capable of operating above their steady-state rating for significant periods without exceeding allowable temperatures. In many cases, the cables can even operate above traditional maximum temperatures without unduly decreasing cable life. Dynamic rating systems make this uprating methodology possible by determining the conductor temperature in real time based on measured parameters such as load, ambient earth temperature, and other conditions. A computer can record recent loading data, pipe, shield, or duct temperatures (and fluid temperature for an HPFF system), and ambient earth temperature, and calculates allowable ratings for future periods. The operator has the ability to determine the allowable loading for a certain period of time, determine the length of time permitted before temperature limits are exceeded, and so on. Dynamic ratings can permit ampacity increases of 20%–30%, depending upon operating conditions, with a relatively small investment in equipment.

14.2.11 Soil Thermal Properties and Controlled Backfill

The earth portion of the cable thermal circuit accounts for the greatest percentage of thermal resistance for buried cables—often more than half the total resistance. Native soil thermal resistivity can vary by an order of magnitude along a cable route, and it can vary by a factor of 3 at one location as a function of seasonal moisture content. Accurately characterizing thermal resistivities, developing dry out curves, and choosing the proper value to use in ampacity calculations are important parts of cable system design.

Soil testing is often done in the field (in situ) or laboratory (using samples) to determine the thermal characteristics of the soil in which the cables will be installed. A thermal property analyzer (TPA) is used for these types of measurements (Fig. 14-85). For a thermal resistance test, a thermal needle

FIGURE 14-85 Thermal property analyzer or "TPA." (Courtesy of Geotherm, Inc.)

consisting of a heater and thermister is placed into the soil sample (Fig. 14-86). During the test, a constant heat output is applied to the thermal needle while the change in temperature is recorded; the slope of the recorded time-temperature curve is proportional to the soil thermal resistivity. This information is then used for ampacity calculations and to design the backfill materials to place in the cable trench.

In the laboratory, thermal dry-out curves may also be prepared that shows the effect of soil moisture content on thermal resistivity. Generally, as soils have increased moisture content, the thermal resistivity decreases (Fig. 14-87). Since cables produce heat, some drying should be considered when evaluating ampacities.

Significant ampacity increases can be achieved at reasonable cost by placing a controlled backfill with a low, stable thermal resistivity around the cables, ducts, or pipes. A good controlled backfill is characterized by low-thermal resistivity, less than 1 K°-m/W, when completely dry, and a fairly flat curve of thermal resistivity versus moisture content. The proper material should be designed for each project using locally available materials, when possible, to provide the best installation and thermal characteristics at a reasonable cost. Well-graded sands or limestone screenings have been used since 1950s. Recently, many utilities have been installing FTB, which is a low thermal resistivity, free-flowing engineered material consisting of natural mineral aggregates, sands, cement, water, and a fluidizer (Fig. 14-88). It is delivered in ready-mix concrete trucks, and flows throughout the trench so there is no need for compaction.

14.2.12 Electrical Characteristics

Calculation of Electrical Parameters. Electrical characteristics for cables are calculated using various established methods. Resistance, capacitance, and inductance can be calculated using the industry

FIGURE 14-86 Thermal probe being inserted into an auger during geotechnical testing.

standard procedures for cable ampacity.[7] Sequence impedances for cables can be approximated using various sources.[23,24] Rigorous calculations for pipe cables are difficult because of the presence of steel (ferromagnetic) pipe; Ref. 24 has traditionally been considered the best approach available for pipe type, though it is known to be in error in many cases because of the great variability in line pipe permeability. For a typical single-core (XD, SCFF) transmission cable installations, a detailed procedure exists.[25] but does not easily lend itself to hand calculations. Induced sheath voltages may be calculated using the appropriate IEEE standard.[4]

Although surge impedance loading is never an issue for cables (unlike overhead lines) because cables ratings are always constrained by thermal limits, system studies sometimes require the surge impedance for modeling power systems. This can be calculated using the following formula where f is the power frequency, ε is the dielectric constant of the insulation, D_i is the diameter of the cable over the insulation, and D_c is the diameter of the cable conductor.

$$Z_S = \frac{f}{\sqrt{\varepsilon}}\, ln\left(\frac{D_i}{D_c}\right) \qquad (14\text{-}99)$$

Fault current capability of a cable can be an issue, particularly in stiff power systems. The fault current capability of underground cables can be calculated assuming adiabatic conditions using the

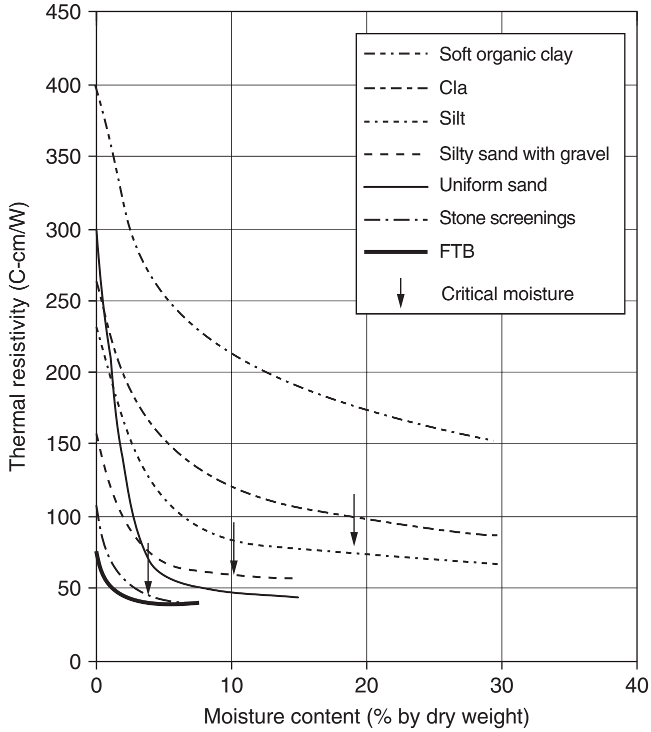

FIGURE 14-87 Soil thermal dry-out curves.

FIGURE 14-88 FTB being installed in a cable trench.

following equation where conductor area is in square millimeters, and time is in seconds (i.e., at 60 Hz, 30 cycle clearing time will be 0.5 s). T_1 is the temperature of the sheath or conductor prior to the fault in °C, T and k are material parameters for conductor or sheath material (see Table), and T_2 is the allowable maximum temperature for the insulation or jacket material (whichever is lower) in contact with the conductor or sheath. Conductor cross-sectional area is specified in square millimeters.

$$I_{SC} = (\text{Conductor Area})\sqrt{\frac{k}{time}ln\left(\frac{T_2 - T}{T_1 - T}\right)} \tag{14-100}$$

Conductor/Sheath Material	Constant, k	Inferred Temperature of Zero Resistance, T °C
Copper	50237	−234.5
Aluminum	21144	−228.0
Lead	1641	−236.5

Though polyethylene jackets are often used, many manufacturers allow higher shield/sheath temperatures than 150°C (some up to 250°C) based on experimental evaluation and the conservative adiabatic assumptions.

Insulation/Jacket Material	Temperature, T_2 °C
High-density polyethylene	150
Cross-linked polyethylen	250
Polyvinyl chloride	150
Ethylene propylene rubber	250

14.2.13 Magnetic Fields

Magnetic fields are generated by underground cables as a result of current flowing in the conductors of the cables. The intensity of magnetic fields is a function of conductor and shield currents, phase spacing, and distance from the source and can be calculated using the Biot-Savart Law as follows:

$$B = \frac{\mu_0 I}{4\pi}\int \frac{dS \times r}{r^2} = \frac{\mu_0 I}{2\pi r} \tag{14-101}$$

with μ_0 is the permeability of free space ($4\pi \times 10^{-7}$ Wb/m^2), I is the conductor current in amperes, and r is the distance from the conductor in meters. Magnetic fields are reported in micro-tesla (μT) or milli-Gauss (mG); 1 T is 10^4 G, so 1 mG is equal to 0.1 μT.

Magnetic fields generated by 3-phase cable circuits must account for the individual cable phase current magnitude and phase angle and that the magnetic field is actually the resultant of the minor and major (real and imaginary) axes of the rotating elliptical magnetic field phasor. This can be done easily with the use of a computer for cables that do not have ferromagnetic elements such as the steel armor on submarine cables, the metal casing often used with directionally drilled cables, or the steel pipe around pipe-type cables. Cable systems with ferromagnetic components should be modeled using finite element software to account for the nonlinear nature of the problems and the variability in the permeability of steel with field intensity. CIGRE has developed procedures to calculate magnetic fields for cables with[26] (HPFF) and without[27] (XD, SCFF) ferromagnetic components; these methods use empirical relationships to account for the shielding effects of the iron-based shielding.

The importance of magnetic field management is a topic that varies depending largely on public perception of the issue. Some utilities have investigated various magnetic field management methods to find the best solution for a particular application.[28]

14.2.14 Installation

XD and SCLF Cables. Installation of single-core transmission cables (SCLF and XD) requires that the cables either be directly buried or installed in conduits, although they are sometimes installed in troughs or mounted on the inside of tunnels. Preferably, the cables are installed direct buried—usually to a nominal depth of 1 m cover over the top cable—with center-line spacing of approximately 300 mm. Joint bay locations for direct buried cables or manholes for conduit systems are dictated by cable reel lengths (typically limited to 2600 ft or 800 m for large cables), local restrictions on the permissible length of open trench, or by maximum permitted sheath voltages. Depending upon the route plan and profile, allowable pulling tensions or sidewall pressures can limit spacing for cables installed in conduit. When cables are to be installed in conduits or pipes, it is important to consider the maximum pulling tension that may be encountered during the installation.[29] Fluid reservoirs for SCLF cables are spaced according to elevation changes or maximum transient hydraulic pressures during load cycling. Generally, each substation end has a set of reservoirs, although they may be placed in manholes as needed. Reference 30 gives details of a typical SCLF cable installation.

For conduit systems, the ducts are installed first and the cables pulled in and splicing done later (Fig. 14-89). This type of installation has benefits for urban environments where lengths of open trench must be limited and surface restoration must be done promptly. Many utilities install spare conduits so that additional cables or other utilities can be installed along the same conduit run.

FIGURE 14-89 Duct bank being backfilled.

FIGURE 14-90 Cable trench with final FTB layer installed.

Direct buried installations require that the trench be opened for an entire pull section. Depending on cable dimensions and reel limitations, this can be 500–800 m of trench. The trench frequently must have sheathing and bracing installed to prevent itself from collapsing. Where thermal sand or FTB will be used, a layer of the material is placed in the trench prior to placing cable rollers along the route. Then, the cable is pulled from one end to the other along the rollers using a winch. Once all cable phases have been pulled, thermal sand or FTB is placed around and above the cables (see Fig. 14-90). Additional backfill, a concrete cap, or marking tape can then be placed on top of the envelope around the cables before restoring surface conditions.

14.2.15 HPFF Cables

Pipe-type cables require much more complex installation procedures and specialized equipment than extruded-dielectric cables.[23, 31] They are most commonly installed in city streets, where the narrow trench requirement, speed with which the pipe sections (approximately 12 m) can be installed, and ruggedness of the pipe offer advantages. Trench openings more than 200 m are preferred, and pipe installation can progress at several hundred feet per day, depending upon subsurface congestion, traffic conditions, and so on. The trench can be backfilled (often with a controlled backfill) as soon as a pipe section is placed, welded, the weld tested, coated, and the integrity of the pipe coating is checked. Manhole-to-manhole sections of 700–1000 m in length can be installed, vacuum/pressure tested, and pressurized with dry nitrogen until cable is installed later.

Cable is delivered to the site on large sealed steel reels and placed in a special trailer as shown in Fig. 14-91, lagging is removed from the reels, the three phases are brought together into a single pulling yoke, and the cable is pulled to the adjacent manhole. Characterizing the pulling tension is important to avoid damage to the cable or jamming of the cables in the pipe. One critical factor to consider is the coefficient of friction to use for the cable pipe and pulling rope.[32] Pulling cables through the steel pipe is accomplished using a specialized pulling winch (see Fig. 14-92). Pressure-tight "night caps" are placed over the cable ends, the pipe is evacuated, and slightly pressurized with a nitrogen gas until splicing begins. A splicing trailer is placed over the manhole to provide a work area and maintain humidity control in the manhole. A 345-kV splice takes 5–7 days to complete.

Each termination takes about a day to assemble. Humidity-controlled enclosures are used for 345- and 230-kV cables, and occasionally for 138-kV cables. For both splices and terminations, it is important to maintain a dust-free and low-moisture environment during installation work.

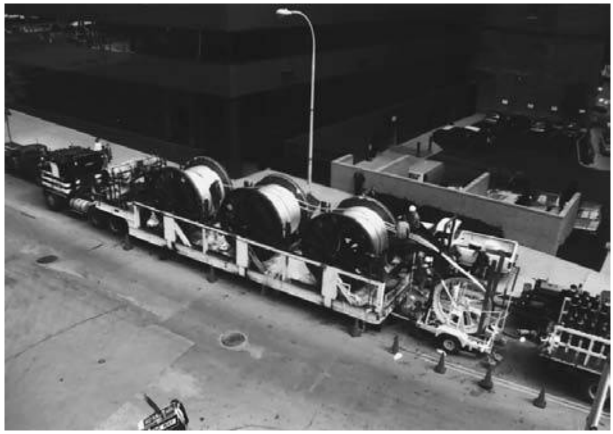

FIGURE 14-91 Reel trailer.

Pressurizing plants for HPLF cables are generally assembled in weatherproof enclosures at the manufacturing facility, shipped to the site and set in place on foundations (which may include a moat), where electrical and hydraulic connections are made. Before they are energized, the cables must be pressurized very slowly to prevent insulation damage and ensure that any minor amounts of gas in the cable are dissolved in the dielectric liquid.

14.2.16 GITL

Since the enclosures are rigid and diameters are large (e.g., 40 cm for a single phase of a 345-kV system), this cable type does not have as much flexibility as extruded-dielectric or pipe-type cables. Bends of more than a few degrees require a specially made elbow. Many systems have been installed directly buried, but most new designs call for installation in a trough that minimizes corrosion concerns and allows rapid access for maintenance. Care must be taken to properly design for thermal expansion of both the enclosure and the conductor.

FIGURE 14-92 Pulling winch trailer.

FIGURE 14-93 GITL installation. (Courtesy of CGIT/AZZ.)

The compressed-gas-insulated system is seldom installed in city streets; most applications are within substations or power plants, or on the utility right-of-way. Figure 14-93 shows a typical installation.

14.2.17 Special Considerations

Submarine Installations and Water Crossings. Short water crossings, less than 2 km, can be accomplished by horizontal directional drilling in many cases, and the cable system can be pulled into the casing pipe or directly into the bore in some instances. Traditional cut-and-cover installations are suitable where water bottom conditions and environmental considerations permit. Extruded-dielectric, pipe-type, and self-contained cables can be suitable for these short crossings.

Longer water crossings have sometimes been installed by laying the cables on the bottom, but the high incidence of ship anchor and trawler sled damage have caused almost all new installations to be buried by trenching, jetting, or plowing using special equipment to embed the cable below the water bottom. The cable laying ship, with special navigation and positioning equipment, pays off cable from a large turntable to an embedder that augers or water jets a trench for the cable to fall into during the laying operation (Fig. 14-94). The cable laying ship has the capacity to hold several miles of cable, depending on the size, which minimizes the number of splices that must be installed.

Thermal analysis of water-bottom material is important, especially for lake and river crossings where sediments tend to accumulate. Cables have failed because of drying out of sediment material around the cables, even though the water depth at the failure location was more than 10 m.

Self-contained liquid-filled cables have been used for major ac installations.[33, 34] Extruded-dielectric cables are becoming more common for ac submarine cable installations.[35] Solid-type cables are commonly applied for long dc cable installations.[36] The 1990s and 2000s have seen a great deal of interest in submarine cable applications, worldwide.

Horizontal Directional Drilling (HDD). Horizontal directional drilling is becoming a common way to install cables under rivers, major highways, and other locations where trenching is not feasible.

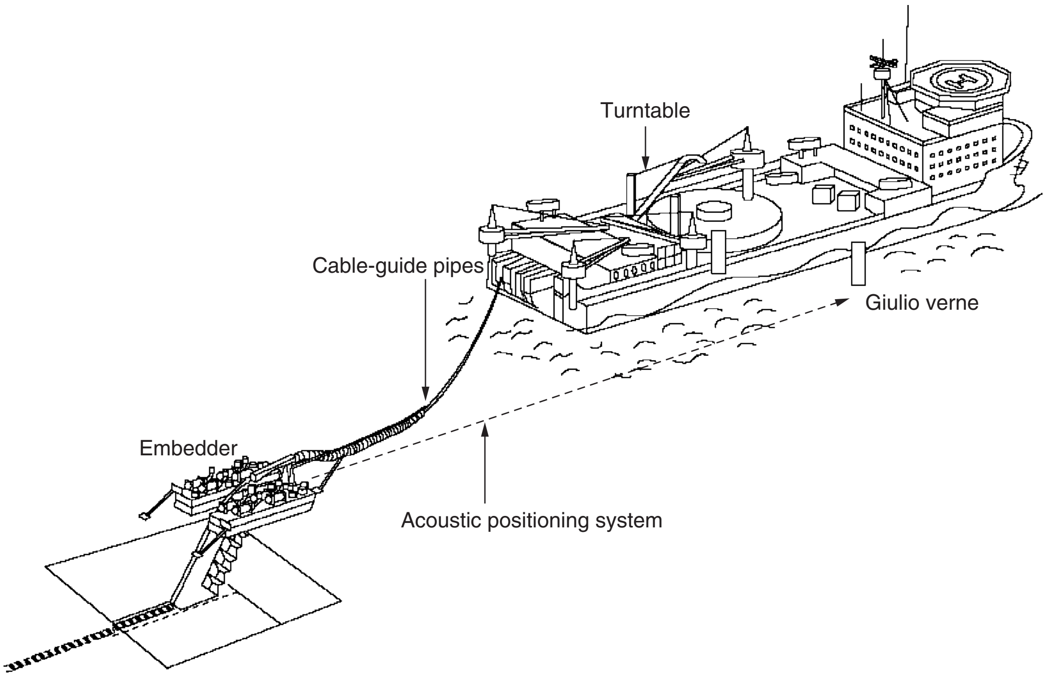

FIGURE 14-94 Cable laying ship and sea bottom embedder. (Courtesy of Prysmian.)

Drilling unit capabilities have increased, and prices have decreased, as the technology has matured. A recent installation in South Carolina successfully installed a pipe-type cable along a 7100 ft (2.2 km) HDD crossing. HDD installations are even being made in city streets, to avoid other utilities, to minimize traffic disruption, and to minimize the amount of contaminated soil that may be encountered.

Careful design work, including characterization of the materials along the drill path, must be performed so the proper drilling equipment can be selected to ensure a successful installation without loss of drilling fluid to the surface. Detailed thermal analysis is required to properly account for the 10–30 m burial depth. The utility must decide whether to install a casing pipe, either plastic or steel, which will require a larger bore and may decrease ampacity but will help ensure successful cable installation. Entry and exit angle requirements of 8–12 degrees can require a large setback for deep borings. Figure 14-95 shows a guided boring rig for a river crossing. Staging areas can be large, especially since casing pipe and ducts or cable pipe should be madeup beforehand and installed without stopping—the drilling mud may begin to set up.

Since the cable will be inaccessible for repairs, utilities should consider stocking a section of spare cable that is the full length of the bore. For pipe-type cables, or three XD cables installed in a single duct or pipe, the spare cable must be 3 times the length of the bore. In the case of extruded cables, some utilities have installed a fourth cable in a spare duct, to speed reenergization in the event of cable failure.

14.2.18 Accessories

General. Although accessory cost is usually a small percentage of the total project cost, proper selection and application of accessories are extremely important for long-term reliability of underground cable systems. Historically, outages due to accessories are more frequent than those due to

FIGURE 14-95 Guided boring equipment for a river crossing.

problems in the cable itself. Much of the development activity, especially in extruded-dielectric cables, has been directed at simpler, easier-to-install, reliable splices, and terminations. (Note that a splice is the electrical reconstructing of the electrical insulation and shielding. A joint also includes housing, fluid supply, and so on.)

XD Cables. Different splice designs have been applied as the industry has matured, including taped splices, taped and molded splices, prefabricated and premolded splices, back-to-back SF_6 potheads, and a miniature extrusion facility set up in a manhole. In the late 1990s, premolded joints became the standard for field installation at most voltage levels. These joints were fully tested in the factory, and they required less assembly time in the field. In cross-bonded systems, the splice must accommodate an insulator in the outer shielding, to isolate electrically the shields/sheaths of adjacent cable sections.

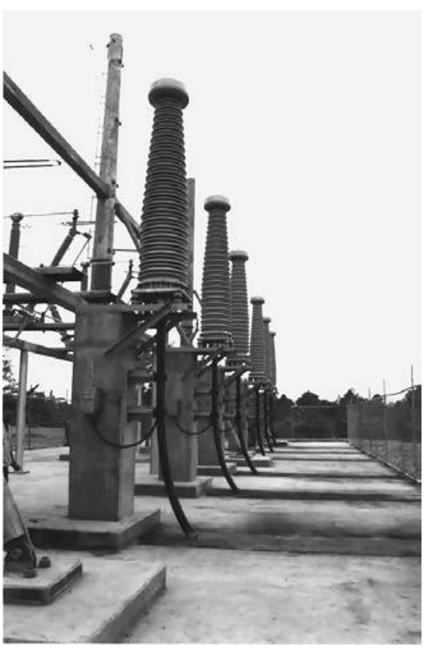

FIGURE 14-96 Terminations mounted on concrete risers.

Terminations are typically slip-on, with a dielectric liquid to fill any voids in the high-stress regions. The area above the liquid contains a compressible sponge, or simply an air space, to accommodate fluid expansion. Some designs require a small fluid reservoir for this purpose. Porcelain housings have traditionally been used, but polymer housings are becoming more common, especially for applications where the terminations are mounted directly on riser poles as shown in Fig. 14-96. Terminations are available for air installation, installation in single-phase SF_6 bus, and installation in 3-phase SF_6 bus.

Link boxes permit connections among the sheaths for grounding and cross bonding. The links must be removed when the cable jacket is tested electrically as part of routine maintenance. A sheath voltage limiter, resembling a distribution-class surge arrester, is often placed at the nongrounded end of a cable sheath to limit overvoltages, which might damage the jacket.

HPFF Cable Splice. These types of cable splices are normally individual hand-taped assemblies which are bound together using an aluminum "spider" to maintain spacing and reduce flexing. They are contained in a 3- or 5-piece welded steel joint casing that can be 40 cm diameter and 3.5 m long. Trifurcating splices provide the transition from three cables in a steel pipe to individual cables in stainless-steel pipes rising up to a termination. Special "stop joints" are installed on high-pressure liquid-filled (HPLF) cables to minimize fluid loss in the event of a major leak, and to permit maintenance on the cable without draining large amounts of liquid.

Terminations (also called potheads) have paper "piano rolls" to help grade the electrical stress. Many 230-kV terminations and all 345-kV terminations have capacitor stacks inside the termination body to smoothly grade the electrical stress from ground to line potential. The HPLF terminations are pressurized with liquid from the cable pipe through filters and check valves that limit liquid loss in event of termination failure. HPGF terminations are typically just pressurized with nitrogen gas from the cable pipe, although some designs have a liquid-filled termination.

Pressurizing plants are sized to accommodate the maximum liquid demand and expulsion under all loading conditions. The plants contain a reservoir tank (typically 8000–40,000 L), pressurizing pumps, controls, and alarms. Since pressurization is critical to keep a line in service, backup pressurizing pumps are provided, sometimes including nitrogen-driven pumps that can operate during power outages. Emergency generators are supplied in some instances.

Cathodic protection is applied to protect the steel pipe in case the corrosion coating is damaged. The system consists of a rectifier to provide the -0.85 V needed to ensure that current flows from the earth to the pipe, plus a polarization cell (or solid-state equivalent) to provide a low-impedance path to earth for fault currents.

SCLF Cables. Normal joints are single-phase assemblies that have a special connector or ferrule to permit liquid flow through the conductor core. They are spliced in the same manner as a pipe-type splice and have a nonmagnetic lead, copper, or aluminum housing. Insulators are placed in the housing to permit cross bonding of the cable sheaths. Stop joints are placed every 1200–3000 m to isolate the liquid-supply sections. These joints may have to be placed closer together in areas with substantial elevation changes.

Terminations are very similar to those for pipe-type cables. Trifurcating joints are generally not required since almost all transmission-voltage self-contained cables are single-conductor design.

Liquid reservoirs are spaced along the circuit. Distances depend upon elevation changes, cable core diameter, and maximum allowable pressures. Typical spacings are 1500–5000 m. These reservoirs have alarms to indicate low liquid level or pressure. These alarms must be run back to the substation, typically in a separate communication duct, to notify operators of cable system problems.

GITL accessory requirements. These accessory requirements are minimal. Splices are an integral part of the assembly, and terminations are factory-made and attach to the cable in a similar manner as to a normal joint. The system contains alarms to warn of low pressure or high moisture content. Joints occur every 12–18 m (see Sec. 14.2.15) but are simple and straightforward. Expansion and contraction of the insulating gas is accommodated by allowing the pipe pressure to increase or decrease. Thermal-mechanical expansion of the aluminum bus is permitted by the use of bellows at bus connection points. The aluminum enclosure must be protected from corrosion using protective coatings and cathodic protection if the system is buried.

14.2.19 Manufacturing

Manufacturing of transmission cable should be done using quality materials and an environment free of contaminants. Impregnated-paper insulation technology has existed since the late 1800s and is the basis for substantial use of HPFF transmission cable in the United States. Extruded dielectrics, particularly cross-linked polyethylene (XLPE) insulation, have been used increasingly in recent years as the manufacturing technology to use this type of insulation up to 500 kV is developed.

Manufacturing requires that copper or aluminum wire be drawn and wrapped together for the required conductor cross section. Depending on the size of the conductor, the conductor may be formed in segments—typically four for HPFF and XD cables and six for SCLF cables—that must be laid together. A binder tape may be applied to hold the segments together, and a taped shield is applied over the conductor on paper cables.

Insulation is applied over the conductor by drawing the conductor through an appropriate type of machine. For paper-insulated cables, the paper tapes are applied dry by wrapping the insulation around the conductor until sufficient insulation has been built up for the operating voltage. The paper cable is then heated under vacuum to remove moisture before dielectric liquid is applied in an impregnation tank. XD cables have insulation applied using a catenary, horizontal or vertical extrusion machine. A "triple extrusion head" is a modern approach to applying extruded insulation where the conductor screen (shield), insulation, and insulation screen (shield) are applied in one process.

After the insulation is applied and impregnated, HPFF cables are often wrapped with a Mylar tape intercalated with a metallic shielding tape. Then skid wires are applied helically over the tapes to prevent mechanical damage to the cables when the three phases are pulled into the pipe. The cable is placed onto shipping reels, and the reels are sealed and blanketed with dry nitrogen to limit gas and moisture ingress.

In single-core cables, bedding may be placed over the insulation screen to prevent damage to the cable during thermal expansion of the cable. If a wire shield is to be installed, this is normally put in direct contact with the outer insulation shield prior to applying the bedding layer. Additional bedding in SCLF cables or a water-swellable tape or powder in XD cables is then applied before a metallic sheath. The sheath is most commonly made of lead, corrugated stainless steel, copper, or aluminum, and can be applied in an extrusion or using a seam weld and a press. Finally, a jacket made of polyethylene or polyvinyl chloride is extruded over the sheath. The cable is placed on a cable reel with the cable ends sealed to prevent moisture from getting into the cable. Typically, a pulling eye is attached at the factory for use during installation.

14.2.20 Operation and Maintenance

Operation and maintenance requirements of underground transmission cables are small compared with most electrical power equipment and are essentially confined to the dielectric fluid-handling systems for HPFF and SCLF cables, the outer cable jacket or pipe protective coating, and the corrosion protection systems for HPFF cables.

Extruded dielectrics and SCLF transmission cables have an outer jacket typically constructed of polyethylene or polyvinyl chloride. The jacket is periodically tested to verify that there is no damage. Damage to the jacket may result in localized corrosion and unexpected circulating currents in the sheath that will cause I^2R losses in the sheath, lowering the effective ampacity or overheating the cable. If the cables are cross-bonded, the link boxes should be checked to be sure that the sheath voltage limiters are not damaged and there is good ground continuity for the local earthing (Fig. 14-97).

All SCLF and HPFF terminations and some XD terminations contain small amounts of dielectric liquid (200–600 L). The terminations should be inspected to be sure that there are no fluid leaks. In areas with high levels of air pollution, such as near the ocean, near unpaved roads, or in industrial areas, it is important that the outside surface of the terminations be cleaned to avoid surface tracking. Porcelain terminations should be free of cracks or other mechanical damage.

Dissolved gas analysis is a useful tool for HPFF and SCLF cables to determine the condition of a cable by examining the ratio of certain gases in the dielectric liquid. Field dissipation factor measurement can also be performed.[37] For both dissolved gas analysis and dissipation factor measurements, the trend with time rather than an absolute value is of interest for monitoring any degradation with time. Many utilities perform tests once per annum. Joints in locations susceptible to thermomechanical bending should be x-rayed every few years. Semiannual or quarterly dew-point readings should be taken on CGIT lines.

A few utilities have experienced problems with dielectric fluid leaks in HPFF cables caused by a combination of several factors including coating failure, cathodic protection problems, and stray currents in the earth. Monitoring of cathodic protection system performance and periodic testing of the pipe coating can limit the possibility of leaks, and leak detection and location using per-fluorocarbons tracers or leak detection wire buried along the cable pipe have been used with success.

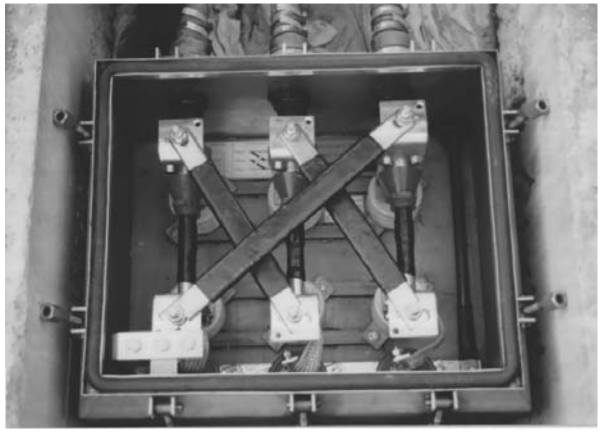

FIGURE 14-97 Cross-bonding box with links installed.

14.2.21 Fault Location

Although they are very uncommon, cable failures can be difficult to locate as compared to overhead lines where it is possible to visually inspect the entire line route. Locating cable faults requires the application of two types of techniques: terminal methods and tracer methods. Terminal methods are applied from one or the other end of the faulted cable and give an approximate location of a failure. Terminal methods include cable radar, bridge techniques, and time domain reflectometry. Tracer methods involve putting some type of signal on the faulted cable and then detecting changes in the signal when in close proximity to the fault location. Tracer techniques include tone sets, earth gradient, capacitive discharge ("thumping"), and magnetic pulse detection. Many times, the location of a failure is approximated with a terminal technique and then followed by a tracer technique precisely to locate the failure.

Pipe-type cable failures are particularly challenging. If fluid circulation is used on an HPFF cable, circulation should be stopped immediately once there is an indication of a failure to avoid contaminating the dielectric fluid. Since visible damage will generally not be apparent once the detection method has located the apparent fault location, the cable pipe must be x-rayed to determine if the exact location of the cable failure has been found. The liquid in the cable pipe must then be frozen on either side of the failure before the pipe can be cut and a repair initiated.

A good summary of classical fault location techniques can be found in Ref. 38. The IEEE Insulated Conductors Committee Working Group 12-48 is developing a guide for fault location.

14.2.22 Corrosion

Corrosion of underground cables can result from two phenomena; galvanic and electrolytic corrosion. Galvanic corrosion results from the electrochemical interaction of two or more materials, such as zinc and copper, with the level of galvanic action depending on the galvanic potential of the two materials. Steel, such as in a HPFF cable, can undergo corrosion from oxygen in acidic soil. Galvanic corrosion can be prevented by isolating the cable or pipe from other materials by using a protective coating or jacket. Pipe-type cables are often connected to a cathodic protection system where a negative voltage (relative to ground) is applied to the pipe using a rectifier and a polarization cell (or its solid-state equivalent is used) to provide a low-impedance path to ground for fault currents. Sacrificial anodes can also provide protection in the event the pipe-coating is damaged. Some utilities actively monitor the cathodic protection systems on the cable pipe to detect damage to the pipe coating as early as possible.

Electrolytic corrosion results from an externally imposed current leaving a conductive element where an anode zone is created. This might occur on the armor of a submarine cable. Protecting a cable from an electrolytic corrosion can be difficult because it is generally not possible to eliminate the source of the stray current that causes electrolytic corrosion. Instead, imposed cathodic current protection (ICCP) is used. In this scheme, anode beds are connected to the positive terminal of a rectifier, and the cable armor, for example, is connected to the negative terminal. Anode beds are placed along the cable to produce an imposed current on the cable armor. The level of stray currents will designate the current density, which must be produced by the ICCP system and anode beds in order to protect the cable.[39]

14.2.23 Testing

There are various tests performed on underground cable systems during design, after manufacture, before and after installation (commissioning tests), and as part of maintenance. Various IEEE, IEC, AEIC, and ICEA standards have been developed that address this subject.

A manufacturer often performs a long-term "type test" prior to commercial production to prove the integrity of a cable and its accessories. Some purchasers of a cable system may also require that a type test be performed as part of their cable order, generally when a large cable system will be supplied or when a new set of accessories is being used with a cable for the first time.

As part of manufacturing, routine and sample tests are performed and verified by the purchaser's representative to confirm that the cable was manufactured according to the designated specifications. Accessories also undergo routine tests and some purchasers choose to observe these tests or at least review completed test reports. Routine tests may include partial discharge (PD) testing, particularly on extruded cable systems, as well as capacitance, conductor resistance, dissipation factor (tan δ), and jacket integrity tests on extruded cables. Pipe-type cables on shipping reels may have the dew point and nitrogen pressure tested prior to shipping, and self-contained cables may have a check of dielectric fluid pressure rise to be sure that there is no air in the system. Some of these tests may be performed just prior to cable installation after cable reels are on site to be sure that the cable reels were not damaged during shipping.

After laying tests (commissioning tests) may include checks of conductor resistance, cable phasing, jacket integrity tests (on extruded or self-contained cables), a dc high-potential ("hi-pot") test on paper insulated cables (only), as well as tests on dielectric fluids before filling cable pipes or pressure reservoirs. XLPE-insulated cables generally are subjected to an ac "soak" test (energized without carrying load) or may be subjected to some higher voltage if available within the connected substation. Very low-frequency (VLF) tests sets may be employed for testing XLPE cables although they have limited availability at the higher transmission voltages. Utilities are increasingly using variable frequency resonant test sets to apply multiples of rated voltage to an XLPE cable system where the higher voltage is not available locally; this has some advantages including very low-fault current energy to apply to a fault in the event a problem is detected during the test.

Tests during operation and maintenance include periodic jacket integrity tests, PD, dissipation factor measurements (mainly on paper-insulated cables), and the various methods used to locate cable faults as described earlier. Dielectric fluid testing is performed on paper cable to check for dissolved gases (dissolved gas analysis or "DGA"), which is often a good indicator of various problems with a cable system.

14.2.24 Future Developments

Research & Development (R&D) Efforts. R&D work on cable systems themselves has waned as the industry entered the twenty-first century. As some paper-insulated transmission cables reached 40 years of operation, studies were done in the mid 1990s to evaluate loss of life and end of life effects. Many cable manufacturers continue to push the upper voltage limits for cross-linked polyethylene cable systems with systems available up to 500 kV from several suppliers. Superconducting cables, which had been evaluated and set-aside in the 1970s, have moved past the prototype stage and are seeing limited commercial applications. Manufacturers are pursuing more practical ways of offering HVDC cable systems, but most of this work relates to the connected converter stations rather than the cables themselves; one manufacturer offers a polymeric dc cable for this purpose.

Magnetic fields were once a critical issue for many utilities, but technical interest in this topic no longer seems to be a high priority. However, dynamic ratings and uprating methods are of great interest since these methods generally allow utilities to run their cable systems closer to the ultimate limit.

SECTION 15
DIRECT CURRENT POWER TRANSMISSION

Michael P. Bahrman
ABB, Inc.

CONTENTS

15.1 INTRODUCTION

High voltage direct current (HVDC) transmission is widely recognized as being advantageous for long-distance, bulk-power delivery, asynchronous interconnections and long submarine cable crossings. HVDC lines and cables are less expensive and have lower losses than those for 3-phase ac transmission.

Typical HVDC lines utilize a bipolar configuration with two independent poles and are comparable to a double circuit ac line. Because of their controllability HVDC links offer firm capacity without limitation due to network congestion or loop flow on parallel paths. Higher power transfers are possible over longer distances with fewer lines with HVDC transmission than with ac transmission. Higher power transfers are possible without distance limitation to HVDC cables systems using fewer cables than with ac cable systems due to their charging current.

HVDC systems became practical and commercially viable with the advent of high voltage mercury-arc valves in the 1950s. Solid-state thyristor valves were introduced in the late 1960s, leading to simpler converter designs with lower operation and maintenance expenses and improved availability. In the late 1990s a number of newer converter technologies were introduced permitting wider use of HVDC transmission in applications, which might not otherwise be considered. A list of HVDC projects currently in operation or under construction is given in Table 15-1.

15.2 APPLICATIONS

The significant increase in HVDC transmission can be attributed to one or more of the following reasons:

Economical. HVDC transmission systems often provide a more economical alternative to ac transmission for long-distance, bulk-power delivery from remote resources such as hydroelectric developments, mine-mouth power plants, or generation from large-scale wind farms. Whenever long-distance transmission is discussed, the concept of "breakeven distance" frequently arises. This is where the savings in line costs and lower capitalized cost of losses offsets the higher converter station costs. A bipolar HVDC line uses only two insulated sets of conductors rather than three. This results in narrower right-of-way (ROW), smaller transmission towers, and lower line losses than with ac lines of comparable capacity. A rough approximation of the savings in line construction is 30%. Although breakeven distance is influenced by the costs of ROW and line construction with a typical value of 500 km, the concept itself is misleading because in many cases more ac lines are needed to deliver the same power over the same distance due to system stability limitations. Furthermore, the long-distance ac lines usually require intermediate switching stations and reactive power compensation. For example, the generator outlet transmission alternative for the ±250 kV, 500 MW Square Butte Project was two 345 kV series-compensated ac transmission lines. Similarly, the ±500 kV, 1600 MW Intermountain Power Project (IPP) ac alternative comprised two 500 kV ac lines. The IPP takes advantage of the double circuit nature of the bipolar line and includes a 100% short-term and 50% continuous monopolar overload. The first 6000 MW stage of the transmission for the Three Gorges Project in China would have required 5 × 500 kV ac lines as opposed to 2 × (±500) kV, 3000 MW bipolar HVDC lines (Fig. 15-1).

For underground or submarine cable systems there is considerable savings in installed cable costs and cost of losses with HVDC transmission. Depending on the power level to be transmitted, these savings can offset the higher converter station costs at distances of 40 km or more. Furthermore, there is a rapid drop-off in cable capacity with ac transmission over distance due to the reactive component of charging current. Although this can be compensated by intermediate shunt compensation for underground cables, it is not practical to do so for submarine cables. For a given cable conductor area, the line losses with HVDC cables, can be less than half those of ac cables. This is due to more conductors, reactive component of current, skin effect, and induced currents in the cable sheath and armor.

Functional. The controllability and asynchronous nature of HVDC transmission provides a number of advantages for certain transmission applications. HVDC transmission capacity is firm and utilization usually runs higher due to its controllability. This is because congestion or loop flow on parallel transmission paths does not result in schedules curtailments for transmission loading relief.

With a cable system, unequal loadings or risk of postcontingency overloads often results in use of a series-connected phase-shifting transformer. These potential problems do not exist with a controlled HVDC cable system.

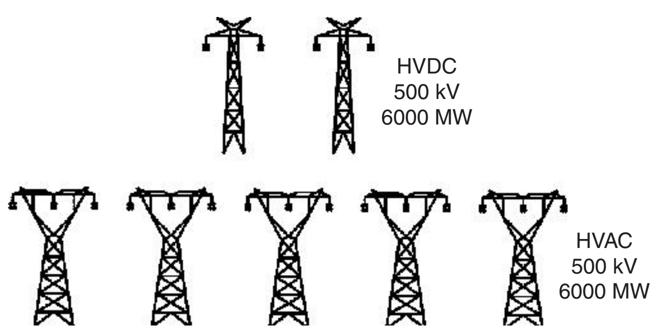

FIGURE 15-1 HVDC and EHV ac alternatives for first stage of three Gorges outlet transmission.

With HVDC transmission systems, interconnections can be made between asynchronous networks for more economic or reliable operation. The asynchronous interconnection allows interconnections of mutual benefit but provides a buffer between the two systems. Often these interconnections use back-to-back converters with no transmission line. The asynchronous links act as an effective "firewall" against propagation of cascading outages in one network from passing to another network. Many asynchronous interconnections exist in North America between the eastern and western interconnected systems, between the Electric Reliability Council of Texas (ERCOT) and its neighbors, that is, Mexico, Southwest Power Pool (SPP) and the western interconnect, and between Quebec and its neighbors, that is, New England and the Maritimes. The August 2003 northeast blackout provides an example of the firewall against cascading outages provided by asynchronous interconnections. As the outage propagated around the lower Great Lakes and through Ontario and New York, it stopped at the asynchronous interface with Quebec. Quebec was unaffected, the weak ac interconnections between New York and New England tripped, but the HVDC links from Quebec continued to deliver power to New England.

Environmental. HVDC allows delivery of more power over fewer lines with narrower ROW. This is especially important in trying to access diverse resources in remote locations where lines may pass through environmentally sensitive or scenic areas. There is no induction or alternating electromagnetic fields from HVDC transmission. There is no physical restriction limiting the distance for underground cables. Underground cables can be used on shared ROW with other utilities without impacting reliability concerns over use of common corridors. Lower cable losses improves efficiency and results in less heating in the earth.

15.3 HVDC FUNDAMENTALS

15.3.1 Converter Behavior and Equations

Conventional HVDC transmission schemes utilize line-commutated, current-source converters. Such converters require a synchronous voltage source in order to operate. The basic building block used for HVDC conversion is the 3-phase, full-wave bridge referred to as a 6-pulse or Graetz bridge (Fig. 15-2). The term 6-pulse is due to the characteristic harmonic ripple in the dc output voltage, which is at multiples of 6 times the fundamental frequency. Each 6-pulse bridge is comprised of 6 controlled switching elements or thyristor valves. Each valve comprises a number of series-connected thryristors to achieve the desired dc voltage rating.

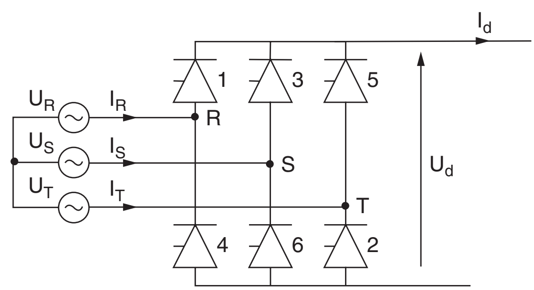

FIGURE 15-2 6-pulse bridge.

Converter dc output voltage is controlled by means of a delayed firing angle. Valve switching is synchronized to the ac source voltages via a phase-locked loop. The bridge is coupled to the ac bus via a converter transformer. Commutation of converter currents from one phase to another results in a converter voltage drop. Converter voltage drop is proportional to transformer reactance and current level I_d, resulting in a reduction of the dc voltage level U_d, due to commutation overlap u.

A set of equations has been derived to calculate U_d as a function of the phase voltages, the commutation reactance I_d, and the delay angle α. For rectifier operation converter polarity is positive, whereas for inverter operation it is negative bucking the direction of direct current flow. Equations describing inverter operation use extinction angle γ.

The direct voltage across the 6-pulse bridge is calculated by Eq. (15-1) for rectifier operation and Eq. (15-2) for inverter operation.

$$\frac{U_{dR}}{2} = U_{diOR}\cdot\left[\cos\alpha - (d_{xR} + d_{rR})\frac{I_d}{I_{dN}}\frac{U_{diORN}}{U_{diOR}}\right] - U_T \tag{15-1}$$

$$\frac{U_{dI}}{2} = U_{diOI}\cdot\left[\cos\gamma - (d_{xI} - d_{rI})\frac{I_d}{I_{dN}}\frac{U_{diOIN}}{U_{diOI}}\right] + U_T \tag{15-2}$$

The nominal relative inductive direct voltage drop is defined by Eq. (15-3), where X_t is the commutation reactance which includes the converter transformer reactance and any other reactances in the commutation circuit.

$$d_{xN} = \frac{3}{\pi}\frac{X_t\cdot I_{dN}}{U_{diON}} \tag{15-3}$$

The relative resistive direct voltage drop is defined by Eq. (15-4) where P_{cu} is the transformer and smoothing reactor load losses and R_{th} is current dependent voltage drop over the thyristors. The factor 2 is due to the fact that there are always two valves conducting at the same time.

$$d_r = \frac{P_{cu}}{U_{diON}\cdot I_{dN}} + \frac{2\cdot R_{th}\cdot I_{dN}}{U_{diON}} \tag{15-4}$$

The overlap angle for the rectifier and inverter are described by Eqs. (15-5) and (15-6), respectively.

$$\cos(\alpha + \mu_R) = \cos\alpha - 2\cdot d_{xNR}\frac{I_d}{I_{dN}}\frac{U_{diONR}}{U_{diOR}} \tag{15-5}$$

$$\cos(\gamma + \mu_I) = \cos\gamma - 2\cdot d_{xNI}\frac{I_d}{I_{dN}}\frac{U_{diONI}}{U_{diOI}} \tag{15-6}$$

The reactive power consumption for a 12-pulse converter (two 6-pulse converters with 30° shift in valve voltages) connected in series is calculated with Eq. (15-7).

$$Q_d = 2\cdot\chi\cdot I_d\cdot U_{diO} \tag{15-7}$$

where c is the overlap function described by Eq. (15-8) for rectified operation and Eq. (15-9) for inverter operation.

$$\chi = \frac{1}{4}\cdot\frac{2\cdot\mu + \sin 2\alpha - \sin 2(\alpha + \mu)}{\cos\alpha - \cos(\alpha + \mu)} \tag{15-8}$$

$$\chi = \frac{1}{4}\cdot\frac{2\cdot\mu + \sin 2\gamma - \sin 2(\gamma + \mu)}{\cos\gamma - \cos(\gamma + \mu)} \tag{15-9}$$

The relationship between the no-load phase-phase ac voltage on the valve side and the ideal no-load direct voltage is shown in Eq. (15-10). The rms value of the rated ac current on the valve side of the converter transformer is shown in Eq. (15-11). The total rated MVA of the 3-phase transformer group feeding the 6-pulse converter bridge is according to Eq. (15-12).

$$U_{vo} = \frac{U_{diO}}{\sqrt{2}}\cdot\frac{\pi}{3} \tag{15-10}$$

$$I_{vN} = \sqrt{\frac{2}{3}}\cdot I_{dN} \tag{15-11}$$

$$S_N = \sqrt{3}\cdot U_{vN}\cdot I_{vN} = \frac{\pi}{3}\cdot U_{diON}\cdot I_{dN} \tag{15-12}$$

Figure 15-3 illustrates the commutation process and its effect on valve currents and dc voltage due to delay angle and overlap. The solid upper envelope of the phase voltages is the voltage top of the bridge

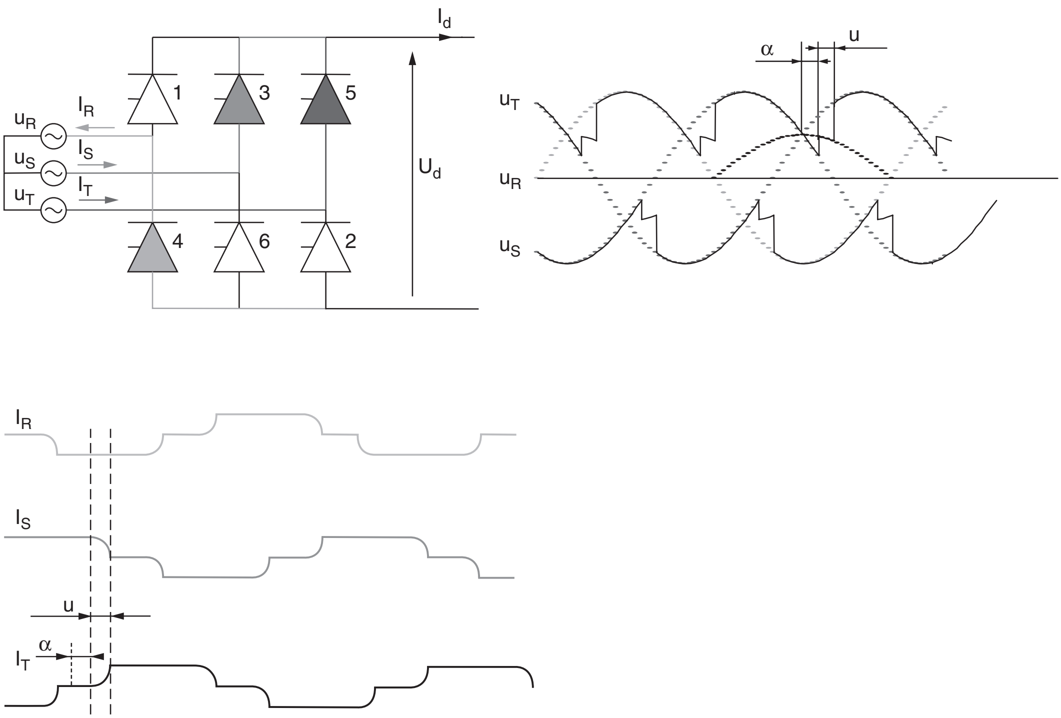

FIGURE 15-3 6-Pulse bridge commutation with delay angle and overlap.

with common valve cathodes, while the lower solid envelope is the voltage at the bottom of the bridge with the common valve anodes. The differential voltage across the bridge is the dc voltage U_d. The effect of the delay angle and commutation overlap on the dc voltage is evident. During commutation two valves in the same half bridge conduct simultaneously and the instantaneous voltage is half their sum.

The 6-pulse converter bridge can be used in rectifier operation with positive output voltage, $0 > \alpha < 90°$, converting ac to dc or in inverter operation with an output voltage that is negative with respect to the direction of dc current flow, $90 > \alpha < 180°$. By connecting two converters in series at opposite ends of a transmission line, one controlling dc voltage and the other controlling dc current, dc power transmission is achieved. The characteristic current harmonics ($f = 6n \pm 1$) are filtered on the ac side and the characteristic voltage harmonics ($f = 6n$) are filtered on the dc side to meet voltage distortion and telephone interference requirements.

The dc terminals of two 6-pulse bridges with ac voltage sources phase displaced by 30° can be connected in series for 12-pulse operation. In 12-pulse operation, the characteristic current and voltage harmonics have frequencies of $12n \pm 1$ and $12n$, respectively. The 30° phase displacement can easily be achieved by feeding one bridge through a transformer with a wye-connected secondary and the other transformer through a delta-connected secondary (Fig. 15-4). Most modern HVDC transmission

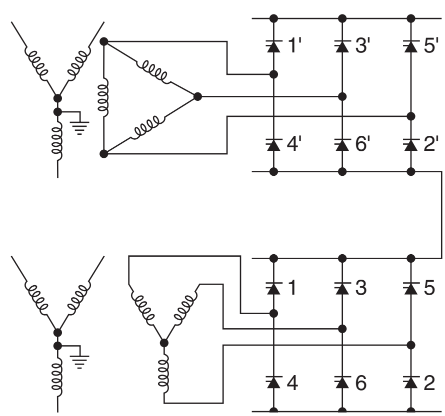

FIGURE 15-4 12-Pulse bridge.

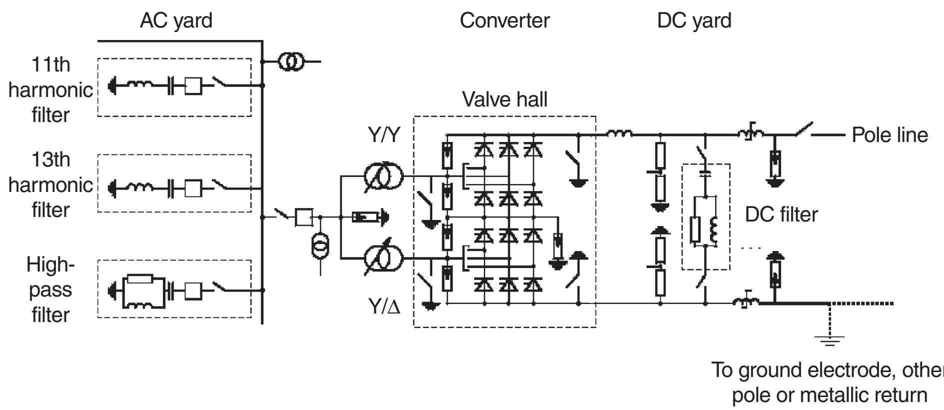

FIGURE 15-5 Simplified single line diagram for monopole.

schemes utilize 12-pulse converters to reduce the additional harmonic filtering requirements required for 6-pulse operation, for example, fifth and seventh on the ac side and sixth on the dc side. This is because although these harmonic currents still flow through the valves and the transformer windings, they are 180° out of phase and cancel out on the primary side.

15.3.2 Station Layout and System Configuration

A simplified single-line diagram for one pole with a 12-pulse converter is shown in Fig. 15-5. A CAD drawing and a photo of a monopolar converter station are shown in Figs. 15-6 and 15-7, respectively.

An HVDC converter station comprises the following major subsystems:

FIGURE 15-6 Monopolar converter station.

- Thyristor valves
- Converter transformers
- AC harmonic filters
- DC harmonic filters
- Valve cooling
- Control and protection
- Auxiliary power
- Valve hall building

The converter station layout depends on a number of factors such as the station configuration, that is, monopolar (Fig. 15-8), bipolar (Fig. 15-9) or back-to-back asynchronous tie (Fig. 15-10), valve design, ac system interconnection, filtering requirements, reactive power compensation requirements, land availability, and the local environment. In most cases, the thyristor valves are air-insulated, water-cooled, and enclosed in a converter building often referred to as a valve hall. For back-to-back ties with their characteristically low dc voltage, thyristor valves can be housed in prefabricated electrical enclosures in which case a valve hall is not required.

To obtain a more compact station design and reduce the number of insulated high voltage wall bushings, converter transformers are often placed adjacent to the valve hall with valve winding bushings protruding through the building walls for connection to the valves. Double or quadruple valve structures housing valve modules are used within the valve hall. Valve arresters are located immediately adjacent to the valves. Indoor motor-operated grounding switches are used for personnel safety

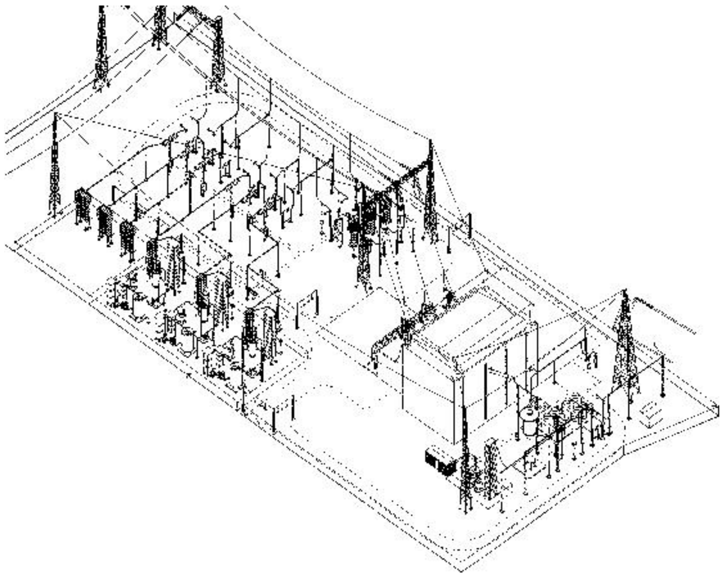

FIGURE 15-7 CAD drawing of monopolar converter station.

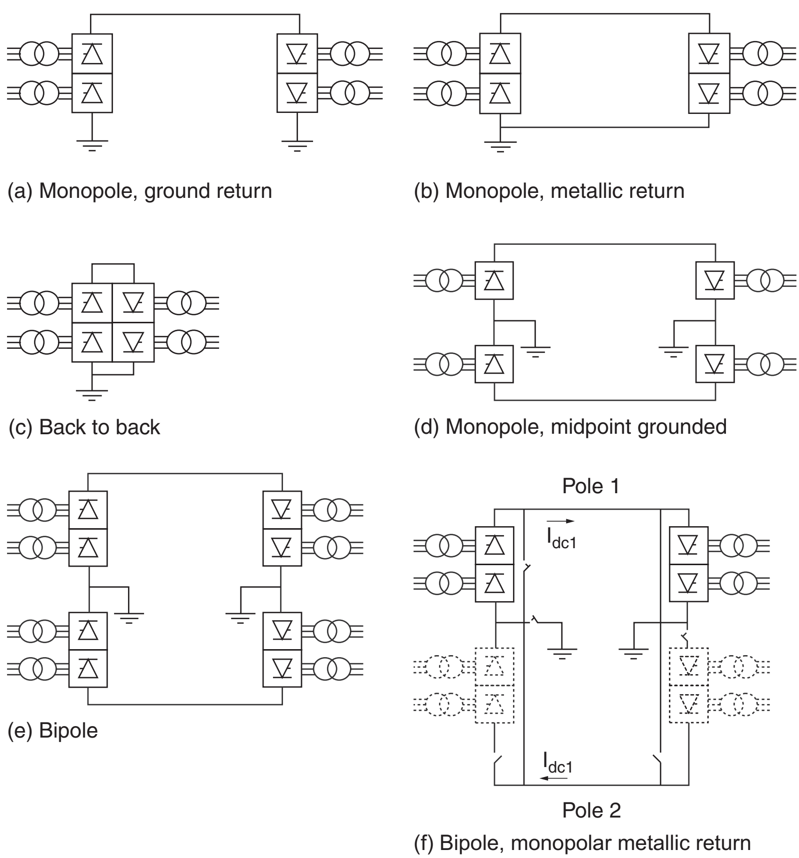

FIGURE 15-8 HVDC operating configurations/modes.

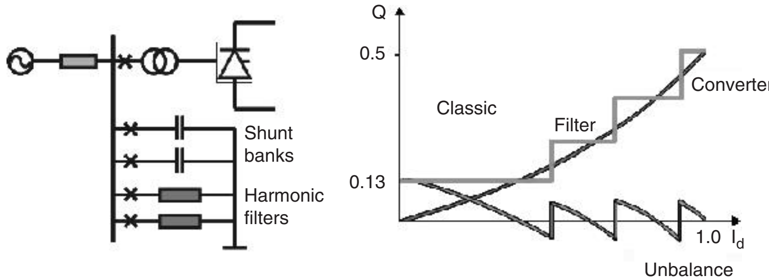

FIGURE 15-9 Reactive power balance.

during maintenance. Closed loop valve cooling systems are used to circulate the cooling medium through the indoor thyristor valves with heat transfer to dry coolers or evaporative cooling towers located outdoors.

Monopolar systems with ground return are the simplest and least expensive systems for moderate power transfers since only two converters and one insulated cable or line conductor is required. Such systems are commonly used with low voltage electrode lines and sea electrodes to carry the return current in submarine cable crossings.

In some areas conditions are not conducive to monopolar earth or sea return. This could be the case areas in heavily congested areas, fresh water cable crossings, or areas with high earth resistivities. In such cases a metallic neutral or low voltage cable is used for the return path and the dc circuit uses a simple ground local ground reference.

Back-to-back stations are used for interconnection of asynchronous networks and use ac lines to connect on either side. In such systems power transfer is limited by the relative capacities of the adjacent ac systems at the point of coupling.

As an economic alternative to a monopolar system with metallic return, the midpoint of a 12-pulse converter can be connected to earth directly or through an impedance and two half voltage cables or line conductors can be used. The converter is only operated in 12-pulse mode, so there is no earth current.

The most common configuration for modern overhead HVDC transmission lines is bipolar with a single 12-pulse converter for each pole at each terminal. This gives two independent dc circuits each capable of half capacity. For normal balanced operation there is no earth current. Monopolar earth return operation, often with overload capacity, can be used during outages of the opposite pole.

Earth return operation can be minimized during monopolar outages by using the opposite pole line for metallic return via pole/converter bypass switches at each end. This requires a metallic-return transfer breaker in the ground electrode line at one of the dc terminals to commutate the current from the relatively low resistance of the earth into that of the dc line conductor. Metallic return operation

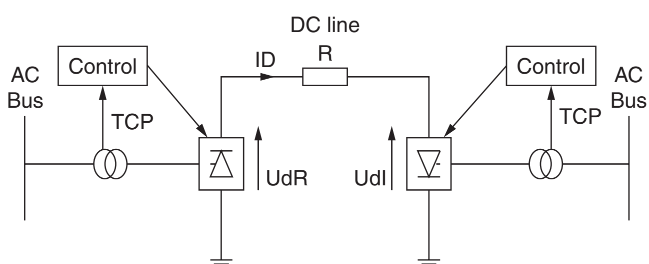

FIGURE 15-10 HVDC control system.

capability is provided for most dc transmission systems. This is not only effective during converter outages but also during line insulation failures where the remaining insulation strength is adequate to withstand the low resistive voltage drop in the metallic return path.

15.3.3 Reactive Power Compensation

As shown by Eqs. (15-7) through (15-9) in Sec. 15.3.1, HVDC conversion with line-commutated converters demands reactive power from the ac network at each HVDC terminal. The reactive power demand is a function of the firing angle in rectifier operation and extinction angle in inverter operation, the direct current and the overlap angle. The overlap angle is a function of the ac commutating voltage, the commutation reactance, and the dc current. As a rough approximation nominal reactive power demand at each terminal is about half the active power transfer.

The total reactive power produced by all the ac harmonic filters at each terminal is usually in the range of 30% to 40% of the converter rating. The filters therefore provide most of the reactive power compensation to meet the converter reactive power demand. The remaining reactive power necessary at the higher power levels can be provided from shunt capacitor banks, synchronous condensers, and static var compensators or nearby generation. Any reactive power mismatch must be provided or absorbed by the local ac system. Figure 15-9 shows the reactive power demand of a converter station, the reactive power from the filters, and the reactive power exchange with the ac network as a function of power transfer.

With weaker ac networks, that is, networks where the 3-phase symmetrical short circuit capacity is low compared to the rating of the dc converter station, various system constraints impact the reactive power compensation. With weaker systems, the size of the reactive power compensation elements may need to be reduced due to the voltage change on switching and the allowable reactive power exchange with the ac network. This may mean that filter banks may have to be subdivided with smaller branches. Sometimes, the minimum filtering requirements, for example, those at low power, exceed the reactive power demand of the converters, and shunt reactors are also required to absorb the excess vars from the filters.

15.3.4 Control and Operation of HVDC Links

The fundamental objectives of an HVDC control system are:

- To control basic system quantities such as dc line current, dc voltage, and transmitted power accurately and with sufficient speed of response
- To maintain adequate commutation margin in inverter operation so that the valves can recover their forward blocking capability after conduction before their voltage polarity reverses
- To control higher level quantities such as frequency in isolated mode or provide power oscillation damping to help stabilize the ac network
- To compensate of loss of a pole, a generator, or ac transmission circuit by rapid readjustment of power
- To ensure stable operation with reliable commutation in the presence of system disturbances
- To minimize system losses and reactive power consumption
- Ensure proper operation with fast and stable recoveries during system faults and disturbances

With HVDC transmission one terminal sets the dc voltage level, while the other regulates the dc current by controlling its output voltage relative to that maintained by the voltage-setting terminal. Since the dc line resistance is low, large changes in current and hence power can be made with relatively small changes in firing angle. Two independent methods exist for controlling the converter dc output voltage. These are (1) by changing the ratio between the direct voltage and the ac voltage by varying the delay angle α or (2) by changing the converter ac voltage via load tap changers (LTC) on the converter transformer. Although the former method is rapid, the latter method is slow due to

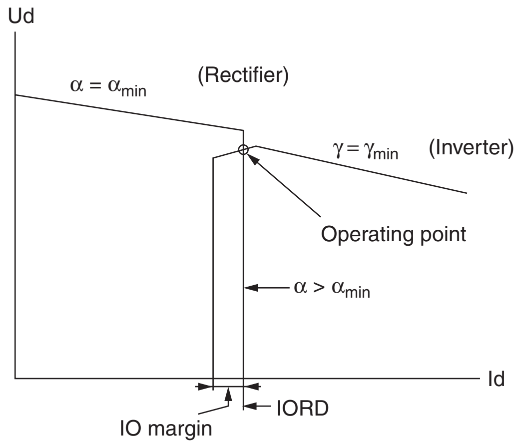

FIGURE 15-11 Static operating characteristics.

the limited speed of response of the LTC. Use of high delay angles to achieve a larger dynamic range, however, increases the converter reactive power consumption. To minimize the reactive power demand while still providing adequate dynamic control range and commutation margin, the LTC is used at the rectifier terminal to keep the delay angle within its desired steady-state range, for example, 13° to 18°, and at the inverter to keep the extinction angle γ within its desired range, for example, 17° to 20°, if the angle is used for dc voltage control or maintain rated dc voltage if operating in minimum commutation margin control mode.

Cooperation between the two terminals allows for efficient operation and provides for backup control modes for abrupt changes to the system voltages during disturbances. The converter control system at each terminal provides a static control characteristic. The intersection of the static control characteristics at the rectifier and inverter terminals determines the operating point. With the rectifier operating in constant current control and the inverter in constant angle control, as shown in Fig. 15-11, presents a stable operating point.

Each converter terminal is equipped with a closed loop current control or current control amplifier (CCA) as shown in Fig. 15-12. The backup current regulator at the inverter comes into effect when the rectifier ac voltage is suddenly reduced, forcing the rectifier characteristic down resulting in a new operating point with the rectifier minimum firing angle setting the dc voltage and the inverter current order setting the current. This shift in operating point is referred to a mode shift. A dc voltage regulator may also be used with or without current compounding to achieve a positive slope at the inverter with minimum extinction angle or commutation margin as a backup. A mode shift can also occur for a sudden increase in inverter ac voltage if operating in constant extinction angle control.

Other control functions are needed to synchronize the valve firing to the ac system commutation voltages, to clear and recover from dc line faults, to translate the alpha orders to firing pulses and

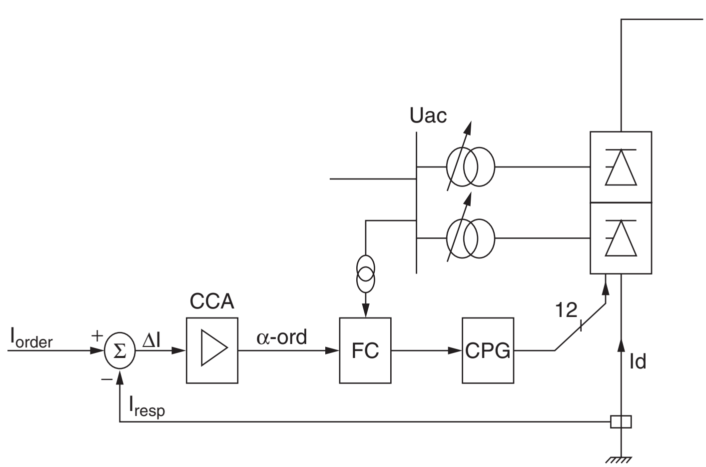

FIGURE 15-12 Closed loop current control system.

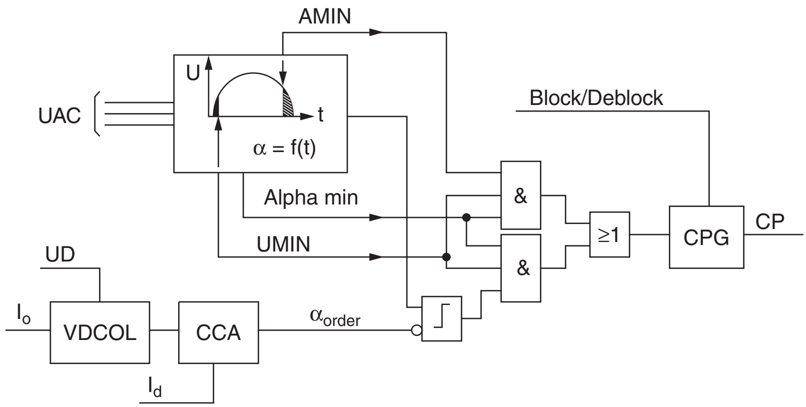

FIGURE 15-13 Converter firing control.

distribute them to the high-voltage valves, to minimize the reactive power consumption and achieve stable recoveries from large signal disturbances and faults in the ac network. Figure 15-13 shows these basic functions in the converter firing control (CFC).

The current order I_o is received from the pole power control. If the dc voltage is very low as during faults, the current order is limited by the voltage-dependent current order limiter, VDCOL. The alpha firing order is then limited as to its minimum and maximum value and minimum valve firing voltage (UMIN) in the converter firing control. Alpha min is used in inverter operation to prevent firing in rectifier operation. Minimum commutation margin control is used in inverter operation to maintain the minimum voltage time area to ensure successful recovery of forward blocking capability after valve conduction.

Figure 15-14 shows the static characteristics of the rectifier and inverter with addition of the VDCOL. The VDCOL acts to limit the dc current order below its normal set point if the dc current is above its break point and the dc voltage is lower than its break point. Taking into account dynamic performance, the current limitation is very fast acting during decreasing voltage due to faults, while the recovery is slower upon system voltage recovery depending on ac system strength or ability to deliver reactive power to the converter during recovery.

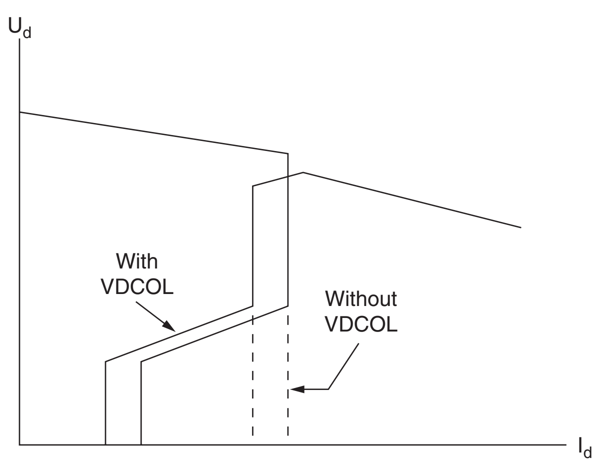

FIGURE 15-14 U_d-I_d characteristics with VDCOL.

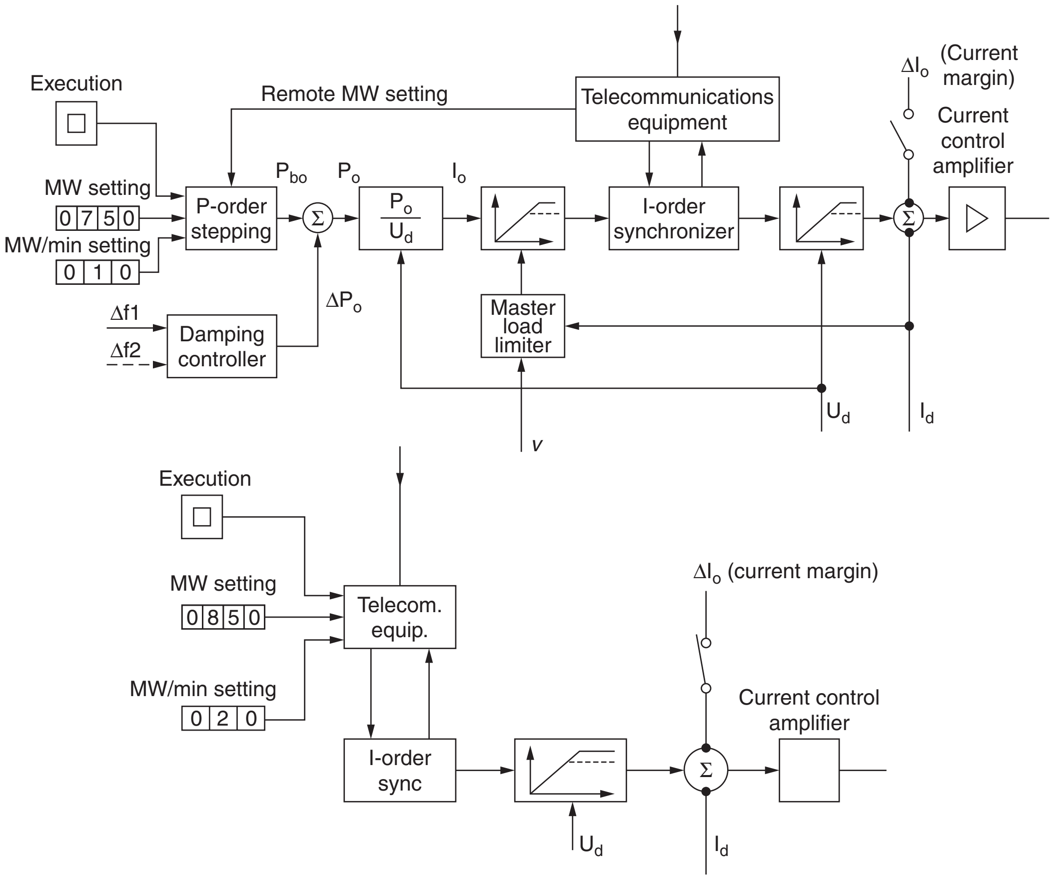

FIGURE 15-15 Master power control and current order synchronization.

The fundamental control functions described in the previous paragraphs are applied at the pole level and are independent of those on the other pole in a bipolar system. Coordination of the current orders between the terminals is required during ramping of the dc power during schedule changes. This is done during normal operation with secure communications between the terminals. Backup control strategies have been developed for communications outages. In a bipolar system, a master control is used for coordinated schedule changes and calculation of the current orders for each pole. The master control is used for compensation for loss of a pole by doubling the current order on the remaining pole subject to the equipment ratings. Figure 15-15 shows the current order coordination between the two terminals. For bipolar operation, the voltage fed to the power controller is the bipolar voltage assuring equal current orders to each pole. Upon loss of a pole this voltage is cut in half. Normally, the master control is intentionally slow being only used for schedule changes. For loss of a pole, however, its response time is fast. The master control can also handle supplemental control functions such as power oscillation damping and frequency control. Synchronization of the current order is such that the current margin is maintained.

15.3.5 Multiterminal Operation

The same control principles used for two-terminal operation can be applied to multiterminal operation with one terminal being assigned to voltage control, while the other terminals control their

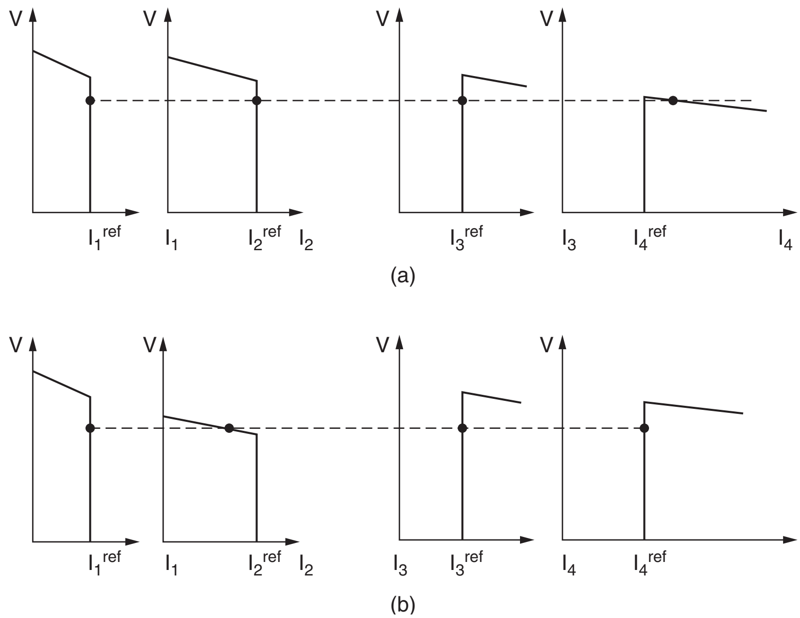

FIGURE 15-16 Static characteristics for 4-terminal HVDC system illustrating mode shift from inverter 4 (upper set) to Rectifier 2 (lower set) due to depressed ac voltage at Rectifier 2.

respective dc current orders (Fig. 15-16). The master control must also ensure that the sum of the rectifier current orders equals the sum of the inverter current orders on a per pole basis during all operating conditions. If one of the terminals is limited or tripped, the residual mismatch is allocated among the remaining stations according to prioritized distribution factors to ensure that Kirchoff's law is met. If the tripped station is the voltage setting terminal (VST), one of the remaining stations must be assigned to voltage control. The same method for clearing dc line faults, force retard of the rectifier(s) to invert off the dc current, can be used along with fast-acting pole-isolating switches which in turn can be used to isolate a faulty terminal without using special purpose dc breakers.

15.3.6 Economics and Efficiency

The following factors influence the optimum solution for HVDC transmission systems:

- Power transfer requirements
- Transmission distance
- Capitalized cost of losses
- System configuration, that is, bipolar, monopolar, back-to-back OVHD line or cable system
- System connection voltages
- Relative system strength
- Reactive compensation requirements
- Environmental conditions
- Future expandability
- Transformer transport limitations

There is an economy of scale for HVDC transmission. It would cost less per kilowatt to transfer 3000 MW a distance of 800 km at ± 500 kV than it would to transfer 1000 MW. It would cost less

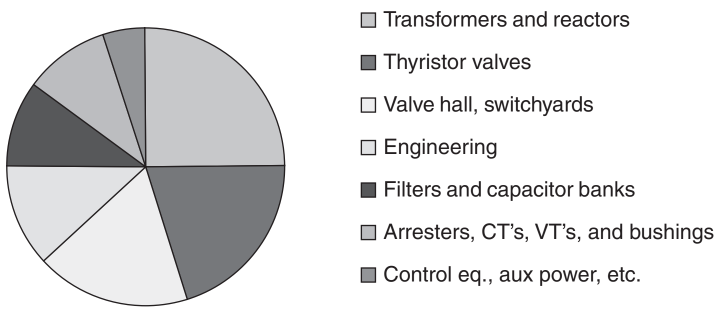

FIGURE 15-17 Terminal cost.

per kilowatt to transfer 600 MW over a monopolar submarine cable system than it would to transfer the same power on a 2-pole cable system with each pole rated at half the capacity. A 550-MW back-to-back asynchronous link would cost less per kilowatt than a 150-MW link.

HVDC applications at locations with relatively low short circuit capacities typically cost more per kilowatt due to constraints on reactive power compensation and dynamic overvoltage mitigation measures. A typical terminal cost breakdown of an HVDC transmission system for an OVHD line is shown in Fig. 15-17.

15.4 ALTERNATIVE CONFIGURATIONS

15.4.1 Capacitor-Commutated Converters

Converters with series capacitors connected between the valves and the transformers were introduced in the late 1990s for weak-system back-to-back applications. These converters are referred to as capacitor-commutated converters (CCC). The series capacitor provides some of the converter reactive power compensation requirements automatically with load current and provides part of the commutation voltage improving voltage stability. The overvoltage protection of the series capacitors is simple since the fault currents are limited by the impedance of the converter transformers. The CCC configuration allows higher power ratings in areas where the ac network is close to its voltage stability limit. The asynchronous Garabi interconnection between Brazil and Argentina consists of 4 × 550 MW parallel CCC links. The Rapid City Tie between the eastern and western interconnected systems consists of 2 × 100 MW parallel CCC links (Fig. 15-18). Both installations use a modular design with converter valves located within prefabricated electrical enclosures.

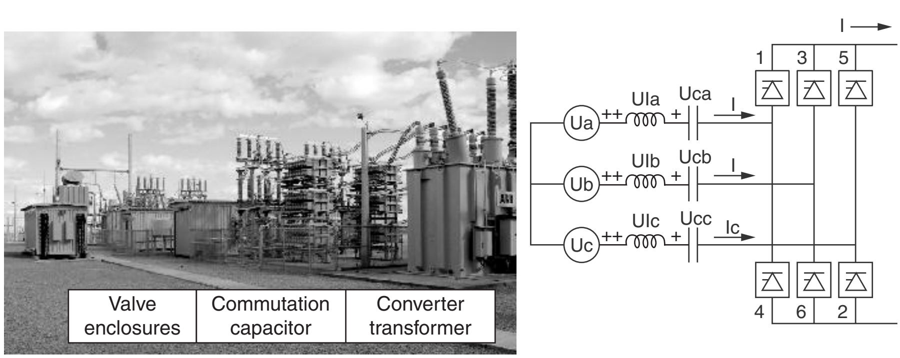

FIGURE 15-18 Rapid City Tie with modular 2 × 100 MW capacitor commutated converters.

15.4.2 Grid Power Flow Controller

A variation of the line-commutated design using a single 6-pulse converter has been used for a small back-to-back tie application. The term grid power flow controller (GPFC) has been used to describe this system design. By using a 6-pulse converter, there is no need for a second transformer secondary connection to obtain the requisite 30° phase displacement for 12-pulse operation. More ac harmonic filtering in the form of fifth and seventh branches is required, however. By using a 6-pulse converter and connecting the filters on the valve side, a simpler transformer connection can be utilized for matching the system voltage and blocking zero-sequence currents from flowing into the ac network. The ungrounded system has a large zero-sequence third order harmonic voltage component, however, appearing on the ungrounded neutrals and on the dc pole voltages, which increases the insulation levels. Despite using only one 6-pulse converter, the same number of series-connected thyristors is needed for the same dc voltage level.

15.4.3 Variable Frequency Transformer (VFT)

A technology that competes with HVDC for small capacity back-to-back ties in the 100 MW range was introduced in the early 2000s. A variable frequency transformer (VFT) is a machine rotating at the slip frequency between the two networks with high current between the rotor and stator passing through slip rings. The angle of the rotor is positioned to achieve a scheduled power flow by means of dc drives. The machine is connected to the network via step-up transformers. The reactive power demands of the VFT must be supplied by mechanically switched capacitor banks. Power control is slow due to having to move the inertia of the rotor, so it cannot respond quickly to a trip of generation on one the isolated network, for example. It cannot respond rapidly to variations in frequency or phase angle in the network so there will be inadvertent flow for fast variations. The VFT and its transformers provide an impedance, albeit a high one of around 40%, between the two networks. Therefore, the VFT will act as a voltage divider for faults in the network. This means that reactive power will be drained from one network due to a fault in the other. Losses of the VFT are higher than those for conventional HVDC.

15.5 STATION DESIGN AND EQUIPMENT

15.5.1 Thyristor Valves

For HVDC conversion, the thyristor valve must perform the following functions:

- Sequentially connect selected ac phases to the dc system per control pulses
- Conduct high current with low forward drop
- Block high voltages in both the forward and reverse directions
- Controllable and self monitoring
- Even voltage distribution and current turn-on
- Damp switching transients
- Fault tolerant and robust
- Accommodate cooling medium in high voltage environment

Thyristor valves are built up of series-connected thyristor modules and saturable reactors to limit valve turn-on di/dt. Each module contains a number of series-connected thyristors mounted on heat sinks. Each thyristor level is paralleled by an RC network for even voltage distribution and damping of commutation overshoots. Voltage measurement across each thyristor level is provided for thyristor monitoring, forward protection, and recovery protection.

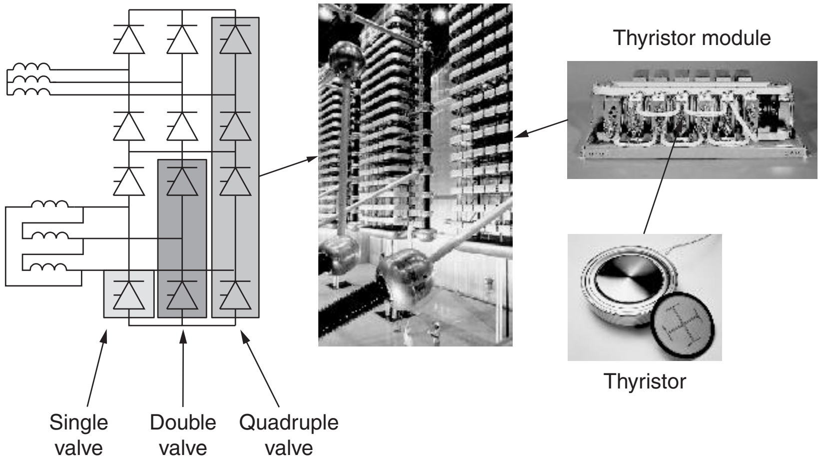

FIGURE 15-19 12-Pulse quadruple thyristor valve arrangement.

Each thyristor is coupled to the valve firing control at ground potential by means of two fiber optic links, one to carry valve trigger pulses to the thryistor gate circuit and the other for thyristor monitoring. Two types of thyristor triggering are used, electrically triggered thyristors (ETT) and light-triggered thyristors (LTT). Both triggering methods require voltage measurement at each thyristor level for monitoring and protection. ETT derives energy for gating from the RC damping circuit and gating is initiated by trigger pulses generated by light-emitting diodes. LTT thyristors have an optical turning-on region integrated on the thyristor wafer itself and use higher-power trigger pulses provided by laser diodes. Each thyristor level is equipped with forward protection which gates the thyristor on if the forward blocking voltage becomes too high due to, for example, absence of a trigger pulse. In inverter operation, during the thyristor recovery time after conduction, the forward protection level can be temporarily lowered. This is called recovery protection. ETT permits recovery protection to be implemented independently at the individual thyristor level (Fig. 15-19).

15.5.2 Converter Transformers

Converter transformers are the link between the ac and dc systems. They provide isolation between the two systems, preventing dc voltage and current from reaching the ac system. They also provide the phase displacement necessary for 12-pulse operation through wye- and delta-valve winding connections. Converter transformers have regulating windings with load-tap changers to maintain the ac voltage and converter firing angle within a narrow band across the entire converter operating range. Converter transformer impedance also limits the valve short-circuit levels to within their handling capability. As shown by Eq. 15-12, the 3-phase rating of the converter transformer for a 6-pulse bridge is proportional to U_{diON} and I_{dN}.

Converter transformer losses are those due to the fundamental frequency of load current plus those due to harmonics. The insulation design for converter transformers must take into account the direct voltage stresses superimposed on the normal ac voltage stresses. The ac stresses distribute as it would in a capacitive network while the dc voltage stresses distribute as according to a resistive network.

Transformer design depends on the bridge rating and type of converter connection and takes into account spare parts requirements and transport restrictions. For a small back-to-back, for example, a

3-phase bank with double secondary (wye and delta) may be used, that is, nine windings on a single core structure in a common tank for each 12-pulse converter bridge. For larger converters, three, single-phase transformers with double secondary windings may be used for each 12-pulse bridge. For the largest converter ratings where there may be some transport limitations, single-phase, two-winding transformers may be used, that is, six transformers per 12-pulse bridge (Fig. 15-20).

FIGURE 15-20 Single-phase, three-winding converter transformer for a 3100 MW bipole.

15.5.3 Smoothing Reactor

A smoothing reactor is connected in series with the converter on the dc side to reduce the harmonic ripple in the dc current as well as reduce transient currents during faults. The smoothing reactor also protects the converter valves from voltage surges coming in on the dc line. The dc smoothing reactor together with shunt-connected dc filters serve to limit telephone interference disturbing currents from flowing on the dc line. Most smoothing reactors are air-core, naturally air-cooled.

15.5.4 AC Filters

Converters inject harmonic currents into the ac network. AC filters are used to prevent these harmonic currents from flowing into the ac network impedance causing voltage distortion and induced telephone interference in the audible frequency range. AC filters provide a low-impedance path to ground at the harmonic frequencies. The ac filter comprises high-voltage capacitor banks and lower-voltage reactors, resistors, and capacitors, which together form a circuit tuned to the characteristic harmonic(s). The lower-order filters are single- or double-tuned, band-pass filters, while the higher harmonics are often taken care of by high-pass filters (Fig. 15-21).

AC harmonic filter design involves calculating the harmonic currents generated and estimating harmonic impedance characteristics of the ac network across the whole range of operating conditions and tolerances. A filter design is then developed to meet the required performance requirements. Filter components are then rated with an adequate margin the particular application.

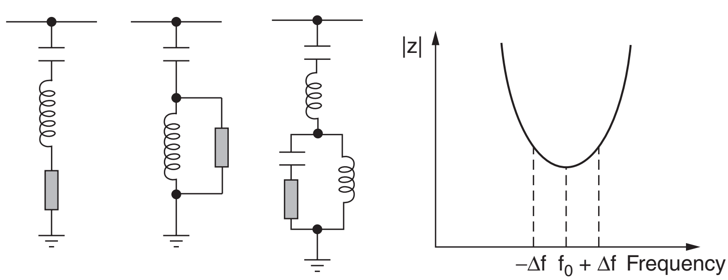

FIGURE 15-21 (*a*) Bandpass filter, (*b*) highpass filter, (*c*) double bandpass filter, (*d*) impedance vs. frequency.

The most common filter performance criteria are individual and total harmonic voltage distortion, D_T and D_h, and weighted telephone interference factor (TIF), calculated as follows:

$$D_h = 100 \times V_h/V_1$$

$$D_T = \left(\sum_{h=2}^{49} D_h^{\,2}\right)^{1/2}$$

$$\text{TIF} = \left[\sum_{h=2}^{49}\left(F_h \cdot \frac{V_h}{V_1}\right)^2\right]^{1/2}$$

15.5.5 DC Filters

Filters are required on the dc side for dc to limit interference with communication circuits, which are inductively coupled to the dc line, for example, parallel telephone lines. The design criterion for dc harmonic filters is a function of relating to the flow of harmonic currents at any point along the dc line to the interference with adjacent telephone lines. Significant parameters are the relative location of telephone lines with respect to the dc line, their shielding, the presence of any ground wires, and the earth's resistivity. This criterion is typically expressed as equivalent disturbing current I_{eq}. Disturbance levels are lower in normal balanced bipolar mode, due to cancellation effects, than in monopolar mode.

DC filter design must take into account the entire dc network with all harmonic sources and operating modes. DC harmonic filters consist of band-pass and high-pass filters connected in shut outside the smoothing reactor. Many modern HVDC links use a single 12th harmonic band-pass filter on each pole with active filtering for the higher order harmonics (Fig. 15-22). Active filtering consists of measuring the actual dc-side harmonics from the converter and counter-injecting the same amount with opposite polarity.

15.5.6 Power Line Carrier (PLC) Filters

Commutation in HVDC converters discharges stray capacitances and generates electrical noise at the lower end of the power line carrier spectrum (PLC), that is, strongest at 30 to 70 kHz. This noise may pass onto the interconnecting ac and dc lines. Where low-level carriers exist at the lower end of the PLC spectrum, filters may be required.

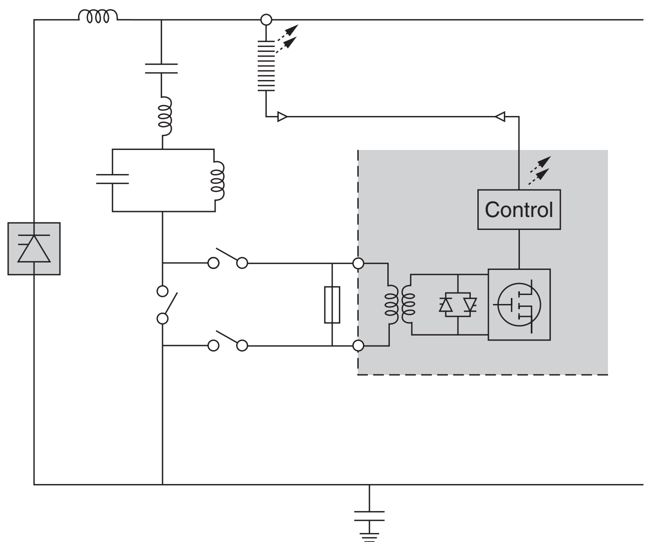

FIGURE 15-22 Active dc harmonic filter.

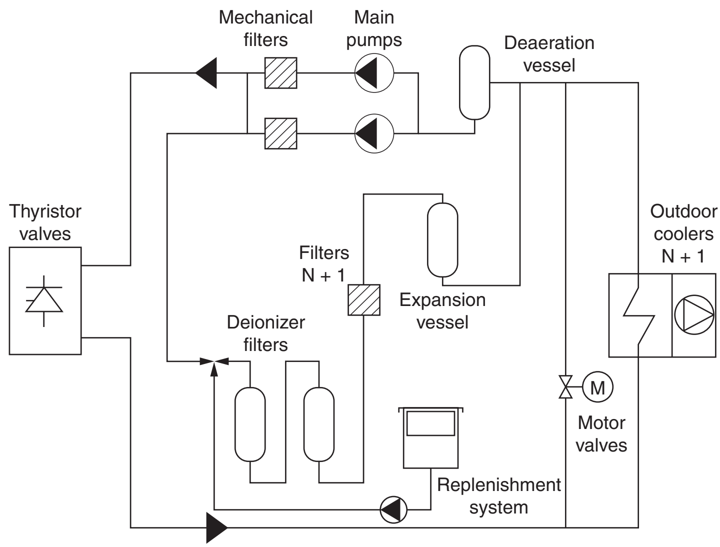

FIGURE 15-23 Closed-loop water cooling system.

15.5.7 Valve Cooling System

Thyristor valves must be cooled to avoid too high thyristor junction temperatures and to dissipate heat from the valve damping circuits and reactors. Valve cooling is accomplished by a deionized water loop circulating via insulated tuning to the individual thyristor heat sinks. Waste heat is passed to outdoor liquid-to-air coolers. Redundant variable speed pumps and coolers fed from redundant power supplies are used for reliability, availability, and ease of maintenance (Fig. 15-23).

