1.1 THE SI UNITS

The units of the quantities most commonly used in electrical engineering (volts, amperes, watts, ohms, etc.) are those of the metric system. They are embodied in the International System of Units (*Système International d'Unités*, abbreviated *SI*). The SI units are used throughout this handbook, in accordance with the established practice of electrical engineering publications throughout the world. Other units, notably the cgs (centimeter-gram-second) units, may have been used in citations in the earlier literature. The cgs electrical units are listed in Table 1-9 with conversion factors to the SI units.

The SI electrical units are based on the mksa (meter-kilogram-second-ampere) system. They have been adopted by the standardization bodies of the world, including the International Electrotechnical Commission (IEC), the American National Standards Institute (ANSI), and the Standards Board of the Institute of Electrical and Electronics Engineers (IEEE). The United States is the only industrialized nation in the world that does not mandate the use of the SI system. Although the U.S. Congress has the constitutional right to establish measuring units, it has never enforced any system. The metric system (now SI) was legalized by Congress in 1866 and is the only legal measuring system, but other non-SI units are legal as well.

Other English-speaking countries adopted the SI system in the 1960s and 1970s. A few major industries converted, but many people resisted—some for very irrational reasons, denouncing it as "un-American." Progressive businesses and educational institutions urged Congress to mandate SI. As a result, in the 1988 Omnibus Trade and Competitiveness Act, Congress established SI as the *preferred* system for U.S. trade and commerce and urged all federal agencies to adopt it by the end of 1992 (or as quickly as possible without undue hardship). SI remains voluntary for private U.S. business. An excellent book, *Metric in Minutes* (Brownridge, 1994), is a comprehensive resource for learning and teaching the metric system (SI).

1.2 CGPM BASE QUANTITIES

Seven quantities have been adopted by the General Conference on Weights and Measures (CGPM[†]) as *base quantities*, that is, quantities that are not derived from other quantities. The base quantities are length, mass, time, electric current, thermodynamic temperature, amount of substance, and luminous intensity. Table 1-1 lists these quantities, the name of the SI unit for each, and the standard letter symbol by which each is expressed in the International System (SI).

TABLE 1-1 SI Base Units

Quantity	Unit	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature*	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd

*Celsius temperature is, in general, expressed in degrees Celsius (symbol °C).

The units of the base quantities have been defined by the CGPM as follows:

meter. The length equal to 1 650 763.73 wavelengths in vacuum of the radiation corresponding to the transition between the levels $^2p_{10}$ and $^5d_5$ of the krypton-86 atom (CGPM).

kilogram. The unit of mass; it is equal to the mass of the international prototype of the kilogram (CGPM).

EDITOR'S NOTE: The prototype is a platinum-iridium cylinder maintained at the International Bureau of Weights and Measures, near Paris. The kilogram is approximately equal to the mass of 1000 cubic centimeters of water at its temperature of maximum density.

second. The duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium = 133 atoms (CGPM).

ampere. The constant current that if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 meter apart in vacuum would produce between these conductors a force equal to 2×10^{-7} newton per meter of length (CGPM).

kelvin. The unit of thermodynamic temperature is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water (CGPM).

EDITOR'S NOTE: The zero of the Celsius scale (the freezing point of water) is defined as 0.01 K below the triple point, that is, 273.15 K. See Table 1-27.

mole. That amount of substance of a system that contains as many elementary entities as there are atoms in 0.012 kilogram of carbon-12 (CGPM).

[†]From the initials of its French name, *Conference Générale des Poids et Mesures.*

NOTE: When the mole is used, the elementary entities must be specified. They may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles.

candela. The luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} Hz and that has a radiant intensity in that direction of 1/683 watt per steradian (CGPM).

EDITOR'S NOTE: Until January 1, 1948, the generally accepted unit of luminous intensity was the *international candle*. The difference between the candela and the international candle is so small that only measurements of high precision are affected. The use of the term *candle* is deprecated.

1.3 SUPPLEMENTARY SI UNITS

Two additional SI units, numerics which are considered as dimensionless derived units (see Sec. 1.4), are the radian and the steradian, for the quantities plane angle and solid angle, respectively. Table 1-2 lists these quantities and their units and symbols. The supplementary units are defined as follows:

radian. The plane angle between two radii of a circle that cut off on the circumference an arc equal in length to the radius (CGPM).

steradian. The solid angle which, having its vertex in the center of a sphere, cuts off an area of the surface of the sphere equal to that of a square with sides equal to the radius of the sphere (CGPM).

TABLE 1-2 SI Supplementary Units

Quantity	Unit	Symbol

Solid angle	steradian	sr

1.4 DERIVED SI UNITS

Most of the quantities and units used in electrical engineering fall in the category of SI derived units, that is, units which can be completely defined in terms of the base and supplementary quantities described above. Table 1-3 lists the principal electrical quantities in the SI system and shows their equivalents in terms of the base and supplementary units. The definitions of these quantities, as they appear in the *IEEE Standard Dictionary of Electrical and Electronics Terms* (ANSI/IEEE Std 100-1988), are

hertz. The unit of frequency 1 cycle per second.

newton. The force that will impart an acceleration of 1 meter per second per second to a mass of 1 kilogram.

pascal. The pressure exerted by a force of 1 newton uniformly distributed on a surface of 1 square meter.

joule. The work done by a force of 1 newton acting through a distance of 1 meter.

watt. The power required to do work at the rate of 1 joule per second.

coulomb. The quantity of electric charge that passes any cross section of a conductor in 1 second when the current is maintained constant at 1 ampere.

volt. The potential difference between two points of a conducting wire carrying a constant current of 1 ampere, when the power dissipated between these points is 1 watt.

farad. The capacitance of a capacitor in which a charge of 1 coulomb produces 1 volt potential difference between its terminals.

ohm. The resistance of a conductor such that a constant current of 1 ampere in it produces a voltage of 1 volt between its ends.

siemens (mho). The conductance of a conductor such that a constant voltage of 1 volt between its ends produces a current of 1 ampere in it.

lumen. The flux through a unit solid angle (steradian) from a uniform point source of 1 candela; the flux on a unit surface all points of which are at a unit distance from a uniform point source of 1 candela.

lux. The illumination on a surface of 1 square meter on which there is uniformly distributed a flux of 1 lumen; the illumination produced at a surface all points of which are 1 meter away from a uniform point source of 1 candela.

Table 1-4 lists other quantities and the SI derived unit names and symbols useful in engineering applications. Table 1-5 lists additional quantities and the SI derived units and symbols used in mechanics, heat, and electricity.

1.5 SI DECIMAL PREFIXES

All SI units may have affixed to them standard prefixes which multiply the indicated quantity by a power of 10. Table 1-6 lists the standard prefixes and their symbols. A substantial part of the extensive range (10^{36}) covered by these prefixes is in common use in electrical engineering (e.g., gigawatt, gigahertz, nanosecond, and picofarad). The practice of compounding a prefix (e.g., micromicrofarad) is deprecated (the correct term is picofarad).

1.6 USAGE OF SI UNITS, SYMBOLS, AND PREFIXES

Care must be exercised in using the SI symbols and prefixes to follow exactly the capital-letter and lowercase-letter usage prescribed in Tables 1-1 through 1-8, inclusive. Otherwise, serious confusion

TABLE 1-6 SI Prefixes Expressing Decimal Factors

Factor	Prefix	Symbol	Factor	Prefix	Symbol

10^{15}	peta	P	10^{-2}	centi	c
10^{12}	tera	T	10^{-3}	milli	m
10^{9}	giga	G	10^{-6}	micro	μ
10^{6}	mega	M	10^{-9}	nano	n
10^{3}	kilo	k	10^{-12}	pico	p
10^{2}	hecto	h	10^{-15}	femto	f
10^{1}	deka	da	10^{-18}	atto	a

may occur. For example, pA is the SI symbol for 10^{-12} of the SI unit for electric current (picoampere), while Pa is the SI symbol for pressure (the pascal).

The spelled-out names of the SI units (e.g., volt, ampere, watt) are not capitalized. The SI letter symbols are capitalized only when the name of the unit stands for or is directly derived from the name of a person. Examples are V for volt, after Italian physicist Alessandro Volta (1745–1827); A for ampere, after French physicist André-Marie Ampère (1775–1836); and W for watt, after Scottish engineer James Watt (1736–1819). The letter symbols serve the function of abbreviations, but they are used without periods.

It will be noted from Tables 1-1, 1-3, and 1-5 that with the exception of the ampere, all the SI electrical quantities and units are derived from the SI base and supplementary units or from other SI derived units. Thus, many of the short names of SI units may be expressed in compound form embracing the SI units from which they are derived. Examples are the volt per ampere for the ohm, the joule per second for the watt, the ampere-second for the coulomb, and the watt-second for the joule. Such compound usage is permissible, but in engineering publications, the short names are customarily used.

Use of the SI prefixes with non-SI units is not recommended; the only exception stated in IEEE Standard 268 is the microinch. Non-SI units, which are related to the metric system but are not decimal multiples of the SI units such as the calorie, torr, and kilogram-force, are specially to be avoided.

A particular problem arises with the universally used units of time (minute, hour, day, year, etc.) that are nondecimal multiples of the second. Table 1-7 lists these and their equivalents in seconds, as well as their standard symbols (see also Table 1-19). The watthour (Wh) is a case in point; it is equal to 3600 joules. The kilowatthour (kWh) is equal to 3 600 000 joules or 3.6 megajoules (MJ). In the mid-1980s, the use of the kilowatthour persisted widely, although eventually it was expected to be replaced by the megajoule, with the conversion factor 3.6 megajoules per kilowatthour. Other aspects in the usage of the SI system are the subject of the following recommendations published by the IEEE:

TABLE 1-7 Time and Angle Units Used in the SI System (Not Decimally Related to the SI Units)

Name	Symbol	Value in SI unit
minute	min	1 min = 60 s
hour	h	1 h = 60 min = 3 600 s
day	d	1 d = 24 h = 86 400 s
degree	°	$1° = (\pi/180)$ rad
minute	′	$1' = (1/60)° = (\pi/10\,800)$ rad
second	″	$1'' = (1/60)' = (\pi/648\,000)$ rad

Frequency. The CGPM has adopted the name *hertz* for the unit of frequency, but cycle per second is widely used. Although cycle per second is technically correct, the name *hertz* is preferred because of the widespread use of cycle alone as a unit of frequency. Use of cycle in place of cycle per second, or kilocycle in place of kilocycle per second, etc., is incorrect.

Magnetic Flux Density. The CGPM has adopted the name *tesla* for the SI unit of magnetic flux density. The name *gamma* shall not be used for the unit nanotesla.

Temperature Scale. In 1948, the CGPM abandoned *centigrade* as the name of the temperature scale. The corresponding scale is now properly named the *Celsius scale*, and further use of *centigrade* for this purpose is deprecated.

Luminous Intensity. The SI unit of luminous intensity has been given the name *candela*, and further use of the old name *candle* is deprecated. Use of the term *candle-power*, either as the name of a quantity or as the name of a unit, is deprecated.

Luminous Flux Density. The common British-American unit of luminous flux density is the lumen per square foot. The name *footcandle*, which has been used for this unit in the United States, is deprecated.

micrometer and micron. The names *micron* for micrometer and *millimicron* for nanometer are deprecated.

gigaelectronvolt (GeV). Because billion means a thousand million in the United States but a million million in most other countries, its use should be avoided in technical writing. The term *billion electronvolts* is deprecated; use gigaelectronvolts instead.

British-American Units. In principle, the number of British-American units in use should be reduced as rapidly as possible. Quantities are not to be expressed in mixed units. For example, mass should be expressed as 12.75 lb, rather than 12 lb or 12 oz. As a start toward implementing this recommendation, the following should be abandoned:

1. British thermal unit (for conversion factors, see Table 1-25).
2. horsepower (see Table 1-26).
3. Rankine temperature scale (see Table 1-27).
4. U.S. dry quart, U.S. liquid quart, and U.K. (Imperial) quart, together with their various multiples and subdivisions. If it is absolutely necessary to express volume in British-American units, the cubic inch or cubic foot should be used (for conversion factors, see Table 1-17).
5. footlambert. If it is absolutely necessary to express luminance in British-American units, the candela per square foot or lumen per steradian square foot should be used (see Table 1-28A).
6. inch of mercury (see Table 1-23C).

1.7 OTHER SI UNITS

Table 1-8 lists units used in the SI system whose values are not derived from the base quantities but from experiment. The definitions of these units, given in the *IEEE Standard Dictionary* (ANSI/IEEE Std 100-1988) are

electronvolt. The kinetic energy acquired by an electron in passing through a potential difference of 1 volt in vacuum.

NOTE: The electronvolt is equal to 1.60218×10^{-19} joule, approximately (see Table 1-25B).

unified atomic mass unit. The fraction 1/12 of the mass of an atom of the nuclide ^{12}C.

NOTE: u is equal to $1.660\,54 \times 10^{-27}$ kg, approximately.

TABLE 1-8 Units Used with the SI System Whose Values Are Obtained Experimentally

Name	Symbol
electronvolt	eV
unified atomic mass unit	u
astronomical unit*	
parsec	pc

*The astronomical unit does not have an international symbol. AU is customarily used in English, UA in French.

astronomical unit. The length of the radius of the unperturbed circular orbit of a body of negligible mass moving around the sun with a sidereal angular velocity of 0.017 202 098 950 radian per day of 86 400 ephemeris seconds.

NOTE: The International Astronomical Union has adopted a value for 1 AU equal to 1.496×10^{11} meters (see Table 1-15C).

parsec. The distance at which 1 astronomical unit subtends an angle of 1 second of arc. 1 pc = 206 264.8 AU = 30 857 × 10^{12} m, approximately (see Table 1-15C).

1.8 CGS SYSTEMS OF UNITS

The units most commonly used in physics and electrical science, from their establishment in 1873 until their virtual abandonment in 1948, are based on the centimeter-gram-second (cgs) electromagnetic and electrostatic systems. They have been used primarily in theoretical work, as contrasted with the SI units (and their "practical unit" predecessors, see Sec. 1.9) used in engineering. Table 1-9 lists the principal cgs electrical quantities and their units, symbols, and equivalent values in SI units. Use of these units in electrical engineering publications has been officially deprecated by the IEEE since 1966.

The cgs units have not been used to any great extent in electrical engineering, since many of the units are of inconvenient size compared with quantities used in practice. For example, the cgs electromagnetic unit of capacitance is the gigafarad.

1.9 PRACTICAL UNITS (ISU)

The shortcomings of the cgs systems were overcome by adopting the volt, ampere, ohm, farad, coulomb, henry, joule, and watt as "practical units," each being an exact decimal multiple of the corresponding electromagnetic cgs unit (see Table 1-9). From 1908 to 1948, the practical electrical units were embodied in the International System Units (ISU, not to be confused with the SI units). During these years, precise formulation of the units in terms of mass, length, and time was impractical because of imprecision in the measurements of the three basic quantities. As an alternative, the units were standardized by comparison with apparatus, called *prototype standards*. By 1948, advances in the measurement of the basic quantities permitted precise standardization by reference to the definitions of the

basic units, and the International System Units were officially abandoned in favor of the absolute units. These in turn were supplanted by the SI units which came into force in 1950.

1.10 DEFINITIONS OF ELECTRICAL QUANTITIES

The following definitions are based on the principal meanings listed in the *IEEE Standard Dictionary* (ANSI/IEEE Std 100-1988), which should be consulted for extended meanings, compound terms, and related definitions. The United States Standard Symbols (ANSI/IEEE Std 260, IEEE Std 280) for these quantities are shown in parentheses (see also Tables 1-10 and 1-11). Electrical units used in the United States prior to 1969, with SI equivalents, are listed in Table 1-29.

Admittance (Y). An admittance of a linear constant-parameter system is the ratio of the phasor equivalent of the steady-state sine-wave current or current-like quantity (response) to the phasor equivalent of the corresponding voltage or voltage-like quantity (driving force).

Capacitance (C). Capacitance is that property of a system of conductors and dielectrics which permits the storage of electrically separated charges when potential differences exist between the conductors. Its value is expressed as the ratio of an electric charge to a potential difference.

Coupling Coefficient (k). Coefficient of coupling (used only in the case of resistive, capacitive, and inductive coupling) is the ratio of the mutual impedance of the coupling to the square root of the product of the self-impedances of similar elements in the two circuit loops considered. Unless otherwise specified, coefficient of coupling refers to inductive coupling, in which case $k = M/(L_1L_2)^{1/2}$, where M is the mutual inductance, L_1 the self-inductance of one loop, and L_2 the self-inductance of the other.

Conductance (G)

1. The conductance of an element, device, branch, network, or system is the factor by which the mean-square voltage must be multiplied to give the corresponding power lost by dissipation as heat or as other permanent radiation or as electromagnetic energy from the circuit.
2. Conductance is the real part of admittance.

Conductivity (γ). The conductivity of a material is a factor such that the conduction current density is equal to the electric field strength in the material multiplied by the conductivity.

Current (I). *Current* is a generic term used when there is no danger of ambiguity to refer to any one or more of the currents described below. (For example, in the expression "the current in a simple series circuit," the word *current* refers to the conduction current in the wire of the inductor and to the displacement current between the plates of the capacitor.)

Conduction Current. The conduction current through any surface is the integral of the normal component of the conduction current density over that surface.

Displacement Current. The displacement current through any surface is the integral of the normal component of the displacement current density over that surface.

Current Density (J). *Current density* is a generic term used when there is no danger of ambiguity to refer either to conduction current density or to displacement current density or to both.

Displacement Current Density. The displacement current density at any point in an electric field is (in the International System) the time rate of change of the electric-flux-density vector at that point.

Conduction Current Density. The electric conduction current density at any point at which there is a motion of electric charge is a vector quantity whose direction is that of the flow of positive charge at this point, and whose magnitude is the limit of the time rate of flow of net (positive) charge across a small plane area perpendicular to the motion, divided by this area, as the area taken approaches zero in a macroscopic sense, so as to always include this point. The flow of charge may result from the movement of free electrons or ions but is not in general, except in microscopic studies, taken to include motions of charges resulting from the polarization of the dielectric.

Damping Coefficient (δ). If F is a function of time given by

$$F = A \exp(-\delta t) \sin(2\pi t/T)$$

then δ is the damping coefficient.

Elastance (S). Elastance is the reciprocal of capacitance.

Electric Charge, Quantity of Electricity (Q). Electric charge is a fundamentally assumed concept required by the existence of forces measurable experimentally. It has two forms known as positive and negative. The electric charge on (or in) a body or within a closed surface is the excess of one form of electricity over the other.

Electric Constant, Permittivity of Vacuum (Γ_e). The electric constant pertinent to any system of units is the scalar which in that system relates the electric flux density D in vacuum, to E, the electric field strength ($D = \Gamma_e E$). It also relates the mechanical force between two charges in vacuum to their magnitudes and separation. Thus, in the equation $F = \Gamma_r Q_1 Q_2 / 4\pi \Gamma_e r^2$, the force F between charges Q_1 and Q_2 separated by a distance $r\Gamma_e$ is the electric constant, and Γ_r is a dimensionless factor which is unity in a rationalized system and 4π in an unrationalized system.

NOTE: In the cgs electrostatic system, Γ_e is assigned measure unity and the dimension "numeric." In the cgs electromagnetic system, the measure of Γ_e is that of $1/c^2$, and the dimension is $[L^{-2}T^2]$. In the International System, the measure of Γ_e is $10^7/4\pi c^2$, and the dimension is $[L^{-3}M^{-1}T^4I^2]$. Here, c is the speed of light expressed in the appropriate system of units (see Table 1-12).

*Electric Field Strength (**E**).* The electric field strength at a given point in an electric field is the vector limit of the quotient of the force that a small stationary charge at that point will experience, by virtue of its charge, as the charge approaches zero.

Electric Flux (Ψ). The electric flux through a surface is the surface integral of the normal component of the electric flux density over the surface.

*Electric Flux Density, Electric Displacement (**D**).* The electric flux density is a quantity related to the charge displaced within a dielectric by application of an electric field. Electric flux density at any point in an isotropic dielectric is a vector which has the same direction as the electric field strength, and a magnitude equal to the product of the electric field strength and the permittivity ϵ. In a nonisotropic medium, ϵ may be represented by a tensor and $\boldsymbol{D}$ is not necessarily parallel to $\boldsymbol{E}$.

*Electric Polarization (**P**).* The electric polarization is the vector quantity defined by the equation $\boldsymbol{P} = (\boldsymbol{D} - \Gamma_e \boldsymbol{E})/\Gamma_r$, where $\boldsymbol{D}$ is the electric flux density, Γ_e is the electric constant, $\boldsymbol{E}$ is the electric field strength, and Γ_r is a coefficient that is set equal to unity in a rationalized system and to 4π in an unrationalized system.

Electric Susceptibility (χ_e). Electric susceptibility is the quantity defined by $\chi_e = (\epsilon_r - 1)/\Gamma_r$, where ϵ_r is the relative permittivity and Γ_r is a coefficient that is set equal to unity in a rationalized system and to 4π in an unrationalized system.

Electrization ($\boldsymbol{E}_i$). The electrization is the electric polarization divided by the electric constant of the system of units used.

Electrostatic Potential (V). The electrostatic potential at any point is the potential difference between that point and an agreed-on reference point, usually the point at infinity.

Electrostatic Potential Difference (V). The electrostatic potential difference between two points is the scalar-product line integral of the electric field strength along any path from one point to the other in an electric field, resulting from a static distribution of electric charge.

Impedance (Z). An impedance of a linear constant-parameter system is the ratio of the phasor equivalent of a steady-state sine-wave voltage or voltage-like quantity (driving force) to the phasor equivalent of a steady-state sine-wave current or current-like quantity (response). In electromagnetic radiation, electric field strength is considered the driving force and magnetic field strength the response. In mechanical systems, mechanical force is always considered as a driving force and velocity as a response. In a general sense, the dimension (and unit) of impedance in a given application may be whatever results from the ratio of the dimensions of the quantity chosen as the driving force to the dimensions of the quantity chosen as the response. However, in the types of systems cited above, any deviation from the usual convention should be noted.

Mutual Impedance. Mutual impedance between two loops (meshes) is the factor by which the phasor equivalent of the steady-state sine-wave current in one loop must be multiplied to give the phasor equivalent of the steady-state sine-wave voltage in the other loop caused by the current in the first loop.

Self-impedance. Self-impedance of a loop (mesh) is the impedance of a passive loop with all other loops of the open-circuited network.

Transfer Impedance. A transfer impedance is the impedance obtained when the response is determined at a point other than that at which the driving force is applied.

NOTE: In the case of an electric circuit, the response may be determined in any branch except that which contains the driving force.

Logarithmic Decrement (Λ). If F is a function of time given by

$$F = A \exp(-\delta t) \sin(2\pi t/T)$$

then the logarithmic decrement $\Lambda = T\delta$.

Magnetic Constant, Permeability of Vacuum (Γ_m). The magnetic constant pertinent to any system of units is the scalar which in that system relates the mechanical force between two currents in vacuum to their magnitudes and geometric configurations. For example, the equation for the force F on a length l of two parallel straight conductors of infinite length and negligible circular cross section, carrying constant currents I_1 and I_2 and separated by a distance r in vacuum, is $F = \Gamma_m \Gamma_r I_{12} l/2\pi r$, where Γ_m is the magnetic constant and Γ_r is a coefficient set equal to unity in a rationalized system and to 4π in an unrationalized system.

NOTE: In the cgs electromagnetic system, Γ_m is assigned the magnitude unity and the dimension "numeric." In the cgs electrostatic system, the magnitude of Γ_m is that of $1/c^2$, and the dimension is $[L^{-2}T^2]$. In the International System, Γ_m is assigned the magnitude $4\pi \times 10^{-7}$ and has the dimension $[LMT^{-2}I^{-2}]$.

*Magnetic Field Strength (**H**).* Magnetic field strength is that vector point function whose curl is the current density and which is proportional to magnetic flux density in regions free of magnetized matter.

Magnetic Flux (Φ). The magnetic flux through a surface is the surface integral of the normal component of the magnetic flux density over the surface.

*Magnetic Flux Density, Magnetic Induction (**B**).* Magnetic flux density is that vector quantity which produces a torque on a plane current loop in accordance with the relation $\boldsymbol{T} = IA\boldsymbol{n} \times \boldsymbol{B}$, where $\boldsymbol{n}$ is the positive normal to the loop and A is its area. The concept of flux density is extended to a point inside a solid body by defining the flux density at such a point as that which would be measured in a thin disk-shaped cavity in the body centered at that point, the axis of the cavity being in the direction of the flux density.

*Magnetic Moment (**m**).* The magnetic moment of a magnetized body is the volume integral of the magnetization. The magnetic moment of a loop carrying current I is $\boldsymbol{m} = (1/2)\int \boldsymbol{r} \times d\boldsymbol{r}$, where $\boldsymbol{r}$ is the radius vector from an arbitrary origin to a point on the loop, and where the path of integration is taken around the entire loop.

NOTE: The magnitude of the moment of a plane current loop is IA, where A is the area of the loop. The reference direction for the current in the loop indicates a clockwise rotation when the observer is looking through the loop in the direction of the positive normal.

*Magnetic Polarization, Intrinsic Magnetic Flux density (**J**, $\boldsymbol{B}_i$).* The magnetic polarization is the vector quantity defined by the equation $\boldsymbol{J} = (\boldsymbol{B} - \Gamma_m \boldsymbol{H})/\Gamma_r$, where $\boldsymbol{B}$ is the magnetic flux density, Γ_m is the magnetic constant, $\boldsymbol{H}$ is the magnetic field strength, and Γ_r is a coefficient that is set equal to unity in a rationalized system and to 4π in an unrationalized system.

Magnetic Susceptibility (χ_m). Magnetic susceptibility is the quantity defined by $\chi_m = (\mu_r - 1)/\Gamma_r$, where μ_r is the relative permeability and Γ_r is a coefficient that is set equal to unity in a rationalized system and to 4π in an unrationalized system.

*Magnetic Vector Potential (**A**).* The magnetic vector potential is a vector point function characterized by the relation that its curl is equal to the magnetic flux density and its divergence vanishes.

Magnetization ($\boldsymbol{M}, \boldsymbol{H}_i$). The magnetization is the magnetic polarization divided by the magnetic constant of the system of units used.

Magnetomotive Force ($\boldsymbol{F}_m$). The magnetomotive force acting in any closed path in a magnetic field is the line integral of the magnetic field strength around the path.

Mutual Inductance (M). The mutual inductance between two loops (meshes) in a circuit is the quotient of the flux linkage produced in one loop divided by the current in another loop, which induces the flux linkage.

Permeability. *Permeability* is a general term used to express various relationships between magnetic flux density and magnetic field strength. These relationships are either (1) *absolute permeability* (μ), which in general is the quotient of a change in magnetic flux density divided by the corresponding change in magnetic field strength, or (2) *relative permeability* (μ_r), which is the ratio of the absolute permeability to the magnetic constant.

Permeance (P_m). Permeance is the reciprocal of reluctance.

Permittivity, Capacitivity (ϵ). The permittivity of a homogeneous, isotropic dielectric, in any system of units, is the product of its relative permittivity and the electric constant appropriate to that system of units.

Relative Permittivity, Relative Capacitivity, Dielectric Constant (ϵ_r). The relative permittivity of any homogeneous isotropic material is the ratio of the capacitance of a given configuration of electrodes with the material as a dielectric to the capacitance of the same electrode configuration with a vacuum as the dielectric constant. Experimentally, vacuum must be replaced by the material at all points where it makes a significant change in the capacitance.

Power (P). Power is the time rate of transferring or transforming energy. *Electric power* is the time rate of flow of electrical energy. The *instantaneous electric power* at a single terminal pair is equal to the product of the instantaneous voltage multiplied by the instantaneous current. If both voltage and current are periodic in time, the time average of the instantaneous power, taken over an integral number of periods, is the *active power,* usually called simply the *power* when there is no danger of confusion.

If the voltage and current are sinusoidal functions of time, the product of the rms value of the voltage and the rms value of the current is called the *apparent power;* the product of the rms value of the voltage and the rms value of the in-phase component of the current is the *active power;* and the product of the rms value of the voltage and the rms value of the quadrature component of the current is called the *reactive power*.

The SI unit of instantaneous power and active power is the watt. The germane unit for apparent power is the voltampere and for reactive power is the var.

Power Factor (F_p). Power factor is the ratio of active power to apparent power.

Q. *Q,* sometimes called *quality factor,* is that measure of the quality of a component, network, system, or medium considered as an energy storage unit in the steady state with sinusoidal driving force which is given by

$$Q = \frac{2\pi \times (\text{maximum energy in storage})}{\text{energy dissipated per cycle of the driving force}}$$

NOTE: For single components such as inductors and capacitors, the Q at any frequency is the ratio of the equivalent series reactance to resistance, or of the equivalent shunt susceptance to conductance. For networks that contain several elements and for distributed parameter systems, the Q is generally evaluated at a frequency of resonance. The *nonloaded* Q of a system is the value of Q obtained when only the incidental dissipation of the system elements is present. The *loaded* Q of a system is the value Q obtained when the system is coupled to a device that dissipates energy. The "period" in the expression for Q is that of the driving force, not that of energy storage, which is usually half of that of the driving force.

Reactance (X). Reactance is the imaginary part of impedance.

Reluctance (R_m). Reluctance is the ratio of the magnetomotive force in a magnetic circuit to the magnetic flux through any cross section of the magnetic circuit.

Reluctivity (ν). Reluctivity is the reciprocal of permeability.

Resistance (R)

1. The resistance of an element, device, branch, network, or system is the factor by which the mean-square conduction current must be multiplied to give the corresponding power lost by dissipation as heat or as other permanent radiation or as electromagnetic energy from the circuit.
2. Resistance is the real part of impedance.

Resistivity (ρ). The resistivity of a material is a factor such that the conduction current density is equal to the electric field strength in the material divided by the resistivity.

Self-inductance (L)

1. Self-inductance is the quotient of the flux linkage of a circuit divided by the current in that same circuit which induces the flux linkage. If v = voltage induced, $v = d(Li)/dt$.
2. Self-inductance is the factor L in the $\frac{1}{2}Li^2$ if the latter gives the energy stored in the magnetic field as a result of the current i.

NOTE: Definitions 1 and 2 are not equivalent except when L is constant. In all other cases, the definition being used must be specified. The two definitions are restricted to relatively slow changes in i, that is, to low frequencies, but by analogy with the definitions, equivalent inductances often may be evolved in high-frequency applications such as resonators and waveguide equivalent circuits. Such "inductances," when used, must be specified. The two definitions are restricted to cases in which the branches are small in physical size when compared with a wavelength, whatever the frequency. Thus, in the case of a uniform 2-wire transmission line it may be necessary even at low frequencies to consider the parameters as "distributed" rather than to have one inductance for the entire line.

Susceptance (B). Susceptance is the imaginary part of admittance.

Transfer Function (H). A transfer function is that function of frequency which is the ratio of a phasor output to a phasor input in a linear system.

Transfer Ratio (H). A transfer ratio is a dimensionless transfer function.

Voltage, Electromotive Force (V). The voltage along a specified path in an electric field is the dot product line integral of the electric field strength along this path. As defined, here voltage is synonymous with potential difference only in an electrostatic field.

1.11 DEFINITIONS OF QUANTITIES OF RADIATION AND LIGHT

The following definitions are based on the principal meanings listed in the *IEEE Standard Dictionary* (ANSI/IEEE Std 100-1988), which should be consulted for extended meanings, compound terms, and related definitions. The symbols shown in parentheses are from Table 1-10.

Candlepower. Candlepower is luminous intensity expressed in candelas (term deprecated by IEEE).

Emissivity, Total Emissivity (ϵ). The total emissivity of an element of surface of a temperature radiator is the ratio of its radiant flux density (radiant exitance) to that of a blackbody at the same temperature.

Spectral Emissivity, ϵ(λ). The spectral emissivity of an element of surface of a temperature radiator at any wavelength is the ratio of its radiant flux density per unit wavelength interval (spectral radiant exitance) at that wavelength to that of a blackbody at the same temperature.

Light. For the purposes of illuminating engineering, light is visually evaluated radiant energy.

NOTE 1: Light is psychophysical, neither purely physical nor purely psychological. Light is not synonymous with radiant energy, however restricted, nor is it merely sensation. In a general nonspecialized sense, light is the aspect of radiant energy of which a human observer is aware through the stimulation of the retina of the eye.

NOTE 2: Radiant energy outside the visible portion of the spectrum must not be discussed using the quantities and units of light; it is nonsense to refer to "ultraviolet light" or to express infrared flux in lumens.

Luminance (Photometric Brightness) (L). Luminance in a direction, at a point on the surface of a source, or of a receiver, or on any other real or virtual surface is the quotient of the luminous flux (Φ) leaving, passing through, or arriving at a surface element surrounding the point, propagated in directions defined by an elementary cone containing the given direction, divided by the product of the solid angle of the cone ($d\omega$) and the area of the orthogonal projection of the surface element on a plane perpendicular to the given direction ($dA \cos \theta$). $L = d^2\Phi/[d\omega(da \cos \theta)] = dI/(dA \cos \theta)$. In the defining equation, θ is the angle between the direction of observation and the normal to the surface.

In common usage, the term *brightness* usually refers to the intensity of sensation which results from viewing surfaces or spaces from which light comes to the eye. This sensation is determined in part by the definitely measurable luminance defined above and in part by conditions of observation such as the state of adaptation of the eye. In much of the literature, the term *brightness,* used alone, refers to both luminance and sensation. The context usually indicates which meaning is intended.

Luminous Efficacy of Radiant Flux. The luminous efficacy of radiant flux is the quotient of the total luminous flux divided by the total radiant flux. It is expressed in lumens per watt.

Spectral Luminous Efficacy of Radiant Flux, $K(\lambda)$. Spectral luminous efficacy of radiant flux is the quotient of the luminous flux at a given wavelength divided by the radiant flux at the wavelength. It is expressed in lumens per watt.

Spectral Luminous Efficiency of Radiant Flux. Spectral luminous efficiency of radiant flux is the ratio of the luminous efficacy for a given wavelength to the value at the wavelength of maximum luminous efficacy. It is a numeric.

NOTE: The term *spectral luminous efficiency* replaces the previously used terms *relative luminosity* and *relative luminosity factor.*

Luminous Flux (Φ). Luminous flux is the time rate of flow of light.

Luminous Flux Density at a Surface. Luminous flux density at a surface is luminous flux per unit area of the surface. In referring to flux incident on a surface, this is called *illumination (E)*. The preferred term for luminous flux *leaving* a surface is *luminous exitance (M)*, which has been called *luminous emittance*.

Luminous Intensity (I). The luminous intensity of a source of light in a given direction is the luminous flux proceeding from the source per unit solid angle in the direction considered ($I = d\Phi/d\omega$).

Quantity of Light (Q). Quantity of light (luminous energy) is the product of the luminous flux by the time it is maintained, that is, it is the time integral of luminous flux.

Radiance (L). Radiance in a direction, at a point on the surface, of a source, or of a receiver, or on any other real or virtual surface is the quotient of the radiant flux (P) leaving, passing through, or arriving at a surface element surrounding the point, and propagated in directions defined by an elementary cone containing the given direction, divided by the product of the solid angle of the cone ($d\omega$) and the area of the orthogonal projection of the surface element on a plane perpendicular to the given direction ($dA \cos \theta$). $L = d^2P/d\omega(dA \cos \theta) = dI/(dA \cos \theta)$. In the defining equation, θ is the angle between the normal to the element of the source and the direction of observation.

Radiant Density (w). Radiant density is radiant energy per unit volume.

Radiant Energy (W). Radiant energy is energy traveling in the form of electromagnetic waves.

Radiant Flux Density at a Surface. Radiant flux density at a surface is radiant flux per unit area of the surface. When referring to radiant flux incident on a surface, this is called *irradiance (E)*. The preferred term for radiant flux *leaving* a surface is *radiant exitance (M)*, which has been called *radiant emittance.*

Radiant Intensity (I). The radiant intensity of a source in a given direction is the radiant flux proceeding from the source per unit solid angle in the direction considered ($I = dP/d\omega$).

Radiant Power, Radiant Flux (P). Radiant flux is the time rate of flow of radiant energy.

1.12 LETTER SYMBOLS

Tables 1-10 and 1-11 list the United States Standard letter symbols for quantities and units (ANSI Std Y10.5, ANSI/IEEE Std 260). A *quantity symbol* is a single letter (e.g., I for electric current) specified as to general form of type and modified by one or more subscripts or superscripts when appropriate. A *unit symbol* is a letter or group of letters (e.g., cm for centimeter), or in a few cases, a special sign, that may be used in the place of the name of the unit.

Symbols for quantities are printed in *italic* type, while symbols for units are printed in roman type. Subscripts and superscripts that are letter symbols for quantities or for indices are printed in roman type as follows:

C_p	heat capacity at constant pressure p
a_{ij}, a_{45}	matrix elements
I_i, I_o	input current, output current

For indicating the vector character of a quantity, ***boldface italic*** type is used (e.g., $\boldsymbol{F}$ for force). Ordinary italic type is used to represent the magnitude of a vector quantity.

The product of two quantities is indicated by writing ab. The quotient may be indicated by writing

$$\frac{a}{b}, \qquad a/b, \qquad \text{or} \qquad ab^{-1}$$

If more than one solidus (/) is required in any algebraic term, parentheses must be inserted to remove any ambiguity. Thus, one may write $(a/b)/c$ or a/bc, but not $a/b/c$.

Unit symbols are written in lowercase letters, except for the first letter when the name of the unit is derived from a proper name, and except for a very few that are not formed from letters. When a compound unit is formed by multiplication of two or more other units, its symbol consists of the symbols for the separate units joined by a raised dot (e.g., N · m for newton = meter). The dot may be omitted in the case of familiar compounds such as watthour (Wh) if no confusion would result. Hyphens should not be used in symbols for compound units. Positive and negative exponents may be used with the symbols for units.

When a symbol representing a unit that has a prefix (see Sec. 1.5) carries an exponent, this indicates that the multiple (or submultiple) unit is raised to the power expressed by the exponent.

Examples:

$$2\ \text{cm}^3 = 2(\text{cm})^3 = 2(10^{-2}\ \text{m})^3 = 2 \cdot 10^{-6}\ \text{m}^3$$

$$1\ \text{ms}^{-1} = 1(\text{ms})^{-1} = 1(10^{-3}\ \text{s})^{-1} = 10^3\ \text{s}^{-1}$$

Phasor quantities, represented by complex numbers or complex time-varying functions, are extensively used in certain branches of electrical engineering. The following notation and typography are standard:

	Notation	Remarks
Complex quantity	Z	$Z = \|Z\| \exp(\mathrm{j}\phi)$ $Z = \mathrm{Re}\, Z + \mathrm{j}\, \mathrm{Im}\, Z$
Real part	Re Z, Z'	
Imaginary part	Im Z, Z''	
Conjugate complex quantity	Z^*	$Z^* = \mathrm{Re}\, Z - \mathrm{j}\, \mathrm{Im}\, Z$
Modulus of Z	$\|Z\|$	
Phase of Z, Argument of Z	arg Z	arg $Z = \phi$

Conductivity	γ, σ	siemens per meter	$\gamma = 1/\rho$ The symbol σ is used in field theory, as γ is there used for the propagation coefficient.
Reluctance	$R, R_m \cdots \mathcal{R}$	reciprocal henry	Magnetic potential difference divided by magnetic flux
Permeance	$P, P_m \cdots \mathcal{P}$	henry	$P_m = 1/R_m$
Impedance	Z	ohm	
Reactance	X	ohm	
Capacitive reactance	X_C	ohm	For a pure capacitance, $X_C = -1/\omega C$
Inductive reactance	X_L	ohm	For a pure capacitance, $X_L = \omega L$
Quality factor	Q	(numeric)	See Q in Sec. 1.10.
Admittance	Y	siemens	$Y = 1/Z = G + jB$
Susceptance	B	siemens	$B = \text{Im } Y$
Loss angle	δ	radian	$\delta = (R/\|X\|)$
Active power	P	watt	
Reactive power	$Q \cdots P_q$	var	
Apparent power	$S \cdots P_s$	voltampere	
Power factor	$\cos \phi \cdots F_p$	(numeric)	
Reactive factor	$\sin \phi \cdots F_q$	(numeric)	
Input power	P_i	watt	
Output power	P_o	watt	
Poynting vector	S	watt per square meter	
Characteristic impedance	Z_o	ohm	
Surge impedance			
Intrinsic impedance of a medium	η	ohm	
Voltage standing-wave ratio	S	(numeric)	
Resonance frequency	f_r	hertz	
Critical frequency	f_c	hertz	
Cutoff frequency			
Resonance angular frequency	ω_r	radian per second	
Critical angular frequency	ω_c	radian per second	
Cutoff angular frequency			
Resonance wavelength	λ_r	meter	
Critical wavelength	λ_c	meter	
Cutoff wavelength			
Wavelength in a guide	λ_g	meter	
Hysteresis coefficient	k_h	(numeric)	
Eddy-current coefficient	k_e	(numeric)	
Phase angle	ϕ, θ	radian	
Phase difference			

†(λ) is not part of the basic symbol but indicates that the quantity is a function of wavelength.