15.5.8 Reliability and Availability

To meet high levels of reliability and availability plus facilitate ease of maintenance, redundancy is commonly used in HVDC converter station design. Typical guaranteed unavailability values are 0.5% for forced outages and 1.0% for scheduled outages.

Redundant series-connected thyristor levels are used in the valves. The failure mode is short circuit of the thyristor, so operation can continue until a convenient time for restoring full redundancy. Redundant cooling pumps and cooler units are used. Use of redundant control and protection systems is often used. For major main circuit components, spare parts are provided at site to minimize the time for replacement.

15.6 VOLTAGE SOURCE CONVERTER (VSC) BASED HVDC TRANSMISSION

15.6.1 System Characteristics

Conventional HVDC transmission employs line-commutated, current-source converters with thyristor valves. These converters require a relatively strong synchronous voltage source in order to commutate. The conversion process demands reactive power from filters, shunt banks, or series capacitors, which are an integral part of the converter station. Any surplus or deficit in reactive power must be

TABLE 15-2 HVDC VSC Projects Listing

Project	Year commissioned	Power rating, MW	DC voltage, kV	Cable, km	Location
Hellsjon	1997	3	± 10	10	Sweden
Gotland Light	1999	50	± 80	70	Sweden
Direct Link	2000	3 × 60	± 80	65	Australia
Tjaerborg	2000	7.2	± 9	4.4	Denmark
Cross Sound Cable	2002	330	± 150	40	United States
Murraylink	2002	200	± 150	180	Australia
Troll Offshore	2005	2 × 42	± 60	70	Norway
Estlink	2006	350	± 150	105	Estonia/Finland

accommodated by the ac system. This difference in reactive power needs to be kept within a given band to keep the ac voltage within the desired tolerance. The weaker the system or the further away from generation, the tighter the reactive power exchange must be to stay within the desired voltage tolerance.

HVDC transmission using voltage-source converters (VSC) with pulse-width modulation (PWM) was introduced as HVDC Light® in the late 1990s by ABB. These VSC-based systems are force-commutated with insulated-gate bipolar transistor (IGBT) valves and solid-dielectric, extruded HVDC cables (Table 15-2).

HVDC transmission and reactive power compensation with VSC technology has certain attributes which can be beneficial to overall system performance. VSC converter technology can rapidly control both active and reactive power independently of one another. Reactive power can also be controlled at each terminal independent of the dc transmission voltage level. This control capability gives total flexibility to place converters anywhere in the ac network since there is no restriction on minimum network short-circuit capacity. Forced commutation with VSC even permits black start, that is, the converter can be used to synthesize a balanced set of 3-phase voltages like a virtual synchronous generator. The dynamic support of the ac voltage at each converter terminal improves the voltage stability and increases the transfer capability of the sending and receiving end ac systems.

15.6.2 Applications

The aforementioned attributes of VSC-based HVDC transmission makes it especially suitable in certain applications. These applications are summarized as follows:

Underground Cable. HVDC cable systems do not face the distance limitations or suffer the higher losses of ac cable systems. Therefore, long-distance HVDC cable transmission is possible. Extruded HVDC cables are lighter, more flexible, and easier to splice than the mass-impregnated, oil-paper cables (MIND) used for conventional HVDC transmission, thus making them more conducive for land cable applications where transport limitations can drive up costs. The lower cost cable installations made possible by the extruded HVDC cables makes long-distance underground transmission economically feasible for use in areas with ROW constraints.

Power Supply to Insular Load. Forced-commutation, dynamic voltage control, and black-start capability allow VSC HVDC transmission to serve isolated loads on islands over long-distance submarine cables without any need for running expensive local generation.

Offshore. The VSC transmission is compact and can feed production or transportation loads on offshore oil or gas platforms from shore. This can eliminate the need for more expensive, less efficient, or higher emission offshore power production. The VSC converters can operate at variable frequency to more efficiently drive large compressor or pumping loads using high-voltage motors.

Asynchronous Interconnections. Interconnections between asynchronous networks are often at their periphery where the networks tend to be weak relative to the desired power transfer. The dynamic voltage support and improved voltage stability offered by VSC-based converters permits higher power transfers without as much need for ac system reinforcement. The VSC converters do not suffer commutation failures allowing fast recoveries from nearby ac faults. Economic power schedules, which reverse power direction, can be made without any restrictions since there is no minimum power or current restrictions.

Urban Infeed. Power supply for large cities depends on local generation and power import capability. Local generation is often older and less efficient than newer units located remotely. Often, however, the older, less-efficient units located near the city center must be dispatched out-of-merit because they must be run for reliable voltage support or inadequate transmission. New transmission into large cities is difficult to site due to ROW and land-use constraints. Compact VSC-based underground transmission circuits can be placed on existing dual-use ROW to bring in power as well as provide voltage support, allowing a more economical power supply without compromising reliability. The receiving terminal acts like a virtual generator delivering power and voltage regulation. Stations are compact and housed mainly indoors making siting in urban areas somewhat easier.

Outlet Transmission for Large-Scale Wind Generation. Large remote wind generation arrays require a collector system, reactive power support, and outlet transmission. Transmission for wind generation must often traverse scenic or environmentally sensitive areas or bodies of water. The VSC-based HVDC transmission allows efficient use of long-distance land or submarine cables and provides reactive support to the wind generation complex.

Multiterminal Systems. The VSC HVDC transmission reverses power through reversal of current direction rather than polarity. This makes it easier to reverse power at an intermediate tap independently of the main power flow direction since voltage polarity reversal is not required. Conventional HVDC transmission requires switching for converter opposite pole connection or polarity reversal.

15.6.3 VSC Station Configuration and Design

HVDC transmission systems based on VSC converter technology are configured as shown in Fig. 15-24.

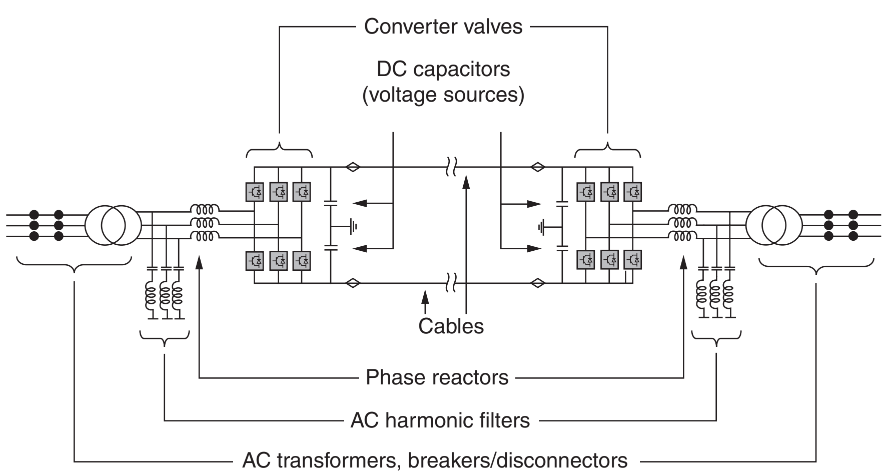

FIGURE 15-24 VSC-based HVDC.

The transmission circuit consists of a bipolar two-wire HVDC system with converters connected pole-to-pole. The dc capacitors are used to provide a dc voltage source. The dc capacitors are grounded at their electrical center point to establish the earth reference potential for the transmission system. There is no earth return operation. The converters are coupled to the ac system through ac phase reactors and power transformers. Harmonic filters are located between the phase reactors and power transformers. Therefore, the transformers are exposed to no dc voltage stresses or harmonics loading allowing use of ordinary power transformers.

A simplified single line diagram for a two-level VSC converter station is shown in Fig. 15-25. Principal station components are described in the following paragraphs.

Power Transformer. The transformer is an ordinary single- or 3-phase power transformer with load tap changer. The secondary voltage, that is, the filter bus voltage, can be controlled with the tap changer to achieve the maximum active and reactive power, both consumption and generation, from the converter. The tap changer is located on the secondary side, which has the largest voltage swing, and also to ensure that the ratio between the line winding and a possible tertiary winding is fixed. The current in the transformer windings contains hardly any harmonics and is not exposed to any dc voltage. In order to maximize the active power transfer, the converter can generate a low frequency zero-sequence voltage ($<$0.2 pu), which is blocked by the ungrounded transformer secondary winding.

The transformer may be provided with a tertiary winding to feed the station auxiliary power system.

Converter Reactors. The converter reactor is installed in series in each phase and is one of the key components in a voltage source converter to permit continuous and independent control of active and reactive power.

The main purposes of the converter reactors are to:

- Provide low-pass filtering of the PWM pattern to give the desired fundamental frequency voltage. The converter generates harmonics related to the switching frequency. The harmonic currents are blocked by the converter reactor and the harmonic content on the ac bus voltage is reduced by an ac filter.
- Provide active and reactive power control. The fundamental frequency voltage across the reactor defines the power flow (both active and reactive) between the ac and dc sides. Refer to typical P-Q diagram and active and reactive power definitions.
- Limit the short-circuit currents.

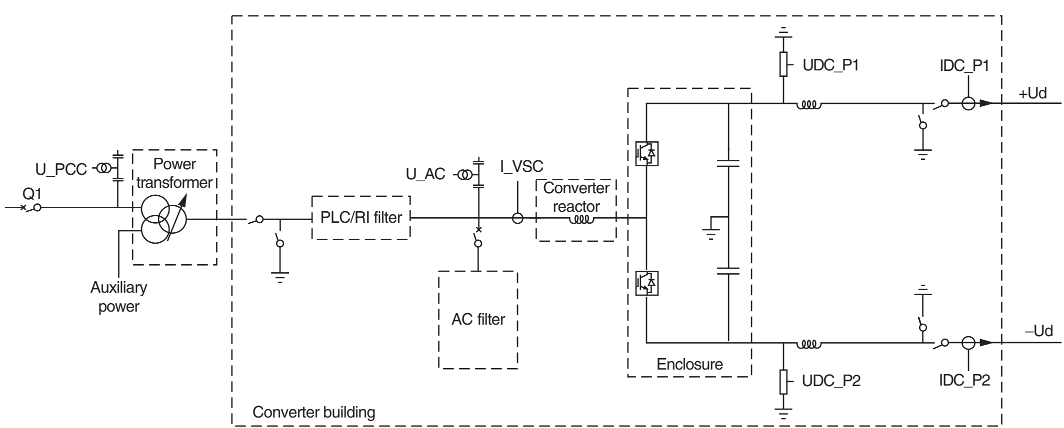

FIGURE 15-25 Simplified SLD for VSC station.

DC-Capacitors. The primary objective of the valve dc side capacitor is to provide a low-inductance path for the turn-off switching currents and provide energy storage. The capacitor also reduces the harmonic ripple on the direct voltage. Disturbances in the system (e.g., ac faults) will cause dc voltage variations. The ability to limit these voltage variations depends on the size of the dc side capacitor. Since the dc capacitors are used indoors, dry capacitors are used.

AC-Filters. Voltage source converters can be operated with different control schemes most of which use pulse width modulation to control the ratio between dc and ac side fundamental frequency voltage. Looking at the ac voltages on the converter side of the reactor, the voltage to ground consists of a square wave as indicated by Fig. 15-3. Connection of a large voltage source converter to a transmission or distribution system requires ac filters to remove the high-frequency components from introducing distortion or interference into the network. This is achieved by means of the converter reactor and the ac filters. The harmonics generated by VSC converters with PWM are higher in frequency than those from conventional HVDC converters. Therefore, smaller filter components can be used to meet performance requirements without large fundamental frequency reactive power generation. This makes the VSC converters better suited to weak-system applications.

The distorted waveform of the converter terminal voltage can be described as a series of harmonic voltages

$$E = \sum_{h=1} E_h \cos(h\Omega_1 t + \alpha_h)$$

where E_h is the hth harmonic EMF. The magnitude of the harmonic EMFs will, naturally, vary with the dc voltage, the switching frequency (or pulse number) of the converter, etc. It will also depend on the chosen PWM control method and topology of the converter. For example, a converter can use sinusoidal PWM with third harmonic injection, that is, when a third harmonic is added on the fundamental frequency modulator to increase the power rating of the converter, or some form of harmonic cancellation such as optimized pulse width modulation, OPWM, can be used. Higher level converters can also be used to switch between a higher number of dc voltage levels, for example, a three level converter can switch between the positive, zero, and negative dc voltage level. In a typical VSC scheme, ac filters contain two- or three-tuned or high-pass filter branches, which can be either grounded or ungrounded.

DC Filters. For VSC converters in combination with extruded dc cables, the filtering on the dc side by the converter dc capacitor and the line smoothing reactor on the dc side is considered to give sufficient suppression of harmonics. However, under certain circumstances, if the dc cable route shares the same right of way or runs close by telephone circuits, railroad signaling wires, or similar, there is a possibility of exposure to harmonic interference from the cable. Under these circumstances and for conditions where a local preventive measure is not feasible, for example, improving the shielding of subscriber wires, the communications company should be consulted for permissible interference limits. A typical requirement can be expressed as an equivalent weighted residual current fed into the cable pair at each station. The current is calculated as

$$I_{eq} = (1/P_{800}) \times \sqrt{\sum_h (P_{hf_1} \times I_h)^2}$$

where I_{eq} = weighted, 800 Hz equivalent disturbing current
I_h = vector sum of harmonic currents in cable pair conductors and screens at harmonic h
P_{hf1} = weighting at the frequency of h times the fundamental frequency

High-Frequency (HF) Filters. In voltage source converters, the necessarily high *dv/dt* in the switching of valves means that the high-frequency (HF) noise generation is significantly higher than for conventional HVDC converters. To prevent this HF noise spreading from the converter to the connected power grids, particular attention is given to the design of the valves, to the shielding of the housings, and to ensuring proper HF grounding connections.

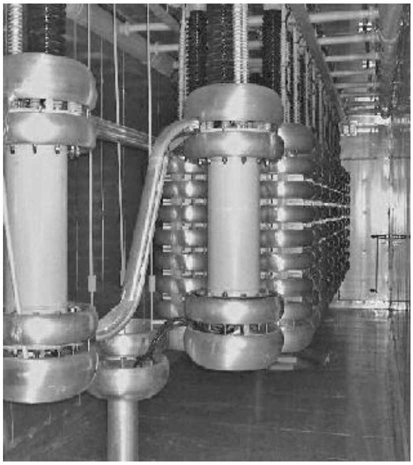

FIGURE 15-26 IGBT valve stacks with corona shields.

IGBT Valves. The insulated gate bipolar transistor (IGBT) valves used in VSC converters are compromised of series-connected IGBT positions. The IGBT is a hybrid device exhibiting the low forward drop of a bipolar transistor as a conducting device (Fig. 15-26). Instead of the regular current-controlled base, the IGBT has a voltage-controlled capacitive gate, as in the MOSFET device.

A complete IGBT position consists of an IGBT, an antiparallel diode, a gate unit, a voltage divider, and a water-cooled heat sink. Each gate unit includes gate-driving circuits, surveillance circuits, and optical interface. The gate-driving electronics control the gate voltage and current at turn-on and turn-off, to achieve optimal turn-on and turn-off processes of the IGBT.

To be able to switch voltages higher than the rated voltage of one IGBT, many positions are connected in series in each valve similar to thyristors in conventional HVDC valves. All IGBTs must turn on and off at exactly the same moment, to achieve an evenly distributed voltage across the valve. Higher currents are handled by paralleling IGBT components or press packs.

15.6.4 Converter Control

The fundamental frequency base apparent power of the converter measured at the filter bus between phase reactor and the ac harmonic filters along with its active and reactive power components are defined by the following equations. Voltage and current phasors used in these equations are according to Fig. 15-27.

$$S_b = P + jQ = \sqrt{3} \times U_F \times I_R^*$$

$$P = \frac{U_F \times U_C \times \sin\delta}{\omega L}$$

$$Q = \frac{U_F \times (U_F - U_C \times \cos\delta)}{\omega L}$$

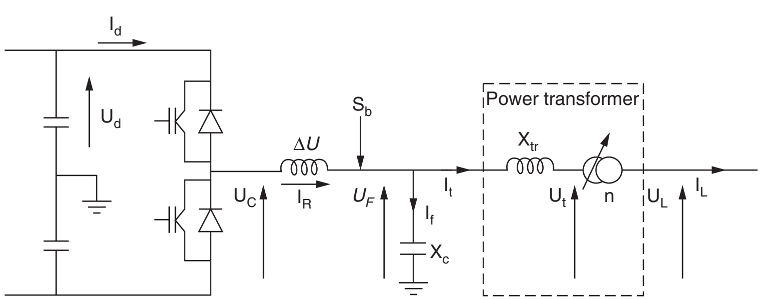

FIGURE 15-27 Voltage source converter.

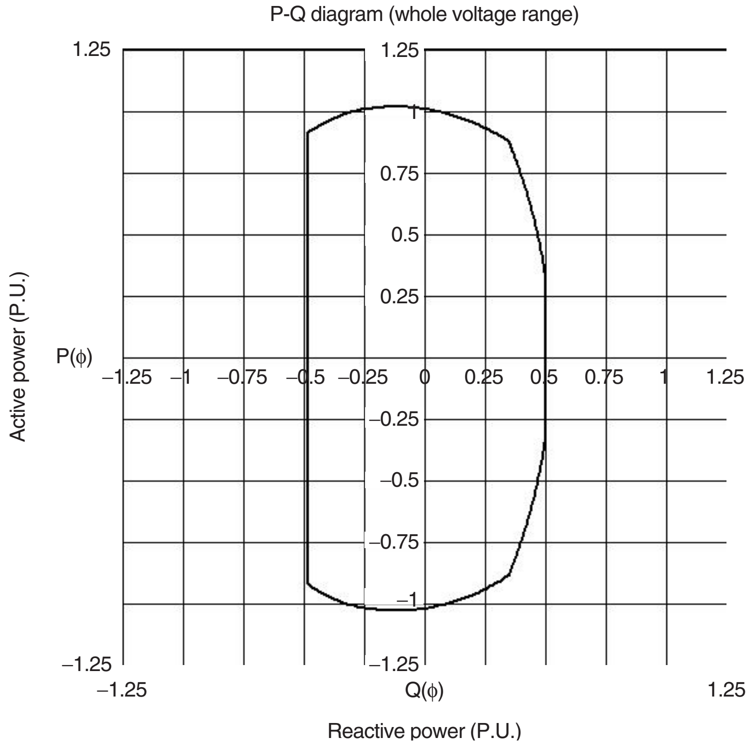

FIGURE 15-28 VSC station net P-Q characteristics with practical limitations.

The inductance of the converter phase reactor is represented by L, and the phase angle between the filter voltage U_F and converter voltage U_C is represented by δ.

The equations illustrate that the power can be controlled by changing the phase angle of the converter voltage with respect to the filter bus voltage, whereas the reactive power can be controlled by changing the magnitude of the converter voltage with respect to the filter bus voltage. By controlling these two aspects of the converter voltage operation in all four quadrants is possible as illustrated in the converter P-Q characteristics shown in Fig. 15-28. This means that the converter can be operated in the middle of its reactive power range near unity power factor to maintain dynamic reactive power reserve for contingency voltage support. It also means that the power transfer can be changed rapidly without altering the reactive power exchange with the ac network or waiting for switching of shunt compensation.

Being able to independently control ac voltage magnitude and phase relative to the system voltage allows use of separate active and reactive power control loops for HVDC system regulation.

The active power control loop can be set to control either the active power or the dc side voltage. In a dc link, one station will then be selected to control the active power while the other must be set to control the dc side voltage. The reactive power control loop can be set to control either the reactive power or the ac side voltage. Either of these two modes can be selected independently at either end of the dc link (Fig. 15-29).

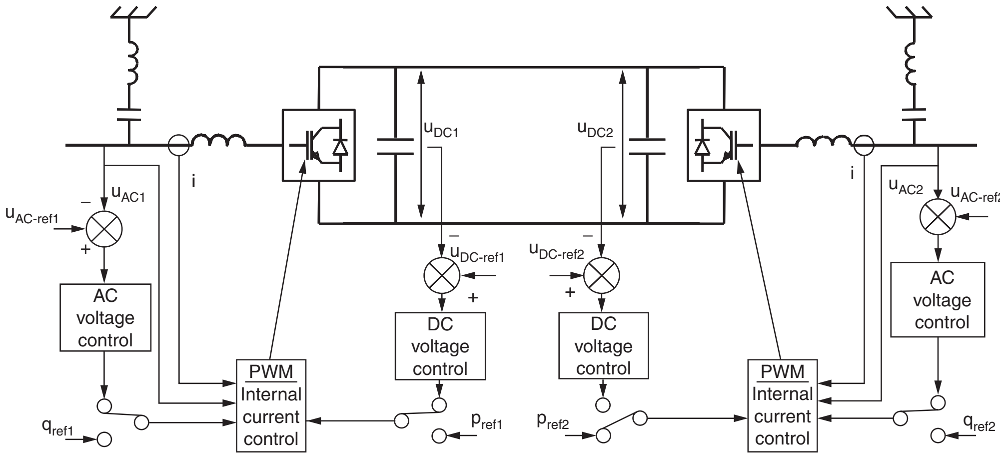

FIGURE 15-29 VSC-based HVDC system control.

15.6.5 Pulse-Width Modulation (PWM) and Harmonic Generation

Pulse width modulation (PWM) of voltage source converters enables independent control of active and reactive power at a constant HVDC voltage using simple two-level converter topology as shown in Fig. 15-30.

A two-level VSC converter can synthesize a balanced set of 3-phase ac converter voltages by injecting either the positive or negative dc voltage on the converter side of the phase reactor. By varying the duration of the positive or negative voltage injections, a sinusoidal voltage with fundamental component at the system frequency can be created. Various PWM switching patterns can be used to minimize harmonics and lower converter switching losses. A PWM pattern with harmonic cancellation or optimized PWM and its harmonic content is shown in Fig. 15-31.

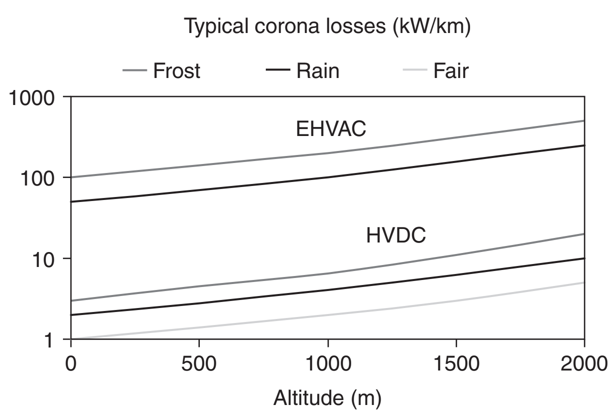

FIGURE 15-32 Foul weather corona loss comparison of EHVAC and HVDC Lines as a function of altitude.

15.7 OVERHEAD LINES AND CABLES

15.7.1 Overhead Transmission Lines

General design criteria for transmission lines can be grouped in the following five categories:

- Power transmission capability
- Power losses
- Insulation coordination
- Corona and field effects
- Mechanical loading

Power transmission capacity is limited by the conductor sag and thermal capacity of the line for the ambient conditions. Emergency loading limits are sometimes used taking into account local conditions and increased sag. These factors affect both EHV ac and HVDC lines. Permissible power transfer levels on EHV ac lines are also affected by surge impedance loading, reactive power compensation, voltage profile, contingency reserve, and stability limits. Transmission on HVDC lines is not limited to reactive power constraints. The HVDC lines cannot become overloaded since the power flow is controlled, therefore contingency reserve is not usually required.

Power losses are due to resistive losses and corona losses. For a given ampacity, resistive losses are lower for an HVDC line than an EHV ac line since the same current is flowing in two sets of conductors in a bipolar dc line compared to three conductors for a 3-phase ac line. Furthermore, the ac resistance is somewhat higher due to skin effect. Although corona losses for EHV ac lines are about the same as those for HVDC lines during fair weather conditions, they increase much more during foul weather conditions, for example, rain, frost, or snow (Fig. 15-32). This means that larger conductor bundles are needed for EHV ac. Dimensions of corona rings are less critical with HVDC. Due to the lower corona levels with HVDC lines, especially during foul weather, fewer bundled conductors are required to meet given requirements on audible noise (AN) or radio interference (RI).

Air clearance requirements are significantly lower for HVDC lines than for EHV ac lines but are more sensitive to altitude effects. Switching surges are significantly lower for HVDC lines than for EHV ac lines. Switching overvoltages govern the clearances for EHV ac lines whereas lightning overvoltages govern the clearances for HVDC lines.

Insulators made of conventional or composite materials can be used for HVDC. The dc operating voltage grading across the insulator string is resistive rather than capacitive. The lower clearance requirements on insulator string length together with the resistive voltage grading make insulator creepage distance more important for HVDC insulators, especially in areas prone to atmospheric pollution. The frequency and intensity of rain are also an important factor since rain washes away accumulated deposits periodically more so on the top surfaces. Additional insulator creepage distance can be achieved with larger sheds, longer skirts, or longer string lengths. A creepage distance of 2.8 cm/kV for lightly contaminated areas can be considered typical. Special considerations exist for insulator cap-an-pin design and choice of materials due to potential for external leakage currents. Collector rings can be used to trap contaminants mitigating uneven deposition along the insulator surface in polluted areas.

There is no electromagnetic induction from HVDC lines. There is an essential difference in acceptance level for dc fields than for ac fields with higher levels for static fields. The International Commission on Nonionizing Radiation Protection (ICNIRP), places a guideline of 40 μT on the maximum static electromagnetic field for continuous exposure to the general public. This compares to the nominal earth magnetic field of 50 μT. The dc magnetic field is very small for two conductors with current flowing in opposite directions at distances several multiples of the conductor spacing.

The HVDC line towers must bear less static and dynamic loading than EHV ac towers due to fewer conductors and insulators. The ROW requirements are narrower with HVDC. In areas where ROW widths are constrained, vertical configurations require less tower height. Balanced structure loading for vertical configurations can be achieved by use of "portal" structures with pole conductors passing through the center of the structure suspended with V-strings.

15.7.2 Underground and Submarine Cables

The HVDC is attractive for higher power transfers over longer distances due to the absence of charging currents and reactive power losses. Fewer cables are needed than for a 3-phase ac circuit. Furthermore, since there is no induction effect with HVDC, cable sheaths do not need to carry the same currents and steel armor can be used for stronger submarine cables.

In ac cables, stress created by the electrical field is distributed in inverse proportion to the capacitance of the cable dielectric. This results in the highest stresses close to the conductor. In dc cables, voltage distribution is determined by insulation resistance and space charges and is dependent on temperature. At higher conductor to sheath temperature gradient, the stress may become highest near the sheath.

Two types of cables are in common use for HVDC transmission, mass-impregnated, nondraining paper-insulated solid cables (MIND), and extruded polymer cables for lower voltage VSC applications (Figs. 15-33 and 15-34). Fig. 15-35 shows voltage waveforms for transformer secondary winding, thyristor valve and dc voltage inside the smoothing reactor. With conventional HVDC, power reversal is achieved by voltage polarity reversal of the cable and 12-pulse harmonic voltages can be imposed on the cable insulation depending on the dc filter design. Fig. 15-36 shows phase reactor voltage, valve voltage and direct voltage for a VSC converter. With VSC transmission, the voltage polarity is constant regardless of transmission direction and switching transients are absorbed by the dc capacitor.

15.7.3 Ground Electrodes

Ground and sea return operation has been used for HVDC transmission to decrease investment costs and lower losses in monopolar submarine cable systems and as a temporary return path for pole outages in bipolar systems. Electrode design always ensures safe step potentials, but other important design factors must be taken into account.

Continuous earth return operation is not always possible due to local soil and geological conditions. With typical earth characteristics, return current penetrates deep within the earth and earth surface potential gradients are low and fall off

rapidly with distance from the electrode. In cases with shallow, high-resistivity underlying bedrock, however, the current tends to flow more in the surface layer and the potential gradient extends further from the electrode site. If other conducting underground utilities, such as pipelines, traverse the potential gradient near the electrode, there is risk of stray current pickup and discharge. Over a long period of time, stray current discharge could cause localized corrosion. Corrosion mitigation

TABLE 15-3 Comparison of Number of Lines for Given Power Transfer with UHVAC and UHVDC

	kv	Cond. diam. mm	Thermal limit (line) GW	Thermal limit(s/s) GW	SIL GW	1.5 × SIL GW	Required no. of lines 8 GW	12 GW
EHVAC	800	5 × 35	7.5	5.5	2.5	3.8	4	5
	1000	8 × 35	15.0	6.9	4.3	6.5	3	3
HVDC	±600	3 × 50	8.0	5.8	n.a.	n.a.	2	3
	±800	5 × 50	17.7	5.8	n.a.	n.a.	2	3

methods, such as controlled cathodic protection systems, insulating flanges, or sacrificial anodes, can be used or the ampere-hours for earth return operation can be limited through use of metallic return.

15.8 ULTRA-HIGH VOLTAGE DIRECT CURRENT (UHVDC) TRANSMISSION

Most long-distance HVDC transmission systems with power levels above 1000 MW are at a bipolar voltage level of ± 500 kV. Voltage level for the 2 × 3150 MW Itaipu HVDC transmission system in Brazil has been operating at ± 600 kV since the mid-1980s. Transmission voltages of ± 600 kV to ± 800 kV are classified as UHVDC. Higher-power transfers can be achieved over longer distances with lower losses by increasing the dc voltage level into the UHVDC range. A considerable body of work is ongoing in this area for potential applications in China, India, and North America. The controllability and the mechanical and electrical characteristics of UHVDC lines make them in many respects more favorable for long-distance bulk power transmission than UHVAC lines. Figures 15-37 to 15-39 and Table 15-3 compare differences between UHVAC and UHVDC transmission lines.

16.1 THE ENERGY MANAGEMENT SYSTEM

16.1.1 Introduction

The management of the real-time operation of an electric power network is a complex task requiring the interaction of human operators, computer systems, communications networks, and real-time data-gathering devices in power plants and substations. There are several concerns that operations departments must take into account in the operation of an electric power system. First and most important is the safety of its personnel and the public. This requires that steps in switching the network be made in accordance with safety procedures so that the lives of utility personnel in the affected substations are not endangered. Next, operating departments are concerned with the security or reliability of the supply of electric energy to customers. In most modern societies, the continuous supply of electric energy is extremely important, and any interruption of a large number of customers at one time is considered an emergency. Finally, the operations department is charged with operating the power system as economically as possible within safety and security limits.

This section deals with the systems that are used to manage a modern utility network. Such a system is usually called an *energy management system* (EMS) and consists of computers, display devices, software, communications channels, and remote terminal units that are connected to control actuators and transducers in substations and power plants. Broadly speaking, these systems are broken down into the following tasks:

Generation control and scheduling

Network analysis

Operator training

The task of managing the generation of a large power system starts with the control of generation to maintain system frequency and tie-line flows while keeping the generators at their economic output. To this are added the economic dispatch, which determines the most economic output of each generator for a given load, the on/off scheduling or commitment of generators to meet varying load demands, and the determination of the pricing and amount of energy to buy and sell with neighboring utilities.

The task of managing the transmission system network requires the monitoring of thousands of telemetered values, the estimation of the electrical state of the network given the telemetered values, and the estimation of the effect of any plausible outage on the operation of the network. The security-analysis problem requires that the EMS be capable of analyzing hundreds or thousands of possible outage events and informing the operator of the best strategy to handle these outages if they result in an overload or voltage limit violation.

The operators must be highly trained in the use of the EMS and how to respond to emergencies. To be sure that operators are trained effectively, most utilities incorporate a simulator into their EMS that is capable of simulating the effects of an emergency on the power system. The operator is then required to "respond" by taking actions on the simulator that corrects the emergency problem. In this way new operators can be introduced to emergency procedures and experienced operators can have their training refreshed.

The EMS systems now in use in a modern power-system operations department are very large computer systems that require a large maintenance staff. The EMS is usually one of the largest computer systems in use in a utility company and often has within its database the needed information for many of the other engineering and design departments. In recent years, the concept of open systems has taken hold within utility EMS systems so that they are approaching a truly distributed form of command and control system.

16.1.2 Overview of Energy Management System Functions

Supervisory Control and Data Acquisition (SCADA) Subsystem. Supervisory control supports operator control of remote (or local) equipment, such as opening or closing a breaker, with security features, such as authorization and a select-verify-execute procedure. The data-acquisition subsystem gathers telemetered data for use by all other functions within the EMS. Data are obtained from various sources including remote terminal units (RTUs) installed in plants and substations and devices near to the system control center by local input-output (I/O) equipment.

A SCADA system provides three critical functions in the operation of an electric utility network:

Data acquisition

Supervisory control

Alarm display and control

Data-Acquisition Function. The data-acquisition subsystem periodically collects data in processed or raw form from remote terminal units. Data acquisition consists of five functional areas:

Data collection

Data processing

Data monitoring

Special calculations

Scan configuration control

Data collection is responsible for periodically acquiring data from remote terminal units at the appropriate rate. In addition, data collection monitors the various scans to make sure they initiate and complete within the current time period.

Data processing is responsible for converting analog values from raw data to engineering units. It is also responsible for converting digital status points to a system convention of device states (0 for closed and 1 for open). Data for points that are manually replaced in the database are not usually processed. Data processing is also responsible for handling data obtained from data links to other computer systems.

Data monitoring interfaces with the alarm processor and notifies it when the following occur:

Devices change state

Values exceed operating limits

Data monitoring also provides deadband and return-to-normal features.

Special calculations support various standard calculations such as

Copy a value

MVA from MW and Mvar measurements

MVA from kV and amperes

Amperes from MVA and kV measurements

Other common periodic calculations

Calculated values are derived periodically from scanned data in the database.

Scan configuration control removes a terminal unit from the scan or switches the channel assignment when sustained communications errors occur. Scan configuration control periodically attempts to reestablish communications with terminals, which have been removed from the scan.

Supervisory Control Function. This function allows the operator to control remote devices and to condition or replace values in the database. All operations are multistep procedures. Selection of the device to be operated is the first step. Next is the visual verification step, and the final step is operator execution or cancellation. Data conditioning includes operations such as the following:

Manual replacement of telemetered data

Alarm inhibit/enable

Reverse normal (change definition of the normal state of a device)

Bypass enter (of failed telemetry)

Tag/tag clear

Summary displays support the manual replace, alarm inhibit/enable, and tag/tag clear functions. Entries on these summaries are typically in inverse chronological order, the most recent entry being at the top of the summary.

Alarm Display and Control Function. The subsystem is responsible for the presentation of alarms to the operator. It supports alarm presentation and alarm presentation control. Alarm presentation is responsible for constructing the alarm message, organizing alarms in categories, maintaining an alarm summary display and abnormal summary, maintaining console logs, initiating audio/visual annunciators, and interfacing to other functions (e.g., the mapboard). Presentation control assigns priorities to alarm messages, recognizes points which are inhibited from alarming or manually replaced by the operator, and provides operator functions such as alarm acknowledgment.

User Interface Subsystem. The most visible feature of an energy management system is the user interface (UI) subsystem, which includes the following:

Presentation of system data on visual displays

Entry of data into the EMS through a keyboard

Validation of data entry

Support of supervisory control procedures

Output of displays to a printer or video copier

Operator execution control of application programs

Displays are created by using an interactive display builder, which allows definition of linkages between areas on the display and the EMS database for retrieval and entry of data. Also, the user can define function keys or function keys/display locations (poke points) when building a display to cause the presentation of another display or to initiate the execution of an application program.

The display builder allows the operator to create or modify the static elements of the display and add, modify, or delete the data and control linkages of the display. When the operator is satisfied with the display, the display definition is saved in the display file for later use by UI.

Displays are presented on a cathode ray tube (CRT) display at a console. An EMS console consists of one or more CRTs having full graphics capability, a display controller, a keyboard, and a trackball or mouse.

The flexibility in display format provided to the user allows a single subsystem to support a wide range of display types. These typically include

Menu or index displays

One-line schematic circuit diagrams

System overviews
Substation and generation displays
Transmission line displays
Summary displays
System configuration displays
Application program displays
Trend or plot displays
Disturbance data collection displays
Historical data storage displays
Report displays
Other displays

Communications Subsystem. The communications subsystem encompasses management of a local-area network supporting the EMS itself, such as a dual-redundant Ethernet, token ring, or fiberoptic communications medium, and support of communication with other computing systems and field equipment.

In addition to the users within the control room, there may be schedulers, trainees, programmers, engineers, and executives who require access to the EMS through standard console displays, remote displays, or even personal computers. All these have to be connected to the EMS via a local area network that may extend outside the control center building to other facilities.

Other connections within the utility may include off-line engineering systems for planning or long-range scheduling, other control systems, for example, load management, distribution, or plant management, and control and corporate (billing and customer) computer systems. External communications are typically with other utilities or power pools.

Information Management Subsystem. The information management subsystem supports definition of and access to data used by the EMS. This includes all the static data descriptive of the power system, the EMS configuration, and data shared with other systems. It also includes organization of data for specific uses, for example, for data acquisition and monitoring and for network analysis algorithms.

In current EMS configurations, the database is distributed. This results in a need to facilitate data access without burdening either the operator or the applications programmers and other system users. Evolution of software standards and tools in the computer industry has led to products that support these needs, such as relational database managers and computer network file and resource managers.

Applications Subsystem. The applications extend the usefulness of an EMS, allowing data gathered by the SCADA system to be used to optimize and control the power system. An EMS overview is shown in Fig. 16-1.

Generation Control Applications. An interconnected system is made up of one or more control areas, each of which is defined as that portion of an interconnected system to which a common generation control scheme is applied. It also may be regarded as that portion of the interconnected system which is expected to regulate its own generation to follow its own load changes. It may consist of a single utility, or a part of one, or a whole group of pooled utilities. In each case, a control area would include all the generating units, loads, and lines that fall within its prescribed boundaries. All the control areas of an interconnection, taken together, should account for all the generation, load, and ties of the interconnected system.

A single-area system is one in which the entire interconnected system is encompassed within one control area. One control system provides the basic regulation for the entire interconnection and does not distinguish between the locations of load changes within the interconnection. A multiple-area system is one in which there are many control areas, each with its own control system, each normally

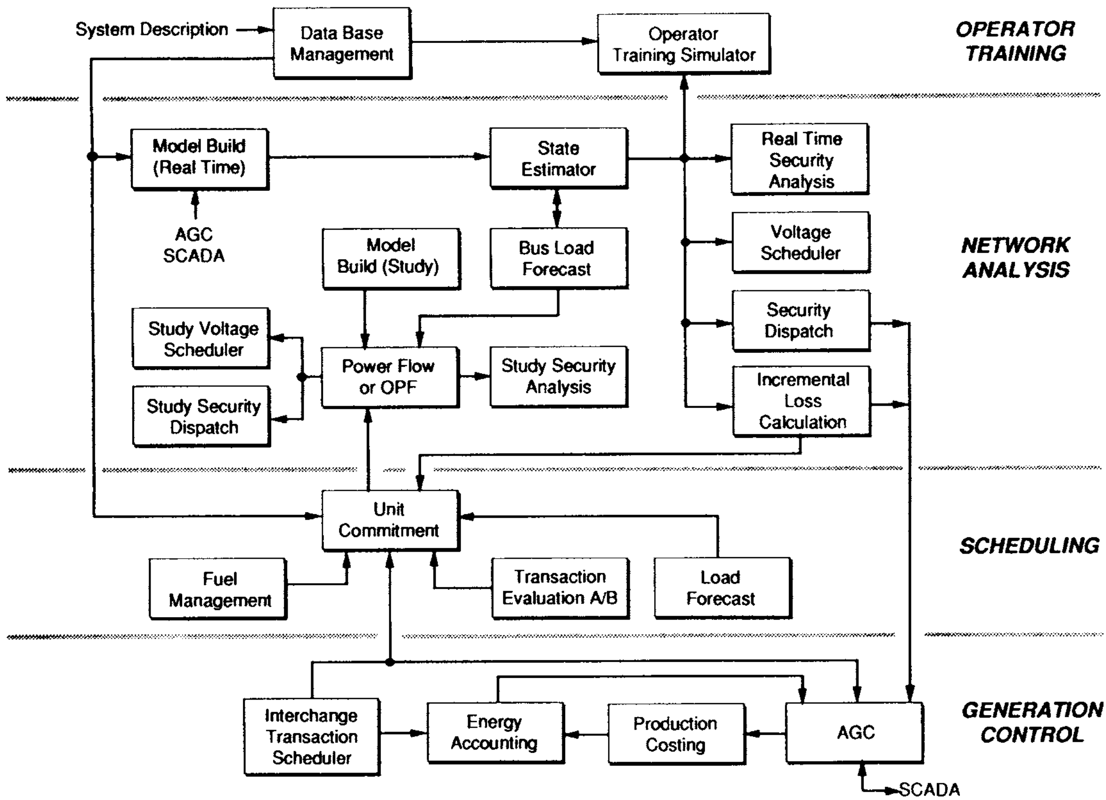

FIGURE 16-1 Energy management system.

adjusting its own generation in response to load changes within its own area. All the interconnected systems in the United States and Canada operate on a multiple-area basis.

Speed Governor. The generating unit's speed governor, along with governor-controlled steam valves (in a thermal plant) and a speed changer which provides for adjustment of the governor set point, constitutes the primary control loop for maintaining frequency at the unit level. The steady-state speed regulation characteristic of the speed governor relates a per-unit change in rated speed (y axis) to a per-unit change in rated load (x axis) and is a straight line with negative slope (called *droop*). Thus, with the speed changer set to provide rated speed for a given load, changing the set point shifts the straight-line characteristic along the x axis so that more or less output is demanded for constant rated speed. The automatic generation control (AGC) signal to raise/lower the set point (or signal for a directed set point) closes the system-level control loop and is also referred to as *supplementary control.*

Operating Objectives of Generation and Power-Flow Control. Automatic control of generation and power flow is an essential need for the smooth, neighborly, and effective operation of a widespread interconnected system. On a multiple-area interconnection, the regulating or control objectives are threefold:

Objective 1. Total generation of the interconnection as a whole must be matched, moment to moment, to the total prevailing customer demand. This in itself is achieved by the self-regulating forces of the system.

Objective 2. Total generation of the interconnected system is to be allocated among the participating control areas so that each area follows its own load changes and maintains scheduled power flows over its interties with neighboring areas. This objective is achieved by area regulation.

Objective 3. Within each control area, its share of total system generation is to be allocated among available area generating sources for optimum area economy, consistent with area security and environmental considerations. This objective is achieved by economic dispatch, supplemented as required by security and environmental dispatch.

The means of achieving objectives 2 and 3 are referred to as *supplementary control,* or currently—and more generally—as AGC. Such control may be regarded as a reallocation control redistributing the systemwide governing responses to load changes in various areas to generators within the areas that had the change. Each area then follows its own load change, with scheduled internal distribution. On a single-area system, objective 2 does not apply.

These functions act at the overall system level to regulate the real power output of generation, economically allocate demand among committed units, calculate various reserve quantities, determine production costs, and account for interchange of power between utilities and/or control areas.

Automatic Generation Control. Automatic generation control, sometimes called *load-frequency control* (LFC), regulates power system in terms of maintaining scheduled system frequency and scheduled net interchange. Automatic generation control is implemented as a closed-loop feedback controller. The error signal is determined either as a computed area control error (ACE) for a control area or a given area requirement (AR) in some power pool control structures. Positive ACE indicates overgeneration; positive AR indicates undergeneration. The ACE calculation is based on frequency deviation from schedule, net interchange deviation, or a composite tie-line bias. In tie-line bias control mode, interconnected control areas jointly participate in maintaining frequency, which is uniform among areas, but are individually responsible for maintaining each area's scheduled net interchange. The formula for this is

$$\text{ACE} = B(f_{\text{actual}} - f_{\text{scheduled}}) + (\sum \text{TMW} - I_{\text{scheduled}})$$

where the summation is over all tie-line megawatts (TMW), I is the current scheduled net interchange level, and B is tie-line bias, which converts frequency deviation to real power, usually expressed as MW/tenth Hz. B is characteristic of the installed capacity (MW) of the control area and is usually a constant. Additional terms or modifications to the formula are used to account for correction of time errors, inadvertent interchange payback, and so on.

Area control error is a noisy signal and so requires processing. Processing also includes provision for proportional, integral, and anticipatory (or derivative) control characteristics for AGC as a feedback controller. Integral control is necessary to prevent long-term offset in frequency and to ensure that ACE crosses zero (the normal set point) frequently. System control requirements thus determined from processed ACE are allocated to generating units based on several criteria.

Unit Control Considerations. Key considerations are

The deviation in each unit's loading from the most recent economic assignment—MW level

The deviation of total system load since the last economic dispatch

The current value of ACE

Economic base points are assigned by the economic dispatch (ED) function, and LFC will drive unit loading toward these assignments unless there are overriding conditions. This mode is termed *mandatory* unit control (mandatory with respect to economics).

An overriding condition may be that ACE exceeds a threshold beyond which correcting ACE takes precedence. In this case, AGC is operating in a *permissive* mode (with respect to economics). Here units are inhibited from moving against correction of ACE. If ACE exceeds a larger threshold, an *emergency assist* mode is entered. Here all units move to correct ACE and may move against their economic directions, that is, away from economically assigned base points.

Units participate in ACE reduction in proportion to regulating participation factors, which may be operator-entered or calculated from various criteria according to individual company or pool operating policies. Units participate in adjusting to the deviation in system load since the last ED by use of economic participation factors, produced by ED. In some systems, a single set of participation factors is used.

Unit desired generation is calculated according to the preceding rules, and control output is sent to generating station RTUs either as MW set points or raise/lower signals as appropriate to the local generating unit plant-control equipment.

Control of each unit assigned to automatic regulation is performed by a separate unit-control loop (feedback controller). Here the set point is unit desired generation already obtained. Models of individual unit dynamic response to previously issued control commands are compared with actual telemetered output of the unit in determining the degree of new control to be issued.

AGC Operator/Dispatcher User Interface. Typical AGC displays used by system operators include

System summary—provides an overview of system control information such as area control error, reserve quantities, incremental costs, lambda (from ED), and AGC control mode states and allows the operator to change these states or enter key parameters.

Generation summary—summarizes current status and output of all generating units and may provide for operator changes to unit status.

Station/plant summary—shows detail related to operation of individual units, limits, fuels, costs, and so on.

Tie-line summary—shows telemetered real and reactive power flow on all tie lines and net total real power interchange and may show line limits.

Figure 16-2 shows an overview of a typical AGC program.

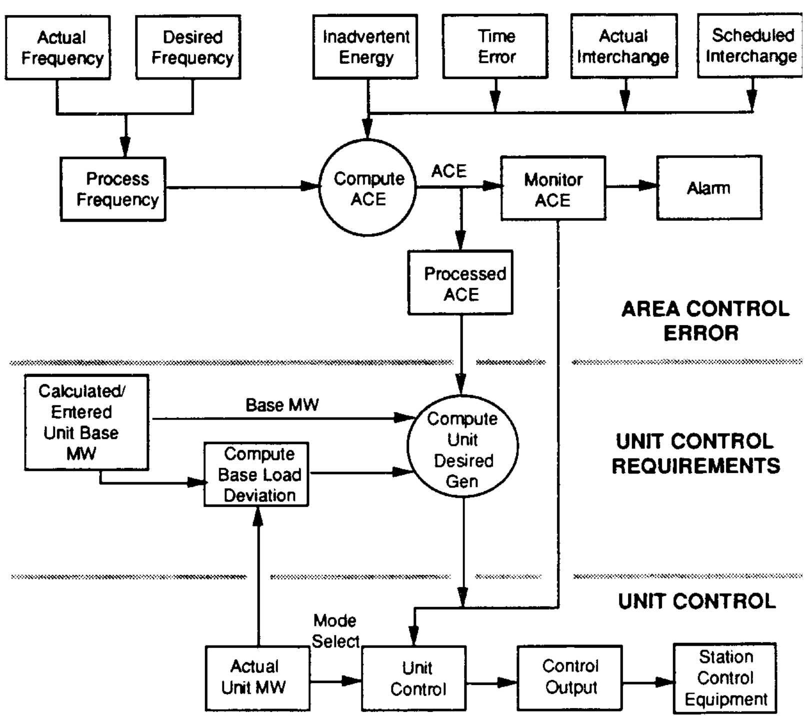

FIGURE 16-2 Overview of an automatic generation control system.

Interchange Scheduling. The interchange transaction scheduler (ITS) function supports the operator in entering (defining), editing, and reviewing power interchange schedules with neighboring control areas/utilities. The schedules are usually negotiated by the operator over the telephone with other operators in control rooms at other utilities. These schedules are utilized principally by AGC and energy accounting.

Schedules are established by utility and by account within each utility. Examples of accounts include firm or nonfirm energy and capacity purchases, sales, and so on. Schedules may be defined on a daily hour-by-hour basis or on a start/stop date and time basis according to company or pool operating procedures. Various entry displays support definition of such schedules. Other displays are used to summarize transactions by company, account, or chronology.

Given a multitude of concurrently active transactions, a net profile of interchange is constructed in order to provide AGC with the instantaneous net scheduled interchange needed for real-time system regulation. At the end of each hour, scheduled transactions are compared with actual data in the energy accounting function to maintain historical records.

An emergency scheduling capability allows the operator to enter a single net schedule of interchange to override all other currently active schedules. Other entries associated with transactions may include cost, price, ramp rates (MW/minute), and additional information associated with third-party or "wheeling" transactions.

Economy A Transaction Evaluation. Economy A Transaction Evaluation is a user-oriented program for evaluating short-term interchange transactions with a neighboring utility. It applies to transactions, which do not involve altering the commitment of generating units.

The idea behind Economy A transactions is to find an amount of power to interchange with a neighboring system so that both systems achieve maximum benefit. Essentially, this means that the system with lower incremental cost of generation will sell power to a neighbor with higher incremental cost. The optimal amount of power interchange is that which brings the two systems to the same incremental cost.

To find the optimal interchange, agreed increments or blocks of interchange are added or subtracted to the base economic dispatch. For each block, a price or cost increment is calculated. The operators in each system then use the block information to determine the number of blocks to use in reaching a final interchange value.

The program also can use the economic dispatch package in a study mode to calculate incremental and production costs under a variety of conditions specified by the operator. Parameters for these calculations can include generation conditions, interchange schedules, and unit costs.

Input. Economy A obtains the following from automatic generation control:

Economic and operating limits, mode, and assigned or base generation

Fuel costs

Starting megawatts

Efficiency factor

Heat-rate curve selection

Operator inputs consist of requests, modification of the preceding data, and definition of the transaction and system parameters.

Output. Results of Economy A Transaction Evaluation are presented in CRT displays and also can be sent to a printer. This output includes

System results, such as production costs, spinning reserve, and incremental losses, for each block evaluated

Economically assigned generation for each unit

Energy Accounting. The energy accounting (EA) function maintains accumulated operating data in accounts ordered on an hourly, daily, monthly, and/or yearly basis. These accounts typically relate to energy exchanged via tie lines, plant generation, large-customer consumption, and on/off peak cumulative inadvertent energy exchanges. Additional data such as production costs or purchase/sale costs also may be accumulated, and in a hydroelectric system, discharge of water or pond levels may be recorded. In practice, generalized calculation and report functions are configured to provide energy accounting capabilities.

Accumulating energy data is accomplished either by field equipment such as pulse accumulators (counters) which provide energy data to be telemetered or by telemetering power (megawatt) values to the EMS, where these are integrated to obtain energy data (MW-hours).

Daily power system values are collected on an hourly basis. Correspondingly, monthly values are collected and stored once a day so that there is a value for each day of the month. The following paragraphs describe typical energy accounting processing that is performed on either a daily or monthly basis.

Daily Features. Energy accounting collects the instantaneous tie-line megawatt values every minute and at the end of the hour produces the integrated values for all tie lines. It then subtracts these values from the corresponding tie-line pulse accumulator values and stores the difference. The absolute difference is compared with a tolerance (for each tie line). This allows the accuracy of tie-line telemetry information to be continuously monitored.

Energy accounting maintains actual tie-line data for each hour of the day. It also classifies the values according to whether the hour of the day is an off-peak or on-peak hour. On-peak and off-peak start and stop times are defined via the information management function. Holidays and Sundays are considered off-peak. This allows interchange (both actual and scheduled) and inadvertent calculation to be divided into on-peak and off-peak accumulations. Daylight savings time conversion days (23-h or 25-h days) are also supported. For these days, the appropriate amount of data is collected and processed accordingly.

At the end of each hour, the hourly actual interchange values collected are added into running totals of on-peak and off-peak energy (depending on the hour). The scheduled interchange values provided by ITS are also added to on-peak and off-peak accumulations. Following the accumulation of interchange (scheduled and actual), the inadvertent energy for the hour is computed as the deviation between actual and scheduled interchange.

The inadvertent energy value for the hour is then saved. The hourly value is then used to update the cumulative (on-peak or off-peak) inadvertent energy value. The appropriate cumulative inadvertent energy value is then made available to AGC.

Energy accounting also may collect and maintain production cost data for each hour of the day. At the end of each hour, the production cost data for each generator and the system are collected and stored. Additionally, energy accounting supports the calculation and storage of system net generation and control area net load for each hour of the day. For all values maintained on a daily basis, the running daily total for each quantity is also updated and retained.

Production-Cost Calculation. Production costing (PC) calculates the hourly production cost for each generating unit and the entire system. Production costing is synchronized with execution of the economic dispatch program and supports the following features:

Production costing executes periodically throughout the hour, and the average hourly production cost is calculated at the end of the hour.

Several sets of production cost values can be calculated from the current actual unit generation levels and for the generation levels recommended by the economic dispatch.

System dispatch performance is monitored by computing actual generation costs, dispatched production costs, and ideally dispatched production costs (manual dispatch).

A set of unit fuel consumption values can be computed from actual unit generation values.

Unit and system daily logs are provided showing all relevant hourly and daily values via the energy accounting and reporting support functions.

The periodic production costs are calculated by integration of the area under the incremental cost curves or by separate I/O curves and can include the effect of incremental and fixed maintenance costs, fuel cost, and efficiency.

The periodic unit actual fuel consumption is calculated and includes the effect of the unit's efficiency. The unit actual fuel consumptions are summed to yield the current system fuel consumption. All unit production costs are summed to give the system production cost values.

The periodic values are integrated over the hour to produce hourly unit fuel consumption and production cost values. The hourly production costs and fuel consumption values are saved at the end of each hour. These values are then stored in a historical database by energy accounting.

Generation Scheduling Applications. The forecast and scheduling applications within an energy management system gather, organize, and use large amounts of historic and economic information. This group of related software packages puts that information to work in forecasting loads, scheduling units and generation, evaluating Economy B type transactions with other utilities, and tracking fuel contracts. Forecast and scheduling applications are tailored to the power system they serve. For example, a unique load forecast model is developed for each case.

Load Forecast. This program forecasts hourly loads 1 to 7 days in advance. Load-forecasting methods are based on similar days according to season, day of the week, and so on, with further adjustment for weather effects by using

Nonlinear, dynamic, adaptive weather model
Correlation of load to temperature, humidity, light intensity, and wind speed
Adaptation to real-time load and actual weather conditions

Unit Commitment. This program schedules hourly status (on line/off line) and output for each online unit, 1 to 7 days in advance. The calculations consider

Production cost models
Start-up cost model
Shutdown cost
No-load (spin) cost
Incremental maintenance costs
Network losses

Unit commitment runs with two sets of constraints. System constraints are

Load forecast
Interchange schedules
Reserve requirements
Regulation requirements

Unit constraints are

Prescheduled status or output
Derations
Multiple limits
Rate limits
Up- and downtime limits
Reserve limits
Plant start-up limits

Each unit can be assigned these models

Thermal
Combustion turbines
Combined cycle
Ramping times
Start times
Multifuel

Economy B Transaction Evaluation. Economy B transactions are similar to Economy A except that generating units must be added or taken off line to meet the contract. This program does a before-the-fact evaluation of proposed interchange transactions. After the fact, it can make the same analysis to evaluate the worth of each transaction. It can

Perform multiple commitments against levels of prioritized interchange
Recommend prices
Make buy/sell analysis
Use fixed, operator-entered, or variable prices

Fuel Management. The fuel-management programs incorporate fuel constraints into unit commitment schedules so as to optimize the use of fuel contracts. Contracts can be

Take or pay
Fixed price
One hour to one month

Contract limits can be

Hourly to monthly
Rate of consumption
Total consumption

Network Analysis Applications. These monitor the security of the system and assist the operator in optimizing system performance. The *model-build program* responds to switching operations in the transmission system. With this information it determines the current network configuration. This constantly updated real-time model is used by other network analysis programs.

Inputs to the program are all measurements (including MW, Mvar, kV, and amperes), zero injections, and calculated loads. The *state estimator* uses statistical methods to check for bad data and to establish a consistent network solution as a basis for security analysis and power flow studies.

The *bus-load forecast* provides a forecast for each individual bus, for any specified hour of the week. Forecasts are based on the history of user-defined load groups. Both MW and reactive ratio histories are used. This information is used for studies and also can be used to support temporarily outaged telemetry.

Voltage scheduling is an optimization program that minimizes power losses in the system by adjusting unit voltages, load tap changing (LTC) taps, and phase-shifter taps. The program performs this optimization while maintaining voltages and Mvars within permissible ranges.

Optimal power flow (OPF) enables the operator to study a network solution, which describes the steady-state power flow that would result from specified network conditions. It can optimize system variables to enhance power system security and/or economy.

Security analysis determines the security of the power system under specified contingencies. It stimulates the steady-state power flow for each case and then checks for out-of-range conditions. Security analysis also handles split bus, altered topology, and islanded systems.

Security dispatch detects overloads in the real-time network model and determines control actions such as generator shifts that will alleviate the overload or that will avoid an overload after a contingency. The program can incorporate phase shifters, interchanges, and load shedding as well as unit outputs to solve problems.

Operator Training Simulator. With an operator training simulator (OTS), it has become possible to improve the quality of training for power system operators. The OTS allows operators to be exposed to simulated power system emergencies and to practice alleviating these emergencies. Similarly, operators may practice system restoration under simulated conditions. Since operators may be exposed to simulated emergency and restorative conditions on the OTS, frequently and at will, as opposed to rarely and by chance on the job, the time required to train a new operator may be significantly shortened. Similarly, with an OTS, it becomes possible to expose experienced operators to emergencies and restoration procedures as part of refresher training.

The simulator can present results to the operators, which are as accurate as those observed by the EMS using typical power-system telemetry. The operator uses a user interface and applications functions which are identical in the OTS and in the EMS.

The OTS includes long-term dynamic models of the electrical network, loads, generators, turbines, and boilers. The OTS also includes the control functions of the EMS: SCADA, power applications, and their user interface. In addition, an educational subsystem is provided with features that allow the instructor to construct groups of one or more training events or power system disturbances and to store and retrieve these groups of events.

Other significant features of the OTS include

The power-system model in the OTS is the same as the model used in the EMS.

The OTS uses multiple consoles to support team training and an instructor position.

The OTS supports a load model which includes the effect of frequency, voltage, load management, and subtransmission reactive shunts and taps.

The OTS supports system restoration/blackstart exercises.

Underfrequency load shedding is modeled in the OTS.

The OTS allows representation of a wide range of power-system events or disturbances.

The OTS may include a model of the AGC systems of external companies.

The OTS includes relay models for over/undervoltage, inverse time overcurrent, over/underfrequency relays, synchro check relays, time switching, volts/Hz, over/underexcitation, and automatic reclosure.

The OTS includes features that allow the instructor to play the role of power-plant operators, substation operators, and neighboring company operators.

OTS Functional Description. The overall simulator system can be logically divided into four principal subsystems: the power-system model (PSM), the control-center model (CCM), the educational system, and the user interface.

The PSM simulates response of load, generation, and network conditions (flows and voltages) to control actions, which were initiated either by the operator or by AGC, and to preset events from the training system. The PSM includes a load-model program, network modeling, which is implemented as a network topology processor, and a fast decoupled load-flow algorithm and a set of prime mover models and frequency-response programs. The control-center model includes a replica of the control functions in the EMS. Included are the SCADA/AGC functions and selected network analysis functions. The educational subsystem provides a means for sequences of events to be defined, stored, and retrieved by the instructor. Separate displays are used to define each sequence and to catalog by title those presently stored. The user interface relates to all the previous subsystems. It provides display and control, via the workstation display and keyboard, and logging of all system events.

The operator simulation process differs from the operating models primarily in the time frame considered. Transient time scales are on the order of cycles (0.016 s), and longer dynamic stability

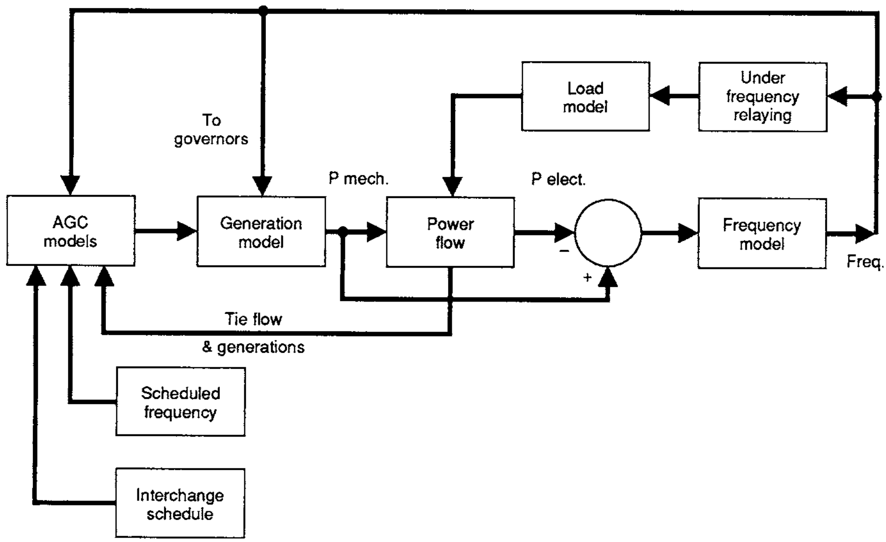

FIGURE 16-3 OTS control-response model.

runs last only a few seconds. The time frame for response of human control actions is the determining factor in the design of the simulation. Events that are beyond the range of human perception are not of interest, especially when viewed by telemetry with 10-s scans and through workstations with sampling of about 2 s. At the other extreme, it is important that the simulation be run in real time and be economical for runs of a half hour or more. These considerations result in an emphasis on prime mover dynamics and system frequency behavior in the structure of the simulation.

Because of the time response of AGC and operator control, we are dealing with low-speed phenomena rather than the transient and synchronizing effects not observed by the controller (either AGC or human). Also, because of the requirement for real-time response of the simulated power system, extensively detailed models of components with small time constants would require a short integration time step and a correspondingly heavy computational burden, so in this case we require a rather coarse time step (1 s) as compared with transient stability.

During steady-state operation conditions, line flows and losses are the result of generation, excitation, and load. The network solution is, therefore, more than adequately modeled by an efficiently coded load flow. A schematic of the control-response model is shown in Fig. 16-3.

16.2 RELAYING AND PROTECTION

By GUSTAVO BRUNELLO

The fundamental concept of protective relaying is to detect and isolate faults and other destructive phenomena in the shortest possible time consistent with economics and security. The principles vary at different points in the power system because of differing constraints. Distribution-system relaying must coordinate with fuses and reclosers for faults while ignoring “cold-load pickup,” capacitor bank switching, and transformer energization.

Transmission line relaying, on the other hand, must be sufficiently discriminating to locate and isolate any type of fault and do so with sufficient speed to preserve stability, to reduce fault damage, and to minimize the impact on the power system. This dictates the use of one or more pilot relaying systems.

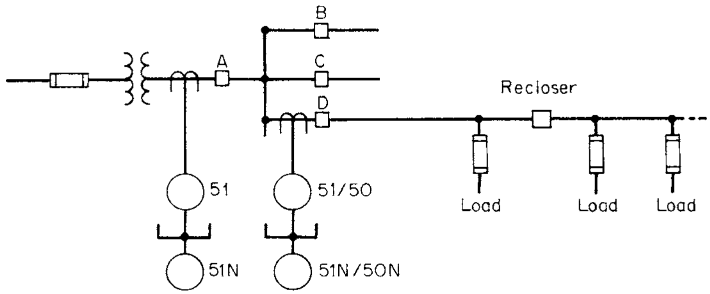

FIGURE 16-4 Typical distribution circuit relaying.

Subtransmission relaying varies from complete pilot relaying to simple directional overcurrent relaying depending on the importance and general nature of the subtransmission system.

Distribution-System Relaying. Typical distribution circuit relaying is shown in Fig. 16-4. Only one set of feeder relays is shown. This arrangement would be repeated for each feeder. The time-delayed phase and ground relays 51 and 51 N usually have a high degree of inverseness in their current-time characteristic to coordinate with the fuses and reclosers that are farther out on the circuit. The instantaneous units 50 and 50 N are typically set to trip the feeder breaker and protect the fuses when a temporary fault occurs beyond the fuse. For this type of fault, the feeder is removed from service by a reclosing relay that allows the fuse to blow when reclosing into a permanent fault.

The 51 N relay must be set with care to avoid its operation on loss of single-phase lateral load when a fuse blows. The "normal" load unbalance can be controlled to a reasonable degree by carefully supervising the balance of load connected to each individual phase (usually a 4-wire circuit with line-to-neutral connected loads). The opening of a fuse to clear a fault, and thereby drop load associated with one phase, will produce a much higher than normal load unbalance. This must not be allowed to cause operation of the ground relay. Its sensitivity is largely regulated by this consideration.

Cold-load pickup is the phenomenon whereby a feeder being reenergized after a long outage will experience a load appreciably in excess of maximum steady-state load (as a result of loss of diversity by thermostatically controlled devices). The feeder relays must ignore this if sectionalized reenergization is to be avoided. The relays on breaker *A* in Fig. 16-4 provide primary protection for the bus and backup protection for the feeder relays and breakers. In general, they are time-delayed and coordinate with the feeder relays with the accepted sacrifice of clearing speed for bus faults. These phase relays provide some measure of thermal protection for the supply transformer.

Modern microprocessor-based systems contain not only the instantaneous and time-delay relaying described above but, in addition, may contain reclosing, instrumentation, and fault data storage facility.

Subtransmission Relaying. Loops and multiple power sources used in feeding loads from the subtransmission system usually dictate the use of directional overcurrent relaying, distance relaying, or pilot relaying. In general, a subtransmission system is not intended to transmit bulk power from one location to another. Multiple sources are used purely in the interests of continuity of service.

Figure 16-5 shows an example requiring directional overcurrent relaying. A fault on the upper line would cause equal currents to flow in relays *A* and *B*. For this fault case, it is desired that relay *A* trip and *B* restrain. A fault on the lower line also causes equal current to flow in relays *A* and *B*. For this case, it is desired that relay *B* operate and relay *A* restrain. These two cases produce requirements that are mutually exclusive using simple overcurrent relays. The requirements can be met with directional overcurrent relays. If directional, the *A* relays would respond only to faults on the upper line and the *B* relays only to faults on the lower line. Coordination between *A* and *B* then becomes unnecessary.

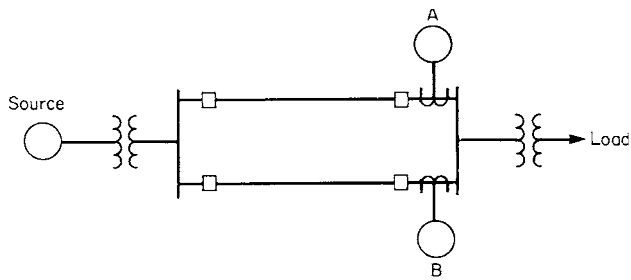

FIGURE 16-5 Partial one-line diagram of typical subtransmission system showing locations where directional relays are required.

Figure 16-6 defines in the simplest form a criterion for establishing where directional overcurrent relays are desirable.

Relay *R* in Fig. 16-6 requires consideration of distinctly different criteria, depending on whether instantaneous or intentional time delay tripping is involved. An instantaneous device at *R* must be set in such a way that it will never respond to a fault beyond bus *B*. The setting will be dictated by the maximum fault contribution (phase-fault contribution for phase relays or ground-fault contribution for ground relays or *phase relays*) for a fault at *B* and by the influence on the measuring unit of the dc component in the fault current. For example, a maximum fault at *B*, producing 20 A in relay *R*, would require a setting in excess of 20 A. If the maximum overreach factor for the particular instantaneous unit in use were 1.3 and a 10% margin were desired, a setting of 1.3 (1.1) (20) = 28.6 A would be required.

If a reverse fault such as a fault near bus *A* on other circuits could cause current in relay *R* to exceed 20 A (symmetrical), a higher setting would be required for this instantaneous unit than 28.6 A because the same overreach and margin factors would apply.

Since the extent of line coverage is dependent on the setting of the device as well as the source-line impedance ratio, a reverse fault which dictated a higher setting would cause the extent of line coverage to be smaller. By using directional control, no consideration need be given to reverse faults.

If the magnitude of relay current for this maximum magnitude reverse fault were less than 20 A, no consideration need be given to the inclusion of directional control for the instantaneous unit. A nondirectional relay will be satisfactory in this application because the relative fault currents make the relay inherently directional.

Time-delay overcurrent relays differ in their criteria from those of the instantaneous unit. In the interests of backup protection, relay *R* should always be able to detect the minimum fault on and beyond bus *B*. Further, in any time-delay relay applications, this minimum case should produce an adequate multiple of pickup current in the relay to ensure a clearly predictable operating time.

If, for example, the minimum fault at *B* produced 14 A in relay *R*, a setting of 7 A would be required (to give a multiple of pickup of 2 for this minimum fault case). If a reverse fault could deliver current sufficiently large to cause operation of a relay set at this level, consideration should be given to the use of directional control of the time unit. A frequently used conservative summary of this concept is that if the maximum reverse fault current can exceed 25% of the minimum fault current at the next bus, use directional control.

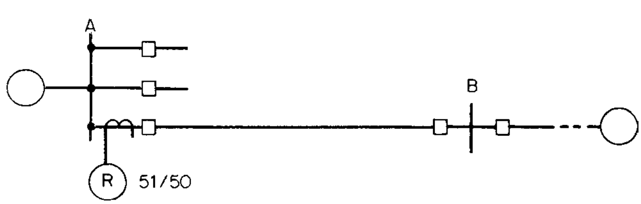

FIGURE 16-6 Directional relaying criterion.

The combined criterion for these concepts is—use directional control if a reverse fault could influence the sensitivity of relaying used to detect forward faults or if selectivity would not otherwise be possible. If source variations restrict instantaneous coverage to less than 50% of the protected line, or if the tripping times realizable for time-delay relays become undesirably long, distance relays should be used.

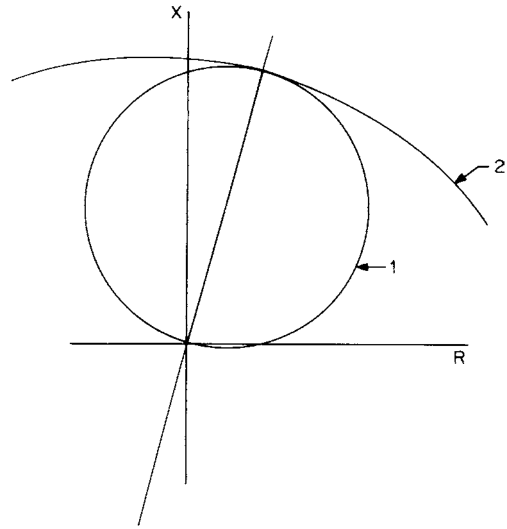

FIGURE 16-7 Resistance-reactance plot of distance relay characteristics.

Distance relays respond to the voltage and current applied to them and are usually more highly responsive at some lagging current angle. Figure 16-7 shows a typical *R-X* diagram that describes the behavior of these devices. Most distance relays in current use, phase and ground, have a characteristic similar to curve 1 or curve 2. Faults producing an apparent impedance at the relay location that falls inside the characteristic circle will cause the relay to operate. Since a distance relay has a distinct "reach" irrespective of source impedance and is directional, it is said to protect a "zone." Zone 1 relays are set to cover a portion such as 80% to 90% of a subtransmission or transmission line. Zone 2 relays respond to faults at all locations on the line and also to others in proximity of the line end. This is shown in Fig. 16-8. Zone 2 relays are typically set to cover 100% of the protected line plus 25% to 75% of the shortest line departing from the remote bus. Since they overreach the next bus at the end of the protected line, they must have a time delay or be associated with a pilot relaying system in order to preserve selectivity with other relays. A zone 2 relay should not be set to overreach any zone 1 relay at the next forward station.

A zone 3 relay is also often used and may be directional in the same sense or opposite sense as the zone 1 and zone 2 relays, or in some applications may be nondirectional. Figure 16-8 shows a one-line diagram with a "reverse-looking" zone 3 relay. The user shall carefully verify that the impedence reach for zone 3 is less than the load impedence presented to the relay under the most unfavorable steady-state operating conditions (overhead and overvoltage) of the system.

Microprocessor-based distance relay systems provide multiple zones, complete phase are ground distance protection, plus pilot logic, instrumentation, fault-data storage, and oscillographic information. However, in the past, simplified distance-relaying schemes were sometimes used in the interests of economy. One type used a complete complement of relays for one zone, which was initially set for a zone 1 function. A "starting" unit (overcurrent or distance) used to sense the presence of a fault. After a time delay, the setting (reach) of the relay was extended to zone 2 and still later to zone 3 (forward). A further abbreviation of this scheme allowed the starting units to identify the type of fault and to connect the appropriate voltages and currents to a single distance unit. These systems vary substantially in complexity, redundancy, dependability, and cost. The choice of one system over the

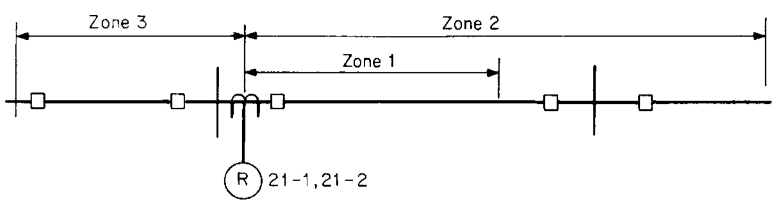

FIGURE 16-8 One-line diagram showing concept of distance relay zones.

others is dictated by the relative importance that is placed on each of these factors and the significance of the compromises involved in making such a choice.

Transmission Line Relaying. High-speed clearing of faults is universally required on transmission systems in the interests of maintaining stability, minimizing disturbance to wide areas of the power system, and decreasing fault damage. Pilot relaying is an important ingredient in this process. Pilot relaying entails the use of information obtained from one or more remote terminals as well as local information to establish the need to trip (or refrain from tripping) a local breaker. The remote information is transmitted by power line carrier, microwave, tones, pilot wires, optical fiber, or some combination thereof. An abundance of pilot-relaying systems are in use, each having its individual strengths and marginal weaknesses and each having varying degrees of dependence on the integrity of the channel.

Pilot Channels. Figure 16-9 shows one of the many types of pilot channels in use. This particular arrangement uses "power line carrier." The pilot channel is chosen sufficiently higher than the power frequency to allow separation to be achieved easily, generally 30 to 300 kHz.

Types of Protective Relaying Systems. Two basic systems form the nucleus for the families of pilot-relaying systems applied to transmission lines. They are the directional-comparison and the phase-comparison systems.

Directional-Comparison Relaying. The fundamental concept of the directional-comparison system is shown in Fig. 16-9. A directional relay at *A* responds to faults to its right as shown by the directional arrow in the figure. A similar relay at *B* responds to faults to the left of *B*. Both relays respond simultaneously only to faults on the protected line. The communication channel informs *A* about the state of *B*, and another informs *B* about the state of *A*.

One-to-one and a-half-cycle initiation of tripping is commonly achieved at both terminals following the occurrence of a fault on such a protected line. No tripping of these relays occurs for faults on other line sections. Abbreviated descriptions of the commonly used directional comparison schemes follow.

Directional-Comparison Blocking. In this system, each of the terminals is equipped with tripping and carrier-starting relays. The tripping relays are directional toward the protected line and are set to respond to all faults on the protected line and 25% to 50% beyond. This is called an overreaching setting. The carrier signal is required to prevent tripping for faults in that 25% to 50% overreaching area. Tripping at *A* is blocked by a signal transmitted from *B* and received at *A*. Transmission of the signal is initiated by a carrier-starting relay that operates for faults outside the protected line section.

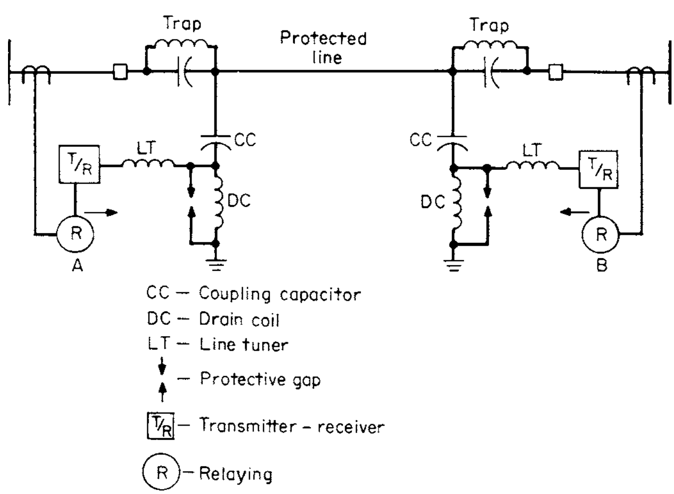

FIGURE 16-9 Representative channel for pilot relaying.

Internal faults are cleared by the tripping relays at all terminals, which have overriding control to stop all carrier transmission. A single-frequency on-off carrier may be used for both directions of transmission (A to B and B to A) because all carriers are turned off for an internal fault.

Underreach Blocking. This system uses a zone-extension scheme to limit, in the interests of economy, the number of distance units required. A relay set to cover zone 1 (the area from the relay location out to 80% or 90% of the protected transmission-line length) is stepped, after a coordinating delay such as 4 ms to zone 2 reach (covers the entire line) provided blocking carrier is not received from other terminals. If carrier is received, zone extension is still carried out, but at a much later time (often 15 cycles), to provide backup coverage for remote bus line sections and apparatus. Different carrier frequencies are required for the two carrier channels. Station A carrier cannot be allowed to block station A tripping because carrier cannot be stopped for some internal faults.

Acceleration. Zone extension is again used with this system. A frequency-shift carrier channel is preferred because transmission through a fault on the protected line may be required. A guard frequency is transmitted during nonfault conditions. The protective relays are given a zone 1 setting. All faults on the protected line are seen by one or both of the relays at the two ends of the line. Each causes carrier to be shifted to a trip frequency.

Receiving trip frequency causes the zone 1 setting of each local relay to be extended to zone 2 distance immediately. All faults in the area of overlap of the two zone 1 settings will be cleared without regard to the carrier signal. End-zone faults (faults not covered by the zone 1 relays at one of the terminals) will be cleared at high speed and essentially simultaneously once zone 1 extends to zone 2 reach.

Permissive Transfer Trip. In a permissive scheme, tripping occurs when the distance relay operates at each terminal and a trip signal is received at that terminal. The distance relays at the two ends of the line cooperate to clearly identify a fault as being "internal" to the protected line or "external." Permissive transfer-trip relaying systems are identified as *overreaching* or *underreaching* system, depending on the setting of the directional distance relay that keys the frequency shift tone or carrier transmitter at each line terminal.

If the system has a setting that causes it to respond to faults on the protected line and additionally to faults beyond the end of the protected line, it overreaches the remote relay, and the system is identified as an *Permissive Overreaching-Transfer-Trip (POTT)* system.

Underreaching schemes have the distance relays set to respond to faults within 80% of the protected line length. When they operate, they key the frequency-shift channel transmitter from "guard" to "trip" as well as immediately tripping the local breaker(s) without regard to action at the remote terminal. The two categories of these systems are identified as *direct* and *permissive.*

In the *Direct-Underreaching-Transfer-Trip (DUTT)* system, receiving the channel trip causes tripping of the terminal breaker(s). No local fault-detector relay operation is required. Strictly speaking, the direct scheme is not a directional-comparison system, because operation of the zone 1 relay issues a command to trip all breakers associated with the protected line, and no comparison takes place.

In the permissive underreach scheme, a local directional distance element, that overreaches the remote terminal, is required to supervise the tripping. Each terminal has two measuring elements: a zone 1 distance that underreaches the remote terminal and a supervisory element that sees faults beyond it. This scheme is called *Permissive-Underreach Transfer Trip (PUTT).*

Note that permissive transfer-trip systems require that a signal be received by the channel equipment in order for tripping to take place. These systems are usually committed to channels that are not dependent on the integrity of the protected power line itself such as pilot wires and microwave.

Unblock System. The unblock pilot relaying system is virtually identical to the overreaching-transfer-trip system but contains provision for allowing short time (100 to 150 ms usually) tripping when the channel fails, provided a local overreaching distance relay operates. Trapping of the transmission line prevents "loss of channel" from occurring on external faults. Loss of channel not accompanied by operation of a distance relay merely sounds an alarm to indicate that condition.

Each of these schemes represent varying layers of complexity imposed on the basic concept of allowing one or more distance relays at each terminal to identify the existence of and the direction to a fault. Use of the pilot channel allows the two terminals to share this information and to initiate the appropriate action based on the comparison. While the description is in terms of 2-terminal applications, they may in general be applied to the protection of 3-terminal lines. These systems incorporate subtle differences and small variations in their levels of security and dependability. They do differ in cost and capability, and their choice is greatly influenced by personal choice and individual previous experience.

Phase-Comparison Relaying. This form of pilot relaying compares, over a communication channel, the instantaneous direction of current at the two ends of the transmission line. To allow the use of a single channel, some such systems use a combination of the individual phase currents to generate a single-phase quantity for comparison. Others use a combination of the symmetrical components (positive, negative, and zero sequence) of the phase currents, and by applying appropriate weighting factors to each and adding the combination, a single-phase sinusoidal voltage is produced and converted to a square wave for comparison at the two terminals.

The concept of the scheme is that external faults will cause the local and received remote quantities to be essentially equal in magnitude but opposite in direction, while internal faults will cause them to be possibly different in magnitude but essentially in phase. In the comparison, the local quantity is delayed by an amount equal to the inherent channel delay, providing near-perfect coincidence for external faults.

The *segregated-phase-comparison* system compares the instantaneous direction of current at the two ends of the transmission line for each phase rather than utilizing some weighted combination of the currents or their symmetrical components. Modern high-speed channels allow information related to four subsystems (3 phases and ground) to be transmitted over a single voiceband in each direction. A local sinusoidal voltage proportional to phase current is converted, for each phase, to a square wave delayed by an amount dependent on channel delay and compared to the received remote quantity for the corresponding phase. Internal faults will produce essentially in-phase comparisons. External faults will produce comparisons essentially 180° out of phase. Considerable angular variation in these comparisons will still provide precise information regarding fault location. The ground comparison uses $3I_o$ current at the two ends of the transmission line.

Current Differential Relaying. To acquire the advantages of differential relaying for transmission lines similar to those obtained for generators and transformers, a scheme is in use that allows the waveform at each transmission-line terminal to be made available at the other. By using pilot wires, fiber optic, a microwave, or multiplexed digital channels the information is transmitted to the other terminal from which a phasor quantity is derived for comparison to the local quantity (delayed by the appropriate amount commensurate with channel time). This is accomplished using all the various technological forms: electromechanical, solid-state, and microprocessor. Excellent sensitivity and speed ($1^1/_2$ cycles) are achieved with this system and because of the abundant availability of digital communication channels, current differential applied to transmission lines becoming very popular.

Generator Relaying. Generators are a vital part of a power system, and their protection deserves is critical consideration. For the larger machines, 50,000 kW and above, a consistent pattern of protection has evolved. For the smaller machines, economics usually dictates that greater risks be accepted.

Large-Machine Protection

Hazards. The hazards against which protective devices guard are faults, unbalanced currents, loss of field, field ground, instability, and other miscellaneous phenomena that will be described later.

Phase Faults. Phase-fault protection is invariably provided by differential relays as shown in Fig. 16-10. By using identical ratio and accuracy-class current transformers, any "through" phenomenon such as load, external faults, or power swings will produce essentially equal restraint currents I_{R1} and I_{R2}. For external faults, operating current I_{OP} will be the difference of the two ct (current-transformer) error currents, or zero in the case of equal or negligible errors.

Internal faults generally will cause I_{R2} to reverse with respect to I_{R1} and I_{OP} to equal the transformed total fault current. The relays that are usually applied here have a sensitivity that is dependent on the restraint. For high through current, restraint is high, and the required I_{OP} is high, thereby restraining properly for possible high differences in error currents. For low internal fault current, restraint is much lower, and the I_{OP} required is much lower, allowing sensitive detection of the fault.

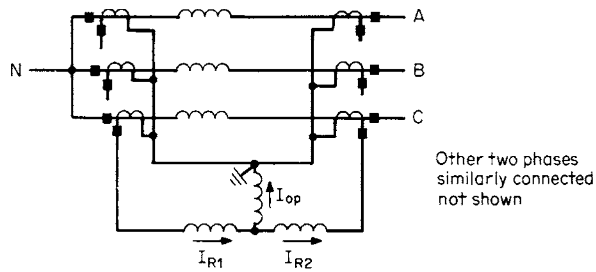

FIGURE 16-10 Typical differential protection for generator.

With this concept, large differential currents during external faults are ignored and the relay is sensitive for small differential current of internal faults.

Ground Faults. Stator faults involving conductor contact with grounded elements may cause essentially no current flow or current comparable to phase-fault levels, depending on the system neutral grounding. Most large machines are unit-connected, meaning the turbine, the generator, and the transformer are treated as a unit, with no fault switching at generator voltage level. The low-voltage winding of the unit transformer is delta-connected, providing zero-sequence isolation from all other segments of the power system. The generator neutral is grounded through a high-impedance circuit, usually a distribution transformer loaded with a secondary resistor. This combination limits ground-fault current to a few amperes, which is undetectable by the generator differential relay. With this widely used grounding method, the generator neutral shift is dependent on fault location. A ground fault at a generator terminal will cause full line-to-neutral voltage to exist between neutral and ground. The closer the fault to the neutral, the lower is the magnitude of this voltage.

A relay connected across the secondary terminals of the distribution transformer will be able to detect this voltage. It can be given sufficient sensitivity to detect faults from the line terminal down to approximately 4% of the neutral. It must ignore the normal third harmonic voltage, neutral to ground, to achieve this sensitivity.

The protection just described is blind to faults very close to the neutral point and consideration shall be given to complement with other relays or replace it with another principle. These schemes use the third harmonic voltage neutral to ground and sense its absence for a neutral-to-ground fault, or they interject a current at another frequency and supervise its level. Neutral-to-ground faults rarely occur and, in themselves, are of no consequence. A second ground fault not only will go undetected with neutral-to-ground fundamental-voltage-detection but also may destroy the generator.

Unbalanced Faults. Inherent in unbalanced faults is the fact that negative-sequence current is present. Flux associated with negative sequence rotates in a direction opposite to rotor rotation. This causes appreciable current flow in rotor structural parts that are not designed for such current, and excessive heating occurs. A relay designed to respond in a similar way to the machine is applied for this protective function. It is $I_2^2 t$ responsive, where I_2 is per-unit negative-sequence current (on the machine full-load current base) and t is time in seconds. Generators vary in capability from $I_2^2 t$ of 5 to 40 for negative-sequence currents in excess of full load, depending on the type and size of machine.

The negative-sequence current relay protects the generator against a prolonged contribution to an unbalanced fault beyond the generator breaker. It often contains provision for "alarming" at a lower level than the tripping level to annunciate the hazard of a sustained unbalanced current condition.

Loss of Field. Field failure caused by any event, such as loss of regulator, opening of field breaker, field short, or field open, will cause a large var flow into the machine and generally a substantial reduction in terminal voltage. This may or may not seriously jeopardize the machine, or it may jeopardize the stability of other adjacent machines. It requires detection and removal of the machine from the system.

Most loss-of-field devices utilize generator terminal voltage and phase current to obtain impedance and phase angle. Loss of field causes impedance at the relay to decrease and current to lead more. This

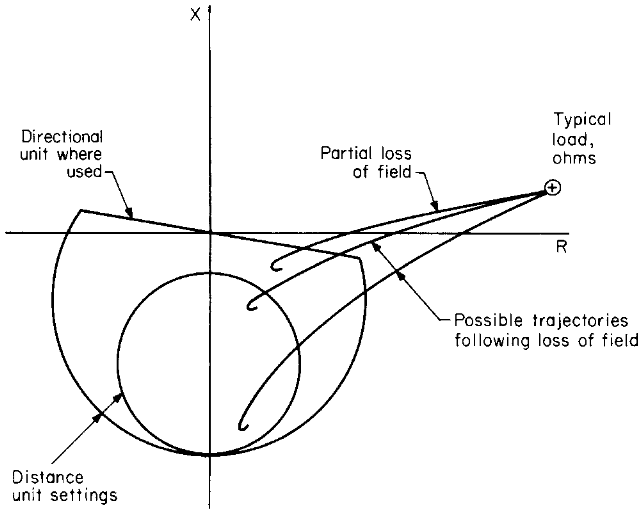

FIGURE 16-11 Detection of generator loss of field by measurement of impedance.

phenomenon is usually detected by "distance" relays as shown in Fig. 16-11. Apparent ohms as viewed from the machine terminals enter the characteristic circle of the relay, causing it to operate.

All such relays are equipped with time delay to avoid undesired tripping on power swings. Some contain directional and undervoltage units to permit additional sensitivity to partial loss of field and allow coordination with regulator minimum excitation units, the machine capability curve, and the steady-state stability curve.

Field Ground. A single field ground causes no machine distress. Allowed to go uncorrected until a second field ground occurs, it can cause sufficient magnetic unbalance to produce *catastrophic* vibration. For "brush-type" machines, detection of the first ground is usually accomplished by detecting current flow in a high-impedance dc-measuring circuit to ground. AC is also used in other devices through the introduction of an ac voltage between the dc field circuit and ground and monitoring the low-magnitude normal current that is allowed to flow.

Where a "brushless" arrangement is used, no normal access exists to the field circuit because there are no nonrotating parts at field voltage level as there are in brush-type machines. Monitoring for grounds is achieved by periodically dropping, manually or automatically, pilot brushes onto collector rings provided for the purpose. One collector is connected to the neutral of the 3-phase ac exciter, and the other is connected to the rotor structure itself. Measurement of the voltage between these two points with an overvoltage relay allows detection of a ground fault at any point in the field circuit.

Instability. When the electrical center appears to be in the transmission system, distance relays applied to protect the transmission lines can be used to detect instability and to separate the two system parts. This usually can be done discriminatingly with out-of-step blocking at some locations and tripping at others, all done in the interests of maintaining as nearly as possible a generation-load match after the separation.

On the other hand, when the electrical center falls in the unit transformer or in the machine, the normal complement of relays applied to generator or transformer protection either will not detect the out-of-step condition or will be time delayed to the point of being unreliable for this function. In these cases, out-of-step relaying is applied.

Figure 16-12 demonstrates the system behavior for a fault condition and for an out-of-step condition as viewed from the machine terminals and plotted in terms of a resistance-reactance diagram. Advantage is taken of the fact that emergence from the area between the blinder lines is on the same

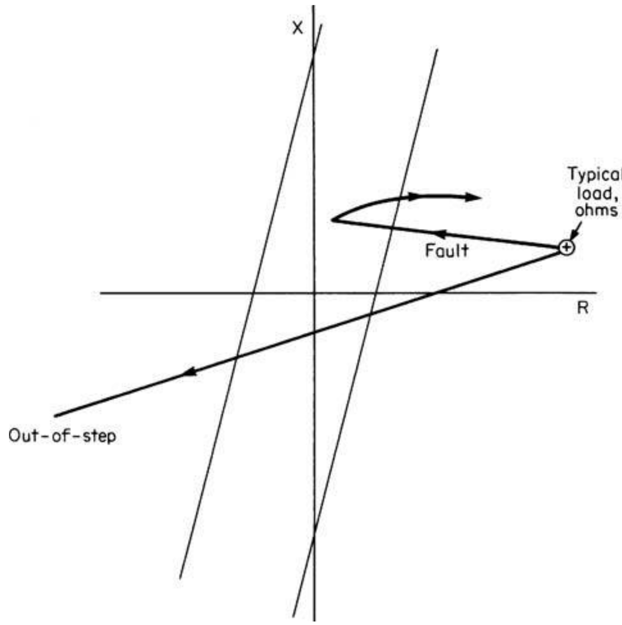

FIGURE 16-12 Blinder scheme for generator out-of-step detection.

side as entry for normal fault clearing and on the opposite side from entry for an out-of-step condition. A blinder-type out-of-step relay trips for the latter case.

Other Protection. For large, important units, relaying is included to detect motoring of the generator, inadvertent energization when the machine is at standstill, excessive volts per hertz that in turn causes excessive transformer and generator iron heating, stator and field overcurrent, and any malfunction not detected by the first line relaying (i.e., backup must be included to prevent catastrophic failure in the event of protective device malfunction).

Small-Machine Protection. Much individual preference goes into the choice of protective equipment for small machines. For the very small, only voltage-restrained or supervised overcurrent relays may be used. In some cases only over- or undervoltage and frequency detection is applied. In other cases, protection approaching that for larger machines is used.

In some cases, compromises with the more elaborate protection are used. For very small machines, time-delayed overcurrent relays with insensitive settings are used in the differential configuration. Specially connected watt relays are used for a combination loss-of-field and out-of-step detection function. Modern microprocessor packages contain most or all of the relaying functions necessary for generator protection plus monitoring, fault recording, and oscillography. They provide very low burden, self-checking, and greatly reduced panel-space requirements.

Motor Protection. Both synchronous and induction motors have protective requirements similar to those of generators. One important difference is that motors are accelerated by applying full or reduced voltage to their terminals, while generators are brought up to speed by their prime mover before being connected to the power system. Large starting current, then, is a normal expected phenomenon associated with motors that generators do not experience. Both types of devices contribute to external phase faults. Motor neutrals are not generally grounded, so no ground current will flow in an unfaulted motor.