TABLE 1-11 Standard Symbols for Units

Unit	Symbol	Notes
ampere	A	SI unit of electric current
ampere (turn)	A	SI unit of magnetomotive force
ampere-hour	Ah	Also A · h
ampere per meter	A/m	SI unit of magnetic field strength
angstrom	Å	1 Å = 10^{-10} m. Deprecated.
atmosphere, standard	atm	1 atm = 101 325 Pa. Deprecated.
atmosphere, technical	at	1 at = 1 kgf/cm^2. Deprecated.
atomic mass unit (unified)	u	The (unified) atomic mass unit is defined as one-twelfth of the mass of an atom of the ^{12}C nuclide. Use of the old atomic mass (amu), defined by reference to oxygen, is deprecated.
atto	a	SI prefix for 10^{-18}
attoampere	aA	
bar	bar	1 bar = 100 kPa. Use of the bar is strongly discouraged, except for limited use in meteorology.
barn	b	1 b = 10^{-28} m^2
barrel	bb1	1 bb1 = 42 gal$_{US}$ = 158.99 L
barrel per day	bb1/d	This is the standard barrel used for petroleum, etc. A different standard barrel is used for fruits, vegetables, and dry commodities.
baud	Bd	In telecommunications, a unit of signaling speed equal to one element per second. The signaling speed in bauds is equal to the reciprocal of the signal element length in seconds.
bel	B	
becquerel	Bq	SI unit of activity of a radionuclide
billion electronvolts	GeV	The name *gigaelectronvolt* is preferred for this unit.
bit	b	In information theory, the bit is a unit of information content equal to the information content of a message, the *a priori* probability of which is one-half. In computer science, the bit is a unit of storage capacity. The capacity, in bits, of a storage device is the logarithm to the base two of the number of possible states of the device.
bit per second	b/s	
British thermal unit	Btu	
calorie (International Table calorie)	cal$_{IT}$	1 cal$_{IT}$ = 4.1868 J. Deprecated.
calorie (thermochemical calorie)	cal	1 cal = 4.1840 J. Deprecated.
candela	cd	SI unit of luminous intensity
candela per square inch	cd/in^2	Use of the SI unit, cd/m^2, is preferred.
candela per square meter	cd/m^2	SI unit of luminance. The name *nit* is sometimes used for this unit.
candle	cd	The unit of luminous intensity has been given the name *candela;* use of the name *candle* for this unit is deprecated.
centi	c	SI prefix for 10^{-2}
centimeter	cm	
centipoise	cP	1 cP = mPa · s. The name centipoise is deprecated.
centistokes	cSt	1 cSt = 1mm^2/s. The name centistokes is deprecated.
circular mil	cmil	1 cmil = $(\pi/4) \cdot 10^{-6}$ in^2
coulomb	C	SI unit of electric charge
cubic centimeter	cm^3	
cubic foot	ft^3	
cubic foot per minute	ft^3/min	
cubic foot per second	ft^3/s	
cubic inch	in^3	
cubic meter	m^3	
cubic meter per second	m^3/s	
cubic yard	yd^3	

(*Continued*)

TABLE 1-11 Standard Symbols for Units (*Continued*)

Unit	Symbol	Notes
curie	Ci	A unit of activity of radionuclide. Use of the SI unit, the becquerel, is preferred, 1 Ci = 3.7×10^{10} Bq.
cycle	c	
cycle per second	Hz, c/s	See hertz. The name *hertz* is internationally accepted for this unit; the symbol Hz is preferred to c/s.
darcy	D	1 D = 1 cP (cm/s) (cm/atm) = 0.986 923 μm^2. A unit of permeability of a porous medium. By traditional definition, a permeability of one darcy will permit a flow of 1 cm^3/s of fluid of 1 cP viscosity through an area of 1 cm^2 under a pressure gradient of 1 atm/cm. For nonprecision work, 1 D may be taken equal to 1 μm^2 and 1 mD equal to 0.001 μm^2. Deprecated.
day	d	
deci	d	SI prefix for 10^{-1}
decibel	dB	
degree (plane angle)	. . . °	
degree (temperature):		
degree Celsius	°C	SI unit of Celsius temperature. The degree Celsius is a special name for the kelvin, for use in expressing Celsius temperatures or temperature intervals.
degree Fahrenheit	°F	Note that the symbols for °C, °F, and °R comprise two elements, written with no space between the ° and the letter that follows. The two elements that make the complete symbol are not to be separated.
degree Kelvin		See kelvin
degree Rankine	°R	
deka	da	SI prefix for 10
dyne	dyn	Deprecated.
electronvolt	eV	
erg	erg	Deprecated.
exa	E	SI prefix for 10^{18}
farad	F	SI unit of capacitance
femto	f	SI prefix for 10^{-15}
femtometer	fm	
foot	ft	
conventional foot of water	ftH_2O	1 ftH_2O = 2989.1 Pa (ISO)
foot per minute	ft/min	
foot per second	ft/s	
foot per second squared	ft/s^2	
foot pound-force	ft · lbf	
footcandle	fc	1 fc = 1 lm/ft^2. The name *lumen per square foot* is also used for this unit. Use of the SI unit of illuminance, the lux (lumen per square meter), is preferred.
footlambert	fL	1 fL = $(1/\pi)$ cd/ft^2. A unit of luminance. One lumen per square foot leaves a surface whose luminance is one footlambert in all directions within a hemisphere. Use of the SI unit, the candela per square meter, is preferred.
gal	Gal	1 Gal = 1 cm/s^2. Deprecated.
gallon	gal	1 gal_{UK} = 4.5461 L 1 gal_{US} = 231 in^3 = 3.7854 L
gauss	G	The gauss is the electromagnetic CGS unit of magnetic flux density. Deprecated.
giga	G	SI prefix for 10^9
gigaelectronvolt	GeV	
gigahertz	GHz	

TABLE 1-11 Standard Symbols for Units (*Continued*)

Unit	Symbol	Notes
gilbert	Gb	The gilbert is the electromagnetic CGS unit of magnetomotive force. Deprecated.
grain	gr	
gram	g	
gram per cubic centimeter	g/cm^3	
gray	Gy	SI unit of absorbed dose in the field of radiation dosimetry
hecto	h	SI prefix for 10^2
henry	H	SI unit of inductance
hertz	Hz	SI unit of frequency
horsepower	hp	The horsepower is an anachronism in science and technology. Use of the SI unit of power, the watt, is preferred.
hour	h	
inch	in	
conventional inch of mercury	inHg	1 inHg = 3386.4 Pa (ISO)
conventional inch of water	inH_2O	1 inH_2O = 249.09 Pa (ISO)
inch per second	in/s	
joule	J	SI unit of energy, work, quantity of heat
joule per kelvin	J/K	SI unit of heat capacity and entropy
kelvin	K	In 1967, the CGPM gave the name *kelvin* to the SI unit of temperature which had formerly been called *degree kelvin* and assigned it the symbol K (without the symbol °).
kilo	k	SI prefix for 10^3
kilogauss	kG	Deprecated.
kilogram	kg	SI unit of mass
kilogram-force	kgf	Deprecated. In some countries, the name kilopond (kp) has been used for this unit.
kilohertz	kHz	
kilohm	kΩ	
kilometer	km	
kilometer per hour	km/h	
kilopound-force	klbf	Kilopound-force should not be misinterpreted as kilopond (see kilogram-force).
kilovar	kvar	
kilovolt	kV	
kilovoltampere	kVA	
kilowatt	kW	
kilowatthour	kWh	Also kW · h
knot	kn	1kn = 1 nmi/h
lambert	L	1 L = $(1/\pi)$ cd/cm^2. A GGS unit of luminance. One lumen per square centimeter leaves a surface whose luminance is one lambert in all directions within a hemisphere. Deprecated.
liter	L	1 L = 10^{-3} m^3. The letter symbol 1 has been adopted for *liter* by the GGPM, and it is recommended in a number of international standards. In 1978, the CIPM accepted L as an alternative symbol. Because of frequent confusion with the numeral 1 the letter symbol 1 is no longer recommended for U.S. use. The script letter ℓ, which had been proposed, is not recommended as a symbol for liter.
liter per second	L/s	
lumen	lm	SI unit of luminous flux
lumen per square foot	lm/ft^2	A unit of illuminance and also a unit of luminous exitance. Use of the SI unit, lumen per square meter, is preferred.
lumen per square meter	lm/m^2	SI unit of luminous exitance
lumen per watt	lm/W	SI unit of luminous efficacy

(*Continued*)

TABLE 1-11 Standard Symbols for Units (*Continued*)

Unit	Symbol	Notes
lumen second	lm · s	SI unit of quantity of light
lux	lx	1 lx = 1 lm/m^2. SI unit of illuminance
maxwell	Mx	The maxwell is the electromagnetic CGS unit of magnetic flux. Deprecated.
mega	M	SI prefix for 10^6
megaelectronvolt	MeV	
megahertz	MHz	
megohm	MΩ	
meter	m	SI unit of length
metric ton	t	1 t = 1000 kg. The name *tonne* is used in some countries for this unit, but use of this name in the U.S. is deprecated.
mho	mho	Formerly used as the name of the siemens (S).
micro	μ	SI prefix for 10^{-6}
microampere	μA	
microfarad	μF	
microgram	μg	
microhenry	μH	
microinch	μin	
microliter	μL	See note for *liter*.
micrometer	μm	
micron	μm	Deprecated. Use micrometer.
microsecond	μs	
microwatt	μW	
mil	mil	1 mil = 0.001 in
mile (statute)	mi	1 mi = 5280 ft
miles per hour	mi/h	Although use of mph as an abbreviation is common, it should not be used as a symbol.
milli	m	SI prefix for 10^{-3}
milliampere	mA	
millibar	mbar	Use of the bar is strongly discouraged, except for limited use in meteorology.
milligram	mg	
millihenry	mH	
milliliter	mL	See note for *liter*.
millimeter	mm	
conventional millimeter of mercury	mmHg	1 mmHg = 133.322 Pa. Deprecated.
millimicron	nm	Use of the name *millimicron* for the nanometer is deprecated.
millipascal second	mPa · s	SI unit-multiple of dynamic viscosity
millisecond	ms	
millivolt	mV	
milliwatt	mW	
minute (plane angle)	. . . ′	
minute (time)	min	Time may also be designated by means of superscripts as in the following example: $9^h46^m30^s$.
mole	mol	SI unit of amount of substance
month	mo	
nano	n	SI prefix for 10^{-9}
nanoampere	nA	
nanofarad	nF	
nanometer	nm	
nanosecond	ns	
nautical mile	nmi	1 nmi = 1852 m

TABLE 1-11 Standard Symbols for Units (*Continued*)

Unit	Symbol	Notes
neper	Np	
newton	N	SI unit of force
newton meter	N · m	
newton per square meter	N/m^2	SI unit of pressure or stress, see pascal.
nit	nt	1 nt = 1 cd/m^2 The name *nit* is sometimes given to the SI unit of luminance, the candela per square meter.
oersted	Oe	The oersted is the electromagnetic CGS unit of magnetic field strength. Deprecated.
ohm	Ω	SI unit of resistance
ounce (avoirdupois)	oz	
pascal	Pa	1 Pa = 1 N/m^2 SI unit of pressure or stress
pascal second	Pa · s	SI unit of dynamic viscosity
peta	P	SI prefix for 10^{15}
phot	ph	1 ph = lm/cm^2 CGS unit of illuminance. Deprecated.
pico	p	SI prefix for 10^{-12}
picofarad	pF	
picowatt	pW	
pint	pt	1 pt (U.K.) = 0.568 26 L 1 pt (U.S. dry) = 0.550 61 L 1 pt (U.S. liquid) = 0.473 18 L
poise	P	Deprecated.
pound	lb	
pound per cubic foot	lb/ft^3	
pound-force	lbf	
pound-force foot	lbf · ft	
pound-force per square foot	lbf/ft^2	
pound-force per square inch	lbf/in^2	Although use of the abbreviation psi is common, it should not be used as a symbol.
poundal	pdl	
quart	qt	1 qt (U.K.) = 1.136 5 L 1 qt (U.S. dry) = 1.101 2 L 1 qt (U.S. liquid) = 0.946 35 L
rad	rd	A unit of absorbed dose in the field of radiation dosimetry. Use of the SI unit, the gray, is preferred. 1 rd = 0.01 Gy.
radian	rad	SI unit of plane angle
rem	rem	A unit of dose equivalent in the field of radiation dosimetry. Use of the SI unit, the sievert, is preferred. 1 rem = 0.01 Sv.
revolution per minute	r/min	Although use of rpm as an abbreviation is common, it should not be used as a symbol.
revolution per second	r/s	
roentgen	R	A unit of exposure in the field of radiation dosimetry
second (plane angle)	. . . ″	
second (time)	s	SI unit of time
siemens	S	1 S = 1 Ω^{-1} SI unit of conductance. The name mho has been used for this unit in the U.S.
sievert	Sv	SI unit of dose equivalent in the field of radiation dosimetry. Name adopted by the CIPM in 1978.
slug	slug	1 slug = 14.5939 kg
square foot	ft^2	
square inch	in^2	

(*Continued*)

Unit	Symbol	Notes
square meter	m^2	
square meter per second	m^2/s	SI unit of kinematic viscosity
square millimeter per second	mm^2/s	SI unit-multiple of kinematic viscosity
square yard	yd^2	
steradian	sr	SI unit of solid angle
stilb	sb	1 sb = 1 cd/cm^2 A CGS unit of luminance. Deprecated.
stokes	St	Deprecated.
tera	T	SI prefix for 10^{12}
tesla	T	1 T = 1 N/(A · m) = 1 Wb/m^2. SI unit of magnetic flux density (magnetic induction).
therm	thm	1 thm = 100 000 Btu
ton (short)	ton	1 ton = 2000 lb
ton, metic	t	1 t = 1000 kg. The name *tonne* is used in some countries for this unit, but use of this name in the U.S. is deprecated.
(unified) atomic mass unit	u	The (unified) atomic mass unit is defined as one-twelfth of the mass of an atom of the ^{12}C nuclide. Use of the old atomic mass unit (amu), defined by reference to oxygen, is deprecated.
var	var	IEC name and symbol for the SI unit of reactive power
volt	V	SI unit of voltage
volt per meter	V/m	SI unit of electric field strength
voltampere	VA	IEC name and symbol for the SI unit of apparent power
watt	W	SI unit of power
watt per meter kelvin	W/(m · K)	SI unit of thermal conductivity
watt per steradian	W/sr	SI unit of radiant intensity
watt per steradian square meter	$W/(sr \cdot m^2)$	SI unit of radiance
watthour	Wh	
weber	Wb	Wb = V · s SI unit of magnetic flux
yard	yd	
year	a	In the English language, generally yr.

1.13 GRAPHIC SYMBOLS

An extensive list of standard graphic symbols for electrical engineering has been compiled in IEEE Standard 315 (ANSI Y32.2). Since this standard comprises 110 pages, including 78 pages of diagrams, it is impractical to reproduce it here. Those concerned with the preparation of circuit diagrams and graphic layouts should conform to these standard symbols to avoid confusion with earlier, nonstandard forms. See also Sec. 28.

1.14 PHYSICAL CONSTANTS

Table 1-12 lists the values of the fundamental physical constants, compiled by Peter, J. Mohr and Barry N. Taylor of the Task Group on Fundamental Constants of the Committee on Data for Science and Technology (CODATA), sponsored by the International Council of Scientific Unions. Further details on the methods used to adjust these values to form a consistent set are contained in Ref. 10. Table 1-13 lists the values of some energy equivalents.

Source: *CODATA recommended values of the fundamental physical constants: 2002; Peter J. Mohr and Barry N. Taylor; *Rev, Mod, Phys.* January 2005, vol. 77, no. 1, pp. 1–107.

[a] Value recommended by the Particle Data Group (Hagiwara et al., 2002).

[b] Based on the ratio of the masses of the W and Z bosons m_W/m_Z recommended by the Particle Data Group (Hagiwara *et al.*, 2002). The value for $\sin^2 \theta_W$ they recommend, which is based on a particular variant of the modified minimal subtraction ($\overline{\text{MS}}$) scheme, is $\sin^2 \hat{\theta}_W (Mz) = 0.231\ 24(24)$.

[C] The hellion, symbol h, is the nucleus of the ^{3}He atom.

[d] This and all other values involving m_τ are based on the value of $m_\tau c^2$ in MeV recommended by the Particle Data Group (Hagiwara *et al.*, 2002), but with a standard uncertainty of 0.29 MeV rather than the quoted uncertainty of –0.26 MeV, +0.29 MeV.

[e] The numerical value of F to be used in coulometric chemical measurements is 96 485.336(16) [1.7×10^{-7}] when the relevant current is measured in terms of representations of the volt and ohm based on the Josephson and quantum Hall effects and the internationally, adopted conventional values of the Josephson and von Klitzing constants K_{J-90} and R_{K-90}.

[f] The entropy of an ideal monoatomic gas of relative atomic mass A_r is given by $S = S_0 + 3/2\ R \ln A_r - R \ln (p/p_0) + 5/2\ R \ln (T/K)$.

1.15 NUMERICAL VALUES

Extensive use is made in electrical engineering of the constants π and ϵ and of the numbers 2 and 10, the latter in logarithmic units and number systems. Table 1-14 lists functions of these numbers to 9 or 10 significant digits. In most engineering applications (except those involving the difference of large, nearly equal numbers), five significant digits suffice. The use of the listed values in computations with electronic hand calculators will suffice in most cases to produce results more than adequate for engineering work.

1.16 CONVERSION FACTORS

The increasing use of the metric system in British and American practice has generated a need for extensive tables of multiplying factors to facilitate conversions from and to the SI units. Tables 1-15 through 1-28 list these conversion factors.

Table	Quantity	SI unit	Subtabulation	Basis of grouping
1-15	Length	meter	1-15A	Units decimally related to one meter
			1-15B	Units less than one meter
			1-15C	Units greater than one meter
			1-15D	Other length units
1-16	Area	square meter	1-16A	Units decimally related to one square meter
			1-16B	Nonmetric area units
			1-16C	Other area units
1-17	Volume/capacity	cubic meter	1-17A	Units decimally related to one cubic meter
			1-17B	Nonmetric volume units
			1-17C	U.S. liquid capacity measures
			1-17D	British liquid capacity measures
			1-17E	U.S. and U.K. dry capacity measures
			1-17F	Other volume and capacity units
1-18	Mass	kilogram	1-18A	Units decimally related to one kilogram
			1-18B	Less than one pound-mass
			1-18C	One pound-mass and greater
			1-18D	Other mass units
1-19	Time	second	1-19A	One second and less
			1-19B	One second and greater
			1-19C	Other time units
1-20	Velocity	meter per second		
1-21	Density	kilogram per cubic meter	1-21A	Units decimally related to one kilogram per cubic meter
			1-21B	Nonmetric density units
			1-21C	Other density units
1-22	Force	newton		
1-23	Pressure	pascal	1-23A	Units decimally related to one pascal
			1-23B	Units decimally related to one kilogram-force per square meter
			1-23C	Units expressed as heights of liquid
			1-23D	Nonmetric pressure units
1-24	Torque/bending moment	newton meter		
1-25	Energy/work	joule	1-25A	Units decimally related to one joule
			1-25B	Units less than 10 joules
			1-25C	Units greater than 10 joules
1-26	Power	watt	1-26A	Units decimally related to one watt
			1-26B	Nonmetric power units
1-27	Temperature	kelvin		
1-28	Light	candela per square meter	1-28A	Luminance units
		lux	1-28B	Illuminance units

Statements of Equivalence. To avoid ambiguity, the conversion tables have been arranged in the form of statements of equivalence, that is, each unit listed at the left-hand edge of each table is stated to be equivalent to a multiple or fraction of each of the units to the right in the table. For example, the uppermost line of Table 1-15B represents the following statements:

Column 2. 1 meter is equal to 1.093 613 30 yards

Column 3. 1 meter is equal to 3.280 839 89 feet

Column 4. 1 meter is equal to 39.370 078 7 inches

Column 5. 1 meter is equal to $3.937\ 007\ 87 \times 10^4$ mils

Column 6. 1 meter is equal to $3.937\ 007\ 87 \times 10^7$ microinches

1 calendar year = (Gregorian)	31 556 952	525 949.2	8 765.82	365.242 5	52.117 5	**1**

NOTES: The conventional calendar year of 365 days can be used in rough calculations only; the modern calendar is based on the Gregorian year of 365.2425 mean solar days, the value chosen by Pope Gregory XIII in 1582. This value requires that a leap-year day be introduced every four years as February 29, except that centennial years (1900, 2000, etc) are leap years only when divisible by 400. The remaining difference between the Gregorian year and the tropical year (see below) introduces an error of 1 day in 3300 years.

The tropical year is the interval between successive vernal equinoxes and has been defined by the International Astronomical Union for noon of January 1, 1900 as 31 556 925.974 7 seconds = 365.242 198 79 mean solar days. The tropical year decreases by approximately 5.3 milliseconds per year.

The sidereal year is the interval between successive returns of the sun to the direction of the same star. Sidereal time units, given in Table 1-18C, are used primarily in astronomy. The SI second, defined by the atomic process of the cesium atom, is equal to the mean solar second within the limits of their definition.

1 phot (ph) = 1 lumen per square centimeter (lm/cm²).
1 footcandle (fc) = 1 lumen per square foot (lm/ft²).

This table contains similar statements relating the meter, yard, foot, inch, mil, and microinch to each other, that is, conversion factors between the non-SI units as well as to and from the SI unit are given. In all, these tables contain over 1700 such statements. Exact conversion factors are indicated in **boldface** type.

Tabulation Groups. To produce tables that can be contained on individual pages of the handbook, units of a given quantity have been arranged in separate subtabulations identified by capital letters. Each such subtabulation represents a group of units related to each other decimally, by magnitude or by usage. Each subtabulation contains the SI unit,* so equivalent values can be found between units that are tabulated in separate tables. For example, to obtain equivalence between pounds per cubic foot and tonnes per cubic meter, we read from the fourth line of Table 1-21B:

1 pound per cubic foot is equal to 16.018 463 4 kilograms per cubic meter

From the first line of Table 1-21A, we find:

1 kilogram per cubic meter is equal to 0.001 metric ton per cubic meter

Hence,

1 pound per cubic foot is equal to 16.018 463 4 kilograms per cubic meter
= 0.016 018 463 4 metric ton per cubic meter

Use of Conversion Factors. Conversion factors are multipliers used to convert a quantity expressed in a particular unit *(given unit)* to the same quantity expressed in another unit *(desired unit)*. To perform such conversions, the *given unit* is found at the left-hand edge of the conversion table, and the *desired unit* is found at the top of the same table. Suppose, for example, the quantity 1000 feet is to be converted to meters. The given unit, foot, is found in the left-hand edge of the third line of Table 1-15B. The desired unit, meter, is found at the top of the first column in that table. The conversion factor (**0.304 8**, exactly) is located to the right of the given unit and below the desired unit. The given quantity, 1000 feet, is multiplied by the conversion factor to obtain the equivalent length in meters, that is, 1000 feet is $1000 \times 0.304\ 8 = 304.8$ meters.

The general rule is: Find the given unit at the left side of the table in which it appears and the desired unit at the top of the same table; note the conversion factor to the right of the given unit and below the desired unit. Multiply the quantity expressed in the given unit by the conversion factor to find the quantity expressed in the desired unit.

Listings of conversion factors (see Refs. 1 and 7) are often arranged as follows:

To convert from	*To*	*Multiply by*
(Given unit)	(Desired unit)	(Conversion factor)

The equivalences listed in the accompanying conversion tables can be cast in this form by placing the given unit (at the left of each table) under "To convert from," the desired units (at the top of the table) under "To," and the conversion factor, found to the right and below these units, under "Multiply by."

Use of Two Tables to Find Conversion Factors. When the given and desired units do not appear in the same table, the conversion factor between them is found in two steps. The *given unit* is selected at the left-hand edge of the table in which it appears, and an *intermediate conversion factor,* applicable to the SI unit shown at the top of the same table, is recorded. The *desired unit* is then found at the top of another table in which it appears, and another *intermediate conversion factor*, applicable to the SI unit at the left-hand edge of that table, is recorded. The conversion factor between the given and desired units is the product of these two intermediate conversion factors.

*In Tables 1-17C, 1-17D, 1-17E, and 1-18B, a decimal submultiple of the SI unit (the liter and gram, respectively) is listed because it is most commonly used in conjunction with the other units in the respective tables. The procedure for linking the subtables is unchanged.

TABLE 1-29 U.S. Electrical Units Used Prior to 1969, with SI Equivalents

A. Legal units in the U.S. prior to January 1948	
1 ampere (US-INT)	= 0.999 843 ampere (SI)
1 coulomb (US-INT)	= 0.999 843 coulomb (SI)
1 farad (US-INT)	= 0.999 505 farad (SI)
1 henry (US-INT)	= 1.000 495 henry (SI)
1 joule (US-INT)	= 1.000 182 joule (SI)
1 ohm (US-INT)	= 1.000 495 ohm (SI)
1 volt (US-INT)	= 1.000 338 volt (SI)
1 watt (US-INT)	= 1.000 182 watt (SI)
B. Legal units in the U.S. from January 1948 to January 1969	
1 ampere (US-48)	= 1.000 008 ampere (SI)
1 coulomb (US-48)	= 1.000 008 coulomb (SI)
1 farad (US-48)	= 0.999 505 farad (SI)
1 henry (US-48)	= 1.000 495 henry (SI)
1 joule (US-48)	= 1.000 017 joule (SI)
1 ohm (US-48)	= 1.000 495 ohm (SI)
1 volt (US-48)	= 1.000 008 volt (SI)
1 watt (US-48)	= 1.000 017 watt (SI)

For example, it is required to convert 100 cubic feet to the equivalent quantity in cubic centimeters. The given quantity (cubic feet) is found in the fourth line at the left of Table 1-17B. Its intermediate conversion factor with respect to the SI unit is found below the cubic meters to be 2.831 684 66 $\times 10^{-2}$. The desired quantity (cubic centimeters) is found at the top of the third column in Table 1-17A. Its intermediate conversion factor with respect to the SI unit, found under the cubic centimeters and to the right of the cubic meters, is 1 000 000. The conversion factor between cubic feet and cubic centimeters is the product of these two intermediate conversion factors, that is, 1 cubic foot is equal to 2.831 684 66 $\times 10^{-2} \times$ 1 000 000 = 28 316.846 6 cubic centimeters. The conversion from 100 cubic feet to cubic centimeters then yields 100 $\times$ 28 316.846 6 = 2 831 684.66 cubic centimeters.

Conversion of Electrical Units. Since the electrical units in current use are confined to the International System, conversions to or from non-SI units are fortunately not required in modern practice. Conversions to and from the older cgs units, when required, can be performed using the conversions shown in Table 1-9. Slight differences from the SI units occur in the electrical units legally recognized in the United States prior to 1969. These differences involve amounts smaller than that customarily significant in engineering; they are listed in Table 1-29.

2.1 ELECTRIC AND MAGNETIC CIRCUITS

Definition of Electric Circuit. An *electric circuit* is a collection of electrical devices and components connected together for the purpose of processing information or energy in electrical form. An electric circuit may be described mathematically by ordinary differential equations, which may be linear or

*The authors thank Nate Haveman for assisting with manuscript preparation.

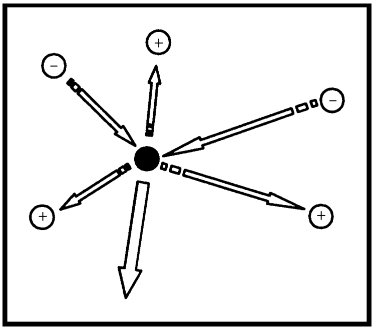

FIGURE 2-1 Electric charges.

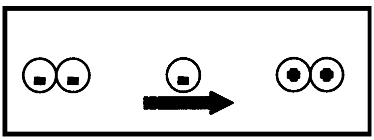

FIGURE 2-2 Electric voltage.

nonlinear, and which may or may not be time varying. The practical effect of this restriction is that the physical dimensions are small compared to the wavelength of electrical signals. Many devices and systems use circuits in their design.

Electric Charge. In circuit theory, we postulate the existence of an indivisible unit of charge. There are two kinds of charge, called *negative* and *positive* charge. The negatively charged particle is called an *electron*. Positive charges may be atoms that have lost electrons, called *ions;* in crystalline structures, electron deficiencies, called *holes,* act as positively charged particles. See Fig. 2-1 for an illustration. In the International System of Units (SI), the unit of charge is the coulomb (C). The charge on one electron is 1.60219×10^{-19} C.

Electric Current. The flow or motion of charged particles is called an *electric current*. In SI units, one of the fundamental units is the ampere (A). The definition is such that a charge flow rate of 1 A is equivalent to 1 C/s. By convention, we speak of current as the flow of positive charges. See Fig. 2-2 for an illustration. When it is necessary to consider the flow of negative charges, we use appropriate modifiers. In an electric circuit, it is necessary to control the path of current flow so that the device operates as intended.

Voltage. The motion of charged particles either requires the expenditure of energy or is accompanied by the release of energy. The voltage, at a point in space, is defined as the work per unit charge (joules/coulomb) required to move a charge from a point of zero voltage to the point in question.

Magnetic and Dielectric Circuits. Magnetic and electric fields may be controlled by suitable arrangements of appropriate materials. Magnetic examples include the magnetic fields of motors, generators, and tape recorders. Dielectric examples include certain types of microphones. The fields themselves are called *fluxes* or *flux fields*. Magnetic fields are developed by magnetomotive forces. Electric fields are developed by voltages (also called *electromotive forces,* a term that is now less common). As with electric circuits, the dimensions for dielectric and magnetic circuits are small compared to a wavelength. In practice, the circuits are frequently nonlinear. It is also desired to confine the magnetic or electric flux to a prescribed path.

2.1.1 Development of Voltage and Current

Sources of Voltage or Electric Potential Difference. A voltage is caused by the separation of opposite electric charges and represents the work per unit charge (joules/coulomb) required to move the charges from one point to the other. This separation may be forced by physical motion, or it may be initiated or complemented by thermal, chemical, magnetic, or radiation causes. A convenient classification of these causes is as follows:

a. Friction between dissimilar substances
b. Contact of dissimilar substances
c. Thermoelectric action
d. Hall effect
e. Electromagnetic induction
f. Photoelectric effect
g. Chemical action

Voltage Effect or Contact Potential. When pieces of various materials are brought into contact, a voltage is developed between them. If the materials are zinc and copper, zinc becomes charged positively and copper negatively. According to the electron theory, different substances possess different tendencies to give up their negatively charged particles. Zinc gives them up easily, and thus, a number of negatively charged particles pass from it to copper. Measurable voltages are observed even between two pieces of the same substance having different structures, for example, between pieces of cast copper and electrolytic copper.

Thomson Effect. A temperature gradient in a metallic conductor is accompanied by a small voltage gradient whose magnitude and direction depend on the particular metal. When an electric current flows, there is an evolution or absorption of heat due to the presence of the thermoelectric gradient, with the net result that the heat evolved in a volume interval bounded by different temperatures is slightly greater or less than that accounted for by the resistance of the conductor. In copper, the evolution of heat is greater when the current flows from hot to cold parts, and less when the current flows from cold to hot. In iron, the effect is the reverse. Discovery of this phenomenon in 1854 is credited to Sir William Thomson (Lord Kelvin), an English physicist.

The Thomson effect is defined by

$$q = \rho J^2 - \mu J \frac{dT}{dx}$$

where q is the heat production per unit volume, ρ is the resistivity of the material, J is the current density, μ is the Thomson coefficient, and dx/dT is the temperature gradient.

Peltier Effect. When a current is passed across the junction between two different metals, an evolution or an absorption of heat takes place. This effect is different from the evolution of heat described by ohmic (i^2r) losses. This effect is reversible, heat being evolved when current passes one way across the junction, and absorbed when the current passes in the opposite direction. The junction is the source of a Peltier voltage. When current is forced across the junction against the direction of the voltage, a heating action occurs. If the current is forced in the direction of the Peltier voltage, the junction is cooled. Refrigerators are constructed using this principle. Since the Joule effect (see Sec. 2.1.8) produces heat in the conductors leading to the junction, the Peltier cooling must be greater than the Joule effect in that region for refrigeration to be successful. This phenomenon was discovered by Jean Peltier, a French physicist, in 1834.

The Peltier effect is defined by

$$Q = \prod_{AB} . I$$

where Q is the heat absorption per unit time, $Q = \prod_{AB}$ is the Peltier coefficient, and I is the current.

Seebeck Effect. When a closed electric circuit is made from two different metals, two (or more) junctions will be present. If these junctions are maintained at different temperatures, within certain ranges, an electric current flows. If the metals are iron and copper, and if one junction is kept in ice while the other is kept in boiling water, current passes from copper to iron across the hot junction. The resulting device is called a *thermocouple,* and these devices find wide application in temperature measurement systems. This phenomenon was discovered in 1821 by Thomas Johann Seebeck.

The Seebeck effect is defined by

$$V = \int_{T_1}^{T_2} S_B(T) - S_A(T)dT$$

where V is the voltage created, S is the Seebeck coefficient, and T is the temperature at the junction.

The Thomson, Peltier, and Seebeck equations are related by

$$\prod = S \cdot T$$

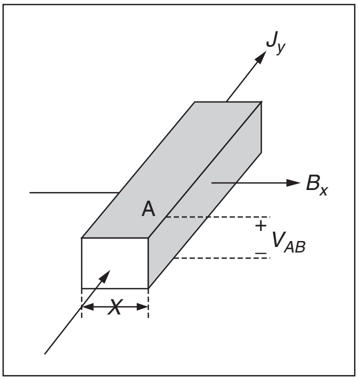

FIGURE 2-3 Hall-effect model.

Hall Effect. When a conductor carrying a current is inserted into a magnetic field that is perpendicular to the field, a force is exerted on the charged particles that constitute the current. The result is that the particles will be forced to the side of the conductor, leading to a buildup of positive charge on one side and negative charge on the other. This appears as a voltage across the conductor, given by

$$V_{AB} = -\frac{J_y B_x x}{en} = -vB_x x \tag{2-1}$$

where x is width of the conductor, B_x is magnetic field strength, J_y is current density, n is charge density, e is electronic charge, and v is velocity of charge flow.

This phenomenon is useful in the measurement of magnetic fields and in the determination of properties and characteristics of semiconductors, where the voltages are much larger than in conductors. See Fig. 2-3. This effect was discovered in 1879.

Faraday's Law of Induction. According to Faraday's law, in any closed linear path in space, when the magnetic flux ϕ (see Sec. 2.1.2) surrounded by the path varies with time, a voltage is induced around the path equal to the negative rate of change of the flux in webers per second.

$$V = -\frac{\partial \phi}{\partial t} \qquad \text{volts} \tag{2-2}$$

The minus sign denotes that the direction of the induced voltage is such as to produce a current opposing the flux. If the flux is changing at a constant rate, the voltage is numerically equal to the increase or decrease in webers in 1 s.

The closed linear path (or circuit) is the boundary of a surface and is a geometric line having length but infinitesimal thickness and not having branches in parallel. It can vary in shape or position.

If a loop of wire of negligible cross section occupies the same place and has the same motion as the path just considered, the voltage v will tend to drive a current of electricity around the wire, and this voltage can be measured by a galvanometer or voltmeter connected in the loop of wire. As with the path, the loop of wire is not to have branches in parallel; if it has, the problem of calculating the voltage shown by an instrument is more complicated and involves the resistances of the branches.

For accurate results, the simple Eq. (2-2) cannot be applied to metallic circuits having finite cross section. In some cases, the finite conductor can be considered as being divided into a large number of filaments connected in parallel, each having its own induced voltage and its own resistance. In other cases, such as the common ones of D.C. generators and motors and homopolar generators, where there are sliding and moving contacts between conductors of finite cross section, the induced voltage between neighboring points is to be calculated for various parts of the conductors. These can then be summed up or integrated. For methods of computing the induced voltage between two points, see text on electromagnetic theory.

In cases such as a D.C. machine or a homopolar generator, there may at all times be a conducting path for current to flow, and this may be called a *circuit,* but it is not a closed linear circuit without parallel branches and of infinitesimal cross section, and therefore, Eq. (2-2) does not strictly apply to such a circuit in its entirety, even though, approximately correct numerical results can sometimes be obtained.

If such a practical circuit or current path is made to enclose more magnetic flux by a process of connecting one parallel branch conductor in place of another, then such a change in enclosed flux does not correspond to a voltage according to Eq. (2-2). Although it is possible in some cases to describe a loop of wire having infinitesimal cross section and sliding contacts for which Eq. (2-2) gives correct numerical results, the equation is not reliable, without qualification, for cases of finite cross section and sliding contacts. It is advisable not to use equations involving $\partial\phi/\partial t$ directly on complete circuits where there are sliding or moving contacts.

Where there are no sliding or moving contacts, if a coil has N turns of wire in series closely wound together so that the cross section of the coil is negligible compared with the area enclosed by the coil, or if the flux is so confined within an iron core that it is enclosed by all N turns alike, the voltage induced in the coil is

$$V = -N\frac{\partial \phi}{\partial t} \qquad \text{volts} \tag{2-3}$$

In such a case, $N\phi$ is called the *number of interlinkages of lines of magnetic flux with the coil,* or simply, the *flux linkage*.

For the preceding equations, the change in flux may be due to relative motion between the coil and the magnetomotive force (mmf, the agent producing the flux), as in a rotating-field generator; it may be due to change in the reluctance of the magnetic circuit, as in an inductor-type alternator or microphone, variations in the primary current producing the flux, as in a transformer, variations in the current in the secondary coil itself, or due to change in shape or orientation of the loop of coil. For further study, refer to the Web site http://www.lectureonline.cl.msu.edu/~mmp/applist/induct/ faraday.htm.

2.1.2 Magnetic Fields

Early Concepts of Magnetic Poles. Substances now called *magnetic,* such as iron, were observed centuries ago as exhibiting forces on one another. From this beginning, the concept of magnetic poles evolved, and a quantitative theory built on the concept of these poles, or small regions of magnetic influence, was developed. André-Marie Ampère observed forces of a similar nature between conductors carrying currents. Further developments have shown that all theories of magnetic materials can be developed and explained through the magnetic effects produced by electric charge motions. Magnetic fields may be seen in Fig. 2-4.

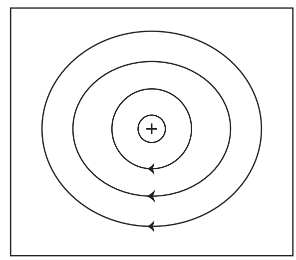

FIGURE 2-4 Magnetic fields.

Ampere's Formula. The magnetic field intensity dB produced at a point A by an element of a conductor ds (in meters) through which there is a current of i A is

$$dH = i\,ds\left(\frac{\sin\alpha}{4\pi r^2}\right) \qquad \text{A/m} \tag{2-4}$$

where r is the distance between the element ds and the point A, in meters, and α is the angle between the directions of ds and r. The intensity dH is perpendicular to the plane containing ds and r, and its direction is determined by the right-handed-screw rule given in Fig. 2-45.

The magnetic lines of force due to ds are concentric circles about the straight line in which ds lies. The field intensity produced at A by a closed circuit is obtained by integrating the expression for dH over the whole circuit.

An Indefinitely Long, Straight Conductor. The magnetic field due to an indefinitely long, straight conductor carrying a current of i A consists of concentric circles which lie in planes perpendicular to the axis of the conductor and have their centers on this axis. The magnetic field intensity at a distance of r m from the axis of the conductor is

$$H = \frac{i}{2\pi r} \qquad \text{A/m} \tag{2-5}$$

its direction being determined by the right-handed-screw rule (Sec. 2.1.22). See Fig. 2-5 for an illustration.

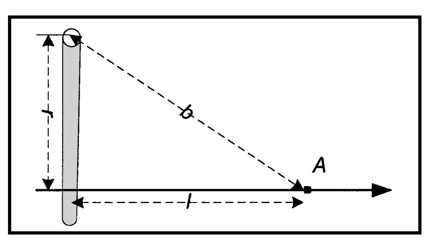

FIGURE 2-5 Magnetic field along the axis of a circular conductor.

Magnetic Field in Air Due to a Closed Circular Conductor. If the conductor carrying a current of i A is bent in the form of a ring of radius r m (Fig. 2-5), the magnetic field intensity at a point along the axis at a distance b m from the ring is

$$H = \frac{r^2 i}{2b^3} = \frac{r^2 i}{2(r^2 + l^2)^{3/2}} \qquad \text{A/m} \tag{2-6}$$

When $l = 0$,

$$H = \frac{i}{2r} \tag{2-7}$$

and when l is very great in comparison with r,

$$H = \frac{r^2 i}{2l^3} \tag{2-8}$$

Within a Solenoid. The magnetic field intensity within a solenoid made in the form of a *torus ring,* and also in the middle part of a *long, straight solenoid,* is approximately

$$H = n_1 i \qquad \text{A/m} \tag{2-9}$$

where i is the current in amperes and n_1 is the number of turns per meter length.

Magnetic Flux Density. The magnetic flux density resulting in free space, or in substances not possessing magnetic behaviors differing from those in free space, is

$$B = \mu H = 4\pi \times 10^{-7} H \tag{2-10}$$

where B is in teslas (or webers per square meter), H is in amperes per meter, and the constant $\mu_0 = 4\pi \times 10^{-7}$ is the *permeability* of free space and has units of henrys per meter. In the so-called practical system of units, the flux density is frequently expressed in *lines* or *maxwell per square inch*. The maxwell per square centimeter is called the *gauss*.

For substances such as iron and other materials possessing magnetic density effects greater than those of free space, a term μ_r is added to the relationship as

$$B = 4\pi \times 10^{-7} \mu_r H \tag{2-11}$$

where μ_r is the relative permeability of that substance under the conditions existing in it compared with that which would result in free space under the same magnetic-field-intensity condition. μ_r is a dimensionless quantity.

Magnetic Flux. The magnetic flux in any cross section of magnetic field is

$$\phi = \int B \cos \alpha dA \qquad \text{webers} \tag{2-12}$$

where α is the angle between the direction of the magnetic flux density B and the normal at each point to the surface over which A is measured. In the so-called practical system of units, the magnetic *line* (or *maxwell*) is frequently used, where 1 Wb is equivalent to 103 lines.

Density of Magnetic Energy. The magnetic energy stored per cubic meter of a magnetic field in free space is

$$\frac{dW}{dv} = \frac{1}{2}\mu_0 H^2 = 2\pi \times 10^{-7} H^2 = \frac{B^2}{2\mu_0} = \frac{B^2}{8\pi \times 10^{-7}} \qquad \text{J/m}^3 \tag{2-13}$$

In magnetic materials, the energy density stored in a magnetic field as a result of a change from a condition of flux density B_1 to that of B_2 can be expressed as

$$dW/dt = \int_{B_1}^{B_2} HdB \qquad (2\text{-}14)$$

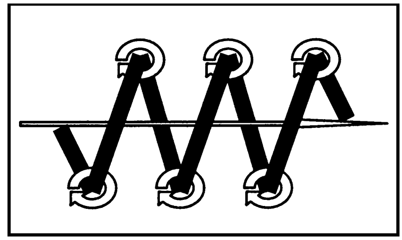

FIGURE 2-6 Magnetic field.

Flux Plotting. Flux plotting by a graphic process is useful for determining the properties of magnetic and other fields in air. The field of flux required is usually uniform along one dimension, and a cross section of it is drawn. The field is usually required between two essentially equal magnetic potential lines such as two iron surfaces. The field map consists of lines of force and equipotential lines which must intersect at right angles. For the graphic method, a field map of curvilinear squares is recommended when the problem is two dimensional. The squares are of different sizes, but the number of lines of force crossing every square is the same.

In sketching the field map, first draw those lines which can be drawn by symmetry. If parts of the two equipotential lines are straight and parallel to each other, the field map in the space between them will consist of lines which are practically straight, parallel, and equidistant. These can be drawn in. Then extend the series of curvilinear squares into other parts of the field, making sure, first, that all the angles are right angles and, second, that in each square the two diameters are equal, except in regions where the squares are evidently distorted, as near sharp comers of iron or regions occupied by current-carrying conductors. The diameters of a curvilinear square may be taken to be the distances between midpoints of opposite sides. An example of flux plotting may be seen in Fig. 2-6.

The magnetic field map near an iron comers is drawn as if the iron had a small fillet, that is, a line issues from an angle of 90° at 45° to the surface.

Inside a conductor which carries current, the magnetic field map is not made up of curvilinear squares, as in free space or air. In such cases, special rules for the spacing of the lines must be used. The equipotential lines converge to a point called the *kernel*.

Computer-based methods are now commonly available to do the detailed work, but the principles are unchanged.

2.1.3 Force Acting on Conductors

Force on a Conductor Carrying a Current in a Magnetic Field. Let a conductor of length l m carrying a current of i A be placed in a magnetic field, the density of which is B in teslas. The force tending to move the conductor across the field is

$$F = Bli \qquad \text{newtons} \qquad (2\text{-}15)$$

This formula presupposes that the direction of the axis of the conductor is at right angle to the direction of the field. If the directions of i and B form an angle α, the expression must be multiplied by sin α.

The force F is perpendicular to both i and B, and its direction is determined by the right-handed-screw rule. The effect of the magnetic field produced by the conductor itself is increase in the original flux density B on one side of the conductor and decrease on the other side. The conductor tends to move away from the denser field. A closed metallic circuit carrying current tends to move so as to enclose the greatest possible number of lines of magnetic force.

Force between Two Long, Straight Lines of Current. The force on a unit length of either of two long, straight, parallel conductors carrying currents of medium (that is, not near masses of iron) is

$$\frac{F}{L} = \frac{2 \times 10^{-7} i_1 i_2}{b} \qquad (2\text{-}16)$$

where F is in newtons and L (length of the long wires) and b (the spacing between them) are in the same units, such as meters.

The force is an attraction or a repulsion according to whether the two currents are flowing in the same or in opposite directions. If the currents are alternating, the force is pulsating. If i_1 and i_2 are effective values, as measured by A.C. ammeters, the maximum momentary value of the force may be as much as 100% greater than given by Eq. (2-16). The natural frequency (resonance) of mechanical vibration of the conductors may add still further to the maximum force, so a factor of safety should be used in connection with Eq. (2-16) for calculating stresses on bus bars.

If the conductors are straps, as is usual in bus bars, the following form of equation results for thin straps placed parallel to each other, b m apart:

$$\frac{F}{L} = \frac{2 \times 10^{-7} i_1 i_2}{s^2}\left(2s \tan^{-1}\frac{s}{b} - b\log_e \frac{s^2 + b^2}{b^2}\right) \qquad \text{N/m} \qquad (2\text{-}17)$$

where s is the dimension of the strap width in meters, and the thickness of the straps placed side by side is presumed small with respect to the distance b between them.

Pinch Effect. Mechanical force exerted between the magnetic flux and a current-carrying conductor is also present within the conductor itself and is called *pinch effect*. The force between the infinitesimal filaments of the conductor is an attraction, so a current in a conductor tends to contract the conductor. This effect is of importance in some types of electric furnaces where it limits the current that can be carried by a molten conductor. This stress also tends to elongate a liquid conductor.

2.1.4 Components, Properties, and Materials

Conductors, Semiconductors, and Insulators. An important property of a material used in electric circuits is its conductivity, which is a measure of its ability to conduct electricity. The definition of conductivity is

$$\sigma = J/E \qquad (2\text{-}18)$$

where J is current density, A/m^2, and E is electric field intensity, V/m.

The units of conductivity are thus the reciprocal of ohm-meter or siemens/meter. Typical values of conductivity for good conductors are 1000 to 6000 S/m. The reciprocal of conductivity is called *resistivity*. Section 4 gives extensive tabulations of the actual values for many different materials. Copper and aluminum are the materials usually used for distribution of electric energy and information. Semiconductors are a class of materials whose conductivity is in the range of 1 mS/m, though this number varies by orders of magnitude up and down. Semiconductors are produced by careful and precise modifications of pure crystals of germanium, silicon, gallium arsenide, and other materials. They form the basic building block for semiconductor diodes, transistors, silicon-controlled rectifiers, and integrated circuits. See Sec. 4.

Insulators (more accurately, dielectrics) are materials whose primary electrical function is to prevent current flow. These materials have conductivities of the order of nanosiemens/meter. Most insulating materials have nonlinear properties, being good insulators at sufficiently low electric field intensities and temperatures but breaking down at higher field strengths and temperatures. Figure 2-7 shows the energy levels of different materials. See Sec. 4 for extensive tabulations of insulating properties.

Gaseous Conduction. A gas is usually a good insulator until it is ionized, which means that electrons are removed from molecules. The electrons are then available for conduction. Ionized gases are good conductors. Ionization can occur through raising temperature, bringing the gas into contact with glowing metals, arcs, or flames, or by an electric current.

Electrolytes. In liquid chemical compounds known as *electrolytes,* the passage of an electric current is accompanied by a chemical change. Atoms of metals and hydrogen travel through the liquid in the direction of positive current, while oxygen and acid radicals travel in the direction of electron current. Electrolytic conduction is discussed fully in Sec. 24.

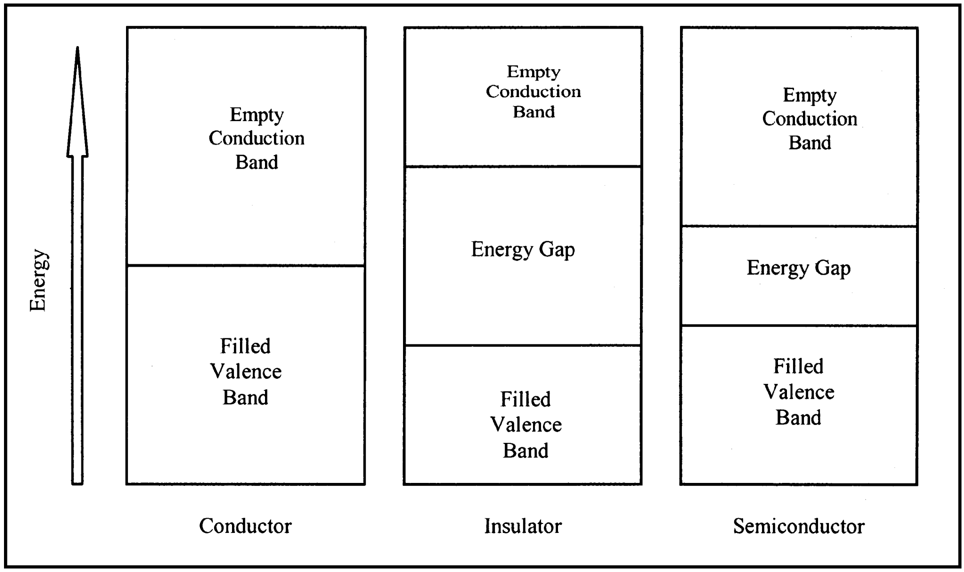

FIGURE 2-7 Component energy levels.

2.1.5 Resistors and Resistance

Resistors. A resistor is an electrical component or device designed explicitly to have a certain magnitude of resistance, expressed in ohms. Further, it must operate reliably in its environment, including electric field intensity, temperature, humidity, radiation, and other effects. Some resistors are designed explicitly to convert electric energy to heat energy. Others are used in control circuits, where they modify electric signals and energy to achieve desired effects. Examples include motor-starting resistors and the resistors used in electronic amplifiers to control the overall gain and other characteristics of the amplifier. A picture of a resistor may be seen in Fig. 2-8.

Ohm's Law. When the current in a conductor is steady and there are no voltages within the conductor, the value of the voltage v between the terminals of the conductor is proportional to the current i, or

$$v = ri \tag{2-19}$$

An example of Ohm's law may be seen in Fig. 2-9, where the coefficient of proportionality r is called the *resistance* of the conductor. The same law may be written in the form

$$i = gv \tag{2-20}$$

where the coefficient of proportionality $g = 1/r$ is called the *conductance* of the conductor. When the current is measured in amperes and the voltage in volts, the resistance r is in ohms and g is in siemens (often called mhos for reciprocal ohms). The phase of a resistor may be seen in Fig. 2-10.

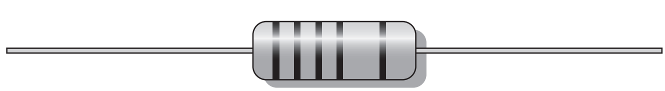

FIGURE 2-8 Resistor.

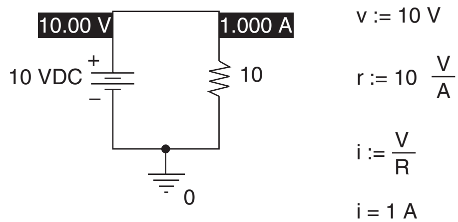

FIGURE 2-9 Ohm's law.

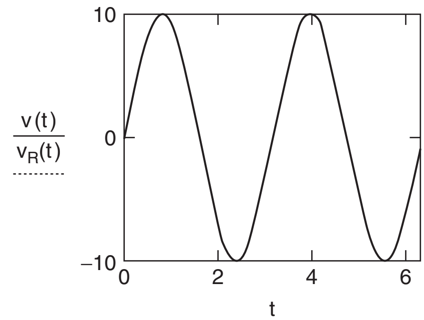

FIGURE 2-10 Phase of resistor.

Cylindrical Conductors. For current directed along the axis of the cylinder, the resistance r is proportional to the length l and inversely proportional to the cross section A, or

$$r = \rho \frac{l}{A} \tag{2-21}$$

where the coefficient of proportionality ρ (rho) is called the *resistivity* (or *specific resistance*) of the material. For numerical values of ρ for various materials, see Sec. 4.

The conductance of a cylindrical conductor is

$$g = \sigma \frac{A}{l} \tag{2-22}$$

where σ (sigma) is called the *conductivity* of the material. Since $g = 1/r$, the relation also holds that

$$\sigma = \frac{1}{\rho} \tag{2-23}$$

Changes of Resistance with Temperature. The resistance of a conductor varies with the temperature. The resistance of metals and most alloys increases with the temperature, while the resistance of carbon and electrolytes decreases with the temperature.

For usual conditions, as for about 100°C change in temperature, the resistance at a temperature t_2 is given by

$$R_{t_2} = R_{t_1}\left[1 + \alpha_{t_1}(t_2 - t_1)\right] \tag{2-24}$$

where R_{t_1} is the resistance at an initial temperature t, and α_{t_1} is called the *temperature coefficient of resistance* of the material for the initial temperature t_1. For copper having a conductivity of 100% of the International Annealed Copper Standard, $\alpha_{20} = 0.00393$, where temperatures are in degree Celsius (see Sec. 4).