Any protective device applied to protect a motor must ignore the conditions of starting current, load, and "through-fault" current, at the same time being able to sense low-magnitude internal-fault current. Differential relays perform this function well, often using a through-type current transformer with the two leads associated with each phase physically inserted through the ct window. Equal in-and-out currents generate no secondary voltage, so no operation of the relay connected to the ct secondary occurs. Internal faults cause unequal currents which generate a secondary voltage to cause instantaneous relay tripping. For larger motors, differential relaying schemes identical to those used for generators are used for phase-fault detection.

A ground-relaying variation of the "through-type ct" scheme requires that all 3-phase conductors be inserted through the ct window. Only ground faults on the motor side of the ct can cause the relay to operate. This is a widely used scheme. Another important element for detecting a fault in a motor is an instantaneous-trip phase device. It must, of course, be set above motor starting current, but available phase-fault current magnitude usually will greatly exceed the starting current magnitude, and very effective use can be made of this inexpensive and simple device.

Thermal Protection. Motors are usually equipped with devices that detect and relieve motor overloading. These are either devices that experience a heating effect comparable with that of the motor itself and act accordingly or are relays that detect the temperature of a resistance-temperature detector (RTD) (through a measurement of its resistance) embedded between conductors in the stator slot. As the motor temperature increases beyond the allowable level, the RTD resistance rises, and tripping of the controller takes place. Modern digital relays provide sophisticated models for the thermal behavior of the motor that operates when the thermal capability is violated.

Locked-Rotor Protection. Neither of the relays used for thermal protection will, in general, protect a motor with a locked rotor. A time overcurrent relay receiving one phase current will normally perform this locked-rotor protective function adequately. In some special large-motor applications where permissible locked-rotor time is less than the required starting time, distance relays have been used successfully to run timers to protect for the locked-rotor condition based on a measurement of a combination of motor impedance and phase angle.

Unbalance Protection. Any degree of voltage unbalance at the motor terminals will manifest itself in the form of increased heating in the motor, well beyond that which could be predicted from the increase in stator current. This can be sensed by a relay which measures voltage unbalance or negative-sequence voltage. Buses that supply a large number of motors are usually equipped with this kind of protection. Phase-current magnitude comparison also has been used very successfully on circuits supplying a single large motor.

Synchronous-Motor Protection. Because of the unique characteristics of synchronous motors, they are usually equipped with loss-of-field and out-of-step protection. This is often provided by a relay responsive to volt-amperes at an angle representative of the var flow into the motor on loss of field. It also will respond on loss of synchronism if the rate of pole slippage is compatible with the relay operating time or if the relay has a delayed resetting characteristic.

Transformer Relaying. Protection of large transformers generally consists of differential protection, gas space or oil rate-of-rise of pressure, or gas accumulation detection plus time overcurrent relays for backup.

Differential Relaying. The differential-relaying concept is applicable to transformer protection in a manner similar to that for generator protection, but distinct differences exist. While current transformers having essentially identical ratios and characteristics are obtainable in generator protection, no such identity is possible with the ct's used in transformer protection. Inherently, they *must* have different ratios and probably will have quite different characteristics. Also, inrush current on initial energization and following external fault removal is a very real phenomenon that must be accommodated by the transformer differential relay. These two circumstances, different ct's and inrush, makes the transformer differential relay different from the one described for the generator.

In addition to the fact that "through" conditions such as load or external faults produce different currents on the two sides of the transformer (to cause equal ampere turns in the windings), for a wye-delta or delta-wye transformer there is also a phase shift between the line currents on the two sides. Further, the standard ratios of ct's (such as 1200:5, 600:5, 100:5) used on the two sides of the transformer do not generally produce equal secondary currents for comparison by the differential relays for through conditions. As a result of these considerations:

1. Delta-side ct's are connected in wye.
2. Wye-side ct's are connected in delta.
3. Balance of input currents in the ratio of as much as 3:1 may be done inside the relay.
4. Inrush current is distinguished from internal-fault current in most transformer differential relays by using all harmonics, a combination of harmonics, or second harmonic only for inrush restraint.
5. Restraint is produced in proportion to the magnitude of the through current causing the relay to be sensitive at low current where ct error is likely to be low and to be insensitive at high current where ct error will be higher.

Microprocessor relays are able to perform these functions, previously assigned to electromechanical and solid-state relays. They allow all the current transformers to be connected in wye, irrespective of the protected transformer connection, through the use of an algorithm that supplies the appropriate phase shifting. This permits retention of phase designations for the monitoring and oscillographic display.

A widely used scheme for protecting a wye winding of a transformer against ground faults is shown in Fig. 16-13. The auxiliary transformer is carefully chosen with a ratio that will minimize the effect of ct error for external faults and force a restraint condition (currents not flowing into the winding polarity markers simultaneously) to exist. Internal faults produce a reversal in the operating current direction with respect to the polarizing (reference) current direction causing the relay to operate. Another common application uses a time overcurrent relay supplied by a neutral ct connected in a wye-winding ground connection. It must be time-coordinated with other ground relays on the power system connected to the wye winding. Where differential relays are used, the primary function of this neutral ground relay is to back up these other devices.

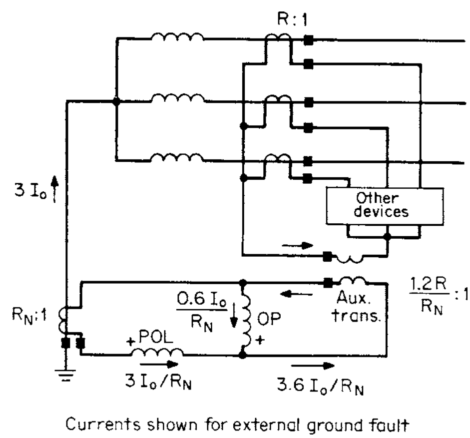

FIGURE 16-13 Transformer wye-winding differential protection.

A neutral-ground relay may accomplish a primary (or first-line) relaying function where low-resistance grounding is used and high-voltage fuses are used. The typical fuse size required for full-load capability will not detect a low-voltage winding failure to ground in such a case. The ground relay will, depending on fault-current level. Remote tripping of a breaker feeding the fused transformer will be required. Tripping of a low-voltage breaker will not clear this type of fault.

Rate of Rise of Pressure or Gas Accumulation. Depending on whether a transformer is designed to have a nitrogen space above oil or to have a "conservator tank" and be completely filled with oil, use will be made of a rate of rise of gas pressure or a rate of rise of oil pressure device in larger transformers. Normal load cycling causes pressure change, but the rate of change is moderate. Faults under oil cause a much higher rate of change, and this distinction allows this type of device to distinguish between load change and faults. Gas-accumulation relays collect any gas generated under oil by arcing or excessive temperature and base their fault detection on the extent of this collection.

16.3 POWER-SYSTEM COMMUNICATIONS

BY GEORGE R. STOLL

16.3.1 Introduction

Power-system communications play a vital role in the safe and efficient operation of the electric power grid. Real-time automation and control of electric utility generation, transmission and distribution systems are dependent upon reliable and secure communication networks. Through an ever-expanding role, the communications' networks enable the application of more computer and microprocessor-controlled devices. These networks and devices support the better utilization of extensive EMS and corporate information technology infrastructure. In addition, they enable the provision of new energy-related services and enhance the reliability and the safety of personnel and equipment.

Power-system communications application typically support various elements of a power utility's control, planning, accounting, and administrative functions. With deregulation of the U.S. electric utility environment, additional functions, including the marketing of bulk electric energy and transmission line access is also required.

This section will primarily address communication functions and the systems they support for power-system *operations*. The operation functions have certain communication requirements that are unique to the electric utility industry. Many of the other utility telecommunication functions, such as administrative voice and data, have communication requirements similar to those of other large business enterprises.

16.3.2 Communications/Control Hierarchy

Most power systems are vertically integrated; they perform the functions of generation, transmission and distribution, typically owned by the same entity. With deregulation, this model is in transition and ownership, and operations responsibilities vary with the country, the type of ownership and the size of the utility. In the United States today, the power marketing function (including the scheduling of generation, sale of bulk energy and transmission line capacity) has been separated from the transmission grid operations. This is to allow for an independent, nonbiased marketing of energy and transmission line capacity in a competitive market place. Previously, these functions were integrated into the same dispatch and operations center and frequently performed by the same personnel.

While deregulation is changing the way many companies are organized and requiring more communications infrastructure, the basic communications functions between the various control centers, generating facilities, transmission, and distribution elements are fundamentally similar. Figure 16-14 is a simplified overview of the current U.S. model, illustrating the relationship between major power-system elements along with their communication requirements.

16.3.3 Utility Communications Network Design Considerations

Most private utility optical and microwave wide area networks use time division multiplex (TDM) as the means for allocating a portion of a network's bandwidth to an individual circuit. By implementing a high sampling rate for each individual circuit, a very high quality, low delay (also termed *low latency*) channel can be transported over the private network. This high-quality and low-latency circuit format is well suited to the mission critical and oftentime sensitive circuit requirements of an electric utility. And, this is not unlike the common carrier and public network cable, wireless and optical transport schemes used until recently.

With the advent of the Internet and associated technologies, wide acceptance of a form of packet-switching protocol, termed Internet Protocol (IP), is starting to become widely used in wide area, public communication networks. Unlike TDM circuits, a packet circuit is not continuously connected. The packet circuit divides the information to be sent into packets, and each packet may take a different route through the network (or series of networks) to reach its destination. At the destination,

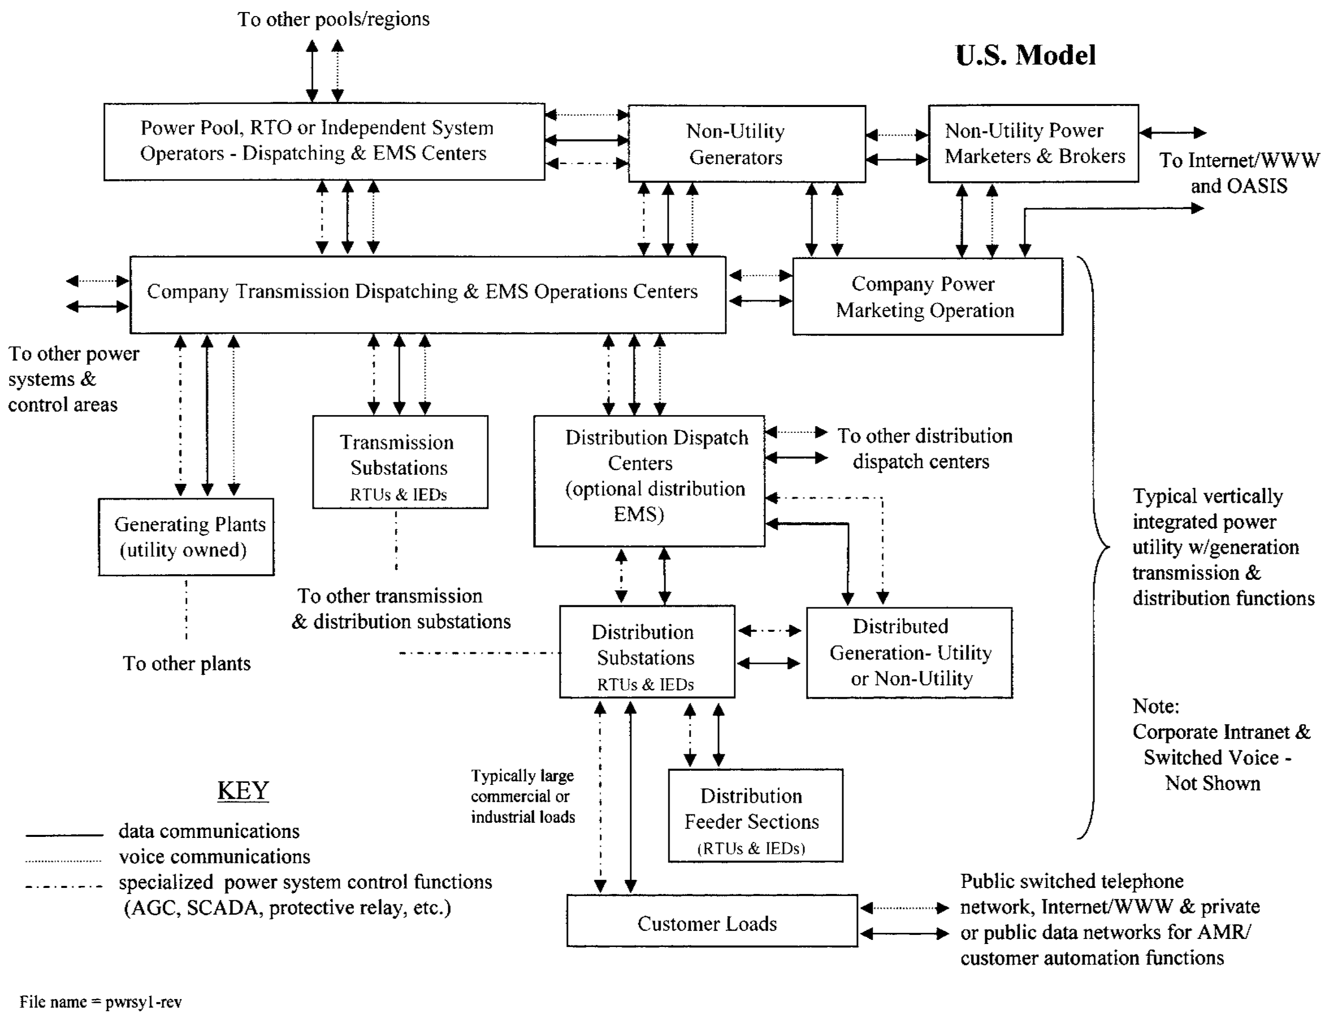

FIGURE 16-14 Interconnected power-systems—telecommunications requirements U. S. model.

the packets are assembled into a sequence matching the information originally transmitted. When no information is being transmitted, no network resources are utilized. This feature allows other users of the network to use its capability, or share the resource and thus increase its efficiency when used for less time critical data transmissions.

However, the disassembly, transmission time and reassembly of packets of information over IP networks add latency to all information being transmitted. Depending on the quality and capacity of the IP network and other technical factors, the information transmitted may be delayed anywhere from tens of milliseconds to several seconds. While acceptable for many types of data and even voice, these delays are not acceptable for many types of power-system operation channels.

This does not mean that IP cannot be used to implement operations circuits. With the use of significant additional bandwidth, IP formats can be transported with the latency and constant delay required. With excessive bandwidth, TDM circuits can be emulated over IP. However, this is typically only implemented over optical fiber networks where the utility manages the network. Because of the low cost of IP equipment and the availability of private utility company fiber networks with much more bandwidth than microwave, more IP networks for utility communication systems will be implemented in the future.

16.3.4 Specialized Power System Communications

In addition to the voice and data network communications typical in many multifacility industrial or business complexes, there are communication requirements unique to the electric power industry. These include:

- Protective relay
  Transmission line protection
  High-voltage switching equipment protection
  Generator and transformer protection
- Telemetering and telecontrol
  Analog and digital telemetering
  SCADA
  Remote alarms
  AGC
  Remote metering—real-time metering—revenue metering
- Voice communications
  Dedicated dispatch phones
  Two-way radio dispatch
- Other data communication links
  Computer to computer links
  Open access same time information system (OASIS) and the Internet
  Regional transmission organizations

16.3.5 Protective Relay Communication Channel Requirements

Protective relaying is unique in that the communications channel is faced with very stringent security and reliability requirements. Security requires that the communication channel never cause a false trip output. Reliability requires that the channel always be in service and function when needed. This requirement must be met even as the communication equipment is subjected to the harsh electronic environment present at substations, switchyards, and generating plants. Protective relay equipment must operate during and after a fault condition and in the presence of electrical noise, ground potential rise, and transient voltages common to these environments.

In addition, the communication channel must not add excessive time delay to the overall protective relaying function. Where the electrical circuit breaker is located at a remote location from the sensing relays, the channel is usually allocated up to 16 ms (about the time required for one cycle of the power-system frequency) total transit time. Extensive industry experience led the U.S. North American Electric Reliability Council to issue typical protective relay communication channel timing and redundancy requirements. Most protection schemes require communication channel times less than 16 ms. An exception to this is blocking schemes; requiring channel times less than 4 ms.[1]

Typical analog communication channel transit times range from 10 to 16 ms. These speeds are attained with direct links between the substations and usually via microwave or fiber communication systems. This is a function of the distance between the terminals, modulation methods, and the medium. An all-digital communication system can be faster than older analog transmission methods because there are no voice-frequency filters and baseband conversions, which add delays. However, in digital systems, application of digital access and cross connect functions or higher-order multiplexers can add unacceptable protective relay channel delays. Without the higher-order multiplexing and switching, one digital microwave equipment manufacturer reported a total channel transit time of 5.3 ms for a 640-km, all-digital microwave protective relay channel.[2] This channel transit time is inclusive of the transmitter time, the propagation time for the signal to travel to the remote end, the receiver detection time, and the operating time of the communications output device.

A majority of the total time required to clear a fault is a function of the breaker's operating time and the protective relay's detection time. These are those characteristics that cannot be readily changed. The communications channel is often the only variable element in the total timing required to detect and clear remote faults on the power system. With higher transmission line voltages, the longer the fault clearing time, the greater the potential damage to the utility's electrical equipment. Thus, the justification for the emphasis on protective relay communications channel speed.

16.3.6 Telemetering and Telecontrol

Telemeter and telecontrol signals provide information to the operators and may also serve as computer system input signals. Telemetering permits remote measurement of current, voltage, real and reactive power, position, flow, and other data relevant to operation of the power system.

Digital systems typically have an RS-232, RS-485, or an Ethernet interface to the communications media. Older analog systems typically use a transducer to convert the parameter being measured to a dc voltage or current. Telemetering equipment at the remote location linearly converts the dc voltage or current from the transducers to a sub-audible frequency, usually in the range of 10 to 30 Hz. This subaudible frequency is used to modulate frequency shift tone transmitters with an output in the range of 420 to 3300 Hz or higher. These signals can be transmitted over standard voice-grade communication channels carried on telephone, microwave, or optical fiber links. At the receiving end, tone receivers convert the audible frequencies back to voltages or currents (typically 0 to 100 mV or 0 to 20 mA), which in turn are used as inputs to monitoring, recording, control, or computing equipment.

With the emergence of sophisticated SCADA systems, a great deal of analog telemetry is being replaced with full digital systems or integrated into the SCADA system. The SCADA systems are designed to provide telemetry and control functions of multiple points (or subsystems) within a station. The SCADA's computer and electronics located at the remote location (such as a substation) are termed RTUs. The RTUs communicate with a master located at the dispatch or EMS center. Master and remote units communicate with each other using a series of digital messages that convey the addressing, control or status information and error checking. This communication can take place over a voice grade communication channel or via an all-digital communication link.

Supervisory control and data acquisition communication between RTUs and the master take place with one of three access sequences. These basic access methods include a polling format, a scheduled or a contention access.

Polling Access. The master periodically sends a request for information/control command sequence to the RTU.

Scheduled Access. The RTU initiates communications to the master on a predetermined schedule.

Contention Access. The RTU or the master may initiate a communications process whenever a control command needs to be transmitted or a status changes. The communications process includes the intelligence to perform data transmission collision avoidance, detection, and retransmission functions.

Combinations of these access methods is also common. In one variation, an RTU may not communicate with a master station unless a control status or data value has changed, termed *report by exception*. In other variations, certain critical events at the substation may trigger a normally polled RTU's immediate communication with its master station. Rather than wait for its assigned time slot in a polled sequence, it communicates virtually instantaneously with its master.

RTUs and Microprocessor Technology. The role of the RTU in the electric power substation is changing. The advent of intelligent electronic devices (IEDs) and programmable logic controllers (PLC) means more devices, such as protective relays, have electronic intelligence and the ability to be dynamically controlled and monitored. Rather than provide a dedicated communications channel to each IED or PLC, these devices may communicate with the local RTU. The RTU, in addition to its primary data collection and control function, acts as a data concentrator and protocol converter. It is becoming common place to see the IEDs and controlled devices networked together within a substation via a local area network (LAN).

16.3.7 Automatic Generation Control

Automatic generation control provides the telemetry and telecontrol to support tie-line and load-frequency control functions. These systems scan (sample) the individual unit generation and tie-line power flows. Via centralized computer control, they generate the raise/lower control pulses sent to individual electric generators. These systems can be very time-critical, but usually do not have as stringent a communications channel requirement as protective relaying. Formerly all analog and using dedicated channels, many of these systems today are now digital or incorporated into the EMS functions.

16.3.8 Voice Communications

Voice communication with and between field personnel and the various dispatch, power pool, and EMS centers takes place over telephone and radio systems. In addition to use of the public switched telephone networks, power systems frequently include dedicated circuits between the dispatch and control centers. Often these are configured so that minimal or no dialing is required. The circuit may be transported over private or dedicated networks. These are termed *hotline* or *ringdown circuits*. They allow dispatchers to communicate with each other without the normal 10- to 20-s delay caused by dialing and the public network's switching, routing, and signaling functions.

Two-way radio communications are used for communications with field personnel performing operations, maintenance, and electric service restoration. These systems operate in the very high frequency (VHF) 30 to 300 MHz or ultra high frequency (UHF) 300 to 1000 MHz portions of the radio spectrum. Larger utilities may use trunked radio systems, where multiple radio channels and their use is computer controlled. In a trunked radio system, the channels are dynamically assigned as needed, allowing efficient use of the radio spectrum. Smaller radio systems use conventional, dedicated radio channels. These are analogous to a "party line" environment, where all the users on the channel can hear each other. In these configurations, an individual radio channel may be shared by the various functions within the utility.

Large dispatch and energy control centers have radio dispatch consoles. These consoles consolidate all the radio system control functions, allowing the system operators to quickly access the mobile radio systems and to communicate with field personnel throughout their service territory. These radio consoles may be stand-alone units or have voice telephone functions integrated into them.

16.3.9 Other Data Communication Links

Bulk data information exchange takes place between the various power-system's computers. Data traffic over these links may include the EMS system's generation scheduling, fuel cost and generator availability, transmission capacity, load predictions, interchange billing, frequently weather information, and other data relevant to power-system operation. These data links are usually over dedicated communication channels and vary in data speeds from a single DS-0 (64 kbits/s) to T1 or E1 rates.

Oasis and the Internet. In the United States, the Federal Energy Regulatory Commission (FERC) established requirements for implementing open access to the electric transmission grid.[3] Ultimately, this open access to electric transmission lines will allow almost any generator of electric energy to sell to any purchaser. Implementation requires additional communications, establishment of wholesale power marketers and independent system operators who act independently of the utility that owns the transmission lines and/or generates the electric energy. To address how transmission line capacity and availability information would be made available to everyone at the same time, on a uniform basis, FERC defined an application of the Internet.[4] All entities that generate electricity for the open market, own electric transmission lines, or buy energy from these parties will need to use the Internet to exchange information. Termed OASIS, these Internet based, specialized information services allow anyone with access to the Internet to view the capacity, availability, and associated costs of electric power and its transmission. OASIS is currently serving as a shared database of information. It may develop into an intelligent system capable of performing generation scheduling, and control.

FERC Order 2000. Following implementation of the transmission line open access rules, FERC released an order requiring all the U.S. high-voltage transmission line owners to tell FERC how they would organize regional transmission organizations (RTOs)[5]. Regional transmission organizations are intended to be a consolidation of independent system operators (ISOs). The objective was to lower the number of ISOs and simplify the communications and marketing communications. Today, there are both RTOs and ISOs and the exact definition of the bulk transmission and generation model is still evolving. From a communications perspective, all variations of these power system models require additional voice and computer communication links along with more real-time data of power grid operations.

16.3.10 Communication Alternatives

As communication alternatives are considered for power-system operations, factors including circuit capacity, reliability, latency, jitter, and other technical parameters along with cost must be considered. Many organizations categorize their circuit requirements into *level of service* categories. Levels of power system telecommunication service can be grouped into three general categories.

System Critical. These are communication links that are extremely reliable and which support process and control functions requiring near real-time communications. Communication paths are available full time, they are usually dedicated to specific functions and the process or control function they support is usually computer controlled and has total response times ranging from milliseconds up to several seconds. Examples of system critical power-system communication links include protective relay channels, LFC, AGC, tie-line control, many SCADA systems, and some computer links.

System Priority. These are communication links that support voice and data functions with total response and control times ranging from several tens of seconds up to 1 h. Communication links may be dedicated or shared and provided by the power utility or a public carrier. The process or function supported may require or allow human intervention. The communication channels are usually very reliable and seldom blocked, or not available. Examples of system priority communication links include voice dispatch circuits, the voice two-way radio systems, computer-to-computer data links, and local and wide area data networks. They also include commercial and industrial electric load shedding, metering of large commercial and industrial loads, less time-sensitive SCADA functions, and distribution and feeder network automation systems.

System Administration and Support. These are communication links that support power-system functions where near real-time or very time-sensitive communications are not required. Channels support functions or processes with acceptable response and control exchanges ranging from minutes to days. If a communication exchange is interrupted or lost, it can be resent without severe implications to the safe and efficient operation of the electric power system. This category includes all types of administrative voice and data via the public-switched networks, private branch exchange systems and metering, planning, scheduling, billing, and customer service communications. In the U.S. model, it also includes use of the Internet for many of the transmission access scheduling and power-system marketing functions.

The level of service, process response times and media/provider selection criteria for typical power-system communications functions are represented in Fig. 16-15.

16.3.11 Communications Media/Service Type

Power-system communication networks are typically composed of systems using several technologies and, often, multiple service providers. Following are some of the most popular types of systems and services used to support the specialized needs of the power utility.

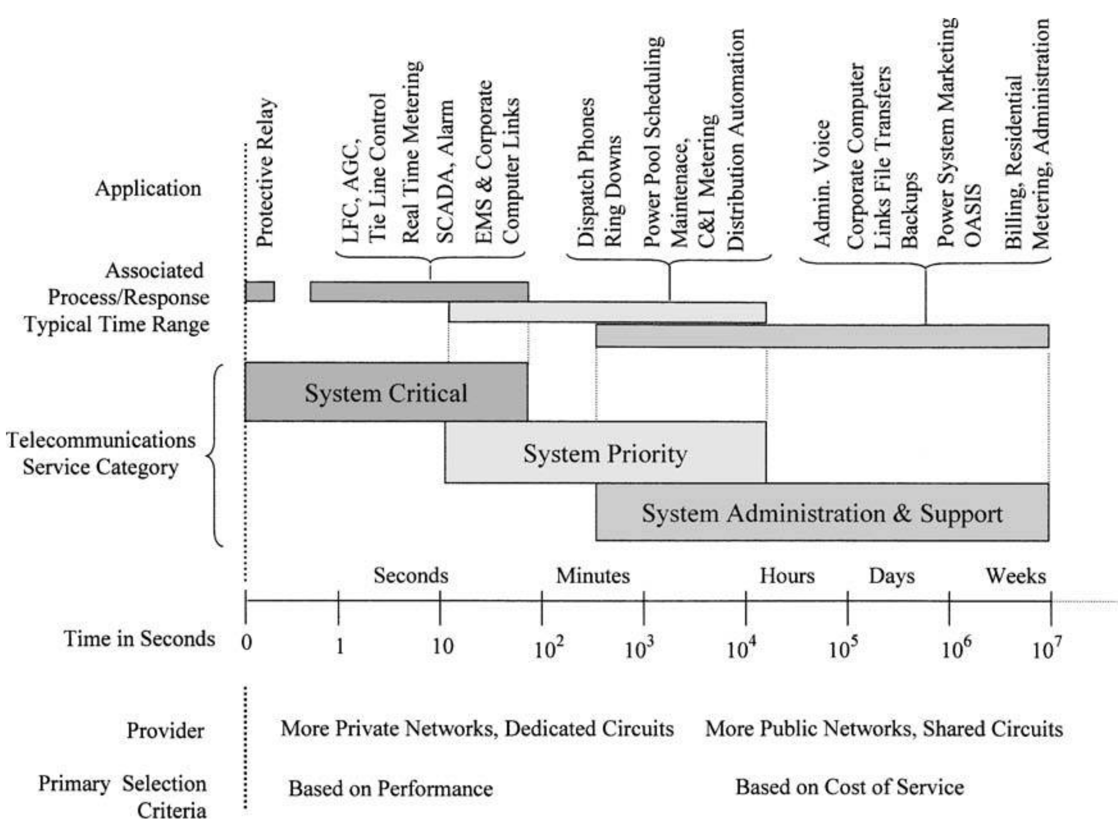

FIGURE 16-15 Power-system communications—application vs. service category.

16.3.12 Private Point-to-Point Microwave Systems

Private microwave systems have proven to be a very reliable and cost-effective method of supporting a wide range of communications needed for power-system operations. These systems operate in assigned frequencies ranging from 2 to 23 GHz. Very reliable links can be established for distances up to 80 km each, depending on the intervening terrain, the operating frequency and the height of the antenna systems. Multiple stations (repeaters) can be "chained" together for end-to-end system distances of thousands of kilometers. Most systems require licenses, although some spread spectrum systems with limited capacity and range are available for short-haul services.

A drawback to microwave systems is their requirement for a line-of-sight path between stations, often requiring large towers to support the antenna systems (Fig. 16-16). Spectrum may not be available

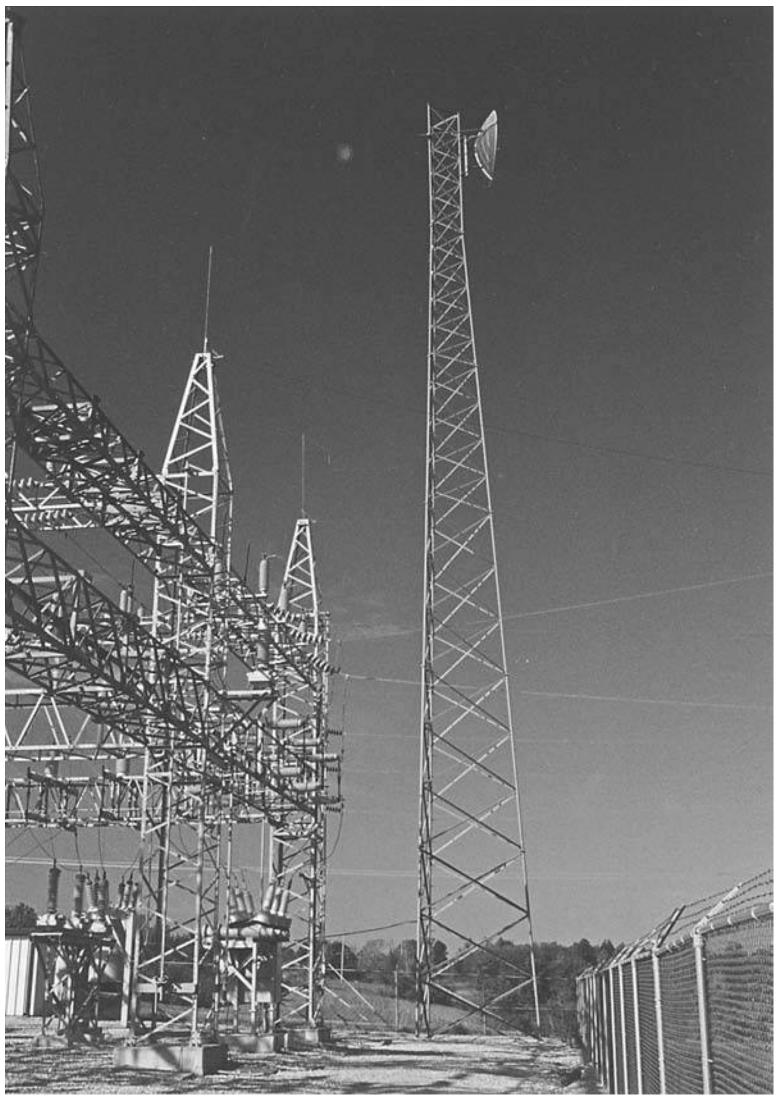

FIGURE 16-16 Microwave systems require large towers for line-of-sight paths between stations.

due to heavy use of the limited amount of assigned frequencies. Systems operating at 10 GHz and higher are more sensitive to rain and atmospheric conditions, resulting in shorter path lengths.

Digital point-to-point microwave systems can be designed to provide very high reliability with error rates of 10^{-9} or better. They also can be configured to provide minimum channel delay, so they are ideally suited for protective relay channel service. Once microwave systems are installed to provide required power-operations communications, it can be cost effective to use them also to transport the power system's administrative voice circuits and other corporate communications.

16.3.13 Leased Telephone Circuits

Telephone circuits, both dedicated, direct point-to-point, and the switched lines that are transported through the public telephone networks are widely used for power-system operations. They can be cost-effective for the system priority and system administration and support category functions that do not have extremely demanding availability, reliability, and error rate requirements. Switched circuits, also termed dial-up circuits, can be ordered and installed quickly in most populated areas. Error rates vary over a wide range and are a function of the quality of the local telephone company's cable plant and distances to central office equipment. Another concern with leased telephone circuits is that they are often transported by multiple carriers, making it difficult to identify intermittent problems.

Voice grade, dial-up circuits may be able to transport data rates to near 56 Kbps in metropolitan areas that are close to the telephone company's central offices. Rural environments can expect much lower data rates. Digital leased circuits are available in some areas that will transport data rates to DS-3 (45 mbit/s) or higher with good error rates, but these can be costly.

A majority of leased telephone circuits use a metallic conductor in some portion of the circuit, usually in the last mile segment where they enter and exit the power company facility. Their metallic conductor and cable sheath make them susceptible to induced noise and voltages (magnetic induction) and ground potential rise that are common in power-system environments. With ground potential rise, a local fault may cause the voltage potential of the electric station ground grid to rise to several thousands of volts, while the telephone company's central office ground remains at zero potential. This difference in ground voltage appears as a high-voltage on the utilities equipment connected to the telephone circuit. This cannot only damage equipment and the cable, but also presents a safety hazard to personnel working on the electronic equipment.

To protect the connected equipment and personnel in near proximity to these metallic cables, transmission substations typically require sophisticated telephone line protection devices. These are required to eliminate the harmful voltages that would otherwise be present on the telephone cables and the cable sheath. These devices may take the form of short fiber-optic links (with the fiber and all interface electronics mounted in a dielectric cabinet), isolating transformer or neutralizing transformer installations. The fiber-optic devices are generally replacing the neutralizing and isolating transformer installations because they do not require as careful a design or remote grounding considerations.

16.3.14 Satellite Services

Most traditional communication satellite systems use a single satellite placed in a geostationary orbit, 36,000 km above the earth's equator, functioning as a microwave signal repeater. Several newer systems use multiple satellites in lower orbits categorized as low-earth-orbit (LEO) and medium-earth-orbit (MEO) systems. Power-system operations have made only limited use of satellite technology.

Traditional satellite systems can transmit large amounts of digital information, in the form of voice or data, with low error rates. However, a characteristic of all geostationary satellites that eliminates them for most power-system-critical communications is the propagation time associated with the microwave signal. Transmitting the signal 36,000 km from the earth to the satellite and back again adds approximately 250 ms to the communication channel time. Many systems use a double-hop technology, where all signals are relayed through a large earth station, boosting the signal and thus allowing for the application of small parabolic antennas at remote stations (termed *very small* *aperture terminals,* or VSATs). This doubles the delay, yielding an overall channel propagation time of nearly 1/2 second. Add to this the access and back haul times, error correction and overhead, and round-trip times can be in the order of 2 to 3 seconds. This delay creates problems for the polling and response timing in many EMS systems and causes geostationary satellite technology to be totally unacceptable for protective relaying.

Other Satellite Services. Low-earth-orbit (under 2000 km from the Earth's surface) and medium-earth-orbit (10,000 km) systems are in service and are used in a limited manner for power operations that are not time critical (certain types of remote metering). These multiple satellite systems offer voice and data, usually on a worldwide basis. Low-earth-orbit systems are being used that can offer meter reading and some types of SCADA services. Because these systems are closer to the earth's surface, there is a considerable improvement in transmission delay times versus geostationary satellite systems. Primarily using packet data formats, there are still time delay issues.

16.3.15 Private and Commercial Land Mobile Radio Systems

Land mobile radio systems are widely used to support power-system field operations. They operate in the VHF region (30 to 300 MHz) or the lower portion of the UHF region (300 to 900 MHz). They primarily support voice operations over narrow bandwidth channels. Some systems also support limited mobile data and status messaging. However, with data rates over this bandwidth limited radio channel typically below 9600 bits/s, only a minimum amount of data and status information can reasonably be transmitted.

Many utilities have private systems (owned and operated by the utility) although a wide variety of commercial services are available. These systems use conventional (half or full duplex) communications over individual dedicated radio channels or for large systems, trunked access over multiple channels.

Commercial systems typically use more trunking and spectrum efficient systems and often cover wider service areas. They are seldom used for power-system dispatch operations because of concerns over reliability and channel access during busy periods or regional disasters.

Limitations of land mobile systems include the limited availability of additional spectrum, congestion on existing channels, and the requirement of an often complex licensing process. Radio propagation at UHF frequencies limits the system range to near line-of-site distances with somewhat greater distances for VHF. Installation of a wide area system requires locating the transmitting equipment on tall towers, buildings, or mountaintops.

16.3.16 Cellular and PCS Wireless Services

Cellular radio service (operating in the 800 to 900 MHz spectrum) and personal communications services (PCS) (operating in the 1.9 to 2 GHz spectrum) are used by power-system operations for the *system administration and support* category of mobile voice or low priority, low data rate (typically under 56 kbits/s) mobile data communications.

Cellular and PCS systems provide service in metropolitan and many rural areas. Low power mobile or handheld transceivers communicate with nearby radio base stations configured in a cellular pattern. The base stations (termed cell sites) are linked with each other and the public telephone network. The system is designed so that the base stations can reuse the radio channels of other nearby cells, thus allowing many subscribers to simultaneously use the spectrum.

Their circuits often do not meet the quality or reliability criteria needed for higher priority power-system operations. Serving as wireless telephones and frequently as low speed data transceivers, they are not designed with the same grade of service as the U.S. wire-line public telephone network. During busy periods, calls can be blocked from accessing the cellular network and calls in progress may experience interference or may be terminated.

In addition to the popular mobile voice communications, cellular service is also widely used in power-system operations to support low priority, occasional dial-up or unsolicited alarms from remote locations where more expensive, higher reliability EMS systems are not justified.

16.3.17 VHF and UHF Radio Data Links

Very high-frequency and UHF radio systems are frequently used to support EMS and telemetry links. These data-only systems can be configured as point-to-point circuits (typically in the VHF frequency region) or as point to multipoint (the UHF frequencies). Point-to-multipoint systems are also termed multiple address systems. Characteristics of most of these systems include data rates in the 2400 to 9600 bits/s range, but actual throughput is much lower than this, since most systems use a shared channel or some form of polling access. System error rates can be as high as 10^{-4}, but error correction and packet data transmission formats provide acceptable performance for many applications.

Limitations of these systems include lower data speeds and throughput rates and the requirement to obtain licenses for the radio channels. Most of the VHF and UHF radio spectrum allocated for this type of service is congested or assigned to mobile radio applications, making licensing in some areas difficult. They also require line-of-sight or near line-of-sight paths between the remote and the master station antennas, often requiring tall towers. Typical range of these systems varies from 10 to 40 km, which is a function of the operating frequency, intervening terrain, and height of the antenna systems. Despite their limitations, they are widely used in power-system data and SCADA systems because they can be designed to meet many *system priority* category communication requirements.

16.3.18 Power-Line Carrier

Power-line carrier (PLC) or carrier current systems transmit very low-frequency (65 to 300 kHz) radio signals over utility transmission and distribution wires. Although voice transmission is possible, most systems are used for telemetry and protective relaying. PLC systems provide a very reliable method of long-distance protective relay signaling for high-voltage transmission lines. More recently, distribution line carrier systems have been used successfully for automating distribution applications and automatic meter reading.

PLC systems can reliably transmit their low-frequency signals over transmission lines in excess of 200 km in length. Since existing transmission or distribution lines are used, no right-of-way or licensing is required. The primary limitation of these systems is their limited bandwidth, usually transporting two to four voice-equivalent channels. In addition, transformers and capacitor banks used for power factor correction severely attenuate the PLC signal.

16.3.19 Privately Owned Fiber Optic Cable Systems

Fiber-optic systems provide some of the highest quality transmission systems available with more capacity than any other telecommunications media today. Properly designed systems have extremely low bit error rates, on the order of 10^{-12} or better and capacities to 320 Gbits/s. Fabricated from very pure forms of glass, the hair-thin fiber strands are nonconductors, and thus not susceptible to the induced voltages and ground potential rise problems found in electric plant and substation environments. Fiber-optic cable is widely used for instrumentation, wide area networks and local area networks in and between the utility company's plants, substations, and offices.

Numerous utility companies are placing optical fiber cables (Fig. 16-17) in their electric-line rights-of-way. These can be used solely for internal communications, or excess capacity may be sold to other carriers. Specialized cable arrangements have been fabricated, suitable for the high-voltage transmission line environment.

There are several dozen variations of fiber-optic cable, protective sheath, and cable/messenger configurations used by utility companies on their electric transmission lines. A majority of the fiber being deployed on electric transmission line right-of-way today is in one of four arrangements. These include:

Direct Buried. An armored sheath protects a bundle of fibers. The sheath can be metallic or plastic.

Buried in Conduit. The conduit is usually nonconductive plastic or polyvinyl chloride style with two to four interior subducts. The multiduct conduit allows additional or replacement cables to be pulled into the duct system at a future date.

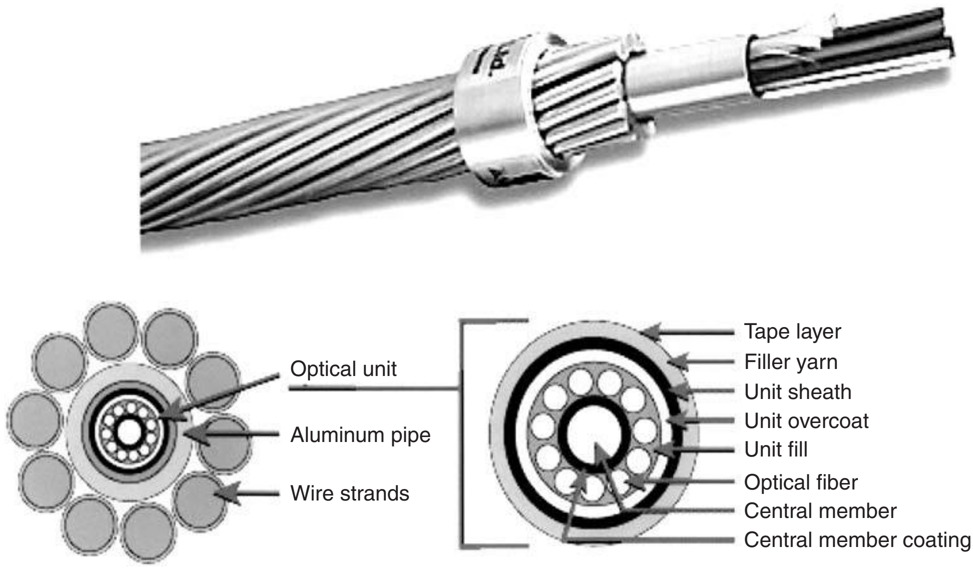

FIGURE 16-17 Optical ground wire.

All Dielectric Self-supporting Cable (ADSS). An aerial cable with a nonconducting protective jacket with Kevlar or fiberglass supporting members (Fig. 16-18). The nonconductive construction allows this type of cable to be placed close to the electrical conductors. This type of cable typically contains anywhere from 12 to 96 optical fibers.

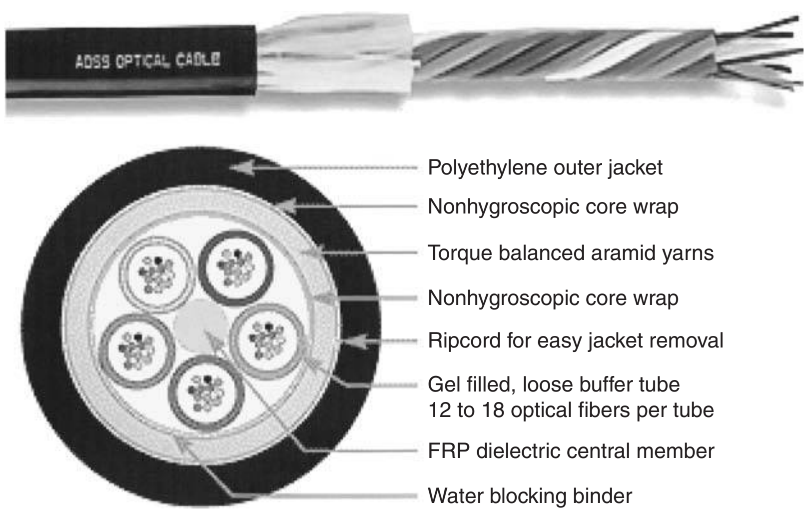

FIGURE 16-18 All dielectric self-supporting.

Optical Ground Wire (OPGW). The optical fibers are placed inside the metallic shield wire (also called a *static wire*) and suspended above the electrical conductors. In this application, the OPGW serves two functions: (1) it acts as a grounded shield wire protecting the electrical conductors from direct lightning strikes, and (2) it carriers the fiber-optic communication cables. This type of cable is available with up to 144 fibers. Fiber counts above 96 fibers are less common due to the physical weight of the added fibers and support materials.

These wide area network fiber-cable systems use single-mode fiber cable, allowing distances up to 100 km without repeater stations. New fiber-optic cables and the application of optical amplifiers allow even greater distances. Most systems in service today transmit one or two optical wavelengths in the 1310 or 1550-nm regions. New technology allows multiple optical wavelengths to be transmitted over an individual fiber (wavelength division multiplexing), significantly increasing existing and future system's transmission capacity.

16.4 INTELLIGENT DISTRIBUTION AUTOMATION

BY DOUG STASZESKY

Supervisory control and data acquisition has long been used to control transmission systems to provide the operational flexibility and speed, required for efficient and reliable performance. The use of SCADA in the distribution system is becoming increasingly important as utilities move into a deregulated, competitive environment. The acronym SCADA has been generally replaced by the term distribution automation (DA), which incorporates the principle of operating switching, fault interrupting, and other control devices automatically in response to events in the system. Automated switching of distribution feeder circuits provides significant improvements in reliability, enhances operational flexibility, and increases the utilization of distribution assets and personnel.

Feeder switching and protection systems utilizing powerful IED's, sophisticated algorithms, a plethora of sensing devices, and all connected by increasingly fast and secure data communications enable the implementation of distributed intelligence, which is fundamental to implementation of an intelligent grid now and in the future. As DA supplanted SCADA as the term *du jour* for such systems, it is likely that a new term IDA—intelligent distribution automation—will come to represent the real needs of utility planners, engineers, and operators to meet long-term customer needs as well as the demands of regulatory bodies.

Just as mainframe systems are being replaced with flexible, fast-distributed computing networks made of PCs, centralized control of the distribution power system will move to distributed computing to become the intelligent grid. The intelligent grid will deliver benefits far beyond that, which can be delivered by conventional reclosers, switches, automatic sectionalizers, and other devices, which do not share information about the status of the grid. Distributing system intelligence effectively eliminates communication bottlenecks and time delays associated with more conventional, centrally controlled SCADA systems, and are sustainable even if single computing nodes do not function. And, when properly designed, systems based on distributed intelligence offer a completely scalable advanced feeder automation system that can easily, and cost effectively meet the challenge of the smallest tactical reliability problem, or grow to deliver system-wide automation functionality and improved asset utilization.

Distributed intelligence will become increasingly important as distributed energy resources (DERs) are deployed on the distribution system. Distributed energy resources, fully incorporated into the intelligent grid will further enhance reliability and power quality and have the potential to significantly improve overall asset utilization. Distributed energy resources are still in a state of growth and flux, so they will not be discussed in detail in this section. However, they are mentioned since it is likely that only an intelligent grid will be able to properly schedule a variety of distributed energy resources—and ensure that they operate safely in an interconnected grid. Intelligent Distribution Automation systems will enable a true "plug-n-play" environment, which will, in turn, truly enable the widespread use of DERs. Plug n play will also simplify system implementation for utilities.

Distribution automation systems today can also provide the means to optimize feeder and substation loading by enabling the shifting of load from one feeder to another in a very short time when needed. This same capability can yield hard dollar cost savings associated with deferment of capital projects when coupled with planning practices that take advantage of the new technologies.

Most importantly, distributed intelligence provides the tools that the utility planner will need to design a distribution system that will meet the increasing demand for reliability and power quality.

The following examples will demonstrate a wide range of system types available for IDA. Each discusses some of the benefits and drawbacks of each system and will provide a reference for the reader to consult when considering deployment of truly IDA on their system for reliability improvement, improved asset management, capital deferment, overtime reduction, improved knowledge of system conditions, and generally better customer service.

16.4.1 Automated Feeder Switching Systems

Recloser Loop Schemes. While they do not utilize distributed intelligence in the sense of intelligence shared via communication systems, recloser loop schemes are discussed because they are a fairly prevalent method for automating a system without the use of a central control logic.

Recloser-based systems typically rely on the idea that some percentage of faults on a system is temporary in nature. By reclosing some number of times for a temporary fault, sufficient time will go by for the fault to fall clear of the line and a subsequent reclosing operation will restore service. A permanent fault will not be cleared by the multiple reclosing operations and the device(s) trying to reclose will eventually lock open (lockout).

A typical line can be broken into two or perhaps three segments using multiple reclosers. The number of segments is typically limited by the ability to establish time overcurrent coordination between multiple reclosers such that only the last one before a faulted section operates to clear. A three-segment circuit would be fairly rare, as coordination would need to occur for, ultimately, four devices in series—the substation breaker, two normally closed reclosers, and, when a loop operates, a tie that would close—this typically proves quite difficult to do in practical application.

Reclosers rely on *local* overcurrent detection, voltage sensing and timers to effect restoration of the loop. When a fault occurs, the recloser immediately upstream of the fault will trip to clear the fault. It will then test the line through repeated application of fault current by reclosing a user-configured number of times. Reclosers downstream of a fault will sense loss of voltage and initiate a loss-of-voltage (LOV) timer. When the timer expires, normally open reclosers will open. A normally open tie recloser will close when its loss-of-voltage timer expires.

Recloser loop schemes typically consist of between fault interrupting reclosers, arranged in a simple loop. A 3-recloser, scheme is shown in Fig. 16-19. R1 and R3 are normally closed reclosers and R2 is a normally open tie between the two circuits.

FIGURE 16-19 3-reclosers loop scheme.

A fault between the substation SB D and R1, for example, will result in a trip of substation breaker D. It will reclose its configured number of times and will lock out for a permanent fault. R1 will sense the loss of voltage on its source and, upon expiration of its loss-of-voltage timer, will open. R2 will close upon expiration of its LOV timer and service will be restored to the unfaulted segment.

Should a permanent fault occur between R1 and R2, for example, then R1 will trip, reclose and lock out. Then, the normally open tie recloser R2 will automatically close into the fault after its loss-of-voltage timer expires in an attempt to restore service, but will trip and lock out. The unfaulted feeder emanating from substation breaker SB B will experience the fault current as well as voltage sag for all customers on the system.

Though such systems are often fitted with SCADA communication from the device back to the SCADA master station, there is no communication between devices and this type of system does not utilize distributed intelligence. Nevertheless, it is an effective way to automatically restore service to unfaulted segments and is easily implemented with little concern about communications.

But, such systems require that load capacity be reserved on each circuit to accommodate any load that may be picked up during a restoration sequence. This reserved capacity is typically based upon peak loading conditions and cannot account for actual time of day and seasonal load diversity factors. Therefore, for the bulk of the time that a circuit is not faulted, it is also an asset that is not being fully utilized.

Intelligent Loop Restoration Systems. Intelligent loop switching may use either switches or reclosers to effect automatic local sectionalizing of looped distribution circuits, then use distributed intelligence and peer-to-peer communications to effect automatic restoration of the system. A typical intelligent loop system using seven switches is shown in Fig. 16-20.

In the intelligent loop restoration system, each system switching device utilizes 3-phase voltage and current sensing to detect the passage of fault current and loss of voltage events following initiation of a fault. Each device also continuously monitors load for use in ensuring that loading limits are not exceeded during the circuit restoration process.

When a fault occurs, each device upstream of the faulted segment will see passage of fault current; each device downstream will see no fault current. All devices will see the loss-of-voltage condition when the upstream protective device operates. Logic dictates that the fault is in the line segment where the upstream switch sees fault current and the downstream switch does not.

The switching devices will open based on either counts of overcurrent or loss of voltage or upon expiration of a loss-of-voltage timer. Once this occurs, the distributed intelligence in each switch control will activate the restoration process. Based on knowledge of prefault loads in each segment and knowing the fault location, the intelligent restoration agent will close open switches only if the unfaulted segment can accommodate the load, and if the switch will not close into a faulted segment.

The use of ongoing voltage, current monitoring, and distributed intelligence ensures that the backup circuit will not be overloaded during the restoration process. This enables higher normal

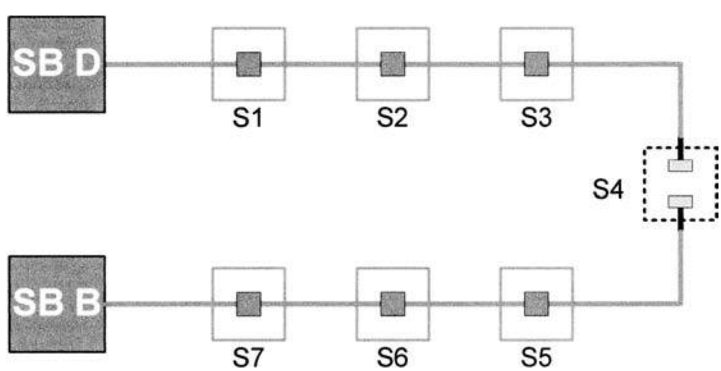

FIGURE 16-20 7-Switch intelligent loop restoration system.

loading than with noncommunicating loop schemes, which only accommodate load by reserving the capacity. Since real-time load monitoring is enabled, the system can take full advantage of load diversity, allowing restoration when able and preventing overload as needed. The result is that normal line loading can be increased to 75% of full-load capability or more depending on the amount of segmentation of the circuit.

And, distributed intelligence means that that there will be no intentional closing of a device into a faulted segment. This significantly improves power quality for customers on the backup circuit when compared to a loop scheme, which intentionally closes the backup circuit into the fault.

An intelligent loop restoration system may use reclosers if proper coordination can be achieved with the desired number of circuit segments. If this is not possible, then switches may be used and the difference will be that more customers will be affected by momentary outages than with the all-switch case. Since intelligent loop restoration schemes are designed to complete the restoration process in less than 60 s, only the customers on the faulted segment of line will see an extended outage.

A side benefit of such schemes is the reduction in line patrol time—after all, a line crew travels to the patrol site at 50 mi/h, but performs the patrol at 5 mi/h. Getting to the faulted segment faster—and reducing patrol time means that restoration is faster—and overtime is potentially reduced.

Intelligent Multigrid Switching. In order to achieve significant jumps in both reliability and greater asset utilization than the systems described above, then a system must accommodate multiple sources. In this way, it is possible for some line segments to have more than one possible alternate source. The one-line shown in Fig. 16-21 consists of four circuits with multiple possible circuit ties through normally open switches.

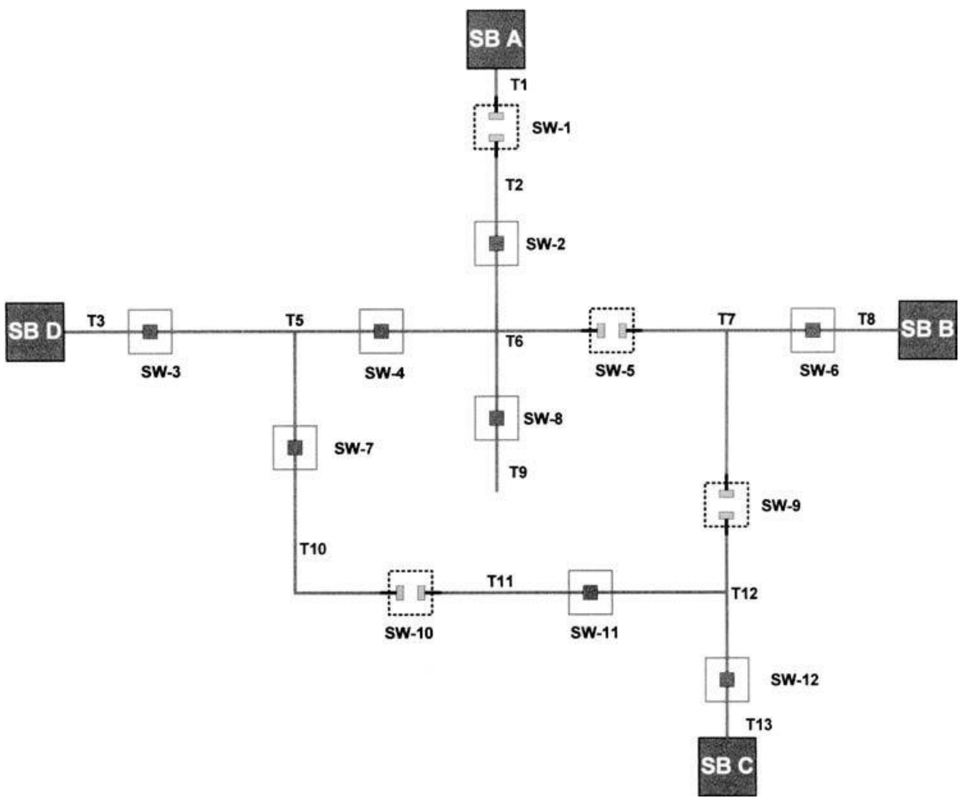

FIGURE 16-21 Intelligent multigrid system.

In the case above, all switching points utilize switches. Effecting time-overcurrent coordination between reclosers in such a system for both initial and contingency conditions would not be feasible due to the complexity of the circuit. For example, a large number of devices could wind up in series after a restoration process has been completed.

An intelligent multigrid system differs from an intelligent loop restoration system, primarily in complexity. The loop restoration system uses an overall circuit-logic approach where the entire system is treated as part of the intelligent restoration logic. The number of possible switching combinations that could come into play in a multigrid system requires a different approach.

The multigrid system breaks up the system logic such that it is resident in individual line segments bounded by intelligent switches (such as segment T6 in Fig. 16-21, which is bounded by four switches SW-4, SW-2, SW-8, and normally open SW-5). The use of a virtual agent assigned to each line segment, or team, can interact with neighboring virtual agents to effect intelligent system restoration using whatever sources are available for each de-energized segment, while still ensuring that the alternate source will not be overloaded when it is re-energized. Since the logic operates on a line segment basis, any number and type of segments can be connected to form an overall distribution system of virtually any size.

Other algorithms are used to allow for priority in choosing among multiple alternate sources when all other factors are equal. In this way, the user can force a certain amount of predictability in system operations to meet a variety of circuit planning criteria.

An example of this would be if a permanent fault occurred on line segment T5 in Fig. 16-21. In this case, substation breaker SB-D would trip, reclose, and eventually lock out. All switches on the circuit emanating from SB-D would open, either on overcurrent counts or loss-of-voltage counts. The intelligent multigrid restoration process would begin as soon as each line segment (team) confirms that the initial fault has been isolated. In the case of team T2, SW-1 will close after the agent in T2 confirms that the prefault load in T2 did not exceed the limit set for SW-1. The same process would be carried out by the agent in team T6; however, in this case, a priority has been set to restore load from team T2 first. Therefore, the process waits a predetermined time for SW-2 to become energized. The agent in team T6 then confers with T2's agent and should sufficient capacity be available to accommodate T6's prefault load, then SW-2 will close.

However, if sufficient load capacity does not exist in T2, then the agent in T6 will proceed to SW-5, where it will confer with T7's agent, perform the load analysis and close if capacity exists. Up to eight sources in a given team can be accommodated using this intelligent analysis.

If no priority is set, then the first available source with sufficient capacity will be used to restore service to a deenergized team.

The use of this distributed logic, in small, logical elements is essential for the construction of large and complex systems. Another advantage of this capability is that more than one contingency is accommodated, as long as alternate sources are available to a team for each subsequent line fault. Even if two of the sources in Fig. 16-21 were lost, some amount of load on any of the circuits could be restored using the remaining sources.

Intelligent multigrid systems do require robust communications, but the use of peer-to-peer radios or other communication devices, along with a segment-based logic will enable the restoration algorithm to function to some degree, even if some devices lose communications.

The other challenge to such a system is change. Such systems represent tools that were not available only a few years ago; conventional distribution circuit planning and design practices do not take full advantage of such systems, so a new way must be learned. However, once the ability to establish multiple circuit ties, safely and reliably, without overloading a system are incorporated into a utility design practice, then the ability to design to meet increasingly stringent customer and regulatory requirements is expanded greatly.

Intelligent Protection, Control, and Restoration Multigrid Systems. The intelligent multigrid system provides significant benefits, but requires operation of an "upstream" protective device—typically a substation breaker—to clear the initial fault. The next leap in function is to incorporate complete protection into such a system, thus eliminating outages for any but the faulted segments and beyond, for any given contingency.

Again, the use of a distributed, segment-based approach lends itself well to addressing both restoration and protection in any kind of circuit configuration. In this case, however, new algorithms and virtual agents must be used to accommodate adaptation of the protection system in addition to the comparatively straightforward restoration process outlined above.

Further, it is extremely advantageous to use highly accurate and fast protective devices and associated relays are required such that many applied in series are coordinated so that only the last device serving the faulted segment clears the fault. A method for fitting of curves based on upstream and downstream protective devices is needed—the curve-fitting agent that is responsible for this task.

This agent is also used to establish initial protective curves that provide coordination on the system in its normal state. As shown in Fig. 16-22, the curves for each substation breaker are not shown, but are designated A1, B1, C1, and D1. Protection curves for devices on the line are designed D2, D3, and D4, for example, with the higher number curve being faster than the lower numbered curve to establish a time-overcurrent coordinated system.

Once a restoration process has been completed, then the protection system must update itself to ensure that the protective coordination is maintained, regardless of the source from which a given segment is fed. An adaptive protection agent, working with the curve-fitting agent carries out this task.

In the case shown in Fig. 16-22, a loss of the source to substation SB-D will result in initiation of a restoration process, which will open the normally closed interrupting devices, then close open points, after checking for load capacity and absence of fault indication on a segment. Note that it is assumed that there is no communication between any of the field fault interrupters and the substation breaker relays.

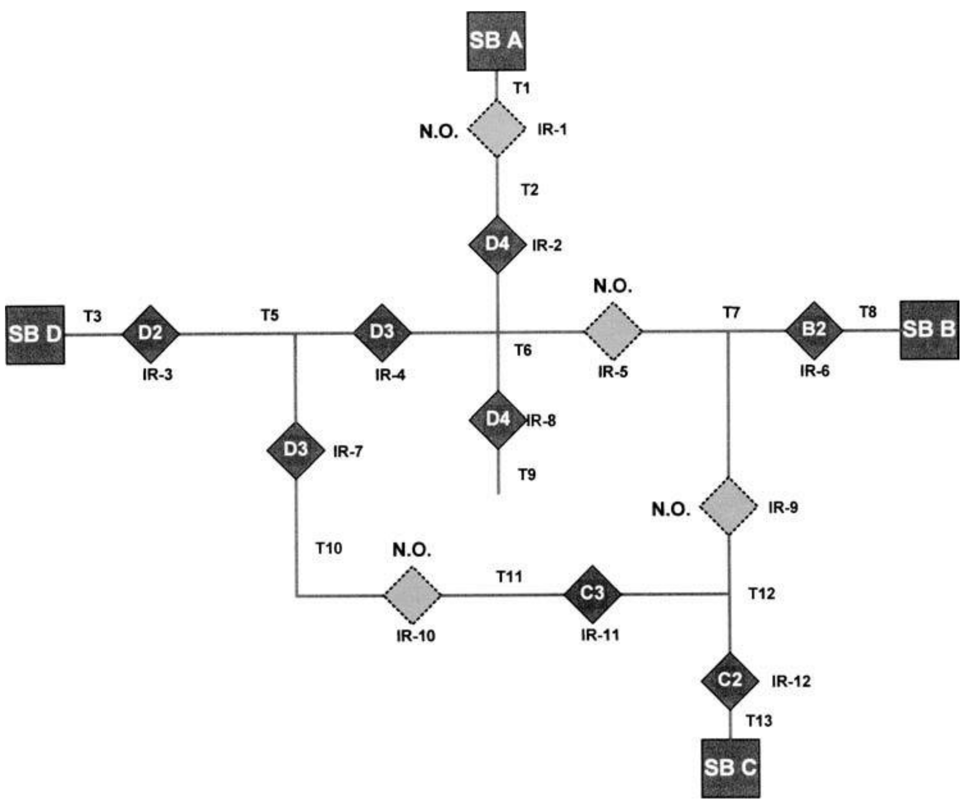

FIGURE 16-22 Intelligent protection, control and restoration multigrid system.

One possible result is for a new circuit to be configured, emanating from SB-C, feeding through IR-12, IR-11, IR-10, IR-7 and then to new open points at IR-3 and IR-4, as shown in Fig. 16-23. Using an adaptive coordination algorithm, each interrupter will talk to its upstream counterpart to ensure that it either has a faster protection setting or the same protection setting as its upstream neighbor.

It is noted that there may not always be sufficient room between protective curves for direct time-overcurrent coordination. In this case, devices must share a common curve. When this condition occurs, coordination is still possible using high-speed communications to effect coordination between devices using a blocking and adaptive coordination, process, whereby all devices that detect fault current passage signal their upstream neighbors. Interrupters that receive the signal increment their protection curve slower by 1.

For example, if a fault were to occur in segment T5 in Fig. 16-23, then interrupters IR-7, IR-10, IR-11, and IR-12 would detect the fault. Since the system uses distributed intelligence, the coordination agent knows that IR-7 and IR-10 share curves and that IR-11 has a setting of C3 which coordinates with C4. Therefore, only the interrupters with shared curves will utilize communications-based coordination. When the fault occurs, IR-7 will detect the fault and send a signal to IR-10. IR-10 will wait a small amount of time and when the signal is received, will decrement to curve C3. C4 did not receive any signal from a downstream device; therefore, it remains at C4. C4 is faster than C3 and all upstream curves; therefore, it is the only device to operate, thus clearing the fault in T5 in a coordinated fashion.

The intelligent protection, control, and restoration multigrid system combines the advantages of fault-interrupting devices while using distributed intelligence to overcome the difficulties in applying such fault-interrupting devices in complex circuit configurations. All the while, such a system also

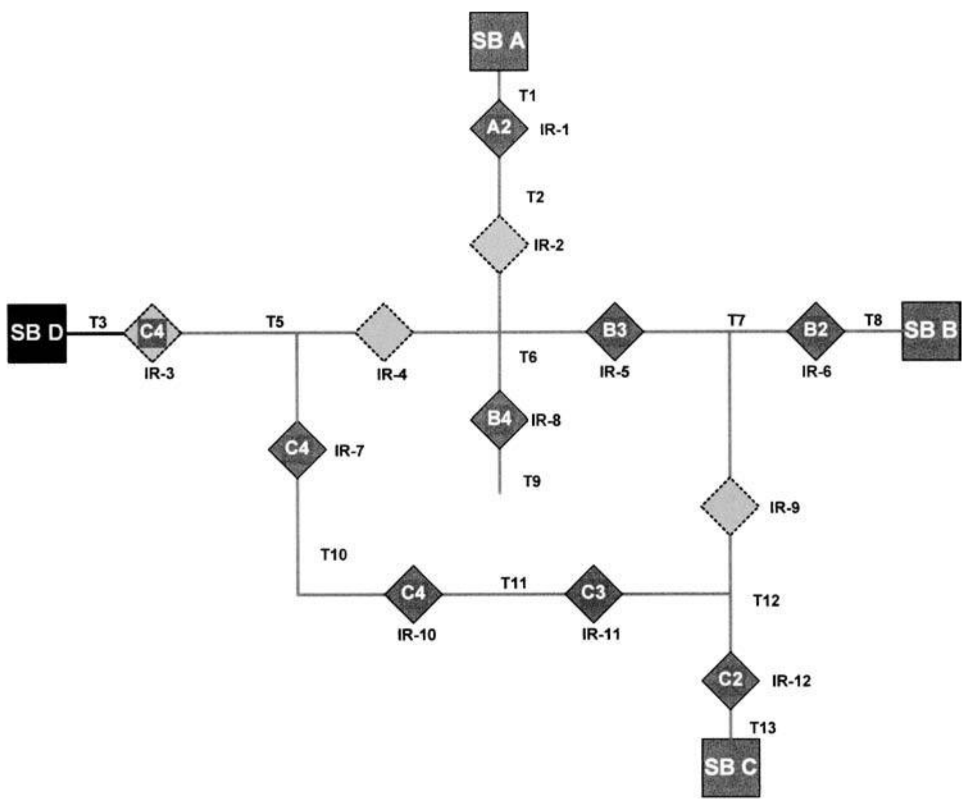

FIGURE 16-23 Reconfigured state of example system.

monitors circuit loading to prevent inadvertent overloading, thus delivering the improved asset management benefits of the intelligent multigrid switching system.

16.4.2 Summary

Each of the circuit protection and restoration systems described in this section are available in the industry as of the writing of this book. It is clear that some are easy to apply, but deliver only simple benefits. The more complex and modern a system is, the more benefits it can provide. But, it also requires a shift in thinking about circuit planning and design to maximize those benefits.

In the end, the use of highly intelligent devices on the distribution feeder—in circuit configurations that are probably difficult for many of us to even conceive of today—will be the answer to meeting the ever-increasing needs of users of electric power. Such systems will also, ultimately, reduce utility workload by moving the operating decisions to an intelligent, distributed system, taking full advantage of advances in computing and communication technologies on an ongoing basis. This will leave utility engineers and planners free to be more creative in their designs.

16.5 IMPACTS OF EFFECTIVE DSM PROGRAMS

By HESHAM SHAALAN and CHRISTA LORBER

16.5.1 Introduction

Demand-side management (DSM) is proving to be a viable means by which utilities can meet their load-shape objectives. Two decades of studies, projections, and pilot programs are suggesting that DSM can be cost-effective and flexible. Demand-side management programs have the potential to target diverse areas of end-use electricity consumption, thus deferring the need to meet growing demand through added capacity. From the utility's perspective, this promotes cash flow that would otherwise be tied up in capital investments and costs. From the customer's perspective, these programs provide incentives that range from lower electricity rates to rebates on the purchases of more efficient appliances and equipment. Therefore, there are benefits which are attractive to both parties. However, another important benefit of DSM is preserving the environment. Electricity reductions that proceed from DSM programs translate into savings by curtailing and delaying the environmental impacts for which pollutants and greenhouse gas (GHG) emissions are greatly responsible.

Commercial-sector DSM programs provide significant options for utilities in meeting growing demand. This section provides an estimation of savings in cost as well as projected GHG emissions based on effective DSM programs in the commercial sector. Realistic estimates of savings based on actual results from two previous utility studies will be presented.

Most electric utility systems in the United States were designed to account for some daily, weekly, and seasonal variability in load. This variability is desirable from the planned maintenance point of view. To account for the fluctuations that occur, different types of generating facilities are used together in various combinations to minimize total costs. This is necessary because the electric utility industry is quite capital-intensive. For every $1.00 of revenue, the utility industry requires $3.50 of capital, compared with the average industry, which needs only $0.80 per dollar of revenue.[1] Aside from the moderate fluctuations in demand, electric power is most efficiently produced when changes in the total system load are kept as small as possible. Ideally, the ratio of average power to peak power, or *load factor,* should be kept high. Interestingly, DSM provides opportunities through which utilities can achieve increasing power-system load factors.

16.5.2 Commercial-Sector DSM

Demand-side management encompasses a variety of activities that influence the pattern and magnitude of a utility's load. Programs are geared to meet one of six main objectives depending on whether the utility is targeting residential, industrial, or commercial customers, since the load curves for each of these sectors vary considerably. The objectives utilities set to change their load shape include peak clipping, valley filling, load shifting, strategic conservation, strategic load growth, and flexible load shape.

Of the preceding six objectives, peak clipping for the commercial sector is of overwhelming interest to power utilities and distribution cooperatives alike. The reason for this is historical. Using existing plants more effectively is preferable over building a new plant. For example, peak clipping makes the power system more reliable, alleviating the need for a peak-load plant that is expensive to run and only necessary 10% of the time to meet peak demand.[1] Moreover, the commercial sector has been the most rapidly growing sector in terms of electricity sales and peak. In fact, between 1970 and 1990, the sales gain for this sector averaged about 24 billion kWh per year, which is 36% of the total gain.[2] Although sales gains over the course of the next two decades are expected to be halved in comparison, electric utilities still have to contend with the increases. For these reasons, commercial-sector DSM programs provide significant options for utilities in the determination of how they will meet growing demands.

16.5.3 Effective DSM Programs and Their Impacts

For most commercial buildings, lighting and air conditioning comprise 70% of electricity consumption, where lighting accounts for 40% and air conditioning accounts for 30%.[3] Such predominance provides opportunities for significant savings that could result from well-planned programs targeting these two consumption types.

Lighting Control Program Savings. Commercial customers perceive lighting as a necessary, fixed load because inadequate or ineffective illumination hampers productivity and sales. Therefore, lighting can be classified as a predictable load from the utility's point of view. Thus, lighting control is a viable candidate for DSM programs which promote increased penetration of energy-efficient lamps and ballasts.

To exemplify the magnitude of savings that can occur, a case in point is essential. Consolidated Edison Company of New York (Con Edison), one of the largest electric utilities in the country, sponsored an Enlightened Energy Rebate Program beginning in 1991 which provided cash rebates for both retrofit and new installations of high-efficiency lighting. Five years of pilot programs precluding the Enlightened Energy Rebate Program provided the experience on which to anticipate success. Con Edison's goals were twofold in promoting the energy rebate. The first objective was to reduce the load on certain transmission and distribution (T&D) equipment, a very cost-effective goal, since increasing T&D capacity in the New York area is quite expensive. The second objective was geared toward increasing profits via incentive rates of return approved by the New York Public Service Commission. Rewards were granted for energy savings rather than capacity reduction; however, in the process of striving for the kWh savings, significant peak reductions occurred. In fact, Con Edison is projecting peak reductions of 22% to 23% by the year 2008.[4]

The Enlightened Energy Rebate Program was offered to 40,000 commercial customers, 2744 of which participated. The verified reductions in 1991 were 157.9 MW of electricity and 241 million kWh.[4] Table 16-1 translates these energy savings into emission savings in terms of quantities and associated costs. The assumptions used in calculating these values are provided in the Appendix along with sample calculations. The total cost is dominated by the CO_2 and SO_2 emission savings, which amount to \$2.35 million and \$1.39 million, respectively.

TABLE 16-1 Projected Emission and Cost Savings: Consolidated Edison Enlightened Energy Program

Millions kWh	241
CO_2 (thousand tons)	173
SO_2 (tons)	343
NO_x (tons)	187
CO (tons)	24.3
VOCs (tons)	2.76
Total cost (million dollars)	4.05
Electricity (MW)	157.9

Air-Conditioner Control Program Savings. Load control is likewise a DSM program with the potential to achieve significant penetration in the commercial sector. Currently, tens of thousands of commercial facilities have been retrofitted or were originally constructed with building energy management and control systems. Weather-sensitive loads often account for the highest peaks in demand seen by utilities, thereby degrading their annual load factors. As a result, these types of loads are excellent load-control candidates. Studies indicate that air conditioners represent the most commonly controlled commercial load.[3] This implies that improved load factors and considerable savings can be realized by air-conditioner control programs.

Available load research data and a previous air-conditioning load management program[1] sponsored by Arkansas Power and Light (AP&L) provide an opportunity to quantify savings for the commercial sector of hot springs. The previous air-conditioning load-control program took place during the summers of 1975 and 1976 and targeted two residential areas to determine the economic feasibility of interrupting central air-conditioning units for short periods of time during peak-load periods. The monitoring of this particular pilot program was implemented using a Motorola radio system with a remote-controlled switch during the hours of 1 to 5 P.M. from June 15 through September 15. Because this was a pilot program, AP&L had several objectives concerning program effectiveness. The first involved determining the contribution of a single unit to peak demand and the amount of air-conditioning load which could be displaced during the system peak-load periods. Determining the threshold of customer inconvenience incurred through implementing control during the peak periods was the second objective. The third focus of the investigation was the feasibility and reliability of a radio-controlled system.

The incentive to the participating customers included a $2.00 return per kVA of air-conditioning capacity per month, free service inspection on the air-conditioning system, and a guarantee that the system would be restored to its pretest condition should any damage result. The results from this test were exceedingly favorable. Each residential central air conditioner contributed 4 kW to the system peak and could be switched off 15 min out of each hour without causing the customer discomfort. A peak-load reduction of 1 kW per unit resulted from this control action. In addition, the tests established that radio control was a viable means of shedding loads during peak conditions. More than 25,000 residential radio switches were installed at the end of 1978, with additional installation plans of 25,000 per year until reaching the saturation goal of 125,000.

Encouraged by the air-conditioning load-control success within the residential sector, AP&L reported plans to extend air-conditioner load control to its commercial sector. In so doing, the average peak demand reduction amounted to 1.6 kW per unit.[3] Figure 16-24 shows the load curve for the month of July generated from AP&L commercial data. The dotted line represents the effect that air-conditioning load control would have if each unit were reduced by 1.6 kW. The kWh savings result from load control between 12 noon and 6:00 P.M. Due to the difference in load shape between the

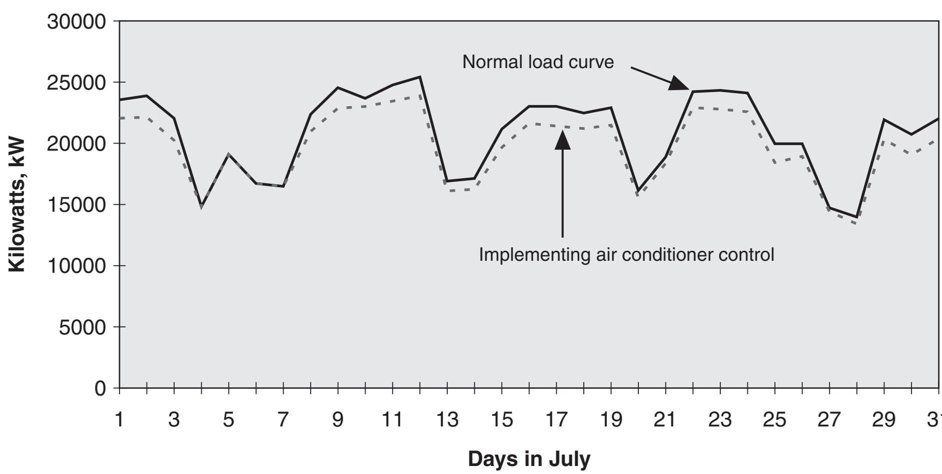

FIGURE 16-24 Load curve for the month of July.

TABLE 16-2 Projected Emission and Cost Savings for July Research Load Data: Arkansas Power & Light Commercial-Sector Air- Conditioner Control

Thousands kWh	248
CO_2 (tons)	178
SO_2 (tons)	0.353
NO_x (tons)	0.192
CO (tons)	0.025
VOCs (tons)	0.003
Total cost (dollars)	4,173
Electricity (MW)	0.248

residential and commercial sectors, the control had to be extended by 2 h in order to effectively shed peak load. Despite the additional 2 h of control, the assumption of a 15-min/h shut-off cycling period remained consistent with the residential control program.

Load data for the month of July was used in Fig. 16-24 because this is the hottest month during which AP&L must provide services. Table 16-2 quantifies the savings that result from air-conditioner control for the month of July, as seen in Fig. 16-24. Once again, CO_2 and SO_2 dominate the total cost savings. CO_2 contributes $2421 to the overall $4173, while SO_2 contributes $1433. Although the reported emissions seem relatively small, the results of Table 16-2 represent a mere 1.3% of the potential commercial customers eligible to participate in air-conditioning load control. In addition, the season for commercial-sector air conditioning is considerably longer than for the residential sector. Thus, significant emission savings are attainable with increased participation for a full season.

16.5.4 Projected Total DSM Program Impacts

Table 16-3 illustrates how all cooling and lighting programs within the commercial sector will impact the environment over the course of the next two decades. The figures reported in the table give combined totals of cooling and indoor/outdoor lighting; however, the lighting contribution is almost twice that of the cooling.

The savings in kWh, emissions, and cost reported in Table 16-3 are evidence of the effectiveness of DSM strategies. By the year 2000, CO_2 emission savings will be above 35 million tons, which alone accounts for $486 million. The electricity and added capacity savings is phenomenal, both short and long term. By 2020, savings will be more than twice that occurring in the year 2000. SO_2 and NO_x emission savings are likewise quite sizable, providing evidence that conservation and preservation can occur with DSM.

16.5.5 Conclusion

Of the many DSM programs that could enable utilities to operate efficiently, lighting and air-conditioner load control are two proven methods by which utilities can reduce their peak and provide savings for themselves, their customers, and the environment. To be effective, a program must be well planned. Therefore, successful programs are usually preceded by a pilot program to ensure

TABLE 16-3 Total Lighting and Cooling Emission and Cost Savings

	Year		
	2000	2010	2020
Billions kWh	4.98	8.50	10.9
CO_2 (million tons)	35.7	61.0	78.1
SO_2 (thousand tons)	70.8	121	155
NO_x (thousand tons)	38.6	66.0	84.4
CO (thousand tons)	5.00	8.55	10.9
VOCs (thousand tons)	0.570	0.973	1.25
Cost (million dollars)	837	1430	1830
Electricity (GW)	66.1	113	145
Added capacity (400-MW plant)	165	282	362

TABLE 16-4 Emission Characteristics of Power Plants in the United States (g/kWh)

Plant type	VOCs	CO	NO_x	SO_2	CO_2
Gas	0.025	0.20	1.00	0.004	490
Oil	0.050	0.19	1.00	5.08	781
Coal	0.010	0.11	1.00	2.00	1030

that the utility's objectives can be met. Furthermore, a utility must build a good relationship with its customer base. Otherwise, future DSM programs may be jeopardized. This can be achieved through frequent customer contact and by giving the customer some decision-making provisions. Support services necessary to a particular DSM program should be established prior to the effective starting date. This is essential in order to monitor the program accurately. Without adequate preparation, gathering data and keeping up with customer inquiries are virtually impossible.

The purpose of DSM is to improve what already exists and make what is new as efficient as possible. Meanwhile, the utility's reputation is at stake. For this reason, a major focus of these programs is the customer. In the process of promoting energy efficiency and establishing trustworthy relationships, it may be easy to overlook environmental impacts and savings. Therefore, any precautionary action that may minimize environmental changes has additional value beyond successful programs and satisfied customers. Thus, it can be argued that sustenance is the hidden value of DSM.

APPENDIX

Assumptions. The information provided herein focuses on the manner in which the values reported in Tables 16-1, 16-2, and 16-3 were calculated. Some basic assumptions have been made in order to obtain those results:

1. Coal has a 70% carbon content.
2. A 400-MW coal plant uses 800,000 MT of coal per year.
3. CO_2 recovery equipment has a 90% removal efficiency.
4. The emission characteristics of power plants in the United States (g/kWh) are shown in Table 16-4. The values shown assume a mix of 10% combustion turbines and 90% steam turbines.
5. The cost of pollutant per ton emitted is shown in Table 16-5.

TABLE 16-5 Cost of Pollutant per Ton Emitted

Pollutant	Cost ($/ton)
CO_2	13.60
SO_2	4060
NO_x	1640
CO	82
VOCs	300

Sample Calculations

- *Emission**
  Tons of pollutant:

(year kWh) × (% generated electricity) × [emission characteristic (g/kWh)] × (conversion factor)

Example	*Savings of Total SO_2 Emissions*	
Gas	Tons SO_2 = (4.98E + 10) × (0.119) × (0.004) × (1.1E − 6) =	26.10
Oil	Tons SO_2 = (4.98E + 10) × (0.039) × (5.080) × (1.1E − 6) =	10,866.76
Coal	Tons SO_2 = (4.98E + 10) × (0.546) × (2.000) × (1.1E − 6) =	59,895.52
	Tons total	70,788.38

*Note that this calculation is performed for all substances listed in the preceding table.

- *Cost*
  Total cost

$$(\text{Total emissions}) \times (\text{cost of pollutant})$$

Example *Total SO_2 Cost Savings*
Cost (million \$) = (70,788) × (4060) = 287

- *Electricity and added capacity savings (based on CO_2 emissions)*
  Added Capacity Savings

$$(CO_2 \text{ emission savings})/(\text{tons of } CO_2 \text{ emitted from 400-MW plant})$$

Electricity (that could be produced with neutral GHG effect)

$$(\text{Added capacity savings}) \times [\text{size of plant (MW)}]$$

Example

Tons of CO_2 emissions = (800,000) × (2.57) × (0.1) = 216,000
Added capacity savings (No. of 400-MW plants − year 2000)
= (35,700,000)/(216,000) = 165
Electricity (GW) = (165) × (400) = 66.1

CONTENTS

17.1 AIR-INSULATED SUBSTATIONS

17.1.1 Function of Substations

Transmission and Distribution Systems. In large, modern ac power systems, the transmission and distribution systems function to deliver bulk power from generating sources to users at the load centers. Transmission systems generally include generation switchyards, interconnecting transmission lines, autotransformers, switching stations, and step-down transformers. Distribution systems include primary distribution lines or networks, transformer banks, and secondary lines or networks, all of which serve the load area.

17.1.2 Design Objectives

As an integral part of the transmission or distribution systems, the substation or switching station functions as a connection and switching point for generation sources, transmission or subtransmission lines, distribution feeders, and step-up and step-down transformers. The design objective for the substation is to provide as high a level of reliability and flexibility as possible while satisfying system requirements and minimizing total investment costs.

Voltage Levels. The selection of optimal system voltage levels depends on the load to be served and the distance between the generation source and the load. Many large power plants are located great distances from the load centers to address energy sources or fuel supplies, cooling methods, site costs and availability, and environmental concerns. For these reasons, the use of transmission voltages as high as 765 kV has occurred. Transmission system substations that provide bulk power operate at voltages from 69 to 765 kV. Common voltage classes used in the United States for major substations include 69, 115, 138, 161, and 230 kV (considered *high voltage* or *HV class*) and 345,500, and 765 kV (considered *extra high voltage* or *EHV class*). Even higher voltages which include 1100 and 1500 kV have been considered. These are referred to as *ultra high voltage* or *UHV class*. Distribution system substations operate at secondary voltage levels from 4 to 69 kV.

Design Considerations. Many factors influence the selection of the proper type of substation for a given application. This selection depends on such factors as voltage level, load capacity, environmental considerations, site space limitations, and transmission-line right-of-way requirements. While also considering the cost of equipment, labor, and land, every effort must be made to select a substation type that will satisfy all requirements at minimum costs. The major substation costs are reflected in the number of power transformers, circuit breakers, and disconnecting switches and their associated structures and foundations. Therefore, the bus layout and switching arrangement selected will determine the number of the devices that are required and in turn the overall cost. The choice of insulation levels and coordination practices also affects cost, especially at EHV. A drop of one level in basic insulation level (BIL) can reduce the cost of major electrical equipment by thousands of dollars. A careful analysis of alternative switching schemes is essential and can result in considerable savings by choosing the minimum equipment necessary to satisfy system requirements.

A number of factors must be considered in the selection of bus layouts and switching arrangements for a substation to meet system and station requirements. A substation must be safe, reliable, economical, and as simple in design as possible. The design also should provide for further expansion, flexibility of operation, and low maintenance costs.

The physical orientation of the transmission-line routes often dictates the substation's location, orientation, and bus arrangement. This requires that the selected site allow for a convenient arrangement of the lines to be accomplished.

For reliability, the substation design should reduce the probability of a total substation outage caused by faults or equipment failure and should permit rapid restoration of service after a fault or failure occurs. The layout also should consider how future additions and extensions can be accomplished without interrupting service.

Bus Schemes. The substation design or scheme selected determines the electrical and physical arrangement of the switching equipment. Different bus schemes can be selected as emphasis is shifted between the factors of safety, reliability, economy, and simplicity dictated by the function and importance of the substation.

The substation bus schemes used most often are

1. Single bus
2. Main and transfer bus
3. Double bus, single breaker
4. Double bus, double breaker
5. Ring bus
6. Breaker and a half

Some of these schemes may be modified by the addition of bus-tie breakers, bus sectionalizing devices, breaker bypass facilities, and extra transfer buses. Figures 17-1 to 17-6 show one-line diagrams for some of the typical schemes listed above.

Single Bus. The single-bus scheme (Fig. 17-1) is not normally used for major substations. Dependence on one main bus can cause a serious outage in the event of breaker or bus failure without the use of mobile equipment. The station must be deenergized in order to carry out bus maintenance or add bus extensions. Although the protective relaying is relatively simple for this scheme, the single-bus scheme is considered inflexible and subject to complete outages of extended duration.

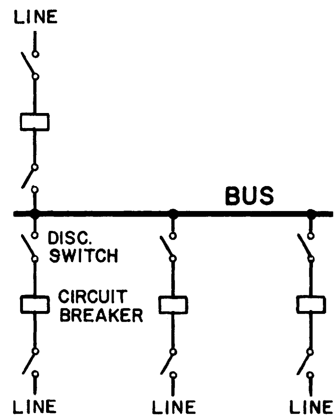

FIGURE 17-1 Single bus.

Main and Transfer Bus. The main- and transfer-bus scheme (Fig. 17-2) adds a transfer bus to the single-bus scheme. An extra bus-tie circuit breaker is provided to tie the main and transfer buses together.

When a circuit breaker is removed from service for maintenance, the bus-tie circuit breaker is used to keep that circuit energized. Unless the protective relays are also transferred, the bus-tie relaying must be capable of protecting transmission lines or generation sources. This is considered rather unsatisfactory because relaying selectivity is poor.

A satisfactory alternative consists of connecting the line and bus relaying to current transformers located on the lines rather than on the breakers. For this arrangement, line and bus relaying need not be transferred when a circuit breaker is taken out of service for maintenance, with the bus-tie breaker used to keep the circuit energized.

If the main bus is ever taken out of service for maintenance, no circuit breakers remain to protect any of the feeder circuits. Failure of any breaker or failure of the main bus can cause complete loss of service of the station.

Due to its relative complexity, disconnect-switch operation with the main- and transfer-bus scheme can lead to operator error and a possible outage. Although this scheme is low in cost and enjoys some popularity, it may not provide as high a degree of reliability and flexibility as required.

Double Bus, Single Breaker. This scheme uses two main buses, and each circuit includes two bus selector disconnect switches. A bus-tie circuit (Fig. 17-3) connects to the two main buses and, when closed, allows transfer of a feeder from one bus to the other bus without deenergizing the feeder circuit by operating the bus selector disconnect switches. The circuits may all operate from either the no. 1 or no. 2 main bus, or half the circuits may be operated off either bus. In the first case, the station

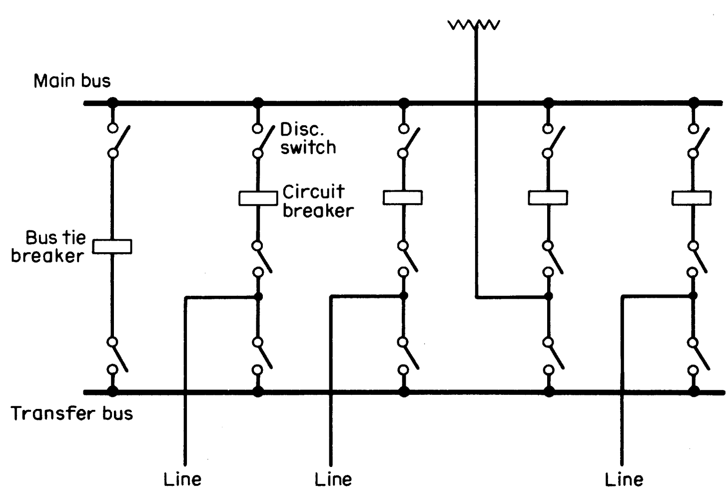

FIGURE 17-2 Main and transfer bus.

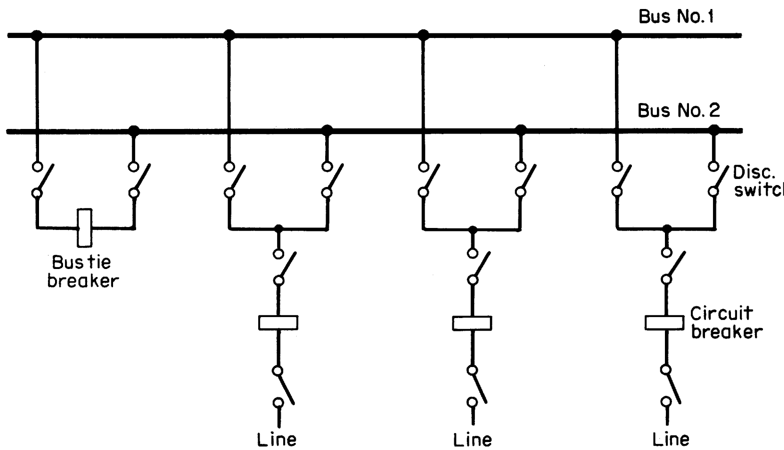

FIGURE 17-3 Double bus, single breaker.

will be out of service for bus or breaker failure. In the second case, half the circuits will be lost for bus or breaker failure.

In some cases circuits operate from both the no. 1 and no. 2 bus, and the bus-tie breaker is normally operated closed. For this type of operation, a very selective bus-protective relaying scheme is required to prevent complete loss of the station for a fault on either bus. Disconnect-switch operation becomes quite involved, with the possibility of operator error, injury, and possible outage. The double-bus, single-breaker scheme is relatively poor in reliability and is not normally used for important substations.

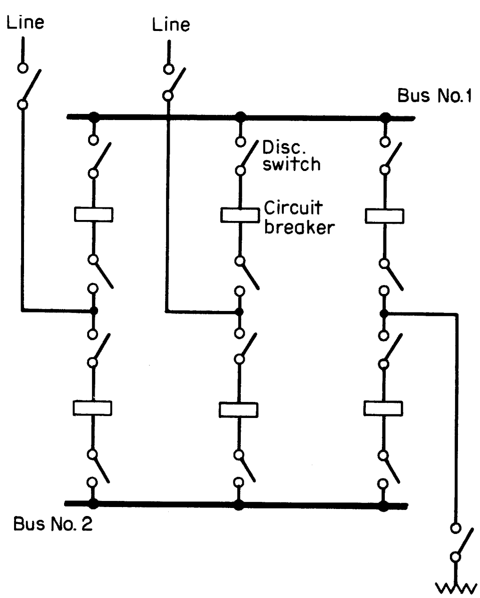

FIGURE 17-4 Double bus, double breaker.