An equation giving the same results as Eq. (2-24), for copper of 100% conductivity, is

$$\frac{R_{t_2}}{R_{t_2}} = \frac{234.4 + t_2}{234.4 + t_1} \tag{2-25}$$

where -234.4 is called the *inferred absolute zero* because if the relation held (which it does not over such a large range), the resistance at that temperature would be zero. For hard-drawn copper of 97.3% conductivity, the numerical constant in Eq. (2-25) is changed to 241.5. See Sec. 4 for values of these numerical constants for copper, and for other metals, see Sec. 4 under the metal being considered.

FIGURE 2-11 Inductor.

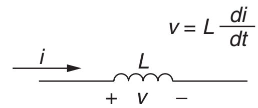

FIGURE 2-12 Inductor model and defining equation.

For 100% conductivity copper,

$$a_{t_1} = \frac{1}{234.4 + t_1} \tag{2-26}$$

When R_{t_1} and R_{t_2} have been measured, as at the beginning and end of a heat run, the "temperature rise by resistance" for 100% conductivity copper is given by

$$t_2 - t_1 = \frac{R_{t_2} - R_{t_1}}{R_{t_1}}(234.4 + t_1) \tag{2-27}$$

2.1.6 Inductors and Inductance

Inductors. An inductor is a circuit element whose behavior is described by the fact that it stores electromagnetic energy in its magnetic field. This feature gives it many interesting and valuable characteristics. In its most elementary form, an inductor is formed by winding a coil of wire, often copper, around a form that may or may not contain ferromagnetic materials. In this section, the behavior of the device at its terminal is discussed. Later, in the sections, on magnetic circuits, the device itself will be discussed. A picture of an inductor may be seen in Fig. 2-11.

Inductance. The property of the inductor that is useful in circuit analysis is called *inductance*. Inductance may be defined by either of the following equations:

$$v = L\frac{di}{dt} \qquad i = \frac{1}{L}\int_0^t v(\tau)d\tau + i(0) \tag{2-28}$$

or

$$W = \frac{1}{2}Li^2 \tag{2-29}$$

where L = coefficient of self-inductance
i = current through the coil of wire
v = voltage across the inductor terminals
W = energy stored in the magnetic field

Figure 2-12 shows the symbol for an inductor and the voltage-current relationship for the device. The unit of inductance is called the *henry* (H), in honor of American physicist Joseph Henry.

The phase of an inductor may be seen in Fig. 2-13.

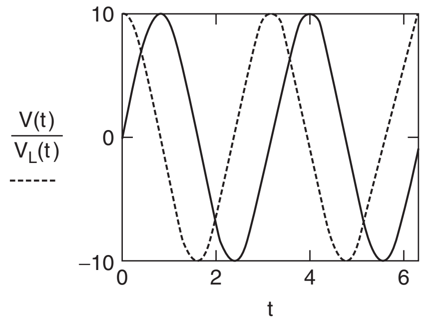

FIGURE 2-13 Phase of inductor.

Mutual Inductance. If two coils are wound on the same coil form, or if they exist in close proximity, then a changing current in one coil will induce a voltage in the second coil. This effect forms the basis for transformers, one of the most pervasive of all electrical

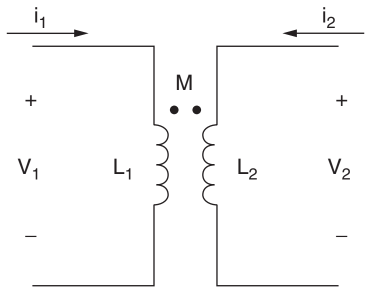

FIGURE 2-14 Mutual inductance model.

devices in use. Figure 2-14 shows the symbolic representation of a pair of coupled coils. The dots represent the direction of winding of the coils on the coil form in relation to the current and voltage reference directions. The equations become

$$v_1 = L_1\frac{di_1}{dt} + M\frac{di_2}{dt}$$
$$v_2 = M\frac{di_1}{dt} + L_2\frac{di_2}{dt} \tag{2-30}$$

Mutual inductance also can be a source of problems in electrical systems. One example is the problem, now largely solved, of cross talk from one telephone line to another.

2.1.7 Capacitors and Capacitance

Charge Storage. A capacitor is a circuit element that is described through its principal function, which is to store electric energy. This property is called *capacitance*. In its simplest form, a capacitor is built with two conducting plates separated by a dielectric. A picture of a conductor may be seen in Fig. 2-15. Figure 2-16 shows the two usual symbols for a capacitor and the defining directions for voltage and current. These equations further describe the capacitor.

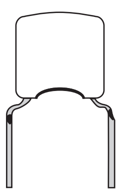

FIGURE 2-15 Capacitor.

$$i = C\frac{dv}{dt} \quad v(t) = \frac{1}{C}\int_0^t i(\tau)d\tau + v(0) \tag{2-31}$$

or

$$W = \frac{1}{2}Cv^2 \tag{2-32}$$

where W = energy stored in the capacitor
τ = dummy variable representing time
C = capacitance in farads

The unit of capacitance is the farad (F), named in honor of English physicist Michael Faraday.
The phase of a capacitor may be seen in Fig. 2-17.

2.1.8 Power and Energy

Power. The power delivered by an electrical source to an electrical device is given by

$$p(t) = v(t)i(t) \tag{2-33}$$

where p = power delivered
v = voltage across the device
i = current delivered to the device

The choice of algebraic sign is important. See Fig. 2-18*a*.

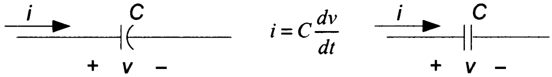

FIGURE 2-16 Capacitor-two symbols and defining equation.

If the device is a resistor, then the power delivered to the device is

$$p(t) = v(t)i(t) = i^2(t)R = \frac{v^2(t)}{R} \qquad (2\text{-}34)$$

an equation known as *Joule's law*. In SI units, the unit of power is the watt (W), in honor of eighteenth century Scottish engineer James Watt.

Energy. The energy delivered by an electrical source to an electrical device is given by

$$W = \int_{t_1}^{t_2} v(t)i(t)dt \qquad (2\text{-}35)$$

where the times t_1 and t_2 represent the starting and ending times of the energy delivery. In SI units, the unit of energy is the joule (J), in honor of English physicist James Joule. Power and energy are also related by the equation

$$p(t) = \frac{dW(t)}{dt} \qquad (2\text{-}36)$$

A commonly used unit for electric energy measurement is a kilowatthour (kWh), which is equal to 3.6×10^6 joules.

Energy Density and Power Density. At times it is useful to evaluate materials and media by comparing their energy storage capability on a unit volume basis. The SI unit is joules per cubic meter, though conversion to other convenient combinations of units is possible. Power density is often an important consideration in, for example, heat or energy flow. The SI unit is watts per square meter, although any convenient unit system can be used.

2.1.9 Physical Laws for Electric and Magnetic Circuits

Maxwell's Equations. Throughout much of the nineteenth century, engineers and physicists developed the theories that describe electricity and magnetism and their interrelations. In contemporary vector calculus notation, four equations can be written to describe the basic theory of electromagnetic fields. Collectively, they are known as *Maxwell's equations*, recognizing the work of James Clerk Maxwell's, a Scottish physicist, who solidified the theory. (Some writers consider only the first two as Maxwell's equations, calling the last two as supplementary equations.) The following symbols will be used in the description of Maxwell's equations:

E electric field intensity	*vol* (or V) enclosed volume in space
D electric flux density	L length of boundary around a surface
H magnetic field intensity	ρ electric charge density per unit volume
B magnetic flux density	J electric current density

Faraday's Law. Faraday observed that a time-varying magnetic field develops a voltage that can be observed and measured. This law is the basis for inductors. One common form of expressing the law is the equation

$$v = -\frac{\partial \phi}{\partial t}$$

where v is the voltage induced by the changing flux. The negative sign expresses the principle of conservation of energy, indicating that the direction of the voltage is such as to oppose the changing flux. This effect is known as *Lenz's law*.

In vector calculus notation, Faraday's law can be written in both integral and differential form. In integral form, the equation is

$$\oint EdL = \int_s \frac{\partial B}{\partial t} dS$$

where the line integral completely encircles the surface over which the surface integral is taken. In differential (point) form, Faraday's law becomes

$$\nabla \times E = -\frac{\partial B}{\partial t} \tag{2-37}$$

Ampere's Law. French physicist André-Marie Ampère developed the relation between magnetic field intensity and electric current that is a dual of Faraday's law. The current consists of two components, a steady or constant component and a time-varying component usually called *displacement current*. In vector calculus notation, Ampere's law is written first in integral form and then in differential form:

$$\oint HdL = I + \int_s \frac{dD}{dt} dS \tag{2-38}$$

$$\nabla \times H = J + \frac{\partial D}{\partial t} \tag{2-39}$$

An illustration of Ampere's law may be seen in Fig. 2-19. For more information, please refer to the Web site http://www.ee.byu.edu./em/amplaw2.htm.

Gauss's Law. Carl F. Gauss, a German physicist, stated the principle that the displacement current flowing over the surface of a region (volume) in space is equal to the charge enclosed. In integral and differential form, respectively, this law is written

$$\oint_s DdS = \int_{\text{vol}} \rho dv \tag{2-40}$$

$$\nabla \cdot D = \rho \tag{2-41}$$

For further study, please refer to the Web site http://www.ee.byu.edu/ee/em/eleclaw.htm.

An illustration of Gauss's law may be seen in Fig. 2-20.

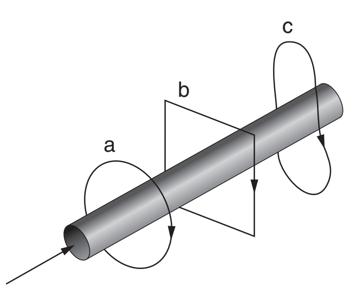

FIGURE 2-19 Ampere's law illustration.

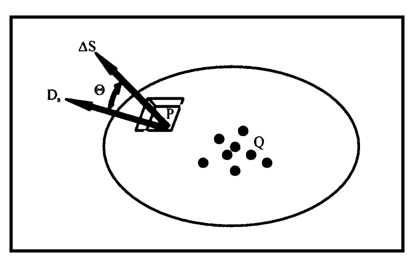

FIGURE 2-20 Gauss's law illustration.

Gauss's Law for Magnetics. One of the postulates of electromagnetism is that there are no free magnetic charges but these charges always exist in pairs. While searches are continually being made, and some claims of discovery of free charges have been made, the postulate is still adequate to explain observations in cases of interest here. A consequence of this postulate is that, for magnetics, Gauss's law become

$$\oint_s BdS = 0 \tag{2-42}$$

$$\nabla \cdot B = 0 \tag{2-43}$$

Kirchhoff's Laws. In the analysis and design of electric circuits, a fundamental principle implies that the dimensions are small. This means that it is possible to neglect the spatial variations in electromagnetic quantities. Another way of saying this is that the dimensions of the circuit are small compared with the wavelengths of the electromagnetic quantities and thus that it is necessary to consider only time variations. This means that Maxwell's equations, which are partial integrodifferential equations, become ordinary integrodifferential equations in which the independent variable is time, represented by t.

Kirchhoff's Current Law. The assumption of small dimensions means that no free electric charges can exist in the region in which a circuit is being analyzed. Thus, Gauss's law (in integral form) becomes

$$\sum i = 0 \tag{2-44}$$

at any point in the circuit. The points of interest usually will be *nodes,* points at which three or more wires connect circuit elements together. This law will be abbreviated KCL and was enunciated by German physicist, Gustav Robert Kirchhoff. It is one of the two fundamental principles of circuit analysis. Figure 2-21 shows a sample circuit simulated in PSPICE. We can see the current flowing through the 3 Ω resistor (3.5 A) is equal to the sum of the current flowing through the 6 Ω resistor (1.5 A) and the current flowing through the 1.5 Ω resistor (2 A).

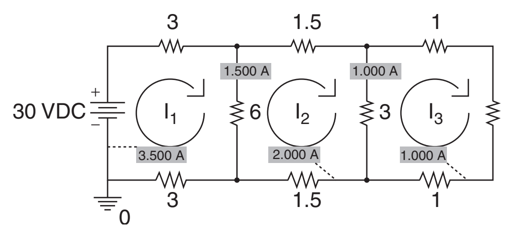

FIGURE 2-21 Kirchhoff's current law.

Kirchhoff's Voltage Law. The second fundamental principle, abbreviated KVL, follows from applying the assumption of small size to Faraday's law in integral form. Since the circuit is small, it is possible to take the surface integral of magnetic flux density as zero and then to state that the sum of voltages around any closed path is zero. In equation form, it can be written as

$$\sum v = 0 \tag{2-45}$$

Figure 2-22 shows a sample circuit simulated in PSPICE. We have

$$\sum V = V_{0->V_1} + V_{V_1->V_2} + V_{V_2->V_7} + V_{V_7->0} = -30 + 10.5 + 9 + 10.5 = 0$$

2.1.10 Electric Energy Sources and Representations

Sources. In circuit analysis, the goal is to start with a connected set of circuit elements such as resistors, capacitors, operational amplifiers, and other devices, and to find the voltages across and currents through each element, additional quantities, such as power dissipated, are often computed. To energize the circuit, sources of electric energy must be connected. Sources are modeled in various ways.

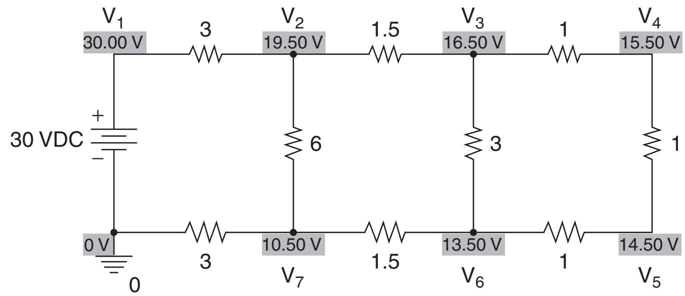

FIGURE 2-22 Kirchhoff's voltage law.

One convenient classification is to consider constant (dc) sources, sinusoidal (ac) sources, and general time-varying sources. The first two are of interest in this section.

DC Sources. Some sources, such as batteries, deliver electric energy at a nearly constant voltage, and thus they are modeled as constant voltage sources. The term *dc sources* basically means *direct-current sources,* but it has come to stand for constant sources as well. Figure 2-23 shows the standard symbol for a dc source. Other sources are modeled as dc current (or constant-current) sources. Figure 2-18*b* and *c* show the symbols used for these models.

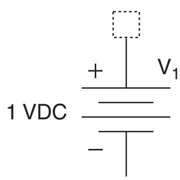

FIGURE 2-23 D.C. source.

AC Sources. Most of the electric energy used in the world is generated, distributed, and utilized in sinusoidal form. Thus, beginning with Charles P. Steinmetz, a German-American electrical engineer, much effort has been devoted to finding efficient ways to analyze and design circuits that operate under sinusoidal excitation conditions. Sources of this type are frequently called ac (for alternating current) sources. Figure 2-24 shows the standard symbol for an ac source. The most general expression for a voltage in sinusoidal form is of the type

$$v(t) = V_m \cos(2\pi ft + \alpha) = V_m \cos(\omega t + \alpha) \tag{2-46}$$

and, for a current

$$i(t) = I_m \cos(2\pi ft + \beta) = I_m \cos(\omega t + \beta) \tag{2-47}$$

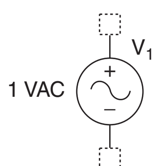

FIGURE 2-24 AC source.

Some writers use sine functions instead of cosine functions, but this has only the effect of changing the angles α and β.

These expressions have three identifying characteristics, the maximum or peak value (V_m or I_m), the phase angle (α or β), and the frequency [f, measured in hertz (Hz) or cycles per second, or ω, measured in radians/second]. A powerful method of circuit analysis depends on these observations. It is called *phasor analysis*.

2.1.11 Phasor Analysis

The Imaginary Operator. A term that arises frequently in phasor analysis is the imaginary operator

$$j = \sqrt{-1} \tag{2-48}$$

(Electrical engineers use j, since i is reserved as the symbol for current. Mathematicians, physicists, and others are more likely to use i for the imaginary operator.)

Euler's Relation. A relationship between trigonometric and exponential functions, known as *Euler's relation*, plays an important role in phasor analysis. The equation is

$$e^{jx} = \cos x + j\sin x \tag{2-49}$$

If this equation is solved for the trigonometic terms, the result is

$$\cos x = \frac{e^{jx} + e^{-jx}}{2} \tag{2-50}$$

$$\sin x = \frac{e^{jx} - e^{-jx}}{2} \tag{2-51}$$

In phasor analysis, this equation is used by writing it as

$$e^{j(wt+\alpha)} = e^{jwt}e^{j\alpha} = \cos(wt + \alpha) + j\sin(wt + \alpha) \tag{2-52}$$

Thus, it is observed that the cosine term in the preceding expressions for voltage and current is equal to the real-part term from Euler's relation. Thus, it will be seen possible to substitute the general exponential term for the cosine term in the source expressions, then, to find the solution (currents and voltages) to the exponential excitation, and finally, to take the real part of the result to get the final answer.

Steady-State Solutions. When the complete solution for current and voltage in a linear, stable, time-invariant circuit is found, two types of terms are found. One type of term, called the *complementary function* or *transient solution,* depends only on the elements in the circuit and the initial energy stored in the circuit when the forcing function is connected. If the circuit is stable, this term typically becomes very small in a short time.

The second type of term, called the *particular integral* or *steady-state solution,* depends on the circuit elements and configuration and also on the forcing function. If the forcing function is a single-frequency sinusoidal function, then it can be shown that the steady-state solution will contain terms at this same frequency but with differing amplitudes and phases. The goal of phasor analysis is to find the amplitudes and phases of the voltages and currents in the solution as efficiently as possible, since the frequency is known to be the same as the frequency of the forcing function.

Definition of a Phasor. The phasor representation of a sinusoidal function is defined as a complexnumber containing the amplitude and phase angle of the original function. Specifically, if

$$v(t) = V_m\cos(wt + \alpha) = V_m\sin(wt + \alpha + \pi/2) \tag{2-53}$$

then the phasor representation is given by

$$V = V_m e^{j\alpha} \tag{2-54}$$

A phasor can be converted to a sinusoidal time function by using the definition in reverse. See Sec. 2.1.12 for an alternative definition of a phasor, which differs only by a multiplicative constant.

Phasor Algebra. It is necessary at times to perform arithmetic and algebraic operations on phasors. The rules of phasor algebra are identical with those of complex number algebra and vector algebra. Specifically,

$$\begin{aligned} V_1e^{j\alpha_1} \pm V_2e^{j\alpha_2} &= (V_1\cos\alpha_1 \pm V_2\cos\alpha_2) + j(V_1\sin\alpha_1 \pm V_2\sin\alpha_2) \\ (V_1e^{j\alpha_1})(V_2e^{j\alpha_2}) &= (V_1V_2)\, e^{j(\alpha_1+\alpha_2)} \\ \frac{V_1e^{j\alpha_1}}{V_2e^{j\alpha_2}} &= \frac{V_1}{V_2}e^{j(\alpha_1-\alpha_2)} \end{aligned} \tag{2-55}$$

A few examples will show the calculations. In the examples, the angles are expressed in radians. Sometimes degrees are used instead, at the option of the analyst.

$$5e^{j\pi/5} + 4e^{j2\pi/3} = (4.05 + j2.94) + (-2.00 + j3.46) = 6.72e^{j1.26}$$
$$(8e^{j\pi/4})(1.3e^{j3\pi/5}) = 10.4e^{j2.67} = -9.27 + j4.72 \tag{2-56}$$

With a modern electronic calculator or one of many suitable computer programs, it is possible to perform these calculations readily, though they may appear tedious.

Integration and Differentiation Operations. Let a phasor be represented by

$$P_1 = P_m e^{j\omega t} e^{j\theta} \tag{2-57}$$

where the frequency is included for completeness. Differentiation and integration become, respectively,

$$\frac{dP_1}{dt} = j\omega P_m e^{j\omega t} e^{j\theta} = \omega P_m e^{j\omega t} e^{j(\theta+90^\circ)} \tag{2-58}$$

$$\int P_1 dt = \frac{1}{j\omega} P_1 e^{j\omega t} e^{j\theta} = \frac{1}{\omega} P_1 e^{j\omega t} e^{j(\theta-90^\circ)} \tag{2-59}$$

Reactance and Susceptance. For an inductor, the ratio of the phasor voltage to the phasor current is given by *jwL*. This quantity is called the *reactance* of the inductor, and its reciprocal is called *susceptance*. For a capacitor, the ratio of phasor voltage to phasor current is $1/(j\omega C) = -j(\omega C)$. This quantity is called the *reactance* of a capacitor. Its reciprocal is called *susceptance*. The usual symbol for reactance is *X,* and for susceptance, *B*.

Impedance and Admittance. Analysis of ac circuits requires the analyst to replace each inductor and capacitor with appropriate susceptances or reactances. Resistors and constant controlled sources are unchanged. Application of any of the methods of circuit analysis will lead to a ratio of a voltage phasor to a current phasor. This ratio is called *impedance*. It has a real (or resistive) part and an imaginary (or reactive) part. Its reciprocal is called *admittance*. The real part of admittance is called the *conductive* part, and the imaginary part is called the *susceptive part*. In Sec. 2.1.15, an analysis of a circuit shows the use of these ideas.

2.1.12 AC Power and Energy Considerations

Effective or RMS Values. If a sinusoidal current $i(t) = I_m \cos(\omega t + \alpha)$ flows through a resistor of $R\ \Omega$, then, over an integral number of cycles, the average power delivered to the resistor is found to be

$$P_{\text{avg}} = \frac{I_m^2}{2} R \tag{2-60}$$

This amount of power is identical to the amount of power that would be delivered by a constant (dc) current of $I_m/\sqrt{2}$ amperes. Thus, the effective value of an ac current (or voltage) is equal to the maximum value divided by $\sqrt{2}$.

The effective value is commonly used to describe the requirements of ac systems. For example, in North America, rating a light bulb at 120 V implies that the bulb should be used in a system where the effective voltage is 120 V. In turn, the voltages and currents quoted for distribution systems are effective values.

An alternative term is root-mean-square (rms) value. This term follows from the formal definition of effective or rms values of a function,

$$F_{\text{rms}} = \sqrt{\frac{1}{T}\int_{t_0}^{t_0+T} (f(t))^2 dt} \tag{2-61}$$

Frequently, when phasor ideas are being used, effective rather than peak values are implied. This is quite common in electric power system calculations, and it is necessary for the engineer simply to determine which is being used and to be consistent.

Power Factor. When the voltage across a device and the current through a device are given, respectively, by

$$v(t) = V_m \cos(\omega t + \alpha) \tag{2-62}$$

and

$$i(t) = I_m \cos(\omega t + \beta) \tag{2-63}$$

a computation of the average power over an integral number of cycles gives

$$P_{\text{avg}} = \frac{V_m I_m}{2} \cos(\alpha - \beta) \tag{2-64}$$

and

$$P_{\text{avg}} = V_{\text{eff}} I_{\text{eff}} \cos(\alpha - \beta) \tag{2-65}$$

The angle $(\alpha - \beta)$, which is the phase difference between the voltage and current, is called the *power factor angle*. The cosine of the angle is called the *power factor* because it represents the ratio of the average power delivered to the product of voltage and current.

Reactive Voltamperes. When the voltage across a device and the current through a device are given, respectively, by

$$v(t) = V_m \cos(\omega t + \alpha) \tag{2-66}$$

and

$$i(t) = I_m \cos(\omega t + \beta) \tag{2-67}$$

a computation of the power delivered to the device as a function of time shows

$$p(t) = \frac{V_m I_m}{2} [\cos(\alpha - \beta) + \cos(2\omega t + \alpha + \beta)] \tag{2-68}$$

In addition to the constant term that represents the average power, there is a double-frequency term that represents energy that is interchanged between the electric and magnetic fields of the device and the source. This quantity is called by the term *reactive voltamperes* (vars). It may be shown that

$$\text{var} = \frac{V_m I_m}{2} \sin(\alpha - \beta) \tag{2-69}$$

and

$$\text{var} = V_{\text{eff}} I_{\text{eff}} \sin(\alpha - \beta) \tag{2-70}$$

Power and Vars. If the phasor voltage across a device and the phasor current through the device are given, respectively, by

$$V_1 = V_{\text{eff}} e^{j\alpha} \tag{2-71}$$

and

$$I_2 = I_{\text{eff}}\, e^{j\beta} \tag{2-72}$$

then the expression

$$VA = V_{\text{eff}} I^*_{\text{eff}} = V_{\text{eff}} I_{\text{eff}}[\cos(\alpha - \beta) + j\sin(\alpha - \beta)] \tag{2-73}$$

where * represents the complex conjugate, which may be used to find both average power and vars. The real part of the expression is the average power, while the imaginary part is the vars.

2.1.13 Controlled Sources

Models. When circuits containing electronic devices such as amplifiers and similar devices are analyzed or designed, it is necessary to have a linear circuit model for the electronic device. These devices have a minimum of three terminals. Currents flow between terminal pairs, and voltages appear across terminal pairs. One terminal may not be common to both pairs. A useful model is provided by a controlled source. Four such models may be distinguished, as shown in Fig. 2-25. Examples of use will appear in the paragraphs on circuit analysis.

Voltage-Controlled Voltage Source (VCVS). If the voltage across one terminal pair is proportional to the voltage across a second terminal pair, then the model of Fig. 2-26*a* may be used. In this model, the output voltage v_{xz} is proportional to the input voltage v_{yx}, with a proportionality constant A. It should be noted, however, that this device is not usually reciprocal, that is, impression of a voltage at the terminals xz will not lead to a voltage at terminals yz'.

Voltage-Controlled Current Source. If the current flow between a terminal pair is proportional to the voltage across another pair, then the appropriate model is a voltage-controlled current source (VCCS). See Fig. 2-26*b*.

Current-Controlled Current Source. If the current flow between a terminal pair is proportional to the current through another terminal pair, then the appropriate model is a current-controlled current source (CCCS), as shown in Fig. 2-26*c*.

Current-Controlled Voltage Source. If the voltage across one terminal pair is proportional to the current flow through another terminal pair, then the appropriate model is a current-controlled voltage source (CCVS), as shown in Fig. 2-26*d*.

2.1.14 Methods for Circuit Analysis

Circuit Reduction Techniques. When a circuit analyst wishes to find the current through or the voltage across one of the elements that make up a circuit, as opposed to a complete analysis, it is often desirable to systematically replace elements in a way that leaves the target elements unchanged, but simplifies the remainder in a variety of ways. The most common techniques include series/parallel combinations, wye/delta (or tee/pi) combinations, and the Thevenin-Norton theorem.

Series Elements. Two or more electrical elements that carry the same current are defined as being in series. Figure 2-27 shows a variety of equivalents for elements connected in series.

Parallel Elements. Two or more electrical elements that are connected across the same voltage are defined as being in parallel. Figure 2-28 shows a variety of equivalents for circuit elements connected in parallel.

Wye-Delta Connections. A set of three elements may be connected either as a wye, shown in Fig. 2-29*a*, or a delta, shown in Fig. 2-29*b*. These are also called *tee* and *pi connections*, respectively. The equations give equivalents, in terms of resistors, for converting between these connection forms.

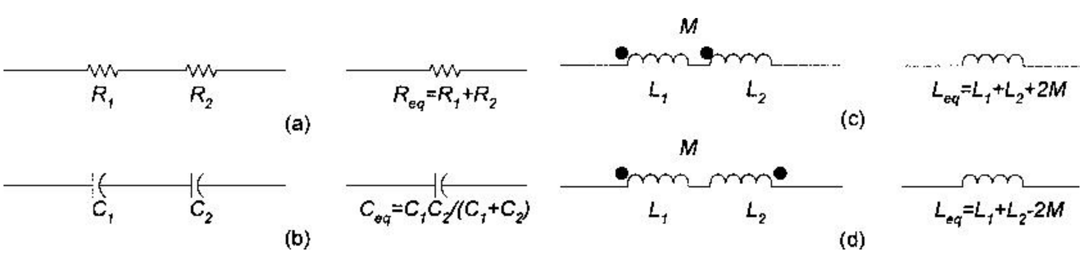

FIGURE 2-27 Series-connected elements and equivalents: (*a*) resistors in series; (*b*) capacitors in series; (*c*) inductors in series, aiding fluxes; (*d*) inductors in series, opposing fluxes.

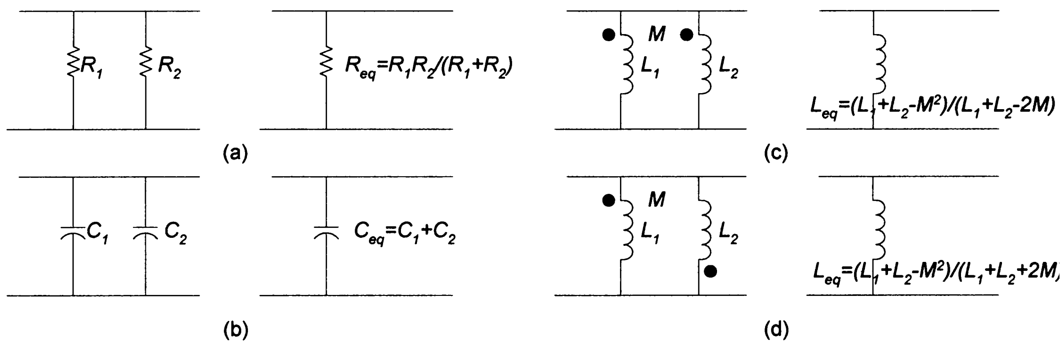

FIGURE 2-28 Parallel-connected elements and equivalents: (*a*) resistors in parallel; (*b*) capacitors in parallel; (*c*) inductors in parallel, aiding fluxes; (*d*) inductors in parallel, opposing fluxes.

$$R_c = \frac{R_1R_2 + R_1R_3 + R_2R_3}{R_1}$$
$$R_b = \frac{R_1R_2 + R_1R_3 + R_2R_3}{R_2} \qquad (2\text{-}74)$$
$$R_a = \frac{R_1R_2 + R_1R_3 + R_2R_3}{R_3}$$

$$R_1 = \frac{R_aR_b}{R_a + R_b + R_c}$$
$$R_2 = \frac{R_aR_c}{R_a + R_b + R_c} \qquad (2\text{-}75)$$
$$R_3 = \frac{R_bR_c}{R_a + R_b + R_c}$$

In practice, application of one of these conversion pairs will lead to additional series or parallel combinations that can be further simplified.

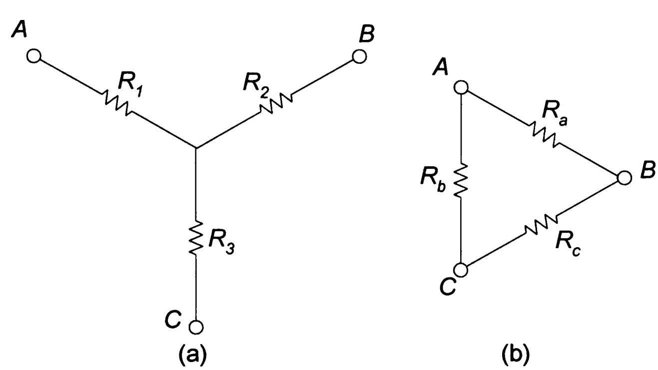

FIGURE 2-29 (*a*) Wye-connected elements; (*b*) delta-connected elements.

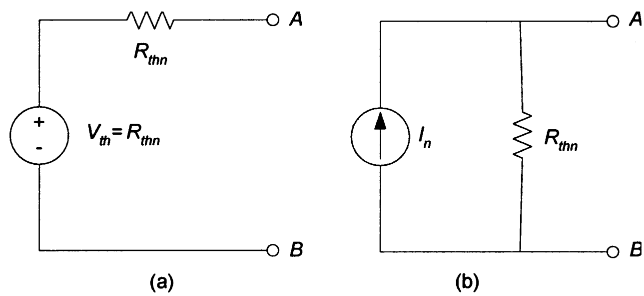

FIGURE 2-30 (*a*) Thevenin equivalent circuit model; (*b*) Norton equivalent ciruit model.

Thevenin-Norton Theorem. The Thevenin theorem and its dual, the Norton theorem, provide the engineer with a convenient way of characterizing a network at a terminal pair. The method is most useful when one is considering various loads connected to a pair of output terminals. The equivalent can be determined analytically, and in some cases, experimentally. Terms used in these paragraphs are defined in Fig. 2-30.

Thevenin Theorem. This theorem states that at a terminal pair, any linear network can be replaced by a voltage source in series with a resistance (or impedance). It is possible to show that the voltage is equal to the voltage at the terminal pair when the external load is removed (open circuited), and that the resistance is equal to the resistance calculated or measured at the terminal pair with all independent sources de-energized. De-energization of an independent source means that the source voltage or current is set to zero but that the source resistance (impedance) is unchanged. Controlled (or dependent) sources are not changed or de-energized.

Norton Theorem. This theorem states that at a terminal pair, any linear network can be replaced by a current source in parallel with a resistance (or impedance). It is possible to show that the current is equal to the current that flows through the short-circuited, terminal pair when the external load is short circuited, and that the resistance is equal to the resistance calculated or measured at the terminal pair with all independent sources de-energized. De-energization of an independent source means that the source voltage or current is set to zero but that the source resistance (impedance) is unchanged. Controlled (or dependent) sources are not changed or de-energized.

Thevenin-Norton Comparison. If the Thevenin equivalent of a circuit is known, then it is possible to find the Norton equivalent by using the equation

$$V_{th} = I_n R_{thn} \tag{2-76}$$

as indicated in Fig. 2-30.

Thevenin-Norton Example. Figure 2-31*a* shows a linear circuit with a current source and a voltage-controlled voltage source. Figure 2-31*b* shows a calculation of the Thevenin or open-circuit voltage. Figure 2-31*c* shows a calculation of the Norton or short-circuit current. Figure 2-31*d* shows the final Norton and Thevenin equivalent circuits.

2.1.15 General Circuit Analysis Methods

Node and Loop Analysis. Suppose b elements or branches are interconnected to form a circuit. A complete solution for the network is one that determines the voltage across and the current through each element. Thus, $2b$ equations are needed. Of these, b are given by the voltage-current relations, for example, Ohm's law, for each element. The others are obtained from systematic application of Kirchhoff's voltage and current laws.

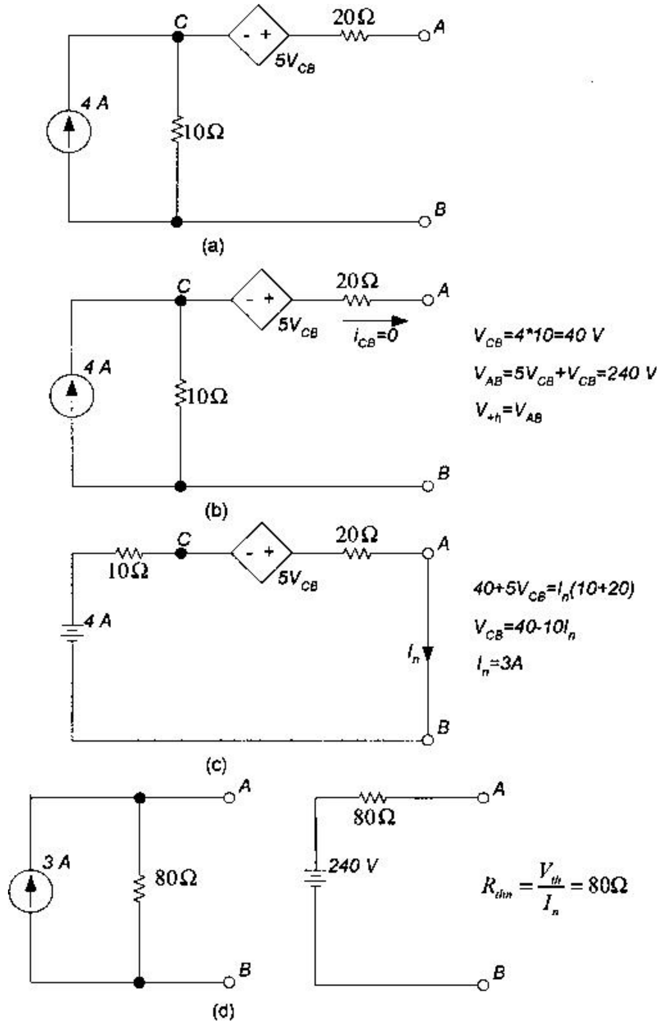

FIGURE 2-31 To illustrate Thevenin-Norton theorem: (*a*) example circuit; (*b*) calculation of Thevenin voltage; (*c*) calculation of Norton current; (*d*) Norton and Thevenin equivalent circuits.

Define a point at which three or more elements or branches are connected as a node (some writers call this an *essential node*). Suppose that the circuit has n such nodes or points. It is possible to write Kirchhoff's current law equations at each node, but one will be redundant, that is, it can be derived from the others. Thus, n–1 KCL equations can be written, and these are independent.

This means that to complete the analysis, it is necessary to write $[b-(n-1)]$ KVL equations, and this is possible, though care must be taken to ensure that they are independent. In practice, it is typical that either KCL or KVL equations are written, but not both. Sufficient information is usually available from either set. Which set is chosen depends on the analyst, the comparative number of equations, and similar factors.

Nodal Analysis. Figure 2-32*a* shows a typical node in a circuit that is isolated for attention. The voltage on this node is measured or calculated with a reference somewhere in the circuit, often but not always the node that is omitted in the analysis. Other nodes, including the reference node, are shown along with connecting elements. To illustrate the technique, five additional nodes are chosen, including the reference nodes. The boxes labeled *Y* are called *admittances*.

Kirchhoff's current law written at the node states that

$$i_{k-2} + i_{k-1} + i_k + i_{k+1} + i_{k+2} = I_{in,k} \tag{2-77}$$

An expression for each of the currents can be written

$$i_{k+1} = (V_k - V_{k+1})Y_{k+1} \tag{2-78}$$

When all the equations that can be written are written, collected, and organized into matrix format, the general result is

$$\begin{bmatrix} Y_{11} + Y_{12} + Y_{13} + \cdots & -Y_{12} & -Y_{13} & \cdots \\ -Y_{21} & Y_{21} + Y_{22} + Y_{23} + \cdots & -Y_{23} & \cdots \\ -Y_{31} & -Y_{32} & Y_{31} + Y_{32} + Y_{33} + \cdots & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ V_3 \\ \vdots \end{bmatrix} = \begin{bmatrix} I_1 \\ I_2 \\ I_3 \\ \vdots \end{bmatrix} \tag{2-79}$$

where the square matrix describes the circuit completely, the column matrix (vector) of voltages describes the dependent variables which are the node voltages, and the column matrix of currents describes the forcing function currents that enter each node.

Nodal Analysis with Controlled Sources. If a controlled source is present, it is most convenient to use the Thevenin-Norton theorem to convert the controlled source to a voltage-controlled current

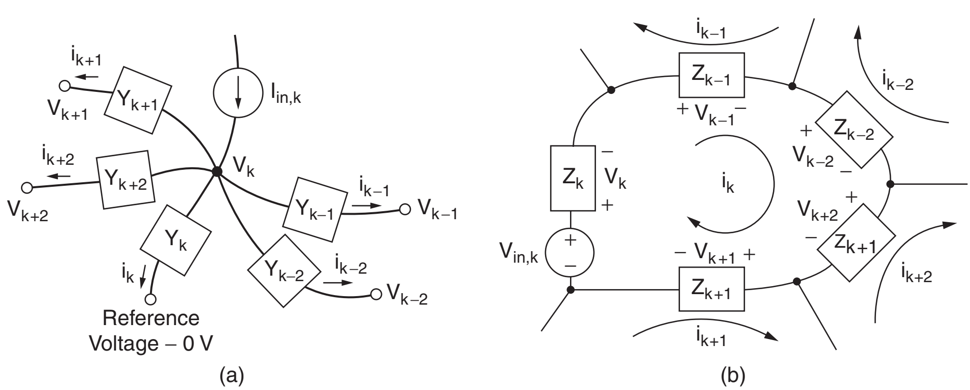

FIGURE 2-32 To illustrate node and loop analysis: (*a*) typical node isolated for study; (*b*) typical loop isolated for study.

source. When this is done, the right side of the preceding equation will contain the dependent variables (voltages) in addition to independent current sources. These voltage terms can then be transposed to the left side of the matrix equation. The result is the addition of terms in the circuit matrix that make the matrix nonsymmetric.

Solution of Nodal Equations. In dc and ac (sinusoidal steady-state) circuits, the Y terms are numerical terms. Calculators that handle matrices and mathematical software programs for computers permit rapid solutions. Ordinary determinant methods also suffice. The result will be a set of values for the various voltages, all determined with respect to the reference node voltage. If the terms in the equation are generalized admittances (see Sec. 2.1.20 on Laplace transform analysis), then the solution will be a quotient of polynomials in the Laplace transform variable s. More is said about such solutions in that section.

Loop Current Analysis. Define a *loop* as a closed path in a circuit and a *loop current* as a current that flows around this path. See Fig. 2-32*b*, which shows one loop that has been isolated for attention, the associated loop current, and loop currents that flow in neighboring loops. It is noted that the current through any given element is found to be the difference between two loop currents if the circuit is planar, that is, can be drawn on a flat surface without crossing wires. (If the circuit is nonplanar, the technique is still valid, but it can become more complex, and some element currents will be composed of three or more loop currents.) The elements labeled Z are called impedances.

Kirchhoff's voltage law written around the loop states that

$$v_{k-2} + v_{k-1} + v_k + v_{k+1} + v_{k+2} = V_{in,k} \tag{2-80}$$

An expression for each of the voltages can be written

$$v_{k+1} = (i_k - i_{k+1})Z_{k+1} \tag{2-81}$$

When all the equations that can be witten are written, collected, and organized into matrix format, the general result is

$$\begin{bmatrix} Z_{11} + Z_{12} + Z_{13} + \cdots & -Z_{12} & -Z_{13} & \cdots \\ -Z_{21} & Z_{21} + Z_{22} + Z_{23} + \cdots & -Z_{23} & \cdots \\ -Z_{31} & -Z_{32} & Z_{31} + Z_{32} + Z_{33} + \cdots & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \\ I_3 \\ \vdots \end{bmatrix} = \begin{bmatrix} V_1 \\ V_2 \\ V_3 \\ \vdots \end{bmatrix} \tag{2-82}$$

where the square matrix describes the circuit completely, the column matrix (vector) of currents describes the dependent variables which are the loop currents, and the column matrix of voltages describes the forcing function voltages that act in each loop.

Loop Current Analysis with Controlled Sources. If a controlled source is present, it is most convenient to use the Thevenin-Norton theorem to convert the controlled source to a current-controlled voltage source. When this is done, the right side of the preceding equation will contain the dependent variables (currents) in addition to independent voltage sources. These current terms can then be transposed to the left side of the matrix equation. The result is the addition of terms in the circuit matrix that make the matrix nonsymmetric.

Solution of Loop Current Equations. In D.C. and A.C. (sinusoidal steady-state) circuits, the Z terms are numerical terms. Calculators that handle matrices and mathematical software programs for computers facilitate the numerical work. Ordinary determinant methods also suffice. The result will be a set of values for the various loop currents, from which the actual element currents can be readily obtained. If the terms in the equation are generalized admittances (see Sec. 2.1.20 on Laplace transform analysis), then the solution will be a quotient of polynomials in the Laplace transform variable s. More is said about such solutions in those paragraphs.

Sinusoidal Steady-State Example. Figure 2-33 shows a circuit with a current source, two resistors, two capacitors, and one inductor. (The network is scaled.) The current source has a frequency of 2 rad/s and is sinusoidal. Figure 2-33*b* shows the circuit prepared for phasor analysis. The equations that follow show the writing of KCL equations for two voltages and their solution, which is shown as a phasor and as a time function.

$$2 = V_1(1 + j2.00 - j0.25) - V_2(-j0.25) \tag{2-83}$$

$$0 = -V_1(-j0.25) + V_2(1 + j2.00 - j0.25) \tag{2-84}$$

$$V_2 = 0.0615 - j0.1077 = 0.124e^{j(2.6224)} \text{ (angle in radians)} \tag{2-85}$$

$$V_2(t) = 0.1240\cos(2t + 2.6224) = 0.1240\cos(2t + 150.25°) \tag{2-86}$$

Computer Methods. The rapid development of computers in the last few years has led to the development of many programs written for the purpose of analyzing electric circuits. Because of their rapid analysis capability, they also are effective in design of new circuits. Programs exist for personal

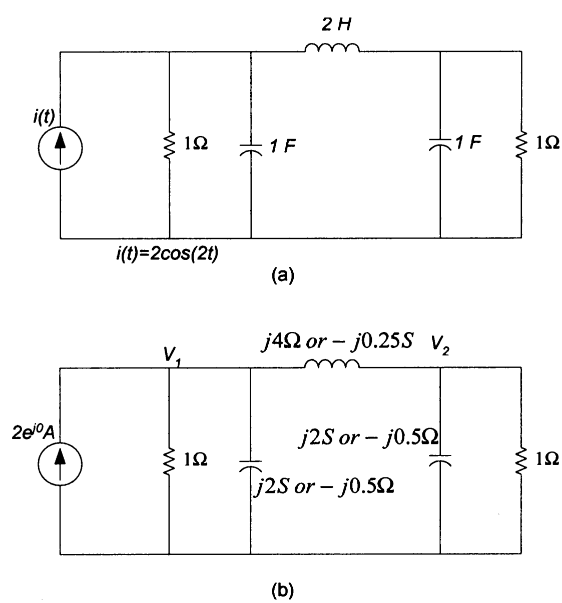

FIGURE 2-33 Sinusoidal steady-state analysis example: (*a*) circuit with sinusoidal source and two nodes; (*b*) phasor domain equivalent circuit.

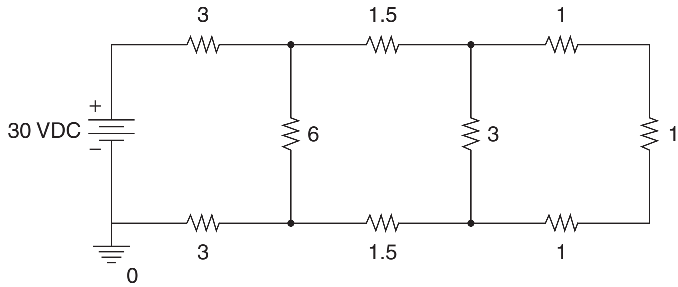

FIGURE 2-34 PSPICE circuit.

computers, minicomputers, and mainframe computers. Probably the most popular is SPICE, which is an acronym for Simulation Program with Integrated Circuit Emphasis. The personal computer version of this program is PSPICE. Most of these programs are in the public domain in the United States. It is convenient to discuss how a circuit is described to a computer program and what data are available in an analysis. Figures 2-34 and 2-35 show a sample PSPICE circuit.

SPICE Circuit Description. The analysis of a circuit with SPICE or another program requires the analyst to describe the circuit completely. Every node is identified, and each branch is described by type, numerical value, and nodes to which it is connected $e^{j(\alpha_1+\alpha_2)}$. Active devices such as transistors and operational amplifiers can be included in the description, and the program library contains complete data for many commonly used electronic elements.

SPICE Analysis Results. The analyst has a lot of control over what analysis results are computed. If a circuit is resistive, then a D.C. analysis is readily performed. This analysis is easily expanded to do a sensitivity analysis, which is a consideration of how results change when certain components change. Further, such analyses can be done both for linear and nonlinear circuits.

If the analyst wishes, a sinusoidal steady-state analysis is then possible. This includes *small-signal analysis,* a consideration of how well circuits such as amplifiers amplify signals which appear as currents or voltages. A frequency response is possible, and the results may be graphed with a variety of independent variables.

Other possible analyses include noise analyses—a study of the effect of electrical noise on circuit performance—and distortion analyses. Still others include transient response studies, which are most important in circuit design. The results may be graphed in a variety of useful ways. References give useful information.

Numerical example for the small-signal analysis is shown in Fig. 2-36.