Double Bus, Double Breaker. The double-bus, double breaker scheme (Fig. 17-4) requires two circuit breakers for each feeder circuit. Normally, each circuit is connected to both buses. In some cases, half the circuits operate on each bus. For these cases, a bus or breaker failure would cause loss of only half the circuits, which could be rapidly corrected through switching. The physical location of the two main buses must be selected in relation to each other to minimize the possibility of faults spreading to both buses. The use of two breakers per circuit makes this scheme expensive; however, it does represent a high degree of reliability.

Ring Bus. In the ring-bus scheme (Fig. 17-5), the breakers are arranged in a ring with circuits connected between breakers. There are the same number of circuits as there are breakers. During normal operation, all breakers are closed. For a circuit fault, two breakers are tripped, and in the event that one of the breakers fails to operate to clear the fault, an additional circuit will be tripped by operation of breaker-failure backup relays. During breaker maintenance, the ring is broken, but all lines remain in service.

The circuits connected to the ring are arranged so that sources are alternated with loads. For an extended circuit outage, the line-disconnect switch may be opened, and the ring can be closed. No changes to protective relays are required for any of the various operating conditions or during maintenance.

The ring-bus scheme is relatively economical in cost, has good reliability, is flexible, and is normally considered suitable for important substations up to a limit of five circuits. Protective relaying and automatic reclosing are more complex than for previously described schemes. It is common practice to build major substations initially as a ring bus; for more than five outgoing circuits, the ring bus is usually converted to the breaker-and-a-half scheme.

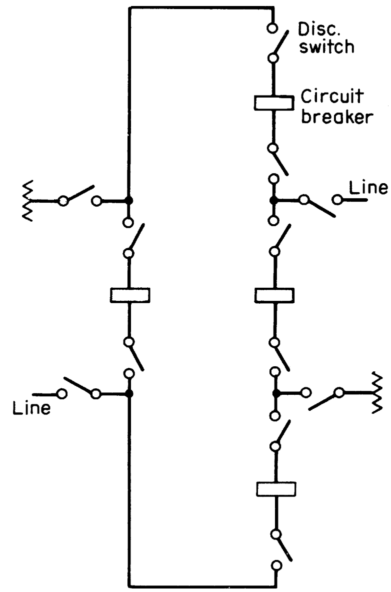

FIGURE 17-5 Ring bus.

Breaker and a Half. The breaker-and-a half scheme (Fig. 17-6), sometimes called the *three-switch scheme*, has three breakers in series between two main buses. Two circuits are connected between the three breakers, hence the term *breaker and a half*. This pattern is repeated along the main buses so that one and a half breakers are used for each circuit.

Under normal operating conditions, all breakers are closed, and both buses are energized. A circuit is tripped by opening the two associated circuit breakers. Tie-breaker failure will trip one additional circuit, but no additional circuit is lost if a line trip involves failure of a bus breaker. Either bus may be taken out of service at any time with no loss of service. With sources connected opposite to loads, it is possible to operate with both buses out of service. Breaker maintenance can be done with no loss of service, no relay changes, and simple operation of the breaker disconnects.

The breaker-and-a-half arrangement is more expensive than the other schemes, with the exception of the double-breaker, double-bus scheme, and protective relaying and automatic reclosing schemes are more complex than for other schemes. However, the breaker-and-a half scheme is superior in flexibility, reliability, and safety.

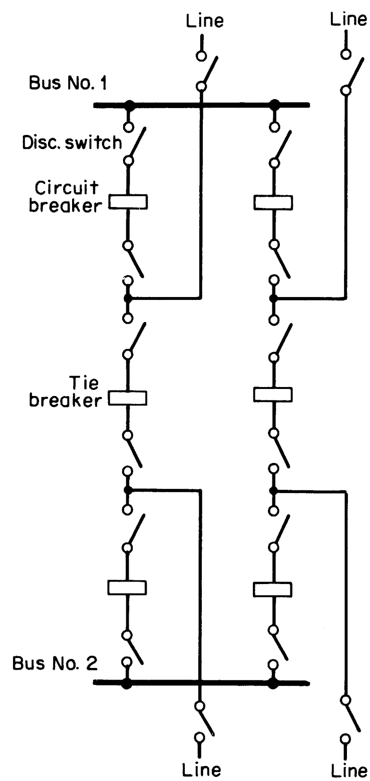

FIGURE 17-6 Breaker-and-a-half scheme.

17.1.3 Reliability Comparisons

The various schemes have been compared to emphasize their advantages and disadvantages. The basis of comparison to be employed is the economic justification of a particular degree of reliability. The determination of the degree of reliability involves an appraisal of anticipated operating conditions and the continuity of service required by the load to be served. Table 17-1 contains a summary of the comparison of switching schemes to show advantages and disadvantages.

TABLE 17-1 Summary of Comparison of Switching Schemes

Switching scheme	Advantages	Disadvantages
1. Single bus	1. Lowest cost.	1. Failure of bus or any circuit breaker results in shutdown of entire substation. 2. Difficult to do any maintenance. 3. Bus cannot be extended without completely deenergizing substation. 4. Can be used only where loads can be interrupted or have other supply arrangements.
2. Double bus, double breaker	1. Each circuit has two dedicated breakers. 2. Has flexibility in permitting feeder circuits to be connected to either bus. 3. Any breaker can be taken out of service for maintenance. 4. High reliability.	1. Most expensive. 2. Would lose half of the circuits for breaker failure if circuits are not connected to both buses.
3. Main and transfer	1. Low initial and ultimate cost. 2. Any breaker can be taken out of service for maintenance. 3. Potential devices may be used on the main bus for relaying.	1. Requires one extra breaker for the bus tie. 2. Switching is somewhat complicated when maintaining a breaker. 3. Failure of bus or any circuit breaker results in shutdown of entire substation.
4. Double bus, single breaker	1. Permits some flexibility with two operating buses. 2. Either main bus may be isolated for maintenance. 3. Circuit can be transferred readily from one bus to the other by use of bus-tie breaker and bus selector disconnect switches.	1. One extra breaker is required for the bus tie. 2. Four switches are required per circuit. 3. Bus protection scheme may cause loss of substation when it operates if all circuits are connected to that bus. 4. High exposure to bus faults. 5. Line breaker failure takes all circuits connected to that bus out of service. 6. Bus-tie breaker failure takes entire substation out of service.
5. Ring bus	1. Low initial and ultimate cost. 2. Flexible operation for breaker maintenance. 3. Any breaker can be removed for maintenance without interrupting load. 4. Requires only one breaker per circuit. 5. Does not use main bus. 6. Each circuit is fed by two breakers. 7. All switching is done with breakers.	1. If a fault occurs during a breaker maintenance period, the ring can be separated into two sections. 2. Automatic reclosing and protective relaying circuitry rather complex. 3. If a single set of relays is used, the circuit must be taken out of service to maintain the relays. (Common on all schemes.) 4. Requires potential devices on all circuits since there is no definite potential reference point. These devices may be required in all cases for synchronizing, live line, or voltage indication. 5. Breaker failure during a fault on one of the circuits causes loss of one additional circuit owing to operation of breaker-failure relaying.
6. Breaker and a half	1. Most flexible operation. 2. High reliability. 3. Breaker failure of bus side breakers removes only one circuit from service. 4. All switching is done with breakers. 5. Simple operation; no disconnect switching required for normal operation. 6. Either main bus can be taken out of service at any time for maintenance. 7. Bus failure does not remove any feeder circuits from service.	1. $1\frac{1}{2}$ breakers per circuit. 2. Relaying and automatic reclosing are somewhat involved since the middle breaker must be responsive to either of its associated circuits.

17.1.4 Arrangements and Equipment

Once a determination of the switching scheme best suited for a particular substation application is made, it is necessary to consider the station arrangement and equipment that will satisfy the many physical requirements of the design. Available to the design engineer are the following:

1. Conventional outdoor air-insulated open-type bus-and-switch arrangement substations (using either a strain bus or rigid bus design)
2. Metal-clad or metal-enclosed substations
3. Gas (sulfur hexafluoride)–insulated substations

Outdoor open-type bus-and-switch arrangements generally are used because of their lower cost, but they are larger in overall physical size. Metal-clad substations generally are limited to 38 kV. Gas-insulated substations are generally the highest in cost but smallest in size.

Substation Components. The electrical equipment in a typical substation can include the following:

Circuit breakers
Disconnecting switches
Grounding switches
Current transformers
Voltage transformers or capacitor voltage transformers
Coupling capacitors
Line traps
Surge arresters
Power transformers
Shunt reactors
Current-limiting reactors
Station buses and insulators
Grounding systems
Series capacitors
Shunt capacitors

Support Structures. In order to properly support, mount, and install the electrical equipment, structures made of steel, aluminum, wood, or concrete and associate foundations are required. The typical open-type substation requires strain structures to support the transmission-line conductors; support structures for disconnecting switches, current transformers, potential transformers, lightning arresters, and line traps, capacitor voltage transformers; and structures and supports for the strain and rigid buses in the station.

When the structures are made of steel or aluminum, they require concrete foundations; however, when they are made of wood or concrete, concrete foundations are not required. Additional work is required to design concrete foundations for supporting circuit breakers, reactors, transformers, capacitors, and any other heavy electrical equipment.

Substation-equipment support structures fabricated of steel or aluminum may consist of single wide-flange or tubular-type columns, rigid-frame structures composed of wide flanges or tubular sections, or lattice structures composed of angle members. Substation strain structures can be wood or concrete pole structures, aluminum or steel lattice-type structures, or steel A-frame structures. Aluminum, weathering steel, and concrete pole structures can be used in their natural unfinished state. Normal carbon-steel structures should have galvanized or painted finishes. Wood structures should have a thermal- or pressure-process-applied preservative finish.

Aluminum structures are lightweight, have an excellent strength-to-weight ratio, and require little maintenance but have a greater initial cost than steel structures. Weathering-steel structures can be field-welded without the special surface preparation and touch-up work required on galvanized or painted steel structures, and the self-forming protective corrosion oxide eliminates maintenance. In addition, the weathering-steel color blends well in natural surroundings. Galvanized- or painted-steel structures have a slightly lower initial cost than weathering-steel structures; however, they require special treatment before and after field welding and require more maintenance.

Lattice-type structures are light in weight, have a small wind-load area, and are low in cost. Single-column support structures and rigid-frame structures require little maintenance, are more aesthetically pleasing, and can be inspected more quickly than lattice structures, but they have a greater initial cost. In order to reduce erection costs, rigid-frame structures should be designed with bolted field connections.

The design of supporting structures is affected by the phase spacings and ground clearances required, by the types of insulators, by the length and weight of buses and other equipment, and by wind and ice loading. For data on wind and ice loadings, see National Electric Safety Code©, IEEE Standard C2-2002, or latest edition. For required clearances and phase spacings, see Part I, Secs. 11 and 12.

Other structural and concrete work required in the substation includes site selection and preparation, roads, control houses, manholes, conduits, ducts, drainage facilities, catch basins, oil containment, and fences.

17.1.5 Site Selection

Civil engineering work associated with the substation should be initiated as early as possible in order to ensure that the best available site is selected. This work includes a study of the topography and drainage patterns of the area together with a subsurface soil investigation. The information obtained from the subsurface soil investigation also will be used to determine the design of the substation foundations. For large substations or substations located in area with poor soils, it may be necessary to obtain additional subsurface soil tests after final selection of the substation site has been made. The additional information should fully describe the quality of the soil at the site, since the data will be used to design equipment foundations.

Open-Bus Arrangement. An air-insulated, open-bus substation arrangement consists essentially of open-bus construction using either rigid- or strain-bus design such as the breaker-and-a-half arrangement shown in Fig. 17-7; the buses are arranged to run the length of the station and are located toward the outside of the station. The transmission-line exits cross over the main bus and are dead-ended on takeoff tower structures. The line drops into the bay in the station and connects to the disconnecting switches and circuit breakers.

Use of this arrangement requires three distinct levels of bus to make the necessary crossovers and connections to each substation bay. Typical dimensions of these levels at 230 kV are 16 ft for the first level above ground, 30 ft high for the main bus location, and 57 ft for the highest level of bus (see Fig. 17-7).

This arrangement, in use since the mid-1920s and widely used by many electric utilities, has the advantage of requiring a minimum of land area per bay and relative ease of maintenance, and it is ideally suited to a transmission-line through-connection where a substation must be inserted into a transmission line.

Inverted Bus. An alternate arrangement is the inverted-bus, breaker-and-a-half scheme for EHV substations. A typical layout is outlined in Fig. 17-8. A one-line diagram of a station showing many variations of the inverted-bus scheme is presented in Fig. 17-9. With this arrangement, all outgoing circuit takeoff towers are located in the outer perimeter of the substation, eliminating the crossover of line or exit facilities. Main buses are located in the middle of the substation, with all disconnecting switches, circuit breakers, and bay equipment located outboard of the main buses. The end result of

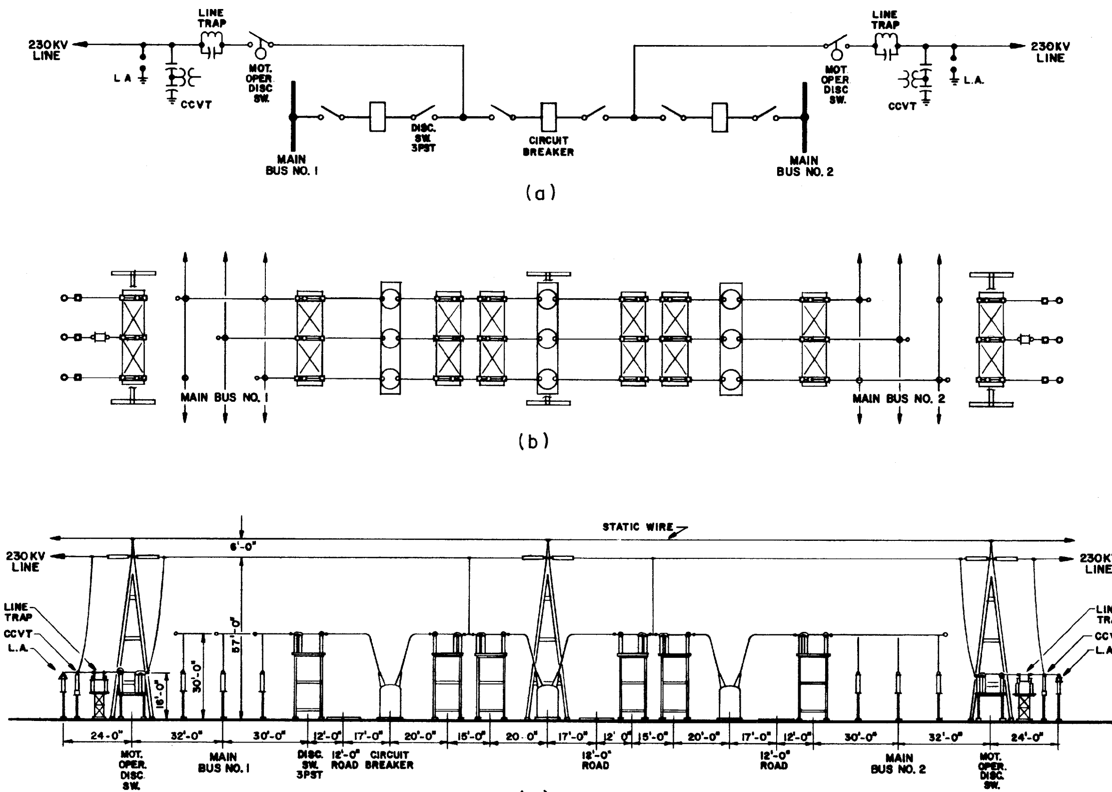

FIGURE 17-7 Typical conventional substation layout, breaker-and-a-half scheme. (*a*) Main one-line diagram; (*b*) plan; (*c*) elevation.

the inverted-bus arrangement presents a very low profile station with many advantages in areas where beauty and aesthetic qualities are a necessity for good public relations. The overall height of the highest bus in the 230-kV station just indicated reduces from a height of 57 ft above ground in the conventional arrangement to a height of only 30 ft above ground for the inverted-bus low-profile scheme.

17.1.6 Substation Buses

Substation buses are an important part of the substation because they carry electric currents in a confined space. They must be carefully designed to have sufficient structural strength to withstand the maximum stresses that may be imposed on the conductors, and in turn on the supporting structures, due to short-circuit currents, high winds, and ice loadings.

During their early development, HV class substations were usually of the strain-bus design. The strain bus is similar to a transmission line and consists of a conductor such as ACSR (aluminum cable steel reinforced), copper, or high-strength aluminum alloy strung between substation structures. EHV substations normally use the rigid-bus approach and enjoy the advantage of low station profile and ease of maintenance and operation (see Fig. 17-8). The mixing of rigid- and strain-bus construction is normally employed in the conventional arrangement shown in Fig. 17-7. Here, the main buses use rigid-bus design, and the upper buses between transmission towers are of strain-bus design. A typical design at 765 kV uses a combination of both rigid and strain buses (Fig. 17-10).

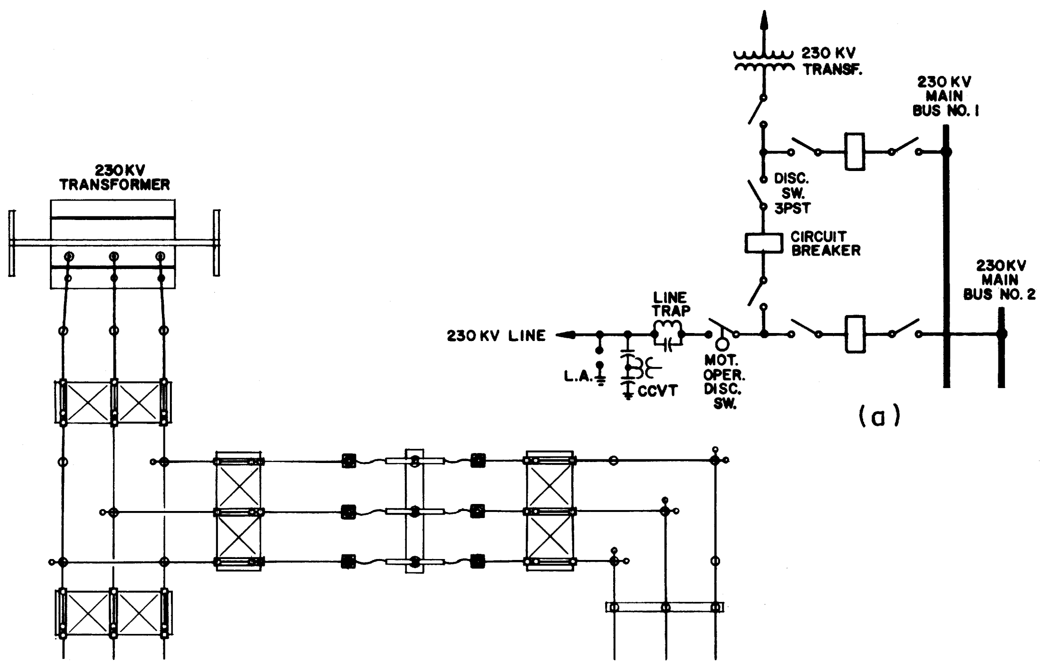

FIGURE 17-8 Typical 130-kV inverted-bus substation. (*a*) One-line diagram; (*b*) plan; (*c*) elevation.

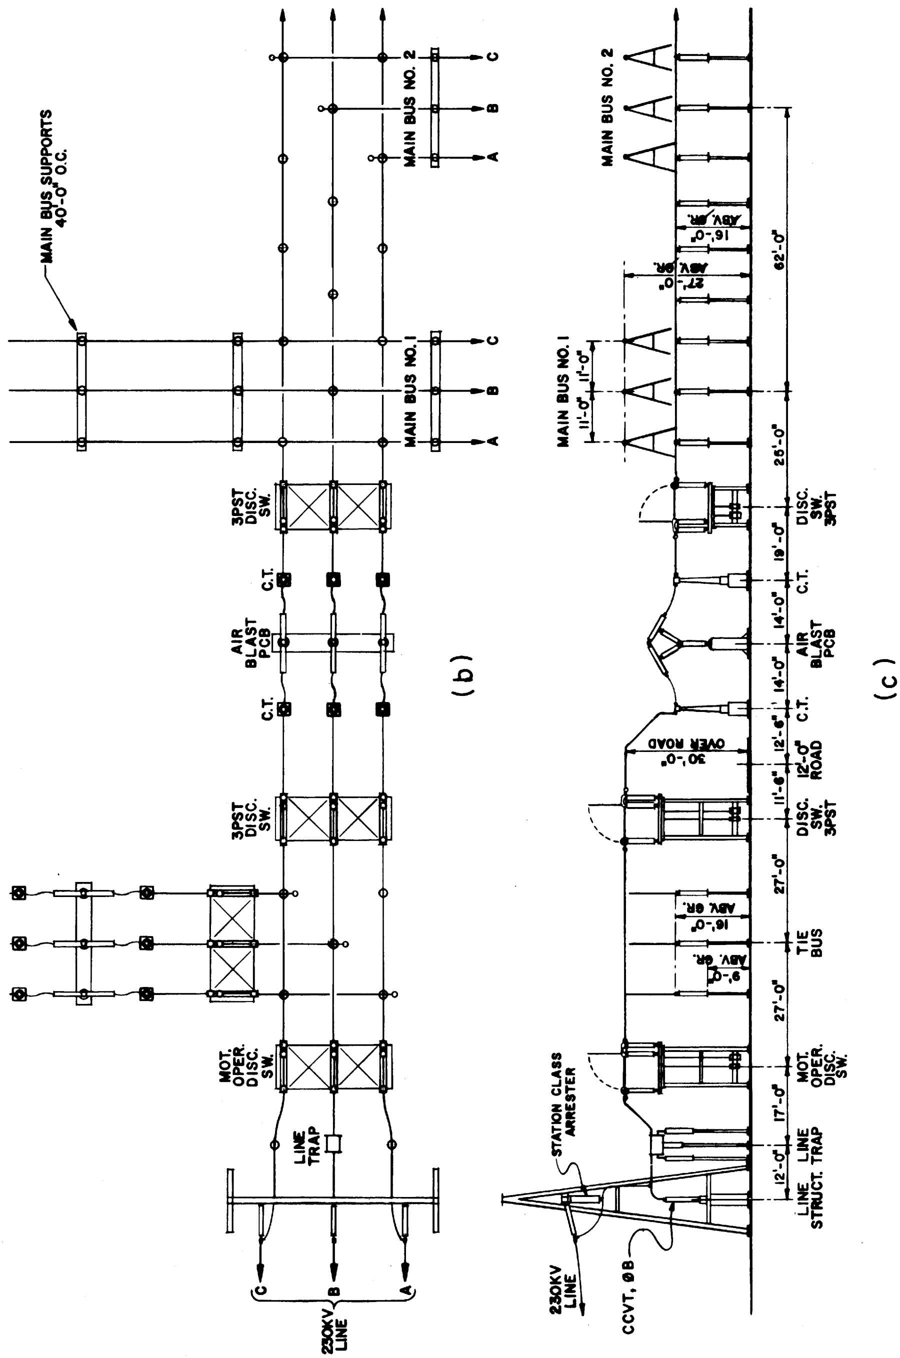

FIGURE 17-8 Typical 130-kV inverted-bus substation. (*a*) One-line diagram; (*b*) plan; (*c*) elevation.

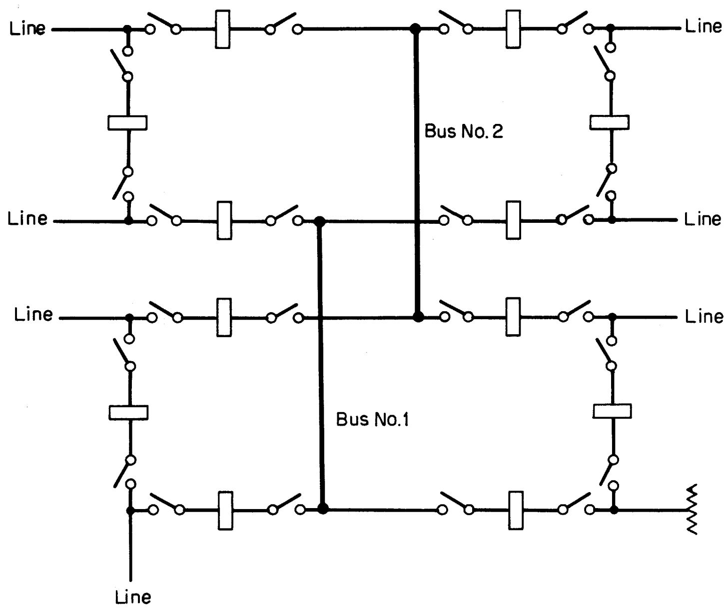

FIGURE 17-9 EHV substation, low-profile, inverted breaker-and-a-half scheme.

A comparison of rigid and strain buses indicates that careful consideration should be given to selection of the proper type of bus to use.

Rigid-bus advantages:

1. Less steel is used, and structures are of a simpler design.
2. Rigid conductors are not under constant strain.
3. Individual pedestal-mounted insulators are more accessible for cleaning.
4. The rigid bus is lower in height, has a distinct layout, and can be definitely segregated for maintenance.
5. Low profile with the rigid bus provides good visibility of the conductors and apparatus and gives a good appearance to the substation.

Rigid-bus disadvantages:

1. More insulators and supports are usually needed for rigid-bus design, thus requiring more insulators to clean.
2. The rigid bus is more sensitive to structural deflections, causing misalignment problems and possible damage to the bus.
3. The rigid bus usually requires more land area than the strain bus.
4. Rigid-bus designs are comparatively expensive.

Strain-bus advantages:

1. Comparatively lower cost than the rigid bus.
2. Substations employing the strain bus may occupy less land area than stations using the rigid bus.
3. Fewer structures are required.

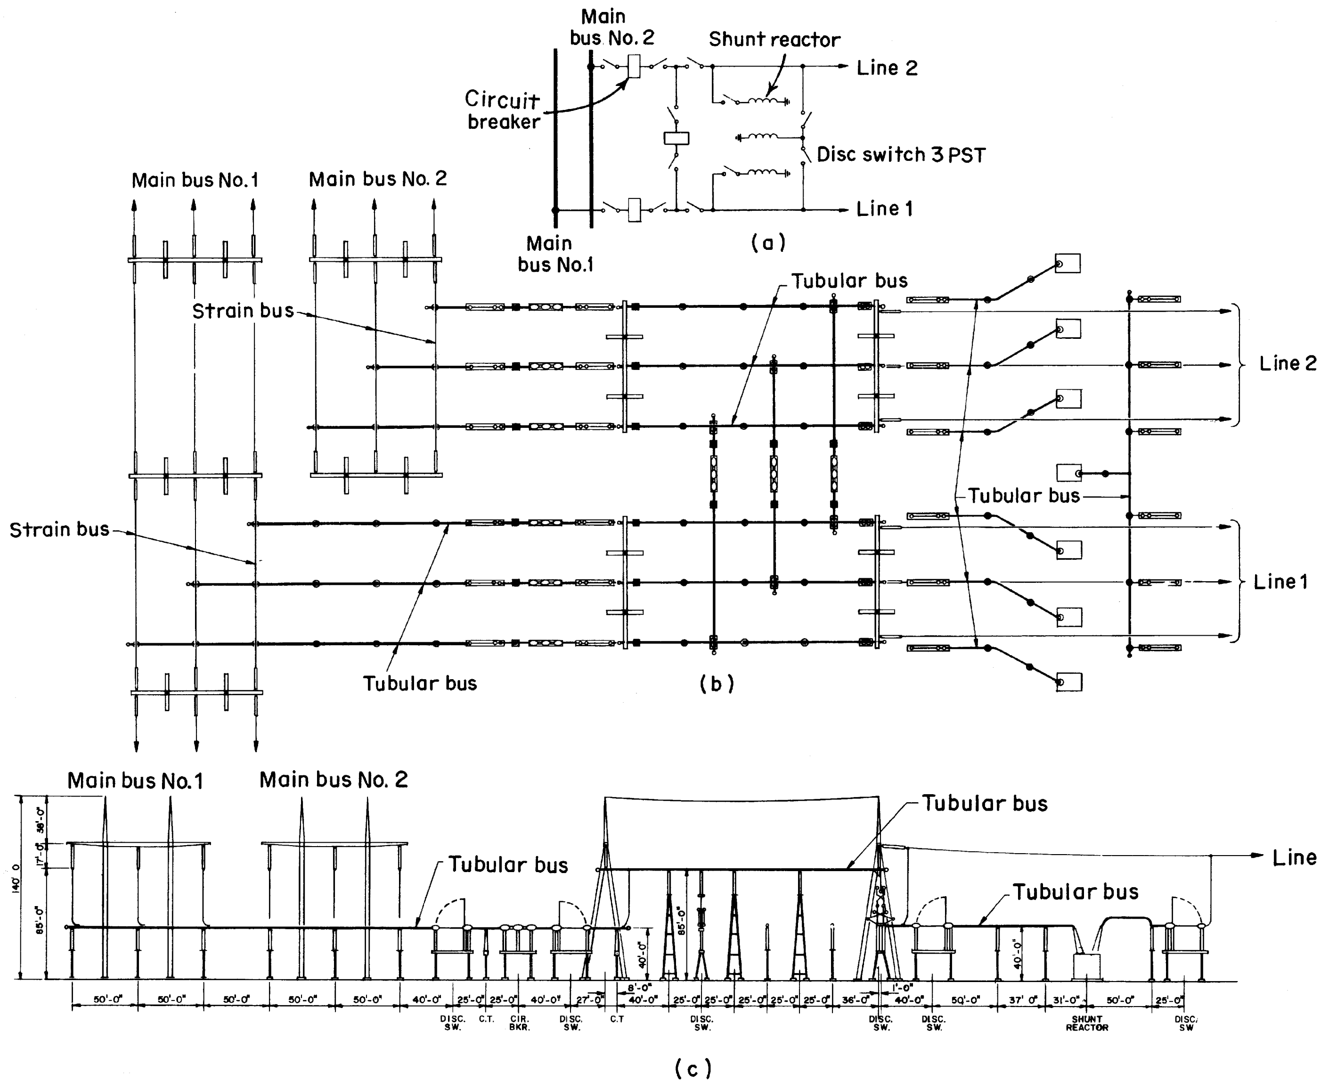

FIGURE 17-10 A 765-kV substation using both rigid- and strain-bus design. (*a*) Main one-line diagram; (*b*) plan; (*c*) elevation.

Strain-bus disadvantages:

1. Strain structures require larger structures and foundations.
2. Insulators are not conveniently accessible for cleaning.
3. Painting of high-steel structures is costly and hazardous.
4. Emergency conductor repairs are more difficult.

The design of station buses depends on a number of elements, which include the following:

1. Current-carrying capacity
2. Short-circuit stresses
3. Minimum electrical clearances

The current-carrying capacity of a bus is limited by the heating effects produced by the current. Buses generally are rated on the basis of the temperature rise, which can be permitted without danger of overheating equipment terminals, bus connections, and joints.

The permissible temperature rise for plain copper and aluminum buses is usually limited to 30°C above an ambient temperature of 40°C. This value is the accepted standard of IEEE, NEMA, and ANSI. This is an average temperature rise; a maximum or hot-spot temperature rise of 35°C is permissible. Many factors enter into the heating of a bus, such as the type of material used, the size and shape of the conductor, the surface area of the conductor and its condition, skin effect, proximity effect, conductor reactance, ventilation, and inductive heating caused by the proximity of magnetic materials.

Rigid-Bus Material. Rigid-bus materials in general use are aluminum and copper. Hard-drawn aluminum, especially in the tubular shape, is the most widely used material in HV and EHV open-type outdoor stations. Aluminum has the advantage of being about one-third the weight of copper and requires little maintenance. The proper use of alloys of aluminum will provide the rigidity needed to serve as a bus material. For a given current rating and for equal limiting temperatures, the required area of aluminum bus is about 133% of the area of the copper bus. Copper and aluminum tubing, as well as other special shapes, are also used for low-voltage distribution substation buses.

Skin Effect. *Skin effect* in a conductor carrying an alternating current is the tendency toward crowding of the current into the outer layer, or "skin," of the conductor due to the self-inductance of the conductor. This results in an increase in the effective resistance of the conductor and in a lower current rating for a given temperature rise. Skin effect is very important in heavy-current buses where a number of conductors are used in parallel, because it affects not only each conductor but also each group of conductors as a unit.

Tubing has less skin-effect resistance than rod or flat conductors of the same cross section, and tubing with a thin wall is affected the least by skin effect. Aluminum conductors are affected less by skin effect than copper conductors of similar cross section because of the greater resistance of aluminum.

Proximity Effect. *Proximity effect* in a bus is distortion of the current distribution caused by induction between the leaving and returning conductors. This distortion causes a concentration of current in the parts of the buses nearest together, thus increasing their effective resistance. The proximity effect must be taken into account for buses carrying alternating current. The effect is less on three-phase buses than on single-phase buses.

Tubular Bus. Tubular conductors used on alternating current have a better current distribution than any other shape of conductor of similar cross-sectional area, but they also have a relatively small surface area for dissipating heat losses. These two factors must be balanced properly in the design of a tubular bus.

Tubing provides a relatively large cross-sectional area in minimum space and has the maximum structural strength for equivalent cross-sectional area, permitting longer distances between supports. In outdoor substations, spans of up to 40 and 50 ft with 6-in-diameter copper or aluminum tubes are considered practicable. The use of long spans reduces the number of insulator posts to a minimum. Current-carrying capacities of copper and aluminum tubular buses of different dimensions are shown in Tables 17-2 and 17-3.

Thermal Expansion. Thermal expansion and contraction of bus conductors is an important factor in bus design, particularly where high-current buses or buses of long lengths are involved. An aluminum bus will expand 0.0105 in/ft of length for a temperature rise of 38°C (100°F). In order to protect insulator supports, disconnecting switches, and equipment terminals from the stresses caused by this expansion, provisions should be made by means of expansion joints and bus-support clamps, which permit the tubing to slide.

Bus Vibration. Long tubular-bus spans have experienced vibration caused by wind blowing across the bus. Over time, this vibration can damage the bus and the equipment connected to the bus. The vibration can be eliminated or reduced by inserting a length of cable inside the tubular bus.

Bus Spacing. The spacing of buses in substations is largely a matter of design experience. However, in an attempt to arrive at some standardization of practices, minimum electrical clearances for standard basic insulation levels were established and published by the AIEE Committee on

Substations. The data are summarized in AIEE Paper 54-80, which appeared in *Transactions* (June 1954, p. 636). This guide, shown in Table 17-4, provides minimum clearance recommendations for electric transmission systems designed for impulse-withstand levels up to and including 1175 kV BIL.

Ongoing studies attempt to extend the clearance recommendations to include the EHV range. The data published in 1954 are satisfactory to withstand anticipated switching-surge requirements of electric systems rated 161 kV and below. For systems rated 230 kV and above, more accurate determination of the switching-surge characteristics of insulation systems was required before final clearance recommendations could be made.

17.1.7 Clearance Requirements

In 1972, the Substations Committee of the IEEE published Trans. Paper T72 131-6, which established recommendations for minimum line-to-ground electrical clearances for EHV substations based on switching-surge requirements. The recommendations are based on a study of actual test data of the switching-surge strength characteristics of air gaps with various electrode configurations as reported by many investigators. The results are shown in Table 17-5 and include minimum line-to-ground clearances for EHV system voltage ratings of 345, 500, and 765 kV. The clearances given in Table 17-4 are considered adequate for both line-to-ground and phase-to-phase values for the voltage

[a] Coordinate kV class and BIL when choosing minimum clearances.
[b] The values above are recommended minimums but may be decreased in line with good practice, depending on local conditions, procedures, etc.
[c] The values above apply to 3300 ft above sea level. Above this elevation, the values should be increased according to IEEE Standard C37.30-1992.
[d] These recommended minimum clearances are for rigid conductors. Any structural tolerances, or allowances for conductor movement, or possible reduction in spacing by foreign objects should be added to the minimum values.
[e] These minimum clearances are intended as a guide for the installation of equipment in the field only, and not for the design of electric devices or apparatus, such as circuit breakers and transformers. 1 in = 25.4 mm; 1 ft = 0.3048 m.

classes up through 230 kV nominal system voltage where air-gap distances are dictated by impulse (BIL) withstand characteristics. The National Electric Safety Code, IEEE Standard C2-2002, also includes clearance requirements to the substation fence (Fig. 17-11).

The Substations Committee of the IEEE has an ongoing effort to review phase-to-phase air clearances and is currently balloting IEEE Standard P1427, Guide for Recommended Electrical Clearances and Insulation Levels in Air Insulated Power Substations.

Considerable information has been published by CIGRE relative to establishing phase-to-phase air clearances in EHV substations as required by switching surges. The CIGRE method is based on nearly simultaneous and equal opposite-polarity surge overvoltages in adjacent phases. The phase-to-ground surge overvoltage is multiplied by a factor of up to 1.8 (the theoretical maximum phase-to-phase voltage would be twice the phase-to-ground surge overvoltage). The estimated value of phase-to-phase overvoltage is then compared with obtained clearances. Refer to an article in CIGRE, *Electra*, no. 29, 1973, "Phase-to-Ground and Phase-to-Phase Air Clearances in Substations," by L. Paris and A. Taschini.

Suggested values of phase-to-phase clearances for EHV substations based on the CIGRE method are shown in Table 17-6. The table was formulated by choosing various phase-to-ground transient voltage values such as are used in Table 17-5. These values of phase-to-ground overvoltage were multiplied by a factor of 1.8 to arrive at a value of estimated phase-to-phase transient overvoltages. An equivalent phase-to-phase critical flashover value of voltage is next assumed by multiplying the switching-surge phase-to-phase voltage by 1.21. Finally, this value is compared with data in the CIGRE article prepared by Paris and Taschini to arrive at air-clearance values based on switching-surge impulse voltages.

EHV substation bus phase spacing is normally based on the clearance required for switching-surge impulse values plus an allowance for energized equipment projections and corona rings. This total distance may be further increased to facilitate substation maintenance.

TABLE 17-5 Minimum Electrical Clearances for EHV Substations Based on Switching Surge and Lightning Impulse Requirements

		2.5	1636	1976	389		
		2.6	1702	2055	415		

Notes:

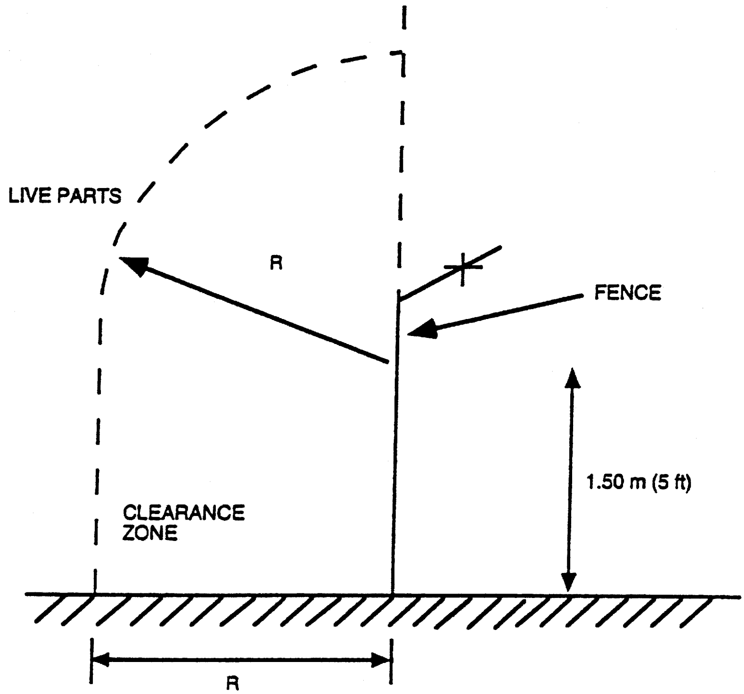
1. Minimum clearances should satisfy either maximum switching-surge or BIL duty requirement, whichever dictates the larger dimension.
2. For installations at altitudes in excess of 3300 ft elevation, it is suggested that correction factors, as provided in IEEE C37.30-1992, be applied to withstand voltages as given above.

SS: switching surge
CFO: critical flashover
1 in = 25.4 mm.

17.1.8 Mechanical and Electrical Forces

A station bus must have sufficient mechanical strength to withstand short-circuit stresses. Two factors are involved: (1) the strength of the insulators and their supporting structure and (2) the strength of the bus conductor.

A simple guide for the calculation of electromagnetic forces exerted on buses during short-circuit conditions is stated in ANSI Standard C37.32-2002, High-Voltage Switches, Bus Supports, and Accessories Schedules of Preferred Ratings, Construction Guidelines and Specifications.



Nominal voltage between phases	Typical BIL	Dimension R m	Dimension R ft
151-7200	95	3.0	10.0

FIGURE 17-11 Substation fence clearance requirements. *(National Electrical Safety Code, IEEE C2-2002.)*

The electromagnetic force exerted between two current-carrying conductors is a function of the current, its decrement rate, the shape and arrangement of conductors, and the natural frequencies of the complete assembly, including mounting structure, insulators, and conductors. Obviously, it is not feasible to cover each and every case with one simple equation, even if some approximations are made, because of the large number of variables involved, including the wide range of constants for support structures.

The force calculated by the following equation is that produced by the maximum peak current. In most cases, the calculated force is higher than that which actually occurs, due to inertia and flexibility

TABLE 17-6 Suggested Electrical Clearances for EHV Substations Based on Switching Surge Requirements and Including U.S. Utility Practice
(Phase to phase)

System voltage, kV		Transient voltage		SS clearances, in*		Present practice
Nom.	Max.	SS L-G PU	Withstand SS crest, kV	Equivalent L-L SS CFO, kV	Rod to rod withstand*	U.S. utility phase spacing, ft

		2.8	1257	2715	294	
765	800	1.5	982	2120	189	45 to 50
		1.8	1178	2545	261	
		2.1	1375	2970	356	
		2.4	1571	3395	480	

Note: 1 in = 25.4 mm; 1 ft = 0.3048 m.

*The values of L-L switching-surge clearances are based on the use of SS L-G crest voltages multiplied by 1.8. This value of L-L SS voltage is then multiplied by 1.21 to indicate an SS CFO value of voltage used to determine the clearances. For a description of method used, refer to CIGRE report by L. Paris and A. Taschini, Phase-to-Ground and Phase-to-Phase Air Clearances in Substations, CIGRE, *Electra*, no. 29, 1973, pp. 29–44. L-G: line-to-ground; L-L: line-to-line; SS: switching surge; CFO: critical flashover.

of the systems, and this fact tends to compensate for the neglect of resonant forces. The equation, therefore, is sufficiently accurate for usual practice conditions.

$$F = M\frac{5.5 \times I^2}{S \times 10^7} \tag{17-1}$$

where F = pounds per foot of conductor
M = multiplying factor
I = short-circuit current, A (defined in Table 17-7)
S = spacing between centerlines of conductors, in

After determining the value of I, select the corresponding M factor from Table 17-7.

Structures with long spans held in tension by strain insulators cannot be calculated for stresses by the preceding procedure, but approximate estimates can be made by following the procedure generally used for calculating mechanical stresses in transmission-line conductors.

TABLE 17-7 Multiplying Factor (M) for Calculation of Electromagnetic Forces

Circuit	Amperes (I) expressed as	Multiplying factor (M)
dc	Max. peak	1.0
ac, 3-phase	Max. peak	0.866
ac, 3-phase	rms asymmetrical	$(0.866 \times 1.63^2) = 2.3$
ac, 3-phase	rms symmetrical	$(0.866 \times 2.82^2) = 6.9$
1 phase of 3 phase or 1 phase	Max peak	1.0
1 phase of 3 phase or 1 phase	rms asymmetrical	$(1.63^2) = 2.66$
1 phase of 3 phase or 1 phase	rms symmetrical	$(2.82^2) = 8.0$

The total stress in an outdoor bus is the resultant of the stresses due to the short-circuit load together with the dead, ice, and wind loads.

1. *Buses up to 161 kV.* The distance between phases and the character of the bus supports and their spacing are such that wind loading usually may be neglected. Ice load of $^1/_2$ in is usually considered.
2. *Buses for 230 kV and higher voltages.* The spacing between phases is usually so large that the mechanical effects of short-circuit currents may not be the determining factor, and such buses, when designed properly for the mechanical loads only, may be found to also satisfy the electrical short-circuit current requirements. However, short-circuit duties on modern systems continue to rise, and the electrical forces should be checked by Eq. (17-1).

Deflections and stresses on aluminum buses can be determined by referring to Tables 17-8 and 17-9. All loads are assumed to be uniformly distributed. Loading includes the dead load of the bus and, in addition, includes ice loadings of $^1/_2$- and 1-in coating on the bus. Wind loads are assumed to be 8 lb/ft^2 of the projected area of tubing including $^1/_2$ in of ice. Large deflections should be avoided even if the maximum bending stress is found to be within safe limits. It is generally satisfactory, in approximation of bus diameter, to allow 1 in of bus outside diameter for every 10 ft of bus span. Refer to the foot notes below Tables 17-8 and 17-9 for the method of support and number of spans.

Stresses on disconnecting switches under short-circuit conditions may be sufficient to open them, with disastrous results; therefore, modern switch designs embody locks, or overtoggle mechanisms, to prevent this from occurring. The force on the switchblade varies as the square of the current. This force will be increased if the return circuit passes behind the switch and will vary inversely with the distance from the center of the switchblade to the center of the return conductor.

Bus supports are designed for definite cantilever strength, expressed in inch pounds and measured at the cap supporting the conductor clamp. Ample margin of safety with regard to insulation and structural strength should be provided, manufacturers' data should be checked carefully, and units should be so selected that allowable values for the particular units are not exceeded. Good practice recommends that the working load must not exceed 40% of the published rating, and short-circuit loads must not exceed the insulator published rating. These loads should include forces for ultimate short-circuit growth and worst mechanical loading.

17.1.9 Overvoltage and Overcurrent Protection

Protective Relaying. A substation can employ many relaying systems to protect the equipment associated with the station; the most important of these are

1. Transmission and distribution lines emanating from the station
2. Step-up and step-down transformers
3. Station buses
4. Breakers
5. Shunt and series reactors
6. Shunt and series capacitors

Substations serving bulk transmission system circuits must provide a high order of reliability and security in order to provide continuity of service to the system. More and more emphasis is being placed on very sophisticated relaying systems which must function reliably and at high speeds to clear line and station faults while minimizing false tripping.

Most EHV and UHV systems now use two sets of protective relays for lines, buses, and transformers. Many utilities use one set of electromechanical relays for transmission-line protection, with a completely separate, redundant set of solid-state relays to provide a second protective relaying package or two completely separate redundant sets of solid-state relays. The use of two separate sets of relays, operating from separate potential and current transformers and from separate station batteries, allows for the testing of relays without the necessity of removing the protected line or bus from service. For more difficult relaying applications, such as EHV lines using series

Source: From *Kaiser Aluminum Electrical Conductor Technical Manual*.

capacitors in the line, some companies always use two sets of solid-state relays to provide the protection systems.

Transmission-line relay terminals are located at the substation and employ many different types of relaying schemes that include the following:

1. Pilot wire
2. Direct underreaching
3. Permissive underreaching
4. Permissive overreaching
5. Directional comparison
6. Phase comparison

Pilot-Wire Relaying. Pilot-wire relaying is an adaptation of the principle of differential relaying to line protection and functions to provide high-speed clearing of the line for faults anywhere on the line. Pilots include wire pilot (using a two-wire pair between the ends of the line), carrier-current pilots, microwave pilots, fiber-optics pilots, and the use of audio-tone equipment over wire, carrier, fiber-optics, or microwave. The transmission lines may have two or more terminals each with circuit breakers for disconnecting the line from the rest of the power system. All the relaying systems described can be used on two-terminal or multiterminal lines. The relaying systems program the automatic operation of the circuit breakers during power-system faults.

Direct Underreaching Fault Relays. These relays (Fig. 17-12) at each terminal of the protected line sense fault power flow into the line. Their zones of operation must overlap but not overreach any remote terminals. The operation of the relays at any terminal initiates both the opening of the local breaker and the transmission of a continuous remote tripping signal to effect instantaneous operation of all remote breakers. For example, in Fig. 17-12, for a line fault near bus *A*, the fault relays at *A* open (trip) breaker *A* directly and send a transfer trip signal to *B*. The reception of this trip signal at *B* trips breaker *B*.

Permissive Underreaching Relays. The operation and equipment for this system are the same as those of the direct underreaching system, with the addition of fault-detector units at each terminal. The fault detectors must overreach all remote terminals. They are used to provide added security by supervising remote tripping. Thus, the fault relays operate as shown in Fig. 17-12 and the fault detectors as shown in Fig. 17-13. As an example, for a fault near *A* in Fig. 17-12, the fault relays at *A* trip breaker *A* directly and send a transfer trip signal to *B*. The reception of the trip signal plus the operation of the fault detector relays at *B* (Fig. 17-13) trip breaker *B*.

Permissive Overreaching Relays. Fault relays at each terminal of the protected line sense fault power flow into the line, with their zones of operation overreaching all remote terminals. Both the

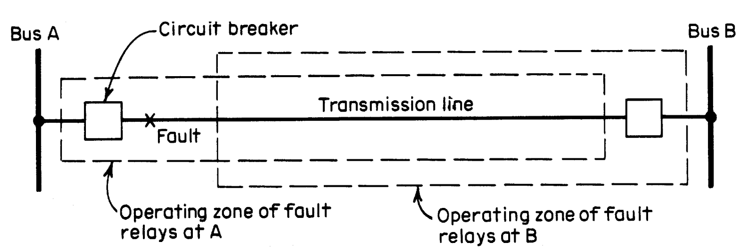

FIGURE 17-12 Fault-relay operating zones for the underreaching transfer trip transmission-line pilot relaying system.

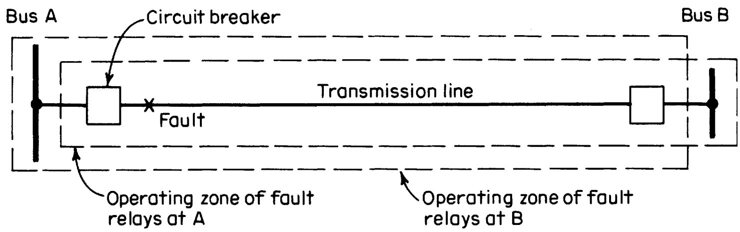

FIGURE 17-13 Fault-relay operating zones for the overreaching transmission-line pilot relaying system.

operation of the local fault relays and a transfer trip signal from all the remote terminals are required to trip any breaker. Thus, in the example of Fig. 17-13 for the line fault near *A*, fault relays at *A* operate and transmit a trip signal to *B*. Similarly, the relays at *B* operate and transmit a trip signal to *A*. Breaker *A* is tripped by the operation of the fault relay *A* plus the remote trip signal from *B*. Likewise, breaker *B* is tripped by the operation of fault relay *B* plus the remote trip signal from *A*.

Directional-Comparison Relays. The channel signal in these systems (Fig. 17-14) is used to block tripping in contrast to its use to initiate tripping in the preceding three systems. Fault relays at each terminal of the protected line section sense fault power flow into the line. Their zones of operation must overreach all remote terminals. Additional fault-detecting units are required at each terminal to initiate the channel-blocking signal. Their operating zones must extend further or be set more sensitively than the fault relays at the far terminals. For example, in Fig. 17-13 the blocking zone at *B* must extend further behind breaker *B* (to the right) than the operating zone of the fault relays at *A*. Correspondingly, the blocking zone at *A* must extend further out into the system (to the left) than the operating zone of the fault relays at *B*.

For an internal fault on line *AB*, no channel signal is transmitted (or if transmitted, it is cut off by the fault relays) from any terminal. In this absence of any channel signal, fault relays at *A* instantly trip breaker *A*, and fault relays at *B* instantly trip breaker *B*. For the external fault to the right of *B* as shown in Fig. 17-13, the blocking zone relays at *B* transmit a blocking channel signal to prevent the fault relays at *A* from tripping breaker *A*. Breaker *B* is not tripped because the *B* operating zone does not see this fault.

Phase-Comparison Relays. The three line currents at each end of the protected line are converted into a proportional single-phase voltage. The phase angles of the voltages are compared by permitting

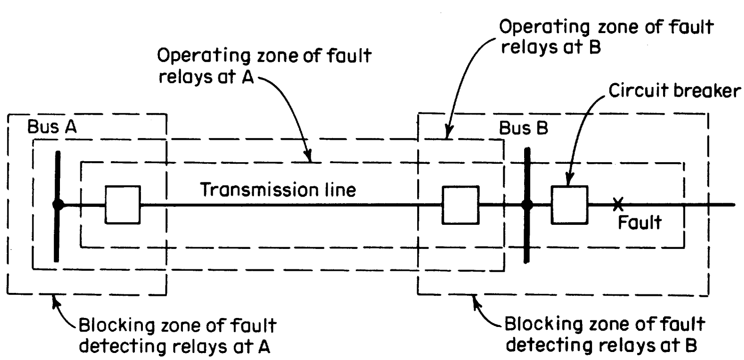

FIGURE 17-14 Fault and blocking relay operating zones for the directional-comparison transmission-line pilot relay system.

the positive half-cycle of the voltage to transmit a half-wave signal block over the pilot channel. For external faults, these blocks are out of phase so that alternately the local and then the remote signal provide essentially a continuous signal to block or prevent tripping. For internal faults, the local and remote signals are essentially in phase so that approximately a half-cycle of no channel signal exists. This is used to permit the fault relays at each terminal to trip their respective breakers.

Station Bus Protection. Station bus protection deserves very careful attention because bus failures are, as a rule, the most serious that can occur to an electrical system. Unless properly isolated, a bus fault could result in complete shutdown of a station. Many methods are employed to protect the station buses. Among them are the use of overcurrent relays, backup protection by relays of adjacent protective zones, directional-comparison schemes, and so forth. By far, the most effective and preferred method used to protect buses consists of percentage differential relaying, using either current or voltage differential relays. Differential relaying is preferred because it is fast, selective, and sensitive.

The relays are available in either electromechanical or solid-state form, with the solid-state units featuring somewhat higher speeds and sensitivity than are available in the electromechanical models. Operating times of 5 to 8 ms can be achieved with solid-state bus differential relays.

Because of the high magnitude of currents encountered during bus faults, current transformers may saturate and thus cause false tripping during external faults. The possibility of ac and dc saturation during faults makes it mandatory that current transformers used for bus differential protection be accurate and of the best quality possible. Also, current transformers should be matched to provide similar ratios and characteristics.

Some bus differential relays developed in solid-state form in Europe have been designed to function correctly even when using current transformers of inferior quality and different ratios. However, it is considered good practice to provide the best possible current transformers for use in bus differential relay applications. For a sensitive bus differential scheme using current percentage differential relays, refer to Fig. 17-15. For a percentage differential scheme using high-impedance-voltage differential relays, refer to Fig. 17-16.

Because the effective resistance of the voltage relay coil circuit is so high, of the order of 3000 Ω, a voltage-limiting element must be connected in parallel with the rectifier branch in order to prevent the CT secondary voltage from being excessive. The overcurrent relay in series with the voltage limiter provides high-speed operation for bus faults of high currents. All current-transformer leads are paralleled at a junction point in the substation near the circuit breakers, and only one set of leads is required to be run into the control house where the relay is normally located.

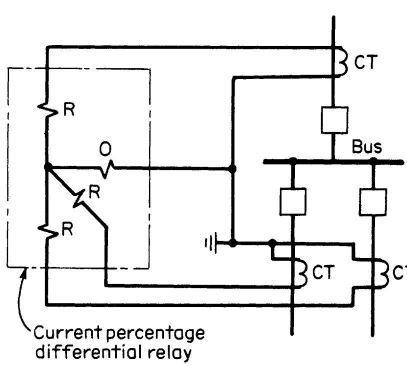

FIGURE 17-15 Bus differential protection using current percentage differential relays (CT, current transformer; O, operating coil; R, restraining coil).

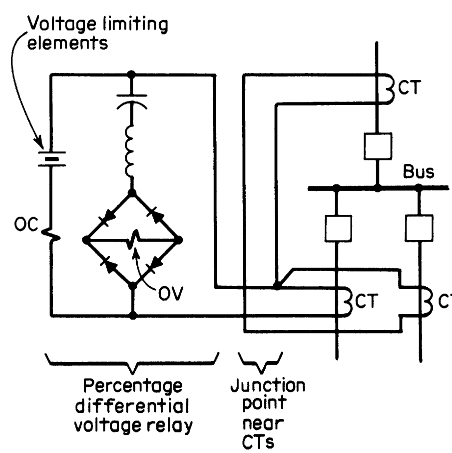

FIGURE 17-16 Bus differential protection using voltage differential relays; (OC, high set overcurrent relays; OV, voltage element; CT, current transformer).

Transformer Protection. Transformers may be subjected to short circuits between phase and ground, open circuits, turn-to-turn short circuits, and overheating. Interphase short circuits are rare and seldom develop as such initially, since the phase windings are usually well separated in a three-phase transformer. Faults usually begin as turn-to-turn failures and frequently develop into faults involving ground.

It is highly desirable to isolate transformers with faulty windings as quickly as possible to reduce the possibility of oil fires, with the attendant resulting cost for replacement. Differential protection is the preferred type of transformer protection due to its simplicity, sensitivity, selectivity, and speed of operation. If the current-transformer ratios are not perfectly matched, taking into account the voltage ratios of the transformer, autotransformers or auxiliary current transformers are required in the current-transformer secondary circuits to match the units properly so that no appreciable current will flow in the relay operating coil, except for internal fault conditions.

In applying differential protection to transformers, somewhat less sensitivity in the relays is usually required, as compared with generator relays, since they must remain nonoperative for the maximum transformer tap changes that might be used. It is also necessary to take into account the transformer exciting inrush current that may flow in only one circuit when the transformer is energized by closing one of its circuit breakers. As a rule, incorrect relay operation can be avoided by imposing a slight time delay for this condition.

Voltage-load tap-changing (LTC) transformers may be protected by differential relays. The same principles of applying differential protection to other transformers hold here as well. It is important that the differential relay be selected carefully so that the unbalance in the current-transformer secondary circuits will not in any case be sufficient to operate the relay under normal conditions. It is suggested that the current transformers be matched at the midpoint of the tap-changing range. The current-transformer error will then be a minimum for the maximum tap position in either direction.

Current-transformer and relay connections for various types of differential protection are indicated (1) in Fig. 17-17 for a Y-delta transformer and (2) in Fig. 17-18 for a three-winding Y-delta-Y transformer. Two rules, frequently used in laying out the wiring for differential protection of transformers whose main windings are connected in Y and delta, are

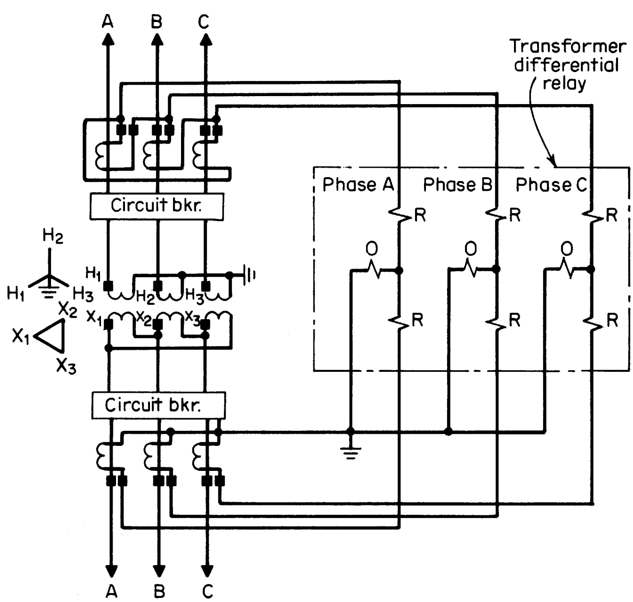

FIGURE 17-17 Transformer differential protection for a Y-Δ transformer.

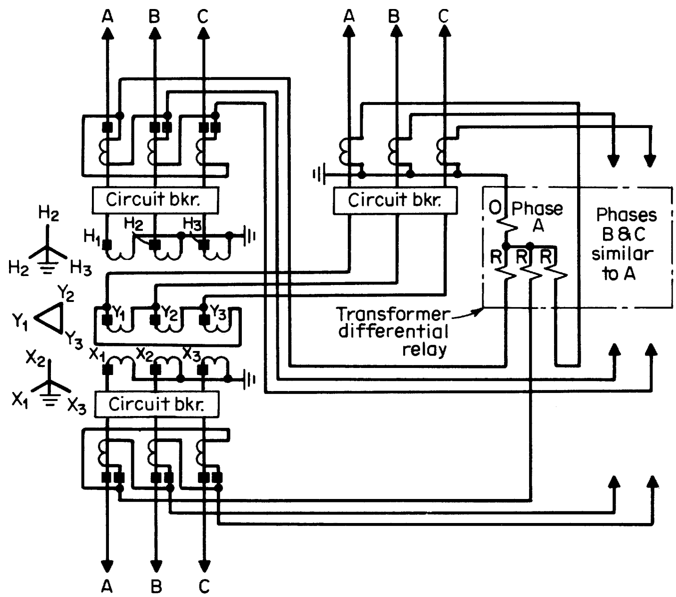

FIGURE 17-18 Transformer differential protection for a Y-Δ Y transformer.

1. The current transformers in the leads to the Y-connected winding should be connected in delta; current transformers in the leads to a delta-connected winding should be connected in Y.
2. The delta connection of the current transformers should be a replica of the delta connection of the power transformers; the Y connection of the current transformers should be a replica of the Y connection of the power transformers.

Current transformers that will give approximately 5-A secondary current at full load on the transformer should be chosen. This will not be possible in all cases, particularly for transformers having three or more windings, since the kVA ratings may vary widely and may not be proportional to the voltage ratings.

Overcurrent protection should be applied to transformers as the primary protection where a differential scheme cannot be justified or as "backup" protection if differential is used. Frequently, faster relaying may be obtained for power flow from one direction by the use of power-directional relays.

Transformer overheating protection is sometimes provided to give an indication of overtemperature, rarely to trip automatically. Overload relays of the replica type may be connected in the current-transformer circuits to detect overloading of the unit. Others operate on top-oil temperature, and still others operate on top-oil temperature supplemented with heat from an adjacent resistor connected to a current transformer in the circuit. A recently developed sensor using a glass chip sensitive to temperature changes employs fiber-optics techniques to measure winding hot-spot temperatures.

Gas- or oil-pressure relays are available for attachment to the top or side of transformer tanks to indicate winding faults, which produce gas or sudden pressure waves in the oil. Rapid collection of gas or pressure waves in the oil, due to short circuits in the winding, will produce fast operation. New, more sophisticated methods to detect incipient failures by frequent monitoring of gas samples are being developed.

Circuit-Breaker Protection. In recent years, great emphasis has been placed on the need to provide backup protection in the event of failure of a circuit breaker to clear a fault following receipt of a trip command from protective relays. For any fault, the protective relays operate to trip the necessary circuit breakers. In addition, these same protective relays, together with breaker-failure fault-detector relays, will energize a timer to start the breaker-failure backup scheme. If any breaker fails to clear the fault, the protective relays will remain picked up, permitting the timer to time-out and trip the necessary other breakers to clear the fault.

Circuit-breaker failure can be caused by loss of dc trip supply, blown trip fuses, trip-coil failure, failure of breaker trip linkages, or failure of the breaker current-interrupting mechanism. The two basic types of failures are (1) mechanical failure and (2) electrical failure of the breaker to clear the fault. Mechanical failure occurs when the breaker does not move following receipt of a trip command because of loss of dc trip supply, trip coil failure, or trip linkage failure. Electrical failure occurs when the breaker moves in an attempt to clear a fault on receipt of the trip command but fails to break the fault current because of misoperation of the current interrupter itself.

In order to clear faults for these two types of breaker failures, two different schemes of protection can be employed. The more conventional breaker-failure schemes consist of using instantaneous current-operated fault detectors which pick up to start a timer when fault relays operate. If the breaker fails to operate to clear the fault, the timer times out and trips necessary breakers to clear the fault. However, if the breaker operates correctly to clear the fault, enough time must be allowed in the timer setting to ensure reset of the fault-detector relay. Total clearing times at EHV using this scheme are quite fast and usually take 10 to 12 cycles from the time of fault until the fault is cleared.

For those faults where mechanical failure of the breakers occurs, an even faster scheme is in use. This scheme depends on a breaker auxiliary switch (normally open type 52-A contact) to initiate a fast timer. The auxiliary switch is specially located to operate from breaker trip linkages to sense actual movement of the breaker mechanism. If the breaker failure is mechanical, the breaker-failure timer is actuated through the auxiliary switch when the protective relays operate. The advantage of using the auxiliary switch is the extremely fast reset time of the breaker-failure timer that can be realized when the breaker operates correctly. Schemes in use with the fast breaker-failure circuit can attain total clearing times of 7.5 cycles when a breaker failure occurs.

Shielding and Grounding Practices for Control Cables. For several years, the increased application of solid-state devices for protective relaying and control and for electronic equipment, such as audio tones, carrier and microwave equipment, event recorders, and supervisory control equipment, in EHV substations has resulted in many equipment failures. Many of these failures have been attributed to transients or surges in the control circuits connected to the solid-state devices. Failures due to transients or surges have been experienced even with conventional electromechanical devices.

The failures being experienced are attributed to the use of EHV (345 kV and higher voltage levels) as well as the presence of unusually high short-circuit currents. One of the major sources of transient voltages is the switching of capacitances, for example, the operation of a disconnect switch which generates high-magnitude, high-frequency oscillatory surge currents. The transient magnetic fields associated with these high-frequency surge currents are both electrostatically and magnetically coupled to cables in the area. Induced voltages have been reported to be as high as 10 kV in cables without shielding, and the frequencies of these induced voltages have been reported to be as high as 3 MHz.

In order to avoid insulation breakdown at 10-kV crest and possible false operation of relays, it is important that station design includes necessary precautions to limit the undesirable surges and control circuit transients to an acceptable minimum.

In any station design there are several precautions that can be taken. All cable circuits that are used in a substation should be run radially, with each circuit separated from any other circuit and with both supply and return conductors contained within the same cable. If a conductor is routed from the control house to a point in the switchyard with the return circuits following different paths, loops may be formed that are inductive and are subject to magnetically induced voltages. However, when the two conductors involved are both affected by the same field, the voltage appearing between them at the open end should be essentially zero.

Because of ground-mat potential differences and longitudinally induced voltages in the radial circuits, proper cable shielding is necessary to maintain lowest possible voltages on the cable leads. The cables that require shielding include control, current, and potential transformer circuits. The shield should be of as low resistance as possible, and it should be connected to the ground grid at least at both ends. To reduce penetration of a magnetic flux through the nonferrous shield (lead, copper, bronze, etc.), a current must flow in the shield to produce a counterflux, which opposes the applied flux. Ground-grid conductors should be placed in parallel to and in close proximity to the shield to maintain as low a resistance between the ends as possible and also to form a small loop to reduce the reactance between ground and the shield. Without close coupling of the conductor and ground shield, the propagation time of the two paths could differ so that a voltage impulse could arrive at the receiving end with a time difference, hence causing an unwanted voltage difference.

All control, potential-transformer, and current-transformer cables should be shielded, with the shield grounded at the switchyard end and at the control-house end. In addition, each group or run of conduits and cables should be installed with a separate No. 4/0 bare stranded copper cable buried directly in the ground and grounded and bonded to the control-cable shield at each end of each cable. The bare copper cable should run as closely as possible to the cable run. The heavy cable functions to provide a low-resistance path in an attempt to prevent heavy fault currents from flowing in the shield and to reduce reactance between ground and shield.

In order to limit induced voltages, the control-cable runs should be installed, where possible, at right angles to high-voltage buses. Where it is necessary to run parallel to a high-voltage bus for any appreciable distance, the spacing between cables and high-voltage buses should be made as great as possible. Distances of at least 50 ft should be maintained.

It is further considered good practice to have both current-transformer and potential-transformer leads installed with the ground for the secondary wye neutral made at the control-house end rather than at the switchyard end. Any rise due to induced voltages will be concentrated at the switchyard and will ensure operator safety at the control switchboard in the control house.

The shield can be grounded by using a flexible tinned copper braid of from $\frac{1}{2}$ to 1 in wide. The shielded-cable outer insulation is peeled back, exposing the sheath. The 1-in braid is wrapped around the sheath and soldered carefully to it. The other end of the braid is connected to a lug, and solder should be run over the lug to the braid connection. The lug is then bolted securely to the ground bus bar. The flexible copper braid circuits should be kept as short as possible and should be run directly to the ground bus without any bends, if possible.

It should be pointed out that the shields should be grounded at multiple points rather than at a single point, because of the tendency to lose any advantage from single-point grounding at 50 kHz and above. As an example, assume that one input and one output terminal of a system are grounded, each at different points on a common ground plane. A small noise voltage will usually exist across these ground points because of currents flowing in the finitely conductive ground plane. If either the load or source ground is lifted, a ground loop is no longer formed, and coupling of unwanted signals is minimized. This is the advantage of having one physical ground.

Removal of one of the ground connections achieves a single-point ground only for dc and low-frequency signals. At higher frequencies, ground loops will be created by capacitance coupling. Frequencies below 50 kHz are considered the arbitrary crossover point for single-point grounding. At EHV, the transient voltages above 50 kHz represent the more serious problem; for this reason, all cable shields should be grounded at least at two points. It should be noted that shielding of control cables is normally provided for substations operating at voltage levels of 138 kV and above.

17.1.10 Substation Grounding

Grounding at substations is highly important. The functions of a grounding system are listed below:

1. Provide the ground connection for the grounded neutral for transformers, reactors, and capacitors
2. Provide the discharge path for lightning rods, arresters, gaps, and similar devices
3. Ensure safety to operating personnel by limiting potential differences, which can exist in a substation
4. Provide a means of discharging and deenergizing equipment in order to proceed with maintenance on the equipment
5. Provide a sufficiently low-resistance path to ground to minimize rise in ground potential with respect to remote ground

Substation safety requirements call for the grounding of all exposed metal parts of switches, structures, transformer tanks, metal walkways, fences, steelwork of buildings, switchboards, instrument-transformer secondaries, etc. so that a person touching or near any of this equipment cannot receive a dangerous shock if a high-tension conductor flashes to or comes in contact with any of the equipment listed. This function in general is satisfied if all metalwork between which a person can complete contact or which a person can touch when standing on the ground is so bonded and grounded that dangerous potentials cannot exist. This means that each individual piece of equipment, each structural column, etc., must have its own connection to the station grounding mat.

A most useful source of information concerning substation grounding is contained in the comprehensive guide IEEE Standard 80-1986, IEEE Guide for Safety in AC Substation Grounding Period. Much of the following information is based on recommendations stated in the IEEE Standard 80.

The basic substation ground system used by most utilities takes the form of a grid of horizontally buried conductors. The reason that the grid or mat is so effective is attributed to the following:

1. In systems where the maximum ground current may be very high, it is seldom possible to obtain a ground resistance so low as to ensure that the total rise of the grounding system potential will not reach values unsafe for human contact. This being the case, the hazard can be corrected only by control of local potentials. A grid is usually the most practical way to do this.

2. In HV and EHV substations, no ordinary single electrode is adequate to provide needed conductivity and current-carrying capacity. However, when several are connected to each other and to structures, equipment frames, and circuit neutrals which are to be grounded, the result is necessarily a grid, regardless of original objectives. If this grounding network is buried in soil of reasonably good conductivity, this network provides an excellent grounding system.

The first step in the practical design of a grid or mat consists of inspecting the layout plan of equipment and structures. A continuous cable should surround the grid perimeter to enclose as much ground as practical and to avoid current concentration and hence high gradients at projecting ground cable ends. Within the grid, cables should be laid in parallel lines and at reasonably uniform spacing. They should be located, where practical, along rows of structures or equipment to facilitate the making of ground connections. The preliminary design should be adjusted so that the total length of buried conductor, including cross connections and rods, is at least equal to that required to keep local potential differences within acceptable limits.

A typical grid system for a substation might comprise 4/0 bare stranded copper cable buried 12 to 18 in below grade and spaced in a grid pattern of about 10 by 20 ft. (Other conductor sizes, burial depths, and grid conductor spacings, however, are frequently used.) At each junction of 4/0 cable, the cables would be securely bonded together, and there might also be connected a driven copper-covered steel rod approximately $^5/_8$ in. in diameter and approximately 8 ft long. In very high-resistance soils it might be desirable to drive the rods deeper. (Lengths approaching 100 ft are recorded.) A typical grid system usually extends over the entire substation yard and sometimes a few feet beyond the fence, which surrounds the building and equipment. Figure 17-19 shows a grounding plan for a typical EHV substation operating at 345 kV.

In order to ensure that all ground potentials around the station are equalized, the various ground cables or buses in the yard and in the substation building should be bonded together by heavy multiple connections and tied into the main station ground. This is necessary in order that appreciable voltage differences to ground may not exist between the ends of cables which may run from the switchyard to the substation building.

Heavy ground currents, such as those that may flow in a transformer neutral during ground faults, should not be localized in ground connections (mats or groups of rods) of small area in order to minimize potential gradients in the area around the ground connections. Such areas should have reinforced wire sizes where necessary to handle adequately the most severe condition of fault-current magnitude and duration.

Copper cables or straps are usually employed for equipment-frame ground connections. However, transformer tanks are sometimes used as part of the ground path for lightning arresters mounted thereon. Similarly, steel structures may be used as part of the path to ground if it can be established that the conductivity, including that of any joints, is and can be maintained as equivalent

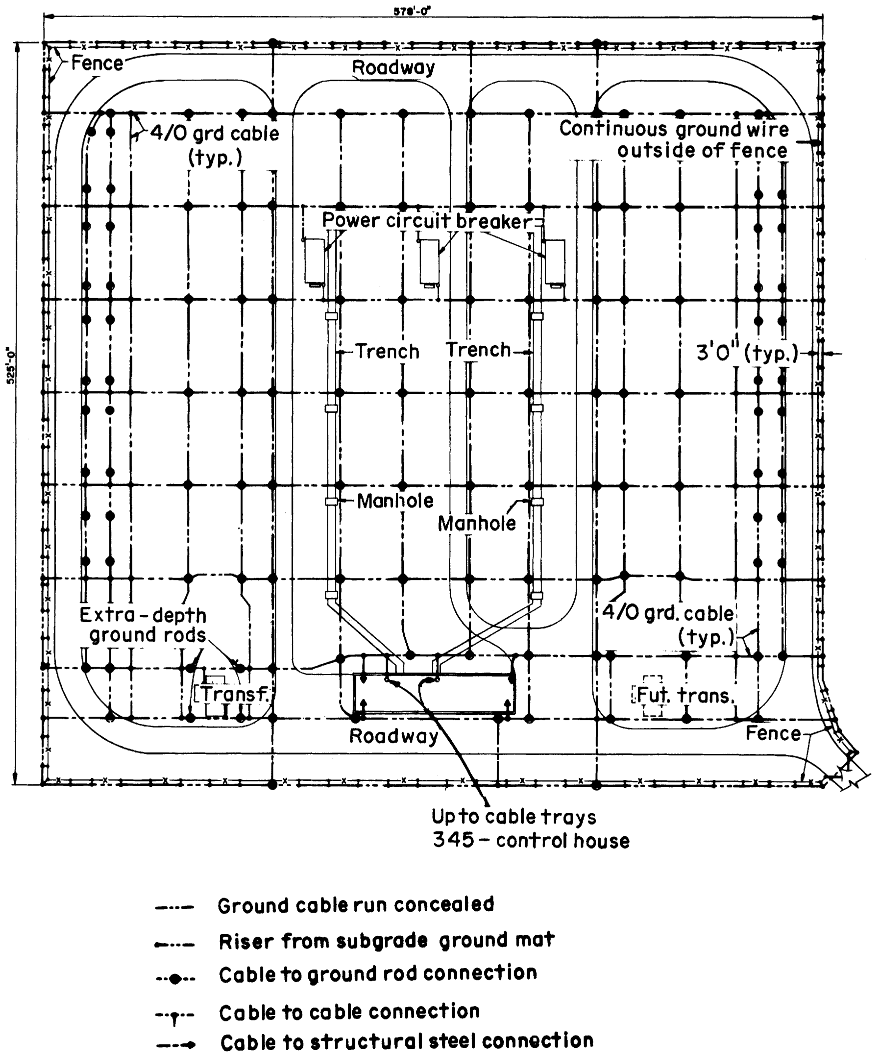

FIGURE 17-19 Grounding plan for a 345-kV substation.

to the copper conductor that would otherwise be required. Studies by some utilities have led to their successful use of steel structures as part of the path to the ground mat from overhead ground wires, lightning arresters, etc. Where this practice is followed, any paint films, which might otherwise introduce a high-resistance joint should be removed and a suitable joint compound applied or other effective means taken to prevent subsequent deterioration of the joint from oxidation.

Connections between the various ground leads and the cable grid and connections within the cable grid are usually clamped, welded, or brazed. Ordinary soldered connections are to be avoided because of possible failure under high fault currents or because of galvanic corrosion.

Each element of the ground system (including grid proper, connecting ground leads, and electrodes) should be so designed that it will

1. Resist fusing and deterioration of electric joints under the most adverse combination of fault-current magnitude and fault duration to which it might be subjected.
2. Be mechanically rugged to a high degree, especially in locations exposed to physical damage.
3. Have sufficient conductivity so that it will not contribute substantially to dangerous local potential differences.

Adequacy of a copper conductor and its joints against fusing can be determined from Table 17-10 and by referring to Fig. 17-20.

If the switchyard is on soil of high resistivity so that it is impossible to obtain suitably low resistance from rods driven within the station, it is possible to reduce the resistance by extending the main ground grid outside the enclosed substation area to a secondary ground mat located adjacent to the substation. The effective resistance of the complete grounding system can be lowered appreciably by the use of a more extensive grid area and of additional grid conductor length. An important reason for trying to lower grid resistance is to minimize ground-potential rise with respect to remote ground during ground faults.

TABLE 17-10 Minimum Copper Conductor Sizes to Avoid Fusing

	Circular mils per ampere		
Time duration of fault, s	Cable only	With brazed joints	With bolted joints
30	40	50	65
4	14	20	24
1	7	10	12
0.5	5	6.5	8.5

Ground-potential rise depends on fault-current magnitude, system voltage, and ground-system resistance. The current through the ground system multiplied by its resistance measured from a point remote from the substation determines the ground-potential rise with respect to remote ground. The current through the grid is usually considered to be the maximum available line-to-ground fault current. For example, a ground fault of 15,000 A flowing into a ground grid with a value of 0.5 Ω resistance to absolute earth would cause an *IR* drop of 7500 V. The 7500-V *IR* drop due to the fault current could cause serious trouble to communications lines entering the station if the communications facilities are not properly insulated or neutralized.

Low-resistance station grounds are frequently difficult to obtain. In such cases, the use of driven grounds will provide the most convenient means of obtaining a suitable ground connection. The arrangement and number of driven grounds will depend on the station size and the nature of the soil. The ground mat of Fig. 17-19 has a value measured to be on the order of 0.5 Ω. The best soils for ground mats are wet and marshy, with clay or clay loam as the next best. Sand and sandy soils are of higher resistance, making it difficult to obtain low-resistance ground connections.

The size of the rods used is determined mainly by the depth to which they must be driven, although small rods can be driven to considerable depths by the use of driving collars. Figure 17-21 shows the relationship between rod size and resistance obtained. Driving more rods in a given space will help reduce resistance, but the reduced resistance

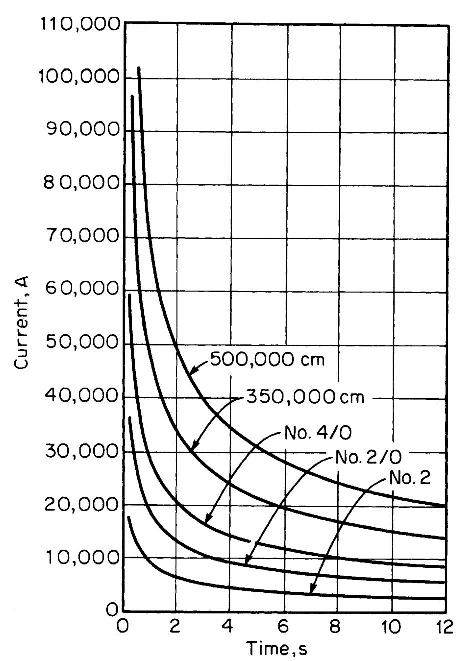

FIGURE 17-20 Short-time fusing curves for copper cable.

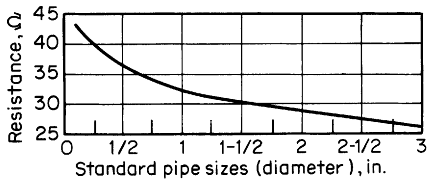

FIGURE 17-21 Relation between pipe diameter and ground resistance. *(NBS Technologic Paper No. 108, June 1918.)*

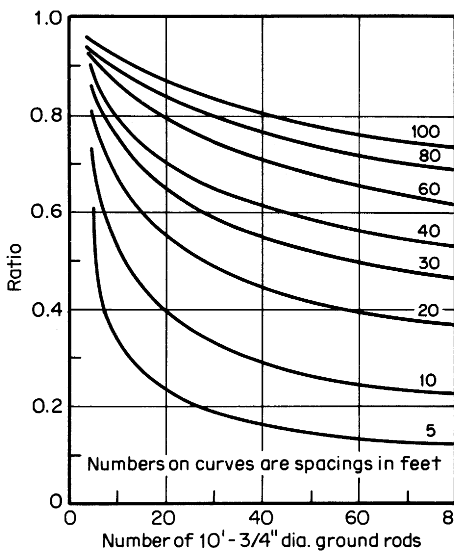

FIGURE 17-22 Ratio of conductivity of ground rods in parallel on an area to that of isolated rods. *(H. B. Dwight, Trans. AIEE, vol. 55, p. 1936.)*

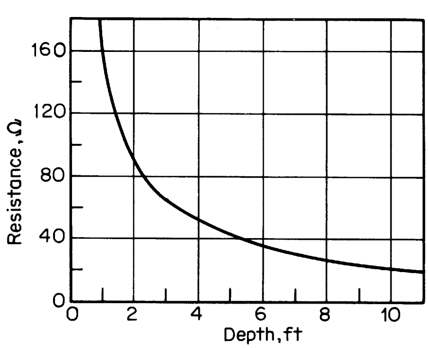

FIGURE 17-23 Variation of resistance of driven pipes with depth. Soil fairly wet. External diameter of pipe is 24.9 mm (1.02 in). *(NBS Technologic Paper No. 108, June 1918.)*

is not a function of the number of rods. Figure 17-22 shows the effect on resistance of spacing and number of rods in square areas. These curves apply to $^3/_4$-in by 10-ft rods. The rods or pipes for permanent stations should be of noncorroding materials. Figure 17-23 shows the effect of increased length of rods in uniform soil. Usually the improvement is much greater than indicated because the rods penetrate into better-conducting earth as they are driven deeper. In addition, where the ground can become frozen, rods must be driven below the frost line to obtain low resistance.

In general, it is advisable to obtain reduced ground resistance by the use of a more extensive mat and more ground rods rather than by treating the earth around the rods with salt because of the impermanence of the treatment. However, treatment of the soil is sometimes the only means whereby suitable resistance can be obtained.

It is not possible to describe all methods of obtaining ground connections of suitably low resistance. The problem sometimes presents great difficulties and calls for considerable extra expense. Substations should not be located on solid rock with little or no topsoil, since the cost of obtaining a low-resistance ground would be excessive. Such a ground would require the use of an extensive counterpoise system with many drilled "wells," in which electrodes would be inserted in treated filling, with provision made for renewing the treatment.

Measuring Ground Resistance. The measurement of ground resistance is necessary both at the time of initial energization of a substation and at periodic intervals thereafter to ensure that the value of ground resistance does not increase appreciably. The measurement of the resistance of a ground connection with respect to absolute earth is somewhat difficult. All results are approximations and require careful application of the test equipment and selection of reference ground points.

There are several methods of testing ground resistance, but all of them are similar in that two reference ground connections are used and a suitable source of current is required for the test. Some form of alternating current is circulated through the ground under test in amounts from a few milliamperes, as in bridge methods and with some of the patented ground testers, up to 100 A or more. The amount of current used depends on the method, and methods using very small currents will give results as accurate as methods using heavy currents if the ground under test is one for which the test method is suitable.

Methods of testing ground resistance fall into three general groups:

1. *Triangulation or three-point methods*, in which two auxiliary test grounds and the point to be measured are arranged in a triangular configuration. The series resistance of each pair of ground points in the triangle is determined by measuring the voltage across and the current through the ground resistance being measured. Resistance measurements are made by the voltmeter-ammeter method or by means of a suitable bridge. For accurate results, the resistance of the auxiliary grounds and the ground under test should be of the same order of magnitude, and results may be meaningless if the test grounds have more than 10 times the resistance of the ground under test. This method is suitable for measuring the resistance of tower footings, isolated ground rods, or small grounding installations. It is not suitable for measurement of low-resistance grounds such as the ground grid at large substations.
2. *Ratio methods,* in which the series resistance R of the ground under test and a test probe is measured by means of a bridge which operates on the null-balance principle. A calibrated slide-wire potentiometer is connected to the two ground connections, with the slider of the potentiometer connected to a second test probe. The potential of the slider to ground is adjusted to zero or null. If D is the total slide-wire resistance and d_1 is the resistance from the slider to the ground under test, the resistance R of the ground under test is $(d_1/D) \times R$. The vibrometer and the groundometer, self-contained test instruments, make use of this principle. This method is much more satisfactory than triangulation methods, since ratios of test-probe resistance to the resistance of the ground under test run as high as 300:1 with test instruments such as the groundometer. Although this method has its limitations in testing low-resistance grounds of large areas, suitable readings can be obtained by locating the test probes in a straight line, in a direction 90° from the substation fence, and with the distance of the farthest probe twice the width of the substation. Best accuracy can be attained by taking measurements at the greatest possible distance from the ground grid being measured.
3. *Fall-of-potential methods,* which include methods using close-in reference grounds, usually less than 1000 ft from the ground under test. The principle of the fall-of-potential method using close-in reference grounds is illustrated by Fig. 17-24. A fixed probe is driven in the ground at point C_2 with a movable probe P_2 set at various points in a straight line between C_2 and the ground mat G

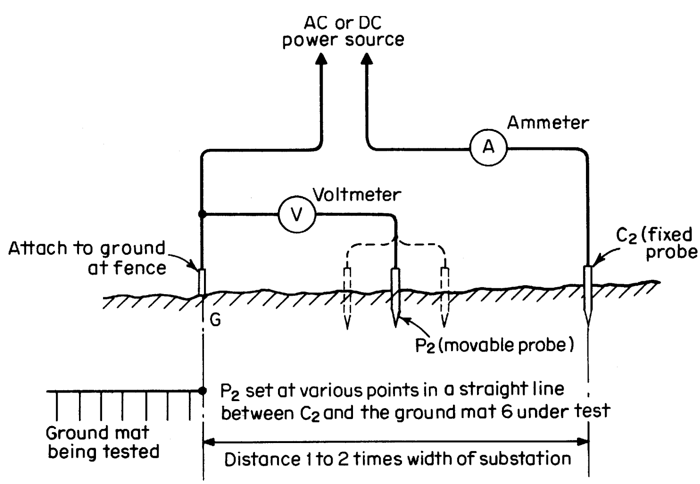

FIGURE 17-24 Field setup for making ground-resistance tests by means of the fall-of-potential method.

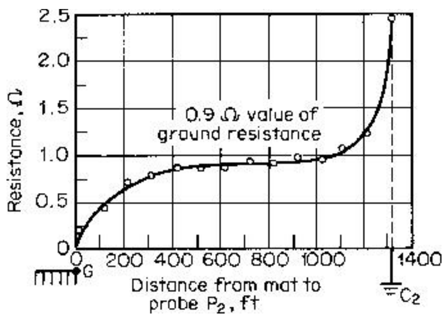

FIGURE 17-25 Ground-resistance curve for a substation ground mat.

under test. Either alternating current or direct current is circulated through ground *G* and fixed test probe C_2. A voltmeter is connected between point *G* and probe P_2, and an ammeter is connected to observe current flow through probe C_2. Voltmeter readings *E* are taken simultaneously with ammeter readings *I*. The reading *E*/*I*, which equals the resistance in ohms, is plotted in Fig. 17-25. The resistance shown on the flat part of the curve or at the point of inflection is taken as the resistance of the ground. This method may be subject to considerable error if stray currents are present. It is normally applied by using several test-probe readings at 10% intervals of the distance from *G* to C_2, with the test probe located midway between *G* and C_2. Self-contained test instruments which make use of this method are available; among them are the ground ohmer and Megger ground tester. These instruments give better results than the voltmeter-ammeter method, since they are designed to eliminate the effects of stray currents.

In recent years, considerable emphasis has been placed on the use of computer programs to calculate the design parameters of substation ground systems. These programs normally employ methods detailed in IEEE Guide 80. Normal input data required to run a typical program consist of the following:

1. System voltage, symmetric rms single-phase-to-ground fault currents, and the clearing time of faults
2. Length and width of substation area
3. Estimated value of ground resistivity in ohm-meters
4. Assumed value of ground conductor length
5. Cross section of conductors available

The following typical information is derived from the program:

1. Size, total length, and number of strands of copper ground conductor
2. Spacing of main grid configuration along width and length
3. Expected ground-mat resistance
4. Depth of grid below ground level
5. Tolerable limits and maximum values of step and touch potentials

It should be noted that the step and touch potentials are defined as follows:

E_{step} is the tolerable potential difference between any two points on the ground surface, which can be touched simultaneously by the feet.

E_{touch} is the tolerable potential difference between any point on the ground where a person may stand and any point which can be touched simultaneously with either hand.

17.1.11 Transformers

Transformers Connections. *Delta-delta–connected* transformers are used mainly on the lower transmission voltages. This is due to the fact that the complete winding must be insulated for full line-to-line voltage; for voltages above 73 kV, the cost increase is appreciable over Y-connected transformers with graded insulation. The delta-delta–connected transformers have one advantage in that the bank can be operated open delta at 86.6% of the capacity of the two remaining transformers.

The delta-star connection is in common use for both step-up and step-down purposes. When used as a step-up transformer, the high-tension winding is Y-connected; when used for step-down purposes, the low-tension winding is usually Y-connected in order to provide a grounded neutral for secondary transmission or for primary distribution.

Delta-connected high-tension windings, however, are seldom used for transmission voltages of 138 kV and above. The delta-Y connection almost completely suppresses the triple harmonics with the neutral solidly grounded. Triple harmonics, which can appear on power systems are the third and its odd multiples. Y-connected windings on the higher voltages are usually provided with graded insulation, the neutral-end turns of which may have very little insulation if the neutral is solidly grounded. If neutral impedance (reactor or resistor) is used, neutral insulation must be equal to or greater than the maximum *IZ* drop of the neutral impedance. If the neutral is to be left ungrounded on either grounded neutral systems or ungrounded neutral systems, the neutral insulation should be the same as it is on the line side to avoid traveling-wave troubles.

Star-star–connected (Y-Y) transformers are used infrequently on high-voltage transmission systems. When used with both neutrals grounded, if single-phase or three-phase shell type, they must be used with Y-connected generators, and a solid neutral connection must be provided between the generator, or generators, and the low-tension transformer neutral in order to minimize triple-harmonic troubles. The various types of Y-Y–connected transformers can be used with both neutrals ungrounded with satisfactory results or with neutrals grounded if of the three-phase core type. The triple harmonics are nearly suppressed in three-phase core-type transformers.

Star-star–connected transformers with a delta-connected third winding (tertiary) overcome the difficulties of the simple Y-Y connection. The tertiary winding may be for the suppression of harmonics only, in which case no connections are brought out with three-phase transformers. Y-delta-Y transformers are frequently used to supply two distribution voltages or a distribution voltage and a secondary-transmission voltage. If the service supplied from the delta-connected winding is four-wire three-phase, the neutral must be obtained from a separate grounding transformer. A common use for the tertiary winding is to provide substation station-service power to operate station auxiliary equipment. Three-winding transformers, all windings of which are used, are frequently rated with two outputs: (1) the individual output of each secondary winding alone with the other secondary winding carrying no load and (2) a simultaneous loading rating in which each secondary winding is given a rated loading with the primary-winding loading the resultant of the two secondary loadings.

Autotransformers are generally used for transforming from one transmission voltage to another when the ratio is 3:1 or less. Such transformers are normally connected in Y with the neutral solidly grounded and when so connected should be provided with a closed delta tertiary winding of adequate capacity for the suppression of harmonics, for ground-fault duty, and to provide station-service power. The tertiary is frequently used to provide a supply of distribution voltage. Autotransformers are superior to separate-winding transformers owing to their lower cost, greater efficiency, smaller size and weight, and better regulation. Autotransformers also may be obtained with zigzag-connected windings or with delta-connected windings. Both these types are free from triple-harmonic troubles but in general are more expensive.

Delta-connected autotransformers have a possible disadvantage in that they insert a phase shift into the transformation, which means that the system being served must be radial or else it must be served by similar transformations at other points.

Transformer Loading Practice. Because of the varying load cycle of most transformers, it is customary to permit loading considerably in excess of the transformer nameplate rating. There may be limitations on the transformer imposed by bushings, leads, tap changers, cables, disconnecting switches, circuit breakers, etc. Good engineering design, however, will permit operation without these limitations.