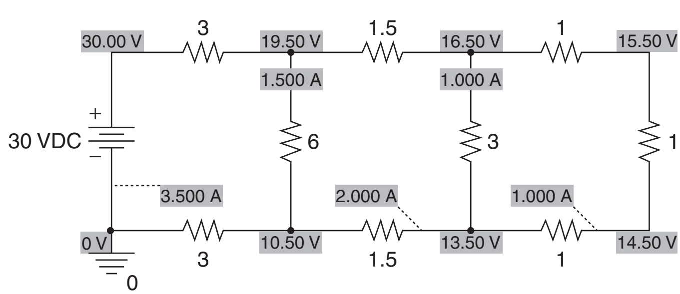

FIGURE 2-35 PSPICE analysis.

Additional Programs. A major advantage of these computer methods is that they work well for all types of circuit—low or high power, low or high frequency, power or communications. This is true even though the program's name might indicate otherwise. However, in some types of analysis, special programs have been developed to facilitate design and analysis. For example, power systems are often described by circuits that have more than 1000 nodes but very few nonzero entries in the circuit matrix. These special characteristics have led to the development of efficient programs for such studies. Several references address these issues.

2.1.16 Electric Energy Distribution in 3-Phase Systems

General Note. In most of the world, large amounts of electric energy are distributed in 3-phase systems. The reasons for this decision include the fact that such systems are more efficient than single-phase systems. In other words, they have reduced losses and use materials more efficiently. Further, it can be shown that a 3-phase system distributes electric power at a constant rate, not at the time-varying rate shown earlier for single-phase systems. It is convenient to consider balanced systems and unbalanced systems separately. Also, both loads and sources need to be considered.

Balanced 3-Phase Sources. A 3-phase source consists of three voltage sources that are sinusoidal, equal in magnitude, and differ in phase by 120°. Thus, the set of voltages shown below is a balanced 3-phase source, shown both in time and phasor format.

$$
\begin{aligned}
v_{ab} &= V_m \cos(377t) && V_m e^{j0} \\
v_{bc} &= V_m \cos(377t - 120°) && V_m e^{-j120°} \qquad (2\text{-}87) \\
v_{ca} &= V_m \cos(377t + 120°) && V_m e^{+j120°}
\end{aligned}
$$

(In these expressions, peak values have been used rather than effective values. Further, degrees and radians are mixed, which is commonly done for the sake of clarity and convention but which can lead to numerical errors in calculators and computers if not reconciled.) Note that the sum of the three voltages is zero.

These three sources may be connected in either of the two ways to form a balanced system. One is the wye (star or tee) connection and the other is the delta (mesh or pi) connection. Both are shown in Fig. 2-37. It is noted that in the wye connection, a fourth point is needed, which is labeled O. The terminals labeled

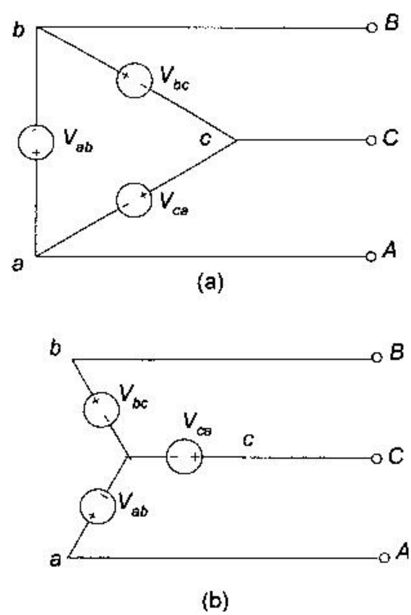

FIGURE 2-37 3-Phase source connections: *(a)* delta connection; *(b)* wye connection.

A, *B*, and *C* are called the *lines* (as opposed to *phases*). In the delta system, it is readily shown that, in phasor notation,

$$V_{AB} = V_{ab} = V_m^{e^{j0}}$$
$$V_{AB} = V_{bc} = V_m^{e^{j-120^\circ}} \qquad (2\text{-}88)$$
$$V_{CA} = V_{ca} = V_m^{e^{j+120^\circ}}$$

while in the wye system,

$$V_{AB} = V_{ab} - V_{bc} = V_{ao} - V_{bo} = \sqrt{3}V_m e^{j30^\circ}$$
$$V_{BC} = V_{bc} - V_{ca} = V_{bo} - V_{co} = \sqrt{3}V_m e^{j-90^\circ} \qquad (2\text{-}89)$$
$$V_{AB} = V_{ca} - V_{ab} = V_{co} - V_{ao} = \sqrt{3}V_m e^{j+150^\circ}$$

Thus, it is seen that in a delta system the line voltages are equal to the phase voltages. In a wye system, the line voltages are increased in magnitude by $\sqrt{3}$ and are shifted in phase by 30°. In a similar fashion, it is readily shown that the line currents in a wye system are equal to the phase currents, while in a delta, the line currents are increased by $\sqrt{3}$ and are shifted in phase by 30°.

Balanced Loads. A balanced 3-phase load is a set of three equal impedances connected either in wye or delta. Equations (2-74) and (2-75) may be used to convert from one to the other if needed.

Power Delivery, Balanced System. The power delivered from a balanced 3-phase source to a balanced 3-phase load is given by

$$P_{av} = \sqrt{3}V_{\text{line}}I_{\text{line}}\cos\phi$$

where $\cos\phi$ is, as before, the power factor of the load.

Unbalanced System. A 3-phase system that has either a nonsymmetric load or sources that differ in magnitude or whose phase difference is other than 120° is said to be unbalanced. Such circuits may be analyzed by any conventional method for circuit analysis.

Power Measurement in 3-Phase Systems. The power delivered to a 3-phase load, whether the system is balanced or unbalanced, may be measured with two wattmeters connected as shown in Fig. 2-38.

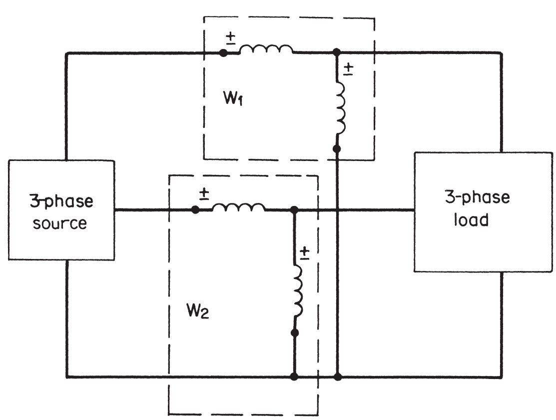

FIGURE 2-38 3-Phase system.

The total power is the sum of the readings of the two meters. If the power factors are small, one meter reading may be negative.

2.1.17 Symmetric Components

Resolution of an Unbalanced 3-Phase System into Balanced Systems. Let the three cube roots of unity, 1, $e^{j(2x/3)}$, $e^{j(4x/3)}$, be 1, a, a^2, where $j = \sqrt{-1}$,

$$a = 1 < 120° = -0.5 + j0.866$$

and

$$a = 1 < 120° = -0.5 - j0.866$$

Any three vectors, Q_a, Q_b, Q_c (which may be unsymmetric or unbalanced, that is, with unequal magnitudes or with phase differences not equal to 120°) can be resolved into a system of three equal vectors, Q_{a_0}, Q_{a_1}, Q_{a_2} and two symmetrical (balanced) 3-phase systems Q_{a_0}, $a^2Q_{a_1}$, Q_{a_2} and Q_{a_0}, aQ_{a_1}, Q_{a_2}, the first of which is of positive-phase sequence and the second of negative-phase sequence. Thus

$$\begin{aligned} Q_a &= Q_{a_0} + Q_{a_1} + Q_{a_2} \\ Q_b &= Q_{a_0} + a^2Q_{a_1} + aQ_{a_2} \\ Q_c &= Q_{a_0} + aQ_{a_1} + a^2Q_{a_2} \end{aligned} \tag{2-90}$$

The values of the component vectors are

$$\begin{aligned} Q_{a_0} &= 1/3(Q_a + Q_b + Q_c) \\ Q_b &= 1/3(Q_a + aQ_b + a^2Q_c) \\ Q_c &= 1/3(Q_a + a^2Q_b + aQ_c) \end{aligned} \tag{2-91}$$

The three equal vectors Q_{a_0} are sometimes called the *residual quantities* or the *zero-phase,* or *uniphase, sequence system*. Any of the vectors Q_a, Q_b, or Q_c may have the value zero. If two of them are zero, the single-phase system may be resolved into balanced 3-phase systems by the preceding equations. The symbol Q may denote any vector quantity such as voltage, current, or electric charge.

There are similar relations for n-phase systems. See "Method of Symmetrical Coordinates Applied to the Solution of Polyphase Networks," by C. L. Fortescue, *Trans. AIEE,* 1918, p. 1027.

Short-Circuit Currents. The calculation of short-circuit currents in 3-phase power networks is a common application of the method of symmetrical components. The location of a probable short circuit of fault having been selected, three networks are computed in detail from the neutrals to the fault, one for positive, one for negative, and one for zero-phase sequence currents. The three phases are assumed to be identical, in ohms and in mutual effects, except in the connection of the fault itself. Let Z_1, Z_2, and Z_0 be the ohms per phase between the neutrals and the fault in each of the networks, including the impedance of the generators.

Then, for a line-to-ground fault

$$I_{a_1} = I_{a_2} = I_{a_3} = \frac{I_c}{3} = \frac{V_a}{Z_1 + Z_2 + Z_0} \tag{2-92}$$

where V_a is the line-to-neutral voltage and I_{a_1} is the positive-phase-sequence current flowing to the fault in phase *a* and similarly for I_{a_2} and I_{a_0}. I_a is the total current flowing to the fault in phase *a*.

The component currents in phases *b* and *c* are derived from those in phase *a*, by means of the relations $I_{b_1} = a^2 I_{a_1}$, $I_{b_2} = aI_{a_2}$, $I_{b_0} = I_{a_0}$, $I_{c_1} = aI_{a_1}$, $I_{c_2} = a^2 I_{a_2}$, $I_{b_0} = I_{a_0}$. Each of the component currents divides in the branches of its own network according to the impedance of that network. Thus, each of the component currents, and therefore, the total current, at any part of the power system can be determined.

For a line-to-line fault between phases *b* and *c*

$$I_{a_1} = -I_{a_2} = \frac{V_a}{Z_1 + Z_2} \tag{2-93}$$

and

$$I_{a_0} = 0 \tag{2-94}$$

For a double line-to-ground fault between phases *b* and *c* and ground

$$I_{a_1} = \frac{V_a}{Z_1 + \dfrac{Z_2 Z_0}{Z_2 + Z_0}}$$

$$I_{a_0} = \frac{I_{a_1} Z_2}{Z_2 + Z_0}$$

and

$$I_{a_2} = -I_{a_1} - I_{a_0} \tag{2-95}$$

If there is no current in the power system before the fault occurs, the voltage V_a of every generator is the same in magnitude and phase. Such a condition often is assumed in calculated circuit-breaker duty and relay currents, although the effects of loads on the system can be included in the analysis.

In calculating power-system stability, however, it must be assumed that current exists in the lines before the fault occurs. The voltage V_a becomes the positive-sequence voltage at the point of fault before the fault occurs. A practical method of computing the positive-sequence current under fault conditions is to leave the positive-sequence network unchanged, with each generator at its own voltage and phase angle. The equivalent *Z* of the network need not be computed. Certain 3-phase impedances are inserted between line and neutral at the location of the fault. For a single line-to-line ground fault, $Z_2 + Z_0$ is inserted; for a line-to-line fault, Z_2 is inserted; and for a double line-to-ground fault, $Z_2 Z_0/(Z_2 + Z_0)$ is inserted. This gives one phase of an equivalent balanced 3-phase circuit for which the positive-sequence currents driven by all the generators in all the branches under fault conditions can be found by means of a network analyzer or computed on a digital computer. The power transmitted after the fault occurs can be determined from these positive-sequence currents.

If it is desired to find the negative-sequence and zero-sequence currents (some relays are operated by the latter), they can be computed from Eqs. (2-92) to (2-95) that do not involve *V*a, after finding I_{a_1} to the fault.

The impedance Z_f of each arc is mainly resistance. It may be brought into the computation. For single line-to-ground and double line-to-ground faults, Z_f is added to each of Z_1, Z_2, and Z_0. For line-to-line faults, Z_f is added to Z_2 only.

Load Studies. In calculations relating to the steady-state operation of power systems, in which it is desired to determine the voltage, power, reactive power, etc. at various points, the loads may be designated by kilowatts and kilovars rather than by impedances. The effect of the impedance of the transmission and distribution lines, transformers, etc. of the network can be computed. The modern method is a process of iterations using a digital computer for the calculations. The division of current in branches, the voltage at various points, and the required ratings of synchronous capacitors can be determined.

Conditions can be estimated at one or two points and a solution for the rest of the network can be calculated on the basis of these assumptions. If the assumptions are not correct, discrepancies will appear at the end of the work. For instance, two different voltages may be obtained for the same point, one calculated before and one after going around a loop of the network. The necessary correction to the first estimates may be based on the discrepancies, thus giving successive approximations which are improvements on the preceding ones.

2.1.18 Additional 3-Phase Topics

Voltage Drop in Unsymmetrical Circuits. The voltage drop due to resistance, self-inductance, and mutual inductance in any conductor of a group of long, parallel, round, nonmagnetic conductors forming a single-phase or polyphase circuit, and with one or more conductors connected electrically in parallel, may be calculated by summing the flux due to each conductor up to a certain large distance u. The vectorial sum of all the currents is zero in a complete system of currents in the steady state, and the quantity u cancels out, so the result is the same no matter how large u may be. The currents may be unbalanced, and in addition, the arrangement of the conductors may be unsymmetrical.

The voltage drop in any conductor a of a group of round conductors a, b, c, ... is

$$I_a R_a = j0.2794(I_a \log_{10} S_a + I_b \log_{10} S_{ab} + I_c \log_{10} S_{ac} + \cdots) \quad \text{V/mi at 60 Hz}$$

where $I_a + I_b + I_c = 0$, the values of the currents being complex quantities; R_a is resistance of conductor a, per mile; G_a is self-geometric mean distance of conductor a; G_a is axial spacing between conductors a and b, etc. The values of G and S should be in the same units.

Armature Windings. The armature winding of a 3-phase generator or motor is an important type of electric circuit. Windings consisting of diamond-shaped coils, with two coil sides per slot, are connected in groups of coils, three groups or phase belts being opposite each pole. In general, the number of slots per pole per phase is a fraction equal to the average number of coils per phase belt. There are a larger number and a smaller number of coils per phase belt, differing by 1. The winding is usually found to be divided into repeatable sections of several poles each, the sections being duplicates of each other.

The number of poles in a section is found by writing the fraction equal to the number of slots divided by the number of poles and canceling factors to the extent possible. The denominator is the number of poles per section, and the numerator is the number of slots per section.

If the final value of the numerator is not divisible by 3, a balanced 3-phase winding cannot be made, since the windings for phases a, b, and c in a section each require the same number of slots, and they must be duplicates except for the phase shift of 120°. This gives rise to the rule for balanced 3-phase windings that the factor 3 must occur at least one more time in the number of slots than in the number of poles.

It can be shown that the slots of a repeatable section have phase angles which, when suitably drawn, are all different and equidistant. They fill the space of 180 electrical degrees like the blades of a Japanese fan. The angle between the vectors in this fan is

$$\beta = \frac{180}{\text{slots per section}} \quad \text{deg} \tag{2-96}$$

The vectors lying from 0° to 59° may be assigned to phase a or $-a$, those from 60° to 119° to phase $-c$ or c, and those from 120° to 179° to phase b or $-b$.

The phase angles for the upper coil sides of the slots should be tabulated to indicate the proper connections of the winding. Since the diamond coils are all alike, the total resulting voltage developed in the lower coil sides of a phase is a duplicate of that developed in the upper coil sides and can be added on by means of the pitch factor.

The phase angle between two adjacent slots is

$$\frac{\text{Poles per section} \times 180}{\text{Slots per section}} = q\beta \quad \text{deg} \tag{2-97}$$

where q is the number of poles in the repeatable section. From this, the phase angle for every slot in the section can be written. To save numerical work, especially where β is a fractional number of degrees, the angles may be expressed in terms of the angle β, as given in the example below. They may be expressed in degrees and fractions of a degree, but decimal values of degrees should not be used in this part of the work. The required accuracy is obtained by using fractions instead of decimals. Appropriate multiples of 180° should be subtracted to keep the angles less than 180°, thus indicating the relative position of each coil side with respect to the nearest pole. When an odd number times 180° has been subtracted, the coil side is tabulated as $-a$ instead of a, etc., since it will be opposite a south pole when a is opposite a north pole. The terminals of a coil marked $-a$ are reversed with respect to the terminals of a coil marked a with which it is in series.

Example 21 slots per repeatable section; 5 poles per section; 11/5 slots per pole per phase.

$$\beta = \frac{180}{21} = 8\frac{4}{7} \qquad \text{deg} \qquad \text{[by Eq. 2-96]}$$

It is more convenient in this case to express the angles in terms of β rather than by fractions of degrees. Note that $21\beta = 180°$ and $7\beta = 60°$. The range for coils to be marked $\pm a$ is from 0 to 6β, inclusive; coils marked $\pm c$ from 7β to 13β; and coils marked $\pm c$ from 14β to 20β. Subtract multiples of $21\beta = 180°$. The angle between two adjacent slots is $q\beta = 5\beta$.

Tabulation of Phase Angles

0	5β	10β	15β	20β	$(25\beta)4\beta$	9β	14β	19β	$(24\beta)3\beta$	8β	13β	18β	$(23\beta)2\beta$	7β	12β	17β	$(22\beta)\beta$	6β	11β	16β	$[(21\beta)0]$
a	a	−c	b	b	−a	c	−b	−b	a	−c	−c	b	−a	c	c	−b	a	a	−c	b	[−a]

The seven vectors of phase a make a regular fan covering $7\beta = 60°$.

The resulting terminal voltage produced by the coils of phase a is equal to the numerical sum of the voltages in those coils multiplied by the "distribution factor"

$$\frac{\sin(n\beta/2)}{n\sin(\beta/2)} \tag{2-98}$$

where n is the number of vectors in the regular fan covering 60° and β is the angle between adjacent vectors, given by Eq. (2-95). The number n is large, and the perimeter approaches the arc of a circle. Equation (2-97) is of the same form as the formula for breadth factor, which also is based on a vector diagram that is a regular fan.

The distribution factor for the winding of the foregoing example is

$$\frac{\sin \dfrac{7 \times 60°}{2 \times 7}}{7 \sin \dfrac{60°}{2 \times 7}} = \frac{\sin 30°}{7 \sin 4\frac{2°}{7}} = \frac{0.5}{7 \times 0.0746} = 0.956$$

Other possible balanced 3-phase windings for this example could be specified by having some of the vectors of phase a lie outside the 60° range. This would result in a lower distribution factor. The voltage, and hence the rating of the machine, would be lower by 2% or more than in the case described. The canceling of the harmonic voltages would apparently not be improved, and there would be no advantage to compensate for the reduction in kVA rating, which would correspond to a loss or waste of 2% or more of the cost of the machine.

2.1.19 Two Ports

Two Ports. A common use of electric circuits is to connect a source of electric energy or information to a load, often in such a way as to modify the signal in a prescribed way. In its basic form, such a circuit has one pair of input terminals and one pair of output terminals. Each of the four

FIGURE 2-39 2-Port model with voltage and current definitions.

wires will have a current flow in or out of the circuit. Between any pair of terminals there will be a voltage.

If the structure of the circuit is such that the current flow into one terminal is equal to the current flow out of a second terminal, then that terminal pair is called a *port*. The circuit of Fig. 2-39 has two such pairs and is called a *2-port*. The circuit variables can be completely characterized at the terminals by the two currents and two voltages indicated in Fig. 2-39.

The last part of this section, "Filters," is devoted to a special type of 2-port called a *filter*. In the section, a variety of relations among the terminal voltages and currents will be discussed. Six such sets are found to be useful. They are known as the open-circuit impedance parameters, short-circuit admittance parameters, hybrid parameters (two types), and transmission-line parameters (two types).

Open-Circuit Impedance Parameters. If the two currents are considered to be independent variables and the two voltages are dependent variables, then this pair of equations can be written as

$$\begin{bmatrix} v_1 \\ v_2 \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{bmatrix} \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} \quad [v] = [z][i] \tag{2-99}$$

The four numbers or functions in the square matrix characterize the network. They may be computed by any conventional method of circuit analysis and often are computed directly by computer-based software. They also may be measured. For example, the term z_{21} can be computed or measured as the ratio v_2/i_1 when i_2 is set to zero if being computed or made zero by an appropriate open circuit when measurements are being taken.

Short-Circuit Admittance Parameters. If the two voltages are dependent variables and the two currents independent, then these equations can be written as

$$\begin{bmatrix} i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} \quad [i] = [y][v] \tag{2-100}$$

Measurements and computations follow principles similar to those of open-circuit impedance parameters.

Hybrid Parameters. Voltages and currents may be mixed in their roles as independent and dependent variables in two ways, as indicated:

$$\begin{bmatrix} v_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} h_{11} & h_{12} \\ h_{21} & h_{22} \end{bmatrix} \begin{bmatrix} i_1 \\ v_2 \end{bmatrix} \quad (h \text{ parameters}) \tag{2-101}$$

$$\begin{bmatrix} i_1 \\ v_2 \end{bmatrix} = \begin{bmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{bmatrix} \begin{bmatrix} v_1 \\ i_2 \end{bmatrix} \quad (g \text{ parameters}) \tag{2-102}$$

Transmission-Line Parameters. The voltage and current at the input port may be used as independent variables with the output quantities as dependent variables, or the roles may be reversed.

$$\begin{bmatrix} v_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} \alpha & \beta \\ \gamma & \delta \end{bmatrix} \begin{bmatrix} v_1 \\ i_1 \end{bmatrix} \qquad (g \text{ parameters}) \tag{2-104}$$

2-Port Parameter Conversions. Any set of 2-port parameters may be converted to any other set through the use of Table 2-1. In this framework,

$$|y| = \det[y] = \det \begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{bmatrix} = y_{11}y_{22} - y_{12}y_{21} \tag{2-105}$$

With comparable interpretations for the other sets.

Equivalent Circuits for Two Ports. Equivalent circuits may be derived for any set of 2-port parameters. The process is shown for the $[h]$ parameters, but the technique is quite similar for the other combinations. Figure 2-40*a* shows the equivalent circuit.

Two-Port Analysis. From the equivalent circuit for a 2-port, circuit analysis is possible. Figure 2-40*b* shows a 2-port, with hybrid parameters, with a voltage source and a load resistor. Application of Kirchhoff's laws shows that

$$\frac{V_{\text{load}}}{V_{\text{source}}} = -\frac{R_L}{(R_{\text{source}} + h_{11})(1 + h_{22}R_{\text{load}}) + h_{12}R_{\text{load}}} \tag{2-106}$$

Similar analyses can be performed for any configuration that may arise.

Transmission Lines. The two sets of parameters denoted [*TL*] and [*TLI*] are called *transmission-line parameters* and are frequently computed or measured for power and communication transmission lines. Analysis with these parameters is substantially the same as that in the section on short-circuit admittance parameters above, though if the length of the line is more than about 10% of the wavelength involved, it is more convenient to use parameters based on standing-wave theory.

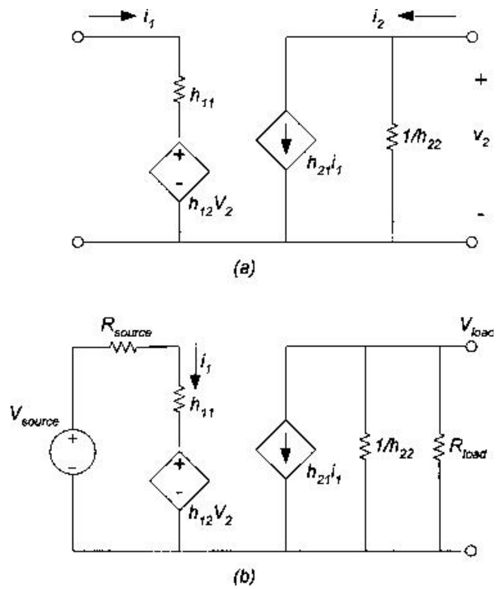

FIGURE 2-40 Transmission lines.

2.1.20 Transient Analysis and Laplace Transforms

Most transient analysis today is done with Laplace transform techniques, which provide the analyst a powerful method for finding both steady-state and transient computations simultaneously. It is necessary, however, to know initial conditions, the energy stored in capacitors and inductors.

Definition of a Laplace Transform. If a function of time $f(t)$ is known and defined for $t \geq 0$, then the (single-sided) Laplace transform is given by

$$Lf(t) = F(s) = \int_{0^-}^{\infty} f(t)e^{-st}\,dt \tag{2-107}$$

where s is a complex variable, $s = \sigma + j\omega$, chosen so that the integral will converge. In turn, σ is the real part of the variable, and ω is the imaginary part, but it becomes the frequency of sinusoidal functions measured in rad/s.

Laplace Transform Theorems. If the function $f(t)$ has the Laplace transform $F(s)$, then the theorems of Table 2-2 apply. In these theorems, the term $f(0^-)$ represents the initial condition, or the value of f at $t = 0$.

Laplace Transform Pairs. Table 2-3 presents a listing of the most common time functions and their Laplace transforms. These are sufficient for much of the analysis that is necessary. References include more extensive tables.

Initial Conditions. If a circuit has initial energy stored in it, that is, if any of the capacitors is charged or if any of the inductors has a nonzero current, then these conditions must be determined before a complete analysis can be done. In general, this will require knowledge of the circuit just before the circuit to be analyzed is connected. Normal circuit analysis methods can be used to determine the initial conditions.

TABLE 2-2 Laplace Transform Theorems

Operation	Theorem
Derivative	$\mathcal{L}\dfrac{df(t)}{dt} = sF(s) - f(0^-)$
nth-order derivative	$\mathcal{L}\dfrac{d^nf}{dt^n} = s^nF(s) - s^{n-1}f(0^-) - \cdots - f^{(n-1)}(0^-)$
Integral	$\mathcal{L}\displaystyle\int_{0^-}^{t} f(x)dx = \dfrac{F(s)}{s}$
Time shift	$\mathcal{L}[f(t - t_0)\, u\,(t - t_0)] = \epsilon_0^{-t} F(s)$
	where u is the unit step function
Frequency shift	$\mathcal{L}\epsilon^{-at}f(t) = F(s + a)$
Frequency scaling	$\mathcal{L}f(at) = \dfrac{1}{a}F\left(\dfrac{s}{a}\right), a > 0$
Initial value	$\lim\limits_{t\to 0} f(t) = \lim\limits_{t\to 0} sF(s)$
	provided the limit exists
	$\lim\limits_{t\to 0} f(t) = \lim\limits_{t\to 0} sF(s)$
	provided the limit exists
Constant multiplier	$\mathcal{L}kf(t) = k\mathcal{L}F(s)$
Addition	$\mathcal{L}[a_1f_1(t) + a_2f_2(t)] = a_1F_1(s) + a_2F_2(s)$
	a_1, a_2 are constants

Transfer Functions. The ratio of the Laplace transform of a response function to the Laplace transform of an excitation function, when initial conditions are zero, is called a *transfer function*. Any or all of the elements of the 2-port parameter matrices can be a transfer function in addition to being numerics. If the substitution $s = j\omega$ is made in a transfer function, then the new function is a function of (sinusoidal) signals of varying frequency. The frequency is measured in rad/s.

Example of Laplace Analysis. Figure 2-41 shows a 2-node circuit with an initial charge on one of the capacitors and the Laplace domain equivalent circuit. Equations (2-108) to (2-112) show Kirchhoff's current law equations for the circuit, a Laplace domain solution for one of the voltages, a partial fraction expansion of the solution, and finally, the inverse transform. (To reduce arithmetic complexity, the network is scaled.)

$$\frac{2s}{s^2 + 4} = V_1(s)\left(1 + \frac{1}{2s} + s\right) - V_2(s)\left(\frac{1}{2s}\right) \tag{2-108}$$

$$0 = -V_2(s)\left(\frac{1}{2s}\right) + V_1(s)\left(1 + \frac{1}{2s} + s\right) - 4 \tag{2-109}$$

$$V_2(s) = \frac{4s^4 + 4s^3 + 18s^2 + 17s + 8}{(s^2 + 4)(s + 1)(s^2 + s + 1)} \tag{2-110}$$

$$V_2(t) = 1.8e^{-1} - 0.1240 \cos(2t - 29.74°) + 2.5420e^{-t/2} \cos(0.8660t + 24.79°) \tag{2-112}$$

2.1.21 Fourier Analysis

Definition of Fourier Series. A periodic function $f(t)$ is defined as one that has the property

$$f(t) = f(t \pm nT) \tag{2-113}$$

where n is an integer and T is the period. If $f(t)$ satisfies the Dirichlet conditions, that is,

$f(t)$ has a finite number of finite discontinuities in the period T,

$f(t)$ has a finite number of maxima and minima in the period T,

the integral $\int_{t_0}^{t_0+T} |f(t)|\,dt$ exists. Then $f(t)$ can be written as a series of sinusoidal terms. Specifically,

$$f(t) = a_0 + \sum_{k=1}^{\infty} \left[a_k \cos(k\omega_0 t) + b_k \sin(k\omega_0 t)\right] \tag{2-114}$$

The coefficients may be found with these equations:

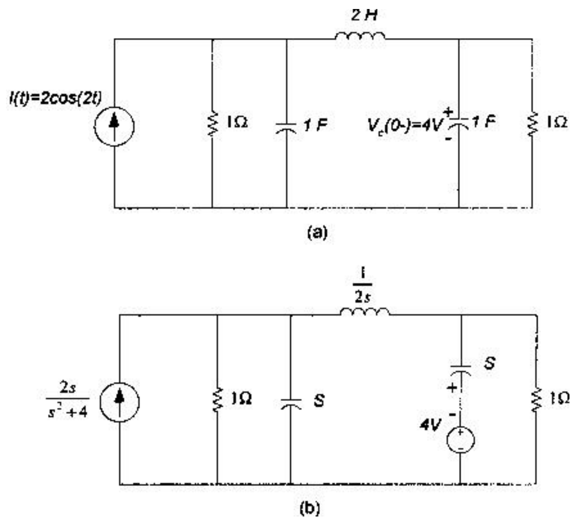

FIGURE 2-41 Example of Laplace transform circuit analysis: (*a*) 2-node circuit with one nonzero initial condition; (*b*) Laplace domain equivalent circuit equations and solution shown as Eqs. (2-108) to (2-112).

$$a_0 = \frac{1}{T}\int_{t_0}^{t_0+T} f(t)dt$$
$$a_k = \frac{2}{T}\int_{t_0}^{t_0+T} f(t)\cos(k\omega_0 t)dt \qquad (2\text{-}115)$$
$$b_k = \frac{2}{T}\int_{t_0}^{t_0+T} f(t)\sin(k\omega_0 t)dt$$

Evaluation of Fourier Coefficients. If an analytic expression for $f(t)$ is known, then the integrals can be used to evaluate the coefficients, which are then a function of the integral variable k. If the function $f(t)$ is known numerically or graphically, then numerical integration is required. Such integration is readily done with suitable computer software.

Effect of Symmetry. If the function $f(t)$ is even, that is, $f(t) = f(-t)$, then the expressions for the coefficients become

$$a_0 = \frac{2}{T}\int_0^{T/2} f(t)dt$$
$$a_k = \frac{4}{T}\int_0^{T/2} f(t)\cos(k\omega_0 t)\,dt \qquad (2\text{-}116)$$
$$b_k = 0 \qquad \text{for all } k$$

If $f(t)$ is odd, that is $f(t) = -f(-t)$, then

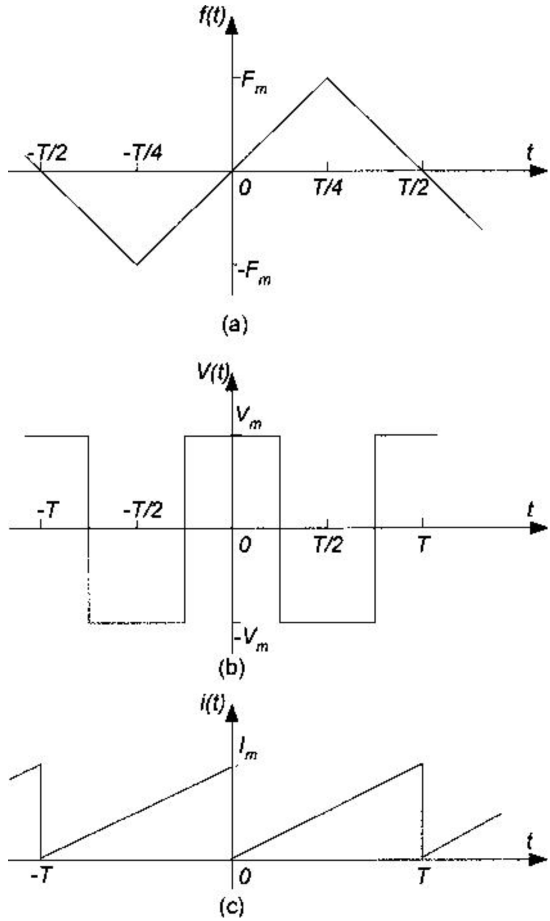

FIGURE 2-42 Waveforms for Fourier analyses [see Eqs. (2-118) to (2-120)]: (*a*) triangular wave, odd symmetry; (*b*) square wave, even symmetry; (*c*) ramp function.

$$a_k = 0 \qquad \text{for} \qquad k = 0, 1, 2, 3, \ldots$$

$$b_k = \frac{4}{T}\int_0^{T/2} \sin(k\omega_0 t)dt \tag{2-117}$$

Fourier Series Examples. Figure 2-42 shows three waveforms: a triangular signal written as an odd function, a square wave written as an even function, and a ramp function. For these three signals, the Fourier series are

$$f(t) = \frac{8F_m}{\pi^2}\sum_{n=1,3,5,\ldots}^{\infty}\frac{1}{n^2}\sin\left(\frac{n\pi}{2}\right)\sin(n\omega_0 t)$$

$$v(t) = \frac{4v_m}{\pi}\sum_{n=1,3,5,\ldots}^{\infty}\frac{1}{n}\sin\left(\frac{n\pi}{2}\right)\sin(n\omega_0 t) \tag{2-118}$$

$$i(t) = \frac{I_m}{2} - \frac{I_m}{\pi}\sum_{n=1}^{\infty}\frac{1}{n}\sin(n\omega_0 t)$$

Average Power Calculations. If the Fourier series given in Eq. (2-114) represents a current or voltage, then the effective value of this current or voltage is given by

$$F_{\text{eff}} = \sqrt{a_0^2 + \frac{1}{2}\sum_{1}^{\infty}(a_k^2 + b_k^2)} \qquad (2\text{-}119)$$

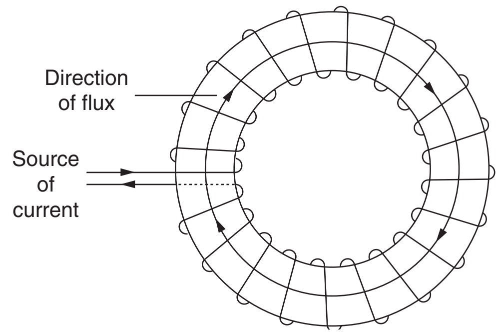

FIGURE 2-43 Closed magnetic circuit.

2.1.22 The Magnetic Circuit

The Simple Magnetic Circuit. A simple magnetic circuit is a uniformly wound torus ring (Fig. 2-43). The relation between the mmf F and the flux ϕ is similar to Ohm's law, namely,

$$F = R\phi \qquad \text{At} \qquad (2\text{-}120)$$

where R is called the *reluctance* of the magnetic circuit. The relation is sometimes written in the form

$$\phi = PF$$

where $p = 1/R$ is called the *permeance* of the magnetic circuit. Reluctance is analogous to resistance, and permeance is analogous to conductance of an electric circuit.

$$F = NI \qquad \text{At} \qquad (2\text{-}121)$$

where N is the number of turns of conductor around the magnetic circuit, as in Fig. 2-43, and I is the current in the conductor, in amperes.

Permeability and Reluctivity. The reluctance of a uniform magnetic path (Fig. 2-43) is proportional to its length I and inversely proportional to its cross section A.

$$R = v\frac{1}{A} \qquad \text{At/Wb} \qquad (2\text{-}122)$$

and

$$P = \mu\frac{A}{l} \qquad \text{Wb/At} \qquad (2\text{-}123)$$

In these expressions, v is called the *reluctivity* and μ the *permeability* of the material of the magnetic path, it being assumed that there is no residual magnetism. The dimensions l and A are in metric units. For a vacuum, air, or other nonmagnetic substance, the reluctivity and permeability are usually written v_0 and μ_0, and their values are $1/(4\pi \times 10^{-7})$ and $4\pi \times 10^{-7}$, respectively.

Magnetic Field Intensity. Magnetic field intensity H is defined as the mmf per unit length of path of the magnetic flux. It is known also as the *magnetizing force* or the *magnetic potential gradient*. In a uniform field,

$$H = \frac{F}{l} \qquad \text{At/m} \qquad (2\text{-}124)$$

In a nonuniform magnetic circuit,

$$H = \frac{\partial F}{\partial l} \qquad (2\text{-}125)$$

Inversely, for a uniform field,

$$F = HI \tag{2-126}$$

and for a nonuniform field,

$$F = \int H dl \tag{2-127}$$

By Ampere's law, when this integral is taken around a complete magnetic circuit,

$$F = \oint H dl = I \tag{2-128}$$

where I is the total current, in amperes, surrounded by the magnetic circuit. The circle on the integral sign indicates integration around the complete circuit. In Eqs. (2-126) to (2-128), it is presumed that H is directed along the length of l; otherwise, the factor $\cos\theta$ must be added to the product Hdl, where θ is the angle between H and dl.

Flux Density. Flux density B is the magnetic flux per unit area, the area being perpendicular to the direction of the magnetic lines of force. In a uniform field,

$$B = \frac{\phi}{A} \qquad \text{T(or Wb/m}^2\text{)} \tag{2-129}$$

Reluctances and Permeances in Series and in Parallel. Reluctances and permeances are added like resistances and conductances, respectively. That is, *reluctances are added when in series, and permeances are added when in parallel*. If several permeances are given connected in series, they are converted into reluctances by taking the reciprocal of each. If reluctances are given in a parallel combination, they are similarly converted into permeances.

Magnetization Characteristic or Saturation Curve. The magnetic properties of steel or iron are represented by a saturation or magnetization curve (Fig. 2-44). Magnetic field intensities H in ampere-turns per meter are plotted as abscissas and the corresponding flux densities B in teslas (webers per square meter) as ordinates.

The practical use of a magnetization curve may be best illustrated by an example. Let it be required to find the number of exciting ampere-turns for magnetizing a steel ring so as to produce in it a flux of 1.68 mWb. Let the cross section of the ring be 10.03 by 0.04 m and the mean diameter 0.46 m. Let the quality of the material be represented by the curve in Fig. 2-44. The flux density is $1.68 \times 10^{-3}/(0.03 \times 0.04) = 1.4$ Wb/m^2. For this flux density, the corresponding abscissa from the curve is about 18 At/m. The total required number of ampere-turns is then $18 \times \pi \times 46 = 2600$.

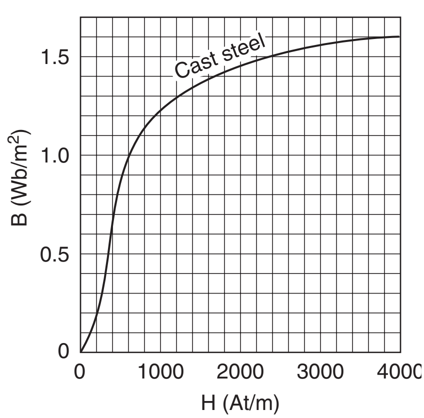

FIGURE 2-44 Typical *BH* curve.

For curves of various grades of steel and iron, see Sec. 4. The principal methods for experimentally obtaining magnetization curves will be found in Sec. 3.

Ampere-Turns for an Air Gap. In a magnetic circuit consisting of iron with one or more small air gaps in series with the iron, the magnetic flux density in each of the air gaps may be considered approximately uniform. If the length across a given air gap in the direction of the flux is l m, the ampere-turns required for that air gap is given by the equation

$$\text{At/m} = \frac{B(T)}{4\pi \times 10^{-7}} = 7.958 \times 10^5 B(T) \tag{2-130}$$

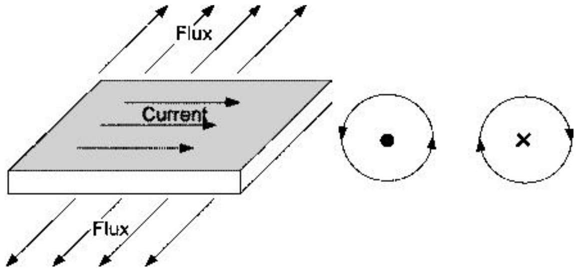

FIGURE 2-45 Relation between direction of current and flux.

The ampere-turns for each portion of iron, computed from iron magnetization curves such as Fig. 2-44, and the ampere-turns for the air gaps are added together to give the ampere-turns for the complete magnetic circuit.

Analysis of Magnetization Curve. Three parts are distinguished in a magnetization curve (Fig. 2-44): the lower, or nearly straight, part; die middle part, called the *knee* of the curve; and the upper part, which is nearly a straight line. As the magnetic intensity increases, the corresponding flux density increases more and more slowly, and the iron is said to approach saturation (see Sec. 4).

Magnetization per Unit Volume and Susceptibility. If a portion of ferromagnetic material is magnetized by an mmf, H At/m, the resulting flux density in teslas may be written as

$$B = \mu_0(H + M) \tag{2-131}$$

where M is the magnetization per unit volume of the material (see Sec. 4).

The ratio of M/H is symbolized by x and is called the *magnetic susceptibility*. It is the excess of the ratio of $B/\mu_0 H$ above unity, that is,

$$x = \frac{B}{\mu_0 H} - 1 \tag{2-132}$$

This is a dimensionless quantity. See Sec. 1.

The Right-Handed-Screw Rule. The direction of the flux produced by a given current is determined as shown in Fig. 2-45 (see also Fig. 2-43). If the current is established in the direction of rotation of a right-handed screw, the flux is in the direction of the progressive movement of the screw. If the current in a straight conductor is in the direction of the progressive motion of a right-handed screw, then the flux encircles this conductor in the direction in which the screw must be rotated in order to produce this motion. The dots in the figure indicate the direction of flux or current toward the reader, and the crosses away from the reader.

Fleming's Rules. The relative direction of flux, voltage, and motion in a revolving-armature generator may be determined with the right hand by placing the thumb, index, and middle fingers so as to form the three axes of a coordinate system and pointing the index finger in the direction of the flux (north to south) and the thumb in the direction of motion; the middle finger will give the direction of the generated voltage (Fig. 2-46). In the same way, in a revolving-armature motor, by using the left hand and pointing the index finger in the direction of the flux and the middle finger in the direction of the current in the armature conductor, the thumb will indicate the direction of

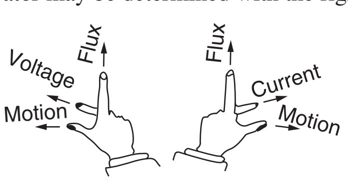

FIGURE 2-46 Flemming's generator and motor rules.

the force and, therefore, the resulting motion. These two rules, indicated in Fig. 2-46, are known as *Fleming's rules*.

Magnetic Tractive Force. The attracting force of a magnet is

$$F = \frac{1}{2}\frac{AB^2}{\mu_0} = \frac{AB^2}{8\pi \times 10^{-7}} \qquad \text{newtons} \tag{2-133}$$

where B is the flux density in the air gap, expressed in teslas (webers per square meter), and A is the total area of the contact between the armature and the core, in square meters. The mass that can be supported is dependent on the gravity field in which the mass and magnet are located.

Magnetic Force, or Torque. The mechanical force, or the torque, between two parts of a magnetic or electric circuit may in some cases be conveniently calculated by making use of the principle of *virtual displacements*. An infinitesimal displacement between the two parts is assumed. The energy supplied from the source of current is then equal to the mechanical energy for producing the motion, plus the change in the stored magnetic energy, plus the energy for resistance loss.

When the differential motion ds m of a part of a circuit carrying a current I A changes its self-inductance by a differential dL H, the mechanical force on that part of the circuit, in the direction of the motion, is

$$F = \frac{1}{2}I^2\frac{dL}{ds} \qquad \text{newtons} \tag{2-134}$$

When the motion of one coil or circuit carrying a current I_1 A changes its mutual inductance by a differential dM H with respect to another coil or circuit carrying a current I_2 A, the mechanical force on each coil or circuit, in the direction of the motion, is

$$F = I_1 I_2 \frac{dM}{ds} \qquad \text{newtons} \tag{2-135}$$

where ds represents the differential of distance in meters. For a discussion of self-inductance and mutual inductance L and M, see Sec. 2.1.6.

2.1.23 Hysteresis and Eddy Currents in Iron

The Hysteresis Loop. When a sample of iron or steel is subjected to an alternating magnetization, the relation between B and H is different for increasing and decreasing values of the magnetic intensity (Fig. 2-47). This phenomenon is due to irreversible processes which result in energy dissipation, producing heat. Each time the current wave completes a cycle, the magnetic flux wave also must complete a cycle, and the elementary magnets are turned. The curve *AefBcdA* in Fig. 2-47 is called the *hysteresis loop*.

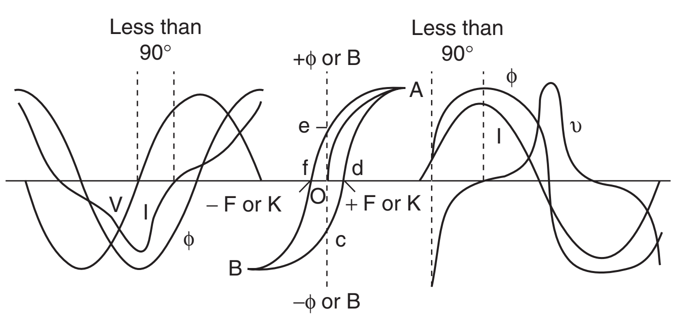

FIGURE 2-47 Periodic waves of current, flux, and voltage; hysteresis loop.

Retentivity. If the coil shown in Fig. 2-43 is excited with alternating current, the ampere-turns and consequently the mmf will, at any instant, be proportional to the instantaneous value of the exciting current. Plotting a *B-H* (or ϕ-*F*) curve (Fig. 2-47) for one cycle yields the closed loop *AefBcdA*. The first time the iron is magnetized, the *virgin*, or *neutral, curve OA* will be produced, but it cannot be produced in the reverse direction *AO* because when the mmf drops to zero there will always be some remaining magnetism ($+Oe$ or $-Oc$). This is called *residual magnetism*; to reduce this to zero, an mmf ($-Of$ or $+Od$) of opposite polarity must be applied. This mmf is called the *coercive force*.

Wave Distortion. In Fig. 2-47 the instantaneous values of the exciting current *I* (which is directly proportional to the mmf) and the corresponding values of the flux ϕ and voltage *V* (or *v*) are plotted against time as abscissas, beside the hysteresis loop. (a) If the voltage applied to the coil is *sinusoidal* (*V*, to the left), the current wave is distorted and displaced from the corresponding sinusoidal flux wave. The latter wave is in quadrature with the voltage wave. (b) If the *current* through the coil is *sinusoidal* (*I*, to the right), the flux is distorted into a flat-top wave and the induced voltage *v* is peaked.

Components of Exciting Current. The alternating current that flows in the exciting coil (Fig. 2-47) may be considered to consist of two components, one exciting magnetism in the iron and the other supplying the iron loss. For practical purposes, both components may be replaced by equivalent sine waves and phasors (Fig. 2-48) (see Sec. 2.1.11). We have

$$I_r = I\cos\theta = \text{power component of current}$$

$$P_h = IV\cos\theta = I_rV = \text{iron loss in watts} \tag{2-136}$$

$$I_m = I\sin\theta = \text{magnetizing current}$$

where *I* is the total exciting current, and *J* the angle of time-phase displacement between current and voltage.

Hysteretic Angle. Without iron loss, the current *I* would be in phase quadrature with *V*. For this reason, the angle $\alpha = 90 - \theta$ is called the *angle of hysteretic advance of phase*.

$$\sin\alpha = \frac{I_r}{I} = \frac{I_rN}{IV} = \frac{W\text{loss}}{VA} \tag{2-137}$$

In practice, the measured loss usually includes eddy currents, so the name *hysteretic* is somewhat of a misnomer.

The energy lost per cycle from hysteresis is proportional to the area of the hysteresis loop (Fig. 2-47). This is a consequence of the evaluation over a cycle of Eq. (2-13).

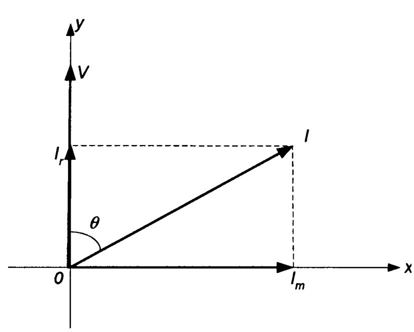

FIGURE 2-48 Components of exciting current; hysteretic angle.

Steinmetz's Formula. According to experiments by C.P. Steinmetz, the heat energy due to hysteresis released per cycle per unit volume of iron is approximately

$$W_h = \eta B_{\max}^{1.6} \tag{2-138}$$

The exponent of $B_{\max}$ varies between 1.4 and 1.8 but is generally taken as 1.6. Values of the hysteresis coefficient 11 are given in Sec. 4.

Eddy-Current Losses. Eddy-current losses are I^2R losses due to secondary currents (Foucault currents) established in those parts of the circuit which are interlinked with alternating or pulsating flux. Refer to

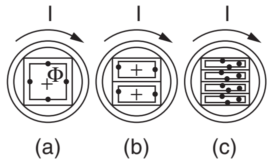

FIGURE 2-49 Section of a transformer core.

Fig. 2-49, which shows a cross section of a transformer core. The primary current I produces the alternating flux Φ, which by its change generates a voltage in the core; this voltage then sets up the secondary current i. Now, if the core is divided into two (b), four (c), or n parts, the voltage in each circuit is $v/2$, $v/4$, v/n, and the conductance is $g/2$, $g/4$, g/n, respectively. Thus, the loss per lamination will be $1/n^3$ times the loss in the solid core, and the total loss is $1/n^2$ times the loss in the solid core. When power is computed, the power is given by

$$P_h = \eta f \beta_{\max}^{1.6} \tag{2-139}$$

Eddy currents can be greatly reduced by laminating the circuit, that is, by making it up of thin sheets each electrically insulated from the others. The same purpose is accomplished by using separately insulated strands of conductors or bundles of wires.

A formula for the eddy loss in conductors of circular section, such as wire, is

$$P_e = \frac{(\pi r f B_{\max})^2}{4\rho} \qquad \text{W/m}^3 \tag{2-140}$$

where r is the radius of the wire in meters, f is the frequency in hertz (cycles per second), $B_{\max}$ is the maximum flux density in teslas, and p is the specific resistance in ohm meters.

A formula for the loss in sheets is

$$P_e = \frac{(\pi r f B_{\max})^2}{6\rho} \qquad \text{W/m}^3 \tag{2-141}$$

where t is the thickness in meters, f is the frequency in hertz (cycles per second), $B_{\max}$ is the maximum flux density in teslas, and ρ is the specific resistance in ohm meters. The specific resistance of various materials is given in Sec. 4.

Effective Resistance and Reactance. When an A.C. circuit has appreciable hysteresis, eddy currents, and skin effect, it can be replaced by a circuit of equivalent resistances and equivalent reactances in place of the actual ones. These effective quantities are so chosen that the energy relations are the same in the equivalent circuit as in the actual one. In a series circuit, let the true power lost in ohmic resistance, hysteresis, and eddy currents be P, and the reactive (wattless) volt-amperes, Q. Then the effective resistance and reactance are determined from the relations

$$i^2 r_{\text{eff}} = P \qquad i^2 x_{\text{eff}} = Q \tag{2-142}$$

In a parallel circuit, with a given voltage, the equivalent conductances and susceptance are calculated from the relations

$$e^2 g_{\text{eff}} = P \qquad e^2 b_{\text{eff}} = Q \tag{2-143}$$

Such equivalent electric quantities, which replace the core loss, are used in the analytic theory of transformers and induction motors.

Core Loss. In practical calculations of electrical machinery, the total core loss is of interest rather than the hysteresis and the eddy currents separately. For such computations, empirical curves are used, obtained from tests on various grades of steel and iron (see Sec. 4).

Separation of Hysteresis Losses from Eddy-Current Losses. For a given sample of laminations, the total core loss P, at a constant flux density and at variable frequency f, can be represented in the form

$$P = af + bf^2 \tag{2-144}$$

where af represents the hysteresis loss and bf^2 the eddy, or Foucault-current, loss, a and b being constants. The voltage waveform should be very close to a sine wave. If we write this equation for two known frequencies, two simultaneous equations are obtained from which a and b are determined.

It is convenient to divide the foregoing equation by f, because the form

$$\frac{P}{f} = a + bf \tag{2-145}$$

represents a straight line relating P/f and f. Known values of P/f are plotted against f as abscissas, and a straight line having the closest approximation to the points is drawn. The intersection of this line with the axis of ordinates gives a; b is calculated from the preceding equation. The separate losses are calculated at any desired frequency from af and bf^2, respectively.

2.1.24 Inductance Formulas

Inductance. The properties of self-inductance and mutual inductance are defined in Sec. 2.1.6. In these paragraphs, inductance relations for common geometries are given.

Torus Ring or Toroidal Coil of Rectangular Section with Nonmagnetic Core (Fig. 2-43). Inductance of a rectangular toroidal coil, uniformly wound with a single layer of fine wire, is

$$L = 2 \times 10^{-7} N^2 b \left(\ln \frac{r_2}{r_1}\right) \qquad \text{henrys} \tag{2-146}$$

where N equals the number of turns of wire on the coil, b is the axial length of the coil in meters, and r_2 and r_1 are the outer and inner radial distances in meters.

Torus Ring or Toroidal Coil of Circular Section with Nonmagnetic Core (Fig. 2-43). A toroidal coil of circular section, uniformly wound with a single layer of fine wire of N turns, has an inductance of

$$L = 4\pi \times 10^{-7} N^2 \left(g - \sqrt{g^2 - a^2}\right) \qquad \text{henrys} \tag{2-147}$$

where g is the mean radius of the toroidal ring and a is the radius of the circular cross section of the core, both measured in meters.

Inductance of a Very Long Solenoid. A solenoid uniformly wound in a single layer of fine wire possesses an inductance of

$$L = \frac{4\pi^2 \times 10^{-7} N^2 R^2}{S} \qquad \text{henrys} \tag{2-148}$$

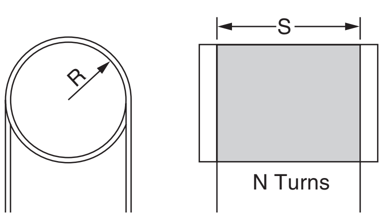

FIGURE 2-50 Cylindrical solenoid.

where R and S are the radius and length of the solenoid in meters, as illustrated in Fig. 2-50. The assumption is made that S is very large with respect to R.

Inductance of the Finite Solenoid. The inductance of a short solenoid is less than that given by Eq. (2-148), by a factor k (a dimensionless quantity). The inductance relation then is

$$L = k \frac{4\pi^2 \times 10^{-7} N^2 R^2}{S} \qquad \text{henrys} \tag{2-149}$$

where the values of k for various ratios of R and S are given in Fig. 2-51. Inductance relations for other configurations of coils are given by Boast (1964).

Inductance per Unit Length of a Coaxial Cable. For low-frequency applications, where skin effect is not predominant (uniform current density over nonmagnetic current-carrying cross sections), the inductance per unit length of a coaxial cable is

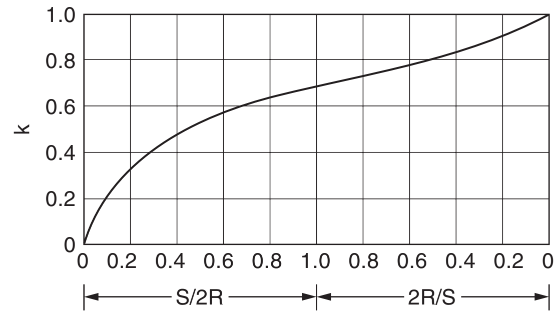

FIGURE 2-51 Factor k of Eq. (2-149). (*From W. B. Boast, Vector Fields, New York, Harper & Row, 1964.*)

$$L = l = \frac{10^{-7}}{2}[1 + 4\ln\frac{R^2}{R_1} + \frac{4R_3^4}{(R_3^2 - R_2^2)^2}\ln\frac{R_3}{R_2} - \frac{3R_3^2 - R_2^2}{R_3^2 - R_2^2}] \quad \text{H/m} \tag{2-150}$$

where R_1, R_2, and R_3 are the radii of the inner conductor, the inner radius of the outer conductor, and the outer radius of the outer conductor, in meters, respectively, as shown in Fig. 2-52. For very thin outer shells, the last two terms drop out of the equation, and for very small inner conductors, the first term becomes less important. For high-frequency applications, the first, third, and fourth terms are all suppressed, and for the extreme situation where all the current is essentially at the boundaries formed by R_1 and R_2, respectively, the inductance per unit length becomes

$$l = 2 \times 10^{-7}\ln(R_2/R_1) \quad \text{H/m} \tag{2-151}$$

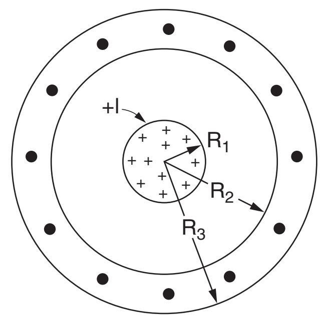

FIGURE 2-52 Coaxial cable.

Inductance of Two Long, Cylindrical Conductors, Parallel and External to Each Other. The inductance per unit length of two separate parallel conductors is

$$l = 10^{-7}\left(1 + 4\ln\frac{D}{\sqrt{R_1R_2}}\right) \quad \text{H/m} \tag{2-152}$$

where D is the distance between centers of the two cylinders and R_1 and R_2 are the radii of the conductor cross sections.

If $R_1 = R_2 = R$ and the skin-effect phenomenon applies as at very high frequencies, the inductance per unit length becomes

$$l = 4 \times 10^{-7}\left(1 + 4\ln\frac{D}{\sqrt{R_1R_2}}\right) \quad \text{H/m} \tag{2-153}$$

Inductance of Transmission Lines. The inductance relationships used in predicting the performance of power-transmission systems often involve the effects of stranded and bundled conductors operating in parallel, as well as configurations of these groups of current-carrying elements of one phase group of the system coordinated with similar groups constituting other phases, in polyphase systems. In such systems, the several current-carrying elements of a phase are considered mathematically as a cylindrical shell of current of radius D_s (meters) called the *self-geometric mean radius* of the phase, and the mutual distances (between the current in a particular phase and the other [return] currents in the other phases) are replaced by a distance D_m (meters) called the *mutual geometric mean distance* to the return. The inductance of all phases may be balanced by transposing the conductors over the length of the transmission line so that each phase occupies all positions equally in the length of the line.

The inductance per phase is then one-half as large as that of Eq. (2.153), that is,

$$l = 2 \times 10^{-7} 4 \ln(D_m/D_s) \qquad \text{H/m} \tag{2-154}$$

The references related to methods for computing the geometric mean distances D_m and D_s are available in Bibliography at the end of the section.

Leakage Inductance. In electrical apparatus, such as transformers, generators, and motors, in which the greater part of the flux is carried by an iron core, the difference between self-inductance and mutual inductance of the primary and secondary windings is small. This small difference is called *leakage inductance*. It is of great importance in the characteristics and operation of the apparatus and is usually calculated or measured separately. The loss in voltage in such apparatus, due to inductance, is associated with the leakage.

Magnetizing Current. The mutual inductance of the windings of apparatus with iron cores is not usually stated in henrys, but the effective alternating current required to produce the flux is stated in amperes and is called the *exciting current*. One component of this current supplies the energy corresponding to the core loss. The remaining component is called *magnetizing current.* Solenoids and other coils with only one winding are usually treated in a similar manner when they have iron cores. The exciting current usually does not have a sine-wave form. See Fig. 2-47.

2.1.25 Skin Effect

Real, or ohmic, resistance is the resistance offered by the conductor to the passage of electricity. Although the specific resistance is the same for either alternating or continuous current, the total resistance of a wire is greater for alternating than for continuous current. This is due to the fact that there are induced emfs in a conductor in which there is alternating flux. These emfs are greater at the center than at the circumference, so the potential difference tends to establish currents that oppose the current at the center and assist it at the circumference. The current is thus forced to the outside of the conductor, reducing the effective area of the conductor. This phenomenon is called *skin effect*.

Skin-Effect Resistance Ratio. The ratio of the A.C. resistance to the D.C. resistance is a function of the cross-sectional shape of the conductor and its magnetic and electrical properties as well as of the frequency. For cylindrical cross sections with presumed constant values of relative permeability μ_r and resistivity ρ, the function that determines the skin-effect ratio is

$$mr = \sqrt{\frac{8\pi^2 \times 10^{-7} f \mu_r r}{\rho}} \tag{2-155}$$

where r is the radius of the conductor and f is the frequency of the alternating current. The ratio of R, the A.C. resistance, to R_0, the D.C. resistance, is shown as a function of mr in Fig. 2.53.

Steel Wires and Cables. The skin effect of steel wires and cables cannot be calculated accurately by assuming a constant value of the permeability, which varies throughout a large range during every cycle. Therefore, curves of measured characteristics should be used. See *Electrical Transmission and Distribution Reference Book,* 4th ed., 1950.

Skin Effect of Tubular Conductors. Cables of large size are often made so as to be, in effect, round, tubular conductors. Their effective resistance due to skin effect may be taken from the curves of Sec. 4. The skin-effect ratio of square, tubular bus bars may be obtained from semiempirical formulas in the paper "A-C Resistance of Hollow, Square Conductors," by A. H. M. Arnold, *J. IEE (London),* 1938,

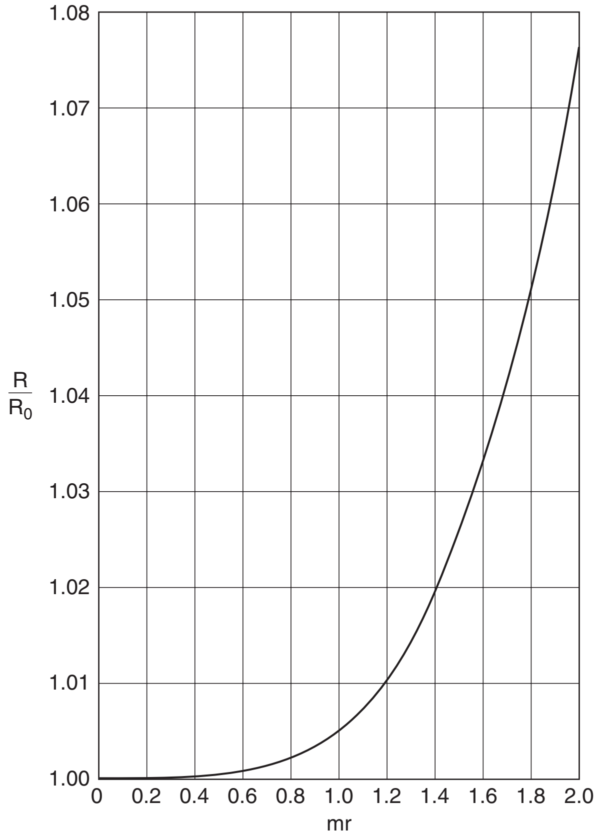

FIGURE 2-53 Ratio of A.C. to D.C. resistance of a cylindrical conductor. (*From W. D. Stevenson, Elements of Power Systems Analysis, New York, McGraw-Hill; 1962.*)

vol. 82, p. 537. These formulas have been compared with tests. The resistance ratio of square tubes is somewhat larger than that of round tubes. Values may be read from the curves of Fig. 4, Chap. 25, of *Electrical Coils and Conductors*.

Penetration Formula. For wires and tubes (and approximately for other compact shapes) where the resistance ratio is comparatively large, the conductor can be approximately considered to be replaced by its outer shell, of thickness equal to the "penetration depth," given by

$$\delta = \frac{1}{2\pi}\sqrt{\frac{10^7\rho}{f\mu_r}} \qquad \text{meters} \tag{2-156}$$

where ρ is the resistivity in ohm-meters, and μ_r is a presumed constant value of relative permeability. The resistance of the shell is then the effective resistance of the conductor. For Eq. (2-156) to be applicable, δ should be small compared with the dimensions of the cross section. In the case of tubes, δ is, evidently, less than the thickness of the tube. See Eq. (30), Chap. 19, of *Electrical Coils and Conductors*.

2.1.26 Electrostatics

Electrostatic Force. Electrically charged bodies exert forces on one another according to the following principles:

1. Like charged bodies repel; unlike charged bodies attract one another.
2. The force is proportional to the product of the magnitudes of the charges on the bodies.
3. The force is inversely proportional to the square of the distance between charges if the material in which the charges are immersed is extensive and possesses the same uniform properties in all directions.
4. The force acts along the line joining the centers of the charges.

Two concentrated charges Q_1 and Q_2 coulombs located R m apart experience a force between them of

$$F = \frac{Q_1 Q_2}{4\pi e_0 R^2} \qquad \text{newtons} \tag{2-157}$$

where $e_0 = 8.85419 \times 10^{-12}$ F/m and is the permittivity of free space.

Electrostatic Potential. The electric potential resulting from the location of charged bodies in the vicinity is called *electrostatic potential*. The potential at R m from a concentrated charge Q C is

$$\phi = \frac{Q}{4\pi e_0 R} \qquad \text{volts} \tag{2-158}$$

This potential is a scalar quantity.

Electric Field Intensity. The electric field intensity is the force per unit charge that would act at a point in the field on a very small test charge placed at that location. The electric field intensity E at a distance R m from a concentrated charge Q C is

$$E = \frac{Q}{4\pi e_0 R} \qquad \text{N/C} \tag{2-159}$$

Electric Potential Gradient in Electrostatic Fields. The space rate of change of the electric potential is the electric potential gradient of the field, symbolized by $\Delta\phi$. The general relationship between the gradient of the electric potential and the electric field intensity is

$$E = -\nabla\phi \qquad \text{V/m} \tag{2-160}$$

The units for the electric potential gradient, volts per meter, are frequently also used for the electric field intensity because their magnitudes are the same.

Electric Flux Density. The density of electric flux D in a region where simple dielectric materials exist is determined from the electric field intensity from

$$D = eE = e_0 KE \qquad \text{C/m}^2 \tag{2-161}$$

where K is a dimensionless number called the *dielectric constant*. In free space K is unity. For numerical values of dielectric constant of various dielectrics, see Sec. 4.

Polarization. The polarization is the excess of electric flux density that results in dielectric materials over that which would result at the same electric field intensity if the space were free of material substance. Thus

$$P = D - e_0 E \qquad \text{C/m}^2 \tag{2-162}$$

Crystalline Atomic Materials. In simple isotropic materials, the directions of the vectors P, D, and E are the same. For crystalline atomic structures that are not isotropic, Eq. (2-162) is the only relationship which is meaningful, and Eq. (2-161) should not be used.

Electric Flux. Electric flux and its density are related by

$$\psi = \int D \cos \alpha dA \qquad \text{coulombs} \tag{2-163}$$

where α is the angle between the direction of the electric flux density D and the normal at each differential surface area dA.

Capacitance. The capacitance between two oppositely charged bodies is the ratio of the magnitude of charge on either body to the difference of electric potential between them. Thus

$$C = \frac{Q}{V} \qquad \text{farads} \tag{2-164}$$

where Q is in coulombs and V is the voltage between the two equally but oppositely charged bodies, in volts.

Elastance. The reciprocal of capacitance, called *elastance*, is

$$S = V/Q \qquad \text{farads} \tag{2-165}$$

Electric Field Outside an Isolated Sphere in Free Space. The electric field intensity at a distance r m from the center of an isolated charged sphere located in free space is

$$E = \frac{Q}{4\pi e_0 r^2} \qquad \text{V/m} \tag{2-166}$$

where Q is the total charge (which is distributed uniformly) on the sphere.

Spherical Capacitor. The capacitance between two concentric charged spheres is

$$C = \frac{4\pi e_0 K}{1/R_1 - 1/R_2} \qquad \text{farads} \tag{2-167}$$

where R_1 is the outside radius of the inner sphere, R_2 is the inside radius of the outer sphere, and K is the dielectric constant of the space between them.

Electric Field Intensity Created by an Isolated, Charged, Long Cylindrical Wire in Free Space. The electric field intensity in the vicinity of a long, charged cylinder is

$$E = \frac{\Lambda}{2\pi e_0 r} \qquad \text{V/m} \tag{2-168}$$

where Λ is the charge per unit of length in coulombs per meter (distributed uniformly over the surface of the isolated cylinder) and r is the distance in meters from the center of the cylinder to the point at which the electric field intensity is evaluated.

Coaxial Cable. The capacitance per unit length of a coaxial cable composed of two concentric cylinders is

$$c = \frac{2\pi e_0 K}{\ln(R_2/R_1)} \qquad \text{F/m} \tag{2-169}$$

where R_1 is the outside radius of the inner cylinder, R_2 is the inside radius of the outer cylinder, and K is the dielectric constant of the space between the cylinders.

Two-Wire Line. The capacitance per unit length between two long, oppositely charged cylindrical conductors of equal radii, parallel and external to each other, is

$$c = \frac{2\pi e_0 K}{\ln\left[\frac{D}{2R} + \sqrt{\left(\frac{D}{2R}\right)^2 - 1}\right]} \qquad \text{F/m} \tag{2-170}$$

where D is the distance in meters between centers of the two cylindrical wires each with radius R and K is the uniform dielectric constant of all space external to the wires.

Capacitance of Two Flat, Parallel Conductors Separated by a Thin Dielectric. The capacitance is approximately

$$C = \frac{e_0 KA}{t} \qquad \text{farads} \tag{2-171}$$

where A is the area of either of the two conductors, t is the spacing between them, and K is the dielectric constant of the space between the conductors. Strictly, the linear dimensions of the flat conductors should be very large compared with the spacing between them. Good results are obtained from Eq. (2-171) even though the conductors are curved provided that the spacing t is small with respect to the radius of curvature.

Induced Charges. The surface of a conducting body, near a charge Q, through which no currents are flowing is an equipotential surface, a condition maintained by the motion of positive and negative charges to the parts of the conductor near Q and distant from it. Hence, the potential at any point on the conductor, due to all the charges of the system, is a constant. The charges on the conductors are said to be induced by Q, and the conductor is said to be electrified by induction.

Electrostatic Induction on Parallel Wires. Two insulated wires running parallel to a wire carrying a charge A C/m display a potential difference (provided that the two wires are not connected to each other or to other conductors) of

$$\phi = \frac{\Lambda}{2\pi e_0} \ln \frac{b}{a} \qquad \text{volts} \tag{2-172}$$

where b and a are the distances of the two insulated wires from the charged wire.

If the two wires are connected together, as, for example, through telephone instruments, the current flowing from one wire to the other is that required to equalize their potential difference.

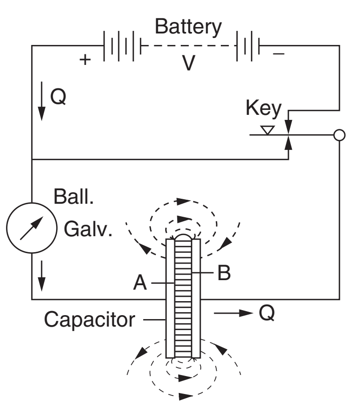

FIGURE 2-54 Circuit containing a capacitor.

2.1.27 The Dielectric Circuit

Circuit Concepts with Capacitive Elements. When a continuous voltage is applied to the terminals of a capacitor (AB, Fig. 2-54), a positive charge of electricity $+Q$ appears on one plate and a negative charge $-Q$ on the other. A quantity of electricity Q flows through the connecting wires, and this quantity of electricity is said to be displaced through the dielectric. An electrostatic field then exists between the two charged plates. Capacitors are introduced in Sec. 2.1.7. Capacitance formulas are given in those paragraphs.

Electrostatic Flux. The space between the plates of a capacitor can be treated as a dielectric circuit through which passes a dielectric flux ψ, in coulombs. In any dielectric circuit, one coulomb of electrostatic flux passes from each coulomb of positive charge to each coulomb of negative charge, and this is true with any insulating substance or group of substances. That is, electrostatic flux lines end only on charges of electricity. Their number is not affected when they pass from one dielectric to another, unless there is a charge of electricity on the surface of separation. Electrostatic flux lines are also called *lines of electrostatic induction*.

Capacitance to Neutral of a Conductor. The capacitance to neutral of a conductor in an AC line is defined as the capacitance that, when multiplied by $2\pi f$ and by the voltage to neutral, gives the charging current of the conductor, f being the frequency. This is not the same as the capacitance to a neutral wire measured electrostatically. The voltage to neutral of a single-phase line is one-half the voltage between conductors. The voltage to neutral of a balanced 3-phase line is equal to the voltage between conductors divided by 1.732.

When the conductors are round wires, for either single-phase or 3-phase overhead lines, the capacitance to neutral is

$$C = \frac{2\pi e_0 K}{\ln\sqrt{\frac{s}{d} + \left[\left(\frac{s}{d}\right)^2 - 1\right]^{1/2}}} \qquad \text{F/m, to neutral} \tag{2-173}$$

or, approximately,

$$C = \frac{0.0388}{\ln(2s/d)} \qquad \mu\text{F/mi, to neutral} \tag{2-174}$$

where s is the axial spacing and d is the diameter of the conductors, in the same units. Values of charging kVA for transmission lines are tabulated in Sec. 14.

The capacitance of a complete single-phase line is one-half the capacitance to neutral of one conductor. The capacitance of stranded conductors may be approximately calculated by using the outside diameter of the conductors. The capacitance of iron or steel conductors is calculated by the same formulas as that of copper conductors.

The preceding relations assume equilateral spacing for 3-phase systems. If unbalanced spacings are present and the phases are balanced by transposing the conductors over the length of the line, the approximate capacitance per phase can be obtained from the concepts of geometric mean distances D_m and D_s. Then, approximately,

$$C = \frac{2\pi e_0 k}{\ln(D_m D_s')} \qquad \text{f/m} \tag{2-175}$$

The self-geometric mean distance n in Eq. (2-175) differs slightly from that for D_s in Eq. (2-154), in that for good conductors, the transverse gradient of the electric field is confined principally to the airspace about the conductors, and D is slightly larger than D_s of Eq. (2-154). In the latter equation, internal flux linkages in the conductor contribute to the meaning of D_s.

Velocity of Propagation on Long Transmission Lines. The inductance and capacitive parameters per unit length of a transmission line determine the velocity with which such effects as switching surges are propagated along the line. The velocity of propagation is

$$\nu = \frac{1}{\sqrt{lc}} \qquad \text{m/s} \tag{2-176}$$

where l is the inductance per unit length from Eq. (2-154), and c is the capacitance per unit length from Eq. (2-175). Substituting these values gives

$$\nu = 3 \times 10^8 = \sqrt{\frac{\ln(D_m/D_s')}{K \ln(D_m/D_s)}} \qquad \text{m/s} \tag{2-177}$$

The fact that D is slightly larger than D_s produces a velocity of propagation along the transmission line which is slightly less than the velocity of propagation of electromagnetic radiation in free space (3 × 108 m/s). Since the dielectric constant K of the atmosphere surrounding the transmission line may be somewhat greater than unity, the velocity of propagation may be reduced slightly more. Magnetic materials in the conductors tend to increase the inductance in the denominator of Eq. (2-176) and reduce further the velocity of propagation by a small amount.

Dielectric Strength of Insulating Materials. The dielectric strength of insulating materials (rupturing voltage gradient) is the maximum voltage per unit thickness that a dielectric can withstand in a uniform field before it breaks down electrically. The dielectric strength is usually measured in kilovolts per millimeter or per inch. It is necessary to define the dielectric strength in terms of a uniform field, for instance, between large parallel plates a short distance apart. If the striking voltage is determined between two spheres or electrodes of other defined shape, this fact must be stated. In designing insulation, a factor of safety is assumed depending upon conditions of operation. For numerical values of rupturing voltage gradients of various insulating materials, see Sec. 4.

2.1.28 Dielectric Loss and Corona

Dielectric Hysteresis and Conductance. When an alternating voltage is applied to the terminals of a capacitor, the dielectric is subjected to periodic stresses and displacements. If the material were perfectly elastic, no energy would be lost during any cycle, because the energy stored during the periods of increased voltage would be given up to the circuit when the voltage is decreased. However, since the electric elasticity of dielectrics is not perfect, the applied voltage has to overcome molecular friction or viscosity, in addition to the elastic forces. The work done against friction is converted into heat and is lost. This phenomenon resembles magnetic hysteresis (Sec. 2.1.23) in some respects but differs in others. It has commonly been called *dielectric hysteresis* but is now often called *dielectric loss*. The energy lost per cycle is proportional to the square of the applied voltage. Methods of measuring dielectric loss are described in Sec. 3.

An imperfect capacitor does not return on discharge the full amount of energy put into it. Sometime after the discharge, an additional discharge may be obtained. This phenomenon is known as *dielectric absorption*.

A capacitor that shows such a loss of power can be replaced for purposes of calculation by a perfect capacitor with an ohmic conductance shunted around it. This conductance (or "leakance") is of such value that its *PR* loss is equal to the loss of power from all causes in the imperfect capacitor. The actual current through the capacitor is then considered as consisting of two components—the leading reactive component through the ideal capacitor and the loss component, in phase with the voltage, through the shunted conductance.

Electrostatic Corona. When the electrostatic flux density in the air exceeds a certain value, a discharge of pale violet color appears near the adjacent metal surfaces. This discharge is called *electrostatic corona*. In the regions where the corona appears, the air is electrically ionized and is a conductor of electricity. When the voltage is raised further, a brush discharge takes place, until the whole thickness of the dielectric is broken down and a disruptive discharge, or spark, jumps from one electrode to the other.

Corona involves power loss, which may be serious in some cases, as on transmission lines (Secs. 14 and 15). Corona can form at sharp corners of high-voltage switches, bus bars, etc., so the radii of such parts are made large enough to prevent this. A voltage of 12 to 25 kV between conductors separated by a fraction of an inch, as between the winding and core of a generator or between sections of the winding of an air-blast transformer, can produce a voltage gradient sufficient to cause corona.

A voltage of 100 to 200 kV may be required to produce corona on transmission-line conductors that are separated by several feet. Corona can have an injurious effect on fibrous insulation. For numerical data in application to transmission lines see Secs. 14 and 15.

3.1 ELECTRIC AND MAGNETIC MEASUREMENTS

3.1.1 General

Measurement of a quantity consists either of its comparison with a unit quantity of the same kind or of its determination as a function of quantities of different kinds whose units are related to it by known physical laws. An example of the first kind of measurement is the evaluation of a resistance

*Grateful acknowledgement is given to Norman Belecki, George Burns, Forest Harris, and B.W. Mangum for most of the material in this section.

(in ohms) with a Wheatstone bridge in terms of a calibrated resistance and a ratio. An example of the second kind is the calibration of the scale of a wattmeter (in watts) as the product of current (in amperes) in its field coils and the potential difference (in volts) impressed on its potential circuit.

The units used in electrical measurements are related to the metric system of mechanical units in such a way that the electrical units of power and energy are identical with the corresponding mechanical units. In 1960, the name *Système International* (abbreviated SI), now in use throughout the world, was assigned to the system based on the meter-kilogram-second-ampere (abbreviated mksa). The mksa units are identical in value with the practical units—volt, ampere, ohm, coulomb, farad, henry—used by engineers. Certain prefixes have been adopted internationally to indicate decimal multiples and fractions of the basic units.

A *reference standard* is a concrete representation of a unit or of some fraction or multiple of it having an assigned value which serves as a measurement base. Its assignment should be traceable through a chain of measurements to the National Reference Standard maintained by the National Institute of Standards and Technology (NIST). Standard cells and certain fixed resistors, capacitors, and inductors of high quality are used as reference standards.

The National Reference Standards maintained by the NIST comprise the legal base for measurements in the United States. Other nations have similar laboratories to maintain the standards which serve as their measurement base. An international bureau—Bureau International des Poids et Mesures (abbreviated BIPM) in Sèvres, France—also maintains reference standards and compares standards from the various national laboratories to detect and reconcile any differences that might develop between the as-maintained units of different countries.

At NIST, the reference standard of resistance is a group of 1-Ω resistors, fully annealed and mounted strain-free out of contact with the air, in sealed containers. The reference standard of capacitance is a group of 10-pF fused-silica-dielectric capacitors whose values are assigned in terms of the calculable capacitor used in the ohm determination. The reference standard of voltage is a group of standard cells continuously maintained at a constant temperature.

The "absolute" experiments from which the value of an electrical unit is derived are measurements in which the electrical unit is related directly to appropriate mechanical units. In recent *ohm* determinations, the value of a capacitor of special design was calculated from its measured dimensions, and its impedance at a known frequency was compared with the resistance of a special resistor. Thus, the ohm was assigned in terms of length and time. The as-maintained ohm is believed to be within 1 ppm of the defined SI unit. Recent *ampere* determinations, used to assign the *volt* in terms of current and resistance, derived the ampere by measuring the force between current-carrying coils of a mutual inductor of special construction whose value was calculated from its measured dimensions. The voltage drop of this current in a known resistor was used to assign the emf of the standard cells which maintain the volt. The stated uncertainty of these ampere determinations ranges from 4 to 7 ppm, and the departure of value of the "legal" volt from the defined SI unit carries the same uncertainty. Since 1972, the assigned emf of the standard cells in the reference group which maintains the legal volt is monitored (and reassigned as necessary) in terms of atomic constants (the ratio of Planck's constant to electron charge) and a microwave frequency by an ac Josephson experiment in which their voltage is measured with respect to the voltage developed across the barrier junction between two superconductors irradiated by microwave energy and biased with a direct current. This experiment appears to be repeatable within 0.1 ppm. It should be noted that while the Josephson experiment may be used to maintain the legal volt at a constant level, it is not used to define the SI unit.

Precision—a measure of the spread of repeated determinations of a particular quantity—depends on various factors. Among these are the resolution of the method used, variations in ambient conditions (such as temperature and humidity) that may influence the value of the quantity or of the reference standard, instability of some element of the measuring system, and many others. In the National Laboratory of the National Institute of Standards and Technology, where every precaution is taken to obtain the best possible value, intercomparisons may have a precision of a few parts in 10^7. In commercial laboratories, where the objective is to obtain results that are reliable but only to the extent justified by engineering or other requirements, precision ranges from this figure to a part in 10^3 or more, depending on circumstances. For commercial measurements such as the sale of electrical energy, where the cost of measurement is a critical factor, a precision of 1 or 2% is considered acceptable in some jurisdictions.

The use of digital instruments occasionally creates a problem in the evaluation of precision, that is, all results of a repeated measurement may be identical due to the combination of limited resolution and quantized nature of the data. In these cases, the least count and sensitivity of the instrumentation must be taken into account in determining precision.

Accuracy—a statement of the limits which bound the departure of a measured value from the true value of a quantity—includes the imprecision of the measurement, together with all the accumulated errors in the measurement chain extending downward from the basic reference standards to the specific measurement in question. In engineering measurement practice, accuracies are generally stated in terms of the values assigned to the National Reference Standards—the *legal* units. It is only rarely that one needs also to state accuracy in terms of the defined SI unit by taking into account the uncertainty in the assignment of the National Reference Standard.

General precautions should be observed in electrical measurements, and sources of error should be avoided, as detailed below:

1. The accuracy limits of the instruments, standards, and methods used should be known so that appropriate choice of these measuring elements may be made. It should be noted that instrument *accuracy classes* state the "initial" accuracy. Operation of an instrument, with energy applied over a prolonged period, may cause errors due to elastic fatigue of control springs or resistance changes in instrument elements because of heating under load. ANSI C39.1 specifies permissible limits of error of portable instruments because of sustained operation.
2. In any other than rough determinations, the *average of several readings* is better than one. Moreover, the alteration of measurement conditions or techniques, where feasible, may help to avoid or minimize the effects of accidental and systematic errors.
3. The *range* of the measuring instrument should be such that the measured quantity produces a reading large enough to yield the desired precision. The deflection of a measuring instrument should preferably exceed half scale. Voltage transformers, wattmeters, and watthour meters should be operated near to rated voltage for best performance. Care should be taken to avoid either momentary or sustained overloads.
4. *Magnetic fields*, produced by currents in conductors or by various classes of electrical machinery or apparatus, may combine with the fields of portable instruments to produce errors. Alternating or time-varying fields may induce emfs in loops formed in connections or the internal wiring of bridges, potentiometers, etc. to produce an error signal or even "electrical noise" that may obscure the desired reading. The effects of stray alternating fields on ac indicating instruments may be eliminated generally by using the average of readings taken with direct and reversed connections; with direct fields and dc instruments, the second reading (to be averaged with the first) may be taken after rotating the instrument through 180°. If instruments are to be mounted in magnetic panels, they should be calibrated in a panel of the same material and thickness. It also should be noted that Zener-diode-based references are affected by magnetic fields. This may alter the performance of digital meters.
5. In measurements involving high resistances and small currents, *leakage paths* across insulating components of the measuring arrangement should be eliminated if they shunt portions of the measuring circuit. This is done by providing a guard circuit to intercept current in such shunt paths or to keep points at the same potential between which there might otherwise be improper currents.
6. Variations in *ambient temperature* or internal temperature rise from self-heating under load may cause errors in instrument indications. If the temperature coefficient and the instrument temperature are known, readings can be corrected where precision requirements justify it. Where measurements involve extremely small potential differences, thermal emfs resulting from temperature differences between junctions of dissimilar metals may produce errors; heat from the observer's hand or heat generated by the friction of a sliding contact may cause such effects.
7. *Phase-defect angles* in resistors, inductors, or capacitors and in instruments and instrument transformers must be taken into account in many ac measurements.
8. Large *potential differences* are to be avoided between the windings of an instrument or between its windings and frame. Electrostatic forces may produce reading errors, and very large potential

difference may result in insulating breakdown. Instruments should be connected in the ground leg of a circuit where feasible. The moving-coil end of the voltage circuit of a wattmeter should be connected to the same line as the current coil. When an instrument must be at a high potential, its case must be adequately insulated from ground and connected to the line in which the instrument circuit is connected, or the instrument should be enclosed in a screen that is connected to the line. Such an arrangement may involve shock hazard to the operator, and proper safety precautions must be taken.

9. *Electrostatic charges* and consequent disturbance to readings may result from rubbing the insulating case or window of an instrument with a dry dustcloth; such charges can generally be dissipated by breathing on the case or window. Low-level measurements in very dry weather may be seriously affected by charges on the clothing of the observer; some of the synthetic textile fibers—such as nylon and Dacron—are particularly strong sources of charge; the only effective remedy is the complete screening of the instrument on which charges are induced.

10. *Position influence* (resulting from mechanical unbalance) may affect the reading of an analog-type indicating instrument if it is used in a position other than that in which it was calibrated. Portable instruments of the better accuracy classes (with antiparallax mirrors) are normally intended to be used with the axis of the moving system vertical, and the calibration is generally made with the instrument in this position.

3.1.2 Detectors and Galvanometers

Detectors are used to indicate approach to balance in bridge or potentiometer networks. They are generally responsive to small currents or voltages, and their sensitivity—the value of current or voltage that will produce an observable indication—ultimately limits the resolution of the network as a means for measuring some electrical quantity.

Galvanometers are deflecting instruments which are used, mainly, to *detect* the presence of a small electrical quantity—current, voltage, or charge—but which are also used in some instances to measure the quantity through the magnitude of the deflection.

The D'Arsonval (moving-coil) galvanometer consists of a coil of fine wire suspended between the poles of a permanent magnet. The coil is usually suspended from a flat metal strip which both conducts current to it and provides control torque directed toward its neutral (zero-current) position. Current may be conducted from the coil by a helix of fine wire which contributes very little to the control torque (pendulous suspension) or by a second flat metal strip which contributes significantly to the control torque (taut-band suspension). An iron core is usually mounted in the central space enclosed by the coil, and the pole pieces of the magnet are shaped to produce a uniform radial field throughout the space in which the coil moves. A mirror attached to the coil is used in conjunction with a lamp and scale or a telescope and scale to indicate coil position.

The pendulous-suspension type of galvanometer has the advantage of higher sensitivity (weaker control torque) for a suspension of given dimensions and material and the disadvantage of responsiveness to mechanical disturbances to its supporting platform, which produce anomalous motions of the coil. The taut-suspension type is generally less sensitive (stiffer control torque) but may be made much less responsive to mechanical disturbances if it is properly balanced, that is, if the center of mass of the moving system is in the axis of rotation determined by the taut upper and lower suspensions.

Galvanometer sensitivity can be expressed in a number of ways, depending on application:

1. The *current* constant is the current in microamperes that will produce unit deflection on the scale—usually a deflection of 1 mm on a scale 1 m distant from the galvanometer mirror.
2. The *megohm* constant is the number of megohms in series with the galvanometer through which 1 V will produce unit deflection. It is the reciprocal of the current constant.
3. The *voltage* constant is the number of microvolts which, in a critically damped circuit (or another specified damping), will produce unit deflection.

4. The *coulomb* constant is the charge in microcoulombs which, at a specified damping, will produce unit ballistic throw.

5. The *flux-linkage* constant is the product of change of induction and turns of the linking search coil which will produce unit ballistic throw.

All these sensitivities (galvanometer response characteristics) can be expressed in terms of current sensitivity, circuit resistance in which the galvanometer operates, relative damping, and period. If we define *current* sensitivity S_i as deflection per unit current, then—in appropriate units—the *voltage* sensitivity (the deflection per unit voltage) is

$$S_e = \frac{S_i}{R}$$

where R is the resistance of the circuit, including the resistance of the galvanometer coil. The *coulomb* sensitivity is

$$\frac{\theta}{Q} = \frac{2\pi}{T_o} S_i \exp\left(\frac{-\gamma}{\sqrt{1-\gamma^2}} \tan^{-1} \frac{\sqrt{1-\gamma^2}}{\gamma}\right)$$

where T_o is the undamped period and γ is the relative damping in the operating circuit. The *flux-linkage* sensitivity is

$$\frac{\theta}{\int e\,dt} \approx S_i \frac{2\pi}{T_o} \frac{1}{2R_c} \frac{1}{1-\gamma_0}$$

for the case of greatest interest—maximum ballistic response—where the galvanometer is heavily overdamped, γ_0 being the open-circuit relative damping, $\int e\,dt$ the time integral of induced voltage or the change in flux linkages in the circuit, and R_c the circuit resistance (including that of the galvanometer) for which the galvanometer is critically damped.

Galvanometer motion is described by the differential equation

$$P\ddot{\theta} + \left(K + \frac{G^2}{R}\right)\dot{\theta} + U\theta = \frac{GE}{R}$$

where θ is the angle of deflection in radians, P is the moment of inertia, K is the mechanical damping coefficient, G is the motor constant (G = coil area turns × air-gap field), R is total circuit resistance (including the galvanometer), and U is the suspension stiffness. If the viscous and circuital damping are combined,

$$K + G^2/R = A$$

the roots of the auxiliary equation are

$$m = \frac{A}{2P} \pm \sqrt{\frac{A^2}{4P^2} - \frac{U}{P}}$$

Three types of motion can be distinguished.

1. *Critically damped* motion occurs when $A^2/4P^2 = U/P$. It is an aperiodic, or deadbeat, motion in which the moving system approaches its equilibrium position without passing through it in the shortest time of any possible aperiodic motion. This motion is described by the equation

$$y = 1 - \left(1 + \frac{2\pi t}{T_o}\right)\exp\left(\frac{-2\pi t}{T_o}\right)$$

where y is the fraction of equilibrium deflection at time t and T_o is the undamped period of the galvanometer—the period that the galvanometer would have if $A = 0$. If the total damping coefficient at critical damping is A_c, we can define relative damping as the ratio of the damping coefficient A for a specific circuit resistance to the value A_c it has for critical damping—$\gamma = A/A_c$, which is unity for critically damped motion.

2. In *overdamped* motion, the moving system approaches its equilibrium position without overshoot and more slowly than in critically damped motion. This occurs when

$$\frac{A^2}{4P^2} > \frac{U}{P}$$

and $\gamma > 1$. For this case, the motion is described by the equation

$$y = 1 - \left(\frac{\gamma}{\sqrt{\gamma^2 - 1}} \sinh \frac{2\pi t}{T_o} \sqrt{\gamma^2 - 1} + \cosh \frac{2\pi t}{T_o} \sqrt{\gamma^2 - 1}\right) \exp\left(\frac{-2\pi t}{T_o} \gamma\right)$$

3. In *underdamped* motion, the equilibrium position is approached through a series of diminishing oscillations, their decay being exponential. This occurs when

$$\frac{A^2}{4P^2} > \frac{U}{P}$$

and $\gamma < 1$. For this case, the motion is described by the equation

$$y = 1 - \frac{1}{\sqrt{1 - \gamma^2}} \left[\sin\left(\frac{2\pi t}{T_o} \sqrt{1 - \gamma^2} + \sin^{-1} \sqrt{1 - \gamma^2}\right)\right] \exp\left(\frac{-2\pi t}{T_o} \gamma\right)$$

Damping factor is the ratio of deviations of the moving system from its equilibrium position in successive swings. More conveniently, it is the ratio of the equilibrium deflection to the "overshoot" of the first swing past the equilibrium position, or

$$F = \frac{\theta_1 - \theta_F}{\theta_F - \theta_2} = \frac{\theta_F}{\theta_1 - \theta_F}$$

where θ_F is the equilibrium deflection and θ_1 and θ_2 are the first maximum and minimum deflections of the damped system. It can be shown that damping factor is connected to relative damping by the equation

$$F = \exp\left(\frac{\pi\gamma}{\sqrt{1 - \gamma^2}}\right)$$

The *logarithmic decrement* of a damped harmonic motion is the naperian logarithm of the ratio of successive swings of the oscillating system. It is expressed by the equation

$$\ln \frac{\theta_1 - \theta_F}{\theta_F - \theta_2} = \ln \frac{\theta_F}{\theta_1 - \theta_F} = \lambda$$

and in terms of relative damping

$$\lambda = \frac{\pi\gamma}{\sqrt{1 - \gamma^2}}$$

The *period* of a galvanometer (and, generally, of any damped harmonic oscillator) can be stated in terms of its undamped period T_o and its relative damping γ as $T = T_o/\sqrt{1 - \gamma^2}$.

Reading time is the time required, after a change in the quantity measured, for the indication to come and remain within a specified percentage of its final value. Minimum reading time depends on the relative damping and on the required accuracy (Table 3-1). Thus, for a reading within 1% of equilibrium value, minimum time will be required at a relative damping of $\gamma = 0.83$. Generally in indicating instruments, this is known as *response time* when the specified accuracy is the stated accuracy limit of the instrument.

TABLE 3-1 Minimum Reading Time for Various Accuracies

Accuracy, percent	Relative damping	Reading time/free period
10	0.6	0.37
1	0.83	0.67
0.1	0.91	1.0

External critical damping resistance (CDRX) is the external resistance connected across the galvanometer terminals that produces critical damping ($\gamma = 1$).