The increase in transformer loading is limited by the effect of temperature on insulation life. High temperature decreases the mechanical strength and increases the brittleness of fibrous insulation and makes transformer failure increasingly likely even though the dielectric strength of the insulation may not be seriously decreased. Overloading should be limited then by giving consideration to the

TABLE 17-11 Percent Daily Peak Load for Normal Life Expectancy with 30°C Cooling Air

Duration of peak load, h	Self-cooled with % load before peak of			Forced-air-cooled up to 133% of self-cooled rating, with % load before peak of			Forced-air-cooled over 133% of self-cooled rating, or forced-oil-cooled, with % load before peak of		
	50%	70%	90%	50%	70%	90%	50%	70%	90%
0.5	189	178	164	182	174	161	165	158	150
1	158	149	139	150	143	135	138	133	128
2	137	132	124	129	126	121	122	119	117
4	119	117	113	115	113	111	111	110	109
8	108	107	106	107	107	106	106	106	105

effect on insulation life and transformer life. For recurring loads, such as the daily load cycles, the transformer would be operated for normal life expectancy. For emergencies, either planned or accidental, loading would be based on some percentage loss of life.

In a typical case for a failure of part of the electrical system, a 2.5% loss of life per day for a transformer may be acceptable. Loading recommendations based on the evaluation of the loss of insulation life as affected by temperature are contained in ANSI Standard C57.91-1995, Institute of Electrical and Electronics Engineers Guide for Loading Mineral-Oil-Immersed Transformers. NEMA Publ. TR98-1964 contains corresponding recommendations for loading power transformers with 65°C average winding rise insulation systems. ANSI Standard C57.91-1995 states that an average loss of life of 1% per year or 5% in any one emergency operation is considered reasonable.

Daily overload cycles consistent with normal life expectancy for air-cooled power transformers at 30°C ambient temperature are given in Table 17-11, which is a condensation of data taken from ANSI Standard C57.91-1995. For a listing of transformer loading above normal with some sacrifice of life expectancy, data given in NEMA Publ. TR98-1964, Part 3, are condensed in Table 17-12.

Ambient temperature affects load capacity by an amount depending on the type of cooling as shown in Tables 17-11 and 17-12. For changes from this average ambient temperature, transformer ratings may be adjusted as shown in Table 17-13. The table applies to both the 55°C and the 65°C average winding-temperature-rise transformers. For the ambient temperature of air-cooled transformers, use the average value over a 24-h period or 10°C under the maximum during the 24-h period, whichever is higher.

The following temperatures and load limitations are generally applied to transformers. The temperature of the top oil should never exceed 100°C. The maximum hot-spot winding temperature should not exceed 150°C for 55°C rise transformers or 180°C for 65°C rise transformers. Short-time peak loading for $^1/_2$ h or more should not exceed 200% rating. At abnormally high temperatures it may be necessary to remove some oil in order to avoid overflow or excessive pressure.

17.1.12 Surge Protection

A substation should be designed to include safeguards against the hazards of abnormally high voltage surges that can appear across the insulation of electrical equipment in the station. The most severe overvoltages are caused by lightning strokes and by switching surges. The main methods to prevent these overvoltages from causing insulation failures include:

1. Use of surge arresters
2. Equipment neutral grounding
3. Proper selection of equipment impulse insulation level

	155	1.00	1.38	1.37	1.36	1.36	1.36	1.36	1.36	1.36	1.27	1.27	1.27	1.27
	171	4.00	1.38	1.37	1.36	1.36	1.42	1.42	1.41	1.41	1.35	1.35	1.35	1.35

Note: For forced-air-cooled transformers, the peak loads are calculated on the basis of all cooling being in use during the period preceding the peak load. When operating without fans, use the tables for OA transformers. Differences in cooling methods used with forced-oil-cooled transformers result in differences in peak-load-carrying ability. Consult the manufacturer before applying loads above the values given in the table.

TABLE 17-13 Effect of Ambient Temperature on kVA Capacity

Type of cooling	% of rated kVA decrease in capacity for each °C increase over 30°C air	% of rated kVA increase in capacity for each °C decrease under 30°C
Self-cooled—OA	1.5	1.0
Forced-air-cooled—OA/FA, OA/FA/FA	1.0	0.75
Forced-air-cooled—FOA, OA/FOA/FOA	1.0	0.75

4. Proper selection and coordination of equipment basic insulation levels

5. Careful study of switching-surge levels that can appear in the substation

The main device used to prevent dangerous overvoltages, flashovers, and serious damage to equipment is the surge arrester. The surge arrester conducts high surge currents, such as can be caused by a lightning stroke, harmlessly to ground and thus prevents excessive overvoltages from appearing across equipment insulation. For a detailed description of the characteristics and application of arresters, refer to Sec. 27.

The important consideration in applying surge arresters and in selecting equipment insulation levels depends greatly on the method of grounding used. Systems are considered to be effectively grounded when the coefficient of grounding does not exceed 80%. Similarly, systems are noneffectively grounded or ungrounded when the coefficient of grounding exceeds 80%.

A value not exceeding 80% is obtained approximately when, for all system conditions, the ratio of zero sequence reactance to positive sequence reactance (X_0/X_1) is positive and less than 3 and the ratio of zero sequence resistance to positive sequence reactance (R_0/X_1) is positive and less than 1. What this says in effect is that if neutrals are grounded solidly everywhere and if a ground occurs on one of the conductors, then the voltage that can appear on the healthy phases cannot exceed 80% of normal phase-to-phase voltage.

Thus, the *coefficient of grounding* is defined as the ratio of maximum sustained line-to-ground voltage during faults to the maximum operating line-to-line voltage. On many HV and EHV systems, the coefficient of grounding may be as low as 70%.

Surge-arrester ratings are normally selected on the basis of the coefficient of grounding; thus, for effectively grounded systems, the 80% arrester is selected when using the conventional gap-type arrester. When using the gapless metal oxide arrester, a lower-value arrester may be selected based on the maximum continuous operating voltage (MCOV) equal to the maximum normal line-to-neutral voltage. For example, a 115-kV system (maximum operating voltage equals 121 kV) can use a 97-kV conventional arrester, that is, 80% of 121 kV, when operating on a solidly grounded system, and can use a gapless-type metal oxide arrester rated 70 kV. It should be noted that other factors, such as resonant conditions and system switching, could increase the value of the coefficient of grounding and thus should be studied in each individual system.

The impulse insulation level of a piece of equipment is a measure of its ability to withstand impulse voltage. It is the crest value, in kilovolts, of the wave of impulse voltage that the equipment must withstand. However, at EHV, the switching-surge insulation level may be lower than the corresponding impulse level, and thus the switching-surge level becomes the dominant factor in establishing insulation levels.

Basically, the coordination of insulation in a substation means the use of no higher-rated arrester than required to withstand the 60-Hz voltage and the choice of equipment insulation levels that can be protected by the arrester. Careful study of switching-surge levels that can occur at the substation as determined, for example, by transient network analyzer studies also can be used to determine and coordinate proper impulse insulation and switching-surge strength required in a substation electrical equipment.

17.2 GAS-INSULATED SUBSTATIONS

By Philip Bolin

17.2.1 Introduction

High-voltage gas-insulated substations have been in service since the early 1960s. Operation of 800-kV equipment has proved successful since the end of 1979. Prototype testing of 1100 through 1600-kV substation equipment proved the feasibility of this equipment at the next generation of voltage levels.

17.2.2 General Characteristics

The basic principle of gas-insulated equipment is that the high-voltage current-carrying parts are within a metal enclosure and are held in a concentric configuration by cast epoxy spacer insulators. The space between the conductor and the enclosure is filled with sulfur hexafluoride gas under moderate pressure.

Medium-voltage to 170-kV equipment is available in three phases in one enclosure; for higher voltages, it is generally in a single-phase enclosure arrangement. The equipment can be installed indoors or outdoors, and it can be designed for any bus scheme. Depending on the voltage level, bus scheme, and whether connecting lines are installed underground or overhead, the land area required for gas-insulated equipment is 10% for 800 kV to 20% for 145 kV of the space required for comparable air-insulated equipment. Because of its smaller size and enclosed current-carrying parts, this equipment is excellently suited for installation where real estate is at a premium, where the environmental constraints dictate a minimum of visual exposure, and where the continuity of service may be threatened by airborne contamination. Typical section and five-bay substation layouts are shown in Figs. 17-26 and 17-27.

The dielectric medium is the sulfur hexafluoride (SF_6) gas, which became commercially available in 1947. SF_6 has been used as an insulating medium in electronic devices, power apparatus, and HVDC converter stations. Its excellent properties make it ideally suited both as an insulating and as an arc-quenching agent. SF_6 gas is colorless, odorless, chemically inert, nontoxic, nonflammable, and noncorrosive. Its dielectric strength is greatly superior to that of air, and it is close to 100 times as effective as air in quenching an electric arc. These characteristics are illustrated in Figs. 17-28 and 17-29, respectively.

Pure SF_6 is heavier than air, which causes it to settle in low areas, thus diluting oxygen in air. It is therefore necessary to learn proper safety rules before entering any area where pockets of SF_6 could accumulate. Although the gas is self-restoring, during its exposure to an electric arc it will yield decomposition by-products. In the presence of moisture, which is especially the case in failed and ruptured equipment, these by-products will hydrolyze, and all resulting reaction products must be considered hazardous.

The level of gas pressure at which the equipment will operate to meet specified ratings is a function of the relationship between diameters of the conductor and the enclosure (the size of the gap), and the temperature at which the equipment will operate. At the higher pressures, the gas would liquefy at higher temperatures, as indicated in Fig. 17-30. At lower pressures, dielectric strength and arc-quenching qualities of the gas would be reduced. Therefore, the gas-insulated equipment operating pressure is usually between 0.35 and 0.52 MPa (50 and 75 lb/in^2, gage).

Environmental effects of SF_6 that might be released to the atmosphere from GIS have been thoroughly studied. SF_6 does not affect the earth's ozone layer, but it is a strong greenhouse gas. Relative to CO_2, it has a global warming potential of 23,400 due to its infrared absorption and emission characteristics and very long life in the atmosphere (half-life is projected to be 3200 years). Fortunately, the concentration of SF_6 in the atmosphere is very low, and with proper handling, leak checking, and recycling, the contribution of SF_6 to anthropogenic global warming due to its use in electrical equipment can be kept below 0.1%.

17.2.3 Equipment

The tubular conductor is made of aluminum or copper, and the enclosure can be of aluminum, steel, or stainless steel. The conductor connections are made by plug-in contacts, and the enclosure is joined by bolted flanges. In order to provide for proper gas seal, the flanges are constructed with O-ring gaskets. Conductor support insulators are of two types. Barrier insulators are used to isolate gas compartments; they must be capable of withstanding 1.5 times the operating pressure on one side and vacuum on the other side. Nonbarrier insulators permit the gas pressure to equalize between the compartments.

The circuit breakers are of dead-tank design and are the same as those installed in air-insulated substations, except that they are connected to the gas-insulated bus. They have standard ratings.

The rating of the disconnecting switches is established by standards; they must be capable of interrupting associated bus charging current. External indicators provide for switchblade position; however, visual verification is required by some users. This is done through a viewport in the enclosure directly over the contact-making area.

Maintenance and fault-closing grounding switches are the two most common types of grounding devices used with gas-insulated equipment. The first is used to provide grounding connection for maintenance purposes and is generally manually operated. The fault-closing grounding switch, in addition to providing for the maintenance function, has the capability of closing into a fault at least twice without damage. It is generally motor-operated. Both types may be furnished with a low-voltage test provision which permits voltage application to the conductor. This can be achieved without removal of the dielectric and without disassembly, except for ground shunt straps, which must be disconnected. Contact position indication can be the same as for disconnecting switches.

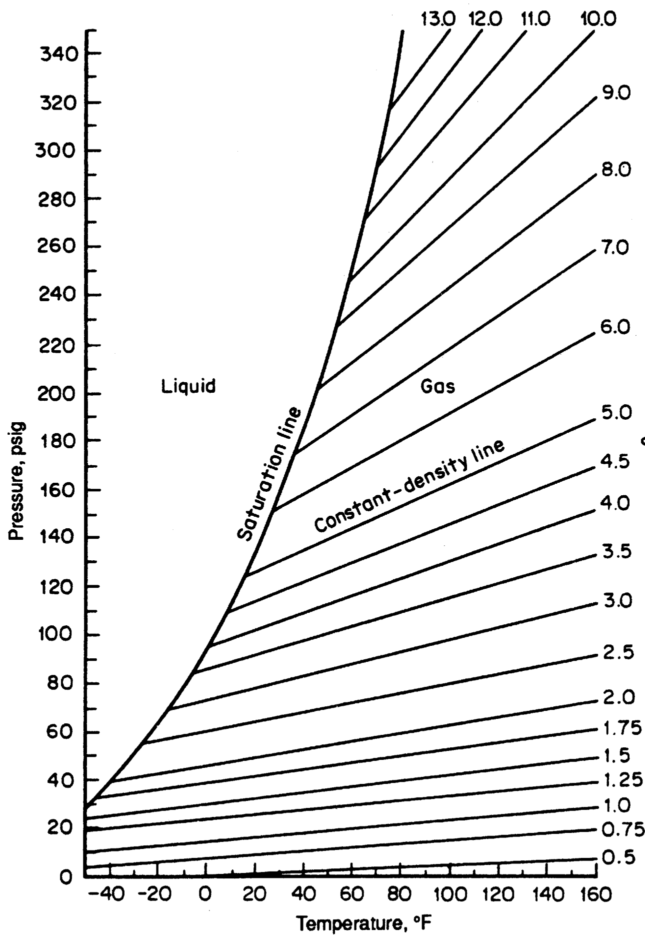

FIGURE 17-30 Pressure variation of SF_6 at constant specific volume.

Current transformers should be positioned so that the current in the enclosure does not affect the accuracy and ratio of the device and does not distort the conductor current being measured. Inductive and capacitive voltage transformers and surge arresters must be provided with disconnecting means for system dielectric tests. The surge-arrester ground connection must be isolated from the enclosure in order to permit monitoring of the leakage current.

The connections from the gas-insulated equipment to transmission lines, transformers, and reactors can be made by SF_6-to-air or SF_6-to-oil bushings. For overhead connection, the SF_6-to-air bushing is usually a hollow porcelain or composite insulator filled with pressurized SF_6 gas. There are two types of SF_6-to-oil bushings: one is for the transformer and the reactor and consists of an expanded bus section that totally encloses the bushing. Provision is made, for both the conductor and the enclosure, to minimize the transfer of transformer or reactor vibrations. The other type of SF_6-to-oil bushing is the power-cable pothead termination into the bus. This bushing must allow for power-cable disconnection from the gas-insulated bus to permit cable dc field testing. Both SF_6-to-oil bushings are provided with barriers which prevent oil migration into the switchgear. Bushings are also available for termination of a solid-dielectric cable into the GIS.

Particle Traps. Any loose conductive particles left within the enclosure can, when the equipment is energized, produce a flashover. When voltage is applied, these particles are moved by the alternating field in a random mode along the lower part of the enclosure. Eventually they reach a particle trap and through its slots fall into the zero-field region where they become permanently trapped and are rendered harmless. Particle traps are placed at the support insulators.

Pressure-Relief Devices. The enclosure is designed so that overpressure caused by internal faults is limited by pressure-relief devices. The location of these devices is such that when activated, the escaping ionized gases do not pose a hazard to personnel. The bursting pressure is coordinated with the rated gas pressure and the pressure rise caused by arcing. If the enclosure material or volume is sufficient to withstand expected overpressure during an internal fault, the pressure-relief devices may not be required.

Desiccant. Depending on the composition of the metal, insulators, and other materials within the equipment and expected moisture content of the dielectric, desiccant may be placed in selected locations to maintain the total moisture content at acceptable levels. It may be contained in especially designed canisters or may be built into spaces of the equipment. The desiccant is also useful in absorbing arcing-related gas by-products.

Expansion. Expansion joints provide for installation alignment and compensate for thermal expansion. If they are to facilitate alignment, they are locked in place when alignment is completed. If they are to compensate for thermal expansion, they are to have means to preserve mechanical integrity of the enclosure and the conductor.

Gas System. For maintenance and monitoring and to restrict damage and contamination in case of a fault, the gas system is divided by means of gas-barrier insulators into basic compartments: each circuit breaker, each terminal compartment, and each main bus section. Each gas compartment has a monitoring system for gas-density with two sets of contacts. Electrically independent contacts operate in two stages: an alarm to refill the gas, normally 5% to 10% below normal, and an alarm to indicate that the pressure has reached minimum level to support equipment ratings. By weight, the individual compartments are not to experience more than 1% leakage per year. The compartments are connected with external gas piping. The piping, which is made of corrosion-resistant material, must be isolated to prevent circulating currents. At each compartment, provisions are made for connecting moisture measurement instrumentation and the gas service cart.

Access. To facilitate maintenance, handholes or manholes, depending on the equipment size, are provided in the enclosure at locations where maintenance-prone devices are located. These gastight accesses are entered only after the dielectric has been evacuated and the compartment thoroughly ventilated.

Associated Systems. Most of the protective and control practices for air-insulated substations apply also for gas-insulated equipment. The principal difference is the requirement for online gas-density alarms for the gas-insulated substations. Another significant difference is that circuit-breaker reclosing is blocked for faults detected anywhere within gas-insulated equipment and its associated gas-insulated transmission-line exits.

In considering the grounding of the gas-insulated equipment, it is essential that the enclosure be bonded so as to present a continuous current path. The current in the conductor induces a voltage in its single-phase enclosure, which causes a longitudinal current flow. When the loads are balanced, this current returns through the enclosure of the adjacent phase. A discontinuity in the enclosure would generate circulating currents and most likely higher-than-desired touch potential.

Field testing of gas-insulated substations requires tests, which may not be required for the conventional equipment. These tests are leak detection, moisture content in the dielectric, and power-frequency testing. In addition to verifying the integrity of the installation, the power-high-voltage frequency test also will reveal the presence of any free conducting particles which may be present.

SECTION 18
POWER DISTRIBUTION

Daniel J. Ward
Principal Engineer, Dominion Virginia Power; Fellow, IEEE; Chair, IEEE Distribution Subcommittee; Chair, ANSI C84.1 Committee, Past Vice Chair (PES), Power Quality Standards Coordinating Committee

CONTENTS

18.1 DISTRIBUTION DEFINED

Broadly speaking, *distribution* includes all parts of an electric utility system between bulk power sources and the consumers' service-entrance equipments. Some electric utility distribution engineers, however, use a more limited definition of distribution as that portion of the utility system between the distribution substations and the consumers' service-entrance equipment. In general, a typical distribution system consists of (1) subtransmission circuits with voltage ratings usually between 12.47 and 345 kV which deliver energy to the distribution substations, (2) distribution substations which convert the energy to a lower *primary system* voltage for local distribution and usually include facilities for voltage regulation of the primary voltage, (3) primary circuits or *feeders*, usually operating in the range of 4.16 to 34.5 kV and supplying the load in a well-defined geographic area, (4) distribution transformers in ratings from 10 to 2500 kVA which may be installed on poles or grade-level pads or in underground vaults near the consumers and transform the primary voltages to utilization voltages, (5) secondary circuits at utilization voltage which carry the energy from the distribution transformer along the street or rear-lot lines, and (6) service drops which deliver the energy from the secondary to the user's service-entrance equipment. Figures 18-1 and 18-2 depict the component parts of a typical distribution system.

Distribution investment constitutes 50% of the capital investment of a typical electric utility system. Recent trends away from generation expansion at many utilities have put increased emphasis on distribution system development.

The function of distribution is to receive electric power from large, bulk sources and to distribute it to consumers at voltage levels and with degrees of reliability that are appropriate to the various types of users.

For single-phase residential users, American National Standard Institute (ANSI) C84.1-1989 defines *Voltage Range A* as 114/228 V to 126/252 V at the user's service entrance and 110/220 V to 126/252 V at the point of utilization. This allows for voltage drop in the consumer's system. Nominal voltage is 120/240 V. Within Range A utilization voltage, utilization equipment is designed and rated to give fully satisfactory performance.

As a practical matter, voltages above and below Range A do occur occasionally; however, ANSI C84.1 specifies that these conditions shall be limited in extent, frequency, and duration. When they do occur, corrective measures shall be undertaken within a reasonable time to improve voltages to meet Range A requirements.

Rapid dips in voltage which cause incandescent-lamp "flicker" should be limited to 4% or 6% when they occur infrequently and 3% or 4% when they occur several times per hour. Frequent dips, such as those caused by elevators and industrial equipment, should be limited to 1½% or 2%.

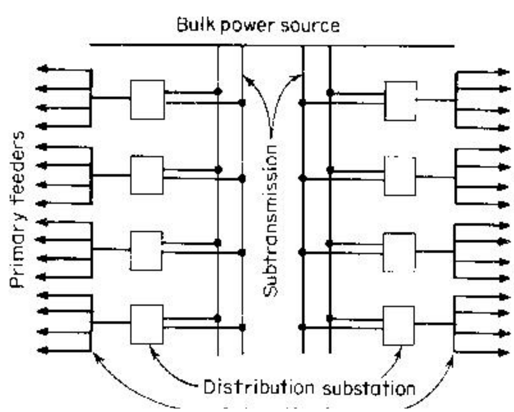

FIGURE 18-1 Typical distribution system.

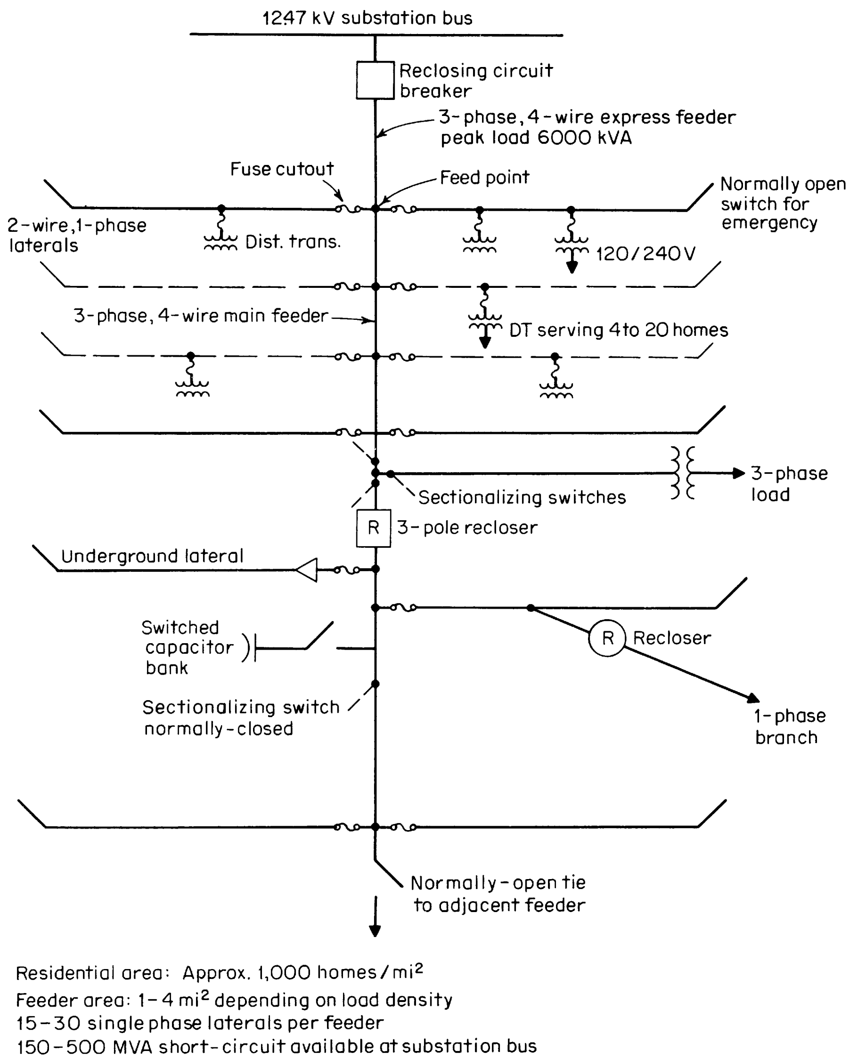

FIGURE 18-2 One-line diagram of typical primary distribution feeder.

Reliability of service can be described by factors such as frequency and duration of service interruptions. While short and infrequent interruptions may be tolerated by residential and small commercial users, even a short interruption can be costly in the case of many industrial processes and can be dangerous in the case of hospitals and public buildings. For such sensitive loads, special measures are often taken to ensure an especially high level of reliability, such as redundancy in supply circuits and/or supply equipment. Certain computer loads may be sensitive not only to interruptions but even to severe voltage dips and may require special power-supply systems which are virtually uninterruptible.

From a system-planning and design point of view, the optimal choice of subtransmission voltage and system arrangement is closely interrelated with distribution substation size and with the primary distribution voltage level. At any given time, the most economical arrangement is achieved when the sum of the subtransmission, substation, and primary feeder costs to serve an area is a minimum over the life of the facilities. In practice, the number, size, and availability of bulk supply sources for feeding the subtransmission may be significant factors as well.

A distribution system should be designed so that anticipated load growth can be served at minimum expense. This flexibility is needed to handle load growth in existing areas as well as load growth in new areas of development.

Overhead and underground distribution systems are both used in large metropolitan areas. In the past in smaller towns and in the less-congested areas of larger cities, overhead distribution was almost universally used; the cost of underground distribution for residential areas was several times that of overhead. During the past 25 to 30 years, the cost of underground residential distribution (URD) has been reduced drastically through the development of low-cost, solid-dielectric cables suitable for direct burial, mass production of pad-mounted distribution transformers and accessories, mechanized cable-installation methods, etc. The cost of a typical URD system for a new residential subdivision is about 50% greater than that of an overhead system in many areas; in others, there is little or no differential due to local land conditions. As a result, some utilities will justifiably have some type of extra charge for underground. With the increased public interest in improving the appearance of residential areas and the declining cost of URD, the growth of URD has been extremely rapid. Today, perhaps as much as 70% of new residential construction is served underground. A number of states have enacted legislation making underground distribution mandatory for new residential subdivisions.

***Undergrounding*[*].** In the last decade, U.S. East Coast and Midwest regions experienced several catastrophic "100 year storms." These storms left widespread electric power outages that lasted several days. Given the critical role that electricity plays in our modern lifestyle, even a momentary power outage is an inconvenience. A days-long power outage presents a major hardship and can be catastrophic in terms of its health and safety consequences, and the economic losses it creates. Why then, don't we bury more of our power lines so they will be protected from storms?

The fact is we already are placing significant numbers of power lines underground. Over the past 10 years, approximately half of the capital expenditures by U.S. investor-owned utilities for new transmission and distribution wires have been for underground wires. Almost 80% of the nation's electric grid, however, has been built with overhead power lines. Would electric reliability be improved if more of these existing overhead lines were placed underground as well?

What the report finds is that burying existing overhead power lines does not completely protect consumers from storm-related power outages. However, underground power lines do result in fewer overall power outages, but the duration of power outages on underground systems tends to be longer than for overhead lines. Also, undergrounding is expensive, costing up to $1 million/mile or almost 10 times the cost of a new overhead power line. This means that most undergrounding projects cannot be economically justified and must cite intangible, unquantifiable benefits such as improved community or neighborhood aesthetics for their justification. Determining who pays and who benefits from undergrounding projects can be difficult and often requires the establishment of separate government-sponsored programs for funding.

How Much Does Undergrounding Improve Electric Reliability? Comparative reliability data indicate that the frequency of outages on underground systems can be substantially less than for overhead systems. However, when the duration of outages is compared, underground systems lose much of their advantage. The data show that the frequency of power outages on underground systems is only about one-third of that of overhead systems. A 2000 report issued by the Maryland Public Service Commission concluded that the impact of undergrounding on reliability was "unclear."

In a 2003 study, the North Carolina Commission summarized 5 years of underground and overhead reliability comparisons for North Carolina's investor-owned electric utilities–Dominion North Carolina Power, Duke Energy, and Progress Energy Carolinas. The data indicate that the frequency of outages on underground systems was 50% less than for overhead systems, but the average duration of an underground outage was 58% longer than for an overhead outage. In other words, for

[*]From "Out of Sight, Out of Mind?," January 2004, Edison Electric Institute (used with permission).

the North Carolina utilities, an underground system suffers only about half the number of outages of an overhead system, but those outages take 1.6 times longer to repair. Based on this data, Duke Power concluded, "Underground distribution lines will improve the potential for reduced outage interruption during normal weather, and limit the extent of damage to the electrical distribution system from severe weather-related storms." However, once an interruption has occurred, underground outages normally take significantly longer to repair than a similar overhead outage.

Reliability Characteristics of Overhead and Underground Power Lines

- Overhead lines tend to have more power outages primarily due to trees coming in contact with overhead lines.
- It is relatively easy to locate a fault on an overhead line and repair it. A single line worker, for example, can locate and replace a blown fuse. This results in shorter duration outages.
- Underground lines require specialized equipment and crews to locate a fault, a separate crew with heavy equipment to dig up a line, and a specialized crew to repair the fault. This greatly increases the cost and the time to repair a fault on an underground system.
- In urban areas, underground lines are 4 times more costly to maintain than overhead facilities.
- Underground lines have a higher failure rate initially due to dig-ins and installation problems. After 3 or 4 years, however, events that affect failures become virtually nonexistent.
- As underground cables approach their end of life, failure rates increase significantly and these failures are extremely difficult to locate and repair. Maryland utilities report that their underground cables are becoming unreliable after 15 to 20 years and reaching their end of life after 25 to 35 years.
- Pepco found that customers served by 40-year-old overhead lines had better reliability than customers served by 20-year-old underground lines.
- Two Maryland utilities have replaced underground distribution systems with overhead systems to improve reliability.
- Water and moisture infiltration can cause significant failures in underground systems when they are flooded, as often happens in hurricanes.
- Due to cost or technical considerations, it is unlikely that 100% of the circuit from the substation to the customer can be placed entirely underground. This leaves the circuit vulnerable to the same types of events that impact other overhead lines, for example, high winds and ice storms.

Other Benefits of Undergrounding. One of the most commonly cited benefits of undergrounding is the removal of unsightly poles and wires. Local communities and neighborhoods routinely spend millions to place their existing overhead power lines underground.

Similarly, when given the option, builders of new residential communities will often pay a premium of several thousand dollars/home to place the utilities underground. These "aesthetic" benefits are virtually impossible to quantify, but are, in many instances, the primary justification for projects to place existing power lines underground.

Underground lines do have other benefits. In 1998, Australia completed a major benefit/cost analysis of undergrounding all existing power lines in urban and suburban areas throughout the country. The study costed more than $1.5 million Australian ($1.05 million U.S. at current rates), and represents what may be the most comprehensive undertaking to date to quantify the benefits and costs related to undergrounding.

In addition to the value of improved aesthetics, the study identified the following potential benefits related to undergrounding that it attempted to quantify:

- Reduced motor vehicle accidents caused by collisions with poles
- Reduced losses caused by electricity outages
- Reduced network maintenance costs
- Reduced tree-pruning costs

- Increased property values
- Reduced transmission losses due to the use of larger conductors
- Reduced greenhouse-gas emissions (lower transmission losses)
- Reduced electrocutions
- Reduced brushfire risks, and
- Indirect effects on the economy such as employment

Of this list, the only four items deemed significant in the study's benefit/cost calculations included:

- Motor vehicle accidents
- Maintenance costs
- Tree-trimming costs, and
- Line losses

The Australian list of benefits does not include improved reliability as a significant benefit of undergrounding. Instead it identifies the reduction in losses from motor vehicle accidents as the largest benefit from undergrounding—something utilities have no control over.

Underground cost data for U.S. utilities indicate that the cost of placing overhead power lines underground is 5 to 10 times the cost of new overhead power lines. Other factors also can result in substantial additional customer costs for undergrounding projects. These include:

- Electric undergrounding strands other utilities, for example, cable and telephone companies, which must assume 100% of pole costs if electric lines are underground. These additional nonelectric costs will likely be passed on to cable and telephone consumers.
- Customers may incur substantial additional costs to connect homes to newly installed underground service, possibly as much as $2000 if the household electric service must be upgraded to conform to current electric codes.

Paying for Undergrounding. In spite of its high cost and lack of economic justification, undergrounding is very popular across the country. In 9 out of 10 new subdivisions, contractors bury power lines. In addition, dozens of cities have developed comprehensive plans to bury or relocate utility lines to improve aesthetics.

For new residential construction, utilities vary on how they charge for the cost of providing underground services. When it comes to converting existing overhead lines to underground, a variety of programs are being utilized. They include special assessment areas, undergrounding districts, and state and local government initiatives.

Placing existing power lines underground is expensive, costing approximately $1 million/mile. This is almost 10 times the cost of a new overhead power line.

While communities and individuals continue to push for undergrounding—particularly after extended power outages caused by major storms—the reliability benefits that would result are uncertain, and there appears to be little economic justification for paying the required premiums.

Indeed, in its study of the undergrounding issue, the Maryland Public Service Commission concluded, "If a 10 percent return is imputed to the great amounts of capital freed up by building overhead instead of underground lines, the earnings alone will pay for substantial ongoing overhead maintenance," implying that utilities could have more resources available to them to perform maintenance and improve reliability on overhead lines if they invested less in new underground facilities.

For the foreseeable future, however, it appears that the undergrounding of existing overhead power lines will continue, justified primarily by aesthetic considerations—not reliability or economic benefits. Many consumers simply want their power lines placed underground, regardless of the costs. The challenge for decision makers is determining who will pay for these projects and who will benefit.

There are several undergrounding programs around the country that are working through these equity issues and coming up with what appear to be viable compromises. Once a public-policy decision is reached to pursue an undergrounding project, it is worthwhile for the leaders involved to evaluate these programs in more detail to determine what is working, and what is not.

Rural Service. Rural service has been extended to most farmers and rural dwellers through the efforts of utilities, cooperatives, and government agencies. Rural construction must be of the least-expensive type consistent with durability and reliability because there may be only a few users per mile of line. Historically, rural construction has been overhead, but the advent of cable-plowing techniques has made underground economically competitive with overhead in some parts of the country, and a growing amount of rural distribution is being installed underground.

Higher primary voltages of 24.9Y/14.4 and 34.5Y/19.92 kV are continuing to grow in usage, although primary voltages in the 15-kV class predominate. The 5-kV class continues to decline in usage. Surveys indicate that in recent years approximately 78% of the overhead and underground line additions are at 15 kV, 11% are at 25 kV, and 7.5% are at 35 kV.

Generally, when a higher distribution voltage is initiated, it is built in new, rapidly growing load areas. The economic advantage of the higher voltages usually is not great enough to justify massive conversions of existing lower-voltage facilities to the higher level. The lower-voltage areas are contained and gradually compressed over a period of years as determined by economics, obsolescence, and convenience. Virtually, all modern primary systems serving residential and small commercial and small industrial loads are 4-wire, multigrounded, common-neutral systems.

18.2 DISTRIBUTION-SYSTEM AUTOMATION

Distribution automation (DA), a system to monitor and control the distribution system in real-time, was gradually introduced in the 1970s more as a concept than a fully developed plan. Unlike the introduction of EMS, where utilities readily saw the benefits of automatic generation control and economic dispatch and adopted the technology, utilities were much more cautious in their approach to distribution automation.

Early distribution automation projects were undertaken by a handful of utilities. The technology was changing and evolving so much so that DA was being touted as an amorphous system capable of covering any imaginable function under the sun. A 1984 EPRI project, Guidelines for Evaluating Distribution Automation, focused attention on what functions could be automated and what value could be attached to those functions. A positive result of this project is that it got people thinking about what functions mattered most. However, it was a little bit ahead of its time in that there wasn't much standardization in systems employed for DA and one couldn't simply select functions of interest and expect to obtain a system that could be built for the total value of the functions selected. Then too, the choice of the communications systems (e.g., telephone, fiber optics, radio, carrier, etc.) proved to be a barrier to widespread implementation.

At the substation level, equipment loadings became an early focus, and asset management became a desired function for DA systems. In addition, the ability to trip distribution circuit breakers and transfer load between substations was commonplace as SCADA was added and this represented the extent of distribution automation to many companies.

Volt/var control, that is, controlling the combination of load tap changers (LTC) or voltage regulators and switched capacitor banks within a substation, was a function many companies incorporated with DA. With adoption of microprocessor relays and fault distance relaying, some incorporated the output information from fault distance relays and diagnostic alarms from various subsystems to be part of the DA package.

Moving outside the substation, controlling automated circuit tie switches was prompted by reliability considerations. Having SCADA links to other reclosers, particularly the ones with microprocessor controls, enabled more ability to remotely control field switching and achieve more rapid restoration of service.

Distribution automation is still evolving with systems incorporating many of the functions previously described. More utilities are employing varying degrees of distribution automation and more standardization is taking place.

18.3 CLASSIFICATION AND APPLICATION OF DISTRIBUTION SYSTEMS

Distribution systems may be classified in according to:

- voltage—120 V, 12,470 V, 34,500 V, etc.
- scheme of connection—radial, loop, network, multiple, and series.
- loads—residential, small light and power, large light and power, street lighting, railways, etc.
- number of conductors—2-wire, 3-wire, 4-wire, etc.
- type of construction—overhead or underground.
- number of phases—single-phase, 2-phase, or 3-phase; and as to frequency: 25 Hz, 60 Hz, etc.

Application of Systems. In American practice, alternating-current (ac) 60-Hz systems are almost universally used for electric power distribution. These systems comprise the most economical method of power distribution, owing in large measure to the ease of transforming voltages to levels appropriate to the various parts of the system. These transformations are accomplished by means of reliable and economical transformers. By proper system design and the application of overvoltage and overcurrent protective equipment, voltage levels and service reliability can be matched to almost any consumer requirement.

Single-phase residential loads generally are supplied by simple radial systems at 120/240 V. The ultimate in service reliability is provided in densely loaded business/commercial areas by means of grid-type secondary-network systems at 208Y/120 V or by "spot" networks, usually at 480Y/277 V. Secondary-network systems are used in about 90% of the cities in this country having a population of 100,000 or more and in more than one-third of all cities with populations between 25,000 and 100,000.

Where secondary-network systems do not supply sufficiently reliable service for critical loads, emergency generators and/or batteries are sometimes provided together with automatic switching equipment so that service can be maintained to the critical loads in the event that the normal utility supply is interrupted. Such loads are found in hospitals, computer centers, key industrial processes, etc.

Single-phase residential loads are almost universally supplied through 120/240-V, 3-wire, single-phase services. Large appliances, such as ranges, water heaters, and clothes dryers, are served at 240 V. Lighting, small appliances, and convenience outlets are supplied at 120 V.

An exception to the preceding comments occurs when the dwelling unit is in a distributed secondary-network area served at 280Y/120 V. In this case, large appliances are supplied at 208 V and small appliances at 120 V.

Three-phase, 4-wire, multigrounded, common-neutral primary systems, such as 12.47Y/7.2 kV, 24.9Y/14.4 kV, and 34.5Y/19.92 kV, are used almost exclusively. The fourth wire of these Y-connected systems is the neutral for both the primary and the secondary systems. It is grounded at many locations. Single-phase loads are served by distribution transformers, the primary windings of which are connected between a phase conductor and the neutral. Three-phase loads can be supplied by 3-phase distribution transformers or by single-phase transformers connected to form a 3-phase bank. Primary systems in the 15-kV class are most commonly used, but the higher voltages are gaining acceptance. Figure 18-2 illustrates a typical radial primary feeder.

The 4-wire system is particularly economic for URD systems because each primary lateral or branch circuit consists of only one insulated phase conductor and the bare, uninsulated neutral rather than two insulated conductors. Also, only one primary fuse is required at each transformer and one surge arrester in overhead installations.

Three-phase, 3-wire primary systems are not widely used for public distribution, except in California. They can be used to supply single-phase loads by means of distribution transformers having primary winding connected between two phase conductors. Single-phase primary laterals consist of two insulated phase conductors; each single-phase distribution transformer requires two fuses and two surge arresters (where used). Three-phase loads are served through 3-phase distribution transformers or appropriate 3-phase banks. Two-phase systems are rarely used today.

18.4 CALCULATION OF VOLTAGE REGULATION AND I^2R LOSS

When a circuit supplies current to a load, it experiences a drop in voltage and a dissipation of energy in the form of heat. In dc circuits, voltage drop is equal to current in amperes multiplied by the resistance of the conductors, $V = IR$. In ac circuits, voltage drop is a function of load current and power factor and the resistance and reactance of the conductors. Heating is caused by conductor losses; for both dc and ac circuits they are computed as the square of current multiplied by conductor resistance in ohms. Watts $= I^2R$, or kW $= I^2R/1000$. Capacitance can usually be neglected for calculation in distribution circuits because its effect on voltage drop is negligible for the circuit lengths and operating voltages used. In circuit design, a conductor size should be selected so that it will carry the required load within specified voltage-drop limits and will have an optimized value of installed cost and cost of losses. Today, a conductor size meeting these criteria will operate well within safe operating temperature limits. In some cases, short-circuit current requirements will dictate the minimum conductor size.

Percent voltage drop or percent regulation is the ratio of voltage drop in a circuit to voltage delivered by the circuit, multiplied by 100 to convert to percent. For example, if the drop between a transformer and the last customer is 10 V and the voltage delivered to the customer is 240, the percent voltage drop is $10/240 \times 100 = 4.17\%$. Often the nominal or rated voltage is used as the denominator because the exact value of delivered voltage is seldom known.

Percent I^2R or percent conductor loss of a circuit is the ratio of the circuit I^2R or conductor loss, in kilowatts, to the kilowatts delivered by the circuit (multiplied by 100 to convert to percent). For example, assume a 240-V single-phase circuit consisting of 1000 ft of two No. 4/0 copper cables supplies a load of 100 A at unity power factor.

$$I^2R = 100^2 \times 2 \times 0.0512 = 1024 \text{ W} = 1.024 \text{ kW}$$

$$\text{Load delivered} = 240 \times 100 = 24{,}000 \text{ W} = 24 \text{ kW}$$

$$\%\ I^2R \text{ loss} = 1.024/24 \times 100 = 4.26\%$$

Direct-current voltage drop is easily calculated by multiplying load amperes I by ohmic resistance R of the conductors through which the current flows (see Sec. 4 for ohmic resistance of various conductors).

Example: A 500-ft dc circuit of two 4/0 copper cables carries 200 A. What is the voltage drop? Resistance of 1000 ft of 4/0 copper cable is 0.0512 Ω.

$$\text{Drop} = IR = 200 \times 0.0512 = 10.24 \text{ V}$$

If 240 is the delivered voltage,

$$\%\ \text{regulation} = 10.24/240 \times 100 = 4.26\%$$

I^2R or conductor loss in dc or ac circuits is calculated by multiplying the square of the current in amperes by ohmic resistance of the conductors through which the current flows. The result is in watts.

In dc circuits, percent voltage drop and percent conductor loss are identical.

$$\%\ \text{voltage drop} = IR/V \times 100$$

$$\%\ I^2R = I^2R/VI \times 100 = IR/V \times 100$$

In ac circuits, the ratio of percent conductor loss to percent voltage regulation is given approximately by the following approximate formula:

$$\frac{\%\ I^2R \text{ loss}}{\%\ \text{voltage drop}} = \frac{\cos\phi}{\cos\theta\,\cos(\phi - \theta)} \tag{18-1}$$

where θ = power-factor angle and ϕ = impedance angle; that is, $\tan\phi = X/R$.

TABLE 18-1 Voltage Drop in Volts per 100,000 A · ft, 2-Wire DC Circuits (Loop)

Conductor size, AWG or kcmil		Volts drop per 100,000 A · ft, 90º copper temp
Copper	Approx. equivalent aluminum	
6	4	102.8
4	2	64.6
2	1/0	40.7
1/0	3/0	25.6
2/0	4/0	20.3
4/0	336	12.8
350	556	7.71
500	795	5.39
1000		2.70
1500		1.80
2000		1.35

Note: 1 ft = 0.3048 m.

Table 18-1 gives voltage drop in volts per 100,000 A · ft for 2-wire dc circuits for a number of conductor sizes. Ampere-feet is the product of the number of amperes of current flowing and the distance in feet between the sending and receiving terminals multiplied by 2 to take into account the drop in both the outgoing and return conductors. Or the feet can be considered to be the total number of conductor feet, outgoing and return.

Table 18-1 also gives the voltage drop for 3-wire circuits when serving balanced loads, where the term "feet" is taken to mean twice the number of feet between sending and receiving terminals.

Example 1. What is the voltage drop and percent voltage drop when 200 A dc flows 1500 ft one way through a 2-wire, 120-V, 556-kcmil aluminum circuit? First determine ampere-feet factor as 100 × 1500/100,000 = 1.5. From Table 18-1, the voltage drop is 7.71 V per 100,000 A · ft. This value multiplied by the 1.5 factor gives the total voltage drop = 1.5 × 7.71 = 11.6 V. The percent voltage drop = 11.6 × 100/120 = 9.64%. The percent conductor loss also is 9.64%, which is equivalent to 120 × 100 × 0.0954 = 1.16 kW.

Example 2. A mine 1 mile from a motor-generator station must receive 100 kW dc at not less than 575 V. Maximum voltage of the generator is 600 V. What conductor size should be used?

$$\text{Max. current} = \frac{100{,}000\ \text{W}}{575\ \text{V}} = 173.9\ \text{A}$$

$$\text{Loop ft} = 2 \times 5280 = 10{,}560\ \text{ft}$$

$$\frac{\text{A} \cdot \text{ft}}{100{,}000} = \frac{173.9 \times 10{,}560}{100{,}000} = 18.36$$

$$18.36 \times \text{voltage drop per } 100{,}000\ \text{A} \cdot \text{ft from Table 18-1} = 25\ \text{V}$$

Therefore, voltage drop per 100,000 A · ft = 25/18.36 = 1.36. From Table 18-1, the copper conductor size corresponding to 1.36 V/100,000 A · ft is 2000 kcmil copper.

Calculating Voltage Drop in AC Circuits. The voltage drop per mile in each round wire of 3-phase 60-Hz line with equilateral spacing D inches between centers or in each wire of a single-phase line D inches between centers is

$$\tilde{V}\,\text{drop} = \tilde{I}R + j\tilde{I}\left(0.2794 \log \frac{D}{r} + 0.03034\,\mu\right) \quad \text{volts in phasor form} \qquad (18\text{-}2)$$

where $\tilde{I}$ is in phasor amperes, R is the 60-Hz resistance of the wire per mile, Ω, log is the log to base 10, r is the radius of round wire, in, and μ is the permeability of the wire (unity for nonmagnetic materials such as copper or aluminum). j in Eq. (18-2) denotes an angle of 90°; $+j$ means 90° leading, $-j$ means 90° lagging. Thus, the expression for phasor current lagging the reference voltage is $\tilde{I} = I_x - jI_y = I\sqrt{\theta^\circ}$ with reference to a conveniently chosen horizontal axis of reference—usually sending- or receiving-end voltage. The symbol ~ over I or V indicates phasor values. Voltage drops determined in this manner are also phasors and are with respect to the reference axis.

When wire is stranded, an equivalent radius must be used for r in Eq. (18-2). $r = 0.528\ \sqrt{A}$ for 7 strands, $r = 0.5585\ \sqrt{A}$ for 19 strands, $r = 0.5675\ \sqrt{A}$ for 37 strands, where r = equivalent radius, in, and A = area of metal, in^2.

Frequency is 60 Hz for the constants in parentheses in Eq. (18-2), which gives reactance X in ohms per mile. For 25 Hz, multiply by 25/60. The equation is sometimes written

$$\tilde{V} \text{ drop per mile} = \tilde{I}\,(R + jX) = \tilde{I}\tilde{Z} \qquad \text{volts in phasor form} \tag{18-3}$$

where I is in phasor amperes and $Z = Z/\phi \cdot \Omega$/mi at 60 Hz.

Three unsymmetrically spaced wires a, b, and c of a 3-phase circuit with correct transpositions can have voltage drop in each wire calculated by Eq. (18-2) by substituting for D the geometric mean of the three interaxial distances:

$$D = \sqrt[3]{D_{ab}D_{bc}D_{ca}}$$

The Phasor Method. In Eq. (18-3), I is in vector amperes,

$$\tilde{I} = I_x - jI_y = I\angle\theta$$

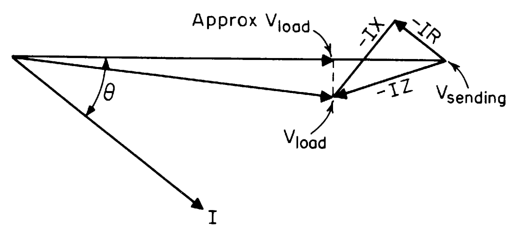

FIGURE 18-3 Phasor diagram showing voltage relationships.

where θ is the angle that the current lags (or leads) the voltage. The sending-end voltage is usually chosen as the axis, or phasor, of reference in drawing the phasor diagram. For example, consider Fig. 18-3, where sending voltage $V_s = V_s\underline{/\theta^\circ}$, load current $I = I\underline{/\theta^\circ}$, circuit impedance $\tilde{Z} = Z\underline{/\theta^\circ} = R + jX$, and load voltage $\tilde{V}_L = \tilde{V}_s - \tilde{I}\tilde{Z}$ (all phasors). The symbol $\angle$ is used for positive angles, assuming that the counterclockwise direction from the phasor or reference is positive and the clockwise directions negative. Assume that $V_s = 230/0^\circ$, $\tilde{I} = 50\underline{/-36.87^\circ}$, $\tilde{Z} = 0.2\underline{/71.57^\circ}$, and $\tilde{Z} = R + jX$. Thus

$$\begin{aligned}
\tilde{V}_L &= 230/0^\circ - 50\,\underline{/36.87^\circ} \times 0.2\underline{/71.57^\circ} \\
&= 230\underline{/\theta^\circ} - 10\underline{/34.70^\circ} \\
&= 230 - 10\cos 34.70^\circ - j\,10 \sin 34.70^\circ \\
&= 230 - 8.22 - j\,5.69 = 221.78 - j\,5.69 \\
&= 221.78 \text{ (very nearly)}
\end{aligned}$$

Neglecting the term $-j\,5.69$ simplifies the final calculation and gives the load voltage within a fraction of 1% of the precise result. This method is sufficiently accurate for practically all distribution engineering calculations and can be thought of as

$$V \text{ drop} = IR\cos\theta + IX\sin\theta = IZ\cos(\phi - \theta) \tag{18-4}$$

where I and Z are absolute magnitudes, not phasor quantities, ϕ is the impedance angle, and θ is the power-factor angle by which the current lags (or leads) the voltage. Calculating the drop in the above example by this method:

$$V \text{ drop} = 50 \times 0.2 \times \cos 71.57° \times \cos 36.87°$$
$$+ 50 \times 0.2 \times \sin 71.57° \times \sin 36.87°$$
$$= 2.53 + 5.69 = 8.22 \text{ V}$$

or

$$V \text{ drop} = IZ \cos(\phi - \theta) = 50 \times 0.2 \times \cos(71.57° - 36.87°)$$
$$= 10 \cos(34.7°) = 10 \times 0.822 = 8.22 \text{ V}$$

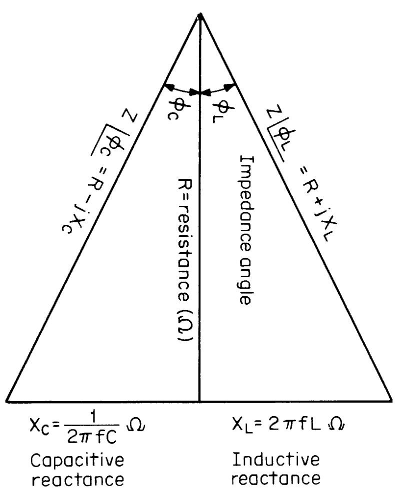

FIGURE 18-4 Impedance diagrams for series connection of resistance and reactance (L = inductance, in henrys; C = capacitance, in farads; F = frequency, in hertz).

Impedance Z can be visualized as the hypotenuse of a right triangle in which the base is the resistance R and the altitude is the reactance X. In phasor form, $\tilde{Z} = R \pm jX$, where the positive sign is used for inductive reactance and the negative sign for capacitive reactance. Impedance also can be expressed as $\tilde{Z} = Z\underline{/\phi°}$, where Z is the absolute magnitude and ϕ is the angle between $\tilde{Z}$ and R in Fig. 18-4. This angle is an absolute value in that it has no relationship to the axis of reference in a phasor diagram, as do voltage and current. Alternating current causes a voltage drop in resistance which is in time phase with the current and in inductive reactance a drop which leads the current by 90 electrical degrees, assuming the positive direction for measurement of angles is counterclockwise. Or conversely, the current in an inductive reactance lags the voltage drop by 90°.

Impedance Values. Tables are available which give 60-Hz impedance values in ohms per 1000 ft for common sizes of wire and cable. The values can be expressed in the form $\tilde{Z} = R + jX$, which can be converted to the form $Z\underline{/\phi°}$ if desired. The latter form is convenient to use in voltage-drop calculations when the current is expressed as $I\underline{/\phi°}$.

Power Factor. In typical distribution loads, the current lags the voltage, as shown in Fig. 18-3, where θ is shown as the angle between current and sending voltage and $\cos\theta$ is referred to as the *power factor* of the circuit. In a purely resistive circuit, the current and voltage are in phase; consequently, the power factor is 1.0 or unity. In a purely inductive circuit, the voltage and current are out of phase by 90 electrical degrees, resulting in a power factor of zero. In a circuit consisting of a resistance in series with a reactance of equal ohmic value ($\phi = 45°$), $\theta = \pm 45°$ also. Thus, the power factor is $\cos 45° = 0.707$, or 70.7%.

In a single-phase ac circuit, the load in kW can be expressed as

$$\text{kW} = EI \cos\theta \tag{18-5}$$

where E = magnitude of rms line-to-neutral voltage, kV
I = magnitude of current, rms amperes
θ = electrical angle between phasor voltage and current

From Eq. (18-5), it is obvious that the magnitude of the current for a given voltage and kilowatt load depends on the power factor, or

$$I = \text{kW}/(E \cos \theta) \tag{18-6}$$

The corresponding equations for balanced 3-phase circuits are

$$\text{kW} = \sqrt{3}\, EI \cos \theta \tag{18-7}$$

and

$$I = \text{kW}/(\sqrt{3}\, E \cos \theta) \tag{18-8}$$

where the symbols are as specified above, and θ is measured as the angle between the line-to-neutral voltage of a given phase and the current in that phase.

Example. Given a load of 500 kW at 80% power factor (lagging), 7.2 kV circuit voltage, 60-Hz, single-phase circuit using 1/0 aluminum conductor spaced 30 in on centers. The load is located 1 mi from the substation. What is the voltage drop? From tables on conductor characteristics,

$$r = 0.185\ \Omega/1000\ \text{ft}$$

$$x = 0.124\ \Omega/1000\ \text{ft}$$

Therefore, $$R + jX = 5.28\,(0.185 + j\,0.124) = 0.9769 + j\,0.6547\ \Omega$$

From Eq. (18-6),

$$I = \frac{\text{kW}}{E \cos \theta} = \frac{500}{7.2 \times 0.8} = 86.81\ \text{A}$$

$$E = 7.2\angle\theta^\circ$$

$$\cos \theta = 0.80$$

$$\theta = 36.87^\circ$$

and $$\sin \theta = 0.60$$

From Eq. (18-4),*

$$\text{Voltage drop} = 2(IR \cos \theta + IX \sin \theta) = (86.81 \times 0.9769 \times 0.8 + 86.81 \times 0.6547 \times 0.6)$$
$$= 2(67.84 + 34.10) = 203.88\ \text{V}$$

Calculation of 3-Phase Line Drops with Balanced Loads. In 3-phase circuits with balanced loads on each phase, the line-to-neutral voltage drop is merely the product of the phase current and the conductor impedance as determined from standard tables. There is no return current with balanced 3-phase loads. Thus, the line-to-line voltage drop is $\sqrt{3}$ times the line-to-neutral drop, or

$$V_{\text{drop}\,L-L} = \sqrt{3}(IR \cos \theta + IX \sin \theta) \tag{18-9}$$

*The factor of 2 is used for a single-phase system to represent the impedance of the outgoing conductor and the return conductor.

For example, assume that the circuit of the preceding example now is a 3-phase 12.47-kV circuit 1 mi long with the same 1/0 aluminum conductors at an equivalent spacing of 30 in and a load of $3 \times 500 = 1500$ kW at 0.8 pf lagging. What is the line-to-line voltage drop? R and X are the same values as previously; that is, $R + jX = 0.9769 + j\,0.6547\ \Omega$.

The current per phase from Eq. (18-7) is

$$I = \frac{\text{kW}}{\sqrt{3}\,E\cos\theta} = \frac{1500}{\sqrt{3}\times 12.47 \times 0.8} = 86.81\text{ A}$$

as before,

$$\begin{aligned} V_{\text{drop } L-L} &= \sqrt{3}\,(IR\cos\theta + IX\sin\theta) \\ &= \sqrt{3}\,(86.81 \times 0.9769 \times 0.8 + 86.81 \times 0.6547 \times 0.6) \\ &= 117.51 + 59.06 = 176.57\text{ V (approx.)} \end{aligned}$$

Calculation of Voltage Drop in Unbalanced Unsymmetrical Circuits. If there are n different wires $a, b, c, d, \cdots, n$ carrying currents $I_a, I_b, I_c, \cdots, I_n$, respectively, whether 2-, 3-phase, the voltage drop in wire a per mile at 60 Hz is

$$I_aR_a + j\left[0.2794\left(I_a\log\frac{1}{r} + I_b\log\frac{1}{D_{ab}} + I_c\log\frac{1}{D_{ac}} + \cdots + I_n\log\frac{1}{D_{an}}\right) + 0.03034\,\mu\,I_a\right] \quad \text{volts in phasor form} \qquad (18\text{-}10)$$

where currents are in phasor amperes, R_a is 60-Hz ohmic resistance of conductor a per mile, r is equivalent radius, in inches, of conductor a, D_{ab}, D_{ac}, and D_{an} are distances, in inches, between centers of conductors a and b, a and c, and a and n, and u is the permeability of conductor a (unity for nonmagnetic material). To get the drop in b, replace all a's by b's and all b's by a's in Eq. (18-10); similarly, to get the drop in c, interchange a's and c's; likewise for n. For 25 Hz, multiply that part of Eq. (18-10) which is in brackets by 25/60. Equation (18-10) gives voltage drop for any degree of load unbalance, power factor, or conductor arrangements. In using this formula, calculations are made easier by choosing voltage to neutral as the reference axis.

Approximate Method of Calculating Voltage Drop in Unbalanced, Unsymmetrical Circuits. Equation (18-10) requires laborious calculations and is used only when exact results are necessary. Voltage drops sufficiently accurate for engineering purposes can be calculated by using an equivalent impedance for each conductor. The reactance component of the equivalent impedance is computed from a spacing D equal to the geometric means of the interaxial distances of the other conductors to the conductor being considered. For instance, if there are four conductors a, b, c, and n for conductor a, $D = \sqrt[3]{D_{ab}, D_{ac}, D_{an}}$; for conductor b, $D = \sqrt[3]{D_{ab}, D_{bc}, D_{bn}}$.

Phasor and Connection Diagrams. Phasor and connection diagrams are drawn in computing voltage drops in unbalanced circuits. Figure 18-5 shows an unbalanced 4-wire 3-phase 4160Y/2400-V circuit with assumed loads, power factors, and equivalent line impedances. Phase-to-neutral drops between source and load are given by the following, using one of the many possible voltage-notation conventions:

$$\begin{aligned} V_{na} - V_{n'a'} &= I_aZ_a + I_nZ_n \\ V_{nb} - V_{n'b'} &= I_bZ_b + I_nZ_n \\ V_{nc} - V_{n'c'} &= I_cZ_c + I_nZ_n \end{aligned} \qquad (18\text{-}11)$$

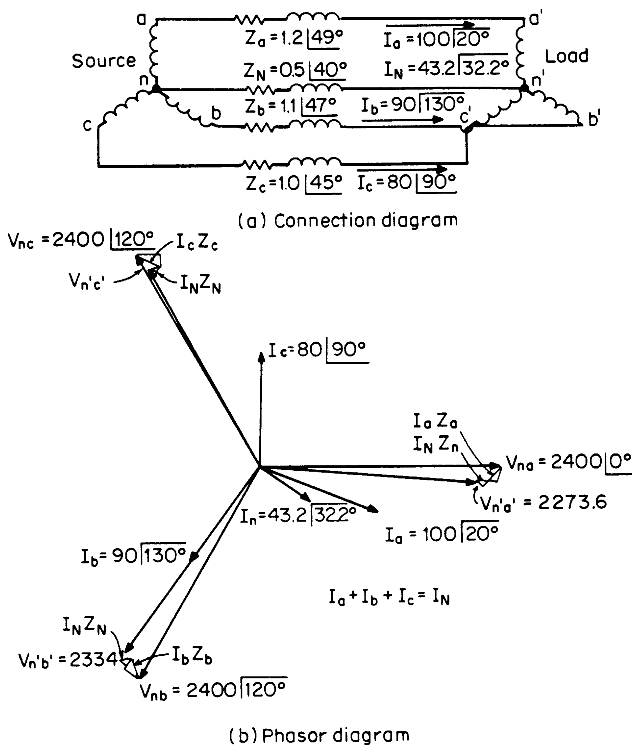

FIGURE 18-5 Connections and phasor diagrams for unbalanced loads and unsymmetrical circuit.

Phase-to-phase drops between source and load are given by the following:

$$
\begin{aligned}
V_{ba} - V_{b'a'} &= I_a Z_a - I_b Z_b \\
V_{ac} - V_{a'c'} &= I_c Z_c - I_a Z_a \\
V_{cb} - V_{c'b'} &= I_b Z_b - I_c Z_c
\end{aligned}
\tag{18-12}
$$

In computing line-to-neutral drop in phase a, it is convenient to choose V_{na} as the axis of reference.

$$
\begin{aligned}
V_{na} - V_{n'a'} &= I_a Z_a + I_n Z_n = (100\angle 20^\circ)(1.2\angle 49^\circ) + \mathrm{X}(43.2\angle 32.2^\circ)(0.5\angle 40^\circ) \\
&= 120\angle 29^\circ + 21.6\angle 7.8^\circ = 126.4 + j61.9
\end{aligned}
$$

Load voltage $V_{n'a'} = 2400 - 126.4 - j61.9 = 2273.6$ V (very nearly)

Likewise, in computing line-to-neutral drop in phase b, it is convenient to choose V_{nb} as the axis of reference. The phasor diagram of Fig. 18-5 must be rotated in a counterclockwise direction 120°; then $I_b = 90\angle 10^\circ$ and $I_n = 43.2\angle 87.8^\circ$.

$$
V_{nb} - V_{n'b'} = I_b Z_b + I_n Z_n = (90\angle 10^\circ(1.1\angle 47^\circ) + (43.2\angle 87.8^\circ)(0.5\angle 40^\circ) = 65.8 + j76.6
$$

Load voltage $V_{n'b'} = 2400 - 65.8 - j76.6 = 2334.2$ V (very nearly)

Drop in the neutral conductor of a 4-wire 3-phase circuit or a 3-wire 2-phase circuit makes resultant drop on the more heavily loaded phases greater than it would be for the same current under balanced conditions. Likewise, net drop is less on more lightly loaded phases than for the same current when balanced.

Distributed Loads, Voltage Drop, and I^2R Loss. Voltage drop and conductor power losses resulting from a concentrated load on a distribution line can be calculated easily as shown in earlier parts of this section. However, distribution circuit loads are generally considered to be distributed—often, but not always, uniformly. Distributed load may be considered as effectively concentrated at one point along the circuit to calculate total voltage drop and at another point to calculate conductor I^2R losses in the conductor. If the load is uniformly distributed along the feeder, the total voltage drop can be calculated by assuming that the entire load is concentrated at the midpoint of the circuit, and the total I^2R losses can be calculated by assuming that the load is concentrated at a point one-third the total distance from the source.

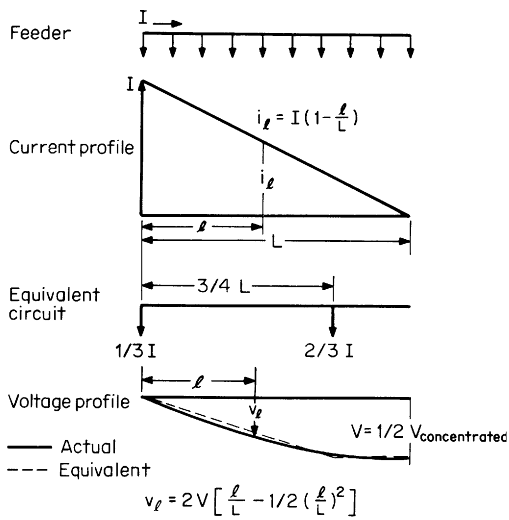

FIGURE 18-6 Uniformly distributed loads.

However, if there is a superimposed through load beyond the given feeder section, this method of calculation becomes cumbersome. It is possible to develop a single precise equivalent circuit for both the voltage-drop and loss calculations. Figure 18-6 shows the load representation and equivalent for uniformly distributed loads. Equivalents also can be developed for other types of distribution. Figure 18-6 shows the equivalent circuit of two-thirds of the total load concentrated at three-quarters of the total distance from the source.

18.5 THE SUBTRANSMISSION SYSTEM

Definition. *Subtransmission* is that part of the utility system which supplies distribution substations from bulk power sources, such as large transmission substations or generating stations. In turn, the distribution substations supply primary distribution systems. Subtransmission has many of the characteristics of both transmission and distribution in that it moves relatively large amounts of power from one point to another, like transmission, and at the same time it provides area coverage, like distribution.

In some utility systems, transmission and subtransmission voltages are identical; in other systems, subtransmission is a separate and distinct voltage level (or levels). This is easy to account for because in the evolutionary development of utility systems, today's transmission voltage naturally tends to become tomorrow's subtransmission voltage, just as today's subtransmission voltage tends to become tomorrow's primary distribution voltage.

Because of the wide range of voltages used in subtransmission, and because of the wide variation in geographic conditions and local ordinances, subtransmission circuits are sometimes built on pole lines on city streets, or on tower lines on private rights-of-way, or in underground cables.

Voltages. Voltages of subtransmission circuits range from 12 to 345 kV, but today the levels of 69, 115, and 138 kV are most common. The use of the higher voltages is expanding rapidly as higher primary voltages are receiving increased usage. Current practice as indicated by an informal utility survey is shown in Fig. 18-7; 115 and 138 kV together comprise about half the usage, 69 kV about 20%; 230 kV usage is becoming substantial, reflecting the growing use of 25- and 34.5-kV primary distribution.

Conductors of ACSR or aluminum generally have supplanted copper in overhead construction, and aluminum conductors are being used increasingly in cables.

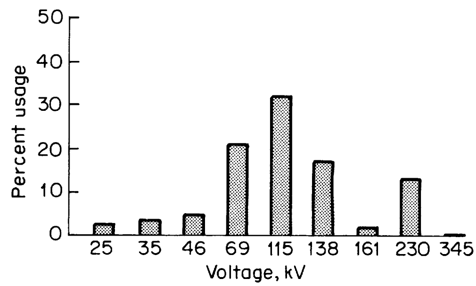

FIGURE 18-7 Use of distribution substation high-voltage rating.

Voltage Regulation of Subtransmission. The size of conductors used in subtransmission systems is determined by (1) magnitude and power factor of the load, (2) emergency loading requirements, (3) distance that the load must be carried, (4) operating voltage, (5) permissible voltage drop under normal and emergency loading, and (6) optimal economic balance between installed cost of the conductor and cost of losses. Table 18-2 gives the line-to-neutral voltage drops per 100,000 A · ft for common cable and overhead conductor sizes and representative power factors for 34.5- and 69-kV subtransmission. Values in the table are based on the approximate formula (18-4)

$$V_{\text{drop}} = IR \cos\theta + IX \sin\theta = IZ \cos(\phi - \theta)$$

where R, X, and Z are 60-Hz resistance, reactance, and impedance in ohms per 1000 ft of a single conductor, θ is the power-factor angle in electrical degrees, and ϕ is the impedance angle, $\tan^{-1}(X/R)$.

Examples of How to Use Table 18-2. Determine the voltage drop when a 3-phase 20,000-kVA load at 95% power factor is carried 10 mi over an overhead 69-kV circuit with No. 2/0 ACSR conductor. Assuming the receiving-end voltage to be 69 kV, the current is

$$I = \frac{\text{kVA}}{\sqrt{3}E} = \frac{20{,}000}{\sqrt{3} \times 69} = 167.35 \text{ A}$$

Circuit feet are

$$10 \times 5280 = 52{,}800 \text{ ft}$$

Thus

$$\frac{\text{A}\cdot\text{ft}}{100{,}000} = \frac{167.35 \times 52{,}800}{100{,}000} = 88.36$$

From the overhead portion of Table 18-2, the voltage drop per 100,000 A · ft at 95% power factor for a No. 2/0 ACSR conductor is 19.1 V. Therefore, the total voltage drop for the example is 88.36 × 19.1 = 1687.68 V line-to-neutral. Since normal line-to-neutral voltage is $69/\sqrt{3} = 39.838$ kV, or 39,838 V, the percent voltage drop is 1687.68 × 100/39,838 = 4.24%.

Assuming that permissible voltage drop is the limiting factor, what overhead ACSR conductor size should be used to supply a load of 40,000 kVA at 95% power factor and receiving-end voltage of 69 kV with a permissible drop of 5% and 8 mi between sending and receiving ends?

$$\text{Current} = \frac{40{,}000}{\sqrt{3} \times 69} = 334.71 \text{ A}$$

$$\text{Circuit feet} = 8 \times 5280 = 42{,}240 \text{ ft}$$

$$\frac{\text{A}\cdot\text{ft}}{100{,}000} = \frac{334.71 \times 42{,}240}{100{,}000} = 141.38$$

TABLE 18-2 Voltage Drops per 100,000 A · ft* for 3-Phase, 60-Hz, 34.5- and 69-kV Subtransmission

	Voltage class

Note: 1 in = 25.4 mm; 1 in^2 = 645 mm^2; 1 ft = 0.3048 m. Regulation of copper conductors can be estimated with reasonable accuracy as that of aluminum conductors two sizes larger. For ampacities of cables, see Tables 18–22 and 18–23.

*Values in the table give the difference in absolute value between sending-end and receiving-end line-to-neutral voltages of a balanced 3-phase circuit.

†Underground cable impedances are based on 90°C conductor temperature with close triangular spacing of cables using typical solid-dielectric insulation, 100% insulation level, single conductor, shielded and jacketed.

‡Overhead conductor impedances are based on 50°C conductor temperature, ACSR construction, 600 A/in^2 density with 60-in equivalent spacing for 35 kV and 90 in for 69 kV.

The permissible voltage drop is $0.05 \times 69{,}000/\sqrt{3} = 1991.92$ V line-to-neutral. The corresponding permissible voltage drop per 100,000 A · ft is

$$\frac{1991.92}{141.38} = 14.1 \text{ V}/100{,}000 \text{ A} \cdot \text{ft}$$

From Table 18-2 it is seen that this corresponds approximately to No. 4/0 ACSR.

Subtransmission System Patterns. A wide variety of subtransmission system designs are in use, varying from simple radial systems to systems similar to networks. The radial system is not generally used because most utilities today plan their subtransmission-distribution substation systems so that one major contingency such as outage of a subtransmission circuit or failure of a distribution substation transformer will not result in loss of load—or at least the loss of load will be of short duration while automatic switching operations take place. Thus, loop and multiple circuit patterns predominate. Figures 18-8 and 18-9 illustrate the basic nature of these two patterns. The loop pattern implies that a single circuit originating at one bulk power source "loops" through several substations before terminating at another bulk source or even at the original source. Reinforcing ties, as indicated by the dotted connection, are used when the number of substations exceeds some predetermined level.

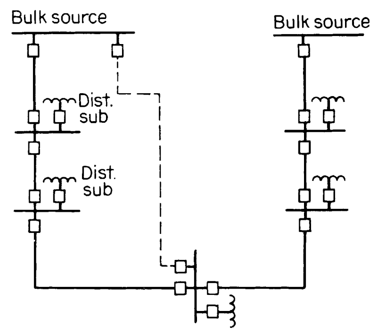

FIGURE 18-8 Loop pattern.

Multiple circuit pattern implies the use of two or more circuits which are tapped at each substation, as illustrated in Fig. 18-9. The circuits may be radial or may terminate in a second bulk power source. Many variations of the two basic patterns are found. From a recent informal survey of approximately 50 major utilities, it appears that the two patterns are about equally used.

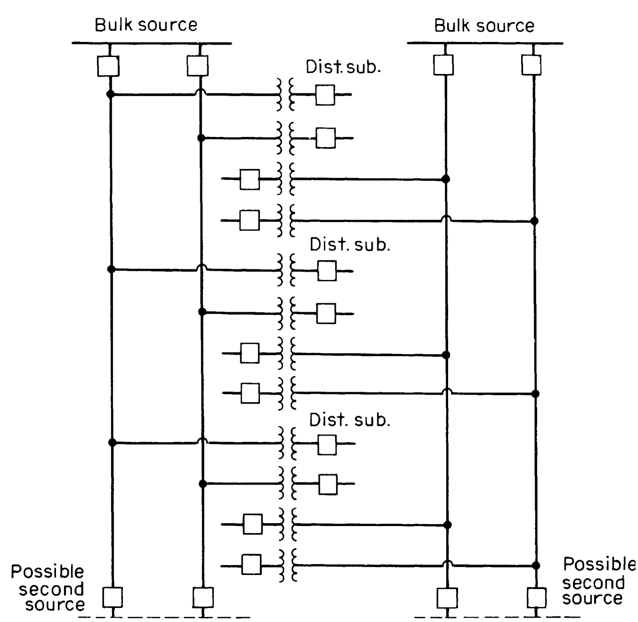

FIGURE 18-9 Multiple pattern.

A vast majority of today's subtransmission is of overhead construction, much of it built on city streets as contrasted with private rights of way. However, appearance and environmental considerations, difficulty in obtaining substation sites and rights of way, and rapid growth of underground distribution are certain to exert continuing pressure on the undergrounding of subtransmission. Even with the use of direct-buried, solid-dielectric cables, the cost of underground subtransmission is many times the cost of overhead circuits, particularly where the overhead subtransmission can be built on city streets.

Thus, a requirement to build future subtransmission underground would have major impact on the balance of overall subtransmission-substation-primary distribution costs. It undoubtedly would focus attention on minimizing the amount of subtransmission circuitry needed to cover the load area, which in turn would favor

Fewer, larger substations

Loop subtransmission pattern rather than multiple parallel circuits

Depending on load density in this area, it *could* favor

Higher primary voltage

Higher subtransmission voltage

Changes in either subtransmission or primary voltage levels are major decisions which require study in depth and ultimately the commitment of large financial resources.

18.6 PRIMARY DISTRIBUTION SYSTEMS

The primary distribution system takes energy from the low-voltage bus of distribution substations and delivers it to the primary windings of distribution transformers.

Overhead Primary Systems. Typically, overhead primary distribution systems have been operated as radial circuits (normally open loops) from the substation outward. Figure 18-2 shows schematically a typical primary feeder in a predominantly residential area; an overhead 12.47Y/7.2-kV system is used for illustrative and functional purposes, but underground systems will be discussed later.

The main feeder backbone usually is a 3-phase 4-wire circuit from which the single-phase lateral or branch circuits are tapped through fuse cutouts to protect the system from faults on the lateral circuits. The single-phase lateral circuits consist of one phase conductor and the neutral. Distribution transformers are connected between the phase and the neutral; in this case they would have a rating of 7200 V.

Utilities use automatic reclosing feeder breakers and line reclosers to minimize service interruptions. However, serious problems involving the main will cause an outage to some or all of the feeder until line crews can locate the problem and manually operate pole-top disconnecting switches appropriately to isolate the problem and to pick up as much load as possible from adjacent feeders. Switches of this kind usually are found in both the main and lateral circuits, as indicated in Fig. 18-2. Also, it is often possible to make and to remove connections while the system is energized through the use of hot-line tools, hot-line clamps, insulated bucket trucks, etc.

Generally, this approach has provided an acceptable level of service because overhead system troubles are relatively easy to locate, and repair times are short. However, when the entire primary system is installed underground, while the frequency of serious trouble is expected to be lower than in overhead systems, it is likely that the time involved in pinpointing the location and making repairs will be much longer than in overhead systems.

Underground System. While a relatively small percentage of new general-purpose feeders is being installed totally underground, the trend is growing and is expected to continue to grow.

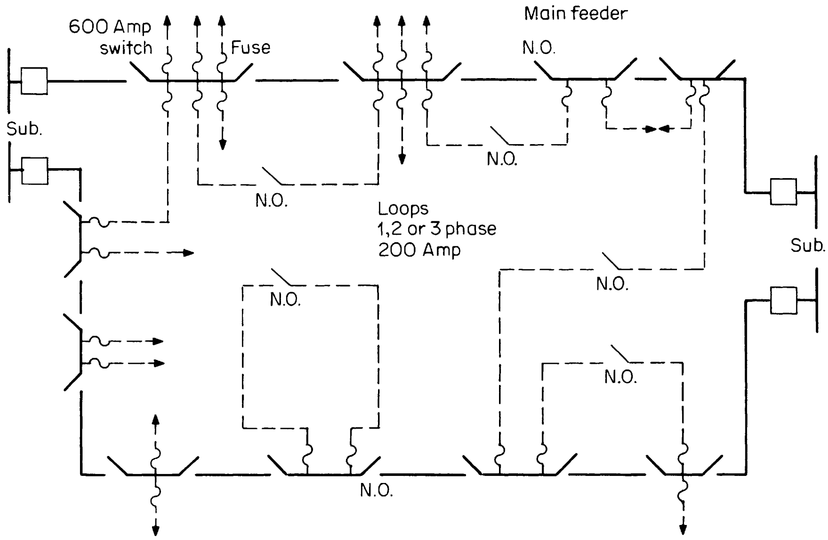

FIGURE 18-10 Typical main-feeder underground circuit. (All switches closed unless shown otherwise.)

Since it is difficult to accomplish many maintenance and operating functions on an underground system while it is "hot," or energized, in contrast to overhead-system practices, specific provisions must be made in the system design to incorporate needed sectionalizing and overcurrent protective equipment.

The main feeder plan shown in Fig. 18-10 is reasonably typical of present practice on underground systems supplying basically residential and small commercial loads. Note that the main feeders are operated radially, but with normally open ties to adjacent main feeders. The main feeder switches usually are 3-phase, 600-A, manually operated load-break switches. The single-phase and 3-phase lateral circuits also are operated as normally open loops.

Switching in the 200-A circuits can be accomplished by means of either load-break switches or separable, insulated cable connectors. Usually, two main feeder switches are grouped along with the lateral circuit switching and protective equipment into one piece of pad-mounted equipment.

The primary feeders supplying secondary-network systems in metropolitan areas usually are radial 3-wire circuits consisting of 3/c cables in underground duct lines. The 3-phase network transformers are T-tapped to the primary feeders.

Automation. With increasing emphasis on reliability of service, a definite trend is under way to make greater use of protective and sectionalizing equipment in the primary system in order to minimize the number of customers involved in an outage and to reduce the outage time. Proposed schemes run the gamut from manually operated devices to automatic devices remotely controlled from distribution centers. The remote-controlled schemes vary from some type of supervisory control to computer-controlled systems with built-in logic to cope quickly with the various problems which may arise.

Primary-Distribution-System Voltage Levels. Since World War II, the 15-kV distribution class has become firmly entrenched and today represents 60% to 80% of all primary distribution activity. Very little expansion of lower-voltage systems is taking place. There is a trend, however, toward increasing usage of primary voltage levels above the 15-kV class. This trend has an impact on substation and subtransmission practices as well because higher primary voltages almost axiomatically lead to larger substations and higher subtransmission voltages.

The two principal voltages above 15 kV are 24.49Y/14.4 kV and 34.5Y/19.92 kV. New line additions at these voltage levels now average more than 20% of those at 15 kV.

To achieve economy, the higher primary voltages also require heavier feeder loadings which could imply reduced service reliability because more customers are affected by primary faults. Greater use of automatic switching and protective equipment can do much toward preserving a level of reliability to which the public has become accustomed. This is another reason that most observers believe that an increased amount of automation is inevitable in our distribution systems.

For example, a typical 12.47-kV feeder serves a normal peak load on the order of 6000 to 7000 kVA. On this basis, the probable peak loading of a fully developed 34.5-kV feeder would be expected to be in the neighborhood of 18,000 to 20,000 kVA.

Why go to high-voltage distribution (HVD)? Most of today's systems in the 15-kV class are not voltage-drop-limited, and cost of higher-voltage laterals and associated equipment needed to cover the load area is greater. The major economic advantages are:

1. Larger (and fewer) substations
2. Fewer circuits
3. Possibility of eliminating a system voltage-transformation level where the new primary voltage is the former subtransmission level

Other advantages of HVD which are difficult to evaluate in dollars are:

1. Reduced losses in early stages of development
2. Reduced voltage regulation
3. Greater distance or area coverage
4. Fewer circuits per route (reduced congestion)
5. Fewer circuit positions at substations
6. Fewer substation sites
7. Greater flexibility in supplying large spot loads

Some of the disadvantages of HVD have been

1. Cost of equipment
2. Reliability due to increased exposure
3. Higher equipment failure rates
4. Operability

Conductor Sizes. The conductor sizes used in overhead primaries generally range from No. 2 AWG to 795 kcmil. ACSR and aluminum conductors have almost entirely displaced copper for new construction. Aerial cable is used occasionally for primary conductors in special situations where clearances are too close for open-wire construction or where adequate tree trimming is not practical. The type of construction more frequently used consists of covered conductors (nonshielded) supported from the messenger by insulating spacers of plastic or ceramic material. The conductor insulation, usually a solid dielectric such as polyethylene, has a thickness of about 150 mils for a 15-kV class circuit and is capable of supporting momentary contacts with tree branches, birds, and animals without puncturing. This type of construction is commonly referred to as *spacer cable*.

The conductor sizes most commonly used in underground primary distribution vary from No. 4 AWG to 1000 kcmil. Four-wire main feeders may employ 3- or 4-conductor cables, but single-conductor concentric-neutral cables are more popular for this purpose. The latter usually employ crosslinked polyethylene insulation, and often have a concentric neutral of one-half or one-third of the main conductor cross-sectional area.

The smaller-sized cables used in lateral circuits of URD systems are nearly always single-conductor, concentric-neutral, crosslinked polyethylene-insulated, and usually directly buried in the earth. Insulation thickness is on the order of 175 mils for 15-kV-class cables and 345 mils for 35-kV class with 100% insulation level.

Stranded or solid aluminum conductors have virtually supplanted copper for new construction, except where existing duct sizes are restrictive. With the solid-dielectric construction, in order to limit voltage gradient at the surface of the conductor within acceptable limits, a minimum conductor size of No. 2 AWG is common for 15-kV-class cables, and No. 1/0 AWG for 35-kV class.

Voltage Regulation of Primary Distribution. Table 18-3 can be used to determine the voltage drop of an existing circuit when the load data are known or to determine minimum conductor size required to meet a given voltage-drop limit. Data are given for various underground-cable and overhead-conductor configurations for 12.47 and 34.5 kV.

Example. What is the voltage drop for a 34.5-kV overhead circuit 3 mi long using 4/0 aluminum conductor and carrying a balanced 3-phase load of 15,000 kVA at 90% power factor: The current is $15{,}000/\sqrt{3} \times 34.5 = 251$ A. The circuit feet are $3 \times 5280 = 15{,}840$ ft. Thus $\text{A} \cdot \text{ft}/100{,}000 = 251 \times 15{,}840/100{,}000 = 39.758$. From Table 18-3, the appropriate voltage drop per 100,000 A · ft is 14.0 V line-to-neutral. Therefore, the total voltage drop for the example is

$$39.758 \times 14.0 = 556.6 \text{ V line-to-neutral}$$

Since normal line-to-neutral voltage is $34{,}500\sqrt{3} = 19{,}920$ V, the percent voltage drop is

$$556.6 \times 100/19{,}920 = 2.79\%$$

Example. What is the minimum aluminum conductor size to carry 6000 kVA at 90% power factor of balanced 3-phase load over a 2-mi, 12.47Y/7.2-kV feeder with no more than a 3% voltage drop? Load current is $6000/\sqrt{3} \times 12.47 = 277.8$ A. Circuit feet $= 2 \times 5280 = 10{,}560$ ft. Thus

$$\frac{\text{A}\cdot\text{ft}}{100{,}000} = \frac{277.8 \times 10{,}560}{100{,}000} = 29.34$$

$$\text{Permissible voltage drop} = 0.03 \times \frac{12{,}470}{\sqrt{3}} = 216 \text{ V}$$

The corresponding drop per 100,000 A · ft is $216/29.34 = 7.36$ V, line-to-neutral. From Table 18-3, this value falls between 477 and 795 kcmil, so that the latter size would be chosen.

Loading. Loading of primary feeders varies greatly depending on primary voltage, load density, emergency loading requirements, etc. Typical peak loads on 15-kV class feeders are 6 to 7000 kVA. Peak loads on 25- and 35-kV class, fully developed feeders probably will be proportionally greater in the future, assuming that appropriate measures can be taken to maintain acceptable reliability of service.

Voltage Drop. Voltage drop in the primary feeder is an important factor in system design; however, it is only one of the many voltage-drop considerations involved in determining the range of voltages delivered to the customers' service entrances. American National Standard, "Voltage Ratings for Electric Power Systems and Equipment (60-Hz)," ANSI C84.1-1995 (R200), defines in detail the voltage ranges which should be observed. Outside the distribution substation, voltage drops occur in the primary system, the distribution transformer, the secondary system, the service drop, and in the users' wiring systems as well. Remedial measures, such as voltage regulators and shunt capacitor banks, can be used to counteract or reduce the voltage drop due to load flow.

A traditional rough rule of thumb has been to allow a voltage drop of about 3% in the primary of urban and suburban systems at time of peak load. Actually, with typical load densities and primary systems of 15-kV class or higher, it is very probable that economic system designs have a primary voltage drop smaller than 3%.

Note: 1 in = 25.4 mm; 1 ft = 0.3048 m. For ampacities of cables, see Tables 18-23 and 18-24. Regulation of copper for overhead conductors can be estimated with reasonable accuracy the same as that of aluminum conductors two sizes larger. For single-phase overhead primaries, the voltage drop is approximately two times the 3-phase values given in the table. For underground single-phase primaries in concentric-neutral, direct-buried cables, see section on URD systems. Cables are 15- and 35-kV classes, respectively.

*Values in the table give the difference in absolute value between sending-end and receiving-end line-to-neutral voltages of a balanced 3-phase circuit, in volts.

†Overhead conductor impedances are based on 50°C conductor temperature, aluminum conductor with 30-in equivalent spacing for 12.47Y kV and 60-in for 34.5Y kV.

In rural systems which are typified by long lines and light load densities, primary voltage drops may be somewhat larger. This is offset somewhat by the absence of secondaries in serving individual farms; however, the service drops often are longer than in urban systems. The design objective, of course, is to keep delivered voltage to all customers in an acceptable and satisfactory range.

18.7 THE COMMON-NEUTRAL SYSTEM

The 4-wire, multigrounded, common-neutral distribution system now is used almost exclusively because of the economic and operating advantages it offers. Usually, the windings of the substation transformers serving the primary system are wye-connected, and the neutral point is solidly grounded. Occasionally, a small amount of impedance is connected between the transformer neutral and ground in order to limit line-to-ground short-circuit currents on the primary system to a predetermined value. The neutral circuit must be a continuous metallic path along the primary routes of the feeder and to every user location. Where primary and secondary systems are both present, the same conductor is used as the "common" neutral for both systems. The neutral is grounded at each distribution transformer, at frequent intervals where no transformers are connected, and to metallic water pipes or driven grounds at each user's service entrance. The neutral carries a portion of the unbalanced or residual load currents for both the primary and secondary systems. The remainder of this current flows in the earth and/or the water system. For typical conditions, it is estimated that about one-half the return current flows in the neutral conductor, although the division can vary widely depending on earth resistivity and the relative routing of the electric and water systems. Figure 18-11 is a schematic representation of a common-neutral system.

Grounding of Neutral. Rules related to grounding on the utility system neutral are given in the National Electrical Safety Code (NESC), ANSI C2, and regulations governing the grounding of the neutral on users' premises are stated in the National Electrical Code (NEC), NFPA 70. In brief, the secondary neutral is grounded at every service through a metallic water-piping system and through "made electrode grounds" such as other underground metal systems, building steel, or driven ground electrodes. The increasing use of nonmetallic water piping and insulating couplings on metal water systems is requiring the use of other grounding means. The secondary neutral also is grounded at the distribution transformer, usually by means of driven grounds. Although it is often

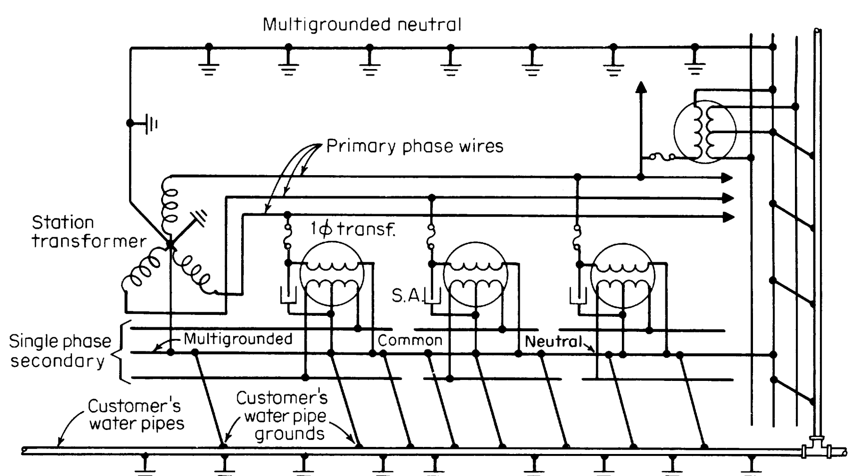

FIGURE 18-11 Common-neutral methods of distribution.

general practice to install a metal butt plate or a wire butt wrap on poles to help in grounding the system neutral and other equipment, the NESC requires two such devices to equal one *made electrode*; as a result, neither can be used to satisfy the NESC requirement for a direct earth ground with a made electrode at each transformer or other arrester location.

The resistance to ground of a typical metallic water-piping system usually is less than 3 Ω. When made electrode grounds are used, they should have a resistance of not more than 25 Ω. Many utilities strive for lower values such as 5, 10, or 15 Ω.

Where there is no secondary neutral as such and no distribution transformers, the primary neutral should be grounded at intervals of not less than 1000 ft. Many utilities require grounding at smaller spacing, such as 500 ft; to meet the NESC requirements for a multigrounded neutral, there must be a minimum of the equivalent of four made electrodes in *each* mile. In URD systems, the primary circuits usually are in direct-buried, concentric neutral cable, so that excellent grounding is obtained.

The neutral must have a continuous metallic path between the substation and users' services. No disconnecting devices should be installed in the common neutral. In no case should the earth or buried metallic-piping systems be used as the only path for the return of normal load current.

Size of Primary Neutral. On single-phase primary circuits (phase and neutral), the neutral conductor should be large enough to carry almost as much current as the phase conductor. Often the same neutral conductor size is used for both, or the neutral has "100%" conductivity.

In 3-phase primary circuits carrying reasonably balanced load, the neutral conductor can be considerably smaller than the phase conductors; 50% conductivity is not uncommon; some utilities specify size of neutral conductor, such as No. 1/0 aluminum, regardless of the size of the phase wires.

Secondary-system neutral conductors are often the same size as the phase conductors where open-wire construction is used. Where triplexed construction is used, the neutral frequently has a reduced cross section.

4-Wire vs. 3-Wire Systems. The 4-wire, common-neutral primary system has many advantages over 3-wire systems:

1. Single-phase branch circuits, or laterals, consist of one insulated phase conductor and the neutral, rather than two insulated phase conductors. The economic advantage is very great in underground systems.
2. On overhead systems, only one lightning arrester is required at each single-phase distribution transformer, rather than two.
3. Only one primary bushing or cable termination is needed on each single-phase distribution transformer, rather than two. In the case of underground systems where the primary "loops through" each distribution transformer, two primary cable terminations or connectors are needed, rather than four.
4. Only one fuse or fuse cutout is needed in the primary of each single-phase distribution transformer. Not only is this a substantial economic advantage, but a short circuit in the primary of the transformer is interrupted positively by the action of a single fuse, and primary voltage is thereby removed from the transformer. In the case of the 3-wire system with the distribution transformer connected phase-to-phase, a second fuse must operate to remove primary voltage and the fault. There may be appreciable time between operation of the two fuses during which fault current continues to flow and abnormal voltages may be experienced by the user.
5. Single-phase primary lateral circuits can be protected by a single fuse cutout, rather than two. Line-to-ground short circuits are promptly cleared by operation of one fuse and voltage removed from the branch circuit. In a 3-wire system (assumed grounded at the substation), single-phase lateral protection, if used, would require two fuse cutouts; a line-to-ground fault would blow only one fuse, leaving all the distribution transformers on that circuit excited at only 58% of normal as long as the faulted phase remains grounded. Under these conditions users' equipment would be exposed to abnormally low voltage. The ability to fuse lateral circuits contributes substantially to

reliability of service, since a major amount of the total circuit exposure comprises the primary laterals in residential areas.

Common-Neutral and Telephone Circuits. Usually, no problems are encountered in the joint use of poles for overhead distribution circuits and telephone circuits, particularly when the telephone circuits are in cable, as is now common practice. Also, in underground residential circuits, power cables and telephone cables often are installed in the same trench with no intentional physical separation of the power and communication facilities, that is, "random lay." Where separate grounding electrodes are employed for supply and communication facilities at customer's premises, the electrodes shall be bonded together with not less than No. 6 AWG copper wire.

18.8 VOLTAGE CONTROL

System Voltage Levels and Voltage Ranges. Since about 1900, there have been several recommendations for certain voltages as standard or preferred for primary and secondary distribution systems, as well as for higher-voltage systems. The latest listing of standard system voltages is American National Standards Institute (ANSI) Standard C84.1-1995(R200), "Voltage Ratings for Electric Power Systems and Equipment (60 Hz)." This standard was formulated by both utilities and manufacturers, and its recommendations are followed by both segments of the industry. Observance of this standard enables the utilities and manufacturers to work in harmony. In many states, ANSI C84 is the basis for rulings of the regulatory commission as far as voltage requirements are concerned.

This standard designates certain standard nominal voltages, including 120/240 V single-phase, 480Y/277 V, 12,470Y/7200 V, as well as the higher primary voltages, 24,940Y/14,400 V and 34,500Y/19,920 V, and others.

Using the nominal 120/240-V system as an example, the standard designates two different ranges of voltage, range A and range B. Range A service voltage specifies that a utility supply system be so designed and operated that most service voltages are within the limits specified, for example, 114/228 and 126/252 V. The occurrence of service voltages outside these limits is to be infrequent.

With the typical voltage drops between the service entrance and the points of utilization, the utilization equipment is designed and rated to give fully satisfactory performance within range A.

Range B service voltage includes voltages above and below range A that necessarily result from practical design and operating conditions on supply or user systems. These conditions are limited in extent, frequency, and duration. When they occur, corrective measures should be undertaken within a reasonable time to improve voltages to meet range A requirements.

Insofar as practicable, utilization equipment is designed to give acceptable performance within range B. The design and operating bogey of the utilities is to provide service voltage to all customers at all times within range A limits.

Voltage Profiles. It is usually convenient to discuss distribution-feeder-voltage regulation in terms of voltage *profiles* of the feeder, because the voltages are everywhere different on the feeder. A profile is simply a graph of feeder-voltage magnitude versus location on the feeder. For a simple case of one load at the end of the feeder (assuming uniform conductor), the one-line diagram and profile are as shown in Fig. 18-12.

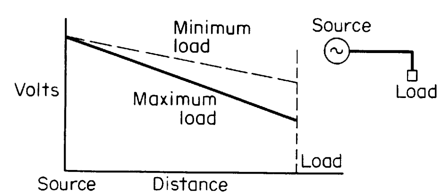

FIGURE 18-12 Voltage profile for concentrated load.

The profile is a straight line between source and the load, and the voltage regulation at any point between is proportional to the distance from the source. It may be, as shown by the dashed-line profile, that minimum load is not zero, in which case the voltage variation is less than the calculated

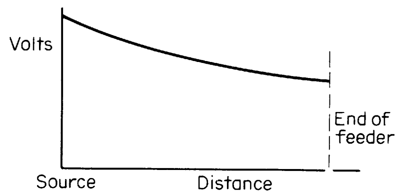

FIGURE 18-13 Voltage profile for distributed load.

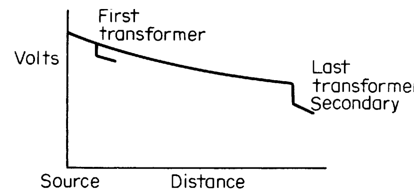

FIGURE 18-14 Additional regulation due to transformer and secondary.

regulation, since regulation is usually calculated on the voltage difference between no-load and full-load conditions. If additional loads are distributed along the feeder, the profile becomes a broken line, and if the load is uniformly distributed, the profile becomes a smooth curve, as shown in Fig. 18-13.

The shape of the profile is of less consequence than knowing the extremes, because there are generally customers connected at all points on the feeder, and no customer's voltage should be too high or too low. Since most feeders neither supply a single load nor are uniformly loaded, it usually is necessary to calculate the voltage profile on a piece-by-piece basis, representing the loads and feeder configurations as accurately as the situation warrants.

In addition to the distribution-feeder-voltage profile, there is additional regulation in the distribution transformer and its secondaries and services. This additional regulation can be added to the profile as shown in Fig. 18-14. For protection of the first customer on the feeder 0 from possible overvoltage, it is usual to assume only a partially loaded transformer rather than one at full load.

It is now possible to establish a limiting band of voltage within which all customers must lie for satisfactory service, usually range A. In turn, this also will establish the maximum permissible difference between the full-load and light-load primary voltage. The problem of holding the right voltage at each customer location at all times may be visualized by referring to Fig. 18-15.

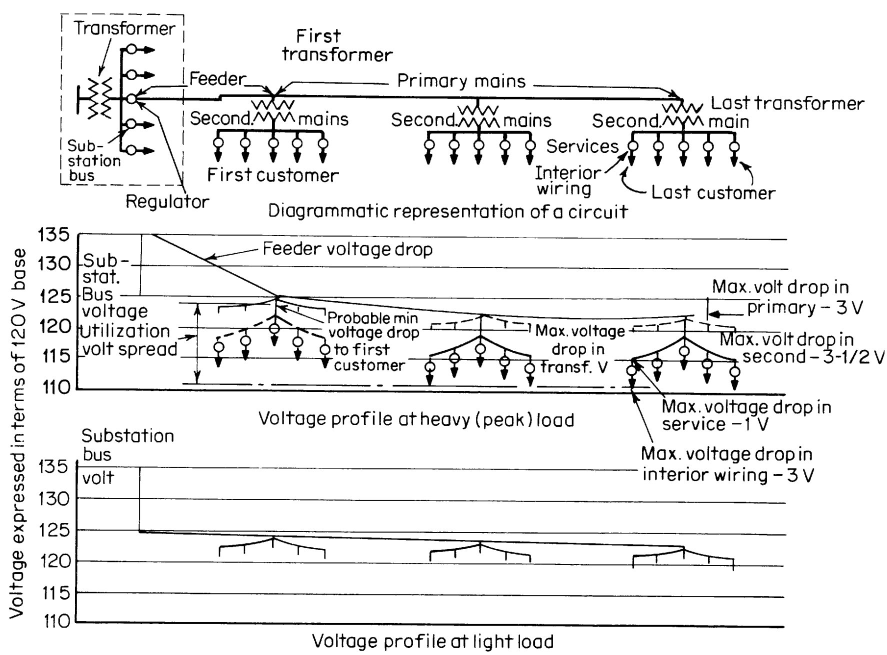

FIGURE 18-15 Distribution circuit with voltage profiles at heavy and light loads.

Voltage Control. As implied in Fig. 18-15, usually there is voltage control equipment in the substation consisting of load-tap changers on the power transformers or bus or feeder voltage regulators. This regulating equipment can control only the voltage *level* of the primary system. It can have no effect on the voltage *spread* between the first and last customers on the feeder.

There are several procedures which can be taken to correct for increasing voltage drops as the load on the feeders grows; among them are capacitors and supplementary feeder-voltage-regulator installations.

The effect of capacitor application is illustrated in Fig. 18-16, where the load is assumed to be uniformly distributed along the feeder, and a capacitor bank is installed as indicated. The capacitor produces a voltage rise because of its leading current flowing through the inductive reactance of the feeder. As is seen in the figure, this voltage rise increases linearly from zero at the substation to its maximum value at the capacitor location. Between the capacitor location and the remote end of the feeder, the rise due to the capacitor is at its maximum value.

When the capacitor voltage-rise profile is combined with the original feeder profile, the resulting net profile is obtained. The capacitor has increased the voltage *level* all along the feeder, resulting also in a reduced voltage *spread*.

In practical applications, the capacitor bank can be a permanently connected or "fixed" bank as shown or an automatically switched bank. The fixed bank is limited in size by the allowable voltage rise during light-load conditions, and therefore may not produce sufficient voltage rise during heavy-load conditions. It can be supplemented by additional switched capacitors which automatically switch on at heavy-load conditions and off again as the load decreases.

The effect of applying a supplementary feeder-voltage regulator is shown in Fig. 18-17. Note that the regulator produces no voltage effect between the source and the regulator location and its entire boost effect is between the regulator location and the remote end of the feeder.

A typical primary feeder serves distributed loads, as well as concentrated loads, and may also have shunt capacitors and supplementary voltage regulation, such that all these previous concepts must be employed in studying voltage conditions.

Voltage Regulation. Voltage regulation in distribution substations usually is accomplished by individual feeder-voltage regulators or by automatic load-tap-changing equipment in the substation transformers. Individual feeder-voltage regulators are advantageous where feeders of differing lengths and diverse load characteristics are supplied from the same substation bus. Automatic load-tap-changing equipment in the power transformer provides voltage control on the substation bus, or group regulation, when feeder lengths and load characteristics are reasonably homogeneous.

Voltage control is needed to compensate not only for the voltage regulation in the subtransmission system and substation transformer, which is measurable at the substation, but also for the voltage regulation which occurs in the distribution transformers and in the primary and secondary systems beyond the substation. The latter portion of the overall system voltage regulation is a function

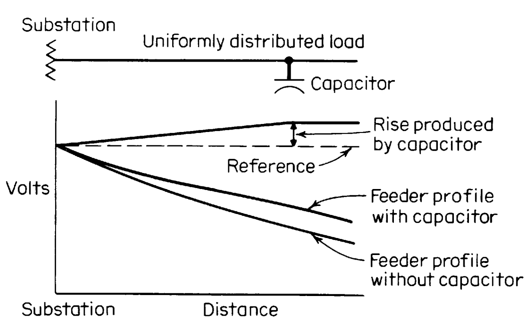

FIGURE 18-16 Effect of shunt-capacitor application.

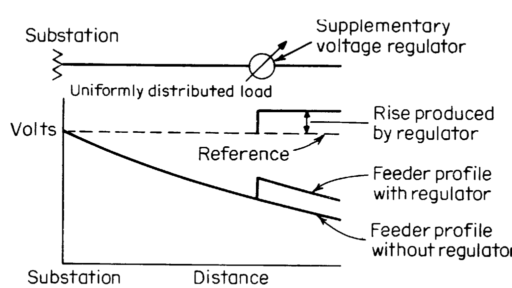

FIGURE 18-17 Effect of supplementary voltage regulator.

of the load flow and system impedances and cannot be measured directly at the substation. Therefore, the control systems of the voltage regulators or tap-changing equipment not only sense the voltage at the substation but also usually contain a "line-drop compensator" which simulates the voltage drop between the station and some point in the distribution system and controls the regulating equipment accordingly. Switched shunt capacitor banks sometimes are installed at the distribution substation as part of the overall system voltage control.

Feeder-Voltage Regulator. In the typical radial primary system, it is often necessary to regulate the voltage of each feeder separately by means of feeder-voltage regulators. These regulators may be of single-phase or 3-phase construction. The former are available in sizes from 25 to more than 400 kVA, the latter from 500 to 2000 kVA. For distribution-system application they are commonly available for voltages from 2.5 kV to 34.5 kV grd Y. Regulators commonly are capable of raising or lowering the voltage delivered to the feeder by 10% and normally are rated on this basis.

Modern voltage regulators all are of the step-voltage type, which has completely supplanted the earlier induction-voltage regulators. The step-voltage regulator basically is an autotransformer which has numerous taps in the series winding. Taps are charged automatically under load by a switching mechanism which responds to a voltage-sensing control in order to maintain voltage as close as practicable to a predetermined level. The voltage-sensing control receives its inputs from potential and current transformers and provides control of system voltage level and bandwidth. In addition, it permits selection of line-drop compensation and provides features such as operation counter, time-delay selection, test terminals, and control switch.

Most feeder-voltage regulators are of the 32-step design. Since they usually operate over a range of voltage of 20%, the voltage change per step is $^5\!/_8$%. If the full range of regulation of $\pm 10\%$ is not required, the regulators can carry more than rated current. For example, operating with a range of $\pm 5\%$, 160% of rated current can be carried.

Line-Drop Compensator. In simplified terms, the regulator voltage (local voltage) is stepped down by means of a potential transformer and fed to the control system, where it is compared with the desired and preset voltage level. If the actual voltage deviates from the preset level by more than $\pm\frac{1}{2}$ of the bandwidth, which also is preset by the operator, the tap-changing mechanism operates, after a preset time delay, to return the voltage within the preset band. From a practical point of view, the minimum bandwidth is twice the size of the voltage step, or $2 \times {}^5\!/_8\% = 1.25\%$. Maintaining a small bandwidth is important in reducing voltage variations and in making full use of the allowable system voltage drop.

The line-drop compensator consists of adjustable resistance and reactance components and is preset to simulate system impedance. By means of a current transformer, current proportional to load current is circulated through the resistance and reactance, producing a voltage signal which is combined with the signal from the local voltage. The net result is that the line-drop compensator causes a higher voltage to be held at the voltage regulator during periods of heavy load. In this way, a constant voltage is held at some point in the system, as determined by the compensator setting. This helps to achieve the goal of minimizing the voltage change with varying loads at any location.

Supplementary Voltage Regulation. In some long primary circuits, such as rural feeders, it is often necessary to provide voltage regulation in addition to that incorporated in substation equipment because of large voltage drops in the system. This supplementary voltage regulation usually is improved by single-phase automatic step regulators in the smaller ratings. These regulators are suitable for pole mounting.

Bus Regulation. Bus regulation at the distribution substation usually is provided by automatic load-tap-changing equipment built into the substation transformer or by large step-voltage regulators.

Switched Shunt Capacitors. Switched shunt capacitors are often applied at distribution substations or out on the primary feeders to accomplish a portion of the overall voltage-regulation job. Most utilities apply shunt capacitors primarily as a tool in economic system design. Usually fixed (unswitched) shunt capacitors are applied to bring the light-load power factor to more or less 100%. Then, additional automatically switched shunt capacitor banks are added to achieve an economic full-load power factor, which is usually in the order of 95% to 100%.

These capacitors, in addition to their economic functions, such as reducing losses and releasing system capacity, improve system conditions substantially. Usually additional voltage control is needed, however, and this is most economically accomplished with voltage-regulating equipment.

18.9 OVERCURRENT PROTECTION

General Principles. Coordination of overcurrent protection devices means their proper arrangement in series along a distribution circuit so that they function to clear faults from the lines and equipment in accordance with a prearranged sequence of operation. Fuse cutouts, automatic circuit reclosers, sectionalizers, and relayed circuit breakers are the overcurrent protective devices most commonly used. Ratings and characteristics can be obtained from appropriate product bulletins of the manufacturers.

When the protective devices are properly applied and coordinated:

They can eliminate service outages resulting from temporary faults.

They reduce the extent of outages, that is, the number of users affected.

They are helpful in locating the fault, thereby reducing the duration of interruptions.

Main-Line Sectionalizing. Usually, the first protective device on a primary feeder is a circuit breaker or a power-class recloser located in the substation. If the circuit is overhead, the circuit breaker often is provided with reclosing relays so that it operates in much the same manner as a recloser. If the circuit is primarily underground, reclosing is not generally used.

If portions of the main feeder and long branches extend beyond the zone of protection of the relayed breaker or recloser at the substation, additional overcurrent protective equipment usually will be installed out on the main feeder. Manually operated sectionalizing equipment such as pole-top disconnecting switches or solid blade cutouts also are installed at strategic locations along the main feeder to

Provide a convenient means of isolating faults so that repairs can be made after other parts of the feeder are restored to service

Provide means of connecting the feeder to adjacent feeders so that service can be maintained to most customers while repair or maintenance operations are taking place

On underground feeders, this sectionalizing equipment is often in the form of 3-phase, manually operated, load-break switches.

Branch-Circuit Protection. It is exceedingly important to isolate faults on branch and subbranch lines, even short ones, in order to maintain service on the rest of the feeder. Not only does the branch-circuit protection protect the rest of the feeder, but it helps to pinpoint the location of the fault.

Also, there is usually much more mileage and much more exposure in the branch circuit or laterals than in the feeder main. The simple expulsion-fuse cutout is almost universally used for branch and subbranch overcurrent protection. It may be used in combination with reclosers.

On underground feeders, the lateral circuits usually are fused at the point where the main feeder is tapped to establish the lateral. Often, the fuses for several lateral circuits are grouped into a sectionalizing equipment which may also incorporate main-feeder and load-break sectionalizing switches.

Temporary Fault Protection. On overhead distribution circuits, a large portion of the faults are of a temporary nature or are potentially of a temporary nature. For example, some types of transitory faults include momentary contacts with tree limbs and lightning flashover of insulators or crossarms where no sustained 60-Hz short-circuit current is established and no protective devices operate. Other types of faults which result in 60-Hz follow current can be of a transient nature if the circuit voltage can be removed quickly for a short period of time and then restored after the fault path has recovered adequate dielectric strength. Such faults can result from lightning flashovers, bird or animal contacts, conductors swinging together, etc. Reclosers and reclosing breakers provide the function of fault deenergization, pause for deionization of the arc path, and reestablishment of voltage.

If the fault has disappeared during the "dead time," the reclosure is successful. If not, one or more additional reclosing cycles may be attempted. If the fault persists after the prescribed number of reclosing operations, the breaker or recloser will lock open, or the fault will be removed by operation of a fuse or sectionalizer.

It should be recognized that the reclosing function is provided to eliminate the effects of *temporary* faults only. If all faults were of a permanent nature, reclosing would be pointless. Also, temporary faults on branch circuits result in a momentary outage to all customers on the feeder when reclosing is used. Some utilities, in an effort to reduce the number of momentaries, are allowing the branch fuse to blow for temporary faults. (This is done by eliminating the instantaneous trip.) While this procedure reduces the number of momentaries seen by customers, it has the negative effect of creating a substantial interruption out of a temporary fault condition for the customers on the affected branch.

To provide effective protection against temporary faults, all parts of the feeder should be within the zone of a reclosing device. That is, if the station recloser or relayed circuit-breaker sensing does not reach to the remote ends of the circuit, it should be supplemented with reclosers out on the line. (The term *reach* here is used with the meaning of "sense" faults or "sense and operate" for faults.)

Permanent Fault Protection. Permanent faults are those which require repairs, maintenance, or replacement of equipment by the utility operating department before voltage can be restored at the point of fault. System overcurrent protection is provided to disconnect the faulted portion of the system automatically so that an outage is experienced by a minimum number of consumers. Isolation of permanent faults is usually accomplished by the operation of fuse cutouts. It is also achieved in some cases by operation (to lock out) of reclosers, circuit breakers, or sectionalizers.

Combination of Permanent and Temporary Fault Protection. If all faults were of a permanent nature, low-cost fuse cutouts would be the best solution for primary line protection. If all faults were temporary, automatic reclosing devices capable of covering the entire circuit would be the best solution. In actual practice, both kinds of faults occur, and the problem becomes one of selecting the type of device or combination of devices to provide best overall results. For selection of a system of overcurrent protection, it is necessary to give proper consideration to many factors such as importance of service, total number of faults per year, ratio of temporary to permanent faults, cost to utility of service interruptions, and annual charge on investment.

Selection of Overcurrent Protective Equipment—General. The one-line diagram of a distribution circuit, as shown in Fig. 18-18, will show how a well-coordinated installation of overcurrent protective equipment can be made.

At the left is the substation, which steps down the voltage from high-voltage subtransmission level to primary-distribution voltage level. It is at this point that the distribution system starts. A distribution substation usually has a number of radial 3-phase feeders radiating from it. However, for the purposes of illustration, only a single feeder will be considered, and it is shown extending to the right from the substation. At various points along the feeder, branch lines or laterals are tapped off and in some cases subbranches are tapped from these branches. There are, of course, loads (residences, stores, garages, etc.) all along the feeder, branches, and subbranches. Only a few of these loads are shown, for the sake of clarity of the diagram.

It is general practice to install a fuse on the primary (incoming) line side of each distribution transformer, as shown in Fig. 18-18. This may be a transformer internal fuse or an external fuse installed in a cutout. Transformer fusing will be discussed later. Figure 18-18 shows the basic system to which additional overcurrent protective equipment must be added to assure good service continuity.

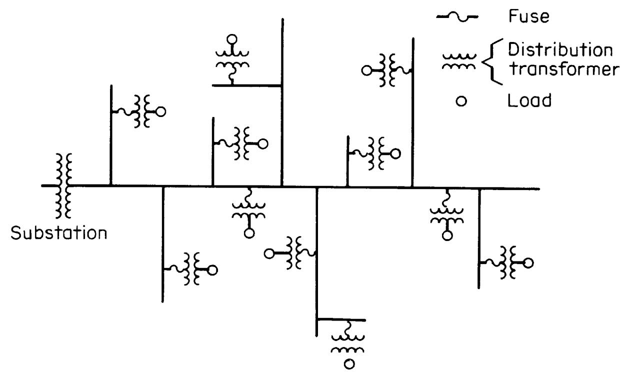

FIGURE 18-18 Distribution feeder.

To properly apply overcurrent protective equipment to this system, it will be necessary to know the highest and lowest (maximum 3-phase and minimum line-to-ground or line-to-line) values of short-circuit currents which can flow if a fault should occur where the feeder leaves the substation, at each branch junction point, and at each subbranch junction point, as well as the minimum line-to-ground short-circuit current which could flow if a fault should occur at the end of any of the branches or subbranches. These short-circuit currents may be calculated easily by conventional methods.

Clearing Nonpersistent or Temporary Faults. Operating records, as well as numerous studies, indicate that a reduction of 75% to 90% in the number of total outages on an overhead system can be attained by the installation of automatic reclosing devices (automatic circuit recloser or reclosing circuit breaker). The recloser or breaker will open the circuit "instantaneously" when a fault occurs, and reclose it after a short period of time.

Referring to Fig. 18-18, automatic circuit reclosers will be applied to protect the entire system against temporary faults. To achieve this sort of protection, the first recloser should be installed on the main feeder at the substation or the power circuit breaker at the substation should be equipped with overcurrent and reclosing relays.

In applying reclosers to do this job, certain factors must be considered: (1) The voltage rating of the recloser must be high enough to meet the requirements of the system. (2) Load current, or the amount of current which flows at the point of installation of the recloser under full-load conditions, should not exceed the amount of current which the manufacturer has rated the recloser to carry continuously (continuous-current rating). Recloser ratings are usually selected to be 140% of the peak load current of the circuit. This allows for normal load growth. (3) The highest value of short-circuit current which will flow through the recloser and which the recloser must interrupt. This value should not be greater than the highest value of current which the recloser is rated to interrupt (interrupting rating). Typically, a recloser will have a continuous rating of 560 A or less and an interrrupting rating of 16,000 A or less. A breaker, on the other hand, will usually handle at least 1200 A continuously and up to about 40 kA under short-circuit conditions.

Referring to Fig. 18-19, a recloser or breaker with reclosing relays will be located at *A* to meet the three application principles mentioned above. This device will be depended on to clear nonpersistent faults which occur in the feeder, branches, or subbranches, anywhere within its protective orbit zone *A* (shown by dotted line in Fig. 18-19). This protective zone extends to the point where the minimum available short-circuit current, as determined by calculation, is equal to the smallest value of current which will cause the device to operate. This value of current required to operate the recloser or breaker is called minimum pickup current. For a recloser it is usually equal to *twice the continuous current rating of the recloser*. A fault beyond this zone may not cause the recloser or breaker *A* to operate, and therefore, another recloser, *B*, with a lower minimum pickup current rating, should be installed just inside of zone *A*, thus resulting in so-called overlapping protection.

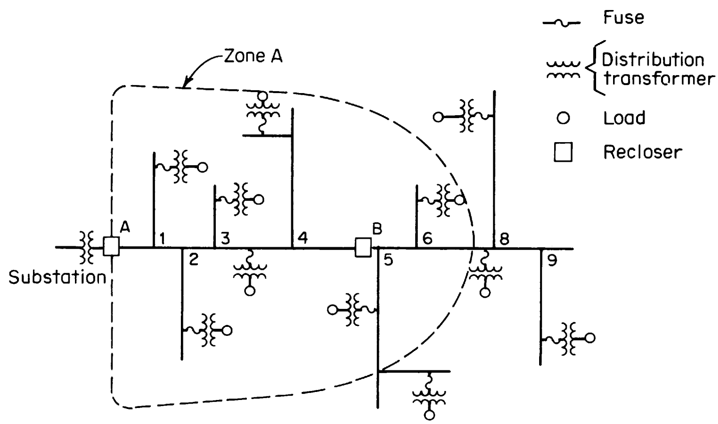

FIGURE 18-19 Distribution feeder with automatic reclosers.

This second recloser, *B* in Fig. 18-19, is placed on the source side (side nearest source of power) of branch 5 so that it can protect the end of this branch from nonpersistent faults which may not cause recloser *A* to operate. It is applied according to the same considerations as was the recloser at *A*. It will be assumed that a fault on the feeder or any branch or subbranch beyond (to the right of) *B* will cause enough current to flow to operate the recloser at *B*. Every point on the entire circuit is now protected against nonpersistent faults because every point is within the protective zone of some reclosing device. Obviously, if every point were not within the protective orbit of some reclosing device, another recloser would have to be installed still farther out on the line.

Clearing Persistent Faults. The first requirement of protecting the circuit against nonpersistent or transient faults has been taken care of by recloser application. It is necessary now to concentrate on the second and third requirements, that is, confining persistent faults to the shortest practical section of line and making persistent faults easy to locate.

If a permanent fault occurs anywhere on the system beyond a recloser, the recloser will operate once, twice, or three times instantaneously, depending on adjustment, in an attempt to clear the fault. However, since a persistent fault will still be on the line at the end of these operations, it must be cleared by some means other than the instantaneous recloser operations. For this reason, the recloser is provided with one, two, or three time-delay operations, depending on adjustment. These additional operations are purposely slower (time-delay operations) to provide coordination with fuses or to allow the fault to "self-clear." If the fault is still on the line after the last opening, the recloser will not close in but lock open.

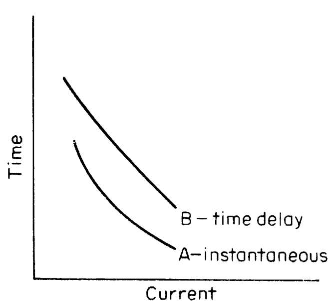

FIGURE 18-20 Recloser tripping characteristics.

Referring to Fig. 18-20, curve *A* represents the instantaneous tripping characteristic with respect to time for the first and second opening of a conventional automatic circuit recloser. Curve *B* represents the tripping characteristics for the third and fourth openings. Following the fourth trip on time delay, the recloser will lock out and must be manually reclosed after the cause of the fault has been remedied.

A persistent fault on a branch or subbranch line *should not* cause a recloser to lock open, since a fault on a relatively unimportant subbranch could shut down the entire circuit, in addition to being extremely difficult to locate. Therefore, some means should be employed to confine outages due to persistent faults to the branch or subbranch on which they occur. This may be done in either of two ways.

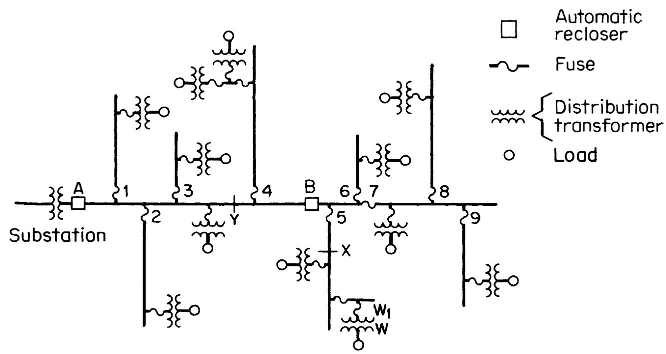

FIGURE 18-21 Distribution feeder with automatic reclosers and fuse cutouts.

One method by which persistent faults can effectively be dealt with is illustrated in Fig. 18-21. A fuse cutout is installed at each branch or subbranch junction to confine outages due to persistent faults to the branch or subbranch on which they occur, that is, fuses 1, 2, 3, 4, etc.

The fuse cutout to be installed at a particular location must be of sufficiently high voltage rating to meet the voltage requirements of the circuit. Its continuous current rating must be equal to or greater than the full-load current at the point of installation. Its interrupting rating must be high enough so that it will successfully open the circuit for any persistent fault occurring beyond it. This may be checked by comparing the interrupting rating of the cutout with the maximum available short-circuit current calculated for the point on the system where the cutout is to be installed.

For an ideal system, when the correct ratings of fuse links are used throughout the system, *no fuse will be blown or even damaged by a temporary fault beyond it; that is, the recloser will open the circuit one, two, or three times on instantaneous operations without the fuse link being damaged*. In many systems, however, where short-circuit levels are very high, it is sometimes impossible to prevent even the largest fuse from operating during a temporary fault. On a permanent fault, the first fuse link on the source side of the fault will be blown, and the circuit thus will be opened by the blowing of the fuse during the third or fourth (time-delay) operation of the recloser, before the recloser will lock open. Hence, the fault will be isolated by the fuse, and the recloser will reset automatically, restoring service everywhere except beyond the blown fuse. The recloser should never lock open on a permanent fault beyond the fuse if it has been properly coordinated with the recloser. Extensive coordination tables are available, as illustrated in Table 18-4, to simplify and facilitate the job of coordinating reclosers with fuse links.

Recloser-Fuse Coordination. Figure 18-22 shows the time-current characteristic curves of the automatic circuit recloser similar to those shown in Fig. 18-20. On these curves, the time-current (TC) characteristics of a fuse *C* are superimposed. It will be noted that fuse curve *C* is made up of two parts; that is, the upper portion of the curve (low current range) represents the total clearing-time TC curve, and the lower portion (high current range) represents the melting TC curve for the fuse. The intersection points of the fuse curves *C* with the recloser curves *A* and *B* illustrate the limits between which coordination will be expected. Basically, this is correct within the interest of simplicity. However, to establish intersection points *a* and *b* accurately and to prepare coordination charts, it is necessary that the characteristic curves of both recloser and fuse be shifted, or modified, to take into account alternate heating and cooling of the fusible element as the recloser goes through its sequence of operations. For example, if the fuse is to be protected for two instantaneous openings, it is necessary to compute the heat input to the fuse during these two instantaneous recloser operations.

Curve A' in Fig. 18-23 is the equivalent TC characteristic of two instantaneous openings (*A*) and is compared with the fuse-damage curve, which is 75% of the melting-time curve of the fuse. This will establish the high current limit of satisfactory coordination indicated by intersection point b'. To establish the low current limit of successful coordination, compare the total heat input to the fuse

TABLE 18-4 Automatic Recloser and Fuse Range of Coordination*

	Max						1500	2200	4000

*Recloser sequence: two instantaneous plus two standard time-delay operations.

represented by curve B', which is equal to the sum of two instantaneous (A) plus two time-delay (B) operations, with the total clearing-time curve of the fuse. The point of intersection is indicated by a'.

On the basis of all corrections added, the fuse will coordinate successfully with recloser between the current limits of a' and b'.

To further clarify what is meant by coordination within prescribed limits, refer to Fig. 18-21—branch 5 and recloser *B*—and also Fig. 18-23 to establish how coordination is achieved between the limits of a' and b'. Assume that fuse 5 beyond recloser *B* is to be protected against blowing or being damaged during two instantaneous operations of the recloser *in the event of a transient fault at X*. If the maximum calculated short-circuit current at the fuse location does not exceed the magnitude of current indicated by b', the fuse will be protected against blowing during all transient faults. By observation of the characteristics in Fig. 18-23, for any magnitude of short-circuit current less than b' but greater than a', the recloser will trip on its instantaneous characteristic once or twice to clear the fault before the fuse-melting characteristic is approached. On the other hand, *if the fault at X is persistent*, the fuse at 5 should blow before the recloser *B* locks out. If the minimum (line-to-ground) calculated short-circuit current available *at the end of branch* 5 is substantially greater than the

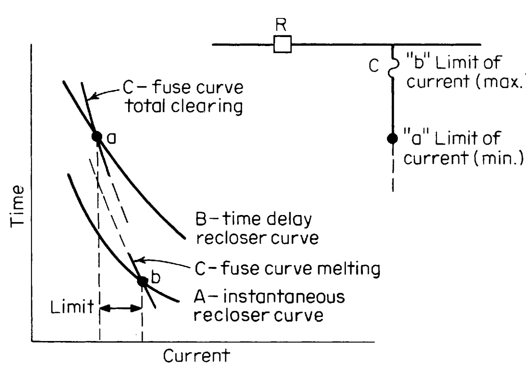

FIGURE 18-22 Recloser and fuse time-current characteristics.

current indicated by a', the fuse will blow (Fig. 18-23) in accordance with the total clearing characteristic, probably before the first time-delay characteristic of the recloser is approached.

The correct fuse link for any application may be selected by comparing its TC characteristics curve with those of the recloser and making certain allowances and corrections as shown. However, tables have been prepared similar to Table 18-4 to simplify greatly the job of coordinating reclosers with fuse links. This table shows the maximum and minimum currents at which certain ratings of fuse links will coordinate with certain ratings of reclosers. The only requirement in their use is a knowledge of the available short-circuit currents and load currents on the system.

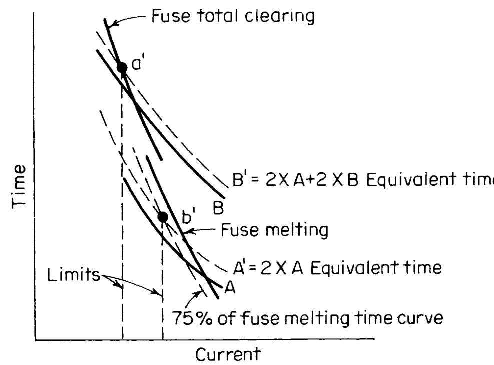

FIGURE 18-23 Recloser and fuse time-current characteristics.

Other sequences of recloser operation can be employed, but one instantaneous and two time-delay operations is the combination most widely used. In some cases, it is necessary to coordinate recloser operation with a relayed breaker at the substation. The principles of coordination are similar to the previous discussions, but a detailed study is beyond the scope of this handbook. This is also true of the application requirements for power-class reclosers for substation and line protection.

Fuse-to-Fuse Coordination. It may be desirable to use more than two fuses in series beyond a recloser in order to reduce the number of consumers affected by an outage. An example of this would be the fuses at points 7, 8 and at transformers on branch 8 in Fig. 18-21. The coordination of these fuses in series beyond the recloser *B* may be accomplished by coordinating adjacent fuses first with each other and then with the recloser in the manner just outlined.

Figure 18-24 illustrates the general principle of coordinating fuses in series. Fuse 7 is called the *protected fuse*, and fuse 8 is called the *protecting fuse*. For perfect coordination, fuse 8 must clear the circuit during a fault anywhere beyond it, such as at *X*, before fuse 7 is damaged or partially melted. From this can be seen the requirement for melting-time–current curves plotted to minimum values and total-clearing-time–current curves plotted to maximum values for each fuse-link rating. *Total-clearing-time* curves represent the total time, including melting time and arcing time, plus manufacturing tolerance, that it takes the fusible elements to clear the circuit. *Melting-time* curves represent the minimum time, based on factory test, at which the fusible element melts for various currents. From the melting-time curves, *damaging-time* curves can be determined by applying a factor of safety. It usually is suggested that the damaging-time curve be made by taking 75% of the melting time (in seconds) of a particular size at various current values.

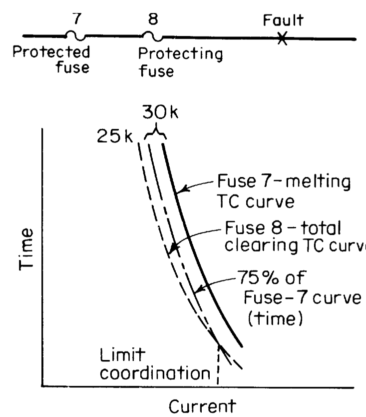

FIGURE 18-24 Fuse time-current characteristics.

To establish coordination of two fuses in series, it is necessary to compare the total-clearing-time–current curve of the protecting fuse with the damage-time–current curve of the protected fuse. If there is no intersection of these two curves throughout their entire current range, coordination or selectivity can be expected. Where there is an intersection of the curves, the current value indicated by the point of intersection will establish the limit of selectivity.

TABLE 18-5 Fuse Ratings

Type K EEI-NEMA ratings, A, of the protecting fuse links (8 in diagram)	Type K EEI-NEMA ratings, A, of the protected fuse links (7 in diagram)

Source: General Electric Company.

Because of the inherent characteristics of fuses, the maximum available short-circuit current in that section (determined by calculation) controlled by the protecting link (8 in Fig. 18-24) is the determining current which establishes coordination possibilities.

Most fuse-link manufacturers publish tables which make coordination very simple. These tables eliminate the necessity of comparing actual fuse-characteristic curves. Table 18-5 is illustrative of tables used for fuse-to-fuse coordination. The values in the left-hand column are the protecting fuse ratings and the values across the top are the protected fuse ratings. The numerical values in the table show the magnitude of current or curve intersection points at which, or below which, fuse 7 will be protected by fuse 8. These current magnitudes are maximum values; in other words, for any short-circuit current greater than that shown, fuse 7 will be damaged. Hence, a larger-rated fuse will have to be selected for location 7 or else its position must be changed.

Isolation by Sectionalizer. Another method of isolating persistent faults is to install a device, known as a *sectionalizer*, at locations where a fuse might otherwise be used. A sectionalizer is a device which counts the operations of a backup automatic-interrupting device such as a recloser. It has no interrupting capacity of its own but operates in a predetermined coordination scheme to open a faulted lateral before the backup device locks out.

The sectionalizer opens the circuit after a predetermined number (usually two or three) of operations of a reclosing device. Its opening operation occurs during a period when the reclosing device is open. It can be used to replace a lateral sectionalizing fuse or to replace a lateral recloser where interrupting requirements have grown beyond the capability of the recloser. Among its operating advantages are

It allows coordination with breakers or reclosers where fault current is above 5000 A. Such coordination usually is impossible with expulsion fuses.

It can provide a new sectionalizing point on an existing circuit without upsetting existing overcurrent coordination, since the device operates as a counter and does not introduce another level of time-current coordination.

Equipment Protection

General. It is necessary to provide overcurrent protection for distribution equipment such as capacitors and distribution transformers:

To protect the system from the effects of equipment failures

To reduce the probability of violent failures

To indicate the location of the fault

A detailed discussion of all aspects of overcurrent protection of equipment is beyond the scope of this handbook. However, because of its importance, a few comments will be included regarding the overcurrent protection of distribution transformers.

Self-Protected Transformers. The term *self-protected distribution transformer* is applied to units which incorporate an internal primary expulsion fuse, a direct-mounted arrester, and an internal secondary circuit breaker. The low-voltage circuit breaker protects the transformer from excessive overload and from some of the faults originating on the secondary system. The expulsion fuse has the sole function of removing a failed transformer from the system.

The rating of the internal expulsion fuse usually is quite large compared with the continuous current rating of the transformer, perhaps 10 to 14 times. This is done

1. To ensure that the fuse is not damaged by the maximum tripping current of the circuit breaker
2. To minimize the possibility of extraneous fuse blowing because of lightning current effects

Another reason is that fuse removal and replacement may require that the transformer be taken to a shop facility.

Transformer internal expulsion fuses are installed at the factory and are given a designating number rather than an ampere rating for coordination purposes. For a 7200-V transformer, the internal expulsion fuse, often called *weak link*, has an interrupting capacity of about 3000 A. Weak links for higher-voltage transformers have somewhat lower interrupting capacity.

Despite the fact that self-protected transformers often are installed at locations on the system where the interrupting capacity of the weak link may be exceeded for a solid fault, experience over the years has been excellent, probably because most transformer failures begin as relatively low fault-current turn-to-turn failures. As the fault current progressively becomes larger, the fuse will operate well before its interrupting capacity is exceeded. Thus, while high-current transformer faults can occur, their frequency of occurrence is very small.

However, there is growing concern among utility companies regarding the occasional violent failures of transformers, and many users are using, or are considering the use of, current-limiting fuses as one method to minimize the energy input into a failed transformer.

The secondary circuit breaker is depended on to provide protection against excessive transformer loads and secondary system faults that occur within its zone of protection, or *reach*. Its TC characteristic should be such that it will always operate before the primary fuse suffers any damage, as illustrated in Fig. 18-25. On the other hand, the breaker should not operate for faults beyond the customer's service-entrance-protective equipment. Likewise, the internal primary fuse should operate to clear transformer faults before damage occurs to the line sectionalizing fuses back toward the source.

Conventional Transformers. Conventional distribution transformers usually are protected by separately mounted expulsion fuse cutouts in series with the primary winding. No secondary overcurrent protection is provided, so protection against extreme overloads or secondary faults, if any, must come from the primary fuse. Therefore, the size of the primary fuse is relatively much smaller than for the self-protected transformer, usually being chosen in the range of 2 to 3 times the full-load current of the transformer.

It is desirable to keep the fuse rating as low as possible consistent with certain application limitations:

1. When a transformer is energized by closing of its cutout or operation of a recloser or other switch, a large "magnetizing inrush" current can occur. Initially, this current can be as much as 20 or more times normal, rapidly decaying to normal in a short time—perhaps $^1/_2$ to 1 s or more. The primary fuse link must be large enough to avoid damage by the magnetizing inrush current, so it usually is selected at least large enough to carry 12 times rated transformer current for 0.1 s without damage.
2. The primary fuse should not be damaged by lightning currents or arrester discharge currents (depending on connection used) or large magnetizing currents which can result from saturation of the core due to lightning currents. Many utilities assign an arbitrary minimum fuse size which they will employ. With expulsion fuses, 10- or 15-A rating is often designated as the minimum size.

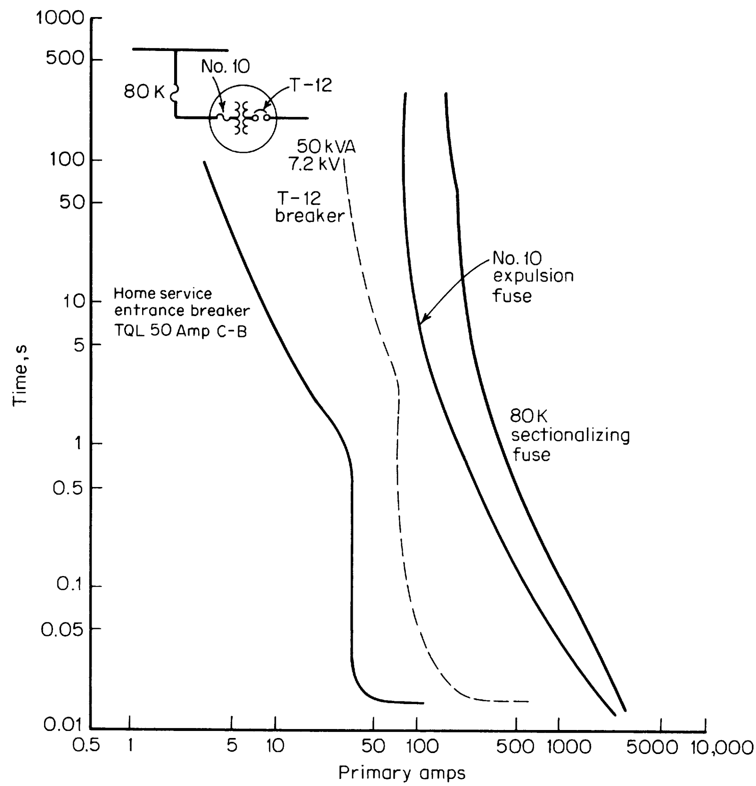

FIGURE 18-25 Overcurrent coordination for self-protected distribution transformer.

With a fuse *rating* of 2 to 3 times rated transformer current, the minimum melting current under long-time conditions will be in the range of 4 to 6 times transformer rating. Consequently, little overload protection is obtained.

In the absence of overload protection, many utilities count on a transformer load-management program or seasonal load-survey techniques to keep their "burnouts" at an acceptable level. Also, the primary fuse has a limited reach as far as secondary faults are concerned; therefore, secondary faults can occur which cannot be "seen" by the fuse. Often these faults—especially on underground systems—will burn clear.

Expulsion Cutouts. Distribution expulsion cutouts are by far the most common type of protective device used on overhead primary-distribution systems. The open-type cutout has generally supplanted the porcelain-enclosed style. The cutout consists of an insulating structure and a hinged fuse tube of hollow cylindrical construction which contains the fuse link. When the fuse link melts, the ensuing arc impinges on the wall of the fibrous tube holder (and usually a small auxiliary tube), generating gas which provides the expulsion action needed to extinguish the fault current. Separation of the fuse link also releases the cutout-latching mechanism so that the fuse holder falls to the open position and can readily be located by operating personnel. The fuse holder also can be switched manually with a switch stick, much like a disconnect switch. In some cases, a solid blade is used in place of the fuse holder to provide a disconnecting function. The cutout also can be provided with load-breaking accessories so that it can be used as a load-break switch.

Generally cutouts are available in 100- and 200-A continuous-current ratings for fuses and 300- or even 400-A with solid blades. Cutouts are available with voltage ratings for all the common primary system voltages and interrupting capacities generally from 1200 up through 16,000 A symmetrical and more.

Fuse links for cutouts are available with a variety of TC characteristics. However, the two most widely used types are the Type K (fast) fuse links and the Type T (slow) links with characteristics as defined in ANSI C37.43. Both types have certain application advantages and disadvantages which must be evaluated by the utility. Ordinarily, a given utility uses one type or the other, not both. Use of the Type K links is believed to be somewhat greater than use of Type T.

Other common types of primary fuses employ fusible elements immersed in oil.

Fuses are not widely used in electric utility secondary systems, with the notable exception of secondary network systems, where *limiters* are frequently used in the secondary cable circuits. Limiters are fusible elements whose TC characteristics are coordinated with the cable size and insulation characteristics to prevent damage to the cable when faults do not burn clear or self-extinguish.

Current-Limiting Fuses. The use of current-limiting fuses in distribution systems has been growing. The fuse generally is constructed of silver wire or ribbon fusible elements—often several in parallel—spirally wound on a core or spider and packed in a quartz-sand filler in a sealed cylindrical glass or epoxy-glass container. Provisions for suitable electrical connections are made at the ends. When operation takes place under high-fault-current conditions, the fusible element melts almost instantaneously at a series of reduced sections all along its length. The resulting arc dissipates its heat rapidly into the surrounding sand, melting the sand around the arc into a glass-like structure called a *fulgorite*. This action builds up the apparent resistance of the fuse extremely rapidly, resulting in a "back voltage" greater than system voltage. Thus, the fault current is limited to a value much less than the available system fault currrent.

Current-limiting fuses are characterized by

1. High-current interrupting ability. Interrupting ratings of 50,000 A symmetrical or greater are commonly available.
2. Operation is noiseless, and there is no expulsion of the arc or arc products. Thus, the fuse can be "packaged" into relatively confined space in transformers and protective equipment, making it extremely attractive for use on underground systems.
3. In the current-limiting mode of operation, the interrupting time is very fast, one-half cycle or less.
4. Current-limiting action and fast operation reduce the amount of I^2t (or fault energy) let through into failed equipment, thereby reducing resultant damage. In the case of distribution transformers applied on systems of high available fault current, protection by current-limiting fuses can virtually eliminate violent failures due to high fault current.

General-purpose current-limiting fuses are designed to clear fault currents over a broad range. They are defined by ANSI Standard C37.40-3.2.2.2 as fuses capable of interrupting all currents from the maximum interrupting current down to the current causing melting of the fusible element in 1 h. Current-limiting fuses inherently are excellent fault-current interrupters in the high current range. Typical general-purpose fuses operate in the current-limiting mode at fault currents equal to *approximately* 25 times rated current or larger.

Special design and construction techniques are required to obtain clearing of low-fault-current values. For operating times greater than about 0.01 s, the fuses have TC characteristics which are plotted on loglog coordination paper in the same manner as expulsion fuse characteristics.

Backup current-limiting fuses are defined by ANSI Standard 37.40-3.2.2.1 as fuses capable of interrupting all currents from the rated maximum interrupting current down to the rated minimum interrupting current as given by the manufacturer. The low current clearing must be accomplished by an auxiliary device, most commonly an expulsion fuse. In this case, the TC characteristics are a composite of the two fuses as shown in Fig. 18-26. The backup current-limiting fuse can be retrofitted into existing pole-type distribution transformer installations which have expulsion fuse protection only.

18.10 OVERVOLTAGE PROTECTION

Lightning. Lightning is the most frequent cause of overvoltages on distribution systems. Basically, lightning is a gigantic spark resulting from the development of millions of volts between clouds or between a cloud and the earth. It is akin to the dielectric breakdown of a huge capacitor.

The voltage of a lightning stroke may start at hundreds of millions of volts between the cloud and earth. Although these values do not reach the earth, millions of volts can be delivered to the building, tree, or distribution line struck. In the case of overhead distribution lines, it is not necessary that a stroke contact the line to produce overvoltages dangerous to equipment. This is so because "induced voltages" caused by the collapse of the electrostatic field with a nearby stroke may reach values as high as 300 kV.

The amount of current in a stroke is a statistical quantity, depending on the energy in the cloud and the voltage difference between the cloud and the earth at the start of the stroke. A few stroke currents in excess of 200,000 A have been measured; however, 50% of all stroke currents are less than 15,000 A.

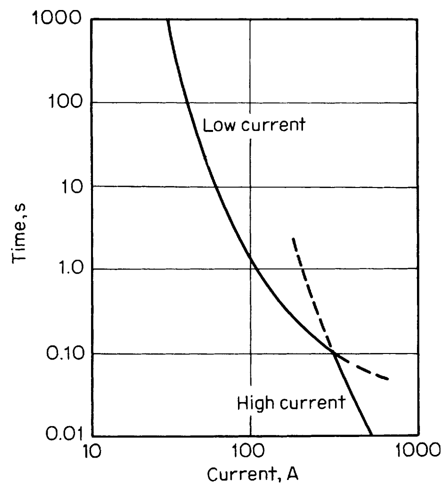

FIGURE 18-26 Time-current characteristic for backup current-limiting fuse in series with expulsion fuse.

The time duration of the current flow in the majority of the high-current strokes is only tens or hundreds of microseconds. Typically, the current rises to its maximum in 0.5 to 10 μs, decreases to half value in 20 to 50 μs, and falls to zero within 100 to 200 μs. On a 60-Hz basis, these are extremely short times if one considers that one-half cycle is equivalent to 1/120 s or 1,000,000/120 = 8333 μs. Numerous field investigations have established the numerical statistics which apply to lightning.

In summary, lightning can produce voltages dangerous to the distribution system and all its component equipment. It poses a major threat to service continuity and must be coped with by means of distribution surge arresters.

Arrester Selection. Choosing an arrester rating for a distribution system is based on the system's line-to-ground voltage and the way it is grounded. The limiting condition for an arrester does not usually have anything to do with the magnitude of the surges (switching or lightning) that it might see. This is in contrast to the selection of arresters for transmission. In distribution, rating of the arrester is based on the maximum steady-state line-to-ground voltage the arrester might see. This limiting condition is normally caused when there ia a line-to-ground fault on one of the other phases.

According to ANSI Standard C62.22, "Guide for the Application of Metal-Oxide Surge Arresters for Alternating-Current Systems," proper application of arresters on distribution systems requires knowledge of "(1) the maximum normal operating voltage of the power system, and (2) the magnitude and duration of temporary overvoltages (TOV) during abnormal operating conditions. This information must be compared to the arrester MCOV rating and to the arrester TOV capability."

The MCOV of the arrester is, however, somewhat easier to define because it is approximately 84% of the arrester duty cycle rating. What this means is that a 10-kV duty cycle rated arrester, typically used for a 13.2-kV system, could be operated continuously with a maximum continuous line-to-ground voltage of 8.4 kV or less.

TABLE 18-6 Commonly Applied Voltage Ratings of Metal-Oxide Arresters on Distribution Systems[a]

System voltage, kV rms		Commonly applied arrester voltage ratings, kV rms duty cycle voltage ratings (MCOV)[b]		
Nominal voltage	Maximum voltage range B[c]	4-Wire multigrounded neutral wye	3-Wire low-impedance[d] grounded[e]	3-Wire high impedance[d] grounded

23000	24340			30 (24.4)
24940Y/14400	26400Y/15240	18 (15.3)	27 (22.0)[f]	
27600Y/15930	29255Y/16890	21 (17.0)	30 (24.4)[f]	
34500Y/19920	36510Y/21080	27 (22.0)	36 (29.0)[f]	

[a]Spacer cable circuits have not been included—there has been insufficient experience with the application of metal-oxide arresters on spacer cable circuits to include them in this table.
[b]For each duty cycle rating, the maximum continuous operating voltage (MCOV) is also listed.
[c]See ANSI C84.1-1989.
[d]Low impedance circuits are typically 3-wire, unigrounded at the source. High impedance circuits are generally ungrounded (i.e., delta). Additional information regarding system grounding is contained in ANSI C62.92, Part 1.
[e]Line-to-ground fault duration not to exceed 30 minutes. For longer durations consult manufacturers' temporary overvoltage capability.
[f]Individual case studies may show lower voltage ratings may be used.

Table 18-6, from ANSI C62.22, shows the commonly applied voltage ratings of metal-oxide arresters for distribution systems. All these duty cycle ratings are the same as the rating for the older gapped silicon carbide arresters except at the 13.8-kV level. Typically, a 13.8-kV, 4-wire, multigrounded system has used 10-kV gapped arresters. Today, most of these same utilities are still using 10-kV MOVs. Some utilities, however, have recognized that the 10-kV arrester is very marginal and possibly should be replaced by a 12-kV rating to be on the more conservative side.

TOV. How much voltage shift which will occur is a function of the type of system grounding. For example, on a delta system, a line-to-ground fault will cause a full offset; that is, the line-to-ground voltage will become the line-to-line voltage. Figure 18-27 illustrates this condition. As can be seen, when a phase has a fault there is no current because the transformer is delta-connected. For a 4-wire multigrounded system, there is less voltage rise (Fig. 18-28). The arresters connected from nominal line-to-neutral voltage multiplied by the product of the regulation factor 1.05 and the voltage rise factor 1.2. This is equivalent to 1.25 times nominal line-to-neutral system voltage. For an MOV type arrester, this voltage is compared with the TOV rating of the MOV. Because the MOV arrester is more sensitive to poor grounding, poor regulation, and the reduced saturation sometimes found in new transformers, it is generally recommended that a 1.35 factor be considered for MOVs.

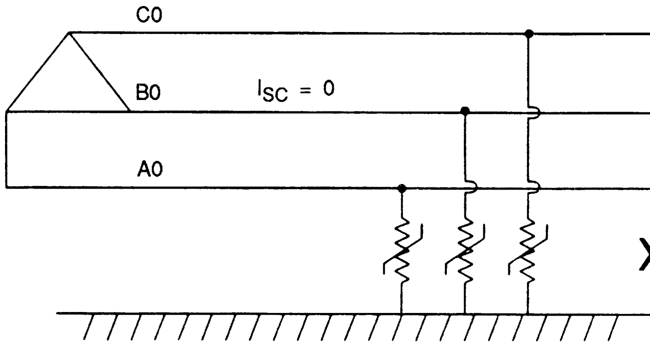

FIGURE 18-27 Line-to-ground fault on a delta system.

A summary of this and other recommendations is as follows:

Open-wire multigrounded system:

$$\text{Rating} = \text{nominal line-to-ground (L-G) voltage} \times 1.25 \text{ (gapped)}$$

$$\text{Rating} = \text{nominal L-G voltage} \times 1.35 \text{ (MOV)}$$

Spacer cable systems:

$$\text{Rating} = \text{nominal L-G voltage} \times 1.5$$

$$\text{Unigrounded rating} = \text{nominal L-G voltage} \times 1.4$$

The temporary overvoltage capability of the arrester as a function of time is shown in Fig. 18-29.

Insulation Coordination

Margins for Overhead Equipment. It is important to note that application of arresters for transmission and distribution is different. In transmission, lightning is of secondary concern in surge

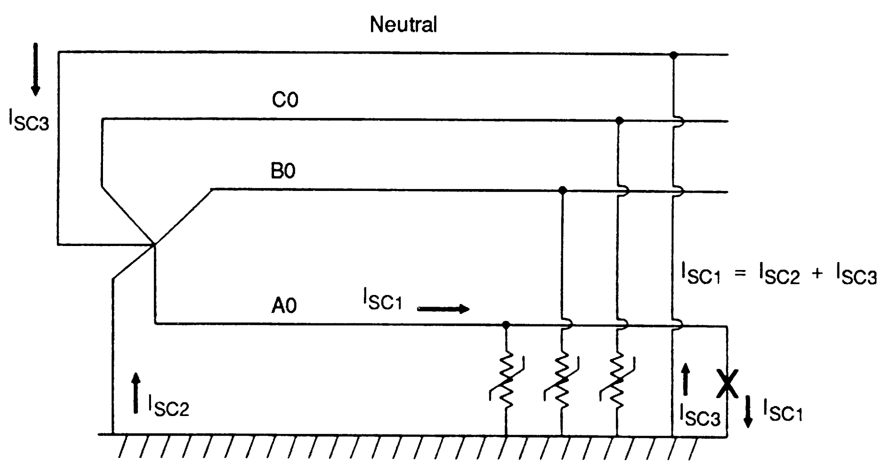

FIGURE 18-28 Line-to-ground fault on a grounded-wye system.

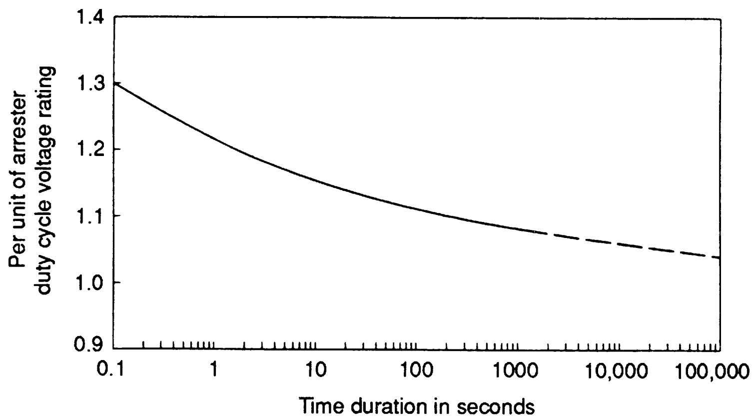

FIGURE 18-29 Example TOV curve (consult arrester manufacturer for exact curve).

arrester application. Primary concern is switching surges. On a distribution circuit, however, the relatively low voltage and short lines tend to make switching surges minimal, and consequently, lightning is of primary importance.

Reflection of this fact can be seen in typical characteristics published for distribution-class arresters, as shown in Tables 18-7 and 18-8. As can be seen, protective characteristics are shown for front-of-wave sparkover and *IR* discharges but not for switching surge waves (as shown for higher rated transmission arresters).

The two protective characteristics normally used for insulation coordination are

Front-of-wave sparkover. This is the first thing that happens to the gapped arrester—it sparks over. It is compared with the fast front equipment insulation characteristics such as the chopped wave insulation level of the transformer. An MOV has no gap but does have an equivalent sparkover, as shown in Table 18-8.

IR discharge at 10 kA. After the arrester sparks over the gap, the lightning current discharges through the block material. Standards recommend that a 10-kA discharge level be used for coordination purposes. (Discharge characteristics across a MOV are very similar to gapped silicon carbide arresters, so the margin calculation is virtually identical.)

TABLE 18-7 Distribution Arrester Characteristics from Handbook—Silicon Carbide

Arrester rating, kV RMS	Maximum ANSI front-of-wave sparkover, kV crest		Maximum discharge voltage, kV crest at indicated 8 × 20-μs impulse current

36	30.4	124.8	107.0	116.6	131.3

*Based on a 10-kA current impulse that results in a discharge voltage cresting in 0.5 μs.

Distribution equipment is normally defined as being in a voltage class such as 15 or 25 kV. Most utility equipment is operated in the 15-kV class. A distribution transformer in the 015-kV class is defined by the following insulation characteristics:

60-Hz, 1-min withstand = 34 kV

Chopped wave (short-time) = 110 kV at 1.8 μs

Basic insulation level (BIL) = 95 kV

Assuming a 12,470-V, 4-wire system (7200 V L-G), we would select the arrester rating based on the rules developed in the preceding section, i.e., a 9-kV arrester (gapped).

We can see from Tables 18-7 and 18-8 that a 9-kV gapped arrester has a sparkover of 39 kV and an *IR* discharge at 10 kA of 36 kV. This could be plotted with the transformer characteristics as in Fig. 18-30.

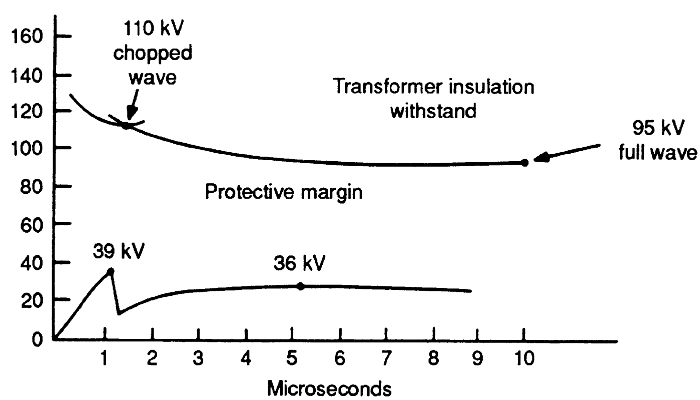

FIGURE 18-30 Insulation coordination.

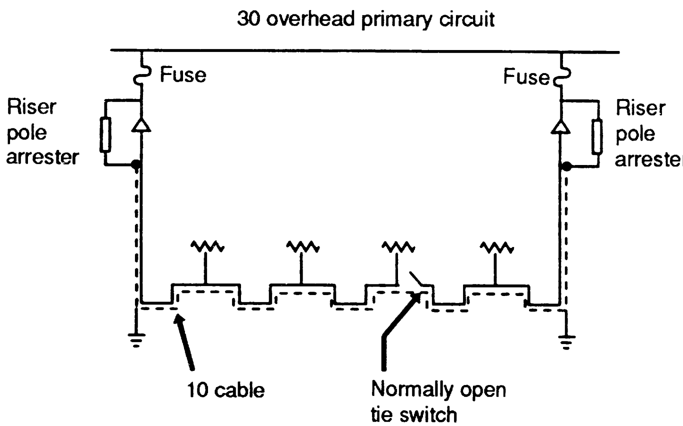

FIGURE 18-31 Underground lateral.

Standards recommend 20% margins calculated by the formula:

$$\text{Margin} = \frac{\text{insulation withstand} - \text{protective level}}{\text{protective level}} \times 100$$

Two margins are calculated, one for the chopped wave and one for the full wave (BIL) of the transformer. These calculations are performed as follows:

$$\text{Margin} = \frac{110 - 39}{39} \times 100\% = 182\% \text{ (chopped wave)}$$

$$\%\ \text{Margin} = \frac{95 - 36}{36} \times 100\% = 164\% \text{ (BIL)}$$

As can be seen, these margins (182% and 164%) are greatly in excess of the recommended 20% and consequently show good protection practice. If we were using an MOV, we would simply use the equivalent sparkover or compare only the *IR* discharge and the BIL, since this is the lesser of the two margins. The margins would be similar.

Margins for Underground Equipment If the system is underground, we must be more concerned with the phenomena of traveling waves and the consequent doubling of voltage surges at an open point. For example, a typical underground residential design is shown in Fig. 18-31. A surge entering the cable will travel to the open point where its voltage will double, as shown in the figure, and start on its way back.

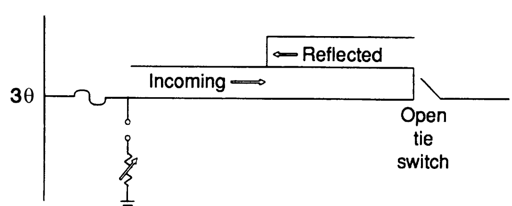

FIGURE 18-32 Reflected surge voltage at open point.

This reflected wave plus the incoming waves impose approximately twice the normal voltage on the entire cable and all the equipment connected to it (Fig. 18-32). For example, if we had an arrester with a 36-kV *IR* discharge level (we are only considering BIL margin), we would now expect to see

72 kV imposed across the insulation of this equipment. The new margin would then be calculated as follows:

$$\% \text{ Margin} = \frac{95 - 72}{72} \times 100 = 32\%$$

For higher voltage levels, where the margins become considerably less, it may be necessary to use an arrester at the open point or riser-pole arresters having lower discharge levels.

18.11 DISTRIBUTION TRANSFORMERS

Distribution transformers convert electrical energy from primary voltages (2.4 to 34.5 kV) to utilization voltages (120 to 600 V). Momentary drops in lighting voltage caused by the starting current of motors often necessitate use of separate transformers where 3-phase motors 20 hp and larger and 1-phase motors 6.5 hp and larger must be served from radial circuits.

Standard Ratings of Single-Phase Distribution Transformers. By agreement between users and manufacturers, certain features of line-transformer design have been standardized for sizes up to 500 kVA and for voltages up to 67,000 V. Capacities are 10, 15, 25, 37 1/2, 50, 75, 100, 167, 250, 333, and 500 kVA.

Voltage ratings on primary windings are 2400/4160Y, 4800/8320Y, 7200/12,470Y, 12,470GrdY/7200, 7620/13,200Y, 13,200GrdY/7620, 12,000, 13,200/22,860GrdY, 13,200, 13,800GrdY/7970, 13,800/23,900GrdY, 13,800, 14,400/24,940GrdY, 16,340, 24,940GrdY/14,400, 19,920/34,500GrdY, 34,500GrdY/19,920, 22,900, and 34,400. On the secondary side, windings are built for 3-wire operation at voltages of 120/240 or for 240/480. For some of the larger kVA sizes, secondary side windings are available at voltages from 2400 to 7970 V. Bushings for secondary terminals are located on the side of the case, except that primary bushings for 7200 V and higher are cover-mounted.

TABLE 18-9 Typical Electrical Characteristics of Single-Phase and 3-Phase 60-Hz Distribution Transformers
Loss factors can vary according to evaluation factors.

Size, kVA	Percent *IR*	Percent *IX*	Percent *IZ*	Percent no-load loss	Percent load loss
Pole-type single-phase transformers—voltage rating 7200/12,470Y to 120/240 V

Supporting lugs are arranged to permit mounting either by bolting to the pole or by hanging on crossarms. Where necessary, provision is made for a grounding connection to the case or from the secondary neutral terminal to the case. Similar standards have been promulgated by ANSI for 3-phase pole-type transformers up to 500 kVA.

Electrical characteristics typical of single- and 3-phase transformers of the 12470Y/7200V class are given in Table 18-9. Distribution transformers with different primary voltages will have values only slightly different from those shown in Table 18-9. Transformer regulation for a kVA load of power factor cos θ, at rated voltage, can be calculated from the formula

$$\text{Percent regulation} = \frac{\text{kVA load}}{\text{kVA transformer}}\left[\%\,IR\cos\theta + \%\,IX\sin\theta + \frac{(\%\,IX\cos\theta - \%\,IR\sin\theta)^2}{200}\right]$$

Transformers are installed on poles in the following ways: transformers 100 kVA and smaller are bolted directly to the pole, and sizes 167 to 500 kVA have support lugs attached to the transformer and intended for bolting to adapter plates for direct pole mounting or hung on crossarms by means of steel hangers attached securely to the transformer.

Banks of three single-phase transformers are hung side by side on heavy double arms, usually located low on the pole, or on a "cluster" bracket which spaces them around the pole. Three or more transformers 167 kVA and larger are installed on a platform supported by two poles set 10 to 15 ft apart. The transformer-platform structure is often placed on the customer's premises to reduce the distance that secondaries must be run and to avoid pole congestion on public thoroughfares.

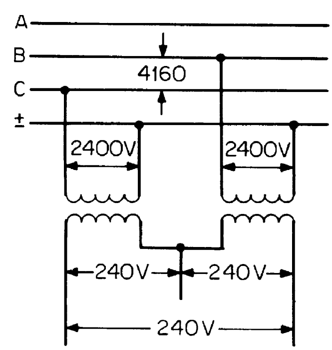

FIGURE 18-33 Open Y connection from 4-wire, 3-phase system.

Transformers are installed in street vaults, in manholes, on pads at ground level, subsurface, or within buildings. When installed within buildings where the possibility of submersion is remote, the overhead or inside types of transformer and cutout are used. Transformer vaults within a building are of fireproof construction, except when transformers are dry type or filled with nonflammable liquid.

Pole-Mounted Regulators. Today 16- or 32-step regulators built for pole mounting cover the customary ±10% voltage range. Voltage-level control and line-drop compensators give them essentially the same characteristics as the larger station regulators.

Open-Δ connection enables small power customers to receive 3-phase service from two transformers connected to a 3-phase circuit, thus reducing the investment in transformers. Open-Δ from a 3-wire system is the usual Δ connection with one transformer omitted. The connection from a 4-wire system is shown in Fig. 18-33, 2-phase wires and neutral being used on the primary side of the transformers. Current in each of two single-phase transformers connected in open Δ is 73% greater than in each of three transformers connected in closed Δ.

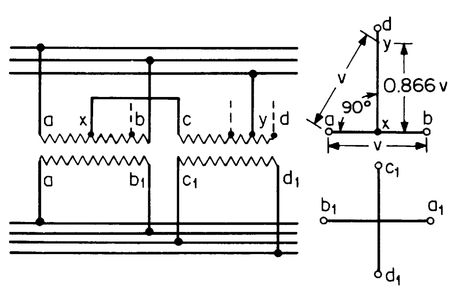

FIGURE 18-34 Balanced T- or Scott-connected transformer connection for 3- to 2-phase transformation.

The *Scott connection* shown in Fig. 18-34 gives an accurate transformation but requires one of the transformers to have an 86.6% tap and the other to have a 50% tap.

18.12 SECONDARY RADIAL DISTRIBUTION

Secondary mains operate at utilization voltage and serve as the local distributing main. In early commercial radial systems, secondary mains that supply general lighting and small power are usually separate from mains that supply 3-phase power because of the dip in voltage caused by starting motors. This dip in voltage, if sufficiently large, causes an objectionable lamp flicker.

Single-phase secondary mains supplying general lighting and small power are usually 3-wire mains operating at 120 V line-to-neutral and 240 V line-to-line. Incandescent lamps, fans, heating devices, small fractional-horsepower motors, and other appliances rated 115 or 120 V are supplied from the 120-V line and neutral. Electric ranges, larger single-phase motors up to 6.5 hp, and large appliances rated 230 or 240 V are supplied 240 V. Some utilities supply these loads at 120/208 V.

Three-phase secondary mains are commonly operated 3-wire 240 V. Some utilities offer 208Y/120-V 3-phase 4-wire service. The 3-phase mains are on the same poles or in the same duct line (but in separate ducts) with single-phase lighting mains. Separate single-phase and 3-phase services are extended to customers who require both types of service. In large commercial and industrial installations, power is often delivered at 480 V to effect an economy in conductor investment.

European practice is to supply 230 V to lighting and appliances from a 230/440-V system. This effects a savings in distribution and interior wiring but results in less efficient incandescent lamps and other small appliances.

In America, large commercial buildings and factories are served at 480Y/277 V because most permanent lighting is fluorescent, which operates efficiently at 277 V, and 480 V is well suited for the numerous 3-phase motors. Such installations have small dry-type transformers to supply 120 V for portable lights, convenience outlets, and tools and for business machines; these transformers are located near the 120-V loads and supplied from the 480-V system.

Fractional-horsepower motors up to about 3/4 hp are regularly supplied by single-phase 120-V mains. Industry committees, sparked by sudden acceptance of home air conditioning, several years ago agreed to permit starting currents not to exceed 50 A for 115-V motors. Special design enabled motors up to 3/4 hp to meet this limitation. Larger motors up to 6.5 hp are usually served at 240 V, although 3- and 6.5-hp motors may require extra care in distribution design to avoid troublesome flicker. Motors larger than 6.5 hp are usually connected 3-phase. Three-phase service is not usually supplied in residential areas.

Light and Power from One Secondary Main. In a *radial* system, 3-phase service is sometimes supplied from a separate secondary main if voltage is affected by elevator motors or other intermittently used load. If separation of light and power service is not necessary, the nature of the connection may depend upon the relative size of light and power loads. When power load is predominant, lighting load may be served by providing additional capacity in one of the transformers and bringing in a neutral from it for the lighting service. The neutral for lighting service is sometimes derived from a transformer connected to one phase of 240- or 480-V power circuits giving 120/240 V for lighting. This is the usual procedure where power is served at 480 V. When the lighting load is predominant, service is often provided at 208Y/120V, 4-wire.

Transformer and Secondary-Main Economy, Overhead Distribution. Several independent studies have been made to determine the proper combination of transformer and radial secondary main that provides satisfactory voltage regulation and costs a minimum per kVA of load served. All these studies indicate that for 120/240-V single-phase distribution, overhead secondary mains should be three No. 1/0 to three No. 4/0 aluminum, the latter being preferred when air conditioning or heating is to be served.

Permissible length of the three No. 1/0 aluminum secondary mains depends on the load density. On the assumption of evenly distributed loads and 3% drop in the mains, for 15 kW/1000 ft, the permissible length is 600 ft, and for 30 kW/1000 ft, 400 ft. Widespread use of ranges and motor-driven appliances establishes an additional limit for flicker at 200 to 300 ft.

Transformer size should be such that the initial peak load is between 75% and 100% of rated capacity. In medium-load densities, 25- and 50-kVA transformers will fulfill this requirement. Transformers should be allowed to remain in service until their winter peak load reaches at least 150% to 180% of rated capacity. When this occurs, the “hot spot” winding temperature is approaching 110°C—the maximum safe temperature.

Load growth should be taken care of by *installing additional transformers* and cutting radial secondaries or by *increasing the size* of the existing transformers where secondary-main regulation permits. The three No. 1/0 to 4/0 aluminum single-phase secondary mains should not be replaced by larger conductors to improve secondary-main regulation. Additional transformers should be installed and parts of the existing mains transferred to the new transformers.

Underground systems should also be designed initially with capacity for growth. In order to accomplish this, many utilities in underground residential distribution (URD) work do not use secondary mains. Rather, one transformer is used to supply four to six homes by installing service drops large enough for future loads from the transformer to each home. With this system design it is relatively easy to change out the transformer to a larger size when the load grows.

Pad-mounted transformers can be sized and operated the same as overhead-type transformers. Advantage can be taken of the short-time overload capability given by ANSI C57.91, “Guide for Loading Mineral Oil Immersed Overhead-Type Distribution Transformers with 55C or 65C Average Winding Rise.” Subsurface transformers in close-fitting cylindrical vaults require special baffles and chimney specified by the manufacturer in order that they might be loaded the same as an overhead-type transformer.

Subway-type transformers should not be replaced or relieved of load until the calculated hot-spot winding temperature exceeds 110°C, provided, of course, that voltage at the ends of the secondary is satisfactory. To calculate hot-spot winding temperature, the maximum load and top-oil (or case) temperatures must be measured. Maximum case temperature has been found to be within 3°C of top-oil temperature. It is assumed in making the calculation that the difference between hot-spot-winding and top-oil temperature is 20°C at full load and that this difference varies as the square of load. This is a conservative assumption. For example, assume maximum case temperature 67°C when 130% load is on the transformer. Then the calculated winding hot-spot temperature is given by

$$67°\text{C} + 3°\text{C} + 20°\text{C}(1.30)^2 = 114°\text{C}$$

Fans to supplement natural air movement have been used to boost safe capability of vault transformers.

Table 18-10 gives the voltage drop per 10,000 A · ft for single-phase and 3-phase secondaries for a variety of load power factors. The underground portion of the table can be used for underground systems and also overhead systems where triplex cable construction is employed. The overhead part of the table gives the voltage-drop information for overhead aluminum conductors on racks. The table can be used to determine voltage drop quickly on any secondary circuit if load, circuit length, and conductor size are known.

All values in the table are for aluminum conductors at 50°C temperature. Values for copper can be determined with satisfactory accuracy by using the table for a conductor of equivalent resistance; that is, use an aluminum conductor two sizes larger than the copper conductor.

In using the table, the first thing required is the number of ampere-feet involved in the problem. This is obtained by multiplying the amperes per phase by length of circuit in feet. (For single-phase, use number of feet between source and load; impedance of return circuit is included in table.) Divide this ampere-feet by 10,000 to determine the multiplier to be used with values in the table. For the proper voltage, conductor size, and power factor, find the voltage-drop factor in the table and multiply by the multiplier determined previously. This will be the absolute line-to-neutral volts difference (drop) between the sending and receiving ends of the circuit. Dividing by the line-to-neutral voltage

Note: 1 in = 25.4 mm; 1 ft = 0.3048 m. Regulation of copper conductors can be estimated with reasonable accuracy the same as that of aluminum conductors two sizes larger.

*Values in the table give the difference in absolute value between sending-end and receiving-end line-to-neutral voltages of balanced 3-phase circuit and phase-to-phase or phase-to-neutral voltages of single-phase circuit.

†Underground cable impedances are based on 50°C conductor temperature with close triangular spacing of cable using typical solid-dielectric insulation, 100% insulation level, single conductor.

‡Overhead conductor impedances are based on 50°C conductor temperature with 8-in equivalent spacing for single-phase and 10-in spacing for 3-phase.

of sending end or receiving end and multiplying by 100 will express this as a percentage of sending- or receiving-end voltage, respectively.

Example. Given a 3-phase 60-Hz secondary 500 ft in length, which consists of No. 4/0 aluminum conductor cable; conductor temperature 50°C; receiving-end load 100 kVA at 0.8 power factor lagging; receiving-end line-to-line voltage 480.

$$A \cdot ft = \frac{100}{\sqrt{3} \times 0.48} \times 500 \text{ ft} = 60{,}142, \text{ or } 6.014 \text{ times tabular value}$$

From Table 18-10 for No. 4/0 cable, 0.8 of the value is 0.902. Line-to-neutral voltage drop is 0.902 × 6.014 = 5.425. This is 5.425/277 × 100 = 1.96% voltage drop on basis of receiving end.

18.13 BANKING OF DISTRIBUTION TRANSFORMERS

Banking. Tying together the secondary mains of adjacent transformers supplied by the same primary feeder is known as *banking*. The practice of banking, when used, is usually applied to the secondaries of single-phase transformers, and all transformers in a bank must be supplied from the

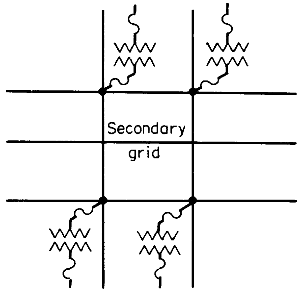

FIGURE 18-35 Fuse application in grid systems.

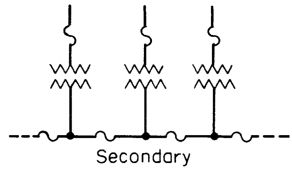

FIGURE 18-36 Fuse application in straight-line systems.

same phase of the primary circuit. The use of banking is not as prevalent as it was formerly. Banked distribution transformers differ from the low-voltage ac network in that one circuit supplies all transformers where secondaries are banked together, whereas different circuits supply adjacent transformers in an ac low-voltage network. Only a few companies operate their transformers banked.

Advantages claimed for banking compared with secondary radial distribution are (1) reduction in lamp flicker caused by starting motors; (2) less transformer capacity required because of greater load diversity among a larger group of customers; (3) better average voltage along the secondary; and (4) greater flexibility for load growth. There are two general types of secondary banking: the grid type and the straight-line type, as shown in Figs. 18-35 and 18-36.

18.14 APPLICATION OF CAPACITORS

Power Factor Correction. It is desirable to add shunt capacitors in the load area to supply the lagging component of current. The cost is frequently justified by the value of circuit and substation capacity released and/or reduction in losses. Installed cost of shunt capacitors is usually least on primary distribution systems and in distribution substations.

The application of a shunt capacitor to a distribution feeder produces a uniform voltage boost per unit of length of line, out to its point of application. Therefore, it should be located as far out on the distribution system as practical, close to the loads requiring the kilovars. There are some cases, particularly in underground distribution, where secondary capacitors are economically justified despite their higher cost per kilovar.

Development of low-cost switching equipment for capacitors has made it possible to correct the power factor to a high value during peak-load conditions without overcorrection during light-load periods. This makes it possible for switched capacitors to be used for supplementary voltage control. Time clocks, temperature, voltage, current, and kilovar controls are common actuators for capacitor switching.

Capacitor Installations. Capacitors for primary systems are available in 50- to 300-kvar single-phase units suitable for pole mounting in banks of 3 to 12 units. Capacitors should be connected to the system through fuses so that a capacitor failure will not jeopardize system reliability or result in violent case rupture. To ensure that the proper fuse protection is provided, the installed capacitor fuse ratings are listed in Tables 18-11 and 18-12 and the probability of rupture is shown in Table 18-13.

[k]For 300-kvar and larger only.

Effect of Shunt Capacitors on Voltage. Proposed permanently connected capacitor applications should be checked to make sure that the voltage to some customers will not rise too high during light-load periods. Switched capacitor applications should be checked to determine that switching the capacitor bank on or off will not cause objectionable flicker. The curves in Fig. 18-37 can be used to compute voltage rise.

Effect of Shunt Capacitors on Losses. The maximum loss reduction on a feeder with distributed load is obtained by locating capacitor banks on the feeder where the capacitor kilovars is equal to twice the load kilovars beyond the point of installation. This principle holds whether one or more than one capacitor bank is applied to a feeder.

Capacitor kilovars up to 70% of the total kilovar load on the feeder can be applied as one bank with little sacrifice in the maximum feeder-loss reduction possible with several capacitor banks. A rule of thumb for locating a single capacitor bank on a feeder with uniformly distributed loads is that the maximum loss reduction can be obtained when the capacitor kilovars of the bank is equal to two-thirds of the kilovar load on the feeder. This bank should be located two-thirds of the distance out on the distributed feeder portion. Deviation of the capacitor bank location from the point of maximum loss reduction by as much as 10% of the total feeder length does not appreciably affect the loss benefit. Therefore, in practice, in order to make the most out of the capacitor's loss reduction and voltage benefits, it is best to apply the capacitor bank just beyond the optimum loss-reduction location.

18.15 POLES AND STRUCTURES*

Overhead Construction. Although overhead distribution construction remains less costly than underground, the vast majority of *new* residential developments are being served by underground systems. However, most new main feeder circuits and rural and semirural systems are being constructed overhead. Also, because of the tremendous amount of overhead distribution plant already in place, it is important to have a good grasp of overhead construction.

Appearance Considerations. For many years, the traditional overhead distribution construction embodied one or more crossarms on each pole for mounting primary insulators, distribution transformers, surge arresters, cutouts, etc. However, back in the early 1960s when public interest in appearance made itself manifest, many new concepts in overhead construction were introduced in the interest of obtaining better-appearing systems. The principal change was the introduction and wide use of "armless" construction wherein insulators and equipment are directly mounted to the poles. Other ideas also were introduced, such as use of shorter poles, cabled secondaries and services, strategic use of steel poles to reduce or eliminate need for guy wires, and fewer circuits per pole. It should be noted, however, that cabled secondaries employ a "covered conductor" which can withstand momentary contact between conductors but which is appropriately considered by the National Electrical Safety Code ANSI C2 to be the same as bare conductor for clearances to other objects and for all other purposes. In addition, the black covering adds both thickness and contrast to the cables when viewed against the sky.

Wood poles have been used almost universally for overhead distribution lines because of the abundance of the material, ease of handling, and cost. The life of wood poles is materially extended with wood preservatives, and cedar, pine, and fir are most commonly used.

Specifications and dimensions for wood poles are presented in ANSI 05.1. Poles meeting the requirements of this standard are grouped into classes based on their circumference at a location 6 ft from the butt. Poles of a given class and length are designed to have approximately the same load-carrying capacity regardless of species. ANSI 05.1 used a uniform methodology for testing poles that

*To avoid inappropriate duplication, certain discussions common to transmission and distribution may be found in Sec. 14.

required a uniform fulcrum-point location. This point generally was 2 ft plus 10% of the length of the pole measured up from the butt of the pole. This same value has been used as a setting depth for many locations but is not sufficiently deep for some soils.

The minimum circumferences specified at 6 ft from the butt have been calculated in order for each species in a given class to develop, at the ground line, appropriate stresses when a given horizontal load is applied 2 ft from the top of the pole. The horizontal loads used in the calculations for identifying the 15 classes are as given in Table 18-14.

TABLE 18-14 Loads Used to Identify Pole Classes

Pole class	Horizontal load, lb
H6	11,400
H5	10,000
H4	8,700
H3	7,500
H2	6,400
H1	5,400
1	4,500
2	3,700
3	3,000
4	2,400
5	1,900
6	1,500
7	1,200
8	740
10	370

Note: 1 lb = 0.4536 kg.

In making the calculations, it was assumed that the pole is used as a simple cantilever and that the maximum fiber stress in the pole due to the bending moment will occur at the ground level. The circumference at the ground line was calculated using standard engineering formulas. This circumference value was then used to calculate the circumference 6 ft from the butt using typical tapers per foot of length between the ground line and the point 6 ft from the butt.

The assumption of maximum fiber stress at the ground line is theoretically correct if the taper of the pole is such that the circumference at the ground line is not more than 1$^1/_2$ times the circumference at the point of loading. If the circumference at ground line is more than 1$^1/_2$ times the circumference at the point of loading, the maximum fiber stress theoretically occurs at a location above the ground line where the circumference is 1$^1/_2$ times the circumference at the point of loading. This makes it necessary to calculate specific loads supported.

Typical tapers used in determining the required circumference 6 ft from the butt circumference range of 0.38 for western cedar to 0.20 for western hemlock. These numerical values are in change in circumference per foot of length.

Concrete poles reinforced with steel originally were employed chiefly for street-lighting standards, where a neat appearance is demanded. But some concrete poles have been used for general distribution as well, usually with a minimum of attached wires and apparatus.

With the increased manufacturing and quality control capability for prestressed concrete poles, and the need for tall structures for narrow rights of way or aesthetic requirements, has come the more frequent use of prestressed concrete poles in transmission lines. As demands for transmission facilities in urban narrow rights of way have increased, they have been most often met with steel single-pole structures, especially where two circuits are required.

Steel poles, ordinarily set in concrete, have long been used to support street lights. More recently, in a more ornamental form and bolted to concrete foundations, they have been used for parkway lighting and, to a limited extent, for distribution where appearance demands.

Aluminum poles also are employed for parkway lighting standards and for certain other locations. They are bolted to concrete foundations to avoid the attack of fresh cement on aluminum. Although use of aluminum on transmission lines has increased, it has been with latticed structures, not generally with poles.

Types of Loading. Poles carrying overhead distribution lines are subject to vertical and horizontal forces, of which some are continuous and others are applied only under abnormal or occasional conditions. Normal vertical forces are the weight of wires, transformers, and other equipment, and these are less than normal horizontal forces in many cases. Abnormal vertical load is imposed when wires are coated with ice, which may increase their normal weight 200% to 400%. For example, the weight of six covered No. 6 copper wires 100 ft long is normally 67 lb, but ice to a radial thickness of 0.5 in increases their weight to about 370 lb.

Normal horizontal forces acting on a pole are the unbalanced component of wire tension at turns and corners, the side pull of service drops, and the horizontal component of weight when the pole is not vertical. Abnormal horizontal stresses are imposed by wind pressure, by breakage of conductors, or by failure of supporting guys.

Application of Loading. Vertical loading of wires and equipment is applied through crossarms and other attachments to the pole. These forces are amply sustained by poles chosen to meet requirements of transverse forces, except that for line transformers, poles having 1-in greater diameter than line poles may be chosen. Transverse forces from unbalanced conductor tension at corners and bends are normally the greatest forces acting on the line. These are usually carried by guy cables secured to suitable anchorages, which relieve the pole itself of the stress. In some cases, the pole is underbraced and carries the entire load.

Ice Loading. When wires are loaded with ice, conductor tension is increased in direct proportion to the added weight of ice and may become two to four times as great as normal. This stress is borne by the conductors and, through them, communicated to the pole and the guying system. Where ice loading occurs, the guying system must have a suitable factor of reserve to meet abnormal loadings. The tension of conductors being increased with ice loading, elasticity in the wire permits a slight increase in length which makes tension less than the calculated amount for nonelastic conductors and supports.

Wind Loading. Loading due to wind pressure becomes appreciable in the design of poles and structures when wind velocities of over 40 mi/h are prevalent. Such forces are most noticeable on overhead lines when the direction of wind is at right angles to the direction of wires, both because the area exposed is greatest at that angle and because the force exerted is sustained by the pole without the aid of guying.

The area of conductors exposed to wind is much increased by a coating of ice, and the combination of ice with high wind is often the most severe loading condition to which a line is subjected. In many parts of the United States such a condition is never experienced, and it is very rare even where ice coatings occur almost every winter, since the conductor movement due to wind tends to break off the ice coating.

However, with the introduction of large-diameter conductors and bundled-conductor configurations, high winds in summer or other storm periods not involving ice may cause the greater problem. As a result, the NESC requires that severe wind conditions be checked if any portion of the structure or conductors exceeds 60 ft above grade.

Strength of Wood Poles. The strength of a wood pole must be sufficient to withstand transverse forces such as wind pressure on the pole and conductors, unbalanced pull on conductors when they are broken, and side pull on curves and corners where guys cannot be provided. These forces place the fiber on the wood under tension, and the load which a pole will carry is determined by the inherent strength of its wood fiber under tension and the moment of forces. The moment is

$$M = PL + P_1L_1 + P_2L_2 + \cdots \tag{18-13}$$

in which P = force, lb, acting at one crossarm, L = height, ft, at which the arm is attached, P_1, P_2, etc. = forces acting on other arms, and L_1, L_2, etc. = respective heights. If s = fiber stress, lb/in^2, and c = circumference at the ground, in, the allowable moment of a pole of given size is

$$M = 0.00026386sc^3 \tag{18-14}$$

Thus, for a pole having a ground-line circumference of 40 in and an allowable fiber stress in an emergency of 2500 lb/in^3, the maximum allowable moment is

$$M = 0.00026386 \times 2500 \times (40)^3 = 42{,}218 \text{ lb} \cdot \text{ft}$$

If the average height of attachments is 30 ft, total force is 42,200/30 = 1407 lb.

The ultimate fiber stresses for various species of wood poles are listed in ANSI 05.1. In practice, the actual pole stresses are limited to some allowable percentages of ultimate stress. The NESC, provides guidelines for allowable stresses under vertical and transverse loading. The National Weather Service now records wind data that include gust speeds. Consult the latest *NESC Handbook* for requirements in effect at the time of line design. Some utilities use larger factors of safety in their designs to allow for errors in tensions, nonuniformity of soils, or special loading requirements; different factors of safety may be used for normal unbalanced forces and for abnormal forces of a temporary nature.

When the maximum fiber stress is above the ground line because of taper of the pole, the allowable moment can be calculated in a manner similar to Eq. (18-14) using the circumference of the pole at the point of load application and the taper of the pole to determine the location where the circumference is $1^1/_2$ times that at the location at the load. Usually decay is greatest at the ground line, and as the pole ages, its ground-line circumference is reduced to make it the point of greatest fiber stress.

Example of Calculation of Pole Size. ANSI 05.1 specifies a value of ultimate fiber stress for western cedar of 6000 lb/in^2. Assume a 40-ft pole and a depth of setting of 6 ft. Assume the pole will carry a transverse pull of 400 lb at a height of 32 ft and another of 90 lb at 30 ft. What class of pole is required and what are its circumferences at ground line and at top?

$$M = PL + P_1L_1 = 400 \times 32 + 90 \times 30 = 15{,}500 \text{ ft} \cdot \text{lb}$$

If a factor of safety of 4:1 is used with respect to the ultimate stress, the allowable fiber stress is 6000/4 = 1500 lb/in^2. From Eq. (18-14),

$$c = \sqrt[3]{\frac{M}{0.00026386s}} = \sqrt[3]{\frac{15{,}500}{0.00026386 \times 1500}}$$

$$= \sqrt[3]{39{,}162} = 33.96 \text{ in at the ground line}$$

From ANSI 05.1, Table 5, this corresponds very closely to a Class 5 pole, which has a circumference of 34.0 in (10.82 in diameter) at 6 ft from the butt. Minimum circumference of this class of pole at the top is 19 in (6.05 in diameter).

If the allowable fiber stress were increased to one-half the ultimate (factory of safety = 2), the moment could be increased to

$$M = 0.00026386 \times 3000 \times (34)^3 = 31{,}112 \text{ ft} \cdot \text{lb}$$

If this were a northern white cedar pole, having an ultimate fiber stress of 4000 lb/in^2 and a safety factor of 4, the ground-line circumference would be

$$c^3 = \frac{15{,}500}{0.00026386 \times 1000} = 58{,}743 \text{ ft} \cdot \text{lb}$$

$$c = \sqrt[3]{58{,}743} = 38.87 \text{ in}$$

From Table 3 of ANSI 05.1, this is very close to the Class 5 pole, which has a specified circumference of 39 in 6 ft from the butt. This also illustrates that the pole classification, in effect, defines the loading capability of the pole regardless of the species.

Wind Pressure. Wind pressure must be taken into account when designing a pole line. For purposes of calculation, the following formulas are often used to calculate pressures due to wind:

$$P = 0.004V^2 \tag{18-15}$$

where P = pressure, lb/in^2, on flat surfaces normal to the wind, and V = wind velocity, mi/h

$$P = 0.0025V^2 \tag{18-16}$$

for cylindrical surfaces such as wires and poles. Values of V can be obtained from weather bureau records for the particular locality.

Wind pressure on a 40-ft pole, of which 34 ft is above ground, with 7 in top diameter and 14 in butt diameter, can be calculated as follows:

$$\text{Projected area} = [(7 + 14) \times \tfrac{1}{2}] \times 34 \times 12 = 4284 \text{ in}^2$$

$$= 4284/144 = 29.75 \text{ ft}^2$$

A wind of 60 mi/h would cause a force calculated by Eq. (18-16):

$$P = 0.0025 \times (60)^2 = 9.0 \text{ lb/ft}^2$$

Since the uniform wind pressure is applied to a long, slender trapezoidal area whose center of gravity is 15.11 ft above the ground line, the resulting moment about the ground line is

$$9 \times 29.75 \times 15.11 = 4046 \text{ ft} \cdot \text{lb}$$

With the diameter of a typical distribution conductor taken as about 0.35 in, the total wind force on a 150-ft span assuming 60 mi/h would be

$$\left(150 \times \frac{0.35}{12}\right) \times 0.0025 \times (60)^2 = 39.375 \text{ lb}$$

On six conductors it would be 236.25 lb. Assuming that the conductors have an effective height of 31 ft at the pole, the resulting moment is $236.25 \times 31 = 7324$ ft · lb. The sum of the moments from wind pressure on pole and wires is

$$4046 + 7324 = 11{,}370 \text{ ft} \cdot \text{lb}$$

When distribution transformers, capacitors, voltage regulators, or other equipment are mounted on the pole, resulting wind forces should be taken into consideration.

In some areas where (1) overhead facilities are subject to high winds; (2) the soil is such as to provide relatively poor overturning resistance; and (3) underground facilities are inappropriate, such as barrier islands subject to hurricane and tidal forces, a unique system is employed to provide for minimum storm damage and quick return to service. In these cases, the structures are deliberately overdesigned relative to their natural foundations so that they will lean, rather than break, under excessive wind loading. Power is turned off as winds reach hurricane speed. After the storm, the lines are inspected, leaning poles are straightened, and service is restored, all with a minimum outage time and expense.