Measurement of damping and its relation to circuit resistance can be accomplished by a simple procedure in the circuit of Fig. 3-1. Let R_a be very large (say, 150 kΩ) and R_b small (say, 1 Ω) so that when E is a 1.5-V dry cell, the driving voltage in the local galvanometer loop is a few microvolts (say, 10 μV). Since circuital damping is related to *total* circuit resistance ($R_c + R_b + R_g$), the galvanometer resistance R_g must be determined first. If R_c is adjusted to a value that gives a convenient deflection and then to a new value R_c' for which the deflection is cut in half, we have $R_g = R_c' - 2R_c - R_b$. Now, let R_c be set at such a value that when the switch is closed, the overshoot is readily observed. After noting the open-circuit deflection θ_o, the switch is closed and the peak value θ, of the first overswing, and the final deflection θ_F are noted. Then

$$\ln \frac{\theta_F - \theta_o}{\theta_1 - \theta_F} = \frac{\pi \gamma_1}{\sqrt{1 - \gamma_1^2}}$$

γ_1 being the relative damping corresponding to the circuit resistance $R_1 = R_g + R_b + R_c$. The switch is now opened, and the first overswing θ_2 past the open-circuit equilibrium position θ_o is noted. Then

$$\ln \frac{\theta_F - \theta_o}{\theta_2 - \theta_o} = \frac{\pi \gamma_o}{\sqrt{1 - \gamma_o^2}}$$

γ_o being the open-circuit relative damping. The relative damping γ_x for any circuit resistance R_x is given by the relation

$$\frac{R_x}{R_1} = \frac{\gamma_1 - \gamma_o}{\gamma_x - \gamma_o}$$

where it should be noted that the galvanometer resistance R_g is included in both R_x and R_1. For critical damping R_d can be computed by setting $\gamma_x = 1$, and the external critical damping resistance $CDRX = R_d - R_g$.

Galvanometer shunts are used to reduce the response of the galvanometer to a signal. However, in any sensitivity-reduction network, it is important that relative damping be preserved for proper operation. This can always be achieved by a suitable combination of series and parallel resistance. In Fig. 3-2, let r be the external circuit resistance and R_g the galvanometer resistance such that $r + R_g$ gives an acceptable damping (e.g., $\gamma = 0.8$) at maximum sensitivity. This damping will be preserved when the sensitivity-reduction network (S, P) is inserted, if $S = (n - 1)r$ and $P = nr/(n - 1)$, n being the factor by which response is to be reduced. The Ayrton-Mather shunt, shown

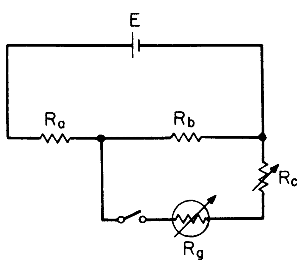

FIGURE 3-1 Determination of relative damping.

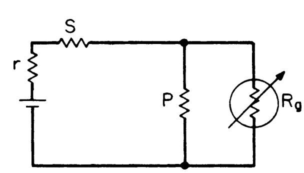

FIGURE 3-2 Galvanometer shunt.

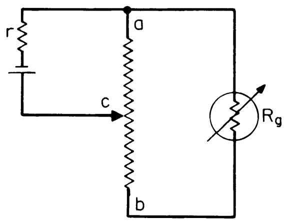

FIGURE 3-3 Ayrton-Mather universal shunt.

in Fig. 3-3, may be used where the circuit resistance r is so high that it exerts no appreciable damping on the galvanometer. R_{ab} should be such that correct damping is achieved by $R_{ab} + R_g$. In this network, sensitivity reduction is

$$n = R_{ac}/R_{ab}$$

and the ratio of galvanometer current I_g to line current I is

$$\frac{I_g}{I} = \frac{R_{ab}}{n(R_g + R_{ab})}$$

The *ultimate resolution* of a detection system is the magnitude of the signal it can discriminate against the noise background present. In the absence of other noise sources, this limit is set by the *Johnson noise* generated by electron thermal agitation in the resistance of the circuit. This is expressed by the formula $e = \sqrt{4k\theta Rf}$, where e is the rms noise voltage developed across the resistance R, k is Boltzmann's constant 1.4×10^{-23} J/K, θ is the absolute temperature of the resistor in kelvin, and f is the bandwidth over which the noise voltage is observed. At room temperature (300 K) and with the assumption that the peak-to-peak voltage is 5 × rms value, the peak-to-peak Johnson noise voltage is $6.5 \times 10^{-10} \sqrt{Rf}$ V. If, in a dc system, we use the approximation that $f = 1/3t$, where t is the system's response time, the Johnson voltage is $4 \times 10^{-10} \sqrt{R/t}$V (peak to peak).

By using reasonable approximations, it can be shown that the random brownian-motion deflections of the moving system of a galvanometer, arising from impulses by the molecules in the air around it, are equivalent to a voltage indication $e = 5 \times 10^{-10} \sqrt{R/T}V$ (peak to peak), where R is circuit resistance and T is the galvanometer period in seconds. If the galvanometer damping is such that its response time is $t = 2T/3$ (for $\gamma \approx 0.8$), the Johnson noise voltage to which it responds is about $5 \times 10^{-10} \sqrt{R/t}$V (peak to peak). This value represents the limiting resolution of a galvanometer, since its response to smaller signals would be obscured by the random excursions of its moving system. Thus, a galvanometer with a 4-s-period would have a limiting resolution of about 2 nV in a 100-Ω circuit and 1 nV in a 25-Ω circuit.

It is not surprising that one arrives at the same value from considerations either of random electron motions in the conductors of the measuring circuit or of molecular motions in the fluid that surrounds the system. The resulting figure rests on the premise that the law of equipartition of energy applies to the measuring system and that the galvanometer coil—a body with one degree of freedom—is statically in thermal equilibrium with its surroundings.

Optical systems used with galvanometers and other indicating instruments avoid the necessity for a mechanical pointer and thus permit smaller, simpler balancing arrangements because the mirror attached to the moving system can be symmetrically disposed close to the axis of rotation. In portable instruments, the entire system—source, lenses, mirror, scale—is generally integral with the instrument, and the optical "pointer" may be folded one or more times by fixed mirrors so that it is actually much longer than the mechanical dimensions of the instrument case. In some instances, the angular displacement may be magnified by use of a cylindrical lens or mirror. For a wall- or bracket-mounted galvanometer, the lamp and scale arrangement is external, and the length of the light-beam pointer can be controlled. Whatever the arrangement, the pointer length cannot be indefinitely extended with consequent increase in resolution at the scale. The optical resolution of such a system is, in any event, limited by image diffraction, and this limit—for a system limited by a circular aperture—is $\alpha \approx 1.2\lambda/nd$, where α is the angle subtended by resolvable points, λ is the wavelength of the light, n is the index of refraction of the image space, and d is the aperture diameter. In this case, d is the diameter of the moving-system mirror, and $n = 1$ for air. If we assume that points 0.1 mm apart can just be resolved by the eye at normal reading distance, the resolution limit is reached at a scale distance of about 2 m in a system with a 1-cm mirror, which uses no optical magnification. Thus, for the usual galvanometer, there is no profit in using a mirror-scale separation greater than 2 m. Since resolution is a matter of subtended angle, the corresponding scale distance is proportionately less for systems that make use of magnification.

The *photoelectric galvanometer amplifier* is a detector system in which the light beam from the moving-system mirror is split between two photovoltaic cells connected in opposition, as shown

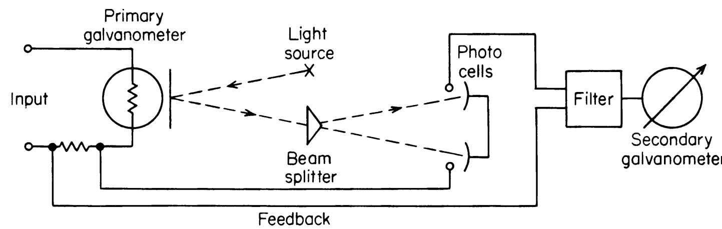

FIGURE 3-4 Photoelectric galvanometer amplifier.

in Fig. 3-4. As the mirror of the primary galvanometer turns in response to an input signal, the light flux is increased on one of the photocells and decreased on the other, resulting in a current and thence an enhanced signal in the circuit of the secondary (reading) galvanometer. Since the photocells respond to the total light flux on their sensitive elements, the system is not subject to resolution limitation by diffraction as is the human eye, and the ultimate resolution of the primary instrument—limited only by its brownian motion and the Johnson noise of the input circuit—may be realized.

Electronic instruments for low-level dc signal detection are more convenient, more rugged, and less susceptible to mechanical disturbances than is a galvanometer. However, considerable filtering, shielding, and guarding must be used to minimize electrical interference and noise. On the other hand, a galvanometer is an extremely efficient low-pass filter, and when operated to make optimal use of its design characteristics, it is still the most sensitive low-level dc detector. Electronic detectors generally make use of either a mechanical or a transistor chopper driven by an oscillator whose frequency is chosen to avoid the local power frequency and its harmonics. This modulator converts the dc input signal to ac, which is then amplified, demodulated, and displayed on an analog-type indicating instrument or fed to a recording device or a signal processor.

AC detectors used for balancing bridge networks are usually tuned low-level amplifiers coupled to an appropriate display device. The narrower the passband of the amplifier, the better the signal resolution, since the narrow passband discriminates against noise of random frequency in the input circuit. Adjustable-frequency amplifier-detectors basically incorporate a low-noise preamplifier followed by a high-gain amplifier around which is a tunable feedback loop whose circuit has zero transmission at the selected frequency so that the negative-feedback circuit controls the overall transfer function and acts to suppress signals except at the selected frequency. The amplifier output may be rectified and displayed on a dc indicating instrument, and added resolution is gained by introducing phase selection at the demodulator, since the wanted signal is regular in phase, while interfering noise is generally random. In detectors of this type, in phase and quadrature signals can be displayed separately, permitting independent balancing of bridge components. Further improvement can result from the use of a low-pass filter between the demodulator and the dc indicator such that the signal of selected phase is integrated over an appreciable time interval up to a second or more.

3.1.3 Continuous EMF Measurements

A *standard of emf* may be either an electrochemical system or a Zener-diode-controlled circuit operated under precisely specified conditions. The *Weston standard cell* has a positive electrode of metallic mercury and a negative electrode of cadmium-mercury amalgam (usually about 10% Cd). The *electrolyte* is a saturated solution of cadmium sulfate with an excess of $Cd \cdot SO_4 \cdot {}^8/_3H_2O$ crystals, usually acidified with sulfuric acid (0.04 to 0.08 N). A paste of mercurous sulfate and cadmium sulfate crystals over the mercury electrode is used as a depolarizer. The saturated cell has a substantial temperature coefficient of emf. Vigoureux and Watts of the National Physical Laboratory have given the following formula, applicable to cells with a 10% amalgam:

$$E_t = E_{20} - 39.39 \times 10^{-6}(t - 20) - 0.903 \times 10^{-6}(t - 20)^2 + 0.00660 \times 10^{-6}(t - 20)^3 - 0.000150 \times 10^{-6}(t - 20)^4$$

where t is the temperature in degree Celsius. Since cells are frequently maintained at 28°C, the following equivalent formula is useful:

$$E_t = E_{28} - 52.899 \times 10^{-6}(t - 28) - 0.80265 \times 10^{-6}(t - 28)^2 + 0.001813 \times 10^{-6}(t - 28)^3 - 0.0001497 \times 10^{-6}(t - 28)^4$$

These equations are general and are normally used only to correct cell emfs for small temperature changes, that is, 0.05 K or less. For changes at that level, negligible errors are introduced by making corrections. Standard cells should always be calibrated at their temperature of use (within 0.05 K) if they are to be used at an accuracy of 5 ppm or better.

A group of saturated Weston cells, maintained at a constant temperature in an air bath or a stirred oil bath, is quite generally used as a laboratory reference standard of emf. The bath temperature must be constant within a few thousandths of a degree if the reference emf is to be reliable to a microvolt. It is even more important that temperature gradients in the bath be avoided, since the individual limbs of the cell have very large temperature coefficients (about +315 μV/°C for the positive limb and −379 μV/°C for the negative limb—more than −50 μV/°C for the complete cell—at 28°C). Frequently, two or three groups of cells are used, one as a reference standard which never leaves the laboratory, the others as transport groups which are used for interlaboratory comparisons and for assignment by a standards laboratory.

Precautions in Using Standard Cells

1. The cell should not be exposed to extreme temperatures—below 4°C or above 40°C.

2. Temperature gradients (differences between the cell limbs) should be avoided.

3. Abrupt temperature changes should be avoided—the recovery period after a sudden temperature change may be quite extended; recovery is usually much quicker in an unsaturated than in a saturated cell. Full recovery of saturated cells from a gross temperature change (e.g., from room temperature to a 35°C maintenance temperature) can take up to 3 months. More significantly, some cell emfs have been seen to exhibit a plateau in their response over a 2- to 3-week period within a week or two after the temperature shock is sustained. This plateau can be as much as 5 ppm higher than the final stable value.

4. Current in excess of 100 nA should never be passed through the cell in either direction; actually, one should limit current to 10 nA or less for as short a time as feasible in using the cell as a reference. Cells that have been short-circuited or subjected to excessive charging current drift until chemical equilibrium in the cell is regained over an extended time period—as long as 9 months, depending on the amount of charge involved.

Zener diodes or diode-based devices have replaced chemical cells as voltage references in commercial instruments, such as digital voltmeters and voltage calibrators. Some of these instruments have uncertainties below 10 ppm, instabilities below 5 ppm per month (including drift and random uncertainties), and temperature coefficient of output as low as 2 ppm/°C.

The best devices, as identified in a testing in selection process, are available as solid-state voltage reference or transport standards. Such instruments generally have at least two outputs, one in the range of 1.018 to 1.02 V for use as a standard cell replacement and the other in the range of 6.4 to 10 V, the output voltage of the reference device itself. The lower voltage is usually obtained via a resistive divider.

Other features sometimes include a vernier adjustment for the lower voltage for adjusting to equal the output of a given standard cell and internal batteries for complete isolation. Such devices have performance approaching that of standard cells and can be used in many of the same applications. Some have stabilities (drift rate and random fluctuations) as low as 2 to 3 ppm per year and temperature coefficient of 0.1 ppm/°C.

The current through the reverse-biased junction of a silicon diode remains very small until the bias voltage exceeds a characteristic V_z in magnitude, at which point its resistance becomes abruptly very low so that the voltage across the junction is little affected by the junction current. Since the voltage-current relationship is repeatable, the diode may be used as a standard of voltage as long as its rated power is not exceeded.

However, since V_z is a function of temperature, single junctions are rarely used as voltage references in precise applications. Since a change in temperature shifts the *I-V* curve of a junction, the use of a forward-biased junction in series with Zener diode permits a current level to be found at which changes in Zener voltage from temperature changes are compensated by changes in the voltage drop across the forward-biased junction.

Devices using this principle fall into two categories: the temperature-compensated Zener diode, in which two diodes are in series opposition, and the reference amplifier, in which the Zener diode is in series with the base-emitter junction of an appropriate *npn* silicon transistor. In each case, the two elements may be on the same substrate for temperature uniformity. In some precision devices, the reference element is in a temperature-controlled oven to permit even greater immunity to temperature fluctuations.

Potentiometers are used for the precise measurement of emf in the range below 1.5 V. This is accomplished by opposing to the unknown emf an equal *IR* drop. There are two possibilities: either the current is held constant while the resistance across which the *IR* drop is opposed to the unknown is varied, or current is varied in a fixed resistance to achieve the desired *IR* drop.

Figure 3-5 shows schematically most of the essential features of a general-purpose constant-current instrument. With the standard-cell dial set to read the emf of the reference standard cell, the potentiometer current *I* is adjusted until the *IR* drop across 10 of the coarse-dial steps plus the drop to the set point on the standard-cell dial balances the emf of the reference cell. The correct value of current is indicated by a null reading of the galvanometer in position G_1. This adjustment permits the potentiometer to be read directly in volts. With the galvanometer in position G_2, the unknown emf is balanced by varying the opposing *IR* drop. Resistances used from the *coarse* and *intermediate* dials and the *slide wire* are adjusted until the galvanometer again reads null, and the unknown emf can be read directly from the dial settings. The ratio of the unknown and reference emfs is precisely the ratio as the resistances for the two null adjustments, provided that the current is the same.

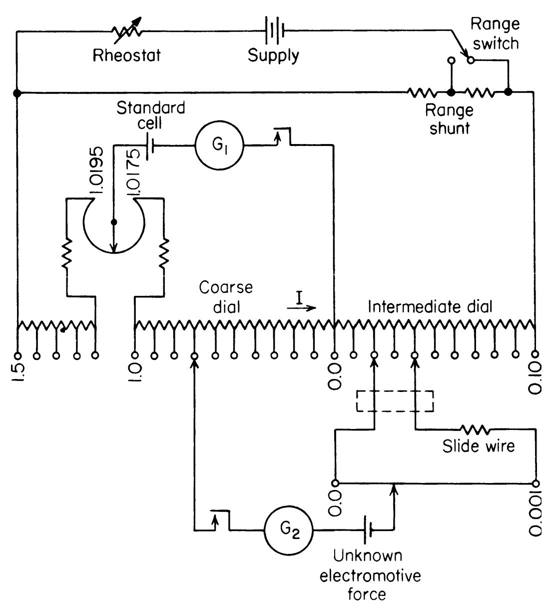

FIGURE 3-5 General purpose constant-current potentiometer.

The switching arrangement is usually such that the galvanometer can be shifted quickly between the G_2 and G_1 positions to check that the current has not drifted from the value at which it was standardized. It will be noted that the contacts of the coarse-dial switch and slide wire are in the galvanometer branch of the circuit. At balance, they carry no current, and their contact resistance does not contribute to the measurement. However, there can be only two noncontributing contact resistances in the network shown; the switch contacts for adjusting the intermediate-dial position do carry current, and their resistance does enter the measurement. Care is taken in construction that the resistances of such current-carrying contacts are low and repeatable, and frequently, as in the example illustrated, the circuit is arranged so that these contributing contacts carry only a fraction of the reference current, and the contribution of their *IR* drop to the measurement is correspondingly reduced.

Another feature of many general-purpose potentiometers, illustrated in the diagram, is the availability of a reduced range. The resistances of the range shunts have such values that at the 0.1 position of the range-selection switch, only a tenth of the reference current goes through the measuring branch of the circuit, and the range of the potentiometer is correspondingly reduced. Frequently, a $\times$ 0.01 range is also available.

In addition to the effect of *IR* drops at contacts in the measuring circuit, accuracy limits are also imposed by thermal emfs generated at circuit junctions. These limiting factors are increasingly important as potentiometer range is reduced. Thus, in low-range or microvolt potentiometers, special care is taken to keep circuit junctions and contact resistances out of the direct measuring circuit as much as possible, to use thermal shielding, and to arrange the circuit and galvanometer keys so that temperature differences will be minimized between junction points that are directly in the measuring circuit. Generally also, in microvolt potentiometers, the galvanometer is connected to the circuit through a special *thermofree* reversing key so that thermal emfs in the galvanometer can be eliminated from the measurement—the balance point being that which produces zero change in galvanometer deflections on reversal.

An example of the constant-resistance potentiometer is shown in the simplified diagram in Fig. 3-6. It consists basically of a constant-current source, a resistive divider *D* (used in the current-divider mode), and a fixed resistor *R* in which the current (and the *IR* drop) are determined by the setting of the divider. The output of the current source is adjusted by equating the emf of a standard cell to an equal *IR* drop as shown by the dashed line. This design lends itself to multirange operation by using tap points on the resistor *R*. Its accuracy depends on the uniformity of the divider, the location of the tap points on *R*, and the stability of the current source.

Another type of constant-resistance potentiometer, operating from a current comparator which senses and corrects for inequality of ampere-turns in two windings threading a magnetic core, is shown in Fig. 3-7. Two matched toroidal cores wound with an identical number of turns are excited by a fixed-frequency oscillator. The fluxes induced in the cores are equal and oppositely directed, so they cancel with respect to a winding that encloses both. In the absence of additional magnetomotive force (mmf), the detector winding enclosing both cores receives no signal.

If, in another winding *A* enclosing both cores, we inject a direct current, its mmf reinforces the flux in one core and opposes the other. The net flux in the detector winding induces a voltage in it. This signal is used to control current in another winding *B* which also threads both cores. When the mmf of *B* is equal to and opposite that of *A*, the detector signal is zero and the ampere-turns of *A* and *B* are equal. Thus, a constant current in an adjustable number of turns is matched to a variable current in a fixed number of turns, and the voltage drop I_BR is used to oppose the emf to be measured.

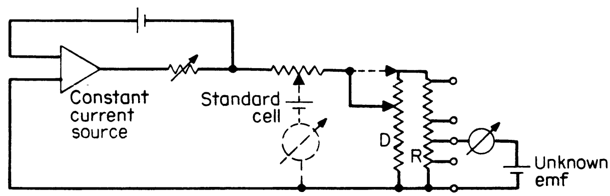

FIGURE 3-6 Constant-resistance potentiometer.

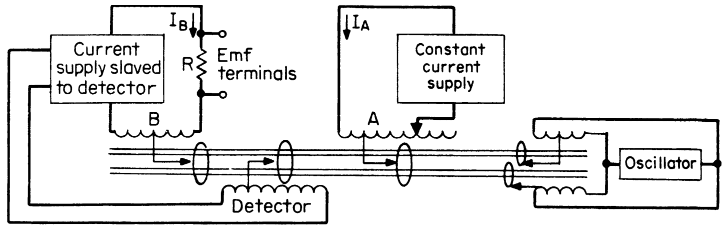

FIGURE 3-7 Current-comparator potentiometer.

The system is made direct-reading in voltage units (in terms of the turns ratio *B*/*A*) by adjusting the constant-current source with the aid of a standard-cell circuit (not shown in the figure). This type of potentiometer has an advantage over those whose continuing accuracy depends on the stability of a resistance ratio; the ratio here is the turns ratio of windings on a common core, dependent solely on conductor position and hence not subject to drift with time.

Decade voltage dividers generally use the Kelvin-Varley circuit arrangement shown in Fig. 3-8. It will be seen that two elements of the first decade are shunted by the entire second decade, whose total resistance equals the combined resistance of the shunted steps of decade I. The two sliders of decade I are mechanically coupled and move together, keeping the shunted resistance constant regardless of switch position. Thus, the current divides equally between decade II and the shunted elements of decade I, and the voltage drop in decade II equals the drop in one unshunted step of decade I. The effect of contact resistance at the switch points is somewhat diminished because of the division of current. The Kelvin-Varley principle is used in succeeding decades except the final one, which has only a single switch contact. Such voltage dividers may have as many as eight decades and have ratio accuracies approaching 1 part in 10^6 of input.

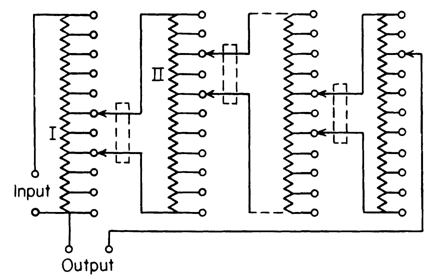

FIGURE 3-8 Decade voltage divider.

Spark gaps provide a means of measuring high voltages. The maximum gap which a given voltage will break down depends on air density, gap geometry, crest value of the voltage, and other factors (see Sec. 27). Sphere gaps constitute a recognized means for measuring crest values of alternating voltages and of impulse voltages. IEEE Standard 4 has tables of sparkover voltages for spheres ranging from 6.25 to 200 cm in diameter and for voltages from 17 to 2500 kV. Sphere gap voltage tables are also available in ANSI Standard 68.1 and in IEC Publication 52.

3.1.4 Continuous Current Measurements

Absolute current measurement relates the value of the current unit—the ampere—to the prototype mechanical units of length, mass, and time—the meter, the kilogram, and the second—through force measurements in an instrument called a *current balance*. Such instruments are to be found generally only in national standards laboratories, which have the responsibility of establishing and maintaining the electrical units. In a current balance, the force between fixed and movable coils is opposed by the gravitational force on a known mass, the balance equation being $I^2(\partial M/\partial X) = mg$. The construction of the coil system is such that the rate of change with displacement of mutual inductance between fixed and moving coils can be computed from measured coil dimensions. Absolute current determinations are used to assign the emf of reference standard cells. A 1-Ω resistance standard is connected in series with the fixed- and moving-coil system, and its drop is compared with the emf of a cell during the force measurement. Thus, the National Reference Standard of voltage is derived from absolute ampere and ohm determinations.

The *potentiometer method* of measuring continuous currents is commonly used where a value must be more accurate than can be obtained from the reading of an indicating instrument. The current to be measured is passed through a four-terminal resistor (shunt) of known value, and the voltage developed between its potential terminals is measured with a potentiometer. If the current is small so that there is no significant temperature rise in the shunt, the measurement accuracy can be 0.01% or better. In general, the accuracy of potentiometer measurements of continuous currents is limited by how well the shunt resistance is known under operating conditions.

Measurement of very small continuous currents, down to 10^{-17} A, have been accomplished by means of *electrometer* tubes—vacuum tubes designed so that the grid has practically no leakage current either over its insulating supports or to the cathode. The current to be measured flows through a very high resistance (up to 10^{12} Ω), and the voltage drop is impressed on the grid of an electrometer tube. The plate current is observed and the voltage drop is duplicated by producing the plate current with a known adjustable voltage. The current can then be calculated from the voltage and resistance.

3.1.5 Analog Instruments

Analog instruments are electromechanical devices in which an electrical quantity is measured by conversion to a mechanical motion. Such instruments can be classified according to the principle on which the instrument operates. The usual types are permanent-magnet moving-coil, moving-iron, dynamometer, and electrostatic. Another grouping is on the basis of use: panel, switchboard, portable, and laboratory-standard. Accuracy also can be the basis of classification. Details concerning performance and other specifications are to be found in ANSI Standard C39.1, Requirements for Electrical Analog Indicating Instruments.

Permanent-magnet moving-coil instruments are the most common type in general use. The operating mechanism consists of a coil of fine wire suspended in such a manner that it can rotate in an annular gap which has a radial magnetic field. The torque, generated by the current in the moving coil reacting to the magnetic field of the gap, is opposed by some form of spring restraint. The restraint may be a helical spring, in which case the coil is supported by a pivot and jewel, or both the support and the angular restraint is by means of a taut-band suspension.

The position which the coil assumes when the torque and spring restraint are balanced is indicated by either a pointer or a light beam on a scale. The scale is calibrated in units suitable to the application: volts, milliamperes, etc. To the extent that the magnetic field is uniform, the spring restraint linear, and the coil positioning symmetrical, the deflection will be linearly proportional to the ampere-turns in the coil.

Because the field of the permanent magnet is unidirectional, reversal of the coil current will reverse the torque so that the instrument will deflect only with direct current in the moving coil. Scales are usually provided with the zero-current position at the left to allow a full-range deflection. However, where measurement is required with either polarity, a zero center scale position is used. The coil is limited in its ability to carry current to 50 or 100 mA.

Rectifiers and thermoelements are used with permanent-magnet moving-coil instruments to provide ac operation. The addition of a rectifier circuit, usually in the form of a bridge, gives an instrument in which the deflection is in terms of the average value of the voltage or current. It is customary to label the scale in terms of 1.11 times the average; this is the correct waveform factor to read the rms value of a sine wave. If the rectifier instrument is used to measure severely nonsinusoidal waveforms, large errors will result. The high sensitivity that can be obtained with the rectifier type of instrument and its reasonable cost make it widely used.

To provide a true rms reading with the permanent-magnet moving-coil instrument, a thermoelement is the usual converter. The current to be measured is fed through a resistance of such value that it will heat appreciably. A thermocouple is placed in intimate thermal contact with the heater resistance, and the output of the couple is used to energize a permanent-magnet moving-coil instrument. The instrument deflection of such a combination is proportional to the square of the current; using a square-root factor in drawing the scale allows it to be read in terms of the rms value of the current. For high-sensitivity use, the thermoelement is placed in an evacuated bulb to eliminate convection heat loss.

The prime advantage of the thermoelement instrument is the high frequency at which it will operate and the rms indication. The upper frequency limit is determined by the skin effect in the heater. Instruments have been built with response to several hundred megahertz. There is one very important limitation to these instruments. The heater must operate at a temperature of 100°C or more to provide adequate current to the movement. Overrange of the current will cause heater temperature to increase as the square of the current. It is possible to burn out the heater with relatively small overloads.

Moving-iron instruments are widely used at power frequencies. The radial-vane moving-iron type operates by current in the coil which surrounds two magnetic vanes, one fixed and one that can rotate in such a manner as to increase the spacing between them. Current in the coil causes the vanes to be similarly magnetized and so to repel each other. The torque produced by the moving vane is proportional to the square of the current and is independent of its polarity.

Figure 3-9 shows two ways in which a wattmeter may be connected to measure power in a load. With the moving coil connected at *A*, the instrument will read high by the amount of power used by the moving-coil circuit. If connection is made at *B*, the wattmeter will read high by the power dissipated in the field coils. When using sensitive, low-range meters, it is necessary to correct for this error. Commercial instruments are available for ranges from a fraction of a watt to several hundred watts self-contained. Range extensions are obtained with current and voltage transformers. In specifying wattmeters, it is necessary to state the current and voltage ranges as well as the watt range.

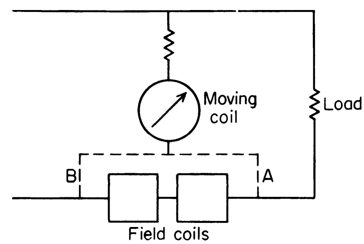

FIGURE 3-9 Alternative wattmeter connections.

Electrostatic voltmeters are actually voltage-operated in contrast to all the other types of analog instruments, which are current-operated. In an electrostatic voltmeter, fixed and movable vanes are so arranged that a voltage between them causes attraction to rotate the movable vane. The torque is proportional to the energy stored in the capacitance, and thus to the voltage squared, permitting rms indication.

Electrostatic instruments are used for voltage measurements where the current drain of other types of instrument cannot be tolerated. Input resistance (due to insulation leakage) amounts to $10^{13}\ \Omega$ approximately for a range of 100 V (the lowest commercially available) to $3 \times 10^{15}\ \Omega$ for 100,000-V instruments (the highest commonly available). Capacitance ranges from about 300 pF for the lower ranges to 10 pF for the highest. Multirange instruments in the lower ranges (100 to 5000 V) are frequently made with capacitive dividers which make them inoperable on direct voltage, since the series capacitor blocks out dc. Other multirange instruments use a mechanical movement of the fixed electrode to change ranges. These can be used on dc or ac, as can all single-range voltmeters.

Electronic voltmeters vary widely in performance characteristics and frequency range covered, depending on the circuitry used. A common type uses an initial diode to charge a capacitor. This may be followed by a stabilized amplifier with a microammeter as indicator. Range may be selected by appropriate cathode resistors in the amplifier section. Such instruments normally have very high input impedance (a few picofarads), respond to peak voltage, and are suitable for use to very high frequencies (100 MHz or more). While the response is to *peak* voltage, the scale of the indicating element may be marked in terms of rms for a sine-wave input, that is, 0.707 × *peak* voltage. Thus, for a nonsinusoidal input, the scale (read as rms volts) may include a serious waveform error, but if the scale reading is multiplied by 1.41, the result is the value of the *peak* voltage.

An alternative network, used in some electronic voltmeters, is an attenuator for range selection, followed by an amplifier and finally a rectifier and microammeter. This system has substantially lower input impedance, and limits of frequency range are fixed by the characteristics of the amplifier. The response in this arrangement may be to *average* value of the input signal, but again, the scale marking may be in terms of rms value for a sine wave. In this case also, the waveform error for nonsinusoidal input must be borne in mind, but if the scale reading is divided by 1.11, the *average* value is obtained. Within these limitations, accuracy may be as good as 1% of full-scale indication in sometypes of electronic voltmeter, although in many cases a 2 to 5% accuracy may be anticipated.

3.1.6 DC to AC Transfer

General transfer capability is essential to the measurement of voltage, current, power, and energy. The standard cell, the unit of voltage which it preserves, and the unit of current derived from it in combination with a standard of resistance are applicable only to the measurement of dc quantities, while the problems of measurement in the power and communications fields involve alternating voltages and currents. It is only by means of transfer devices that one can assign the values of ac quantities or calibrate ac instruments in terms of the basic dc reference standards. In most instances, the rms value of a voltage or current is required, since the transformation of electrical energy to other forms involves the square of voltages or currents, and the transfer from direct to alternating quantities is made with devices that respond to the square of current or voltage. Three general types of transfer instruments are capable of high-accuracy rms measurements: (1) electrodynamic instruments—which depend on the force between current-carrying conductors; (2) electrothermic instruments—which depend on the heating effect of current; and (3) electrostatic instruments—which depend on the force between electrodes at different potentials. While two of these depend on current and the third on voltage, the use of series and shunt resistors makes all three types available for current or voltage transfer. Traditional American practice has been to use electrodynamic instruments for current and voltage transfer as well as power transfer from direct to alternating current, but recent developments in thermoelements have improved their transfer characteristics until they are now the preferred means for *current* and *voltage* transfer, although the electrodynamic wattmeter is still the instrument of choice for *power* transfer up to 1 kHz.

Electrothermic transfer standards for current and voltage use a thermoelement consisting of a heater and a thermocouple. In its usual form, the heater is a short, straight wire suspended by two supporting lead-in wires in an evacuated glass bulb. One junction of a thermocouple is fastened to its midpoint and is electrically insulated from it with a small bead. The thermal emf—5 to 10 mV at rated current in a conventional element—is a measure of heater current. Multijunction thermoelements having a number of couples in series along the heater also have been used in transfer measurements. Typical output is 100 mV for an input power of 30 mW.

3.1.7 Digital Instruments

Digital voltmeters (DVMs), displaying the measured voltage as a set of numerals, are analog-to-digital converters in which an unknown dc voltage is compared with a stable reference voltage. Internal fixed dividers or amplifiers extend the voltage ranges. For ac measurements, dc DVMs are preceded by ac-to-dc converters. DVMs are widely used as laboratory, portable, and panel instruments because of their convenience, accuracy, and speed. Automatic range changing and polarity indication, freedom from reading errors, and the availability of outputs for data acquisition or control are added advantages. Integrated circuits and modern techniques have greatly increased their reliability and reduced their cost. Full-scale accuracies range from about 0.5% for three-digit panel instruments to 1 ppm for eight-digit laboratory dc voltmeters and 0.016% for ac voltmeters.

Successive-approximation DVMs are automatically operated dc potentiometers. These may be based on resistive voltage or current divider techniques or on dc current comparators. A comparator in a series of steps adjusts a discrete fraction of the reference voltage (by current or voltage division in a resistance network) until it equals the unknown. Various "logic schemes" have been used to accomplish this, and the stepping relays of earlier models have been replaced by electronic or reed switches. Filters reduce input noise (which could prevent a final display) but generally increase the response time. Accuracy depends chiefly on the reference voltage and the ratios of the resistance network.

Voltage-to-frequency-converter (V/f) DVMs generate a ramp voltage at a rate proportional to the input until it equals a fixed voltage, returns the ramp to the starting point, and repeats. The number of pulses (ramps) generated in a fixed time is proportional to the input and is counted and displayed. Since it integrates over the counting time, a *V/f* DVM has excellent input-noise rejection. The ramp is usually generated by an operational integrator (a high-gain operational amplifier with a capacitor in the feedback loop so that its output is proportional to the integral of the input voltage). The capacitor is discharged each time by a pulse of constant and opposite charge, and the time interval of the counter is chosen so that the number of pulses makes the DVM direct-reading. Accuracy depends on the integrator and on the charge of the pulse generator, which contains the reference voltage.

Dual-slope DVMs generate a voltage ramp at a rate proportional to the input voltage V_i for a fixed time t_1. The ramp input is then switched to a reference voltage V_r of the opposite polarity for a time t_2 until the starting level is reached. Pulses with a fixed frequency f are accumulated in a counter, with N_1 counts during t_1. The counter resets to zero and accumulates N_2 counts during t_2. Thus, $t_1 = N_1 f$ and $t_2 = N_2 f$.

If the slope of the linear ramp is $m = kV$, the ramp voltage is $V_o = mt = kVt$. Thus $V_i t_1 = V_r t_2$, so $V_i = V_r N_2/N_1$. The time t_1 is controlled by the counter to make N_2 direct-reading in appropriate units. In principle, the accuracy is not dependent on the constants of the ramp generator or the frequency of the pulses. A single operational integrator, switched to either input or reference voltage, generates the ramps. Since there are few critical components, integrated circuits are feasible, leading to simplicity and reliability as well as high accuracy. Because this is an integrating DVM, noise rejection is excellent.

In pulse-width conversion meters, an integrating circuit and matched comparators are used to produce trains of positive and negative pulses whose relative widths are a linear function of any dc input. The difference in positive and negative pulse widths can be measured using counting techniques, and very high resolution and accuracy (up to 1 ppm, relative to an internal voltage reference) can be achieved by integrating the counting over a suitable time period.

Average ac-to-dc converters contain an operational rectifier (an operational amplifier with a rectifier in the feedback circuit), followed by a filter, to obtain the rectified average value of the ac voltage. The operational amplifier greatly reduces errors of nonlinearity and forward voltage drop of the rectifier. For convenience, the output voltage is scaled so that the dc DVM connected to it indicates the rms value of a sine wave. Large errors can result for other waveforms, up to h/n%, with h% of the nth harmonic in the wave, if n is an odd number. For example, with 3% of third harmonic, the error can be as much as 1%, depending on the phase of the harmonic.

Electronic multipliers and other forms of rms-responding ac-to-dc converters eliminate this waveform error but are generally more complex and expensive. In one version, the feedback rms circuit shown in Fig. 3-10, the two inputs of the multiplier M_1 are connected together so that the instantaneous output of M is v_i^2/V_o. The operational filter F(RC circuit and operational amplifier) makes $V_o = V_i^2/V_o$, where V_i^2 is the square of the rms value. Thus, $V_o = V_i$. The conversion accuracy approaches 0.1% up to 20 kHz in transconductance or logarithmic multipliers, without requiring a wide dynamic range in the instrument, because of the internal feedback. A series of diodes, biased to conduct at different voltage levels, can provide an excellent approximation to a square-law function in a feedback circuit like that of Fig. 3-10.

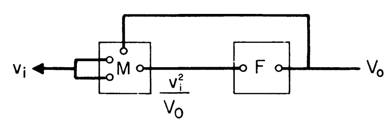

FIGURE 3-10 Electronic rms ac-to-dc converter.

Specifications for DVMs should follow the recommendations of ANSI Standard C39.7, Requirements for Digital Voltmeters. Accuracy should be stated as the overall limit of error for a specified range of operating conditions. It should be in percent of reading plus percent of full scale and may be different for different frequency and voltage ranges. Accuracy at a narrow range of reference conditions is also often specified for laboratory use. The input configuration (two-terminal, three-terminal unguarded, three- or four-terminal guarded) is important. Number of digits and "overrange" also should be stated.

Errors and Precautions. Because of the sensitivity of DVMs, a number of precautions should be taken to avoid in-circuit errors from ground loops, input noise, etc. The high input impedance of most types makes input loading errors negligible, but this should always be checked. On dc millivolt ranges, unwanted thermal emfs should be checked as well as the normal-mode rejection of ac line-frequency voltage across the input terminals. Two-terminal DVMs (chassis connected to one input as well as to line ground) may measure unwanted voltages from ground currents in the common line.

Errors are greatly reduced in three-terminal DVMs (chassis connected to line ground only) and are generally negligible with guarded four-terminal DVMs (separate guard chassis surrounding the measuring circuit). Such DVMs have very high common-mode rejection. Some types of DVMs introduce small voltage spikes or currents to the measuring circuit, often from internal switching transients, which may cause errors in low-level circuits.

Digital multimeters are DVMs with added circuitry to measure quantities such as dc voltage ratio, dc and ac current, and resistance. Voltage ratio is measured by replacing the reference voltage with one of the unknowns. For current, the voltage across an internal resistor carrying the current is measured by the DVM. For resistance, a fixed reference current is generated and applied to the unknown resistor. The voltage across the resistor is measured by the DVM. Several ranges are provided in each case.

3.1.8 Instrument Transformers

The material that follows is a brief summary of information on instrument transformers as measurement elements. For more extensive information, consult American National Standard C57.13, Requirement for Instrument Transformers; American National Standards Institute; American National Standard C12, Code for Electricity Metering; *Electrical Meterman's Handbook*, Edison Electric Institute; manufacturer's literature; and textbooks on electrical measurements.

AC range extension beyond the reasonable capability of indicating instruments is accomplished with instrument transformers, since the use of heavy-current shunts and high-voltage multipliers would be prohibitive both in cost and power consumption. Instrument transformers are also used to isolate instruments from power lines and to permit instrument circuits to be grounded.

The current circuits of instruments and meters normally have very low impedance, and current transformers must be designed for operation into such a low-impedance secondary burden. The insulation from the primary to secondary of the transformer must be adequate to withstand line-to-ground voltage, since the connected instruments are usually at ground potential. Normal design is for operation with a rated secondary current of 5 A, and the input current may range upward to many thousand amperes. The potential circuits of instruments are of high impedance, and voltage transformers are designed for operation into a high-impedance secondary burden. In the usual design, the rated secondary voltage is 120 V, and instrument transformers have been built for rated primary voltages up to 765 kV.

With the development of higher transmission-line voltages (350 to 765 kV) and intersystem ties at these levels, the coupling-capacitor voltage transformer (CCVT) has come into use for metering purposes to replace the conventional voltage transformer, which, at these voltages, is bulkier and more costly. The metering CCVT, shown in Fig. 3-11, consists of a modular capacitive divider which reduces the line voltage V_1 to a voltage V_2 (10–20 kV), with a series-resonant inductor to tune out the high impedance and make available energy transfer across the divider to operate the voltage transformer which further reduces the voltage to V_M, the metering level. Required metering accuracy may be 0.3% or better.

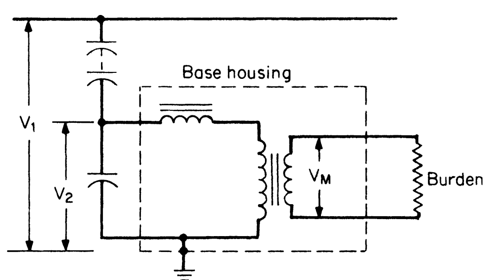

FIGURE 3-11 CCTV metering arrangement.

Instrument transformers are broadly classified in two general types: (1) dry type, having molded insulation (sometimes only varnish-impregnated paper or cloth) usually intended for indoor installation, although large numbers of modern transformers have molded insulation suitable for outdoor operation on circuits up to 15 kV to ground; and (2) liquid-filled types in steel tanks with high-voltage primary terminals, intended for installation on circuits above 15 kV. They are further classified according to accuracy: (1) metering transformers having highest accuracy, usually at relatively low burdens; and (2) relaying and control transformers which in general have higher burden capacity and lower accuracy, particularly at heavy overloads. This accuracy classification is not rigid, since many transformers, often in larger sizes and higher voltage ratings, are suitable for both metering and control purposes.

Another classification differentiates between single and multiple ratios. Multiple primary windings, sometimes arranged for series-parallel connection, tapped primary windings, or tapped secondary windings, are employed to provide multiple ratios in a single piece of equipment. Current transformers are further classified according to their mechanical structure: (1) wound primary, having more than one turn through the core window; (2) through type, wherein the circuit conductor (cable or busbar) is passed through the window; (3) bar type, having a bar, rod, or tube mounted in the window; and (4) bushing type, that is, through type intended for mounting on the insulating bushing of a power transformer or circuit breaker.

Current transformers, whose primary winding is series connected in the line, serve the double purposes of (1) convenient measurement of large currents and (2) insulation of instruments, meters, and relays from high-voltage circuits. Such a transformer has a high-permeability core of relatively small cross section operated normally at a very low flux density. The secondary winding is usually in excess of 100 turns (except for certain small low-burden through-type current transformers used for metering, where the secondary turns may be as low as 40), and the primary is of few turns and may even be a single turn or a section of a bus bar threading the core. The nominal current ratio of such a transformer is the inverse of the turns ratio, but for accurate current measurement, the actual ratio must be determined under loading corresponding to use conditions. For accurate power and energy measurement, the phase angle between the secondary and reversed primary phasor also must be known for the use condition. Insulation of primary from secondary and core must be sufficient to withstand, with a reasonable safety factor, the voltage to ground of the circuit into which it is connected; secondary insulation is much less, since the connected instrument burden is at ground potential or nearly so.

The overload capacity of station-type current transformers and the mechanical strength of the winding and core structure must be high to withstand possible short circuits on the line. Various compensation schemes are used in many transformers to retain ratio accuracy up to several times rated current. The secondary circuit—the current elements of connected instruments or relays—*must never be opened* while the transformer is excited by primary current, because high voltages are induced which may be hazardous to insulation and to personnel and because the accuracy of the transformer may be adversely affected.

Voltage transformers (potential transformers) are connected between the lines whose potential difference is to be determined and are used to step the voltage down (usually to 120 V) and to supply the voltage circuits of the connected instrument burden. Their basic construction is similar to that of a power transformer operating at the same input voltage, except that they are designed for optimal performance with the high-impedance secondary loads of the connected instruments. The core is operated at high flux density, and the insulation must be appropriate to the line-to-ground voltage.

Standard burdens and standard accuracy requirements for instrument transformers are given in American National Standard C57.13 (see Sec. 28).

Accuracy. Most well-designed instrument transformers (provided they have not been damaged or incorrectly used) have sufficient accuracy for metering purposes. See Sec. 10 for typical accuracy curves. Where higher accuracy is required, see Appendix D of ANSI C12, The Code for Electricity Metering.

Another comparison method uses a “standard” transformer of the same nominal rating as the one being tested. Accuracies of 0.01% are attainable. Commercial test sets are available for this work and are widely used in laboratory and field tests. Commercial test sets based on the current-comparator method and capable of 0.001% accuracy are also available. For further details, see ANSI Standard C57.13.

3.1.9 Power Measurement

Electronic wattmeters of 0.1% or better accuracy may be based on a pulse-area principle. Voltages proportional to the applied voltage and to the current (derived from resistors or transformers) govern the height and width of a rectangular pulse so that the area is proportional to the instantaneous power. This is repeated many times during a cycle, and its average represents active power. Average power also can be measured by a system which samples instantaneous voltage and current repeatedly, at predetermined intervals within a cycle. The sampled signals are digitized, and the result is computed by numerical integration. The response of such a system has been found to agree with that of a standard electrodynamic wattmeter within 0.02% from dc to 1 kHz. Depending on sampling speed, measurements can be made to higher frequencies with somewhat reduced accuracy. In the digital instrument, the multiplication involves discrete numbers and thus has no experimental error except for rounding. Such an arrangement is well-adapted to the measurement of power in situations where current or voltage waveforms are badly distorted.

In the thermal wattmeter, where the arrangement is such that if one current v is proportional to instantaneous load voltage and another i is proportional to load current, their sum is applied to one thermal converter and their difference to another. Assuming identical quadratic response of the converters, their differential output may be represented as

$$V_{dc} = \frac{k}{T}\int_0^T [(v + i)^2 - (v - i)^2]dt = \frac{4k}{T}\int_0^T vi\,dt$$

which is by definition average power. Multijunction thermal converters with outputs connected differentially are used for the ac-dc transfer of power, with ac and dc current and voltage signals applied simultaneously to both heaters. DC feedback to current input speeds response and maintains thermal balance between heaters, and the output meter becomes a null indicator. This mode of operation can eliminate the requirement for exact quadrature response, and the matching requirement is also eliminated by interchange of the heaters. The Cox and Kusters instrument was designed for operation from 50 to 1000 Hz with ac-dc transfer errors within 30 ppm, and it may be used up to 20 kHz with reduced accuracy. This instrument also is capable of precision measurement with very distorted waveforms.

Laboratory-standard wattmeters use an electrodynamic mechanism and are in the 0.1% accuracy class for dc and for ac up to 133 Hz. This accuracy can be maintained up to 1 kHz or more. Such instruments are shielded from the effects of external magnetic fields by enclosing the coil system in a laminated iron cylinder. Instruments having current ranges to 10 A and voltage ranges to 300 V are generally self-contained. Higher ranges are realized with the aid of precision instrument transformers.

Portable wattmeters are generally of the electrodynamic type. The current element consists of two fixed coils connected in series with the load to be measured. The *voltage element* is a moving coil supported on jewel bearings or suspended by taut bands between the fixed field coils. The moving coil is connected in series with a relatively large noninductive resistor across the load circuit. The coils are mounted in a laminated iron shield to minimize coupling with external magnetic fields. Switchboard wattmeters have the same coil structure but are of broader accuracy class and do not have the temperature compensation, knife-edge pointers, and antiparallax mirrors required for the better-class portable instruments.

Correction for wattmeter power consumption may be important when the power measured is small. When the wattmeter is connected directly to the circuit (without the interposition of instrument transformers), the instrument reading will include the power consumed in the element connected next to the load being measured. If the instrument loss cannot be neglected, it is better to connect the voltage circuit next to the load and include its power consumption rather than that of the current circuit, since it is generally more nearly constant and is more easily calculated. In some low-range wattmeters, designed for use at low-power factors, the loss in the voltage circuit is automatically compensated by carrying the current of the voltage circuit through compensating coils wound over the field coils of the current circuit. In this case, the voltage circuit must be connected next to the load to obtain compensation.

The *inductance error* of a wattmeter may be important at low-power factor. At power factors near unity, the noninductive series resistance in the voltage circuit is large enough to make the effect of the moving-coil inductance negligible at power frequencies, but with low power factor, the phase angle of the voltage circuit may have to be considered. This may be computed as $\alpha = 21.6fL/R$, where α is the phase angle in minutes, f is the frequency in hertz, L is the moving-coil inductance in millihenrys, and R is the total resistance of the voltage circuit in ohms.

A *3-phase 3-wire circuit* requires two wattmeters connected as shown in Fig. 3-12; total power is the algebraic sum of the two readings under all conditions of load and power factor. If the load is balanced, at unity power factor each instrument will read half the load; at 50% power factor one instrument reads all the load and the other reading is zero; at less than 50% power factor one reading will be negative.

Three-phase 4-wire circuits require three wattmeters as shown in Fig. 3-13. Total power is the algebraic sum of the three readings under all conditions of load and power factor. A 3-phase Y system with

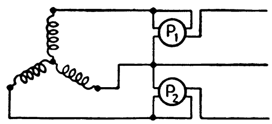

FIGURE 3-12 Power in 3-phase, 3-wire circuit, two wattmeters.

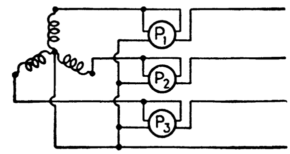

FIGURE 3-13 Power in 3-phase, 4-wire circuit, three wattmeters.

a grounded neutral is the equivalent of a 4-wire system and requires the use of three wattmeters. If the load is balanced, one wattmeter can be used with its current coil in series with one conductor and the voltage circuit connected between that conductor and the neutral. Total power is three times the wattmeter reading in this instance.

Reactive power (reactive voltamperes, or vars) is measured by a wattmeter with its current coils in series with the circuit and the current in its voltage element in quadrature with the circuit voltage.

Corrections for instrument transformers are of two kinds. *Ratio* errors, resulting from deviations of the actual ratio from its nominal, may be obtained from a calibration curve showing true ratio at the instrument burden imposed on the transformer and for the current or voltage of the measurement. The effect of *phase-angle* changes introduced by instrument transformers is modification in the angle between the current in the field coils and the moving coil of the wattmeter; the resulting error depends on the power factor of the circuit and may be positive or negative depending on phase relations, as shown in the table below. If $\cos\theta$ is the *true* power factor in the circuit and $\cos\theta_2$ is the *apparent* power factor (i.e., as determined from the wattmeter reading and the secondary voltamperes), and if K_c and K_v are the true ratios of the current and voltage transformers, respectively, then

$$\text{Main-circuit watts} = K_c K_v \frac{\cos\theta}{\cos\theta_2} \times \text{wattmeter watts}$$

The line power factor $\cos\theta = \cos(\theta_2 \pm \alpha \pm \beta \pm \gamma)$, where θ_2 is the phase angle of the secondary circuit, α is the angle of the wattmeter's voltage circuit, β is the phase angle of the current transformer, and γ is the phase angle of the voltage transformer. These angles—α, β, and γ—are given positive signs when they act to decrease and negative when they act to increase the phase angle between instrument current and voltage with respect to that of the circuit. This is so because a decreased phase angle gives too large a reading and requires a negative correction (and vice versa), as shown in the following table of signs.

Dielectric loss, which occurs in cables and insulating bushings used at high voltages, represents an undesirable absorption of available energy and, more important, a restriction on the capacity of cables and insulating structures used in high-voltage power transmission. The problem of measuring the power consumed in these insulators is quite special, since their power factor is extremely low and the usual wattmeter techniques of power measurement are not applicable. While many methods have been devised over the past half century for the measurement of such losses, the Schering bridge is almost universally the method of choice at the present time. Figure 3-14 shows the basic circuit of the bridge, as described by Schering and Semm in 1920. The balance equations are $C_x = C_s R_1/R_2$ and $\tan\delta_x = \omega R_1 P$, where C_x is the cable or bushing whose losses are to be determined, C_s is a loss-free high-voltage air-dielectric capacitor, R_1 and R_2 are noninductive resistors, and P is an adjustable low-voltage capacitor having negligible loss.

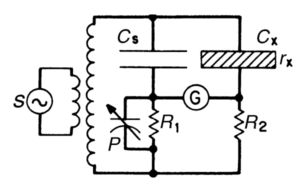

FIGURE 3-14 Schering and Semm's bridge for measuring dielectric loss.

3.1.10 Power-Factor Measurement

The *power factor of a single-phase circuit* is the ratio of the true power in watts, as measured with a wattmeter, to the apparent power in voltamperes, obtained as the product of the voltage and current.

Line power factor	Sign to be used for phase angle					
	α wattmeter		β current transf.		γ voltage transf.	
	Lead*	Lag	Lead	Lag	Lead	Lag
Lead	+	−	−	+	+	−
Lag	−	+	+	−	−	+

*In general, α will be leading only when the inductance of the potential coil has been overcompensated with capacitance.

When the waveform is sinusoidal (and only then), the power factor is also equal to the cosine of the phase angle.

The *power factor of a polyphase circuit* which is balanced is the same as that of the individual phases. When the phases are not balanced, the true power factor is indeterminate. In the wattmeter-voltmeter-ammeter method, the power factor for a balanced 2-phase 3-wire circuit is $P/(\sqrt{2}EI)$, where P is total power in watts, E is voltage between outside conductors, and I is current in an outside conductor; for a balanced 3-phase 3-wire circuit, the power factor is $P/(\sqrt{3}EI)$, where P is total watts, E is volts between conductors, and I is amperes in a conductor. In the two-wattmeter method, the power factor of a 2-phase 3-wire circuit is obtained from the relation $W_2/W_1 = \tan\theta$, where W_1 is the reading of a wattmeter connected in one phase as in a single-phase circuit and W_2 is the reading of a wattmeter connected with its current coil in series with that of W_1 and its voltage coil across the second phase. At unity power factor, $W_2 = 0$; at 0.707 power factor, $W_2 = W_1$; at lower power factors, $W_2 > W_1$. In a 3-phase 3-wire circuit, power factor can be calculated from the reading of two wattmeters connected in the standard way for measuring power, by using the relation

$$\tan\theta = \frac{\sqrt{3}(W_1 - W_2)}{W_1 + W_2}$$

where W_1 is the larger reading (always positive) and W_2 the smaller.

Power-factor meters, which indicate the power factor of a circuit directly, are made both as portable and as switchboard types. The mechanism of a single-phase electrodynamic meter resembles that of a wattmeter except that the moving system has two coils M, M'. One coil, M, is connected across the line in series with a resistor, whereas M' is connected in series with an inductance. Their currents will be nearly in quadrature. At unity power factor, the reaction with the current-coil field results in maximum torque on M, moving the indicator to the 100 mark on the scale, where torque on M is zero. At zero power factor, M' exerts all the torque and causes the moving system to take a position where the plane of M' is parallel to that of the field coils, and the scale indication is zero. At intermediate power factors, both M and M' contribute torque, and the indication is at an intermediate scale position. In a 2-phase meter, the inductance is not required, coil M being connected through a resistance to one phase, while M' with a resistance is connected to the other phase; the current coil may go in the middle conductor of a 3-wire system. Readings are correct only on a balanced load. In one form of polyphase meter, for balanced circuits, there are three coils in the moving system, connected one across each phase. The moving system takes a position where the resultant of the three torques is minimum, and this depends on power factor. In another form, three stationary coils produce a field which reacts on a moving voltage coil. When the load is unbalanced, neither form is correct.

3.1.11 Energy Measurements

The subject of metering electric power and energy is extensively covered in the American National Standard C21, Code for Electricity Metering, American National Standards Institute. It covers definitions, circuit theory, performance standards for new meters, test methods, and installation standards for watthour meters, demand meters, pulse recorders, instrument transformers, and auxiliary devices. Further detailed information may be found in the *Handbook for Electric Metermen,* Edison Electric Institute.

The practical unit of electrical energy is the watthour, which is the energy expended in 1 h when the power (or rate of expenditure) is 1 W. Energy is measured in watthours (or kilowatthours) by means of a *watthour meter*. A watthour meter is a motor mechanism in which a rotor element revolves at a speed proportional to power flow and drives a registering device on which energy consumption is integrated. Meters for continuous current are usually of the mercury-motor type, whereas those for alternating current utilize the principle of the induction motor.

Polyphase Meter Connections. Obviously, it is extremely important that the various circuits of a polyphase meter be properly connected. If, for example, the current-coil connections are interchanged and the line power factor is 50%, the meter will run at the normal 100% power-factor speed, thus giving an error of 100%.

A test for correct connections is as follows: If the line power factor is over 50%, rotation will always be forward when the potential or the current circuit of either element is disconnected, but in one case the speed will be less than in the other. If the power factor is less than 50%, the rotation in one case will be backward.

When it is not known whether the power factor is less or greater than 50%, this may be determined by disconnecting one element and noting the speed produced by the remaining element. Then change the voltage connection of the remaining element from the middle wire to the other outside wire and again note the speed. If the power factor is over 50%, the speed will be different in the two cases but in the same direction. If the power factor is less than 50%, the rotation will be in opposite directions in the two cases.

When instrument transformers are used, care must be exercised in determining correct connections; if terminals of similar instantaneous polarity have been marked on both current and voltage transformers, these connections can be verified and the usual test made to determine power factor. If the polarities have not been marked, or if the identities of instrument transformer leads have been lost in a conduit, the correct connections can still be established, but the procedure is more lengthy.

Use of Instrument Transformers with Watthour Meters. When the capacity of the circuit is over 200 A, instrument current transformers are generally used to step down the current to 5 A. If the voltage is over 480 V, current transformers are almost invariably employed, irrespective of the magnitude of the current, in order to insulate the meter from the line; in such cases, voltage transformers are also used to reduce the voltage to 120 V. Transformer polarity markings must be observed for correct registration. The ratio and phase-angle errors of these transformers must be taken into account where high accuracy is important, as in the case of a large installation. These errors can be largely compensated for by adjusting the meter speed.

Reactive Voltampere-Hour (Var-Hour) Meters. Reactive voltampere-hour (var-hour) meters are generally ordinary watthour meters in which the current coil is inserted in series with the load in the usual manner while the voltage coil is arranged to receive a voltage in quadrature with the load voltage. In 2-phase circuits, this is easily accomplished by using two meters as in power measurements, with the current coils connected directly in series with those of the “active” meters but with the voltage coils connected across the quadrature phases. Evidently, if the meters are connected to rotate forward for an inductive load, they will rotate backward for capacitive loads. For 3-phase 3-wire circuits and 3-phase 4-wire circuits, phase-shifting transformers are used normally and complex connections result.

Errors of Var-Hour Meters. The 2- and 3-phase arrangements described above give correct values of reactive energy when the voltages and currents are balanced. The 2-phase arrangement still gives correct values for unbalanced currents but will be in error if the voltages are unbalanced. Both 3-phase arrangements give erroneous readings for unbalanced currents or voltages; an autotransformer arrangement usually will show less error for a given condition of unbalance than the simple arrangement with interchanged potential coils.

Total var-hours, or “apparent energy” expended in a load, is of interest to engineers because it determines the heating of generating, transmitting, and distributing equipment and hence their rating and investment cost. The apparent energy may be computed if the power factor is constant, from the observed watthours P and the observed reactive var-hours Q; thus var-hours = $\sqrt{P^2 + Q^2}$. This method may be greatly in error when the power factor is not constant; the computed value is always too small.

A number of devices have been offered for the direct measurement of the apparent energy. In one class *(a)* are those in which the meter power factor is made more or less equal to the line power factor. This is accomplished automatically (in the Angus meter) by inserting a movable member in the voltage-coil pole structure which shifts the resulting flux as line power factor changes. In others, autotransformers are used with the voltage elements to give a power factor in the meter close to expected line power factor. By using three such pairs of autotransformers and three complete polyphase watthour-meter elements operating on a single register, with the record determined by the meter running at the highest speed, an accuracy of about 1% is achieved, with power factors ranging from unity down to 40%. In the other class *(b)*, vector addition of active and reactive energies is accomplished either by electromagnetic means or by electromechanical means, many of them very ingenious. But the result obtained with the use of modern watthour and var-hour meters are generally adequate for most purposes.

The *accuracy* of a watthour meter is the percentage of the total energy passed through a meter which is registered by the dials. The watthours indicated by the meter in a given time are noted, while the actual watts are simultaneously measured with standard instruments. Because of the time required to get an accurate reading from the register, it is customary to count revolutions of the rotating element instead of the register. The accuracy of the gear-train ratio between the rotating element and the first dial of the register can be determined by count. Since the energy represented by one revolution, or the *watthour constant,* has been assigned by the manufacturer and marked on the meter, the indicated watthours will be $K_h \times R$, where K_h is the watthour constant and R the number of revolutions.

Reference Standards. *Reference standards* for dc meter tests in the laboratory may be ammeters and voltmeters, in portable or laboratory-standard types, or potentiometers; in ac meter tests, use is made of indicating wattmeters and a time reference standard such as a stopwatch, clock, or tuning-fork or crystal-controlled oscillator together with an electronic digital counter. A more common reference is a standard watthour meter, which is started and stopped automatically by light pulsing through the anticreep holes of the meter under test.

The *portable standard* watthour meter (often called *rotating standard*) method of watthour-meter testing is most often used because only one observer is required and it is more accurate with fluctuating loads. Rotating standards are watthour meters similar to regular meters, except that they are made with extra care, are usually provided with more than one current and one voltage range, and are portable. A pointer, attached directly to the shaft, moves over a dial divided into 100 parts so that fractions of a revolution are easily read. Such a standard meter is used by connecting it to measure the same energy as is being measured by the meter to be tested; the comparison is made by the "switch" method, in which the register only (in dc standards) or the entire moving element (in ac standards) is started at the beginning of a revolution of the meter under test, by means of a suitable switch, and stopped at the end of a given number of revolutions. The accuracy is determined by direct comparison of the number of whole revolutions of the meter under test with the revolutions (whole and fractional) of the standard. Another method of measuring speed of rotation in the laboratory is to use a tiny mirror on the rotating member which reflects a beam of light into a photoelectric cell; the resulting impulses may be recorded on a chronograph or used to define the period of operation of a synchronous electric clock, etc.

Watthour meters used with instrument transformers are usually checked as secondary meters; that is, the meter is removed from the transformer secondary circuits (current transformers must first be short-circuited) and checked as a 5-A 120-V meter in the usual manner. The meter accuracy is adjusted so that when the known corrections for ratio and phase-angle errors of the current and potential transformers have been applied, the combined accuracy will be as close to 100% as possible, at all load currents and power factors. An overall check is seldom required both because of the difficulty and because of the decreased accuracy as compared with the secondary check.

General precautions to be observed in testing watthour meters are as follows: (1) The test period should always be sufficiently long and a sufficiently large number of independent readings should be taken to ensure the desired accuracy. (2) Capacity of the standards should be so chosen that readings will be taken at reasonably high percentages of their capacity in order to make observational or scale errors as small as possible. (3) Where indicating instruments are used on a fluctuating load, their average deflections should be estimated in such a manner as to include the time of duration of each deflection as well as the magnitude. (4) Instruments should be so connected that neither the standards nor the meter being tested is measuring the voltage-circuit loss of the other, that the same voltage is impressed on both, and that the same load current passes through both. (5) When the meter under test has not been previously in circuit, sufficient time should be allowed for the temperature of the voltage circuit to become constant. (6) Guard against the effect of stray fields by locating the standards and arranging the temporary test wiring in a judicious manner.

Meter Constants. The following definitions of various meter constants are taken from the Code for Electricity Metering, 6th ed., ANSI C12.

Register constant K_r is the factor by which the register reading must be multiplied in order to provide proper consideration of the register or gear ratio and of the instrument-transformer ratios to obtain the registration in the desired units.

Register ratio R_r is the number of revolutions of the first gear of the register, for one revolution of the first dial pointer.

Watthour constant K_h is the registration expressed in watthours corresponding to one revolution of the rotor. (When a meter is used with instrument transformers, the watthour constant is expressed in terms of primary watthours. For a secondary test of such a meter, the constant is the primary watthour constant, divided by the product of the nominal ratios of transformation.)

Test current of a watthour meter is the current marked on the nameplate by the manufacturer (identified as TA on meters manufactured since 1960) and is the current in amperes which is used as the basis for adjusting and determining the percentage registration of a watthour meter at heavy and light loads.

Percentage registration of a meter is the ratio of the actual registration of the meter to the true value of the quantity measured in a given time, expressed as a percentage. Percentage registration is also sometimes referred to as the *accuracy* or *percentage accuracy* of a meter. The value of one revolution having been established by the manufacturer in the design of the meter, meter watthours = $K_h \times R$, where K_h is the watthour constant and R is the number of revolutions of rotor in S seconds. The corresponding power in meter watts is $P_m = (3600 \times R \times K_h)/S$. Hence, multiplying by 100 to convert to terms of percentage registration (accuracy),

$$\text{Percentage registration} = \frac{Kh \times R \times 3600 \times 100}{PS}$$

where P is true watts. This is the basic formula for watthour meters in terms of true watt reference.

Average Percentage Registration (Accuracy) of Watthour Meters. The Code for Electricity Metering makes the following statement under the heading, "Methods of Determination":

> The percentage registration of a watthour meter is, in general, different at light load than at heavy load, and may have still other values at intermediate loads. The determination of the average percentage registration of a watthour meter is not a simple matter as it involves the characteristics of the meter and the loading. Various methods are used to determine one figure which represents the average percentage registration, the method being prescribed by commissions in many cases. Two methods of determining the average percentage registration (commonly called "average accuracy" or "final average accuracy") are in common use:
>
> *Method 1.* Average percentage registration is the weighted average of the percentage registration at light load (*LL*) and at heavy load (*HL*), giving the heavy-load registration a weight of 4. By this method:
>
> $$\text{Weighted average percentage registration} = \frac{LL + 4HL}{5}$$
>
> *Method 2.* Average percentage registration is the average of the percentage registration at light load (*LL*) and at heavy load (*HL*). By this method:
>
> $$\text{Average percentage registration} = \frac{LL + HL}{2}$$

In-Service Performance Tests. *In-service performance tests,* as specified in the Code for Electricity Metering, ANSI C12, shall be made in accordance with a *periodic test schedule,* except that self-contained single-phase meters, self-contained polyphase meters, and 3-wire network meters also may be tested under either of two other systems, provided that all meters are tested under the same system. These systems are the *variable interval plan* and the *statistical sampling plan*.

The chief characteristic of the *periodic-internal system* is that a fixed percentage of the meters in service shall be tested annually. In the test intervals specified below, the word *years* means calendar years. The periods stated are recommended test intervals. There may be situations in which individual meters, groups of meters, or types of meters should be tested more frequently. In addition, because of the complexity of installations using instrument transformers and the importance of large loads, more frequent inspection and test of such installations may be desirable. In general, periodic test schedules should be as follows:

1. Meters with surge-proof magnets and without demand registers or pulse initiators—16 years.
2. Meters without surge-proof magnets and without demand registers or pulse initiators—8 years.

The chief weaknesses of the preceding periodic test schedule are that it fails to recognize the differences in accuracy characteristics of various types of meters as a result of technical advance in meter design and construction, and fails to provide incentives for maintenance and modernization programs.

The *variable interval plan* provides for the division of meters into homogeneous groups and the establishment of a testing rate for each group based on the results of in-service performance tests made on meters longest in service without test. The maximum test rate recommended is 25% per year. The minimum test rate recommended for the testing of a sufficient number of meters to provide adequate data to determine the test rate for the succeeding year. The provisions of the variable interval plan recognize the difference between various meter types and encourage adequate meter maintenance and replacement programs. See Section 8.1.8.5 of ANSI C12 for details of operation of this plan.

The *statistical sampling program* included is purposely not limited to a specific method, since it is recognized that there are many acceptable ways of achieving good results. The general provisions of the statistical sampling program provide for the division of meters into homogeneous groups, the annual selection and testing of a random sample of meters of each group, and the evaluation of the test results. The program provides for accelerated testing, maintenance, or replacement if the analysis of the sample test data indicates that a group of meters does not meet the performance criteria. See Section 8.1.8.6 of ANSI C12 for details of the operation of this program.

Ampere-Hour Meters. Ampere-hour meters measure only electrical quantity, that is, coulombs or ampere-hours, and therefore, where they are used in the measurement of electrical energy, the potential is assumed to remain constant at a "declared" value, and the meter is calibrated or adjusted accordingly.

Ampere-hour or volt-hour meters for alternating current are not practical but ampere-squared-hour or volt-squared-hour meters are readily built in the form of the induction watthour meter. Ampere-hours or volt-hours are then obtainable by extracting the square root of the registered quantities.

Maximum-Demand Meters. Some methods of selling energy involve the maximum amount which is taken by the customer in any period of a prescribed length, that is, the maximum demand. Many types of meters for measuring this demand have been developed, but space permits only a brief description of a few. There are two general classes of demand meters in common use: (1) integrated-demand meters and (2) thermal, logarithmic, or lagged-demand meters. Both have the same function, which is to meter energy in such a way that the registered value is a measure of the load as it affects the heating (and therefore the load-carrying capacity) of the electrical equipment.

Integrated-Demand Meters. Integrated-demand meters consist of an integrating meter element (kWh or kvarh) driving a mechanism in which a timing device returns the demand actuator to zero at the end of each timing interval, leaving the maximum demand indicated on a passive pointer, display, or chart, which in turn is manually reset to zero at each reading period, generally 1 month. Such demand mechanisms operate on what is known as the block-interval principle. There are three types of block-interval demand registers: (1) the indicating type, in which the maximum demand obtained between each reading period is indicated on a scale or numeric display, (2) the cumulative type, in which the accumulated total of maximum demand during the preceding periods is indicated during the period after the device has been reset and before it is again reset, that is, the maximum demand for any one period is equal or proportional to the difference between the accumulated readings before and after reset, and (3) the multiple-pointer form, in which the demand is obtained by reading the position of the multiple pointers relative to their scale markings. The multiple pointers are resettable to zero.

Another form of demand meter, usually in a separate housing from its associated watthour meter, is the recording type, in which the demand is transferred as a permanent record onto a tape by printing, punching, or magnetic means or onto a circular or strip chart. A special form of tape recording for demand metering that has come into wide use in recent years is the pulse recorder, in which pulses from a pulse initiator in the watthour meter are recorded on magnetic tape or punched paper tape in a form usable for machine translation by digital-data-processing techniques. Advantages of this system are its great flexibility, freedom from the operating difficulties inherent in inked charts, and freedom from many of the personal errors of manual reading and interpretation of charts.

Thermal, Logarithmic, or Lagged-Demand Meters. These are devices in which the indication of the maximum demand is subject to a characteristic time lag by either mechanical or thermal means. The indication is often designed to follow the exponential heating curve of electrical equipment. Such a response, inherent in thermal meters, averages on a logarithmic and continuous basis, which means that more recent loads are heavily weighted but that, as time passes, their effect decreases. The time characteristics for the lagged meter are defined as the nominal time required for 90% of the final indication with a constant load suddenly applied.

Concordance of Demand Meters and Registers. The measurement of demand may be obtained with meters and registers having various operating principles and employing various means of recording or indicating the demand. On a constant load of sufficient duration, accurate demand meters and registers of both classifications will give the same value of maximum demand, within the limits of tolerance specified. On varying loads, the values given by accurate meters and registers of different classifications may differ because of the different underlying principles of the meters themselves. In commercial practice, the demand of an installation or a system is given with acceptable accuracy by the record or indication of any accurate demand meter or register of acceptable type.

3.1.12 Electrical Recording Instruments

Recording instruments are, in many instances, essentially high-torque indicating instruments arranged so that a permanent, continuous record of the indication is made on a chart. They are made for recording all electrical quantities that can be measured with indicating instruments—current, voltage, power, frequency, etc. In general, the same type of electrical mechanism is used—permanent-magnet moving-coil for direct current and moving-iron or dynamometer for alternating current. The indicator is an inking pen or stylus that makes a record on a chart moving under it at constant speed. This requires a higher torque to overcome friction, so the operating power required for a recording instrument is greater than for a simple indicating instrument. Overshoot is generally undesirable, and recording instruments are slightly overdamped, whereas indicating instruments are usually somewhat underdamped. Some recorders use strip charts; graduations along the length of the chart are usually of time intervals, and the graduations across the chart represent the instrument scale. Alternatively, the chart may be circular, with radial graduations for the instrument scale and time markers around the circumference. The chart paper should be well made and glazed to minimize dimensional changes from temperature and humidity. The ink should be in accordance with the maker's specification for the particular paper used so that it is accepted readily and does not run or blot the paper. Chart drives may be electrical or clockwork. In strip charts, perforations along the edges of the paper are engaged by a drive pinion; circular charts are rotated from a central hub.

Potentiometric self-balancing recorders are systems incorporating dc potentiometers, used either alone or with a transducer to measure various quantities.

Transducers include those for voltage, current, power, power factor, frequency, temperature, humidity, steam or water flow, gas velocity, neutron density, and many other applications.

Types of systems are classified according to the means of detecting and correcting electrical unbalance in the potentiometer circuit.

Accuracy on the order of $^1/_4$% may be expected from potentiometer recorders. To maintain this accuracy, the potentiometer is referenced against a standard cell or a reference voltage provided by a Zener diode. This may be performed by the operator pressing a button to give manual standardization whenever desired. A further refinement is to have automatic standardization, in which the operation is intiated by the chart-drive motor at specified intervals.

Range extension of potentiometric recorders upward is by means of shunt or series resistors. Extension below the basic range of the recorder requires preamplifiers.

Measurement of ac quantities requires the use of ac-to-dc transducers, for example, thermocouples, rectifiers, etc.

Alternating-current potentiometer recorders are simpler than the dc types because they require no standardization against a standard cell or Zener reference voltage and ac-to-dc conversion is not required, eliminating the requirement for a vibrator or saturable reactor. The amplifier and motor-control circuits can be the same as in the dc recorder. By far, the greatest application is with ac bridges, where the ac amplifier acts as an unbalance detector. Strain-gage bridges and bridges which employ platinum or nickel resistive elements for narrow-range temperature measurements frequently employ recorders of this type.

Proximity-type recorders use a high-frequency oscillator whose operation is started or stopped by the insertion of a metal vane into a pair of coils. If the vane is mounted on the pointer of an indicating instrument, the oscillator can sense movement between the pointer and a pair of coils fitted to the oscillator. Servo motion of the coils on displacement of the instrument pointer is accomplished by coupling the oscillator output to the input of a servo amplifier which drives the control motor. This gives a graphic record that follows but does not constrain movement of the instrument pointer. In this way, quantities which can operate an indicating instrument can be recorded without using a transducer.

Telemetering is the indicating or recording of a quantity at a distant point. Telemetering is employed in power measurements to show at a central point the power loads at a number of distant stations and often to indicate total power on a single meter, but practically any electrical quantity which is measured can be transmitted, together with a large number of nonelectrical quantities such as levels, positions, and pressures. Telemetering systems may be classified by type: current, voltage, frequency, position, and impulse.

1. In *current* systems, the movement of the primary measuring element calls for a current in the attached control member to balance the torque created by the quantity measured. This balancing current (usually dc) is sent over the transmitting circuit to be indicated and recorded. Totalizing is possible by the addition of such currents from several sources in a common indicator. The receiver may be as much as 50 mi from the transmitter.
2. In *voltage* systems, a voltage balance may be produced through a control-member voltmeter, or a voltage may be generated by thermocouples heated by the quantity to be measured, or produced as an *IR* drop as a result of a current torque balance, or generated by a generator driven at a speed proportional to the measured quantity. These voltages, however produced, are recorded at a distance by a potentiometer recorder. Here, also, the recorder may be 50 mi from the transmitter.
3. A *variable frequency* may be produced for telemetering by causing the primary element to move a capacitor plate in an rf oscillator or to change the speed of a small dc motor driving an alternator. High-frequency systems cannot be used for transmission over many miles.
4. In *position* systems, the movement of the primary element or of a pilot controlled by the primary element is duplicated at a distance. The pilot may be a bridge balancing resistance or reactance, a variable mutual inductance, or a selsyn motor where the position of a rotor relative to a 3-phase stator is reproduced at the receiver end. Satisfactory operation is usually limited to a few miles.
5. The *impulse* type of transmission of measured quantities is represented by the largest number of devices. The number of impulses transmitted in a given time may represent the magnitude of the quantity being measured, and these may be integrated by a notching device or by a clutch, or the duration of the pulse may be governed by the primary element and interpreted at the receiver. If the impulses are transmitted at high frequency, inductance and capacitance effects in the transmitting line limit the distance of satisfactory transmission; systems using dc impulses operate over 50 to 250 mi.

3.1.13 Resistance Measurements

The SI unit of resistance, the ohm, has been determined directly in terms of the mechanical units by *absolute-ohm* experiments performed at the National Bureau of Standards and at national laboratories in other countries. The reactance of an inductor or capacitor of special construction whose value can be computed from its dimensional properties is compared with a resistance at a known frequency. The value of this resistance can then be assigned in absolute (or SI) units, in terms of length and time—the dimensions of the inductor or capacitor and the time interval corresponding to the comparison frequency. These measurements are made with high precision, and it is believed that the assigned value of the National Reference Standards of resistance, maintained at the NIST, differs from its intended *absolute* value by not more than 1 part in 10^6.

The *National Reference Standard* of resistance is a group of five 1-Ω resistors of special construction, sealed in double-walled enclosures containing dry nitrogen and kept in a constant temperature bath of mineral oil at 25°C at the NIST. To ensure that their values are constant, they are intercompared at least weekly, compared with other standards of differing construction quarterly, and compared with similar groups in other major national laboratories frequently. Absolute experiments to determine their SI values are performed at rather longer intervals because of the complexity of such experiments—a new experiment of this type may require 5 years or more to complete. This reference group serves as the basis for all resistance measurements made in the country.

Resistance standards, used in precise measurements, are made with high-resistivity metal, in the form of wire or strip. Manganin—a copper-nickel-manganese alloy—is generally used in resistance standards because, when properly treated and protected from air and moisture, it has a number of desirable characteristics, including stable value, low temperature coefficient, low thermal emf at junctions with copper, and relatively high resistivity. A copper-nickel-chromium-aluminum alloy, Evanohm, has been used for high-resistance standards, since it has the same desirable characteristics as manganin and a much higher resistivity.

Standards with nominal values exceeding a megohm (a million ohms) are generally of films of metals such as Nichrome, a nickel-chromium alloy, deposited on a glass substrate. Four forms of standard are in general use. The Thomas-type 1-Ω standard is widely used as a primary standard. The Reichsanstalt form was developed in the German National Laboratory; and the NIST form. All three are designed to be used with their current-terminal lugs in mercury cups and are generally suspended in an oil bath to dissipate heat and to hold the temperature constant at a known value during measurements.

The fourth type, in widespread use for secondary references and as a primary standard at the 10,000-Ω level, consists of one or more coils of Evanohm wound on mica cards or cylindrical formers and terminated in binding posts for use on benchtops. The primary standard version of this type of resistor generally has the resistance elements hermetically sealed in an oil-filled container which also contains some type of resistive temperature sensor.

For highest precision, power dissipation must be kept below 0.1 W (calibrations at the NIST are generally performed at 0.01 W), although as much as 1 W can be dissipated in stirred oil with very small changes in value. The maker's recommendations should be followed regarding safe operating current levels. High- and low-resistance standards use different terminal arrangements. In all standards of 1 Ω lower value and standards up to 10,000 Ω intended for use at the part-per-million (ppm) level of accuracy or better, the current and voltage terminals are separated, whereas in other standards they may not be. The four-terminal construction is required to define the resistance to be measured. Connections to the current-carrying circuit range from a few microhms upward and, in a two-terminal construction, would make the resistance value uncertain to the extent that the connection resistance varies. With four-terminal construction, the resistance of the standard can be *exactly* defined as the voltage drop between the voltage terminals for unit current in and out at the current terminals.

Current standards are precision four-terminal resistors used to measure current by measuring the voltage drop between the voltage terminals with current introduced at the current terminals. These standards, designed for use with potentiometers for precision current measurement, correspond in structure to the shunts used with millivoltmeters for current measurement with indicating instruments. Current standards must be designed to dissipate the heat they develop at rated current, with only a small temperature rise. They may be oil- or air-cooled, the latter design having much greater surface, since heat transfer to still air is much less efficient than to oil. An air-cooled current standard of 20 $\mu\Omega$ resistance and 2000-A capacity, has an accuracy of 0.04%. Very low resistance oil-cooled standards are mounted in individual oil-filled containers provided with copper coils through which cooling water is circulated and with propellers to provide continuous oil motion.

Alternating-current resistors for current measurement require further design consideration. For example, if the resistor is to be used for current-transformer calibration, its ac resistance must be identical with its dc resistance within 1/100% or better, and the voltage difference between its voltage terminals must be in phase with the current through it within a few tenths of a minute. Thin strips or tubes of resistance material are used to limit eddy currents and minimize "skin" effect, the current circuit must be arranged to have small self-inductance, and the leads from the voltage taps to the potential terminals should be arranged so that, as nearly as possible, the mutual inductance between the voltage and current circuits opposes and cancels the effect of the self-inductance of the current circuit. Figure 3-15 shows three types of construction. In (*a*) a metal strip has been folded into a very narrow U; in (*b*) the current circuit consists of coaxial tubes soldered together at one end to terminal blocks at the other end; in (*c*) a straight tube is used as the current circuit, and the potential leads are snugly fitting coaxial tubes soldered to the resistor tube at the desired separation and terminating at the center.

Resistance coils consist of insulated resistance wire wound on a bobbin or winding form, hard-soldered at the ends to copper terminal wires. Metal tubes are widely used as winding form for dc resistors because they dissipate heat more readily than insulating bobbins, but if the resistor is to be used in ac measurements, a ceramic winding form is greatly to be preferred because it contributes less to the phase-defect angle of the resistor. The resistance wire ordinarily is folded into a narrow loop and wound bifilar onto the form to minimize inductance. This construction results in considerable associated capacitance of high-resistance coils, for which the wire is quite long, and an alternative construction is to wind the coil inductively on a thin mica or plastic card. The capacitive effect is greatly reduced, and the inductance is still quite small if the card is thin.

Resistors in which the wire forms the warp of a woven ribbon have lower time constants than either the simple bifilar- or card-wound types. Manganin is the resistance material most generally employed, but Evanohm and similar alloys are beginning to be extensively used for very high resistance coils. Enamel or silk is used to insulate the wire, and the finished coil is ordinarily coated with shellac or varnish to protect the wire from the atmosphere. Such coatings do not completely exclude moisture, and dimensional changes of insulation with humidity will result in small resistance changes, particularly in high resistances where fine wire is used.

Resistance boxes usually have two to four decades of resistance so that with reasonable precision they cover a considerable range of resistance, adjustable in small steps. For convenience of connection, terminals of the individual resistors are brought to copper blocks or studs, which are connected into the circuit by means of plugs or of dial switches using rotary laminated brushes; clean, well-fitted plugs probably have lower resistance than dial switches but are much less convenient to use.

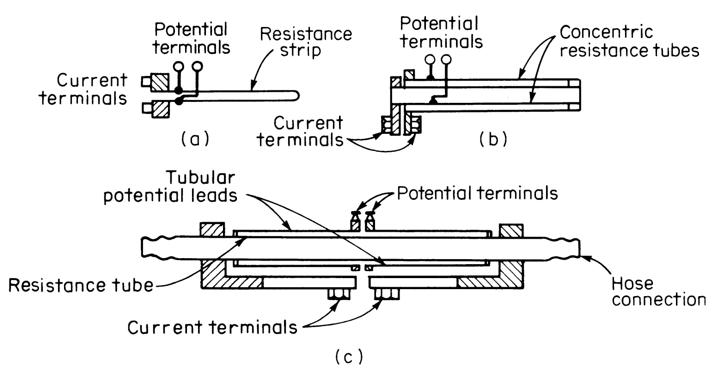

FIGURE 3-15 Types of low-inductance standard resistors.

The residual inductance of decade groups of coils due to switch wiring, and the capacitance of connected but inactive coils, will probably exceed the residuals of the coils themselves, and it is to be expected that the time constant of an assembly of coils in a decade box will be considerably greater than that of the individual coils.

Measurement of resistance is accomplished by a variety of methods, depending on the magnitude of the resistor and the accuracy required. Over the range from a few ohms to a megohm or more, an ohmmeter may be used for an accuracy of a few percent. A simple ohmmeter may consist of a milliammeter, dry cell, and resistor in a series circuit, the instrument scale being marked in resistance units. For a better value, the voltage drop is measured across the resistor for a measured or known current through it. Here, accuracy is limited by the instrument scales unless a potentiometer is used for the current and voltage measurements. The approach is also taken in the wide variety of digital multimeters now in common use. Their manufacturers' specifications indicate a range of accuracies from a few percent to 10 ppm (0.001%) or better from the simplest to the most precise meters. Bridge methods can have the highest accuracy, both because they are null methods in which two or more ratios can be brought to equality and because the measurements can be made by comparison with accurately known standards. For two-terminal resistors, a Wheatstone bridge can be used; for four-terminal measurements, a Kelvin bridge or a current comparator bridge can be used. Bridges for either two- or four-terminal measurements also may be based on resistive dividers. Because of their extremely high input impedance, digital voltmeters may be used with standard resistors in unbalanced bridge circuits of high accuracy.

Digital multimeters are frequently used to make low-power measurements of resistors in the range between a few ohms and a hundred megohms or so. Resolution of such instruments varies from 1% of full scale to a part per million of full scale. These meters generally use a constant-current source with a known current controlled by comparing the voltage drop on an internal "standard" resistor to the emf produced by a Zener diode. The current is set at such a level as to make the meter direct-reading in terms of the displayed voltage; that is, the number displayed by the meter reflects the voltage drop across the resistor, but the decimal point is moved and the scale descriptor is displayed as appropriate. Multimeters typically use three or more fixed currents and several voltage ranges to produce seven or more decade ranges with the full-scale reading from 1.4 to 3.9 times the range. For example, on the 1000-Ω range, full scale may be 3,999.999 Ω. Power dissipated in the measured resistor generally does not exceed 30 mW and reaches that level only in the lowest ranges where resistors are usually designed to handle many times that power. The most accurate multimeters have a resolution of 1 to 10 ppm of range on all ranges above the 10-Ω range. Their sensitivity, linearity, and short-term stability make it possible to compare nominally equal resistors by substitution with an uncertainty 2 to 3 times the least count of the meter. This permits their use in making very accurate measurements, up to 10 ppm, or resistors whose values are close to those of standards at hand. Many less expensive multimeters have only two leads or terminals to use to make measurements. In those cases, the leads from the meter to the resistor to be measured become part of the measured resistance. For low resistances, the lead resistance must be measured and subtracted out, or zeroed out.

The *Wheatstone bridge* is generally used for two-terminal resistors. In the low-resistance range where four-terminal construction is normal, the resistance of connections into the network may be a significant fraction of the total resistance to be measured, and the Wheatstone network is not applicable. Figure 3-16 shows the arrangement of a Wheatstone bridge, where A, B, and C are known resistances, and D is the resistance to be measured. One or more of the known arms is adjusted until the galvanometer G indicates a null; then $D = B(C/A)$. In case D is inductive, the battery switch S_1 should be closed before the galvanometer key S_2 to protect the galvanometer from the initial transient current. In a common form of bridge, B is a decade resistance, adjustable in small steps, while C and A (the ratio arms of the bridge) can be altered to select ratios in powers of 10 from $C/A = 10^{-3}$ to 10^3. If the value of the unknown resistor is not very different from that of a known resistor, accuracy may be improved by substituting the known and unknown in turn into arm D and noting the difference in

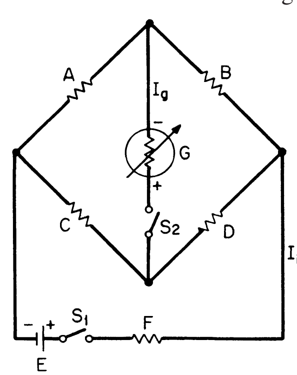

FIGURE 3-16 Wheatstone bridge.

balance readings of the adjustable arm *B*. Since there has been no change in the ratio arms, any errors they may have do not affect the difference measurement, and only those errors in arm *B* which were involved in the difference between the settings affect the difference value; in effect, the unknown is measured in terms of a known resistor by a substitution procedure. An alternative form of Wheatstone bridge is frequently assembled from standards and a ratio box of limited range called a *direct-reading ratio set*. This latter has a nominal ratio of unity, with ratio adjustments ranging from 1.005000 to 0.995000, that is, four decades of adjustment, of which the largest has steps of 0.1%. If a balance is made with the two standards in arms *B* and *D* and a second balance with the standards interchanged, their difference is half the difference between the balance readings. A similar technique can be used wherever small resistance differences are involved, for example, in the determination of temperature coefficients.

Bridge sensitivity can be determined in the following way. The voltage that would appear in the galvanometer branch of the circuit with switch S_2 open is

$$e = \frac{EBD\,\Delta B}{(B + D)^2}$$

where *E* is the supply voltage and ΔB is the amount in proportional parts by which *B* departs from balance. If, now, the voltage sensitivity of the galvanometer is known for operation in a circuit whose external resistance is that of the bridge as seen from the galvanometer terminals, its response for the unbalance ΔB can be computed. The current in the galvanometer with S_2 closed is

$$I_g = \frac{e}{G + BD/(B + D) + AC/(A + C)}$$

where *G* is the resistance of the galvanometer. If there is a large current-limiting resistance *F* in the battery branch of the bridge, the terminal voltage at the *AC* and *BD* junction points should be used rather than the supply voltage *E* in computing *e*. In connecting and operating a bridge, the allowable power dissipation of its components should first be checked to ensure that these limits are not exceeded, either in any element of the bridge itself or in the resistance to be measured.

Resistive voltage dividers can be used to form bridges for either two- or four-terminal resistance measurements. There are two common forms of resistive voltage divider—the Kelvin-Varley divider and the universal ratio set (URS)—with the former being the most commonly encountered. Each behaves as a potential divider with nearly constant input resistance and an open-circuit output potential of some rational fraction of the input, that fraction being given by the dial settings with calibration corrections applied. In the case of the Kelvin-Varley divider, the maximum ratio is 0.99999 . . . *X*, and outputs may be selected with a resolution as great as 1 part in 100 million of the input. Most Kelvin-Varley dividers have input resistances of 10,000 or 100,000 Ω. The URS was specifically designed to calibrate precision potentiometers. Its nominal input resistance is 2111.11 . . . 0 Ω, and that is also its full-scale dial designation. Its resolution, or one step of its least-significant dial, is either 1 or 0.1 mΩ. For bridge applications, either divider type appears as two adjacent (series-connected) bridge elements with a ratio of $r/(R - r)$, where *r* is the dial setting and *R* is the full-scale dial setting. In a Wheatstone or two-terminal type of bridge as shown in Fig. 3-16, the divider appears as resistors *A* and *B*, with *C* being the known resistor, or standard, and *D* being the unknown. In that case, the balance equation is

$$D/C = (R - r)/r$$

assuming that the low input of the divider is connected to the node between resistors *A* and *C* and its high input to the node between *B* and *D*.

Four-terminal applications are more complex, since four separate balances must be made to obtain the ratio between two resistors. The schematic is given in Fig. 3-17. To measure *B* in terms of *A*, the lead resistances between node pairs 1–2, 3–4, and 5–6, which we will call *x*, *y*, and *z*, respectively, must be eliminated. This is done by balancing the circuit with the resistor-side detector lead tied to each of the resistor potential leads at the terminals marked p_1, p_2, p_3, and p_4. The result is

$$\frac{A}{B} = \frac{r_2 - r_1}{r_4 - r_3}$$

where the *r*s are readings obtained by balancing the divider at each of the potential terminals.

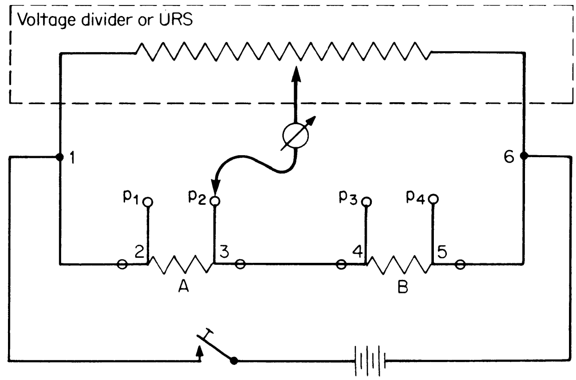

FIGURE 3-17 Four-terminal resistance measurements.

Both types of dividers must be calibrated. This can be done by comparison with a more accurate divider, dial by dial. Such a divider can readily be formed by using a number of nominally equal resistors in series. Each resistor is measured relative to the same standard and the results used to calculate the various ratios in the string of resistors. The string is then used to calibrate each setting of each dial in the voltage divider. In the case of the Kelvin-Varley divider, the dial corrections are interdependent; the correction for the steps in a particular dial depends on the settings of the less-significant dials.

Unbalanced bridge techniques have been made practical by the very high input resistances of modern digital instrumentation and are a satisfactory approach to resistance measurements when the values of the resistors being measured do not differ significantly from one another. They are particularly useful in cases where a process, not expected to change significantly, is being monitored using resistive sensors such as thermistors or copper or nickel resistors. The simplest case is that of a Wheatstone bridge such as that shown in Fig. 3-16. In it, the galvanometer *G* would be replaced by a digital meter of suitable sensitivity and sufficiently high input impedance to make bridge loading errors insignificant. The bridge relationship then becomes

$$\frac{B}{A + B} + \frac{v}{V} = C + D$$

where V is the voltage applied to the bridge, or $(E - I_b F)$, and v is the reading of the digital meter. In practice, the meter is generally used to measure V as well as v. If the individual elements of the resistor pairs $A - B$ and $C - D$ are nearly equal, the bridge is nearly at balance, v is small, and measurements of v and V need not be made at high accuracies. Resolution is not generally a problem for resistance element values of 100 Ω and higher because digital meters with least counts of 0.1 and 1 μV microvolts are commonly available.

A special form of Wheatstone bridge, known as a *Mueller bridge,* is commonly used for four-terminal measurements of the resistance of platinum resistance thermometers (PRTs). In this bridge, shown in Fig. 3-18, the effects of lead resistance of the PRT are eliminated by including two of the leads in adjacent bridge arms and making a second measurement after transposing the leads. The equations are

$$R_1 + l_1 = R_x + l_4 + S_1 \tag{a}$$

$$R_2 + l_4 = R_x + l_1 + S_2 \tag{b}$$

because the bridge is always used with the ratio arms *A* and *B* adjusted to be equal. These two equations may be added to eliminate lead resistances and result in the equation

$$R_x = 0.5\,(R_1 - S_1 + R_2 - S_2)$$

where R_1, S_1, R_2, and S_2 are the dial readings (with corrections applied) for conditions *A*, *B*.