Ice- and wind-loading requirements vary widely throughout the United States, and each utility has adopted design practices suitable for its own conditions of terrain and climate. The NESC, presents some guidelines on conductor loading.

The actual loading on conductors is equal to the resulting loading per foot due to the vertical load on the conductor, assumed ice-covered where appropriate, and the transverse loading due to horizontal wind pressure on the projected area of the conductor, again assumed ice-covered where appropriate. Usually a design constant is added to the loading so calculated.

To establish the guidelines for the loading of overhead lines, the NESC has divided the United States into three loading districts, heavy, medium, and light. These are roughly (1) the northeastern section extending east to west from the Atlantic through the Dakotas and from the Canadian border southward into Texas and the Ohio Valley; (2) the Pacific Northwest and a narrow belt eastward to the Atlantic including parts of Arizona, Texas, Louisiana, Alabama, Georgia, and the Carolinas; and (3) the remaining narrow belt extending from coast to coast and bordered on the south by Mexico and the Gulf of Mexico. These are, respectively, the heavy, medium, and light loading districts.

TABLE 18-15 Conductor Loadings Due to Ice and Wind

	Loading district			
	Heavy	Medium	Light	Extreme wind loading
Radial thickness of ice, in	0.50	0.25	0.00	0.00
Horizontal wind pressure, lb/ft^2	4	4	9	9 to 31
Temperature, °F	0	+15	+30	+60
Constant to be added to the resultant, lb/ft	0.30	0.20	0.05	0.00

Note: 1 lb/ft = 1.488 kg/m; 1 lb/ft^2 = 4.882 kg/m^2; $t_{°C} = (t_{°F} - 32)/1.8$. Selected data from the National Electrical Safety Code, IEEE C2-1997. Since heavy ice does not often form on conductors in a heavy wind, the transverse loading assumed is deemed sufficient for the purpose but is not sufficient to represent the vertical (or combined) load which is imposed on conductors by heavy deposits of ice which frequently form in comparatively still air. In order to apply a total loading to conductors representing more nearly the conditions encountered in practice, constants are added to the conductor loading.

Exact locations of these districts may be found in the *NESC Handbook*. Table 18-15 illustrates suggested loadings. The constant is used only for conductor strength checks. It is not used in applying loads to structures.

Equipment Loading. Poles are subject to heavy loads when used to support equipment such as distribution transformers, voltage regulators, and capacitor banks. Such loads are chiefly vertical but do have a transverse component when the pole is bent or drawn away from a vertical position. The equipment also presents additional transverse loading due to wind pressure. Therefore, poles to be used for supporting equipment usually are specified to be of a better class than those supporting conductors only.

Three-unit installations of distribution transformers normally employ the "cluster-mounting" arrangement in which the transformers are supported directly on the pole by suitable brackets. Three-phase banks as large as 500 and 750 kVA are installed in this manner. The former practice of supporting the transformers on a platform carried by two or more poles has nearly disappeared because of appearance and cost considerations.

Unbalanced Loads. Transverse forces are imposed on a pole where there is a change of direction of the line, that is, where the conductors on either side of the pole form an angle. These forces usually are offset by guys where practicable. The loading on the structure, including guys, is considered to be the resulting load equal to the transverse wind load and the load imposed by the conductors due to the change in direction. If it is not practical to guy, the pole and its setting must have sufficient strength to withstand the stresses imposed. The force applied to the pole at the point of attachment of the conductors can be calculated as in Fig. 18-38. Divergence from a straight line can be determined by joining two points, each 100 ft from the corner pole, by a straight line. The distance A from the corner pole perpendicular to this line can then be used to calculate the transverse force applied by the line wires on the pole.

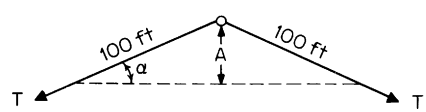

FIGURE 18-38 Determining transverse force on a corner pole.

Assume T to be the total tension, in pounds, of all the wires carried by the pole.

$$\text{Transverse force} = 2T \sin \alpha = 2T \frac{A}{100} \tag{18-17}$$

For example, if A is 10 ft, and if there are six wires having a total tension of

$$T = 6 \times 250 = 1500 \text{ lb}$$

the transverse force due to conductor tension to be sustained normally by the pole is

$$2 \times 1500 \times \frac{10}{100} = 300 \text{ lb}$$

For right-angle turns, α is 45°, $\sin \alpha = 0.707$, and $A = 70.7$ ft. This is the most severe condition ordinarily encountered. In such cases, tensions should be reduced as much as practicable at the corner pole by shortening spans and by transferring a part of the stress to guy wires. Stresses at dead-end poles are treated similarly.

Safety-Code Requirements. The National Electrical Safety Code, in Part 2, sets up minimum safety requirements for loading, strength, and clearance for those parts of supply lines which are involved in crossings of railroad or communication circuits or which come into such proximity to these as to create a "conflict." It also includes joint use of lines and separate use on any public way. The code recognizes differences in degree of estimated hazard, which are assumed to depend on voltage of the supply line, importance of railroad and other communication systems, classification of loading district, types of crossings, etc. The NESC allows reduced loadings where utility facilities are sheltered from the wind, but it requires full loadings to be met if those shelter mechanisms do not exist. Caution is advised in depending on the continued existence of buildings and other artificial objects as a sheltering influence—especially in the case of buildings; they can either (1) be removed or (2) be joined by others and produce channeling effects that would adversely affect the line loading. Similarly, trees are not generally considered to be an effective shelter because of the possibility of clear-cutting or other removal.

18.16 STRUCTURAL DESIGN OF POLE LINES

Pole Location. In residential areas, poles are generally spaced from about 100 to 150 ft apart depending on the size of the lots. The span usually is an integral number of lot widths in length, and poles are set to provide convenient points for connection of services. Longer spans up to 300 ft or longer are used in rural areas. In either case, pole spacing should consider expected future growth and service requirements in the area. The choice of pole spacing is also a function of the load to be carried and the relative economics of longer spans. Pole spacing and line location both are a function of the obstacles in the area. The NESC, ANSI C2, has specific requirements about placement of poles near other poles, roads, buildings, fire hydrants, etc.

Poles are required to be at least 3 ft away from fire hydrants and should be at least 4 ft away. Although these distances are required to allow firefighters access in emergencies, they also give room for personnel working on the pole to move around on the ground. No fire hydrant, telephone pedestal, or other like object should be located on the climbing side of the pole; the climbing side of the pole should be kept clear of protruding obstacles to provide a clear drop zone for line workers if they chip out of the pole and fall.

There are two hazards with the line-worker's gaff cutting out chipping on a pole; the first is the possibility of injury due to picking up splinters from previous gaff marks, and the second is the possibility of injury from the fall. Because of the severe problems caused from splinter injury, some communication line workers (who do not climb as high as supply workers) are taught to climb a pole without belting off until they reach the work height; this allows them to push away from the pole as they go down and allows them to roll when they hit the ground. In such cases, no obstruction should be allowed on the climbing side within 10 ft.

Poles and their supported equipment up to 15 ft above a roadway are required to be located far enough from roadways so that an ordinary vehicle that is using and located on the traveled way will not contact the utility facilities.

Poles are required to be at least 12 ft from railroad rails, except in some limited sidings where the clearance must be 7 ft, and room must be left to unload cars. Where some other facility is the controlling obstruction, the clearance may be reduced from 12 ft but may not be less than 7 ft.

Selection of Poles. The height of poles is determined by required clearances over obstructions, streets, and crossings, the span lengths, and the number and character of conductors or circuits to be carried. The most usual lengths for poles used in distribution construction have been 30, 35, and

40 ft. Armless construction and joint use tend to favor the 40-ft length. In recent years, however, as space for CATV and other facilities is provided on joint-use poles, 45-ft poles are even more commonly used, especially in hilly terrain. The Class 5 and 6 poles are very popular, although larger poles are often required where heavy equipment is to be mounted or longer spans with greater wind loadings are used. The class of pole is determined by stress requirements for the grade of construction being employed.

Where primary conductors are to be carried with joint use, the 35-ft pole usually is the minimum used, and 40 ft is quite common. Without primary conductors and with joint use, 30-ft poles are used occasionally. Joint use of pole lines by two or more public service companies is encouraged where feasible because (1) it makes maximum use of capital investment and avoids undesirable duplication of pole lines, and (2) it provides fewer opportunities for one circuit to fall into another during a storm. When a pole or section of poles is broken as a result of the action of falling trees, flying debris, or errant vehicles, the tendency is for all circuits of a joint-use line to be promptly and automatically deenergized. However, if a conflicting line falls into another line, facilities or personnel working on the other line may be damaged. Thus conflicting line locations are discouraged where joint-use locations are practical. In either case, the NESC, requires greater strengths than for single-circuit installations.

TABLE 18-16 Depth of Wood-Pole Settings

Length of pole, ft	Depth of setting, ft
30	5.5
35	6
40	6
45	6.5
50	7
55	7.5
60	8
70	9

Note: 1 ft = 0.3048 m.

Pole-Setting Depths. Table 18-16 lists typical depths of setting for wood poles of various lengths. These are sufficient for most soils but must be increased for larger poles set in lighter or more fluid soils; these setting depths are based on the fulcrum points used for testing pole strength in ANSI 05.1. They do not vary with pole diameter and may not be sufficient for large poles with large loads.

Guying Longitudinal, Angle, and Dead-End Force with Tensile Guys and Anchors. When the horizontal loads to be carried by poles are greater than can be safely supported by the poles, guys or braces are required to provide additional support. Guys and anchors are commonly used wherever conductor tensions are not balanced, as at dead ends, corners, or where the direction of the line changes substantially. Down guys transmit force from the overhead structure system to a buried anchor system (Fig. 18-39). They are located opposite the forces and use materials in tension to balance the forces. Where it is not practical to place these facilities to continue the imbalanced forces to ground, a compressive guy or pole brace must be used.

Where traffic ways or other obstacles do not allow direct anchoring of the forces at the imbalanced pole, an overhead span guy is used to transmit the force to another pole in line with those forces and in a place that allows a down guy to be used. The best down guy is a straight anchor guy composed of appropriate wire, fastenings, and anchor; it is the most economical to install in most locations, is the least trouble to maintain, deteriorates the least over time, and is the most reliable type of down guy.

The NESC, requires guys to have 4.72 m (15.5 ft) clearance over roadways and 2.89 m (9.5 ft) over spaces or ways accessible to pedestrians only. Where an anchor guy cannot be used because of interference with pedestrian or vehicular traffic, and where there is no practical location for an auxiliary pole and anchor guy that would allow a span guy to be used, a stub guy may have to be used. A stub guy consists of an angled span guy from the imbalanced pole to a short stub pole that is (1) high enough to provide the clearance required for the guy over the affected area and (2) low enough that the resulting moment arm is short enough that the stub can take the forces involved. Often the stub pole will have to be separately braced below ground to take the forces. Obviously, these conditions are not desired, and they are not practical for balancing large forces.

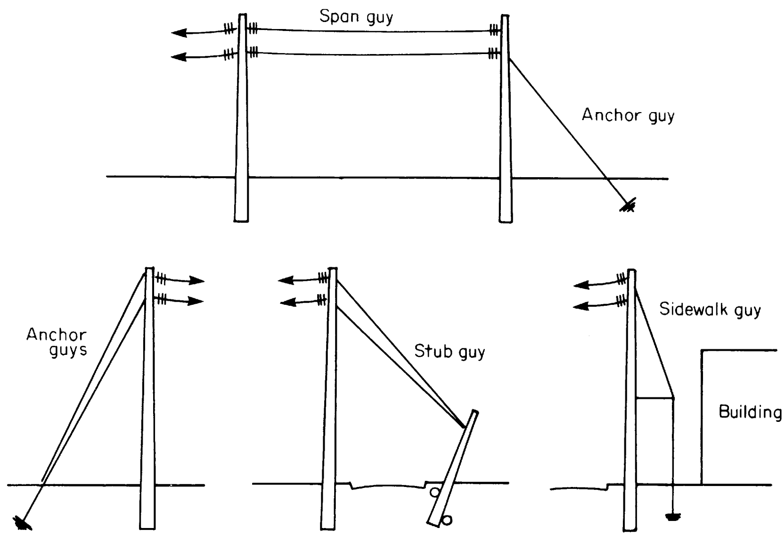

FIGURE 18-39 Tensile guys.

Another down guy used in constrained locations is the sidewalk guy. With the sidewalk guy, a horizontal strut is attached to the pole midway down the pole; the guy wire runs angled from the top of the pole to the strut and straight down to an anchor from there. These guys are most often used to guy small taps off a main line where there is not room for a full-length anchor-guy lead. The strut is usually just long enough to place the anchor back of a sidewalk and high enough to allow pedestrian clearance, hence the name. This guy should not be confused with the compressive guy discussed below; both are sometimes called *strut guys*. Sidewalk guys cannot be used for large forces because they will bow the pole due to their horizontal force; this, in turn, causes serious vertical-loading and bending-moment problems if the forces are great enough.

Where unbalanced tension is experienced by crossarms, such as in sidearm construction or dead ends for heavy conductors, crossarms are often guyed. Often a span guy will be attached to the back of the crossarm at each conductor location and run to another pole in line with the forces; otherwise, excess vertical loading on the crossarms can result.

Guy wires generally are made of stranded steel cable, usually galvanized for weather resistance. Several grades are available, including extra-high strength, which is commonly used. It is available in several diameters in steps of $^1/_{16}$ in from $^3/_{16}$ in up.

The National Electrical Safety Code, ANSI C2-2002, specifies that guy wires be used so that, with the required assumed loads and overload factors, they will not be stressed beyond 90% of ultimate strength, and for dead ends, not beyond 66.67% of ultimate strength. After the tension has been calculated, the guy cables are selected so that these requirements are met. The anchor guys usually are installed at a distance from the pole not less than one-quarter or more than 1 to $1^1/_2$ the height of the guy attachment. Generally a 1:1 slope is preferred. This lessens both the tension in the guy wire itself and the vertical component of forces transmitted to the pole. Where steep angles are used for the guy, or where large forces are otherwise involved, the pole size may need to be increased in order to withstand the vertical forces. In poor soils, this can even push the pole into the ground over time, thus decreasing clearances and twisting the pole, the latter because the now-excessive length of the guy allows the pole to move.

Compressive Guys and Pole-Foundation Underbracing. Where poles with imbalanced forces are so located that tensile guys cannot practically be used, either the forces must be taken by a compressive guy or the pole and its foundation must be made strong enough to take the forces by themselves. A *compressive guy* consists of a pole (or other member capable of taking the imbalanced load) placed at an angle leaning into the imbalanced pole and attached at the top so that it pushes against the force to be balanced. Its common name is a *push guy* for this reason; it is also called a *strut guy* in a few locations—not to be confused with the sidewalk guy. The most common use for a push guy is on the inside of a curve on a mountain road where, in essence, there is no land on the other side of the road in which to place a pole and anchor to use a span guy; span guys are preferred where they are practical because of their relatively simple installation, longer life, and ease of maintenance compared with the push guy. Push guys are difficult to attach to the supported poles, often can only be attached significantly lower than the imbalanced conductors, especially on sharp angles, and require the imbalanced pole to be oversized as a result. It is generally difficult to position the push guy in the ground, or cut it to the right length, so that the imbalanced pole will remain upright under load.

Where poles supporting unbalanced stresses are so situated that it is not practical to support them by either tensile or compressive guying, they must be underbraced to withstand the force imposed with as little deviation from original position as possible. This normally requires that the pole have more than usual diameter and be no taller than absolutely necessary for clearance.

For very long spans or heavy conductors, steel poles are often required. If wood poles are used, top diameters of 8 to 10 in are required for such positions to avoid bending. In addition, the pole is underbraced by timbers bolted to it below ground line and at the butt, as shown in Fig. 18-40. An alternative method, using concrete, is also good. Small boulders or crushed stone may be used in backfill to advantage.

In the use of plank or concrete, the pole is set at a slight angle, or rake, in a direction opposite that from which stress is to be applied, to allow for compacting of soil when wires are pulled up. The area of plank or concrete should be about 4 ft^2, both top and bottom. Where steel poles are used to secure strength, they are usually set in a concrete base of such dimensions as to bear the stresses imposed.

Vertical Clearances above Grade. Rule 232 of the National Electrical Safety Code, ANSI C2-2002, specifies the vertical clearances that utility wires, conductors, and cables must maintain above railroads, roads and other ground areas, and water areas. Before 1990, these clearances were specified when the conductor was at 15.5°C (60°F) conductor temperature (not ambient air temperature) and at specified ice loadings, whichever produced the greater sag. For span lengths greater than the basic span length applicable for the ice-loading area (heavy, medium, or light) and for conductor temperatures above 49°C (120°F), addititional clearances were required.

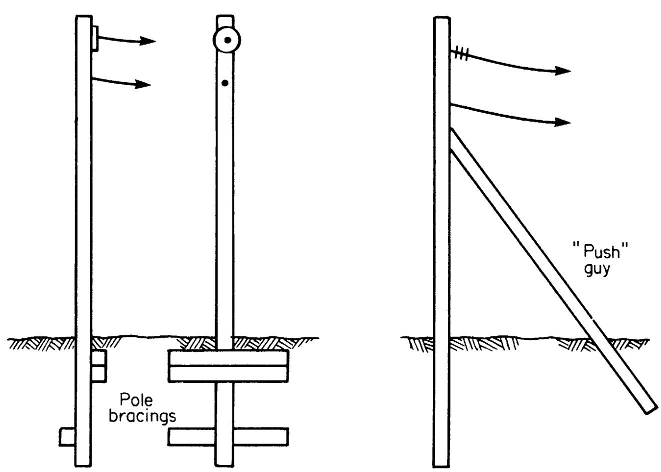

FIGURE 18-40 Comprehensive guy and pole bracing.

In 1990, the National Electrical Safety Code respecified the clearances to apply at maximum-sag conditions and coordinated the clearances with a system of reference dimensions of expected activity under the line and building blocks related to actual or potential voltage levels. For roads, parking lots, and other areas expected to have trucks, the reference dimension is 4.27 m (14 ft). For areas limited to personnel or restricted traffic only, the reference dimension varies from 2.4 to 3.0 m (8 to 10 ft), depending on the expected problem.

The building blocks include 30.42 cm (1.0 ft) for structure arms, 45.72 cm (1.5 ft) for neutrals and communication cables and grounded guys, 0.6 m (2.0 ft) for secondary bushings and jumpers up to 750 V and duplex, triplex, and quadruplex cables with bare neutrals, 0.76 m (2.5 ft) for open (bare or covered) supply conductors up to 750 V, 1.22 m (4.0 ft) for primary voltage bushings up to 22 kV, and 1.37 m (4.5 ft) for primary voltage conductors up to 22 kV. Additional clearances apply above 22 kV or 1 km (3300 ft) above sea level.

The previous 15.5°C (60°F)–based clearance requirements included 0.46 m (1.5 ft) to allow for sag change from 15.5 to 49°C (60 to 120°F) or specified ice-loading conditions. The 5.6-m (18.5-ft) minimum clearance specified in the NESC beginning in 1990 for distribution primary voltage conductors above a road 4.3-m (14-ft) reference dimension plus 1.4-m (4.5-ft) building block produces the same essential clearance requirement as the previous system. Similarly, the minimum clearance for a distribution neutral, guy, or communication cable is 4.7 m (15.5 ft, i.e., 14 + 1.5).

The present system (1) requires the installer to use actual expected changes in sag from the installed sag to the maximum final sag expected; (2) better states the real clearance involved; and (3) does not include the previous clearance penalties for short spans with less than 0.46 m (1.5 ft) of sag change from its 15.5°C (60°F) position.

It is important to stress that the NESC vertical clearances apply when the conductor is at its maximum sag position, even including emergency sag conditions, such as when one power line picks up the load from another line and the line losses heat the conductors above their normal maximum temperature. If special, localized icing conditions apply to the line, they also should be used to determine whether the summer or winter maximum sag conditions will be determinant.

Clearances Between Crossing or Adjacent Wires, Conductors, or Cables Carried on Different Supporting Structures. Where any two wires, conductors, or cables cross or are adjacent in open span without being supported on a common structure, the clearances between them must be sufficient to limit the possibility of contact between them. The effect of movement under wind, thermal, or ice loading must be considered as well as the required clearances between them. The National Electrical Safety Code considers that the two suspended facilities must first be considered to be in their most proximate position relative to each other, assuming that both experience the same ambient conditions (i.e., wind direction and speed, air temperature, and icing conditions); then the distance between them must meet the clearance requirements for the two facilities.

Caution is advised in choosing the most proximate position. The two facilities may move different amounts because of the same wind pressure; one may be unloaded at ambient temperature or fully ice loaded, while the other may be at maximum operating temperature. One could be at initial sag while the other is at final sag. Examination of Rule 233 of the National Electrical Safety Code is recommended.

Determining the closest approach of conductors in winter icing conditions can be confusing. When one line is across the wind and another is with the wind, one loads up with more ice than the other one. In addition, one line can lose its ice before the other one, due to wind or due to thermal loading from line losses. Ice typically forms very near −1.1°C (30°F). If the temperature is significantly colder, the precipitation tends to bounce off rather than coat. However, after the ice has formed, the temperature can fall, bringing with it more heating load and sometimes lighting loads. Thus it is not unusual for an ice-covered conductor to be heated by line losses back up to 0°C (32°F) and eventually melt its ice off. In the meantime, this conductor will be at its maximum sag of 0°C (32°F) with a full coating of ice. The position of the lower conductor for clearances purposes is at the coldest ambient temperature at which the load on the upper conductor could heat it up to 0°C (32°F). This takes care of the cases where the lower conductor has dropped its ice (or was never fully iced) or the lower conductor has come down and is being replaced (without ice) when the upper conductor is at its maximum sag.

Unless the actual relative icing/heating conditions are known, a practical method of choosing an appropriate mismatch in temperature for the winter icing clearances is to use the temperatures used by the National Electrical Safety Code to determine required strengths as the temperature of the lower conductor without ice when the upper conductor is at 0°C (32°F) with the specified ice loading. They are −9.4°C (15°F) for the medium loading district and −17.8°C (0°F) for the heavy loading district. Detailed examination of Rule 233 of the NESC is recommended.

When the suspended facilities are at their closest proximity, both the vertical clearance and the horizontal clearance should be checked to see which is controlling. The horizontal clearance must be at least 1.5 m (5 ft). Where the voltage potential between them exceeds 129 kV, an additional clearance of 0.4 in/kV is required. The basic vertical clearance when the conductors are closest together is 0.6 m (2 ft), with additional clearances required where higher voltages are involved with communications.

Clearances from Buildings and Other Installations. Wires, conductors, and cables which pass by buildings, signs, supporting structures of a second line, pools, bridges, tanks, etc. are required to have clearances from those structures, when not attached to them, that allow normal use of those facilities. Required clearances are given in the NESC. In general, clearances above portions of structures which are accessible to pedestrians or vehicles are the same or similar to those above ground for the same activity. Where pedestrian access is restricted and the area is normally accessible only to workers, lesser clearances are allowed. Clearances allow normal maintenance of the structures being passed by. The minimum horizontal clearance from energized distribution primary voltage conductors to supporting structures of a second line, lighting support of traffic signal support is 1.5 m (5 ft). The minimum vertical clearance above such supporting structures is 1.37 m (4.5 ft).

The vertical clearance required by the NESC for energized distribution primary voltage conductors above building roofs and projections not accessible to pedestrians is 3.81 m (12.5 ft); this allows workers with hand tools the room to work on the roof. Above signs, this clearance drops to 2.4 m (8.0 ft) for open conductors. Vertical clearances to roofs and balconies accessible to pedestrians and catwalks on signs and tanks cannot be less than 4.1 m (13.5 ft) for the distribution primary voltage conductors. Lesser clearances apply for communication and for supply cables and secondary voltages up to 750 V. Greater clearances apply for higher voltages. Bridges have lesser clearances where workers are allowed and generally the same clearances as buildings where pedestrians are allowed. Greater clearances are required around pools and associated structures to accommodate pool skimmer poles, rescue poles, and diving.

Clearances for Facilities Suspended from the Same Structure. The clearances required by the NESC, between wires, conductors, and cables carried on the same supporting structure provide adequate room on the structure for workers to operate and maintain the lines, adequate room out in the span for communication workers to work under supply facilities, and adequate separation between suspended facilities to limit contact by them during operation. Because some communication cables on longer spans will "gallop" in high winds, and because such cables may gallop as high as a straight line between their points of attachment at supports, supply conductors above 750 V generally are prohibited from sagging lower than such a straight line.

The vertical clearance at supports for primary-supply conductors above other facilities is required to be 16 in above neutrals and 40 in above communication (more if above 8700 V). For supply conductors at voltages up to 8700 between conductors, the minimum horizontal clearance provided by the NESC, is 12 in. For higher voltages it is required that 0.4 in be added for each 1000 V above 8700. For sags of more than 24 in, clearances greater than 12 in are required and are determined by the following formulas, where S = sag, in. For wires of No. 2 AWG or larger,

$$\text{Clearance} = 0.3\text{ kV} + 8\sqrt{S/12} \quad \text{in} \tag{18-18}$$

For wires smaller than No. 2 AWG, the rule is

$$\text{Clearance} = 0.3\ \text{kV} + 7\sqrt{(S/3)} - 8 \quad \text{in} \tag{18-19}$$

Multiconductor, spacer, and other cabled types of supply-circuit construction are exempt from the above phase-spacing requirements.

Climbing Space. Climbing space must be provided on poles for workers to move up and through facilities to reach each of the facilities on the structure unless it is the unvarying rule that workers do not climb the poles. If workers climb some portions of the structure and not others, for example, communication but not supply, and the remainder are worked from insulated bucket trucks, only the portions climbed must have climbing space. The climbing space may move around the pole to allow access to other parts or to avoid traveling through certain locations, as long as full space is allowed to facilitate the turns. These dimensions are intended to provide a clear climbing space of 24 in when the conductors bounding the space are covered with appropriate temporary protective covering. The vertical dimension is 40 in above and below the conductors (60 in if above 8700 V). The National Electrical Safety Code, ANSI C2-2002, specifies the horizontal climbing-space dimensions given in Table 18-17. Where conductors of the same voltage classification are on the same crossarm, the horizontal dimensions are projected vertically not less than 40 in above and below the limiting conductors. Equipment such as transformers, regulators, capacitors, surge arresters, and switches when located below the conductors should be mounted outside the climbing space.

TABLE 18-17 Horizontal Climbing-Space Dimensions (Voltage-to-Ground)

Supply conductors	Horizontal climbing space, in
0–750 V	24
750 V–15 kV	30
15–28 kV	36
28–38 kV	40
38–50 kV	46

Note: 1 in = 25.4 mm.

Working Space. Working spaces are required by the National Electrical Safety Code, ANSI C2-2000, at each side of the climbing space and extending to the outermost conductor positions. The size of the working space is linked to the vertical clearances required between conductors at the support and the size of the climbing space, both vertical and horizontal.

Clearances Between Supply and Communication Equipment. The National Electrical Safety Code, ANSI C2-2002, generally requires a minimum of 40-in clearance between supply equipment and communication equipment and between the conductors of each to the equipment of the other. This provides for footroom for the supply workers and headroom for the communication workers. Special provisions are made to allow luminaires to be placed between these facilities.

Vertical and Lateral Conductors. Vertical and lateral conductors may be run within the normal supply space and communication space on a pole if they are so located as to meet the requirements of the National Electrical Safety Code, ANSI C2. Generally such conductors are required to be insulated and placed out of the climbing footroom area or held away from the pole on the opposite side.

18.17 LINE CONDUCTORS

Conductor Factors. Copper and aluminum are the metals most used as conductors in distribution systems. Proportions are fixed by the combined effect of conductivity, weight, strength, and cost. Recent years have seen such a shift in availability and cost that aluminum has gained almost universal use in distribution, supplanting copper, which was preferred for many years.

Conductor Materials. Aluminum has the advantage of about 70% less weight for a given size, but its conductivity is only about 61% that of annealed copper. For distribution, it is commonly rated as equivalent to a copper conductor two AWG sizes smaller, which has almost identical resistance. Its tensile strength is less than copper, and it is commonly used, particularly in the smaller sizes, by stranding aluminum around a steel core of proper size to give the desired tensile strength. In larger sizes, the tensile-strength requirements of distribution are satisfied by stranded aluminum without the reinforcing steel. Another way of obtaining high tensile strength is to combine steel with copper or aluminum wires. Steel is combined with copper in a high-strength strand known as Copperweld, which has 30% to 40% of the conductivity of a copper conductor of equal size. In a similar manner aluminum and steel conductor can be combined into what is known as Alumoweld.

Both copper and aluminum are suitable for use as substation buses, being available in flat bars, tubes, and rods. For very heavy currents, channel shapes are used to make up box-type buses, which are the most economical for such applications.

Use of Copper. Where copper is used for overhead circuits with span lengths of 200 ft or more, it is commonly used in the hard-drawn form because of its greater tensile strength. For common types of local distribution circuit where spans are shorter and flexibility is desirable, medium-hard-drawn, or annealed, copper is used. Mechanical connectors are extensively used for joints and taps on overhead copper.

Underground copper cables are usually made of standard soft copper because of its greater flexibility. The smaller size of copper conductors helps to offset unfavorable price levels because of savings in insulating and sheathing material as well as the ability to put maximum carrying capability in a given size of duct.

Use of Aluminum. In rural line work, where long spans and conductors of high tensile strength are an economic necessity, the combined requirements of conductivity and strength have been met with aluminum stranded around a steel core sized to give the required strength. Such a cable is known as *aluminum cable steel-reinforced* and is commonly designated as ACSR. Development of high-strength aluminum alloys has led to such alternative cables as aluminum conductor alloy-reinforced (ACAR) and all-aluminum-alloy conductor (AAAC), which also combine conductivity with tensile strength. Urban distribution uses ACSR and all-aluminum conductors. Stranded aluminum is common where large conductors are required.

Underground Aluminum Cables. The development of such synthetic insulations as polyethylene has made aluminum almost universally used for underground distribution. In the smaller sizes for URD, a solid conductor is often applied rather than stranded construction. *Jointing of aluminum* requires special care to secure good contact and to guard against corrosion. Jointing is often done with compression devices, although mechanical connectors packed with corrosion-inhibiting compound can be used.

Use of Steel. Steel conductors are rarely used for distribution circuits because of their high resistance. But steel with a heavy covering of copper, known as Copperweld,* or with a heavy covering of aluminum, known as Alumoweld,* has conductivity approaching 40% that of copper and can be used in some applications. Such coated conductors are also very attractive as high-strength strands or reinforcements for composite cables, which get improved conductivity from strands of hard-drawn copper over the Copperweld or hard-drawn aluminum over the Alumoweld.

Conductors reinforced with steel have impedances which increase somewhat as current density increases. Voltage drops are correspondingly higher than those of copper or aluminum conductors of equal conductivity.

Copperweld and Alumoweld are generally more durable than galvanized-steel cables. They have therefore been used to some extent for guy cables. They are also used widely for shield wires.

*Copperweld and Alumoweld are registered trademarks of the Copperweld Bimetallic Group.

18.18 OPEN-WIRE LINES

Crossarms. Southern pine and Douglas fir are the best woods for crossarms because of their thin, straight grain, high tensile strength, and durability. Experience indicates that a cross section 3½ in wide by 4½ in high is ample for the average distribution line. Main lines are commonly built with six-pin arms, and smaller lines use four-pin arms. Minimum spacing of pins is 12 in, and spacings of 14 to 16 in are commonly used. Minimum spacing of pole pins is 30 in to provide climbing space. Crossarms also are used for supporting transformers and other equipment.

Double crossarms are installed on poles at corners, at terminals, and at other points where unusual loads are to be supported. Vertical racks are installed on poles to support secondary and multiple street-lighting wires. They are available with two-, three-, or four-spool insulators. Rack construction is less expensive than crossarms and has supplanted them to a large extent. When services run to houses on both sides of the street, two racks are required, one on each side of the pole. In addition, several pole-top designs mount insulators directly on the pole, eliminating the use of crossarms.

Wire Stringing. In erecting wire, the *tension* should be sufficient to prevent too much sag in the spans and yet not so great as to stress the wire unduly. For practical purposes, the approximate formula given by Rankine may be used:

$$t = S^2 w/8d \qquad \text{lb} \tag{18-20}$$

in which t = tension, lb, S = span length, ft, w = resultant load, including weight of wire, lb/ft of conductor, and d = sag, ft, at the center of a horizontal span. If span length is doubled, tension must be quadrupled in order to keep sag the same. If tension is the same on several spans of different lengths, sag is different in each span. The sag of any span when tension is known is found by changing Eq. (18-20) to the form

$$d = S^2 w/8t$$

Sag Tables. Maximum tension in a span is limited by the strength of the wire and supports. Conductor sags under the assumed loading conditions for the particular loading district (see National Electrical Safety Code, ANSI C2) should be such that the tension of the conductor should not exceed 60% of its ultimate strength. Also, the tension at 60°F, without external load, should not exceed 35% of the conductor ultimate strength under its initial unloaded condition.

It is not unusual to design so that the tension of the conductor will not exceed 50% of its ultimate strength under loaded conditions or a 2000-lb limitation. In some cases, the same sag values are employed for a range of wire sizes so that the appearance of a line carrying different conductor sizes will be improved. The sags given in Table 18-18 are selected from standard sheets of a large utility.

Expansion and Contraction of Conductors with Temperature Change. Changes in sag due to expansion and contraction of conductors under varying temperature conditions are important in the stringing of conductors. Lines erected in winter months are likely to be too slack during the summer unless allowances are made. The length of wire in a span, elastic stretching due to mechanical loading being disregarded, varies as determined by the coefficient of expansion of the conductor and the temperature range,

$$L_t = L_0(1 + \alpha_0 t) \tag{18-21}$$

where α_0 = coefficient of expansion, ft/ft of length/°F above 10°F
t = temperature, °F (above 0°)
L_0 = length of wire at 0°F

For aluminum: α_0 = 0.000024/°C or 0.0000133/°F
For ACSR: α_0 = 0.0000112/°C or 0.0000062/°F (nearly that of steel)
For copper: α_0 = 0.000017/°C or 0.0000094/°F

TABLE 18-18 Sags for Typical Distribution Conductors (Heavy-Loading District—60°F)

Size, AWG or M cmils	Conductor material	Sags (in) for span lengths (ft) of							
		80	100	125	150	175	200	250	300
Open wire:									
No. 1/0	Al alloy, bare		10	16	23	31	40	27*	38*
No. 3/0	Al alloy, bare		10	16	23	31	40	32*	46*
336.4	Aluminum, bare		10	16	23	31	40	75	108
No. 1/0	Al alloy, polyeth.		10	16	23	31	40	59*	90*
No. 3/0	Al alloy, polyeth.		10	16	23	31	40	70	101
336.4	Aluminum, polyeth.		18	27	38	51	66		
Cabled secondaries:									
3 No. 1/0	Al alloy, insul.		10	16	23	31	40		
3 No. 3/0	Al alloy, insul.		18	27	38	51	66		
4 No. 3/0	Al alloy, insul.		18	29	43	60	80		
Cabled service drops:									
3 No. 4	Aluminum, insul.	32	52	73†					
3 No. 1/0	Aluminum, insul.	51	79	116†					
4 No. 3/0	Aluminum, insul.	68	108	171†					

Note: 1 in = 25.4 mm; 1 ft = 0.3048 m; 1 lb = 0.4536 kg.
*Taken up to 2000-lb tension limit for spans over 200 ft.
†For 120-ft service drops, 450-lb limit.

Ampere loadings on distribution circuits often require that the temperature rise of the conductor due to resistance losses must also be taken into account.

18.19 JOINT-LINE CONSTRUCTION

Joint-line construction is used where two or more utilities would otherwise maintain separate pole lines, such as where both power and communication lines are routed along the same street.

Basis of Joint Use. Poles are used jointly under a *joint-ownership agreement* or *under a lease agreement*. Under joint ownership, the cost of providing the pole is borne jointly by the companies which share in its ownership. Division of expense is, in general, made in proportion to the space allotted to respective users. Clearance space, required between power and communication circuits and between the lowest attachment and ground, is disregarded in determining percentage of ownership. Clearance between higher-voltage and lower-voltage power circuits is chargeable to the higher-voltage circuits.

In case of leased space, the lessee acquires only the right to occupy a specified space. The owning company installs and maintains the pole and includes all charges in the rental price. Lessees usually install their own attachments and maintain them, though pin space is sometimes leased where space for only a few wires is required.

Construction Specifications. The types of construction, clearances, and relative levels of different classes of circuit should be provided for by a suitable specification, forming part of the agreement under which joint use is entered into. The general purpose is that construction of all parties be such as not to jeopardize the service or equipment of any of the other parties to the agreement. Construction requirements are set forth in the National Electrical Safety Code, ANSI C2. Some of the most important parts of such a specification are discussed in the following paragraphs.

Relative Levels of Supply and Communication Conductors. When supply and communication conductors are located on the same poles, it is generally desirable that the supply conductors be located at the higher levels. This places the higher voltages near the pole top and the communication conductors at the lower levels. This relative location of facilities provides a lower probability of contact between the two systems since the supply conductors are usually larger than the communication lines. This also provides easier access to the lower-voltage or communication circuits by the line crews and avoids the need to climb through the supply conductors to work on the lower-voltage or communication systems. Where 600-V trolley feeders are carried on joint poles, the feeders are located for convenience at the approximate level of the trolley contact conductor.

Vertical Clearances. Spacing of conductor attachments must be appropriate with the requirements of safety in operation and maintenance. Clearance requirements are spelled out in detail in the National Electrical Safety Code, ANSI C2. Generally, a minimum vertical clearance of 40 in is used between communication conductors (or open wires of 0 to 750 V) and supply conductors operating between 750 and 8700 V to ground. Greater clearances are required for supply conductors operating above 8700 V. If the communication circuits belong to the utility for use in operating supply lines, reduced spacings of 16 and 40 in, respectively, are permitted.

Grades of Construction. Strength of poles must be such as to withstand ice and wind loadings normally experienced in the locality where the line is built, for all of the conductors to be carried. These conditions vary greatly in different parts of the United States, there being no ice in some parts of the country and a greater prevalence of wind in others.

Conductor Size. The size of conductors should be such that they do not experience a tension more than 60% of their rated breaking strength under conditions of maximum loading and not more than 25% of this value for final unloaded tensions at 60°F. Very little use is made in new construction of wire sizes smaller than No. 1/0 stranded aluminum or No. 2 ACSR.

Inductive Coordination. A vast majority of the newer telephone circuits on joint-use distribution lines are in cable, rather than open-wire, and telephone interference is rarely encountered. Where long exposures of open-wire circuits do exist, if may be necessary to make suitable transpositions in both power and communication circuits to eliminate electrical unbalances as much as practicable.

Aerial-Cable Construction. Insulated aerial cables carried by steel messenger cables have been used occasionally in primary distribution circuits where undergrounding is not practicable and special conditions, such as reduced clearances or unusually severe tree problems, exist. This type of cable is fastened to a galvanized-steel cable, or *messenger,* by means of brackets or lashings in a manner similar to large communication cables. Usually it consists of one, two, or three insulated conductors spiraled around the messenger which supports the assembly mechanically and usually serves as a neutral as well. This type of construction is finding very little usage in new system extensions.

Spacer-Cable Construction. Spacer-cable construction provides many of the advantages of aerial cable at lower cost. It consists of primary conductors having less insulation than the cable insulation which is customary for the circuit voltage, supported on a messenger and separated from each other by insulating spacers installed at suitable intervals along the line. Note, however, that the energized phase conductors of spacer cable are not directly cabled together with an effectively grounded neutral. They are held away from the neutral by a plastic spacer. Thus they meet Rule 230D of the National Electrical Safety Code, IEEE C2-1997, and must have the same clearances to other objects as bare conductors.

18.20 UNDERGROUND RESIDENTIAL DISTRIBUTION

During the past 40 years, the evolution of underground distribution systems, particularly single-phase systems to serve residential areas (URD), has proceeded at a rapid rate. For a so-called mature industry, the rate of change has been phenomenal. Costs have been steadily reduced through the introduction of new system concepts, improved installation practices, and the development of specialized equipment.

Nearly every utility in the United States now has a policy covering the installation of URD in new residential tracts. Conditions vary all the way from a substantial differential payment by the developer to a no-charge basis by the utility, although the developer usually is requested to assist with excavation. In addition, a number of states have established legal requirements mandating that all new residential developments in excess of a given number of homes be served by an underground distribution system. As a result, perhaps as many as two-thirds of new residential dwelling units are being served underground.

Cost. Underground distribution systems often cost more than comparable overhead systems. What are the principal factors contributing to the rapid growth of URD? These include

1. Greater public interest in the aesthetic appearance of residential communities.

2. Reduced cost of underground equipment and installations brought about by

Solid dielectric insulated cables—lower-cost—suitable for direct burial without duct systems

Factory-built cable terminations and splices of low cost easily prepared in the field by ordinary line crews without the aid of highly trained cable splicers

Mass production of specialized equipment such as pad-mounted transformers and accessories

Improved installation technique and equipment

Performance. Most observers are of the opinion that the frequency of faults is lower on underground systems than on overhead systems and that the faults are not so likely to "bunch up" because of storm conditions. However, faults are much more difficult and time-consuming to find, to isolate, and to repair on underground systems. This, coupled with the fact that many operating procedures cannot be performed on an underground system while it is energized and that it is impossible to make many of the temporary improvisations on underground circuits that can be accomplished on overhead systems, has led to the development of protective and sectionalizing equipment such as switches and separable cable connectors which often are physically integrated as accessory devices in the underground distribution transformers. In addition, several utilities with significant amounts of older cable have found that they are having more unexpected reliability problems as cables have aged.

Service-restoration requirements also have resulted in primary-system designs which operate as a normally open loop as shown in Fig. 18-41. In the case of a cable fault, this facilitates location and isolation of the failure and more rapid service restoration to all customers on the unfaulted portion of the primary loop. It is estimated that about 85% of primary URD systems are being operated as loops, the remainder being radial. Where radial laterals are used, many utilities provide portable, aboveground cables so that faulted cables can be bypassed temporarily and service restored while repairs are being made.

FIGURE 18-42 Mini-pad distribution transformer. (*General Electric Company*.)

Transformers. The heart of the URD system is the single-phase distribution transformer because the primary cable terminations, switching and sectionalizing equipment, and overcurrent protective equipment usually are housed in the transformer enclosure. Thus most operating procedures require access to one or more distribution transformers. Three general types of single-phase transformers are in use.

Pad-Mounted. Figure 18-42 shows the predominant type of transformer being used for URD. The transformer shown is called the *mini-pad*. The term *pad* derives from the fact that transformers in this category usually are installed on concrete slabs, or pads.

The electrical functions of URD transformers cover essentially the same range as pole-type units. For reasons of safety, of course, they must be built in tamper-resistant configurations with no exposed electrically energized parts because of the proximity of such transformers to the general public.

The mini-pad in Fig. 18-42 has its cover open. The two primary bushings at the upper left are for use with load-break, separable insulated connectors, or elbows. This results in a "dead-front" configuration which is required to achieve the low-height mini-pad construction. The three 120/240-V bushings are at the right-hand side.

Many other combinations of pad-mounted construction and accessory equipment are available, including "live-front" primary connections with stress cones for the cables, internal or external primary fuses and switches, secondary circuit breakers, etc. Refer to appropriate product bulletins of the manufacturers or handbooks for further equipment details. Generally, the loadability of pad-mounted transformers is comparable with that of pole types.

Residential Subsurface Transformers (RST). Although usage of pad-mounted transformers predominates, a number of residential subsurface transformers are used. The RSTs are installed in relatively tight-fitting vaults with the cover grating of the vault at ground level.

Cooling is accomplished by natural convection of the air, although some users increase the efficiency of circulation by means of special chimneys to direct and control the circulation. With properly designed and installed chimneys, the loadability of RSTs is equal to that of pole types.

The RSTs must be submersible and therefore utilize dead-front primary cable terminations, usually the separable insulated connectors or "elbows." Provisions for operation of accessories such as switches, fuses, and circuit breakers are located on the cover of the transformer so that they can be operated by a member of the line crew standing on the surface of the ground. Usually the vault is too small for a person to enter.

Primary Cables. Primary URD cables are almost universally of the single-conductor concentric-neutral type employing polyethylene or cross-linked polyethylene insulation. Specifically, the use of TRXLPE and EPR are increasing in usage. Ordinary polyethylene is a thermoplastic which melts at temperatures in the order of 110°C. The process of "cross-linking" polyethylene converts it into a thermosetting material which does not have a melting point, per se.

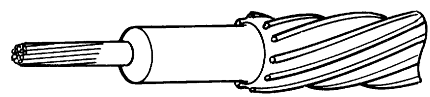

FIGURE 18-43 Concentric-neutral type of primary URD cable.

Figure 18-43 shows a section of primary URD cable. The central conductor is the energized phase conductor, and the external concentric wires serve as the neutral.

Corrosion of the copper concentric-neutral wires of primary URD cables results in reduced cross-sectional area of the wires, increasing their resistance. In some instances, the continuity of the wires is destroyed. Neutral corrosion may cause safety and operating problems on the URD circuit. Corrosion occurs when the neutral wires become anodic, which results in loss of metal. The wires may become anodic due to nearby dissimilar metals or to variations in soil characteristics along the cable route. Determining the location and extent of corrosion damage is a complex procedure which may involve surveys, testing, and in some cases, excavation. Corrective actions for existing cables include replacing portions of the cable, reestablishing the neutral circuit, and installing sacrificial anodes for cathodic protection. Corrosion in new installations can be controlled by the proper selection of materials, cable construction, type of installation, and cathodic protection. The use of jacketed concentric neutral cable to reduce the problem has been increasing over the years and was used by over 80% of respondents in *Transmission and Distribution*'s 1990 survey on underground distribution practices. Most utilities directly bury the primary cables, although the trend to conduit is increasing. Often the URD cables are placed in the same trench as the telephone cables.

The precise calculation of voltage drop in direct-buried, concentric-neutral primary cables is quite complex because a portion of the single-phase load current flows in the concentric-neutral conductors and a portion in the earth surrounding the cable. Also, there may be an induced circulating current in the neutral conductors. Typical values of voltage drop per 100,000 A · ft are shown in Table 18-19.

TABLE 18-19 Single-Phase Voltage Drops per 100,000 A · Ft* for 15- and 35-kV Direct-Buried Concentric-Neutral Cables (Loop Values)

	Voltage class									
	15 kV					35 kV				
	Lagging power factor									
Conductor size	0.7	0.8	0.9	0.95	1.00	0.7	0.8	0.9	0.95	1.00
Underground primary										
Aluminum:										
Concentric-neutral—direct-buried, cross-linked polyethylene, conductor 70°C, neutral 60°C, earth resistivity 90 Ω-cm³, full insulation										
No. 2	44.1	46.6	48.1	48.1	44.8					
1/0	30.9	32.8	34.0	34.1	32.0	31.3	33.0	34.1	34.1	31.7
2/0	25.3	27.0	28.1	28.3	26.8	25.8	27.3	28.3	28.4	26.6
4/0	17.0	18.2	19.1	19.3	18.5	17.5	18.6	19.3	19.5	18.4

*Values in the table give the difference in absolute value between sending-end and receiving-end line-to-neutral voltages, in volts.

To use the table, calculate the ampere-feet as the product of the current in the phase conductor and the distance in feet between the source and the load. The effects of direct burial on impedance of the return current path are included in the tabulated voltage drops.

Secondary Cables. Usually three polyethylene-insulated, single-conductor cables are used for the 120/240-V secondaries and services. These may be separate cables or of triplex construction. In some cases a bare copper neutral conductor is used. The secondary and service cables are usually directly buried.

Cable Terminations. A major advantage of the polyethylene-insulated primary cable, in addition to low cost, is the ease with which it can be terminated in contrast with earlier traditional paper and lead cable, that is, cable insulated with oil-saturated paper with an outer lead sheath or jacket. Termination and splicing of a PILC cable requires a skilled cable splicer working with paper tapes and equipment for soldering and "wiping" the lead cover to potheads or to another section of PILC cable. Several hours are needed to prepare a 15-kV PILC cable termination.

The XLPE concentric-neutral cable can easily be prepared for termination by means of either a factory-made stress cone or a separable insulated connector. This preparation can be done by an ordinary lineworker in a hour or less using cutting jigs and tools to prepare the cable for the installation of the factory-made termination.

When the URD primary cable is terminated by means of a simple stress cone, the electrical connection to the terminal of the connected device usually is an exposed or "live-front" connection. When a separable insulated connection is used for termination, a "dead-front" construction is obtained; that is, all exposed surfaces of the cable and its termination are essentially at ground potential and thus present less of a hazard to operating personnel. In some cases, dead-front configuration allows a reduction in dimensions of the equipment.

Insulated connector modules are available in a great variety of configurations such as the elbow and bushing, multitaps, stand-off bushings for temporary use on parking stands, load-break modules, and T taps. Figure 18-44 illustrates a cutaway view of a switch (load-break) module, and Fig. 18-45 is a similar illustration of an elbow connector and module.

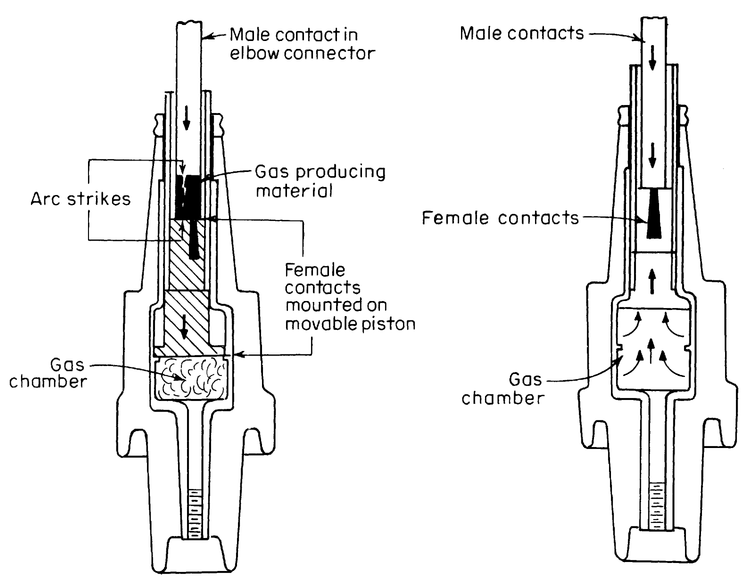

FIGURE 18-44 Piston-action 25-kV connector. (*General Electric Company.*)

The basic separable connector system used with URD distribution transformers usually is rated 200 A continuous and is available to either load-break or non-load-break form. See appropriate product bulletins or handbooks of the manufacturers for further product description.

System Types. About 65% of URD systems are installed along the streets in front of the houses, or "front-lot." The remaining 35% are "rear-lot" systems. There are obvious operating and maintenance problems associated with access to the rear-lot location. At the moment there does not appear to be any strong trend toward either option.

An extremely large number of combinations of transformer equipment are being used, and a detailed discussion of them is beyond the scope of this handbook. However, the following listing is reasonably representative of "typical" practice:

1. Pad-mounted transformer of the mini-pad configuration
2. Primary laterals operated as normally open loops
3. 12.47 grounded Y/7.2-kV primary voltage
4. The primary lateral loops through each distribution transformer, that is, there are two primary cable connections to each transformer (see Fig. 18-41)
5. Front-lot construction
6. Four to eight homes served by each transformer
7. Transformers of dead-front construction load-breaking separable insulated connectors
8. Internal fusing for each transformer
9. Direct-buried, cross-linked polyethylene insulated cables

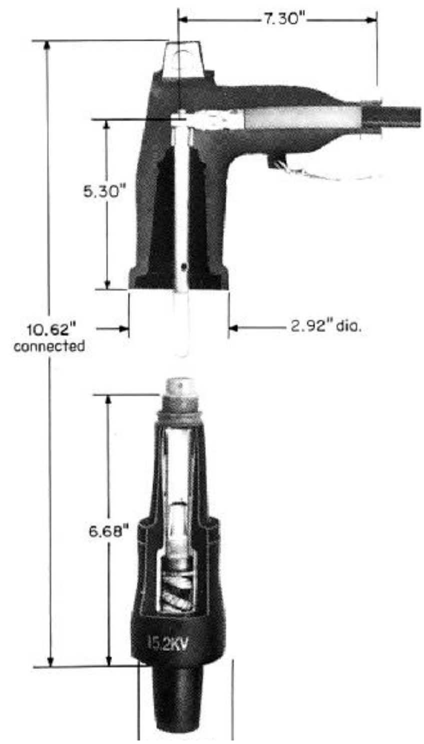

FIGURE 18-45 Cutaway view of elbow connector and switch module. (*General Electric Company.*)

Homes Served per Transformer. There is an optimal number of homes to serve from each transformer depending on the load per home, size of lots, and type of system to be used. For a given load per home and lot size, the cost per kVA of transformer decreases as the number of homes increases. This is so because increasingly larger transformers would be used.

However, as the number of homes per transformer increases, the cost of the secondary and service system increases because of the larger secondary cable required. Since the total cost is the sum of those costs, an optimum number of homes per transformer will exist.

In making such an economic study, it is necessary to examine the secondary-service-system voltage drop. A detailed study also should evaluate transformer and cable losses for the various arrangements.

Four to eight homes served per transformer seems to be reasonably typical of present practice. Larger loads per home and larger lot sizes favor a smaller number of homes per transformer. Conversely, smaller loads per home and smaller lot sizes favor serving more homes from each transformer.

18.21 UNDERGROUND SERVICE TO LARGE COMMERCIAL LOADS

Large commercial loads constitute one of the major segments of utility distribution systems, especially in built-up areas where underground supply systems are a requirement. Demands range from a few hundred to many thousands of kVA per customer, and the engineering and design time to provide adequate service facilities is substantial. Each job is special, requiring selection of appropriate and correctly sized equipment, negotiation of space and layout with building owners or their consultants, and frequently a detailed discussion of facilities, charges, rates, and contracts. The best tool the distribution engineer has is an adequate knowledge of the systems and components which are available, together with guidelines on their cost and reliability. Beyond this, engineering common sense and reasonable operating practices must be combined with the other factors in order to arrive at a decision on the method of service.

Characteristics of Large Commercial Loads. All large commercial loads generally involve the following factors:

1. *Loads* are in the range of 300 to 4000 kVA or more. The larger loads (even up to values of 50 or 75 MVA) are normally supplied by multiples of lower-capacity services.
2. *Utilization voltage* is 480Y/277, although smaller loads may be 208Y/120 and some of the larger institutional loads may be 4160Y/2400 (with the customer providing further step-down).
3. Individual *service size* is limited to about 4000 A by availability of service entrance switching, maximum fuse or breaker sizes, largest commercial wiring systems, and a growing "gut feeling" that this represents enough eggs in any one basket. Providing adequate interrupting capacity is also a definite factor, and single transformers above 4000 A may be priced as specials.
4. *Installation space* is limited and has a high value to the owner. Utility equipment must be as compact as possible and should not require exceptional customer requirements for auxiliaries.
5. Each job is one-of-a-kind and requires much *custom engineering* as well as detailed coordination with the owner of the building facilities. Complex commercial considerations are also involved, covering rates, ownership of facilities, contracts, and future maintenance responsibilities.
6. Service quality must be high, as to both voltage regulation and continuity. Frequent interruptions are not tolerable, and long planned interruptions are not feasible. Service complaints when expressed are long and loud.

Service Arrangements. Several basic service arrangements can be considered for these loads:

1. Radial
2. Primary loop
3. Primary selective
4. Secondary selective
5. Spot network

If radial service were adequate, there would be no need for the succeeding systems because the radial system is the least complex and the least expensive. Unfortunately, when the supply system is underground, it also is the least reliable and generally is unsatisfactory except in special cases. The principal drawback of the radial system is its exposure to long interruptions due to component failure and the necessity for repeated planned interruptions for routine maintenance or new construction.

These five basic service systems are illustrated in Fig. 18-46, which also shows a basic main feeder system of two similar underground feeders.

Radial System. The radial system is exposed to many interruption possibilities, the most important of which are those due to primary cable failure or transformer failure. Either event will be accompanied by a long interruption, reported nominally by utilities as 10 to 12 h. Both components have finite failure rates, and such interruptions are expected and statistically predictable. The system will be satisfactory *only* if the interruption frequency is very low and if there are ways to operate the system without planned outages.

Primary Loop. A great improvement is obtained by arranging a primary loop, which provides two-way feed at each transformer. In this manner, any section of the primary can be isolated, without

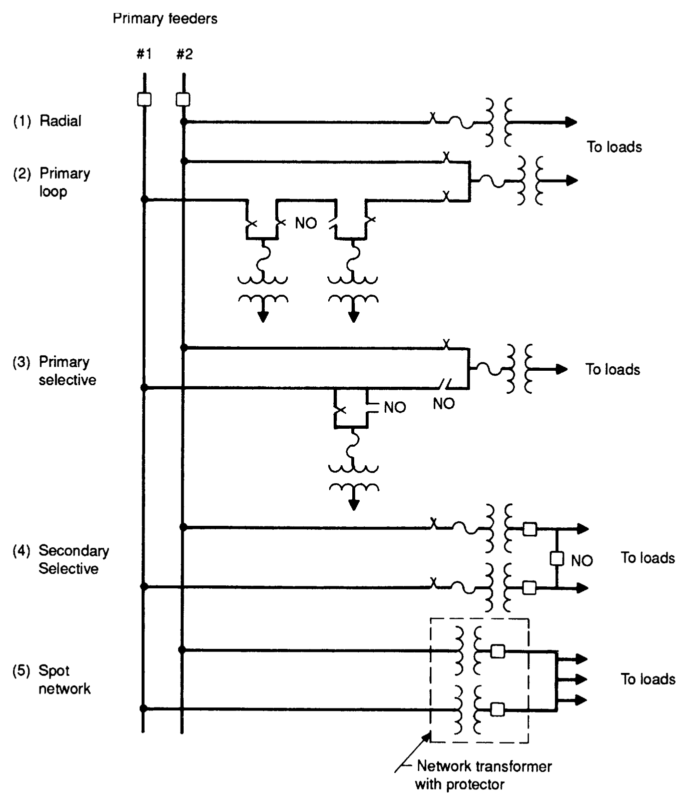

FIGURE 18-46 Five basic service systems.

interruption, and primary faults are reduced in duration to the time required to locate a fault and do the necessary switching to restore service. The cable in each half of the loop must have capacity enough to carry all the load. The additional cable exposure will tend to increase the frequency of faults, but not necessarily the faults per customer. The addition of a loop tie switch at the open point also introduces the possibility of a single equipment fault causing an interruption to both halves of the loop. Murphy's law generally applies to these situations. Automatic loop switching to reduce interruption duration further is very difficult to arrange and is not normally applied to these systems.

Primary Selective. This system uses the same basic components as in the primary loop but arranged in a dual or main/alternate scheme. Each transformer can "select" its source, and automatic switching is frequently used. When automatic, the interruption duration can be limited to 2 to 3 s. Each service represents a potential two-feeder outage (if the open switch fails), but under normal contingencies, service restoration is rapid and there is no need to locate the fault (as with the loop) prior to doing the switching. This scheme is in popular use on many underground systems. Switching times can be improved to less than 1/2 cycle with the use of a static transfer switch (STS).

Secondary Selective. This service system uses two transformers and low-voltage switching. It is not in popular use by utilities for 480-V service but is common in industrial plants and on institutional properties. Primary operational switching is eliminated and with it some causes of difficulty. Duplicate transformers virtually eliminate the possibility of a long interruption due to failure. Load is divided between the two units, and automatic transfer is employed on loss of voltage to either load.

There must be close coordination of utility and customer during planned transfers, and the split responsibility is probably the principal reason for its limited use as a service system.

Secondary Spot Network. Maximum service reliability and operating flexibility are gained by a spot network using two or more transformer/protector units in parallel. The low-voltage bus is continuously energized by all units, and automatic disconnection of any unit is obtained by sensitive reverse power relays in the protector. Maintenance switching of primary feeders can be done without customer interruption or involvement. Spot networks are common in downtown, high-density areas and have been applied frequently in outlying areas for large commercial services where the supply feeders can be made available. This system also represents the most compact and reliable arrangement of components for service in underground systems.

18.22 LOW-VOLTAGE SECONDARY-NETWORK SYSTEMS

Distributed or grid-type secondary network systems have been used for many years by electric utility companies to serve high-density load areas in the downtown section of cities. Secondary networks are used in about 90% of the cities in this country having a population of 100,000 or more and in more than one-third of all cities with population between 25,000 and 100,000.

The service voltage is 208Y/120 V supplying light and power loads in stores, hotels, restaurants, office buildings, apartment houses, and in some cases individual residences. The systems and equipment are entirely underground, and the 208Y/120-V portion consists of grids of interconnected cables supplied at numerous points by network transformers which feed the grid through network protectors.

A given secondary network is supplied by several primary feeders suitably interlaced through the area in order to achieve acceptable loading of the transformers under emergency conditions and to provide a system of extremely high service reliability. Primary voltages are found in the range of 5 to 34.5 kV, with the 15-kV class predominating. See Fig. 18-47.

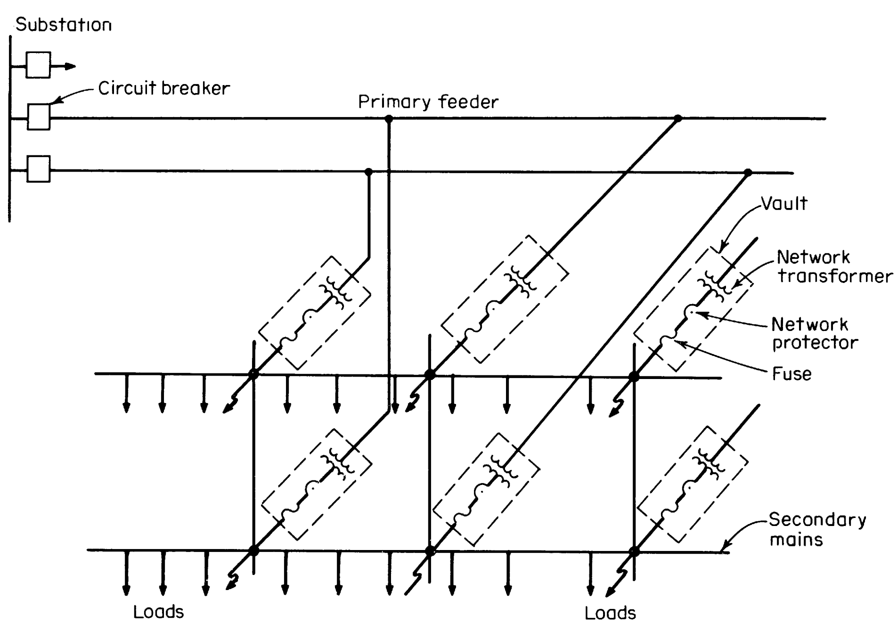

FIGURE 18-47 Schematic diagram of small segment of a secondary network.

The number and routing of the primary feeders are usually based on the assumption that the loss of one or two feeders will not cause a service interruption. For example, the design bogey may be such that the network can operate satisfactorily during the forced outage of one feeder when another feeder is out of service for repairs or maintenance (single contingency).

The secondary cable system is designed so that the loss of one transformer will not cause low voltage or a service interruption. Secondary cable faults in 208Y/120-V networks are allowed to burn clear or are cleared by means of limiters, which essentially are fuses having characteristics proportioned to protect the cable and to coordinate with other protective devices. Secondary faults usually will *not* burn clear on 480Y/277-V networks, so limiters are used extensively in these systems. Usually the secondary mains consist of two or more cables in parallel so that failure of one cable does not result in a service interruption.

Network Transformers. The network protector is mounted on one end of a network transformer, and the primary disconnecting and grounding switch is usually on the other end. In some installations the network protector is isolated from the network transformer, with the connection between the low-voltage terminals of the transformer and the protector made with insulated low-voltage cables. The typical network transformer is 3-phase, 216Y/125 V, oil-cooled, in a heavy corrosion-resistant tank suitable for installation in subsurface vaults under streets or sidewalks. Occasionally, there are installations in dry locations where submersible construction is not required. Five hundred kVA is a very common rating, although 750- and 1000-kVA units are available and in use. (For *spot* networks of 480 Grd Y/277 V, transformer ratings are available through 2500 kVA.) There are only two or three distributed street networks at 480Y/277 V in the United States.

Network Protectors. The network transformer is connected to the secondary network through a network protector (NWP) as shown in Fig. 18-47. The NWP is an air circuit breaker with relays and auxiliary devices and backup fuses, all enclosed in a metal case, which usually is physically mounted on the secondary side of the transformer. The functions of the relays are

1. To open the NWP on power-flow reversal, or in case of a fault in the transformer or in the primary feeder

2. To reclose the NWP when the voltage of the primary feeder is of the correct magnitude and phase relation with respect to the network voltage so that when the NWP closes, power (watts) and vars will flow *from* the feeder *into* the network

Thus, if there is a fault on a primary feeder, it is cleared by operation of the feeder breaker at the substation and the opening of all network protectors on transformers supplied by that feeder. Also, if a feeder breaker is opened manually in preparation for maintenance work on the feeder, all NWPs on that feeder should open automatically because of the reverse power flow caused by excitation of the transformers from the low-voltage side.

Cables. All primary and secondary cables are routed along the streets in duct lines as indicated in Fig. 18-47. Loads are served along the streets and at intersections as shown. Primary cables traditionally have been paper-insulated, lead-covered (PILC), but the solid-dielectric insulated cables have gained rapid acceptance. Secondary cables have commonly used rubber insulating materials, but polyethylene and ethylene propylene rubber insulations now are used extensively. Manholes at street intersections are large enough to hold numerous cable connections and limiters and to allow workers to pull and splice cables.

Continuity of Service. Continuity of service is the outstanding advantage of a network system. When a failure occurs in a primary feeder or in a transformer, the faulty feeder is automatically disconnected, and service continues without interruption. Secondary cable faults are allowed to burn clear or are cleared by means of limiters without loss of service. Substations supplying networks are so designed that typical substation faults will not shut down the network; this is further enhanced by careful interlacing of the primary feeders through the load area and their connection to different bus sections in the substation. It is strongly recommended that a given secondary network be supplied from only one substation. If a network is supplied, for instance, from two different substations, it is possible under some system conditions for power to flow from one substation to the other through the secondary grid and network transformers. Should this occur, some network protectors could "see" reverse power flow and open, thus resulting in the undesirable disconnection of these transformers from the network.

Network Size. A secondary network supplied by five or more feeders will keep transformer loadings at 125% or less during the outage of one primary feeder. If the feeders are in the 15-kV class, each feeder could easily supply six 1000-kVA or twelve 500-kVA network units. Thus five feeders interlaced could supply a 30,000-kVA network under idealized conditions. With 500-ft-square blocks, 1000 kVA per block corresponds to 112 MVA of load per square mile. Some utilities plan for the emergency outage of one feeder while a second is out of service for maintenance.

In general, 208Y/120-V networks are in the order of 30,000 to 40,000 kVA in size. There are many networks smaller than this range and some larger. One important limitation to the size of a secondary network is the ability to restore service after the network has been shut down.

Spot Networks. New commercial buildings in existing 208Y/120-V network areas usually have very large electric loads. These loads frequently are supplied by 480Y/277-V *spot* networks, since it is impractical to handle individual loads much larger than about 200 kVA from the 208Y/120-V street networks, and 480Y/277 V is an excellent voltage for supplying large commercial buildings. In some cases the spot networks are supplied from primary feeders which also serve a distributed network. Early 480Y/277-V spot networks used the same overcurrent protective devices employed successfully for clearing faults in the 208Y/120-V networks. Included are the network relays in the protector for detecting faults on the primary feeders, and the network protector fuses, cable limiters, and service fuses for detecting and isolating faults in the secondary systems. Some 208Y/120-V systems do not use cable limiters, as faults in the 208Y/120-volt network systems are self-clearing under some circumstances.

Operating experience with the 480Y/277-V spot network systems showed that some faults were arcing in nature, drawing significantly less current than that available for a bolted fault. Many of these faults would not self-clear or would self-clear only after extensive damage was done at and around the original point of fault. Also, some of these faults did not draw sufficient current to blow fuses, or else blew fuses only after significant damage was done at the point of fault.

As a result, some utilities have installed devices for detecting and clearing low-current arcing faults in the 480-V portions of the spot-network system. Heat sensors and ground-fault relays are the most commonly installed devices for the detection function. Clearing has been accomplished by tripping of the network protector, which is effective only for faults downstream from the protector terminals. In a few instances, vacuum circuit breakers or interrupters have been installed on the high-voltage side of the network transformer to clear faults in the associated network transformer, network protector, and other portions of the 480-V system.

Network Monitoring. Remote monitoring capability has been added to a few in-service secondary network systems to automatically gather data needed for the operation and planning of the system. Heretofore, such data were obtained from manual measurements at vaults and manholes. With remote monitoring, the data are continuously collected and transmitted to an operations center or other location for manual and computer analysis. Telephone lines, power-line carrier, two-way radio, and fiberoptic cable have been used as the communications links from the network vaults and other monitored sites of the substation or elsewhere. Virtually any quantity which can be digitized can be monitored. Examples of monitored quantities are the load on the protectors, protector position (open or closed), network protector fuses status (okay or blown), network transformer temperature, vault temperature, bus voltage, and vault water level. In several monitoring systems with two-way communications, it is possible to remotely trip or close the network protectors.

High-Rise Buildings. Primary-voltage feeders are being used as the riser feeder in high-rise buildings. A rule of thumb is that if an apartment building is 10 floors or more, it is more economical from an overall point of view to use the primary voltage rather than utilization voltage for the riser feeder. Similarly, for a commercial building with 480Y/277-V utilization, a building of 50 floors or more usually justifies the use of primary voltage feeders as risers in the building.

The primary system pattern within a high-rise building is usually a loop as shown in Fig. 18-48 or multiple as shown in Fig. 18-49. This will allow cable faults to be manually isolated by proper switching so that cable faults will cause only short interruptions to customers. Customers fed radially through a transformer will be without service if the transformer fails until a temporary connection can be made to an adjacent transformer. For more important loads like elevators, hall lighting, and fire pumps, better reliability is often obtained by using a spot network or low-voltage selective system.

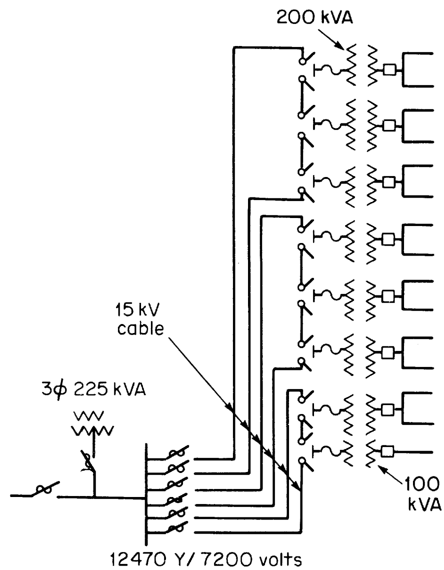

FIGURE 18-48 Schematic diagram of a looped primary system.

Dry-type transformers using air as the insulating medium of the transformers are the most desired for high-rise buildings. This is so because no special provisions have to be made in the transformer room, such as fireproofing for oil-filled or venting the transformer to the outside of the building for nonflammable liquid-filled transformers. Many of the transformer rooms for apartment buildings and some commercial buildings are in the core of the building, which makes it difficult to use the liquid-filled transformer. However, transformers for supplying heavy loads, such as air conditioning in commercial buildings, usually can be located against an outside wall on machinery floors of the building. This makes it relatively easy to vent a nonflammable liquid-filled transformer to the outside of the building. Hence network transformers are often used for this application.

The primary load-break switch or load-break connector with a fuse can be arranged for either the multiple or loop type of feed where the short-circuit current available is within their rating. Usually the primary short-circuit current available is in the 8000- to 10,000-A range. The current-limiting type of fuse is often used for this "inside-the-building" application because it does not discharge ionized gases or noise during interruption.

18.23 CONSTRUCTION OF UNDERGROUND SYSTEMS FOR DOWNTOWN AREAS

Underground construction is required in the built-up downtown areas of cities where the distribution system serves a multiplicity of concentrated commercial loads. Usually the distribution circuits are installed in conduits or duct lines along the city streets. Equipment such as switches and transformers is installed in vaults under the streets or sidewalk or in rooms located within the buildings.

Inflexible conduit systems have not been used widely in the United States except for the early Edison systems and are now completely obsolete. In this system, the conductors were insulated copper rods which were placed in an iron pipe which was then filled with a melted asphaltic compound which solidified on cooling. The tube sections were laid in a trench, joined together, and directly buried. For many years, inflexible conduit systems also were used in Europe; however, in the United States flexible systems gained preference because of the expense and inconvenience of digging through street surfaces in order to make repairs or replacements.

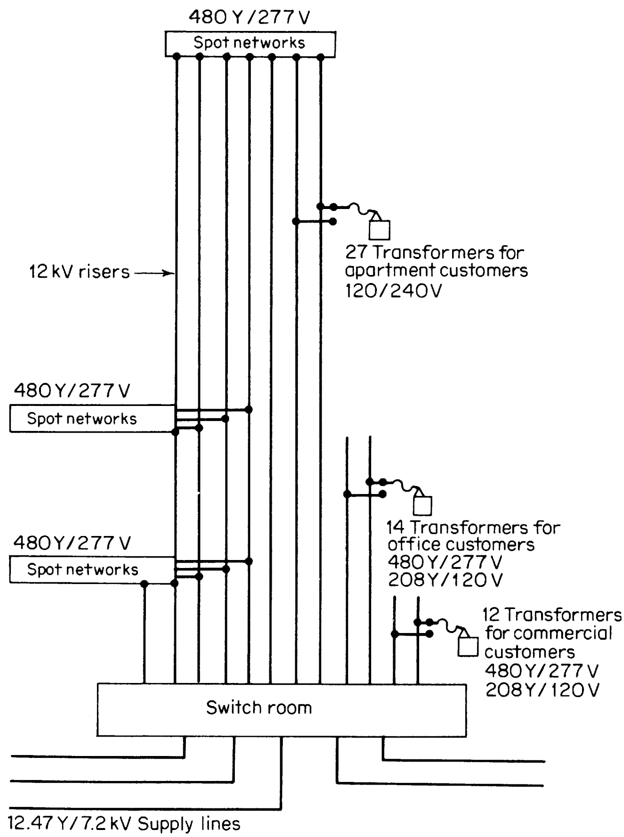

FIGURE 18-49 One-line diagram of the multiple primary system for John Hancock Center.

The flexible undergound system consists of ducts or pipes extending between manholes. This type of system has the advantage of minimum disturbance of street pavement and interference with traffic. Cables can be drawn or withdrawn from manhole locations for repairs or changes. Manholes are placed at all junction points, corners, and as needed for secondary and service cables. The spacing of manholes depends on the types of circuits installed, varying considerably between through-type and local distribution circuits. In straight runs, the intervals may be as great as 500 to 700 ft, depending on the allowable cable-pulling tensions and utility practice.

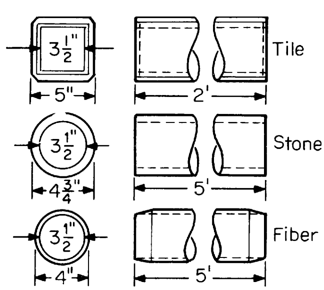

FIGURE 18-50 Types of single duct for underground conduits.

Duct Materials and Practices. Many types of suitable materials have been used for cable ducts, such as fiber-clay tile, concrete, plastic, fiberglass, and soapstone. Preference varies from one utility to another. In general the material should be impervious to water and not degraded by chemical action or electrolysis. The bore usually is round and should be smooth to avoid damage to the cable sheath or jacket. The diameter of the bore should be adequate to accept the largest-diameter cable envisioned for the foreseeable future. Several types of single duct are shown in Fig. 18-50. Diameters ranging from 3½ to 6 in are common.

For underground distribution systems, a duct line usually is built up of a number of single ducts, often arranged in a rectangular array and encased in concrete as shown in Fig. 18-51. For secondary-network systems, duct lines containing 6 to 12 ducts are frequently used.

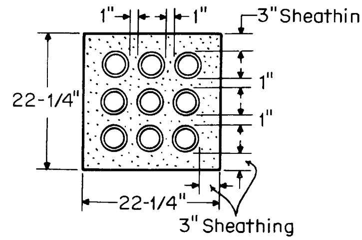

FIGURE 18-51 Arrangement of conduit with concrete sheath.

Number of Ducts. The number of ducts in a given duct line should be sufficient to accommodate anticipated load growth for a number of years in the future. Theoretically, the most economic form of duct structure would be two ducts wide. However, when more than six or eight ducts are required, this design may lead to excessive depth. As a result, usually a rectangular construction, three or four ducts wide and three or four ducts deep, is used, as shown in Fig. 18-51. The maximum number of ducts to be put into a duct line is governed chiefly by thermal limitations. It is desirable to have as many ducts as possible on the outside of the bank in order to facilitate heat transfer to the surrounding earth. Insofar as possible, the inner ducts should be used for cables which produce little heat. Since space for training cables in manholes is limited, it becomes more difficult to rack and train cables when the incoming duct line is several ducts wide and several ducts deep.

Location of Manholes. Manholes provide protected and accessible space in which cables and associated equipment can be operated efficiently. They must be provided in sufficient number to permit pulling in cable without excessive tension, to house necessary transformers and switching equipment, and to provide for splices and service connections.

On long runs the manhole spacing usually is not more than 500 or 600 ft. Where local distribution circuits are involved with numerous service connections, manholes may be located about 100 ft apart. Manholes or vaults to house transformers must be large enough to provide working room and proper ventilation. Location of transformer vaults in the sidewalk area is preferred, and sidewalk gratings are commonly provided to improve ventilation. For locations in the street or in areas accessible to vehicular traffic, the vault roof and gratings must be designed to withstand anticipated loadings.

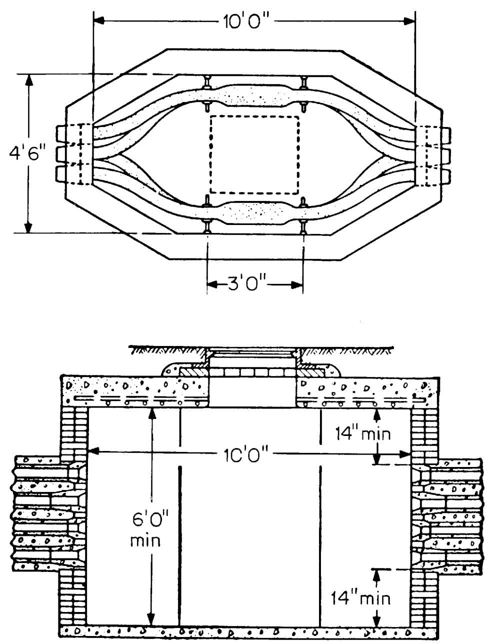

FIGURE 18-52 Straight-type manhole.

Many sizes and shapes of manholes are used. The design used for a particular installation may well be governed by the presence of local obstructions such as gas lines, water pipes, or conduit lines of other utilities. For cable manholes in the streets, many utilities have standardized on a rectangular or coffin-shaped design with the long axis parallel to the duct line. The manhole should be deep enough to allow the lowest duct to enter about a foot above the floor and should have 5 to 6 ft of clear headroom for workers. Also, the bottom of the manhole should be higher than the adjacent sewer system so that a drain can be effective in keeping it dry. Figures 18-52 and 18-53 illustrate two types of cable manholes.

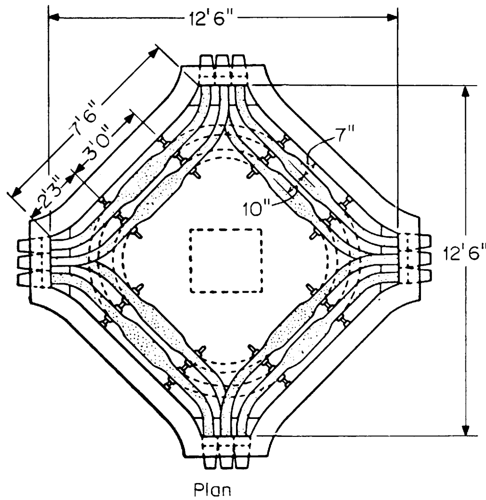

FIGURE 18-53 Nine-duct *X*-type manhole.

Handholes. In some cases, a shallow form known as a *handhole* is used for local-distribution circuit connections. These are usually built above the conduit line so that only the top row of ducts enters the handhole. Secondary distribution circuits are thus accessible for service taps and do not interfere with through lines in the lower ducts.

Installation of Conduit System. Typically there is considerable congestion of underground structures under city streets. Therefore, when a new duct line is planned, a survey should be made to select a location which will present as few obstructions as possible. This is done by noting the position of manholes of existing systems and by consulting whatever map records are available.

The exact final depth of the ditch often cannot be determined until the depths of pipes and conduits crossing it have been disclosed by excavation. Alignment and grades should be established with surveying instruments to ensure proper drainage and avoid pockets. The line may be curved slightly to avoid obstructions, but dips should be avoided where water may accumulate and freeze. Where conditions are suitable, the ditch can be dug so that the earth can be used as the form for the bottom and sides of the concrete encasement.

Structural Design of Cable Manholes. The walls of manholes generally are constructed of brick, nonreinforced concrete, or reinforced concrete. The reinforced-concrete manholes may be poured in the field or may be precast. Many variations in detailed structural design are found with different utilities. The roof must have sufficient strength to support the heaviest street traffic passing over it, which often necessitates use of steel reinforcement or structural steel beams.

To provide access of personnel and the installation of equipment, manhole frames and covers are provided and are supported on the roof of the manhole. The covers for the use of personnel usually are round and made of cast iron or steel. While some square or rectangular covers are used, they usually are heavier for the same effective opening and can fall into the manhole during replacement.

Cable supports or hangers usually are mounted on the walls of the manhole to support the cables in their trained position and to maintain an orderly arrangement of the cables.

Transformer Vaults. When transformers or other equipment are installed beneath streets, sidewalks, or alleys, manholes or vaults are provided. Usually enough room is provided around the equipment so that workers can operate or maintain it. In some cases involving nonnetwork service, commercial loads are supplied from “commercial subsurface transformers” where access to accessory equipment, such as fuses, internal switches, and separable cable terminations, is available from ground level; the vault may be close-fitting since it is not necessary for workers to enter the vault.

The most prevalent types of transformer vaults are found in secondary network systems. They may be located under sidewalks or streets or partly or entirely within buildings. The arrangement, size, and shape of a network vault are determined by the number and rating of network transformers to be installed and the nature of accessory equipment, such as primary switches. Figure 18-54 shows the general arrangement of a sidewalk vault arranged for two network units with network protectors and primary switches. The roof consists of removable slabs of sidewalk concrete (not shown), and access is available at either end by iron steps. Under normal conditions, the entrances are covered with suitable metal gratings or grills which allow for circulation of air.

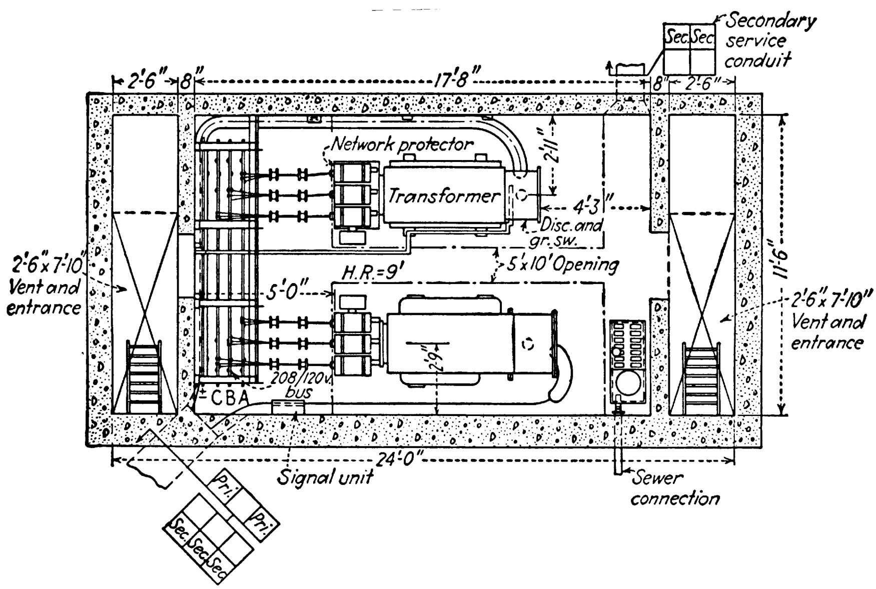

FIGURE 18-54 General arrangement of a network vault under a sidewalk (plan view).

When a nearby sewer is readily available, a drainage connection is often used in street vaults. Sidewalk vaults often do not accumulate enough water to justify a sewer connection and usually are provided with a small sump to facilitate pumping out with portable equipment, if necessary.

18.24 UNDERGROUND CABLES

Types of Cables. Underground distribution systems have been in use for many years in the downtown built-up areas of American cities. In most instances these are secondary network systems with facilities installed beneath streets and sidewalks, and the cables are usually installed in conduit or duct systems. For primary voltage circuits from 5 to 35 kV, paper-insulated, lead-covered (PILC), 3-conductor cable has been used extensively. Single-conductor secondary cables with rubber insulation and neoprene jacket are common. More recently, single-conductor polyethylene-insulated cables are being used for both primary and secondary. Copper conductor predominated in the past, but aluminum has nearly displaced copper in new installations, except where existing duct space is limiting.

In residential and suburban areas, new underground distribution systems to serve commercial loads, such as shopping centers and commercial and industrial parks, often employ direct-buried cables; conduits may be provided in locations where subsequent excavation would be excessively expensive or inconvenient. Aluminum conductors are almost universal. For primary cables, solid-dielectric insulation is used almost exclusively, with cross-linked polyethylene and EPR insulations predominating. Concentric-neutral wires are common. Secondary cables in these systems generally have aluminum conductors and solid-dielectric insulation, with cross-linked polyethylene being the most common. The secondary neutral is usually an insulated conductor, although there is some use of bare copper neutrals.

For most distribution circuits in the 5-kV class or higher, the cables employ a shielded construction. *Shielding* is the use of a conducting or semiconducting material on the surface of insulating material to confine the electric field to the insulation proper and to avoid undesired concentrations of electric stress. Shielding is used on the outer surface of the cable insulation or directly over the main conductor, or both. Outside shielding, often in the form of metallic tapes, metallic sheaths, or concentric wires, must be effectively grounded. This shielding also provides a return path for short-circuit current in the event of cable failure and protects workers from the shock of charging current.

Number of Conductors. Cables can be classified as single-conductor, 2-conductor, 3-conductor, etc., according to the number of separately insulated conductors enclosed by a single sheath or jacket (Fig. 18-55).

Cable Insulation. Electric supply cables are insulated with a wide variety of insulating materials depending on voltage ratings, type of service, installation conditions, etc. In the past, the following have been commonly used:

1. Rubber and rubberlike for 0 to 35 kV
2. Varnished cambric for 0 to 28 kV
3. Impregnated paper of the solid type for voltages up to 69 kV and with pressurized gas or oil up to 345 kV or higher

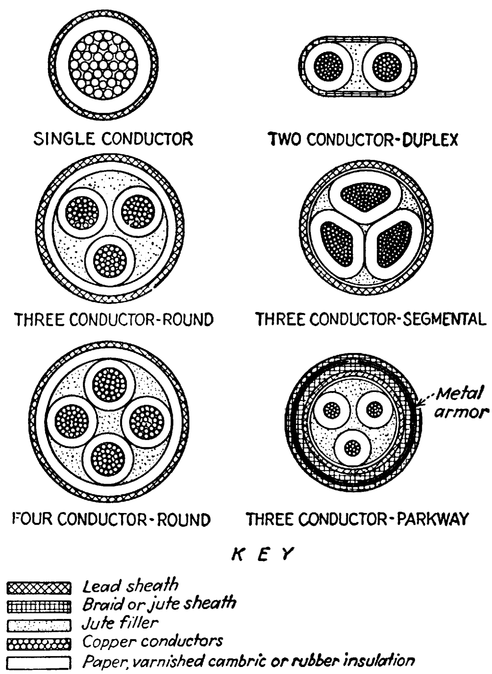

FIGURE 18-55 Cross sections of typical cables.

These insulation systems usually require a sheath or suitable jacket to prevent infiltration of moisture, loss of oil, gas, or impregnant, and to provide protection against corrosion and electrolysis. In some cases, an armor overlay is used to provide mechanical protection. With impregnated-paper insulation of the solid type, a lead sheath is usually provided.

A wide variety of joints, splices, and terminations is used, depending on the voltage, cable insulation, number of conductors, jacketing or sheathing material, and method of shielding. Joints, splices, and terminations are discussed in more detail later in this section.

Single-conductor cables are used, of course, in single-phase primary system for residential service and normally are used in single-phase or 3-phase secondary systems where many taps and connections are involved. Single-conductor cables also are frequently used in direct-buried, 3-phase primary systems. Three-conductor primary cables are often used in duct systems where they have the advantage of occupying only one duct. Several typical cables are shown in Fig. 18-55.

At the present time, solid-dielectric insulating materials such as tree retardant, cross-linked polyethylene, and EPR are receiving the widest application in underground distribution systems, both direct-buried and duct systems. Principal reasons for the wide usage of these insulations are

1. Low cost.
2. Suitability for direct burial or for use in duct systems.
3. Sheath or jacket not generally required.
4. Much easier to tap, splice, and terminate than systems such as solid impregnated paper. Factory-made splices, connectors, and terminations are available and widely used.
5. Excellent mechanical and electrical properties.

In a 2004 survey on procurement practices relating to underground distribution cable covering 60 investor-owned utilities and representing 70% of the total investor-owned utility customers, Dudas and Fletcher reported the following trends:

TABLE 18-20 Insulation Thickness for Cross-Linked, Thermosetting, Polyethylene-Insulated Cable

Rated circuit voltage, phase-to-phase volts	Conductor size, AWG or kcmil	Insulation thickness for 100% and 133% insulation levels	
		mils	mm
0–600	14–9	45	1.14
	18–2	60	1.52
	1–4/0	80	2.03
	225–500	95	2.41
	525–1,000	110	2.79
601–2,000	4–9	60	1.52
	8–2	70	1.78
	1–4/0	90	2.29
	225–500	105	2.67
	525–1,000	120	3.05
2,001–5,000	8–1,000	90	2.29
5,001–8,000	6–1,000	115	2.92
8,001–15,000	2–1,000	175	4.45
15,001–25,000	1–1,000	260	6.60
25,001–28,000	1–1,000	280	7.11
28,001–35,000	1/0–1,000	345	8.76

Note: *100% level* applied where system overcurrent protection is such that ground faults are cleared within 1 min. Applies to the great majority of distribution systems. *133% level* applied where clearing time of 100% level cannot be met, but there is assurance of fault clearing within 1 h. Minimum-size conductors should be in accordance with above values to limit maximum voltage stress on the insulation at the conductor to a safe value.

Source: Adapted from IPCEA Pub. S-66-524, NEMA Pub. WC-7-1471. Revision No. 3, September 1974.

- The survey indicated a significant preference for tree retardant crosslinked polyethylene (TRXLPE) over EPR cable.
- The majority specified concentric neutral on 200 A cable and LC shield, flat strap, flat wire or tape shield on 600 A cable.
- 78% specified an encapsulating jacket rather than an overlaying jacket.
- 95% of the utilities specified an insulating polyethylene compound for their cable jackets.

Insulation thickness for typical cross-linked, polyethylene-insulated, nonjacketed distribution cables are given in Table 18-20. Thickness for most ratings of non-cross-linked polyethylene cables are essentially the same.

Cable Diameters. Overall diameter D of a cable may be computed from the diameter of its conductors d, the thickness of its conductor insulation T, its belt insulation t, and its lead sheath S, as follows:

Single-conductor: $$D = d + 2T + 2S \qquad (18\text{-}22)$$

2-conductor: $$D = 2(d + 2T + t + S) \qquad (18\text{-}23)$$

3-conductor: $$D = 2.155(d + 2T) + 2(t + S) \qquad (18\text{-}24)$$

4-conductor: $$D = 2.414(d + 2T) + 2(t + S) \qquad (18\text{-}25)$$

These formulas apply to conductors of circular cross section. For sector-type 3-conductor cables, the overall diameter

$$D_3 = D - 0.35d \quad \text{approx.} \qquad (18\text{-}26)$$

Electrical Characteristics of Cable. Skin effect is an ac phenomenon whereby alternating current tends to flow more densely near the outer surface of a conductor than near the center. That is, the magnetic-flux linkages of current near the center of the conductor are relatively greater than the linkages of current flowing near the surface of the conductor. The net effect is that the effective resistance of the cable is greater for alternating current than for direct current. This effect increases as the conductor size increases and as the frequency increases. It is also a function of the relative resistance of the conductor material, being less for materials of higher resistance; for example, the skin effect for a given diameter of cable is great if the material is copper rather than aluminum. Because of skin effect, large cables are sometimes built up over a central core of nonconducting material.

The nonuniform distribution of alternating current across the cross section of the cable also has the effect of reducing the effective internal inductance of the cable. Usually, this effect is extremely small in distribution circuits and is neglected.

It should be noted that magnetic flux linking the cable because of nearby current also can affect the cross-sectional distribution of current and can significantly change the effective ac resistance of the cable for multiconductor cables or cables in the same duct. This is known as the *proximity effect*. Most tables of conductor characteristics list factors which combine the results of the skin effect and proximity effect.

If an insulated cable has an outer metallic wrapping such as sheaths, metal pipes, or concentric-neutral conductors installed in such a manner that induced circulating currents can flow normally in these external conductors, losses will occur in these circuits, reducing the ampacity of the cable.

Skin-Effect Coefficients. Skin-effect and proximity-effect coefficients are given in Table 18-20 for copper and aluminum conductors at 25°C. To determine the skin effect on the effective resistance of

Note: 1 ft = 0.3048 m.

*To correct to other temperatures, use the following:

For copper: $R_T = R_{25}\,[(234.5 + T)/259.5]$

For aluminum: $R_T = R_{25}\,[(228 + T)/253]$ where R_T is the new resistance at temperature T(°F) and R_{25} is the tabulated resistance.

†Includes only skin effect (use for cables in separate ducts).

‡Includes skin effect and proximity effect (use for triplex, multiconductor, or cables in the same duct).

a single-conductor 1000-kcmil copper cable operating at 25°C, refer to Table 18-21, where the dc resistance is 0.01079 Ω/1000 ft and the skin-effect coefficient is 1.067. The effective resistance at 60 Hz is 1.067 × 0.01079 = 0.0115 Ω/1000 ft, 6.7% greater than for direct current. For a similar 2000-kcmil, the increase in resistance for alternating current is 23.3%; the ampacity of the cable is reduced to 100/1.233 = 81.1%.

The last two columns of Table 18-21 give the coefficients for multiconductor cables or cables in the same duct. They are used in the same manner as in the previous examples. For the larger conductors, the derating factor is substantial.

Electrostatic Capacitance. The capacitance of a shielded or concentric-neutral single-conductor cable is

$$C = \frac{0.00736K}{10^6 \log_1(D/d)} \tag{18-27}$$

where C = capacitance, farads/1000 ft
K = dielectric constant of insulation
D = diameter over the insulation
d = diameter over the conductor shield

Charging Current. The charging current of a single-conductor cable is

$$I = \frac{0.0463EfK}{1000 \log_1 (D/d)} \tag{18-28}$$

where E = voltage to neutral, kV
f = frequency, Hz
I = amperes per 1000 ft, charging current

For overhead circuits at distribution voltages and power frequencies, the charging current usually is negligible. It may become significant in high-voltage transmission circuits, as discussed in Sec. 14. For insulated cables, the charging current is relatively greater than in overhead circuits because of close spacing and the higher dielectric constant of the cable insulation; $K = 1$ for air and 3.3 for impregnated paper. For unfilled polyethylene $K = 2.3$, and it may run as high as 2.9 for filled, cross-linked polyethylene.

Geometric Factors. Charging current of 3-phase three-core cable is affected by arrangement of conductors (round or sector) and by relative thicknesses of conductor insulation T and belt insulation t. These relations have been put into usable form by working out logarithmic denominators of the equation for various ratios of thickness of insulation to diameter of conductor. This has been termed the *geometric factor*. Charging current of a three-core 3-phase cable is

$$I = \frac{3 \times 0.106EfK}{1000G_2} \quad \text{A/1000 ft} \tag{18-29}$$

For impregnated-paper cable, K is 3.3, and the equation for 60-Hz circuits becomes

$$I = \frac{3 \times 3.3 \times 0.106 \times 60E}{1000G_2} = 0.063\,\frac{E}{G_2} \quad \text{amperes} \tag{18-30}$$

Values of G for single-conductor and G_2 for 3-conductor cable may be taken from Table 18-22.

Geometric Factors of Cables. See Table 18-22. Intermediate values may be found by interpolation.

TABLE 18-22 Table of Geometric Factors of Cables

Ratio $\frac{T+t}{d}$	G Single conductor	Sector factor	Three-conductor cables: G_1 at ratio t/T 0	0.5	1.0	G_2 at ratio t/T 0	0.5	1.0

1.2	1.22	0.921	2.02	2.13	2.23	3.45	3.80	4.25
1.3	1.28	0.928	2.08	2.19	2.29	3.60	3.95	4.40
1.4	1.33	0.935	2.14	2.26	2.36	3.75	4.10	4.60
1.5	1.39	0.938	2.20	2.32	2.43	3.90	4.25	4.75
1.6	1.44	0.941	2.26	2.38	2.49	4.05	4.40	4.90
1.7	1.48	0.944	2.30	2.43	2.55	4.17	4.52	5.05
1.8	1.52	0.946	2.35	2.49	2.61	4.29	4.65	5.17
1.9	1.57	0.949	2.40	2.54	2.67	4.40	4.76	5.30
2.0	1.61	0.952	2.45	2.59	2.72	4.53	4.88	5.42

Example. Find 60-Hz charging kVA for 33-kV cable having three 350,000-cmil sector-type conductors each with 10/32 in of paper and a 5/32-in belt.

$$T = 0.313 \text{ in} \qquad t = 0.156 \text{ in} \qquad d = 0.681 \text{ in} \qquad t/T = 0.5$$

$$(T + t)/d = (0.313 + 0.156)/0.681 = 0.69; \; E = 33/1.73 = 19 \text{ kV}$$

Interpolating in Table 18-22, we find $G_2 = 2.78$.

For sector-type cable, G_2 must be multiplied by the sector factor for 0.69, which is seen to be 0.86 in the sector-factor column in Table 18-22. For such a cable,

$$G_2 = 0.86 \times 2.78 = 2.39 \qquad \text{and} \qquad I = (0.063 \times 19)/2.39 = 0.5\text{A}/1000 \text{ ft}$$

Charging kVA $= 3IE = 3 \times 0.5 \times 19 = 28.5$ kVA/1000 ft, and for a cable having a length of 20 mi it would be $20 \times 5.28 \times 28.5 = 3010$ kVA. For single-conductor cables, $t = 0$ and $(T + t)/d = T/d$, which is used to get the value of G from the values for single-conductor cable in Table 18-22.

Cable Terminations. A cable termination must perform several functions:

1. Provide means for electrical connection of the cable to an equipment or circuit.
2. Control the electrostatic stresses so that there is no electrical-discharge activity in the termination at design voltage levels. One important consideration is to control the voltage stresses where the change is from a uniform radial field within the (shielded) cable to a new configuration beyond the termination of the shield. Other considerations are to provide adequate flashover and creepage strength to nearby grounds.
3. Prevent loss of gas or liquid insulation impregnant from the cable, where needed, or from the termination.

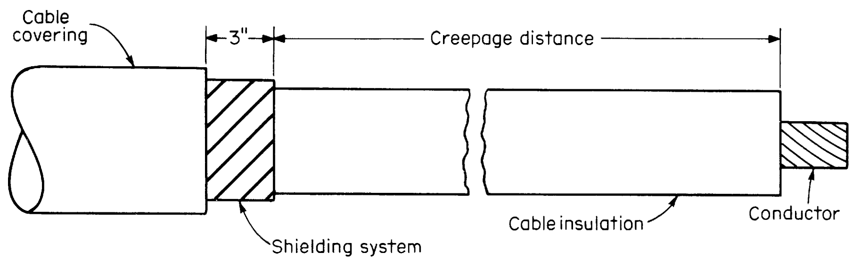

FIGURE 18-56 Elementary plain-shield termination.

4. Provide suitable mechanical and/or hermetic termination of the sheath, where used.
5. Serve as a load-break switch or separable connection, where needed.

Many types of terminations are in use, ranging from those made by hand in the field to factory-made types requiring very little work in the field. Two broad classifications are live-front and dead-front. The former involves exposed, bare electrical connections and possibly lengths of unshielded cable. The latter type of termination is completely enclosed in a semiconducting or metallic structure essentially at ground potential, such that it can be touched without hazardous shock while the equipment is energized.

Elementary Stress-Cone Termination. Figure 18-56 shows a single-conductor shielded cable prepared for termination. Figure 18-57 shows an elementary stress-cone termination. The stress cone may be built up by using tapes of a material compatible with the cable insulation, or it may be a factory-molded stress cone which is slipped over the (solid-dielectric) cable insulation system after the end of the cable has been properly dressed.

The stress cone serves to keep dielectric stresses at acceptable values. Without the stress cone, the plain termination of Fig. 18-56 would experience excessive stresses at normal voltage near the end of the shielding system, leading quickly to failure. Occasionally, an overall cover tape may be provided. Usually, a compression-type connector is installed on the cable conductor to provide a means of electrical connection to the equipment.

Separable Insulated Connectors. Accompanying the rapid growth in the use of single-conductor, concentric-neutral (or shielded cables employing solid-dielectric insulation) has been the development of separable insulated connectors of the dead-front classification. A typical termination consists of

1. An elbow, as shown in Fig. 18-45, which is physically and electrically connected to the end of a properly dressed cable.
2. A load-break switch module where the load-break function is specified (see Fig. 18-44).
3. An apparatus bushing. When a load-break module is not used, the elbow is mated directly to the apparatus bushings.

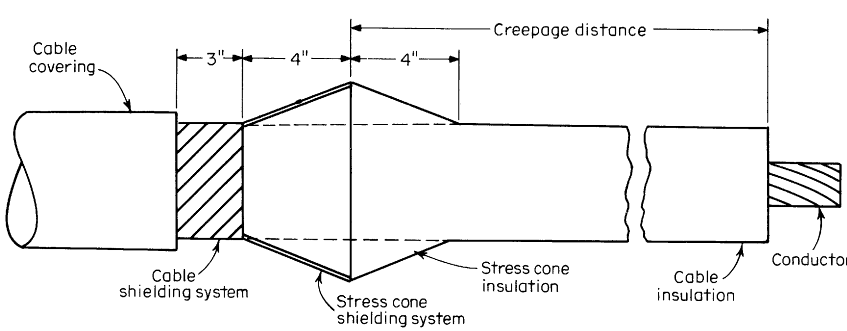

FIGURE 18-57 Elementary stress-cone termination.

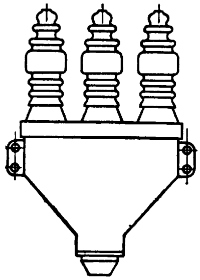

FIGURE 18-58 Three-conductor disconnecting-type pothead.

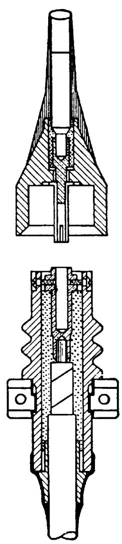

FIGURE 18-59 Disconnecting-type pothead.

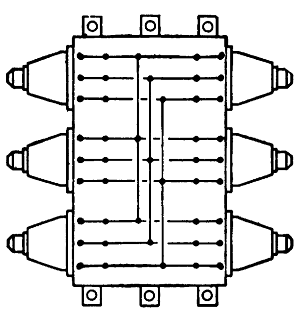

FIGURE 18-60 Six-way disconnecting cable-junction box.

The external shield and the insulation of the elbow and switch module are made of synthetic rubber. The stress-relief function is designed into the molded configuration.

When the elbow is in its normal connected position, the termination is dead-front and submersible.

A wide variety of accessory components are available, including multitaps, insulated bushings, feed-through bushings, insulating caps, etc. so that wide flexibility in operating procedures can be obtained for differing system and equipment configurations.

Separable insulated connectors are available in 200-A ratings for use on grounded-wye systems of the 15-, 25-, and 35-kV classes. Ratings of 600 A also are available, but these usually cannot be opened under load or while the cable is energized.

To install the elbow, the end of the cable is dressed according to the manufacturer's specifications; often a jig is used so that proper removal of semiconducting shield, correct dressing dimensions, exposure of the conductor, etc., are easily obtained. A crimped connector is then installed on the cable conductor, and the elbow is then slipped over the cable, internal male contact installed, and the cable or concentric neutral is connected to the semiconducting outer shield of the elbow.

Obviously, a termination of this kind can be installed much more quickly and with a lower level of skill needed than in terminating the traditional paper-insulated, lead-sheathed cables.

Pothead Terminations. Where cables are connected to overhead systems or to switchgear equipment, they often are terminated by means of potheads, such as that shown in Fig. 18-58. An extremely wide variety of types is in use, depending on

1. System voltage.

2. Type of cable insulation.

3. Single- or multiconductor cable.

4. Type of jacket or sheath.

5. Whether "live" side of pothead is outdoor or within an equipment. Some potheads are of the disconnecting type as indicated in Fig. 18-59.

There is an increasing trend toward the use of factory-made molded-rubber terminations in place of the traditional potheads, particularly with cables having solid-dielectric insulation.

Subway Junction Boxes. Subway junction boxes are sometimes used in cable systems to interconnect distribution circuits at points where it is desired that the connection be opened, at times, for construction or operating purposes and where overhead disconnecting facilities are not available. In low-voltage systems, such as 208Y/120-V secondary networks, such boxes may include sectionalizing fuses or connecting links. They are used in a number of different circuit configurations, a six-way junction box being shown in Fig. 18-60.

Splicing. Cable splices to a great extent resemble "back-to-back" portions of cable terminations. The completed splice provides

1. Electrical connection between the cable conductors, usually by means of crimped connectors.
2. Insulation over the exposed conductors and connector.
3. Jointing of the shielding or concentric neutral systems of the two cable sections so that electrical stresses are properly controlled.
4. Jointing of the jacketing systems or sheaths.
5. A "stop" function where the two cable insulation systems are different, for example, oil-impregnated paper on one side and solid dielectric on the other. Here it is necessary to contain the oil in the paper insulation and to exclude its penetration into the solid dielectric.
6. A disconnecting function, where required.

Factory-made splices are used extensively for splicing cables with solid-dielectric insulation. Where the disconnecting function is required, various combinations of multitaps and elbow terminations are used.

The traditional method of splicing paper-insulated, lead-sheathed cable is shown in Fig. 18-61. This method, which employs hand-wrapped insulating tapes, requires a high level of skill and training as contrasted to the use of factory-made splices for joining solid-dielectric cables. In jointing single-conductor cables, the lead sheath is removed about 6 in back from the end, and enough insulation is cut away to permit a soldered connection to be made. When the connection is complete, the bare parts are wrapped with tape until the equivalent of cable insulation has been applied. A lead sleeve which has previously been slipped over one of the cables is now wiped on the two cable sheaths so as to enclose the joint. Air space around the joint is then filled with hot insulating compound poured into a small hole in one end of the sleeve; a similar hole is left in the other end to allow air to escape. These holes are then closed by soldering. The joint should be allowed to cool before it is moved, so that the compound will hold the parts rigidly in place.

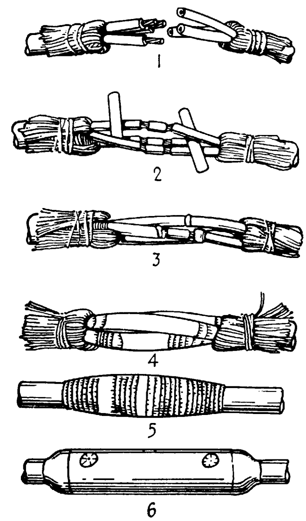

FIGURE 18-61 Successive stages in cable splicing.

In jointing 3-conductor cables, the lead must be removed about 10 in to facilitate taping the conductors (see Fig. 18-61). In making joints for 6600 V and higher, it is important that as little air remain in taping as possible. If paper tape is used, each layer should have compound poured over it before the next is applied.

Installation of Cable. Generally, *direct-buried cable* in underground residential distribution (URD) systems is buried in a trench, usually 36 in or more deep. Often, random lay of the power and telephone cables is employed, with no intentional separation. When soil conditions permit, the trench is backfilled with the original material. In some cases a selected backfill and/or protective covering over the cables may be necessary.

Where URD circuits must be routed under streets or other paved surfaces, or in locations such that it would be impractical to dig in order to repair a faulted cable, duct installation often is used.

Where soil conditions and circuit configurations are favorable, it is possible to directly plow in the cable by means of a special plow which breaks the earth ahead of the cables and guides them into the furrow.

In *duct installations*, the most common method of preparation has been to use wood or metal rods which are pushed into the duct section by section as they are connected together. When the opposite end of the duct is reached, a wire is attached to the end of the last rod and is pulled into the duct as the rods are withdrawn.

When the duct is airtight, a piston with attached flexible wire can be blown through the duct by means of compressed air. This method is quicker and less laborious than the rodding process.

Cables are pulled through the duct by means of a pulling line, usually wire rope, and a power-driven cable-pulling winch. Cables of moderate size and length usually are pulled by means of cable grip, which is a type of woven-wire basket designed to increase its grip on the cable as the tension increases. Often a flexible pull-in tube is used in the manhole to prevent damage to the cable being pulled and to other exposed cables in the manhole.

With long sections or larger cables, it may be necessary to use a pulling eye rather than a cable grip because the pulling tension may exceed the capability of the cable grip. The pulling eye is a steel eye which usually is fastened directly to the cable conductors.

When a new cable is to be installed in an existing duct, it is generally desirable that the diameter of the duct be at least 3/4 in greater than that of the cable. Where the duct section is exceptionally long or contains relatively sharp bends, a clearance of 1 in may be needed. On short, straight sections, 1/2-in clearance may be acceptable. Where several single-conductor cables are to be drawn into the same duct, the cable reels are set up in tandem and all cables are pulled into the duct simultaneously.

Cable Training. The location of cables in manholes is determined primarily by the ducts which they occupy. The cables should be fanned out as they leave their ducts so that they do not cross other cables or ducts. Sufficient length must be left in manholes to permit training on racks around the manhole walls, as shown in Figs. 18-52 and 18-53, and for joining. Radius of bends should be greater than the minimum safe bending radius for the cable, and cable movement also must be considered. The safe bending radius varies with the size, type of sheath or armor, etc. and generally is on the order of 8 to 12 times the overall diameter of the cable for power cables.

With large cables, the periodic load cycles cause repeated flexing and movement in the manholes, and duct-mouth protection is often used to prevent cracking of lead sheaths. This may consist of a piece of galvanized metal inserted under the cable and arranged to prevent the sheath from being pressed against the sharp edges of the duct mouth.

In order to limit damage resulting from cable faults to the failed cable, it is quite common to fireproof the cables in a vault or manhole. Such fireproofing usually is done with asbestos tapes and asbestos or mortar cements.

Sheath Bonding. With cables having a lead or other metallic sheath, it is common practice to bond together the different sheaths in a manhole or vault. Bonding consists of electrically connecting together the various sheaths. Various types of bonding systems are in use to maintain the sheaths at a common potential near ground potential, thus reducing the danger to workers who may be in the manhole when a cable fault occurs. This also eliminates the possibility of serious arcing occurring between the sheaths of the faulted and unfaulted cables.

Selection of Duct Position for Cable. Cables used in local distribution should be installed in the top row of ducts so that manholes for service connections and lateral circuits can be of a relatively shallow construction. In distribution manholes, the higher-voltage cables and cables of through lines should be placed in the lower and outside ducts, where possible, and they should be trained with the least possible interlacing with other cables.

Ambient Earth Temperatures. Ambient earth temperatures vary with geographic location, season, and depth. Average daily air temperature at a given location follows a more or less sinusoidal curve over the seasons of the year. As a result, the earth ambient temperatures also exhibit an annual sinusoidal variation. At depths greater than 1 to 2 ft, there is essentially no daily variation in earth ambient, but there is a seasonal variation which is greater at shallow depths, decreasing with depth. In addition, as the depth increases, the variation in ambient temperature increasingly lags behind the daily ambient air temperature curve; at a depth of 6 ft, this lag may be as great as 6 to 8 weeks. At depths of 20 to 30 ft, the earth temperature remains practically constant at about the mean annual air temperature. As a result, the earth temperature tends to increase with depth in the winter and decrease with depth in the summer. At a depth of 3 1/2 ft, typical temperatures are as follows:

	Temperature, °C	
	Summer	Winter
Northern U.S.	20–25	2–15
Southern U.S	25–30	10–20

Calculation of Ampacities of Cables. The precise calculation of ampacities of cables is extremely complex and has been the subject of numerous technical papers. This complexity is due not only to the characteristics of the thermal circuit, such as heat transfer through the cable insulation and sheath, transfer to duct or earth, and transfer from duct bank to earth but also to the fact that losses in the cable conductor are subject to skin and proximity effects. Also, additional losses can occur in the cable-shielding system depending on the nature of the installation.

Presently accepted methods of calculation, empirical data, and numerous references are treated in the following references:

1. IEEE Standard 835-1994, *IEEE Standard Power Cable Ampacity Tables*, goes into great detail explaining where the numbers came from. The types of cables for which ampacities have been calculated range from simple crosslinked polyethylene insulated 600-volt cables up to various medium voltage cables. The technical introduction covers cable construction, installation conditions, calculation methods, calculation examples and details of the assumptions made in calculating the ampacities that appear in the tables.

2. Ampacities, Including the Effect of Shield Losses for Single Conductor Solid Dielectric Power Cable 15 kV through 69 kV, NEMA WC 50-1976/ICEA P-53-426, 2nd ed. (R1993, R1999).

Maximum Allowable Conductor Temperature. The ICEA temperature ratings for polyethylene (thermoplastic) and cross-linked-polyethylene-insulated power cables are

	Max. conductor temperature, °C	
Insulation	Normal operation	Emergency overload
Polyethylene	75	90
Cross-linked polyethylene	90	130

Maximum conductor temperatures for impregnated paper-insulated cables are given in Table 18-23, as adapted from Publication P-46-426 of the IPCEA.

Ampacity of Cables. There is a growing use of single-conductor, solid-dielectric power cables for important 3-phase distribution circuits in the 15- to 35-kV class. Various shielding systems are in use including concentric wires, ribbons, and tapes. In many cases, on 4-wire primary-distribution circuits, the concentric wires are used as neutral conductors. When the shields are bonded together and grounded at multiple locations, circulating currents can flow in the shields, resulting in I^2R losses and appreciable heating effect. Such losses may be significant when the cables are spaced.

The AIEE-IPCEA ampacity tables do not include the effects of circulating-current losses, but these effects are included in the ampacity tables of IPCEA Publication P-53-426, NEMA Publication WC50-1976, "Ampacities Including Effect of Shield Losses for Single-Conductor Solid-Dielectric Power Cable 15 kV through 35 kV (Copper and Aluminum Conductors)." The ampacity data in Table 18-24 have been taken from this publication and apply to directly buried, solid-dielectric power cable

Table 18-25 has been adapted from the IPCEA Publication P-53-426 (and NEMA Publication WC50-1976) to illustrate typical ampacities of single-conductor, solid-dielectric power cables installed in underground ducts. The type of installation is assumed to be directly buried fiber or plastic duct of inside diameter nominal pipe size to provide a minimum diametral clearance of 0.75 in between cable outside diameter and inside diameter of the duct. The assumed arrangement of the ducts is shown in Fig. 18-62.

18.25 FEEDERS FOR RURAL SERVICE

Basic Conditions. Rural distribution differs from urban in that consumers are farther apart and load units are generally small. Since distances are great, the primary system voltage should be the 15-kV class or higher, and the load per mile being low requires the cost of feeder construction to be as low as is consistent with a reasonable degree of permanence and reliability. One transformer per customer is required in many cases. Rural construction since the late 1930s has made electric service available to practically every farm. Efforts are directed now to bolstering capacity to serve the growing loads.

Poles and Spans. Design of overhead lines for rural service differs from that of urban lines in several respects. Costs are reduced by using longer spans and as few accessories as possible. Longer spans mean greater sag and higher poles to get proper clearance at the low point of the span. The increase in sag may, however, be reduced by use of higher tensile stresses in conductors. This is possible when steel is employed in conjunction with copper or aluminum wires. Steel is combined with copper in a high-strength strand known as Copperweld, which has 30% or 40% of the conductivity of a copper conductor of equal size, or in a similar aluminum and steel conductor known as Alumoweld. When greater conductivity is needed, one or more strands of hard copper are stranded with or around the Copperweld or hard aluminum strands around Alumoweld. Steel is also stranded

with aluminum wires into ACSR conductor. Such types of conductor have ample conductivity for rural lines, and they have been used widely. In level country, spans of 400 to 600 ft are practical, while in hilly country, spans of 800 to 900 ft are occasionally possible.

Cable. Design of underground circuits for rural service is similar to that of urban underground circuits. Concentric-neutral cables are likely to be used in both types of systems. Because the rural circuits have longer uninterrupted runs of cable, there is a better opportunity to plow in the cable rather than digging trenches. Plowing results in lower installed costs per unit length of cable. In fact, some electric suppliers report that the total cost of a rural underground system is less than the cost of an overhead system to serve the same load.

Location of Circuits. Rural-service circuits are run along main highways, where the largest number of users may be reached. Branches along intersecting roads are extended as may be warranted by service requirements. In some cases, private rights of way, maintained for transmission lines, may be utilized.

Voltage. Rural circuits may be extended 5 to 50 mi from the point of supply, and voltage used for primary distribution must be chosen accordingly. Loadings are often so small that the minimum size of conductor required for dependable strength for overhead or cable insulation for underground is sufficient to meet requirements of voltage drop and line loss. This is particularly true when the higher voltages are used.

The most common primary voltage used in rural areas is 12,470Y/7200 V, 4-wire for normal load densities and 24,940Y/14,400 V for very light load densities. There is a trend toward using both 24,940Y/14,400 V and 34,500Y/19,900 V for all types of rural areas.

Single-phase circuits are most economical for the usual light loads found in rural areas and where power units do not exceed 10 hp. Vee-phase circuits consisting of 2-phase conductors and the neutral are an economical method of supplying 3-phase loads using open-wye-open-delta transformer banks. Full 3-phase, 4-wire construction will be desirable for many areas. In some cases there may be relatively small 3-phase loads in a single-phase area. Often these loads can be supplied economically from a single-phase system by means of a phase converter, the output of which is 3-phase voltage.

Limitations of voltage and distance are illustrated by the following table showing kilowatt-miles corresponding to a 5% line drop at 80% power factor for a circuit of 1/0 ACSR, or its equivalent in other metals.

Kilowatts × miles for 5% voltage drop, power factor 80%

System	4.16 kV	12.47 kV	24.94 kV	34.5 kV
Single-phase	82	737	2949	5646
3-phase	488	4375	17919	33815

Values for other sizes are approximately in proportion to relative cross section. In order to determine specific voltage-drop values for 3-phase overhead and underground circuits, refer to Table 18-3.

Conductors and Spans. Because of the economy of using long spans, the choice of span lengths and conductor strength is of much importance in planning rural lines. Single-phase lines are commonly taken from a 3-phase system with neutral grounded. The grounded conductor is carried on a bracket about 2 ft below the phase wire, which rests on an insulator carried on the top of the pole. No crossarm is required, except on a main line of more than one phase.

While the conductivity of No. 4 ACSR or Copperweld may be thermally adequate for the greater part of a rural system, system economics can dictate the use of larger conductors. The strength of No. 4 ACSR or Copperweld is usually ample for spans of 350 to 600 ft, depending upon design-loading conditions. Conductors should be sagged in accordance with the conductor manufacturer's recommendations.

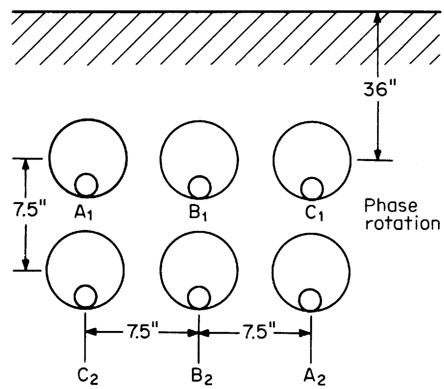

FIGURE 18-62 Arrangement of ducts.

Poles. The strength of poles should be determined for the height required by the methods described in Secs. 18.14 and 18.15. The length of poles required in any situation must be such as to allow for depth of setting and height of wire supports needed to give proper clearance above ground at the low point of the span. Such clearances should be not less than value shown in the NESC. In the case of road and railroad crossings, the necessary clearance may sometimes be more readily had by placing one end of the span near the crossing, thus avoiding having the low part of the span over the crossing. In rolling or hilly areas, it is desirable to locate poles on higher elevations to permit use of longer spans and greater sags.

Where no ice loading is likely, 30-ft poles can be used for two conductors of a single-phase branch on level ground or on long even slopes with span lengths to 400 ft. This often will preclude, however, the addition of communication circuits to the poles. Where ice and wind loading is expected with some regularity, it is necessary to use 35-ft poles for spans exceeding 300 ft. At corners or angles, poles should be supported by guying or bracing to support unbalanced longitudinal stresses.

Crossarms or equivalent equipment are required for the main 3-phase circuits and for lines supplying any user taking 3-phase service for power. A two-pin arm is often used with the third phase on the pole top. The grounded neutral is carried on the side of the pole about 2 ft below the arm.

Transformer Installations. Transformers usually supply not more than one or two customers, and sizes, therefore, are small compared with the average used in urban work, 10 to 15 kVA being average for single-phase installations. Where points of use are more than about 500 ft apart, it is usually most economical to provide separate transformers. When two users are within this distance, they can be served by placing a transformer between them and constructing a secondary. Rural loads on some systems have grown to the point where 15- and 25-kVA transformers are required.

Transformer capacity usually may be selected on the basis of loading the transformer to 150% of nameplate rating for peak loads lasting for 1 to 2 h. Pumping for drainage or irrigation is likely to require rated capacity more nearly equal to load.

Stray Voltages. Stray voltages on dairy farms may cause lowered milk production and increased mastitis in dairy cattle. Dairy cattle are particularly sensitive to low magnitudes of voltage. Voltages on the order of 0.5 V occurring between metal stanchions or metal drinking cups and the concrete floor may be troublesome. It should be noted that the same symptoms may be due to other causes and that stray voltages are not always to blame.

One characteristic of the common-neutral distribution system, in which the neutral conductor is common to both the primary and secondary systems, is the multiplicity of ground connections between the neutral conductor and earth. Unbalanced load conditions on either the farm secondary system or the utility primary system result in current flow in the neutral conductor. Due to the multiplicity of ground connections, some portion of the neutral current flows in earth. These earth currents cause stray voltages to appear in the earth. Deteriorated insulation on farm wiring and machinery can also cause earth currents, and these causes should be eliminated first.

One way to minimize stray voltages in the dairy barn is to cast wire mesh into the concrete floor and to bond the mesh and all metal structures together to establish equal potentials. In cases where current flow in the utility primary neutral is identified as a cause of stray voltages, it may be necessary to isolate the primary and secondary neutrals of the distribution transformer serving the farm. The NESC, IEEEC2-1997, addresses this situation in Section 97D.

18.26 DEMAND AND DIVERSITY FACTORS

Demand Factor. The ratio of maximum demand to total load connected, expressed as a percentage, is termed the *demand factor* of an installation. For example, if a residence having equipment connected with a total rating of 6000 W has a maximum demand of 3300 W, it has a demand factor of 55%. Demand factors of various types of large loads are helpful in designing systems, particularly those in buildings. As an example, a single household electric clothes dryer, of course, has a demand factor of 100%, but 25 dryers in a group have a demand factor of 33%. Similarly, three to five all-electric apartments in a multifamily dwelling have a demand factor of 45%. The lower the demand factor, the less system capacity required to serve the connected load. However, summer air conditioning and winter electric heating are loads that make for high demand factors.

Coincidence or Diversity Factor. The *coincidence factor* is defined as the ratio of the maximum demand of the load as a whole, measured at its supply point, to the sum of the maximum demands of the component parts of a load. The *diversity factor* is the reciprocal of the coincidence factor. Coincidence factors can be applied to known consumer demands for estimating the loading of distribution transformers, lines, and other facilities. Coincidence factors for residential consumers can vary over a wide range for different types of consumers. The coincidence factor for a large group of consumers with no major appliance might be as low as 30%, whereas a group of electric-heating consumers might be as high as 90%.

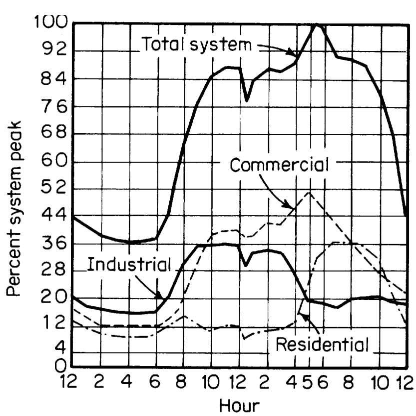

FIGURE 18-63 Characteristic metropolitan load pattern.

Diversity Between Classes of Users. The *daily-load curve* of a utility is a composite of demands made by various classes of users. The load curve on the day of maximum total system peak occurs when class loads gang up to create this maximum demand for the year. This is not necessarily the day, and usually is not the day, of any particular class peak. Class load curves on the day of system peak are illustrated in Fig. 18-63.

Air-conditioning loads have shifted these curves for many systems to cause daytime peaks during hot weather in the summer. Electric house heating builds heavy morning and evening loads during cold weather in the winter.

Diversity in the Feeder System. The diversity of demands of transformers on a radial feeder makes the maximum load on the feeder less than the sum of the transformer loads. The diversity factors of a feeder vary greatly depending on load conditions. Some typical diversity factors are given in Table 18-26. The diversity factor of lighting feeders ranges from 1.1 to 1.5, while that of

TABLE 18-26 Diversity Factors

Elements of system between which diversity factors are stated	Diversity factors for			
	Residence lighting	Commercial lighting	General power	Large users
Between individual users	2.0	1.46	1.45	
Between transformers	1.3	1.3	1.35	1.05
Between feeders	1.15	1.15	1.15	1.05
Between substations	1.1	1.10	1.1	1.1
From users to transformer	2.0	1.46	1.44	
From users to feeder	2.6	1.90	1.95	1.15
From users to substation	3.0	2.18	2.24	1.32
From users to generating station	3.29	2.40	2.46	1.45

mixed light-and-power feeders is likely to be 1.5 to 2 or more. At the substation there is also a diversity factor of 1.05 to 1.25 between the sum of feeder maxima and the substation maximum. A large system has a further diversity factor between substations of 1.05 to 1.25. Total diversity factors in a large system are somewhat as in Table 18-26.

18.27 DISTRIBUTION ECONOMICS

Economic Comparisons. The most straightforward and generally applicable technique to use in distribution system investment problems is that of making economic comparisons on the basis of the present value of all future annual costs. That is, the economic choice is the one with the lowest present value of all future costs. With this as a criterion, the procedure for making an economic comparison between alternatives is a simple two-step operation, that is,

1. Estimate for each alternative the annual costs for each year.

2. If annual costs are not uniform, calculate their present value.

Time Value of Money. Money does have time value, and rent or interest on its use has to be paid. It is obvious that an alternative which requires the least expenditure immediately would be best, everything else being equal.

The process of taking money and finding its equivalent value at some future time is called a *future worth* or *future value* calculation. This calculation is the same as that used in determining the effect of compound interest.

If 8% is the established interest rate, then \$100 today is equivalent to \$100(1 + 0.08) or \$108 a year from now, and $100(1 + 0.08) + 100(1 + 0.08) \times 0.08 = 100(1 + 0.08)^2$ 2 years from now and $100(1 + 0.08)^{10}$ 10 years from now. The expression $(1 + i)^n$ is called the *single-payment compound amount factor*, where i is the interest rate and n is the number of years. These factors and others are readily available for various interest rates and number of years in economic books such as *Principles of Engineering Economy* by Eugene L. Grant.

It should be noted that the use of 8% for the interest rate is for illustrative purposes only. The actual interest rate to use will be determined by the economic conditions at the time.

Hence, to find the future worth of \$100, 10 years later in the preceding example, first look up the compound amount factor in the 8% interest table for year 10; then multiply it by 100. The compound amount factor for this case is 2.159, and the future worth calculates to be 100(2.159) = \$215.90.

The process of finding the equivalent value of money at some earlier time is called a *present worth* or *present value* operation. The present worth calculation is the reverse of the future worth

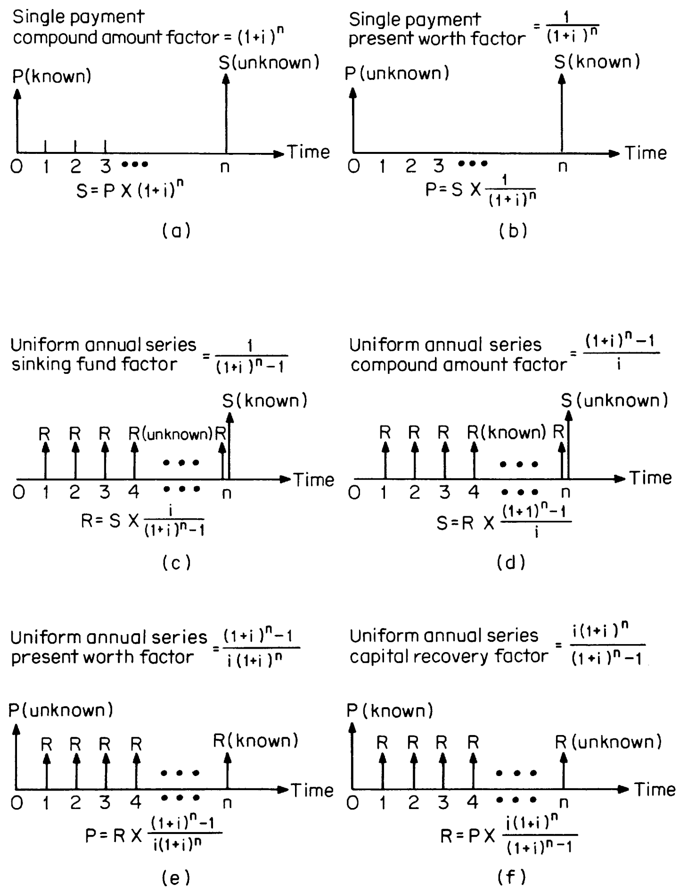

FIGURE 18-64 Graphic interpretation of compound interest factors.

calculation. If \$100 today has a future worth a year from now of \$108, then we can also say that \$108 a year from now has a present worth of \$100 today. The present worth factor is the inverse of the future worth factor, and it also may be found in interest tables. Since the future worth factor for n years is $(1 + i)^n$, where i is the interest rate, the present worth factor is $1/(1 + i)^n$.

To determine the present worth, as of today, of a \$100 cost anticipated to be incurred 2 years from now where the interest rate is 8%, first the present worth factor of 0.8573 is obtained from interest tables. Then multiplying this factor by \$100 gives the present worth of \$100(0.8573) = \$85.73.

Formulas for calculating the compound interest factors and a graphic interpretation of these factors are shown in Fig. 18-64.

Annual Charges. It is desirable to have a convenient method of calculating the annual costs of capital investments made in an alternative scheme. Fortunately, this can be done by using a level carrying charge which is expressed as a percentage of the original investment.

The total revenue requirements of a piece of equipment are the sum of the annual charges for

1. Return on investment
2. Depreciation
3. Income tax

4. Property taxes
5. Insurance
6. Operating and maintenance expenses

The first five of these charges can be conveniently estimated as a percentage of original investment. The operating and maintenance charges should be estimated separately for each project because they do not relate to capital investment as a percentage.

Level Annual Carrying Charges. The level annual carrying charge is the percentage by which the capital investment can be multiplied to determine its annual cost on a uniform basis. The value of this carrying charge is very much dependent on the expected life of the piece of equipment because depreciation varies in accordance with life expectancy. A method of obtaining the level annual carrying charge is as follows: (1) calculate the sum of the annual charges for return on investment, depreciation, income tax, property tax, and insurance for each year of the expected life of the piece of equipment; (2) use the appropriate present worth factor with each annual cost to convert the annual cost to a present worth value; (3) sum up these values to obtain the total present worth of the annual carrying charges; and (4) multiply the total present worth by the capital recovery factor (see Fig. 18-64) to get the equivalent uniform annual charge. Figure 18-65 shows graphically the actual and equivalent carrying charges for a capital investment of a piece of equipment with a 5-year life and an assumed 8% cost of money.

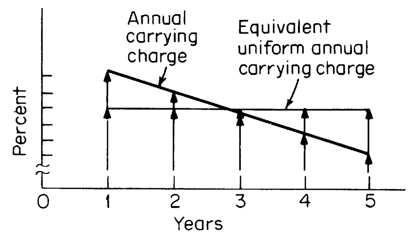

FIGURE 18-65 Representation of carrying charges.

The total carrying charges with 8% cost of money for various service lives are estimated as follows:

Years of life	Level annual total carrying charge in %
5	30.82
10	20.59
15	17.44
20	16.04
25	15.34
30	14.96
35	14.76
40	14.67
45	14.63
50	14.63

Operating and Maintenance Expenses. This cost component varies with the nature of the project. It is usually not a direct function of the capital invested and may have an inverse tendency. That is, alternatives often exist for higher capital expenditures to reduce operating costs. Therefore, it is *not* expressed as a percent of capital investment in most cases. Nevertheless, it should be included in annual costs.

Study Period. When determining the economic comparison of alternates by comparing the present worth of annual costs, the study period should be taken to the point that the alternates are equivalent in capability. If this is not practical, the study should be taken so far into the future that the difference in present worth would be insignificant.

Economic Evaluations. A simple example will show a comparison between two alternatives. Let *CC* represent the capital investment multiplied by the level annual carrying charge, *O&M* represent

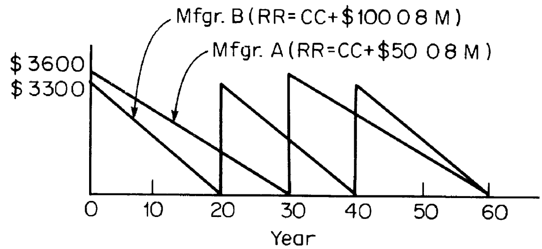

FIGURE 18-66 Time diagram.

annual operation and maintenance, and *RR* represent the total revenue requirement necessary annually to carry the project. A pad-mounted sectionalizing switch is needed for an underground circuit. The choice is between two manufacturers who can supply the switch but with different characteristics as follows:

	Mfr. *A*	Mfr. *B*
Installed cost	$3600	$3300
Operating and maintenance	50/year	100/year
Expected life	30 years	20 years

There is no salvage value at end of life. Determine which alternative is less expensive.
The first step is to draw a time diagram like Fig. 18-66. The common point in time for the two alternatives is 60 years, so two cycles of *A* should be compared with three cycles of *B*.

Present worth analysis:

$$\begin{aligned}\text{PW mfr. } A \text{ alternative} &= 3600 \times 0.1496 \times 11.258 + 50 \times 11.258 \\ &\quad +(3600 \times 0.1496 \times 11.258 + 50 \times 11.258)\, 0.0994 \\ &= 6063.11 + 562.90 + 658.63 \\ &= 7284.64\end{aligned}$$

$$\begin{aligned}\text{PW mfr. } B \text{ alternative} &= 3300 \times 0.1604 \times 9.818 + 100 \times 9.818 \\ &\quad +(3300 \times 0.1604 \times 9.818 + 100 \times 9.818)\, 0.2145 \\ &\quad +(3300 \times 0.1604 \times 9.818 + 100 \times 9.818)\, 0.0460 \\ &= 5196.86 + 981.80 + 1325.32 + 284.22 \\ &= 7788.20\end{aligned}$$

where 3600 = installed cost of mfr. *A* switch
0.1496 = level annual carrying charge for 30-year *A* switch
11.258 = 8%, 30-year uniform annual series present worth factor
50 = *O&M* of *A* switch
0.0994 = 8%, 30-year single-payment present worth factor
3300 = i.nstalled cost of mfr. *B* switch
0.1604 = level annual carrying charge for 20-year *B* switch
9.818 = 8%, 20-year uniform annual series present worth factor
100 = *O&M* of *B* switch
0.2145 = 8%, 20-year-single payment present worth factor
0.0460 = 8%, 40-year-single payment present worth factor

Manufacturer *A* switch would be the overall lowest cost and would be the better deal provided the capability and reliability of the two switches are equivalent.

18.28 DISTRIBUTION SYSTEM LOSSES

About 8% of the total output of a large power system is lost or unaccounted for. Much of this loss is in the distribution system. Since investment must be made in facilities to supply these losses, they should be an important consideration in the engineering design of the system. A knowledge of their magnitude is essential and they should not be omitted from overall comparisons of alternative facilities without a study of each specific situation.

Line Losses. The line losses, which are the sum of the I^2R, or resistance losses, can be easily found when the currents at peak load are known. Simplifying assumptions often can be made in making these calculations. For instance, if the load can be considered as being uniformly distributed, the losses are the same as if the total load were concentrated at a point one-third of the way out on the feeder.

Transformer Losses. Transformers have a no-load loss as well as a load loss. The transformer no-load loss is independent of load, whereas the load loss will vary as the square of the current. These losses for distribution transformers are usually published as no-load and total loss when the transformer is operating at rated voltage and rated kVA. The load loss at full-load current is the difference between total and no-load losses.

Working Principles. The problem of converting kWh of lost energy to dollars and cents has resulted in considerable controversy among system operators because of the difficulty of determining the value of the energy. It is not the purpose of this handbook to take sides in the controversy but rather to show the principles involved so that engineers will be able to evaluate losses using appropriate system costs.

The cost of supplying losses can be broken down into two major parts:

1. Energy component, or production cost to generate kWh losses
2. Demand component, or annual costs associated with system investment required to supply the peak kW of loss

The two components of cost usually are combined into a single figure either in terms of cents per kilowatthour of total energy loss or as dollars per kilowatt of peak loss. Expressing losses in terms of dollars per kilowatt is usually called *capitalized* cost of losses, and it has some advantage in that it shows directly the amount of money that could be economically spent to save 1 kW of loss. However, the expression of cost of losses in cents per kilowatthour is usually a more convenient form to use in most engineering studies.

The cost of losses depends on the point in the system at which they occur. The farther out on the system, the greater value losses have. One kilowatt of loss saved on the secondary system is worth more than 1 kW loss at generation because of the cumulative effect of increments of losses as they pass through various elements of the system.

In calculating loss, present-day or future cost of system investment should be used. The primary interest is to find the incremental investment, in dollars, required to supply an incremental load in kilowatts.

Opinions differ widely as to the degree to which the demand component of losses shall be evaluated. This ranges all the way from the dollar cost per kilowatt for future system expansion to no value at all for this component. The great majority of utility engineers prefer to assign full value to the demand component of losses.

Responsibility Factor. Owing to diversity between classes of loads (i.e., residential, industrial, etc.) on a distribution system, peak loads on distribution, transmission, and generation usually do not

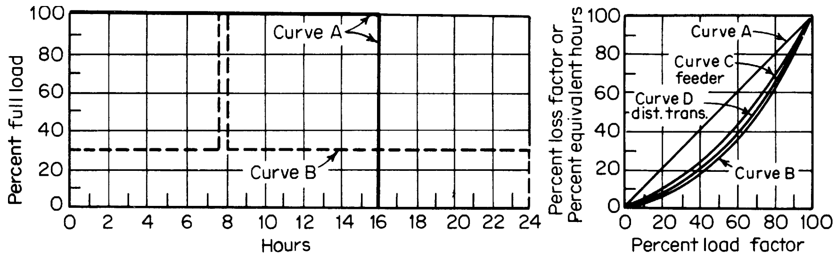

FIGURE 18-67 Relationship between load factor and loss factor or equivalent hours.

occur at the same time. Therefore, a loss which contributes 1 kW to the distribution system peak might contribute less than this to transmission and production plant peak because its maximum does not occur at the same time as the transmission or generation peak. This introduces *peak responsibility factors* used for evaluating cost of losses in various parts of the system.

Loss Factor. If the peak conductor losses of line or transformer have been calculated, it will still be necessary to know the loss factor or percent equivalent hours before it is possible to calculate the actual losses over a period of time. *Loss factor* is usually defined as the ratio of the average power loss, over a designated period of time, to the maximum loss occurring in that period. The term can refer to any part or all of the electric system. It is sometimes referred to as the *load factor of the losses*.

A corollary to loss factor is the term *equivalent hours*. This is defined as the number of hours per day, week, month, or year of peak load necessary to give the same total kilowatthours of loss as that produced by the actual variable load over the selected period of time. The period of time for distribution studies is usually 1 year, and it is obvious that *percent equivalent hours* has the same meaning as the term *percent loss factor*.

Relation Between Loss Factor and Load Factor. Definitions of *loss factor* and *load factor* are quite similar. (*Load factor* is defined as the ratio of average power demand over a stipulated period of time to the peak or maximum demand for that same interval.) Care should be taken that the latter is not used in place of loss factor when considering system losses. There is a relationship between the two factors which depends on the shape of the load curve. Because resistance losses vary as the square of the load, it can be shown that the value of loss factor can vary between the extreme limits of load factor and load factor squared. A number of typical load curves have been studied to determine this relationship for distribution feeders and distribution transformers. The relation is shown in Fig. 18-67. Note that loss factor is always less than load factor except where they are both unity, as would be the case for transformer core losses. The relationship between load factor and loss factor at the distribution transformer can be expressed by the empirical formula

$$\text{Loss factor} = 0.15 \text{ load factor} + 0.85 \text{ (load factor)}^2$$

It should be noted that when the shape of the load curve is known or can be reasonably estimated, the loss factor should be calculated directly and not determined by the empirical formula.

Cost of Losses. The two parts of the cost to supply losses are as follows:

$$\text{Energy component} = 8760 F_L E$$

$$\text{Demand component} = F_S P$$

where F_L = loss factor of load
E = cost of energy, dollars/kWh
F_S = responsibility factor
P = annual cost of system capacity, dollars/kW · year

Annual cost of losses can be combined into one value, in terms of either dollars per kilowatthour or dollars per kilowatt-year of peak loss, with the following formulas:

$$\text{Cost of losses, \$/kWh} = \frac{F_S P}{8760\, F_L} + E$$

$$\text{Capitalized cost of losses, \$/kW-year} = F_S P + 8760\, F_L E$$

18.29 STREET-LIGHTING SYSTEMS

Characteristics. The lighting of streets, parkways, and other roadways is about the only service in which the electric utility is often responsible for the utilization equipment. This involves the complete service of installation, maintenance, and operation of lighting systems during the hours of darkness (approximately 4000 h/yr) when they are required. Series (constant-current) circuits, historically a common supply for street lighting, have become obsolete.

Multiple Circuits. Street-lighting units today are normally supplied directly from the local distribution (120/240 V). The high-intensity-discharge lamps used have compatible balasts for all common voltages, 120, 208, 240, 277, 480 V, designed to strike an arc within the light source and provide stable operating conditions. Ballasts may be high-power-factor or normal-power-factor types. Photoelectric controls are most frequently used integrally with individual lights but also may be used to switch contactors controlling circuits used for lighting only. An example of this is highway lighting where extended systems from a power-supply point are normally designed with 480 V.

Lamps and Luminaires. Present street-lighting systems are designed using high-intensity-discharge sources. The three principal types are clear or phosphor-coated mercury, metal halide, and high-pressure sodium. These lamps are avaliable in several sizes ranging from less than 100 to 1000 W. Metal halide is not widely used because of its short life and poor lumen maintenance. Mercury lighting was the most popular type, since it was used extensively to replace older incandescent and fluorescent systems in the recent past. However, high-pressure sodium is the newest and most efficient lamp available. Its efficiency is over twice as high as mercury. The compact arc also allows for better control of the light distribution by the luminaire. The higher lamp efficiency and better control reduce the street-lighting power requirements to less than half that required for mercury. High-pressure sodium is taking over as the leading lighting system because of its economics.

Luminaires are sealed and also can be filtered. This minimizes the light loss due to dirt collecting in the luminaire. This is done to match the luminaire dirt depreciation so it matches the 4-year lamp life and minimizes the cleaning required during relamping.

There is a large variety of street-lighting equipment. This is required to fit different mounting heights, street widths, and lamp wattage. There are also differences in daytime appearance that are needed to fit the needs of the environment.

Underground Systems. While most utility-owned lighting systems were originally attached to existing wood-pole overhead distribution lines, these convenient supports are increasingly on rear-lot lines or nonexistent (underground distribution). This means that public lighting systems must be designed with underground supply run from the nearest transformer, joint trench, or handhole. Integrating the street-lighting circuits properly with the overall underground system from the outset is essential for proper economics and cost control.

18.30 RELIABILITY

Reliability has always been a major consideration for utilities. In recent years there has been even more interest because loads are becoming more sensitive to even small system disturbances and concern has been expressed that deregulation, with associated cuts in personnel and budgets, will negatively impact system reliability. Distribution reliability is in a state of change. Some of these changes are

- Standardization of indices.
- Mandatory indices in some states.
- Performance-based rates.
- Sags and momentaries equaling outages for some loads.
- Contract penalties for interruptions, sags, etc.
- Maintenance budgets being reduced.

There are many ways to measure reliability. Some of the more common indices used by utilities are CAIDI, SAIDI, and SAIFI, as illustrated in Fig. 18-68.

These three indices are defined for sustained interruptions of 5 minutes or longer:

SAIFI [*system average interruption frequency index (sustained interruptions)*]. The system average interruption frequency index is designed to give information about the average frequency of sustained interruptions per customer over a predefined area. In words, the definition is:

$$\text{SAIFI} = \frac{\text{total number of customer interruptions}}{\text{total number of customers served}}$$

To calculate the index, use the following equation:

$$\text{SAIFI} = \frac{\sum N_i}{N_T}$$

SAIDI (*system average interruption duration index*). This index is commonly referred to as Customer Minutes of Interruption or Customer Hours, and is designed to provide information about the average time the customers are interrupted. In words, the definition is:

$$\text{SAIDI} = \frac{\sum \text{customer interruption durations}}{\text{total number of customers served}}$$

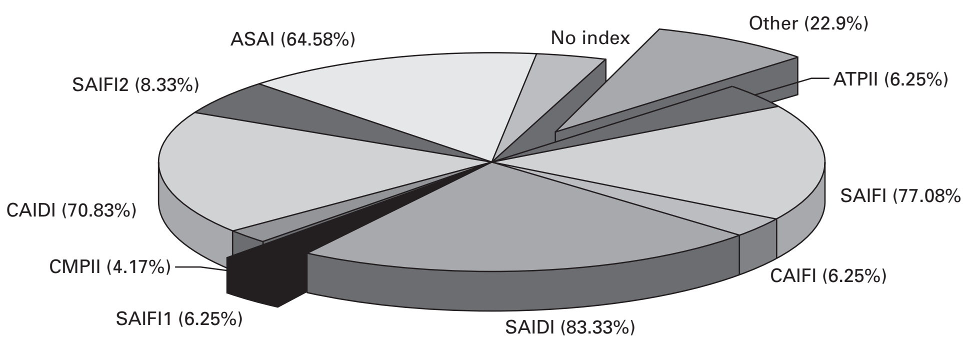

FIGURE 18-68 Percentage of companies using reliability indices (48 companies responded to survey).

To calculate the index, use the following equation:

$$\text{SAIDI} = \frac{\sum r_i N_i}{N_T}$$

CAIDI (*customer average interruption duration index*). CAIDI represents the average time required to restore service to the average customer per sustained interruption. In words, the definition is:

$$\text{CAIDI} = \frac{\sum \text{customer interruption durations}}{\text{total number of customers interruptions}}$$

To calculate the index, use the following equation:

$$\text{CAIDI} = \frac{\sum r_i N_i}{\sum N_i} = \frac{\text{SAIDI}}{\text{SAIFI}}$$

Values of these indices vary widely depending on many factors, including climate (snow, wind, lightning, etc.), system design (radial, looped, primary selective, secondary network, etc.), and load density (urban, suburban and rural). Typical values seen by utilities in the United States are

SAIDI	SAIFI	CAIDI
96 min/yr	1.2 int/yr	80 min/yr

Some utilities are already measuring indices to reflect system disturbances, other than interruptions, that cause sensitive loads to misoperate. One of these, the momentary average interruption-event frequency index (MAIFI_E), is an index to record momentary outages caused by successful reclosing operations of the feeder breaker or line recloser. This index is very similar to SAIFI, but it tracks the average frequency of momentary interruption events. In words, the definition is:

$$\text{MAIFI}_E = \frac{\text{total number of customer momentary interruption events}}{\text{total number of customers served}}$$

To calculate the index, use the following equation:

$$\text{MAIFI}_E = \frac{\sum \text{ID}_E N_i}{N_T}$$

Note. Here, N_i is the number of customers experiencing momentary interruptions events and ID_E equals interrupting device events during reporting period. This index does not include the events immediately preceding a lockout.

Another proposed index to reflect voltage sags caused by faults on other parts of the system is the system average rms (variation) frequency $\text{index}_{\text{Threshold}}$($\text{SARFI}_{\%V}$). This index records the number of specified short-duration rms variation per system customer. Voltage threshold allows assessment of compatibility for voltage-sensitive devices. To calculate the index, use the following equation:

$$\text{SARFI}_{\%V} = \frac{\sum N_i}{N_T}$$

where $\%V$ = rms voltage threshold 140, 120, 110, 90, 80, 70, 50, 10
N_i = number of customers experiencing rms $< \%V$ for variation i (rms $> \%V$ for $\%V > 100$)
N_T = total number of system customers

It is inevitable that more and more utilities will adopt some of these so-called power quality indices as their customers demand even better power for their sensitive loads.

In these days of reduced budgets, when utilities are being required to increase reliability, some of the techniques which cost very little or even nothing to achieve the goal of greater power quality are as follows:

- Purchase better-quality equipment.
- Shorten lead lengths on arresters.
- Use open-tie protection on underground systems.
- Use higher fuse ratings for transformers and laterals.
- Increase the number of homes per transformer.
- Pay attention to proper grounding.
- Use predictive reliability computer analysis to optimize designs.

18.31 EUROPEAN PRACTICES

In a time of deregulation and privatization, it has become common practice for a utility in one part of the world to own a utility in another country. While generation and transmission have relatively similar practices in all parts of the globe, distribution practices are considerably different depending on whether the system is based on American or European practices and standards. The following is a brief comparison of the two systems to familiarize engineers with the fact that in many ways distribution system operation and philosophy are so varied that direct comparison becomes extremely difficult.

Voltage Levels. In the United States, primary voltage levels can be just about anything. Figure 18-69 shows some of the more common voltage levels in the United States, with 13.8 kV probably being the most popular for the distribution primary. European voltage levels are much more standardized. Thus 30, 20, and 10 kV are used throughout the world where European standards are practiced.

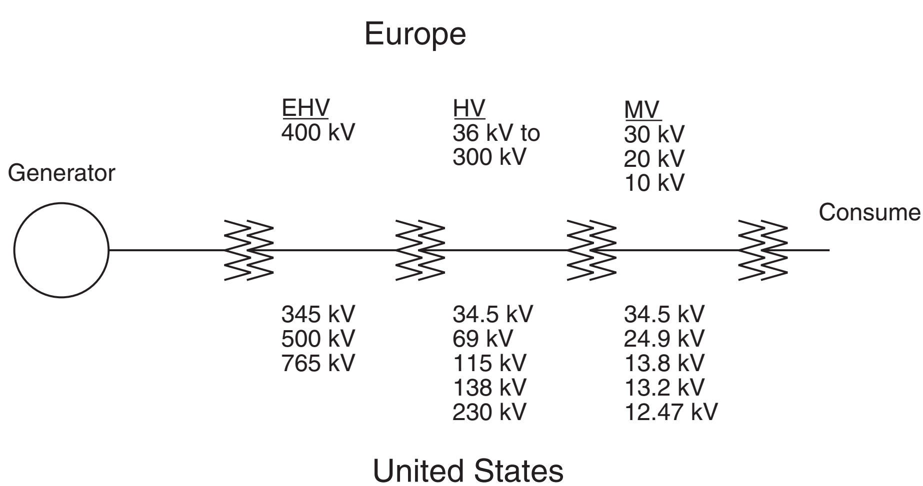

FIGURE 18-69 European and U.S. primary voltage levels.

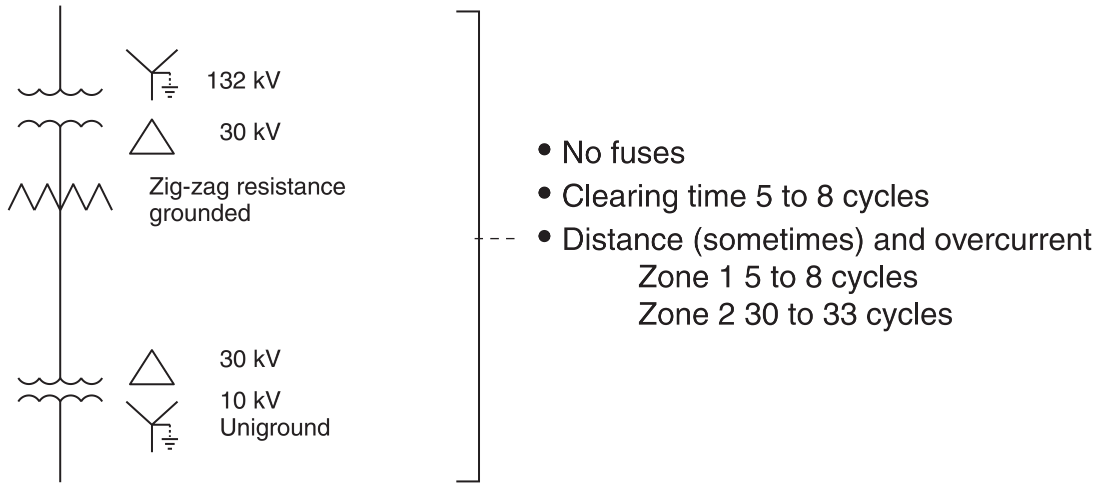

FIGURE 18-70 European distribution system grounding practices.

30-kV/10-kV Distribution. Figure 18-70 is a typical European system design, showing a ungrounded system at the 10-kV level where most of the distribution loads are supplied. This voltage level tends to be radial but can be networked. The 30-kV system, on the other hand, tends to be looped and is a 3-wire delta system sometimes using a grounding transformer to facilitate overcurrent protection.

Residential Distribution. Table 18-27 illustrates some of the major differences in philosophy between the two designs which makes comparison difficult. The major difference is that European practice tends to use 3-phase transformers with a much larger kVA rating to supply many more homes. Higher-density loads and higher secondary voltages are part of the reason for this difference.

Distributed Resources (DR) on the Distribution System. Distributed resources is a term which includes a variety of small generation technologies, including fuel cells, photovoltaics, microturbines, reciprocating engines, wind turbines, etc., with and without battery storage, which could be installed on the distribution system. In addition, many of these resources are becoming more

TABLE 18-27 1-Phase vs. 3-Phase Residential Distribution

United States	Europe
120/240 V	400 Wye/230, 4-wire (Europe)
Single-phase transformers heavily overloaded—25 kVA typical	Less load per home than U.S.
Four homes/transformer fairly typical	3-Phase xfrms >> 1-phase
Fuses are typically expulsion	Residential units in 300–500-kVA range, 5 to 10 radial 3-phase 4-wire secondary feeds, per transformer
	No overload Fuses are current-limiting 100 to 200 dwellings per transformer

modular in design, so that manufacturing economies of scale are driving their costs down. Generally, distributed resources are small in size, ranging from less than 1 kW to a few hundred kWs. The practical size limit for generators on the distribution system is in the area of around 35 MW.

The justification for introducing these newer technologies include the renewable resource aspect and lower environmental impact along with niche opportunities in particular regions when one or more of these technologies might excel. It is claimed that more DR means less T&D investment. Without storage, many DR technologies provide an additional energy source but no demand or investment savings. Then too improved reliability is often touted as a benefit, but this needs to be property evaluated in the context of what technology is being discussed. Without careful engineering, a particular MW level of DR penetration can adversely affect the distribution system.

Distribution designs are based on a number of principles that can be upset by DR including:

- Most distribution circuits are radial in nature with power flow from the substation to the loads.
- Voltage control with line drop compensation through LTC transformers or voltage regulators presumes a dropoff of load and voltage as one proceeds from the substation and, further, that power flow is from the source side to the load side.
- Most overcurrent protective device selection and coordination is based on higher fault current magnitudes at the substation and declining fault current magnitudes toward the end of the circuit.
- Reclosing intervals of circuit breakers and reclosers and reclosing practice in general is based on reasonable fault clearing times and the expectation that the reclosing device will close into a de-energized line.
- Utility restoration practices are based on having a limited number of known sources controlled by switches and other protective devices with known states (energized or de-energized).
- Harmonics are limited to larger known sources and distributed smaller sources.
- Most 3-phase transformer connections on distribution are grounded-wye grounded-wye.

With the arrival of distribution resources, many of these *normal conditions* now change, including:

- Bidirectional power flow and fault current flow along portions of the circuit.
- Load magnitude dropping off along the feeder and then reaching a step change at the DR location(s) and dropping off beyond that point.
- Fault current profile showing the increase in total fault current due to added generation as well as the bidirectional fault current flows from the DRs depending on fault location.
- Automatic reclosing for utility circuit breakers and reclosers will have to be supervised with some form of voltage check and possibly time delay. An alternative is to use transfer-tripping schemes to assure that the DR is off-line before reclosing takes place.
- Many DR advocates seek a delta-wye connection. Under backfeed conditions, a single-line-to-ground fault on the primary will overstress the surge arresters on the unfaulted phases.
- Photovoltaics and many small wind generators are dc machines that rely on invertors to produce an ac waveform and also produce high harmonic content. Induction-type machines draw reactive power from the power system. The combination introduces both voltage drop and power quality concerns.

IEEE Std 1547-2003, Standard for Interconnecting Distributed Resources with Electric Power Systems, was developed to provide a uniform standard for the interconnection of distributed resources with electric power systems. It provides requirements relevant to the performance, operation, testing, safety considerations, and maintenance of the interconnection. Follow-on standards projects to Std 1547 are intended to address the different DR technologies and engineering concerns about the interconnection issues.

A logical concern is—at what level of distributed resources does one have to be concerned with some of these potential issues becoming genuine problems? Unfortunately, we don't yet have an answer to that question.

SECTION 19
WIRING DESIGN FOR COMMERCIAL AND INDUSTRIAL BUILDINGS

John Dagenhart, P. E.
Professional Engineer, Clapp Research Associates. P. C.

CONTENTS

19.1 BASIC INSTALLATION RULES AND INSPECTION

Codes (Definitions). The *National Electrical Code* (NEC)*
The *National Electrical Safety Code* (NESC) establishes the basic standards of electric supply system design and installation for utility-owned conductors and equipment in the United States. It is also revised periodically by a committee drawn from utility groups, industries, state and federal regulators, insurance groups, organized labor, and other interested parties. Its secretariat is the Institute of Electrical and Electronics Engineers; the NESC is American National Standard ANSI C2. The NEC oversees supply and communication wiring that are in and on consumer-owned buildings but not an integral part of a generating plant, substation, or control center. The NEC does not cover communication utility wiring, nor does it cover electric utility generation, transmission, or distribution system wiring. The NESC covers the latter systems. The NESC also covers similar systems under the control of qualified persons, such as those associated with large industrial complexes. In recent years, the provisions of the NESC relating to underground wiring have become increasingly applicable in commercial complexes as extremely large commercial complexes have become more frequent. Some of the latter systems are not unlike those utility systems found in small towns or compact subdivisions.

Lists of Inspected Electrical Equipment and Appliances are issued yearly by the *Underwriters' Laboratories, Inc. Electrical Testing Laboratories, Inc., Factory Mutual Research Corp.*, and *MET Electrical Testing Company, Inc*. are other testing laboratories that function as third-party certifiers of the basic safety of manufactured products used in electrical work. One function of the laboratories

**National Electrical Code* and the acronym *NEC* are registered trademarks of the National Fire Protection Association, Inc., Quincy, Mass. 02269.

Establishes the standards of wiring design and installation practice for consumer-owned wiring and equipment in the United States. Its rules are written to protect the public from fire and life hazards. It is revised periodically by a committee drawn from industry associations, insurance groups, organized labor, and representatives of municipalities. It is sponsored by the National Fire Protection Association, and approved by the American National Standards Institute as ANSI C1. It forms the basis of the vast majority of municipal electrical wiring ordinances, which adopt successive editions of the Code as issued.

is to examine and pass on electrical materials, fittings, and appliances in order to determine if they comply with the standard-test specifications set up by these laboratories.

Legal Status of the Code. The rules in the NEC are enforced by being incorporated in ordinances passed by various cities and towns, covering the installation of electric wiring. The Occupational Safety and Health Administration (OSHA) requires that all new electrical installations conform to all the rules of the NEC. The NESC is adopted by state utilities commissions and is referred to by the NEC for some high-voltage applications.

When installing any electrical equipment, first ascertain whether local installation rules in the form of ordinances are enforced in the community. If so, follow such rules; if none exists, follow the requirements of NEC.

Editions. Where reference is made in this section to installation rules, the 1996 edition of NEC or 1997 NESC is used as a basis.

Code Not a Design Manual. Design of an installation in accordance with the Code minimizes fire and accident hazards but does not guarantee satisfactory or efficient operation of the system. Other design standards are necessary to accomplish the latter purposes.

License. In many areas the installation of electric wiring is controlled by city, county, or state license, often combined with installation rules.

Rules of Electric Service Companies. Electric lighting and power companies generally issue certain rules of their own, based to a large extent on peculiar requirements which are necessary in order to give the best possible service to the greatest number of customers and on NESC requirements.

These rules are concerned mostly with matters of distribution engineering. They relate to locations and details of service entrance, provision for meters, the kind of electricity furnished by the company, its frequency and voltage, the types and sizes of motors, rules in connection with starting characteristics of such motors, and similar matters.

The electric-service company usually supplies copies of its rules at no charge.

Inspection. Every electrical installation should be inspected wherever an experienced inspector is available to ensure that it complies with local and NEC rules. Such inspection is usually mandatory in cities having electrical ordinances. In some areas the fire underwriters maintain inspectors who check electrical wiring, while in others the municipality makes a check through its electrical inspectors. Where inspection is not mandatory, it is always advisable to request the most convenient fire underwriters' bureau to make the necessary inspection.

Federal and state buildings usually require inspection by authorized federal or state inspectors. In these instances inspection includes not only safety considerations but the requirements of the particular job specifications. Other inspection may be required but it is often waived. OSHA compliance officers do make inspections of existing electrical systems at any time.

19.2 METHODS OF WIRING

Wiring Methods Classified. The discussion of wiring methods in this section relates to *interior circuits for light, heat, and power* and does not cover signaling or communication systems.

Numerous methods of wiring are authorized by NEC, most of them used to a greater or lesser extent in commercial and industrial buildings. Those of interest can be grouped as follows:

1. Raceways for general use

- ***a.*** Rigid-metal conduit
- ***b.*** Intermediate-metal conduit (IMC)
- ***c.*** Electric-metallic tubing (EMT)

   - ***d.*** Nonmetallic conduit
   - ***e.*** Surface raceways
   - ***f.*** Flexible metallic and nonmetallic conduit
   - ***g.*** Gutters

2. Cable-assembly systems for general use
   - ***a.*** Nonmetallic sheathed cable
   - ***b.*** Underground feeder and branch-circuit cable
   - ***c.*** Metal-clad cable (armored cable)
   - ***d.*** Mineral-insulated metal-sheathed cable (MIMS)
   - ***e.*** Messenger-supported wiring
   - ***f.*** Nonmetallic-sheathed cable (NM, NMC, NMS)
   - ***g.*** Power and control cable (TC)
   - ***h.*** Armored cable
3. Conductor systems for general use
   - ***a.*** Open wiring on insulators
   - ***b.*** Concealed knob and tube wiring (only as permitted in NEC Sec. 394)
4. Cable-assembly systems for limited use
   - ***a.*** Service-entrance cable
   - ***b.*** Nonmetallic extensions
   - ***c.*** Integrated gas spacer cable (IGS)
   - ***d.*** Medium-voltage cable (MV)
   - ***e.*** Flat conductor cable (FCC)
5. Raceway systems for limited use
   - ***a.*** Flexible-metal conduit and flexible-metal tubing
   - ***b.*** Liquidtight-flexible-metal conduit and liquidtight flexible nonmetallic conduit
   - ***c.*** Underfloor raceway
   - ***d.*** Cellular-metal-floor or cellular-concrete-floor raceway
   - ***e.*** Wireways
   - ***f.*** Cable trays
6. Special systems
   - ***a.*** Busways
   - ***b.*** Cable bus
   - ***c.*** Multioutlet assemblies
   - ***d.*** Electrical floor assemblies
   - ***e.*** Flat cable assemblies

Installation Methods. Requirements to be met in installing each of the foregoing systems are found in the current edition of the NEC. The requirements are specific and detailed and change somewhat as the art progresses; hence reference should be made to the Code for the exact circumstances under which each system is permitted or prohibited, together with the precise rules to be followed in installation.

The discussion in the following paragraphs compares the systems generally and indicates the major limitations on use of each.

19.3 TYPES OF CONDUCTOR

General Provisions Applying to All Wiring Systems. The types of wiring discussed may be used for voltages up to 2000 V unless otherwise indicated. Each type of insulated conductor is approved for certain uses and has a maximum operating temperature. If this is exceeded, the insulation is subject to deterioration. In recent years, conductors with asbestos insulation, formerly used for high-temperature operations, have been removed from the tables of conductor applications and insulations (see Table 19-1). Each conductor size has a maximum current-carrying capacity, depending on type of insulation and conditions of use. These ratings should not be exceeded (see Tables 19-2A through 19-2E and Fig. 19-1 for ratings and underground conduit systems). Conductors may be used in multiple usually in large sizes only (sizes 1/0 and larger, see NEC Sec. 310-4).

Conductors of more than 600 V should not occupy the same enclosure as conductors carrying less than 600 V, but conductors of different light and power systems of less than 600 V may be grouped together in one enclosure if all are insulated for the maximum voltage encountered. In general, communication circuits should not occupy the same enclosure with light and power wiring.

Boxes or fittings must be installed at all outlets, at switch or junction points of raceway or cable systems, and at each outlet and switch point of concealed knob and tube work.

Provisions Applying to All Raceway Systems. The number of conductors permitted in each size and type of raceway is definitely limited to provide ready installation and withdrawal. For conduit and EMT, see Table 19-3. Raceways, except surface-metal molding, must be installed as complete empty systems, the conductors being drawn in later. Conductors must be continuous from outlet to outlet without splice, except in auxiliary gutters and wireways.

Conductors of No. 8 American wire gauge (AWG) and larger must be stranded. Raceways must be continuous from outlet to outlet and from fitting to fitting and shall be securely fastened in place. Conductors and cables exposed to the sun must be sunlight resistant (see NEC Article 310.8(D)).

All conductors of a circuit operating on ac, if in metallic raceway, should be run in one enclosure to avoid inductive overheating. If, owing to capacity, not all conductors can be installed in one enclosure, each raceway used should contain a complete circuit (one conductor from each phase).

Rigid-Metal Conduit, Intermediate-Metal Conduit, and Electrical Metallic Tubing. These systems are systems generally employed where wires are to be installed in raceways. Both conduit and tubing may be buried in concrete fills or may be installed exposed. Wiring installed in conduit is approved for practically all classes of buildings and for voltages both above and below 600 V. Certain restrictions are placed on the use of tubing.

Metal conduit consists of standard-weight steel pipe (preferably either galvanized or cadmium-plated, although it may be black-enameled for use indoors and where not subject to severe corrosive influences) or of aluminum. Electrical metallic tubing has the same internal diameter as conduit but a thinner wall of higher-quality steel.

Note on Tables 19-2A through 19-2E: Use of conductors with higher operating temperatures. Where the room temperature is within 10°C of the maximum allowable operating temperature of the insulation, it is desirable to use an insulation with a higher maximum allowable operating temperature.

Fittings and connectors used with conduit may be threaded or threadless. Electrical metallic tubing fittings are usually threadless.

Nonmetallic rigid conduits, in approximately the same dimensions as rigid-metal conduits, are also a general-use raceway. Some restrictions are imposed, affecting particularly installations exposed to possible mechanical injury. Grounding continuity is provided by an additional grounding conductor pulled into the raceway with the circuit conductors or as part of a cable assembly.

Nonmetallic polyvinyl chloride (PVC) rigid conduits are commonly assembled with matching fittings by adhesives. Field bends are made by softening the plastic in a hot airstream of several hundred degrees from an electric heater-blower.

Nonmetallic PVC raceways of relatively flexible construction and with conductor already drawn in are used for direct burial in airport, highway, parkway, and similar installations.

Polyvinyl chloride and fiber conduits are extensively used in underground distribution. They may be installed directly in earth or encased in concrete envelopes.

TABLE 19-1 Conductor Application and Insulations

Trade Name	Type Letter	Maximum Operating Temperature	Application Provisions	Insulation	Thickness of insulation AWG or kcmil	mm	mils	Outer Covering[a]
Fluorinated ethylene propylene	FEP or FEPB	90°C 194°F	Dry and damp locations	Fluorinated ethylene propylene	14–10 8–2	0.51 0.76	20 30	None

TABLE 19-1 Conductor Application and Insulations (*Continued*)

Trade Name	Type Letter	Maximum Operating Temperature	Application Provisions	Insulation	Thickness of insulation AWG or kcmil	mm	mils	Outer Covering[a]
Modified ethylene tetrafluoro-ethylene	ZW[d]	75°C 167°F	Wet locations	Modified ethylene tetrafluoro-ethylene	14–10	0.76	30	None
					8–2	1.14	45	
		90°C 194°F	Dry and damp locations					
		150°C 302°F	Dry locations—special applications[b]					

[a]Some insulations do not require an outer covering.
[b]Where design conditions require maximum conductor operating temperatures above 90°C (194°F).
[c]For signaling circuits permitting 300-V insulation.
[d]Listed wire types designated with the suffix "2," such as RHW-2, shall be permitted to be used at a continuous 90°C (194°F) operating temperature, wet or dry.
[e]Some rubber insulations do not require an outer covering.
[f]Includes integral jacket.
[g]For ampacity limitation, see 340.80.
[h]Insulation thickness shall be permitted to be 2.03 mm (80 mils) for listed Type USE conductors that have been subjected to special investigations. The nonmetallic covering over individual rubber-covered conductors of aluminum-sheathed cable and of lead-sheathed or multiconductor cable shall not be required to be flame retardant. For Type MC cable, see 330.104. For nonmetallic-sheathed cable, see Article 334, Part III. For Type UF cable, see Article 340, Part III.

Cable-Assembly Systems. These are used extensively for concealed wiring not embedded in masonry or concrete. They may also be installed exposed in dry locations, and depending on the particular construction and ratings, in wet locations. Branch-circuit sizes are conventionally 600 V-rated. Cables rated for 5 through 15 kV are frequently used for primary distribution feeders in large commercial and industrial electrical systems.

In industrial plants and commercial utility areas, cable assemblies are often installed in expanded metal trays, ladder racks, or other approved cable-support systems.

Nonmetallic-sheathed cables are almost universally used in single family house wiring in the United States and in many multifamily occupancies. Armored cable is extensively used in commercial applications (see Fig. 19-2). Armored cable is used in extending branch circuits from outlet boxes on rigid conduit or EMT systems to lighting fixtures in suspended ceiling work.

Metal-clad type MC cable applies to constructions using interlocked armor, close fittings, or flexible corrugated tube over No. 18 copper, No. 12 aluminum, or larger conductors.

Two other metal-sheathed cables of special construction are recognized by the Code. Mineral-insulated metal-sheathed cable is sheathed with a continuous copper or steel outer covering, containing one or more conductors and insulated with highly compressed refractory mineral insulation. It is widely used in industrial power, control wiring and in either wet or dry locations.

MI must be terminated and connected by means of fittings designed and approved for the purpose.

Open wiring on knobs and cleats is rarely encountered in current work. Open feeders are still used in some industrial construction where low cost is a consideration, no safety hazard is involved, and appearance is unimportant (see Fig. 19-3).

Several cable assemblies have been developed for limited or particular uses, rather than for complete wiring systems for a building. The NEC should be consulted for specific requirements in each case.

Service-entrance (SE) cable is a form of armored or nonmetallic-sheathed cable specifically approved for service-entrance use. It is available in two types: SE, with a flame-retardant, moisture-resistant outer covering, and underground service-entrance cable suitable for direct burial in the ground.

*Unless specifically permitted, the overcurrent protection shall not exceed 15 A for 14 AWG, 20 A for 12 AWG, and 30 A for 10 AWG copper; or 15 A for 12 AWG and 25 A for 10 AWG aluminum and copper-clad aluminum after any correction factors for ambient temperature and number of conductors have been applied.

Extensions, Raceways, Conduits, Wireways, and Busways. *Nonmetallic surface extensions* are 2-wire assemblies limited to exposed work in office (or residence) occupancies, where additional outlets are to be installed in the same room with the outlet from which the extension originates. The location must be dry and not subject to corrosive vapors. The voltage should not exceed 150 V between conductors.

Underplaster extensions have been used as a concealed-wiring method to install additional outlets on an existing branch circuit. They were eliminated from the NEC in 1993 as a specific article since other articles addressed this method.

In general, the raceway systems were developed for special purposes and are of more commercial importance and find a more varied use than the special cable-assembly systems discussed earlier. This is particularly true of underfloor and cellular raceways for concealed work and of wireways and busways for exposed work. In cases where great flexibility in the use of electric power is of importance, the application of one of these special systems should be considered. In each case, the NEC should be consulted for specific installation rules.

Flexible-metal conduit, consisting of a flexible metallic tube roughly similar to the armor of armored cable, is used generally with rigid-conduit or electrical metallic tubing systems, to provide flexible connections at motor terminals, for instance, or in place of the rigid product where installations of the latter would be difficult owing to numerous bends, close working quarters, etc. The conductors are installed after the flexible conduit is in place.

Surface metal raceways (see Fig. 19-4) are flat, rectangular wireways used for exposed work in dry locations. They are frequently used to install additional outlets in a building already wired, where concealment of conductors is difficult, and are also used for special purposes, for example, installation of cove lighting and for show-window reflectors. Unless made of a metal at least 0.040 in thick, they are limited to use on circuits not exceeding 300 V.

Liquidtight flexible-metal conduit is, as the name suggests, a type of flexible-metal conduit having an outer jacket impervious to liquids and terminated in liquidtight fitting. It is most widely used for connecting motors to rigid-conduit systems or fixed-equipment enclosures.

71–80	—	—	0.41	—	—	0.41	159–176

*Unless specifically permitted, the overcurrent protection shall not exceed 15 A for 14 AWG, 20 A for 12 AWG, and 30 A for 10 AWG copper; or 15 A for 12 AWG and 25 A for 10 AWG aluminum and copper-clad aluminum after any correction factors for ambient temperature and number of conductors have been applied.

Underfloor raceways (Fig. 19-5) are employed in buildings of fire-resistant construction to provide readily accessible raceways in the floor slab for light and power, telephone, and signal circuits. One, two, or three ducts are installed, depending on the desired uses. Junction boxes which mark each end of a run of raceway, and the tops of which are flush with the floor covering, make it possible to locate accurately the run of duct and, hence, to install additional outlets with the special tools provided by the manufacturer. Owing to its flexibility, this type of construction is particularly suitable for large office areas or where outlet locations are subject to change.

The *cellular-metal-floor raceway* involves a cellular-steel floor (Fig. 19-6*a*), which is a structural load-carrying element whose hollow cells form the wire raceway and a system of transverse headers, together with the necessary fittings and adapters. The headers are also wire raceways, providing electrical access from distribution points to any predetermined number of cells. The system can be designed to provide overall floor and ceiling electrical service for conductors not larger than No. 0 AWG, not only for light and power but also for telephone and signal circuits. The large internal-cell areas (normally on 6-in centers) afford adequate conductor space, while the complete floor and ceiling coverage provides for great flexibility in use during the building life, since access to headers and cells can be obtained at any time for additional outlets, new or rerouted circuits, etc.

Cellular-concrete-floor raceways are precast slabs with tubular "cells" designed to lineup in a continuous raceway. Cells terminate in metallic header ducts and other special fittings for connection to other parts of the electrical systems. Fittings approved for the purpose are inserted into the cell to provide for outlets (see Fig. 19-6*b*).

Structural raceways are formed-steel members which may be assembled to provide for the installation of electrical wires and cables. Such assemblies also provide for the installation of wiring devices in vertical members which may be concealed.

Wireways provide a convenient, exposed rectangular metal raceway or trough for no more than 30 current-carrying conductors or total conductor cross-sectional area not exceeding 20% of the interior cross-sectional area of the wireway. The product is available in several standard lengths, which are bolted together for continuous runs. Access at any point is through hinged covers and conduit knockouts. A complete array of fittings assures flexibility for various installation conditions.

Owing to their size, wireways can be used to advantage for large numbers of conductors, for a group of circuits leaving a branch-circuit panelboard or feeder distribution board.

Busways (Fig. 19-7) are one of the more important recent developments for exposed heavy-capacity feeder and circuit wiring in industrial plants because of their flexibility in use, which makes them readily adaptable to future needs and to changing conditions such as relocation or revamping of production lines. The initial investment can be confined to immediate requirements and additions made at anytime as requirements increase. The system consists essentially of interconnected prefabricated lengths or sections of steel or aluminum duct which enclose bus bars mounted on insulators. Regularly spaced openings in the sides of the duct permit plugging in branch-circuit control devices of the circuit-breaker, fuse, or fused-switch type, for convenient control of individual or group motor drives, lighting or heating circuits, etc. The ease of relocating both the duct and control devices makes its use advantageous for supplying power to machines on assembly lines, mass production manufacturing, and other applications where flexibility of electric supply is essential. Busways are available in capacities ranging from about 125 to about 3000 A, for 3-phase 3- or 4-wire systems.

The so-called trolley duct (Fig. 19-8) is a variation of the busway in which the metal duct and electrical buses (either single-phase or 3-phase) are so arranged that access is had to the buses at any point in the run. Current is collected from the buses by movable trolleys to which are wired portable or movable electrical devices. In industrial plants, the system is used to supply power to cranes and hoists, to portable tools on assembly lines and benches, etc. It has found some application in drafting rooms, stock departments, and similar locations, where ability to move lighting units quickly is of advantage.

Multioutlet assemblies are surface-mounted raceways of metal or plastic with plug receptacle outlets at spaced intervals or provisions for the insertion of receptacles as desired. Multioutlet assemblies are widely used where a number of cord-connected appliances must be served (as along the back of a workbench or laboratory table). They are also used to provide greater convenience for the attachment of portable cords. In this application, they are usually installed along the top of the baseboard (as around the perimeter of a private office).

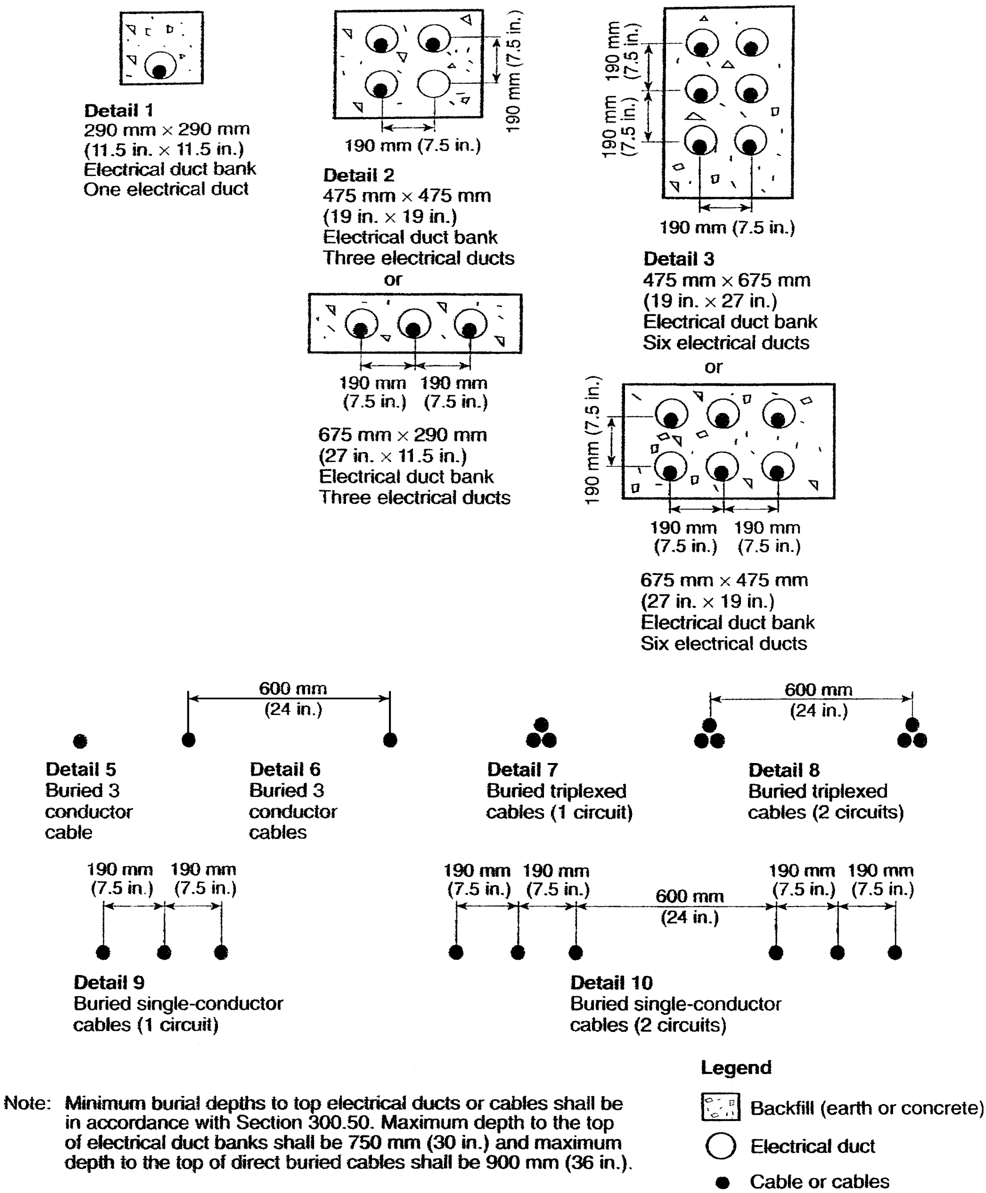

FIGURE 19-1 Configurations for buried systems using conductors in Tables 19-2A and 19-2C. TABLE 19-3 Percent of Cross Section of Conduit and Tubbing for Conductors

Number of Conductors	All Conductors Types
1	53
2	31
Over 2	40

Based on common conditions of proper cabling and alignment of conductors where the length of the pull and the number of bends are within reasonable limits. It should be recognized that, for certain conditions, a larger size conduit or a lesser conduit fill should be considered.

When pulling three conductors or cables into a raceway, if the ratio of the raceway (inside diameter) to the conductor or cable (outside diameter) is between 2.8 and 3.2, jamming can occur. While jamming can occur when pulling four or more conductors or cables into a raceway, the probability is very low.

Conductors for Building Wiring. The various types of conductor available for interior wiring, together with their sizes, insulations, and uses, are indicated in Tables 19-1 and 19-2. Rubber and thermoplastic insulations are available in a number of compounds and constructions for resistance to heat, moisture, or other environmental conditions.

Other insulations used in building wiring include magnesium oxide, fluorinated ethylene propylene, silicone rubber, and the long-familiar varnished-cambric and asbestos constructions, although asbestos is no longer used except under special conditions.

Various connector types are shown in Fig. 19-9.

Dimensions of *insulated conductors* and fixture wires are given in Table 19-4A.

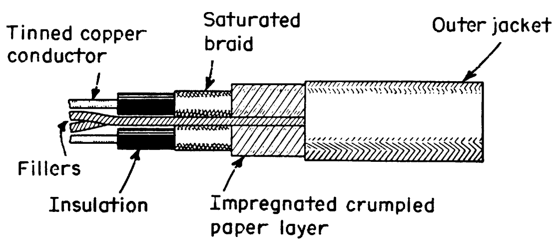

FIGURE 19-2 Nonmetallic sheathed cable.

Current-Carrying Capacity (Ampacity) and Other Properties. As the conductors of an electrical wiring system offer some resistance, a current-carrying conductor dissipates heat. Under practical conditions of installation and operation, the temperatures reached must not result in the destruction of the insulation or risk to surrounding material.

Tables of maximum allowable current-carrying capacity are given in the NEC. Allowable ampacities for insulated conductors are based on an allowable temperature rise above an ambient of 30°C (86°F) and 40°C (104°F). A list of temperature ratings for types of insulated conductors is given in Table 19-1.

Allowable ampacities for copper conductors and aluminum conductors in accordance with the temperature rating of the insulation are given for installation in conduit and for installation in free air in Tables 19-2A through 19-2E (see also Table 19-4B).

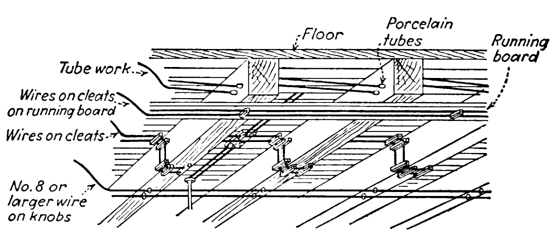

FIGURE 19-3 Methods of supporting open wiring.

To determine the permissible percent raceway fill for conductor combinations, see Table 19-3.*

Conductor and conduit diameters and areas are frequently necessary to calculate allowable fill. Nominal values for conductors are given in Table 19-4A and, for conduit and tubing. Tables 19-5A and 19-5B give resistance and reactance values of conductors in ohms per 304.8 m (1000 ft). Table 19-6 gives dimensions and area of conduit and tubing.

Notes:

1. These resistance values are valid only for the parameters as given. Using conductors having coated strands, different stranding type, and, especially, other temperatures changes the resistance.
2. Formula for temperature change: $R_2 = R_1 [1 + \alpha (T_2 - 75)]$ where $\alpha_{cu} = 0.00323$, $\alpha_{AL} = 0.00330$ at 75°C.
3. Conductors with compact and compressed stranding have about 9% and 3% respectively, smaller bare conductor diameters than those shown. See Table 5A for actual compact cable dimensions.
4. The IACS conductivities used: bare copper = 100%, aluminum = 61%.
5. Class B stranding is listed as well as solid for some sizes. Its overall diameter and area is that of its circumscribing circle.

FPN: The construction information is per NEMA WC8-1992 or ANSI/UL 1581-1998. The resistance is calculated per National Bureau of Standards Handbook 100, dated 1966, and Handbook 109, dated 1972.

Notes:

1. These values are based on the following constants: UL-Type RHH wires with Class B stranding, in cradled configuration. Wire conductivities are 100% IACS copper and 61% IACS aluminum, and aluminum conduit is 45% IACS. Capacitive reactance is ignored, since it is negligible at these voltages. These resistance values are valid only at 75°C (167°F) and for the parameters as given, but are representative for 600-V wire types operating at 60 Hz.

2. *Effective Z* is defined as $R\cos(\theta) + X\sin(\theta)$, where θ is the power factor angle of the circuit. Multiplying current by effective impedance gives a good approximation for line-to-neutral voltage drop. Effective impedance values shown in this table are valid only at 0.85 power factor. For another circuit power factor (*PF*), effective impedance (*Ze*) can be calculated from *R* and X_L values given in this table as follows: $Ze = R \times PF + X_L \sin[\arccos(PF)]$.