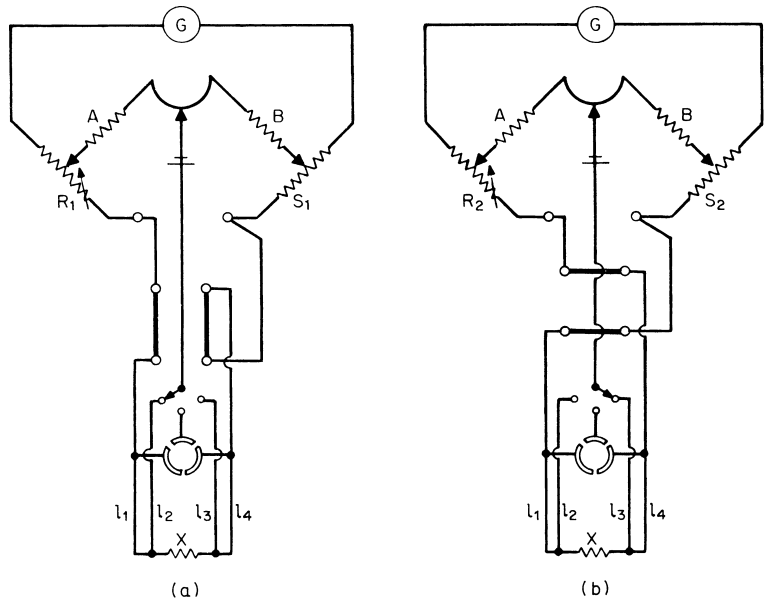

FIGURE 3-18 Mueller bridge.

There is increasing use of low-frequency square- and sinusoidal-wave bridges for PRT measurements. These bridges rely on the inherent ratio stability and accuracy of specially designed transformers and the increased sensitivity available with ac amplifiers to provide accuracies rivaling or surpassing those of the best dc bridges while requiring a minimum amount of upkeep. Both manual and automatic balancing types are available. Many contain one or more resistance reference standards kept at constant temperature in ovens. The transfer accuracies (i.e., accuracy available immediately after the bridge reference resistor has been calibrated) are very nearly equal to their least count, generally 0.1 ppm or better. Such bridges operate at 400 Hz or less to reduce problems with quadrature balances in the resistance being measured and its leads. They usually cover the range below 100 Ω.

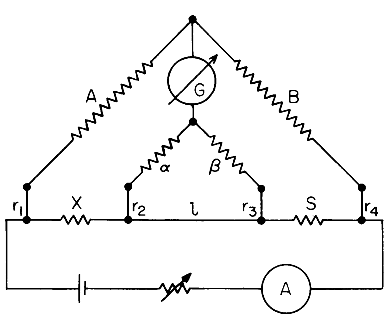

FIGURE 3-19 Kelvin double bridge.

The *Kelvin double bridge* is used for the measurement of low resistances of four-terminal construction, that is, whose current and voltage terminals are separate. Figure 3-19 shows the network. The balance equation is

$$\frac{X}{S} = \frac{A}{B} + \frac{1}{S}\frac{\beta}{\alpha + \beta + 1}\left(\frac{A}{B} - \frac{\alpha}{\beta}\right)$$

If the resistances X and S being compared are small so that the resistance of the link l connecting them is comparable, the term of the balance equation involving l could be significant, but if the ratio A/B is equal to the ratio α/β, the correction term vanishes. This equality can be demonstrated, after the bridge is balanced, by opening the link l; if the inner and outer ratios are equal, the bridge will remain balanced. It should be noted that the resistance of the leads r_1, r_2, r_3, and r_4 between the bridge terminals and the voltage terminals of the resistors may contribute to a ratio unbalance; these lead

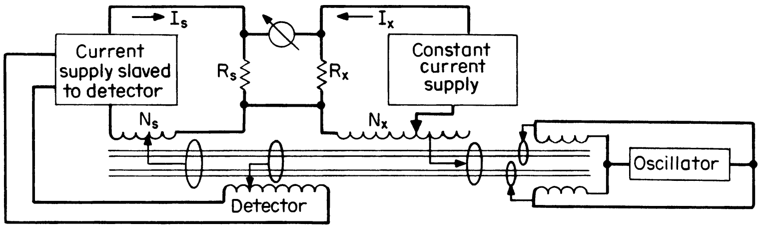

FIGURE 3-20 Current-comparator bridge.

resistances should be in the same ratio as the arms to which they are connected. In some Kelvin bridges, small adjustable resistors are provided for balancing leads; another technique is to shunt the α or β arm with a high resistance until $A/B = \alpha/\beta$ with the link removed. When this balance is achieved, the link l is replaced, and the main bridge balance is readjusted. In some bridges, the outer and inner ratio arms are adjustable only in decimal steps, and the main balance is secured by means of an adjustable standard resistor consisting of a Manganin strip with nine voltage taps of 0.01 or 0.001 Ω each and a Manganin slide wire. Portable bridges may use slide-wire arms and reference resistors to cover a range from 10 $\mu\Omega$ to 10 Ω.

In the *current-comparator bridge,* shown schematically in Fig. 3-20, the ratio of resistor currents is evaluated in the comparator as a balance of ampere-turns in the two circuits. $I_xN_x = I_sN_s$, so $R_x/R_s = N_x/N_s$ when $I_sR_s = I_xR_x$. A resistance determination that depends on the evaluation of a ratio is limited by the stability of that ratio. In Wheatstone and Kelvin bridges, the stability of individual resistors sets that limit; in the current-comparator bridge, the ratio is that of windings on a common magnetic core and therefore stable.

Since this bridge operates in terms of a ratio of currents for equal voltage drops, it can be used to determine power coefficients of low-value resistors. In a Kelvin bridge, the ratio of power dissipated is $P_s/P_x = R_s/R_x$ in the resistors compared; in the comparator bridge, this ratio is $P_s/P_x = R_x/R_s$. Thus, a low-value resistor operated at a substantial power level can be compared directly with a standard of higher resistance operated at a low power level.

Insulation resistance is generally measured by deflection methods. In the case of resistances on the order of a few megohms, a Wheatstone bridge may be used with low to moderate accuracy. A portable megohm bridge is made by General Radio Company. It operates as a Wheatstone bridge with an amplifier and dc indicating instrument as the detector system. A choice of high-resistance ratio arms gives ranges of 0.1 to 10^4 MΩ. On the highest range, the resolution limit is about 10^6 MΩ. The deflection methods fall in two general classes: (1) direct-deflection methods and (2) loss-of-charge methods.

Direct-deflection methods (insulation resistance) involve the simple application of Ohm's law. When the resistance is on the order of 1 MΩ, an ordinary voltmeter can give results that are good enough for most purposes. Two readings are taken, one with the voltmeter directly across the source of voltage, the other with the resistance to be measured connected in series with the voltmeter. The resistance is $R = V(d_1 - d_2)/d_2$, where V is the resistance of the voltmeter, d_1 is the voltmeter deflection on the first reading, and d_2 is the deflection on the second reading. The greater the resistance of the voltmeter per volt, the higher is the resistance that can be measured. For higher resistances, a reflecting galvanometer with high current sensitivity is used. Figure 3-21 is a diagram of the arrangement for measuring the insulation resistance of a cable.

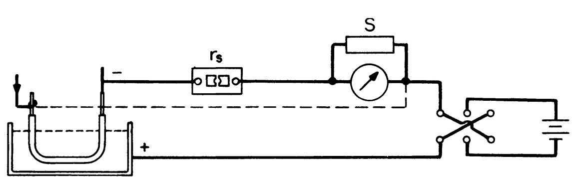

FIGURE 3-21 Diagram for measurement of insulation resistance of cable.

The measurement is made as follows: The galvanometer shunt S is set at the highest shunting value, and the circuit is closed. The shunt is decreased until a large, readable deflection is obtained. The reading is taken 1 min after closing the main switch. This procedure is repeated with only the standard resistor r_s (usually 0.1 or 1 MΩ) in the circuit, the specimen being short-circuited. The resistance of the specimen in megohms is $R = (G/d_1 s_1) - r_s$, where d_1 is the first reading and s_1 the multiplier corresponding to the shunt setting. G, the galvanometer megohm constant, is obtained from the second reading, $G = dr_s s$, where d is deflection, r_s the value of the standard resistor in megohms, and s the shunt multiplier. The conductor is preferably negative to the sheath or water. The standard resistor r_s is left in the circuit as a protection to the galvanometer against accidental short circuit in the sample. The guard for the cable ends is shown by the broken line. Removing braid for several inches at the ends of the sample and dipping the ends in hot paraffin tend to reduce leakage across the face of the insulation from sheath to central conductor, especially in damp weather.

The *loss-of-charge method* of measuring insulation resistance may be used when the resistance is very high, such as the resistance of porcelain and glass and the surface leakage resistance of line insulators. The principle is shown in Fig. 3-22, where the resistance r to be measured is connected in parallel with a capacitor C. Key a is closed and immediately opened, charging the capacitor. Key b is closed immediately after a is opened and the ballistic throw d_1 of the galvanometer noted. The process is repeated, but now a time t s is allowed to pass from the instant of charging before key b is closed and a deflection d_2 observed. The resistance is

$$r = \frac{t}{2.303C \log_{10}(d_1/d_2)} \qquad \text{M}\Omega$$

where C is the capacitance in microfarads.

The insulation resistance of the capacitor is not infinite and should be measured in a similar manner with r removed. The two resistances are in parallel, and the corrected value is

$$r = \frac{r_1 r_2}{r_2 - r_1}$$

where r_1 is the resistance value obtained in the first measurement and r_2 is the resistance of the capacitor. For even higher resistance, a growth-of-charge method may be used. In this case, the resistance to be measured is connected in series with a capacitor (preferably an air capacitor), and a known voltage E is applied for t s, the voltage on the capacitor being e at the end of this time. This value, e, is best measured with an electrostatic voltmeter connected continuously across C. The resistance is

$$r = \frac{t}{2.303C \log_{10}[E/(E - e)]} \qquad \text{M}\Omega$$

The *resistance of earth connections* may be measured by a three-electrode method. In Fig. 3-23, A is the connection whose resistance to earth is to be measured; it is temporarily disconnected from the distribution system while ground connection is preserved through a connection at D, either temporary or permanent. Two additional "grounds," B and C, are established, separated from each other and from A by not less than 15 ft. These auxiliary grounds may be pieces of metal buried in the earth,

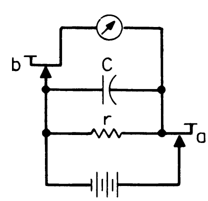

FIGURE 3-22 Leakage method of measuring insulation resistance.

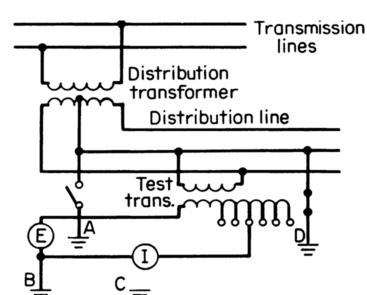

FIGURE 3-23 Resistance of earth connections.

such as a guy wire or a steel pole, making sufficient contact with ground for a good current reading. Resistances between the three electrodes taken in pairs are measured by a voltmeter-ammeter method. These resistances are r_{ab}, r_{bc}, and r_{ac}. Then the resistances are as follows:

$$\text{At } A: \quad R_a = \frac{r_{ab} - r_{bc} + r_{ac}}{2}$$

$$\text{At } B: \quad R_b = \frac{r_{ab} - r_{bc} - r_{ac}}{2}$$

$$\text{At } C: \quad R_c = \frac{r_{bc} - r_{ab} + r_{ac}}{2}$$

The measurement should be made with alternating current, which can be taken from the distribution system through an isolating transformer with secondary taps as shown. A low-range voltmeter is usually required. An Evershed ratio instrument is used for the measurement of ground resistance. One of the moving coils is traversed by the current sent through the ground from the attached hand-operated generator; the other is energized by the voltage drop to an auxiliary, driven electrode.

Faults in electric lines may be divided into two classes, closed- and open-circuit faults. *Closed-circuit faults* consist of *shorts,* where the insulation between conductors becomes faulty, and *grounds,* where the faulty insulation permits the conductor to make contact with the earth. *Open-circuit faults,* or *opens,* are produced by breaks in the conductors.

1. When the short is a low-resistance union of the two conductors, such as at *M* in Fig. 3-24, the resistance should be measured between the ends *AB*; from this value and the resistance per foot of conductor, the distance to the fault can be computed. A measurement of resistance between the other ends *A′B′* will confirm the first computation or will permit the elimination of the resistance in the fault, if this is not negligible.

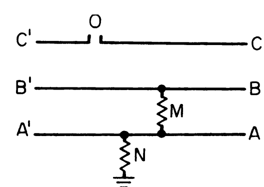

FIGURE 3-24 Line faults.

2. The location of a ground, as at *N* in Fig. 3-24, or of a high-resistance short is made by either of the two classic "loop" methods, provided that a good conductor remains.

Figure 3-25 shows the arrangement of the *Murray loop test*, which is suitable for low-resistance grounds. The faulty conductor and a good conductor are joined together at the far end, and a Wheatstone-bridge arrangement is set up at the near ends with two arms *a* and *b* comprising resistance boxes which can be varied at will; the two segments of line *x* and $y + l$ constitute the other two arms; the battery current flows through the ground; the galvanometer is across the near ends of the conductors. At balance,

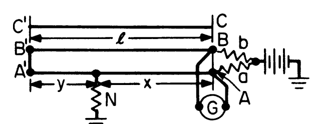

FIGURE 3-25 Murray loop.

$$\frac{a}{b} = \frac{x}{y + l} \quad \text{or} \quad \frac{a + b}{b} = \frac{x + y + l}{y + l} \quad \text{ohms}$$

The sum $x + y + l$ may be measured or known. If the conductors are uniform and alike and x and l are expressed as lengths, say, in feet,

$$x = \frac{2al}{a + b} \quad \text{ft}$$

If the ground is of high resistance, very little current will flow through the bridge with the arrangement of Fig. 3-25. In that case, battery and galvanometer should be interchanged, and thegalvanometer used should have a high resistance. If ratio arms a and b consist of a slide wire (preferably with extension coils), the sum $a + b$ is constant and the computation is facilitated. Observations should be taken with direct and reversed currents, especially in work with underground cables.

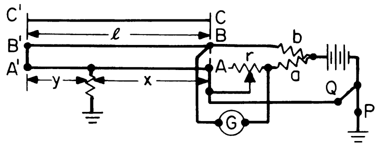

FIGURE 3-26 Varley loop.

In the *Varley loop,* shown in Fig. 3-26, fixed-ratio coils, equal in value, are employed, and the bridge is balanced by adding a resistance r to the near leg of the faulty conductor.

$$\frac{a}{b} = \frac{r + x}{y + l} \quad \text{or} \quad \frac{a + b}{b} = \frac{x + y + l + r}{y + l} \qquad \text{ohms}$$

If $a = b$,

$$x = y + l - r \quad \text{or} \quad x = \frac{1}{2(x + y + l - r)} \qquad \text{ohms}$$

The total line resistance $x + y + l$ is conveniently determined by shifting the battery connection from P to Q and making a new balance, r'. The equation then becomes $x = ½(r' - r)$. When a and b are slightly unequal, a second set of readings should be taken with a and b interchanged and the average values of r and r' substituted in the foregoing equations.

3. *Opens,* such as O in Fig. 3-24, are located by measuring the electrostatic capacitance to ground (or to a good conductor) of the faulty conductor and of an identical good conductor; the position of the fault is determined from the ratio of the capacitances.
4. *Shorts* and *grounds* may be detected by sending through the defective conductor an alternating current of audible frequency, say 1000 Hz. A pickup coil connected to a telephone receiver worn on the head of the tester is then carried along the line; the note in the receiver will cease when the fault has been passed.

3.1.14 Inductance Measurements

The *self-inductance,* or *coefficient of self-induction,* of a circuit is the constant by which the time rate of change of the current in the circuit must be multiplied to give the self-induced counter emf. Similarly, the *mutual inductance* between two circuits is the constant by which the time rate of change of current in either circuit must be multiplied to give the emf thereby induced in the other circuit. Self-inductance and mutual inductance depend upon the shape and dimensions of the circuits, the number of turns, and the nature of the surrounding medium.

Computable standards of self- or mutual inductance have been used traditionally in *absolute-ohm* determinations, but they are not suitable for use in assigning the values of other inductors—they are bulky and have relatively large capacitance to ground and considerable coupling to other circuits, their ratio of inductance to resistance is relatively low, and they exhibit appreciable skin effect even at moderately high frequencies, since they must be wound with rather heavy wire. All these undesirable features inevitably follow from the requirement that their values be computable from measured dimensions. Computable self-inductors and the primaries of computable mutual inductors are wound as single-layer solenoids on a dimensionally stable nonmagnetic form. The best of them are on cylinders of fused silica, and the winding is laid in a groove lapped into the form to ensure uniform winding pitch. The primary winding of a computable mutual inductor is in two or three sections spaced at such intervals that there is a region outside and in its central plane in which its field gradients are very small. The secondary—a multilayer winding—is located in this position so that its position and dimensions will be less critical.

Working standards of inductance are usually multilayer coils wound on nonmagnetic forms of Bakelite, marble, or ceramic to ensure reasonable dimensional stability. A toroidal core gives a coil that is practically immune to external magnetic fields. Approximate astaticism is also achieved by using two equal coils, connected in series and so located with respect to each other that their coupling with external fields tends to cancel each other. Since there is always capacitance associated with a winding, the effective value of an inductor will always be a function of frequency to a greater or lesser extent, and an accurate statement of value must necessarily include the frequency with which the value is associated. Inductance standards for radio frequencies are wound on open frames.

Single-layer winding or "loose basket weave" is essential to reduce the distributed capacitance and the consequent change of effective inductance with frequency. Insulating material is kept to a minimum to reduce dielectric loss.

Inductometers are continuously adjustable inductance standards. The Ayrton-Perry inductometer uses pairs of coaxial coils wound on zones of spheres; the outer pair is fixed, and the inner pair can be rotated about a vertical axis. The coils are so proportional that the scale is uniform over most of its length. This inductometer is not astatic, and its coupling with external fields can cause significant measurement errors. The Brooks inductometer, a better design from several viewpoints, consists of six link-shaped coils. The four stator coils are mounted in pairs above and below the rotor coils, which are located diametrically opposite one another in a flat disk. These two fixed- and moving-coil combinations are so connected that their coupling with external fields tends to cancel. The shape of the link coils gives a scale that is completely uniform except at its extreme ends, and the time constant of the inductometer is much higher than in the Ayrton-Perry arrangement. Ratio of maximum to minimum inductance is about 8:1, and change of calibration with wear in the bearings is negligibly small. Terminals of the fixed and movable coils are usually brought out separately so that inductometers can be used as either adjustable self-inductors or adjustable mutual inductors.

Measurement methods at power and audio frequency are (1) null methods employing bridges if accurate values are required or (2) deflection methods in which the inductance is computed from measured values of impedance and power factor, the measurements being made with indicating instruments—ammeter, voltmeter, wattmeter. At radio frequencies, resonance methods are used.

Bridges for inductance measurements can assume a variety of forms, depending on available components and reference standards, magnitude and time constant of the inductance to be measured, and a variety of other factors. In a four-arm bridge similar to the Wheatstone network, an inductance can be (1) compared with another inductance in an adjacent arm with two resistors forming the "ratio" arms or (2) measured in terms of a combination of resistance and capacitance in the opposite arm with two resistors as the "product" arms. It is generally better, where possible, to measure inductance in terms of capacitance and resistance rather than by comparison with another inductance because the problems of stray fields and coupling between bridge components are more easily avoided. The basic circuits will be described for a few bridges which can be used to measure inductance, but a more detailed reference should be consulted for a discussion of shielding, physical arrangement of components, effects of residuals, etc. In the balance equations which will be stated below, the inductance, L or M, will be expressed in henrys, the resistance R in ohms, capacitance in farads, and ω is $2\pi \times$ frequency in hertz. The time constant of an inductor is L/R; its storage factor Q is $\omega L/R$.

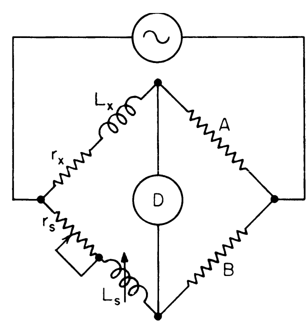

FIGURE 3-27 Inductance bridge.

Inductance comparison is accomplished in the simple Wheatstone network shown in Fig. 3-27, in which A and B are resistive ratio arms, L_x and r_x represent the inductor and the associated resistance being measured, and L_s and r_s are the reference inductor and the associated resistance (including that of the inductor itself) required to make the time constants of the two inductive arms equal. At balance,

$$\frac{A}{B} = \frac{L_x}{L_s} = \frac{r_x}{r_s}$$

An inductometer may be used to achieve balance, together with an adjustable resistance in the same bridge arm, as indicated in the diagram. If only a fixed-value standard inductor is available, balance can be secured by varying one of the ratio arms, but there also must be an adjustable resistance in series with L_x or L_s to balance the time constants of the inductive arms. Care must be taken to ensure that there is no inductive coupling between L_s and L_x, since this would lead to a measurement error.

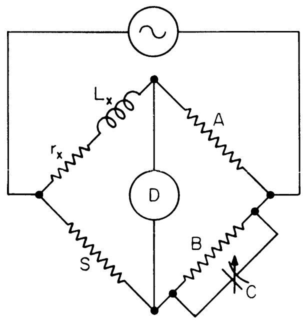

FIGURE 3-28 Maxwell-Wien inductance-capacitance bridge.

The *Maxwell-Wien bridge* for the determination of inductance in terms of capacitance and resistance is shown in Fig. 3-28. The balance equations are $L_x = ASC$ and $r_x = AS/B$. This bridge is widely used for accurate inductance measurements. It is most easily balanced by adjustments of capacitor C and resistor B; these elements are in quadrature, and therefore their adjustments do not interact.

Anderson's bridge, shown in Fig. 3-29, can be used for measurement over a wide range of inductances with reasonable values of R and C. Its balance equations are $L_x = CAS\,(1 + R/S + R/B)$ and $r_x = AS/B$. Balance adjustments are best made with R and r_x. This bridge also has been used to measure the residuals of resistors, a substitution method being employed in which the unknown and a loop of resistance wire with calculable residuals are substituted in turn into the L arm. If A and B are equal and if the resistances of the unknown and the calculable loop are matched, the residuals in the various bridge arms do not enter the final calculation, except the residual of Δr_x, the change in r_x between balances. The elimination of bridge-arm residuals from the *exact* balance equations is characteristic of substitution methods, and quite generally, residuals or corrections to the arms that are unchanged between the balances do not have to be taken into account in the final calculation when the difference is small between the substituted quantities.

Owen's bridge, shown in Fig. 3-30, can be used to measure a wide range of inductance with a standard capacitor C_b of fixed value, by varying the resistance arms S and A. In operation, the resistance S and capacitor $C_b(r_b)$ are usually fixed, balance being secured by successive adjustments of A and R. At balance,

$$r_x + R = (C_b/C_a)S + \omega L_x \omega C_b r_b$$

and $L_x(1 + \tan\delta_b \tan\delta_x) = C_b S(A + r_a)$. If $C_b(r_b)$ is a loss-free air capacitor so that $r_b = 0$ and $\tan\delta_b = 0$, $r_x = (C_b/C_z)S' - R$ and $L_x = C_b S(A + r_a)$. This is a bridge which is much used for examining the properties of magnetic materials; inductance may be measured with direct current superposed.With a low-reactance blocking capacitor in series with the detector and another in series with the source, a dc supply may be connected across the test inductance without current resulting in any other branch of the network; a high-reactance, low-resistance "choke" coil should be connected in series with the dc source.

Mutual inductance can be measured readily if an adjustable standard of proper range is available. Connections are made so the range of measurement is limited to values that can be read with the desired precision. Care should be taken in arranging the circuit to avoid coupling between the mutual inductors.

Iron-cored inductors vary in value with frequency and current, so measurements must be made at known current and frequency; bridge methods can, of course, be adapted to this measurement, care being exercised to ensure that the current capacities of the various bridge components are not exceeded. In such a case, the waveform of the voltage drop across the circuit branch containing the inductor may not be sinusoidal, whereas that across the other side of the bridge, containing linear resistances and reactances, may be undistorted. Generally, a tuned detector should be used.

Resonance methods can be used to measure inductance at radio frequencies. A suitable source is used to establish an rf field whose wavelength is λ m. The inductance L_x (microhenrys) to be measured is placed in this field and connected to a calibrated variable capacitor through a thermocouple

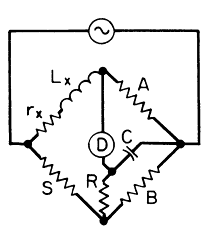

FIGURE 3-29 Anderson's bridge.

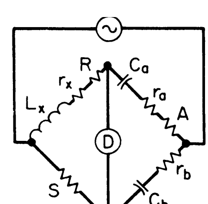

FIGURE 3-30 Owen's inductance-capacitance bridge.

ammeter (i.e., a current-indicating instrument without reactance). The capacitor is adjusted to resonance at a value of C (picofarads). Then, $L_x = 0.2815\lambda^2/C$. If a calibrated inductor L_s of the same order as L_x is available, the wavelength need not be known, and a substitution method can be used. The resonance settings are C_s and C_x, with L_s and L_x, respectively, in the circuit. Then, $L_x = L_s C_s / C_x$. The value of L_x is the effecitve inductance at the frequency of measurement and includes the effect of associated coil capacitance. The frequency of the source must not be affected by the substitution of L_x for L_s.

A *resonance-impedance method,* suitable for high frequencies, is indicated in Fig. 3-31. The capacitor C is adjusted untill the same current is indicated by the ammeter with switch K open or closed. (The applied voltage must be constant.) Then, $L_x = (1/2\omega^2 C)$ H if C is in farads and the frequency is $f = \omega/2\pi$. The waveform must be practically sinusoidal and the ammeter of negligible impedance. This method may be used to measure the effective inductance of choke coils with superposed direct current.

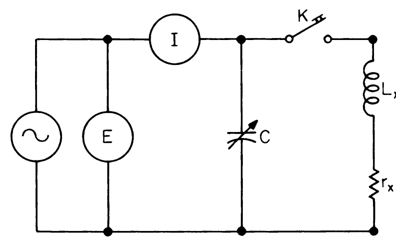

FIGURE 3-31 Reactance-impedance method of measuring inductance.

The *residual inductance* of a resistor or a length of cable at high frequency often can be determined by connecting the resistor in series with a fixed air capacitor and measuring its effective capacitance in an appropriate bridge with and without the series resistor S. If C_1 and C_2 are the measured capacitances in farads, without and with the series resistor, then

$$L = \frac{C_2 - C_1}{\omega^2 C_1 C_2} \qquad \text{and} \qquad S = \frac{1 - \omega^2 L C_1}{\omega C_1} \tan\delta$$

S is the effective resistance in ohms. L is the residual inductance in henrys, and δ is the loss angle of the capacitor-resistor combination computed from the second bridge balance.

3.1.15 Capacitance Measurements

The *capacitance* between two electrodes may be defined for measurement purposes as the charge stored per unit potential difference between them. It depends on their area, spacing, and the character of the dielectric material or materials, which is affected by the electric field between them. The value of a capacitor, measured in farads or a convenient submultiple of this unit, will be influenced quite generally by temperature, pressure, or any ambient condition that changes the dimensions or spacing of the electrodes or the characteristics of the dielectric. The *dielectric constant* of a material is defined as the ratio of the capacitance of a pair of electrodes, with the material occupying all the space affected by the field between them, to the capacitance of the same electrode configuration in vacuum.

Computable capacitors known to 1 part in 10^6 or better have been constructed at the NIST and at certain other national laboratories as a basis for their *absolute-ohm* determinations. Such capacitors now serve as the "base" unit in assigning values to standard capacitors. The electrode arrangement of these computable capacitors conforms to the geometry prescribed in the *Thompson-Lampard theorem:* If four cylindrical conductors of arbitrary sections are assembled with their generators parallel to form a completely enclosed cylinder in such a way that the internal cross capacitances per unit length are equal, then in vacuum these cross-capacitances are each

$$\frac{\ln 2}{4\pi^2 \mu_0 V^2}$$

In the mksa system of electrical units, where μ_0 has the assigned value $4\pi \times 10^{-7}$ and V is the speed of light in vacuum in meters per second, this capacitance is in farads per meter. The capacitance of such a cross capacitor is about 2 pF/m. A practical realization of such a capacitor consists of four equal closely spaced cylindrical rods with their axes parallel and at the corners of a square. Arranged as a three-terminal capacitor and with end effect eliminated, its value can be computed as accurately as its effective length can be measured.

The capacitance of vacuum capacitors with electrodes of simple geometry can be computed approximately in a few cases: (1) Flat, parallel plates with guard ring, $C = 0.08854A/t$ pF, where A is area of the guarded plate in square centimeters and t is spacing in centimeters between electrodes; if dimensions are in inch units, $C = 0.2249A/t$. (2) Coaxial cylinders with guard cylinders at both ends, $C = 0.24161L/\log(R_2/R_1)$ pF for centimeter units, or $C = 0.6137L/\log(R_2/R_1)$ pF for inch units, where L is the length of the guarded cylinder, R_1 is the radius of the inner cylinder, and R_2 the radius of the outer cylinder. (3) Concentric spheres, where R_1 is the radius of the inner sphere and R_2 is the radius of the outer sphere, $C = 1.1127R_1R_2/(R_2 - R_1)$ pF for centimeter units, or $C = 2.8262R_1R_2/(R_2 - R_1)$ pF for inch units. These formulas give only approximate values because they assume no contributing field beyond the edges of the bounding surfaces and take no account of possible eccentricity, lack of parallelism of surfaces, finite width of gap between guard and working electrode, etc., all of which would require small correction terms.

Standard capacitors at levels up to 10^3 pF are generally of a multiple-parallel-plate variety with dry gas (air or nitrogen) as dielectric. Low-temperature coefficient is secured by use of Invar—a low-expansion alloy—as the electrode material and a good degree of stability is achieved by careful, strain-free mounting of fully annealed components and by hermetically sealing the unit. A very high degree of stability has been achieved in a solid-dielectric construction at the 10-pF level in which a disk of fused silica is provided with fired-on silver electrodes. Direct capacitance is through the interior of the disk between its parallel faces, and a silver coating on the cylindrical face acts as guard electrode and confines the field. Very narrow gaps at the edges of the disk between the guard and active electrodes, together with continuation of the shielding in the mounting arrangement, eliminate the possibility of any portion of the measured capacitance being through an outside path between the parallel-plate electrodes. The assembly is hermetically sealed in dry nitrogen, in a shock-resistant, resilient mounting together with a resistance thermometer so that temperature corrections can be accurately applied. Standards of this type have shown variations less than 1 part in 10^7 over a year interval. From 10^3 pF to 1μF, standard capacitors generally have clear mica as dielectric. The electrodes may be metal foils laid out between the mica sheets, the assembly impregnated with paraffin, and the excess wax squeezed out under high pressure. In an alternative construction, the mica sheets are silvered, assembled under pressure, and the assembly hermetically sealed. Neither construction is as stable with time as the lower-value air-dielectric units, and the mica units are characterized by low but appreciable loss angles, whereas the loss angle of the air-dielectric standards is negligible in almost all applications. Continuously adjustable air capacitors have two stacks of interleaved parallel metal plates, one stack being mounted to rotate on an axis. The maximum capacitance occurs when the fixed and movable plates completely overlap; the minimum, a small value but not zero, occurs 180° from this position.

A *three-terminal construction* is required if the value of the capacitor is to be definite and independent of its proximity to other objects. In a nominally two-terminal arrangement, each of the electrodes has some capacitance to surrounding objects or to ground which may depend on spacing and which actually forms a second capacitance circuit in parallel with the capacitor of interest, as will be seen from Fig. 3-32*a* and *b*. It is only in case *c*, where there is an actual third electrode which completely encloses the other two, that the value can be made definite and completely independent of any object or field outside the assembly. A second advantage of the three-terminal construction is that the direct capacitance between the two enclosed electrodes can be made loss-free, since the solid insulation required to support them mechanically can be in the auxiliary capacitances between the enclosing shield electrode and the shielded electrodes.

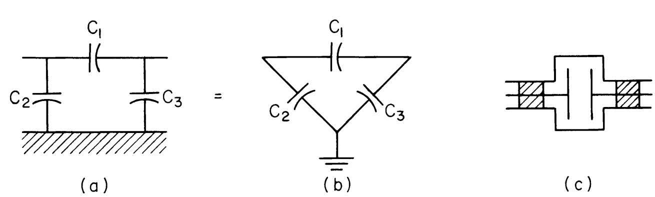

FIGURE 3-32 Two-terminal and three-terminal capacitors.

Methods of measuring capacitance can be classified as *null* methods, which quite generally involve the use of bridges, and *deflection* methods, in which some characteristic, usually impedance, is measured with the aid of indicating instruments. In the equations that follow, the capacitance C will be expressed in farads and resistance A, B, S in ohms. δ will be the *loss angle,* the amount which the current lacks of a true quadrature relation with voltage. The *power factor* of a capacitor is then cos $(\pi/2 - \delta) = \sin\delta$. The dissipation factor D is the name given to $\tan\delta$. It is convenient to represent a capacitor as consisting of a capacitance C (farads) in series with a resistance r (ohms) such that $\tan\delta = 2\pi fCr$ at a frequency f. The *power loss,* for an impressed voltage E (volts), is $P = 2\pi fCE^2 \sin\delta$. Since most bridges yield $\tan\delta$, the power loss can be expressed conveniently as $P = 2\pi fCE^2 \tan\delta$, where δ is small, or $P = \omega CE^2 D$.

Bridge methods for the comparison of capacitors are to be preferred over methods in which capacitance is determined in terms of inductance, since it is simple to shield capacitors so that their values are completely independent of neighboring objects and their electric fields are completely confined, whereas the magnetic fields of inductors cannot be so confined. Error voltages can enter bridges through coupling of an inductor with an external field, through mutual coupling with eddy-current circuits induced by the inductor in neighboring metal objects, etc.

DeSauty's bridge, shown in Fig. 3-33, is a simple Wheatstone network in which capacitors may be compared in terms of a resistance ratio. It should be noted that the loss angles of the two capacitance arms must be equal, so a series resistor is inserted in the branch with the smaller loss angle. In the case illustrated, the resistance S is in series with the reference capacitor C_s. At balance, $C_x = C_s(B/A)$, and $\tan\delta_x = \omega C_x r_x = \omega C_s(r_s + S) = \tan\delta_s + \omega C_s S$.

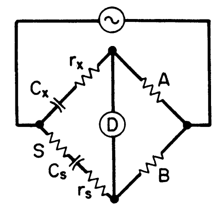

FIGURE 3-33 DeSauty's bridge.

Schering's bridge, shown in Fig. 3-34, has found wide application in measuring the loss angles of high-voltage power cables and high-voltage insulators. For this purpose, the supply voltage is connected as shown, and a ground connection is made at the junction of branches A and B so that the balance adjustments may be made close to ground potential. The adjustable components are generally A and C_p. It is also customary to enclose the A, B, and detector branches in a grounded screen and to protect this low-voltage section against possible breakdown of the test specimen by an air gap paralleling branch A. Such a gap can be set to spark over at 100 V or so, and provides a low-resistance path to ground for breakdown current from the specimen. The balance equations are $C_x = C_s(B/A)(1 + \tan\delta_s \tan\delta_p)$ and $\tan\delta_x = \omega C_p B + \tan\delta_s$. Usually, the reference capacitor C_s is a high-voltage air or compressed-gas capacitor with a negligible phase-defect angle, in which case the correction terms to the balancing equation drop out. The Schering bridge is also an excellent one to use for the comparison of capacitors at low voltage. For this purpose, it is used in its conjugate form with supply and detector branches interchanged to increase sensitivity. C_p must, of course, be connected across branch A instead of B if the loss angle of C_s is greater than that of C_x, with a corresponding modification of the balance equations. When the loss angles of C_s and C_x are both very small, adjustable capacitors must be connected across both A and B arms, and the difference in the phase-defect angles they introduce into the bridge must equal the difference in loss angles of C_s and C_x. This modification of the bridge is made necessary by the fact that the capacitance of an adjustable capacitor cannot be reduced to zero in the usual construction.

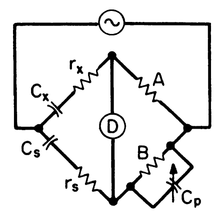

FIGURE 3-34 Schering's bridge.

The *transformer bridge* has been developed into the most precise tool available for the comparison of capacitors, especially for three-terminal capacitors with complete shielding. A three-winding transformer is used so that the bridge ratio is the ratio of the two secondary windings of the transformer which are of low resistance and uniformly distributed around a toroidal core to minimize leakage reactance. A stable ratio, known to better than 1 part in 10^7, can be achieved in this way.

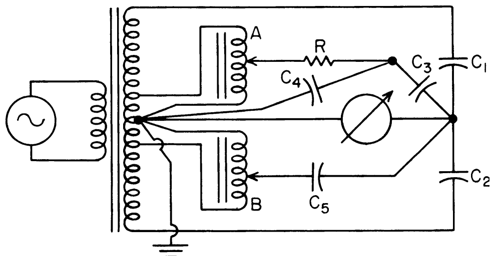

FIGURE 3-35 Transformer bridge for capacitor comparison.

A number of schemes for balancing adjustment have been used successfully. One of these, employing *inductive voltage dividers,* is shown schematically in Fig. 3-35 but simplified by omitting the necessary shielding. Current in phase with the main current is injected at the junction between the capacitors being compared, C_1 and C_2, to balance their inequality in magnitude. This current, through capacitor C_5, is controlled by adjusting the tap position on inductive voltage divider *B*, supplied from an appropriate tap point on the main transformer-ratio arm. Quadrature current, to balance the phase difference between C_1 and C_2, is similarly injected through *R* and the current divider $C_3/(C_3 + C_4)$, controlled by adjusting the tap point on divider *A*. The current divider is used so that *R* may have a reasonable value, a few megohms at most. In the illustrated network, it is assumed that $C_1 > C_2$ and that $\delta_1 < \delta_2$. The balance equations are $C_2 = C_1 + N_B C_5$ and $\delta_2 = \delta_1 + \omega R C_1 \cdot N_A \cdot C_3/(C_3 + C_4)$, where N_B is the fraction of the voltage across C_2 which is impressed on C_5, that is, the product of the tap-point ratios of the main transformer and divider B_5 and N_A is the corresponding fraction of the voltage across C_1 which is impressed on *R*. The reactance of C_3 and C_4 in parallel must be small compared with the resistance of *R*.

New automated impedance measurement instruments have come into being because of the ready availability of microprocessors. Some of these make use of the transformer techniques mentioned earlier, using relays to balance them by selecting ratios computed by the microprocessor from detector output voltages. Many have purely analog quadrature balance features. At least, one measures by passing the same current through the admittance to be measured and a reference resistor and computing the vector impedance of the unknown from the vector ratio of the voltage drops across it and the reference resistor. This is done using a 90° phase reference generated internally using digital synthesis techniques.

Many automated bridges are intended for testing of precision components over a broad range of frequencies and with programmable direct current or voltage biases. Their accuracies range from a few percent at high frequencies to 0.01% or better at audio frequencies. Their calibration is generally done using fixed-value two- or three-terminal or four-pair-terminal standards.

Detectors used in bridge measurements are selected with regard to frequency and impedance. *Vibration galvanometers* can be used at power frequencies in low-impedance circuits; they discriminate well against harmonics and have high sensitivity, but they must be tuned sharply to the use frequency.

Wave analyzers, which are commercially available with internal crystal control, also have a narrow passband and a high rejection of frequencies on either side. They can be used with a preamplifier when maximum sensitivity is required, and it is desirable that the preamplifier itself be sharply tuned in its first stage to improve noise rejection. This system can be used at any frequency throughout the audio region.

Cathode-ray oscilloscopes of adequate sensitivity (or used with tuned preamplifiers) make particularly good null detectors. If a phase-adjustable voltage from the bridge supply is impressed on the horizontal plates and the unbalance signal in the detector branch impressed on the vertical plates, the resulting Lissajous figure is an ellipse which, with proper phase adjustment, will change its opening with magnitude adjustment and the slope of its major axis with quadrature adjustment in the bridge. Balance is indicated by a straight horizontal trace on the screen. It is essential in this system that the initial stages of amplification be sharply tuned or that the bridge input be sinusoidal, for otherwise the pattern on the screen is confused and difficult to interpret. Phase discrimination of this type in the null detector is of considerable value in achieving balance, since it informs the operator of the individual magnitudes of inphase and quadrature unbalance.

Telephone receivers may be used at audio frequencies (maximum sensitivity being at about 1 kHz), but their response is usually quite broad, and the balance point may be masked by the presence of harmonics.

In *resonance methods* at radio frequencies, a thermocouple ammeter can be employed to show the current maximum. A crystal rectifier with an electronic voltmeter is used at ultrahigh frequencies.

Precautions in Bridge Measurements. The effect of stray magnetic fields can be minimized by using twisted-pair or coaxial leads and by avoiding loops in which an emf could be induced. Inductive coupling between bridge components should be avoided. Capacitive coupling existing between parts of the bridge which are not at the same potential will impress shunt capacitance across one or more of the bridge arms and modify the balance condition. Shielding must be used to minimize these effects.

Resonance methods are used for capacitance measurements at radio frequencies, a coil of known inductance L (microhenrys) at a known wavelength λ (m) being employed. Resonance is produced by varying λ and is detected with a thermocouple ammeter. At resonance, $C_x = 0.2815\lambda^2/L$ in picofarads. λ and L need not be known if a substitution method is used in which an adjustable capacitor with a range that includes C_x is connected in place of the unknown capacitor and adjusted to resonance without altering the frequency so that $C_x = C_s$. The leads used to connect the capacitors into the circuit must not be changed in length or position in making the substitution.

A *cavity resonator* can be used at frequencies on the order of 200 to 1000 MHz for measuring the characteristic of insulating material placed between electrodes within the cavity. Resonance is established with excitation of a small loop of wire within the cavity by connection to an oscillator, and resonance is shown by a crystal-rectifier probe connected to an electronic voltmeter.

3.1.16 Inductive Dividers

Inductive dividers are employed in precise voltage- and current-ratio applications. The ratios are used for comparing impedances and for calibrating devices with known nominal ratios such as other dividers, synchros, and resolvers. A divider usually consists of an autotransformer adjustable in decade steps. Such transformers, with high ratio accuracy for voltage or current comparison, have been made by using high-permeability magnetic-core materials and ingenious winding and connection techniques. Such a transformer can be represented electrically by the equivalent circuit of Fig. 3-36. The components of this circuit can be measured directly and will predict the performance of the divider. D is a perfect divider with infinite input impedance and zero output impedance. A' is the transfer ratio of D, the ratio of the voltage between the open-circuited *tap point* and the *low* end to the voltage between the *high* and *low* ends. A' is also the ratio of the short-circuit current between the high and low ends to the current into the tap point and out of the low point. Z_{oc} is impedance between high and low points, with the tap point open-circuited. This impedance is quite high and is a function of input voltage and frequency primarily. Its major components are the winding capacitance, charging inductance, and leakage reactance in parallel. Z_{sc} is the impedance between tap and low points, with the high and low points short-circuited together. This impedance is quite low and is a function of frequency and setting. Its major components are winding and contact resistances and the leakage inductance in series. The autotransformer configuration can produce voltage and current ratios of very high accuracy.

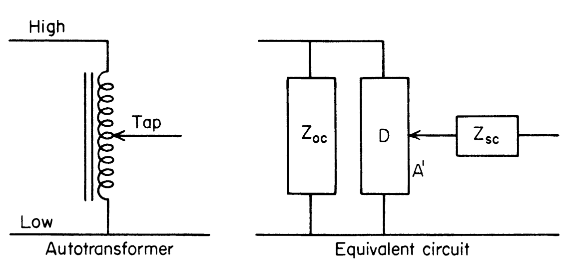

FIGURE 3-36 Autotransformer and equivalent circuit.

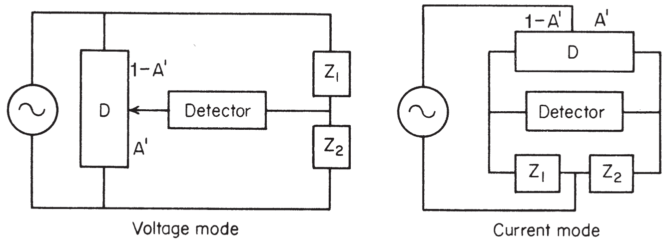

FIGURE 3-37 Voltage mode (*left*) and current mode (*right*) for impedance comparison

As a *voltage divider,* the circuit can be represented by a Thévenin equivalent consisting of a zero-impedance generator, with a voltage which is the product of the input voltage times the transfer ratio, and an output impedance equal to Z_{sc}. This low-output impedance provides high accuracy even with appreciable load admittance. For example, a 5000-Ω load will change the output voltage by only 0.1% if the output impedance is 5 Ω.

As a *current divider,* the circuit can be represented by Norton equivalent consisting of an infinite-impedence generator, with a current which is the product of the transfer ratio A' and the input current and an impedance equal to Z_{oc} in shunt across the output. This high-shunt output impedance provides high accuracy even with appreciable load impedance. For example, a 500-Ω load will receive a current only 0.1% less than short-circuit current if the output impedance Z_{oc} is 500,000 Ω.

Impedance comparison, using the comparison ratio $A'/(1 - A')$, can be accomplished in either the voltage mode of operation or the current mode of operation, as shown in Fig. 3-37. For impedance comparison, the divider impedances Z_{oc} and Z_{sc} are of no consequence. In the voltage-ratio mode, Z_{oc} is outside the bridge circuit, and at null no current is drawn through Z_{sc}. In the current-ratio mode, Z_{sc} is outside the bridge circuit, and at null there is no voltage across Z_{oc}. In either mode, the balance equation is $Z_2 = Z_1 A'/(1 - A')$.

3.1.17 Waveform Measurements

The instantaneous variations of current and voltage in a circuit can be measured by oscillographs, whose basic operating principle may be either that of a D'Arsonval galvanometer whose inertia is low enough to permit it to follow the variations or that of an electron beam which has no sensible inertia and whose deflection is governed by electric or magnetic fields. In addition to tracing waveforms, oscillographs are used for measurements of transient phenomena, such as those which occur in switching operations or in the impulse-voltage testing of insulating structures and disturbances resulting from lightning discharges. Transient phenomena also may be captured using digitizing oscilloscopes and transient digitizers (waveform recorders).

The *galvanometer oscillograph* may have a light low-inertia coil or, for higher-frequency response, a pair of thin metal ribbons tightly stretched across insulating bridges and tied together by a small mirror at their midpoints, mounted in the field of a permanent magnet. A light beam from the galvanometer mirror traces its response to varying current on a moving photographic film or, by means of an intermediate rotating mirror, on a stationary viewing screen. Galvanometer elements have been built with natural response frequencies as high as 8 kHz (a more common construction has a resonance frequency of about 3 kHz) and, if damped at about 0.7 of critical, have a response to signals which is practically free from distortion up to about half their resonant frequency; at resonant frequency, the deflection sensitivity has decreased to about 70% of their dc sensitivity for this damping.

3.1.18 Frequency Measurements

Reed-type frequency meters have a number of steel strips rigidly fastened to a bar at one end and free to vibrate at the other. These strips are located in the field of an electromagnet which is energized from the circuit whose frequency is to be measured. The strips have been accurately adjusted by solder weights to resonant vibration frequencies that differ by ¼ or ½ Hz, and the one with a period corresponding to the alternations of the voltage will be set into vibration.The free ends of the strips or reeds are turned up and painted white so that the reed which is vibrating will be indicated by an extended white band or blur.

The *Weston frequency meter* has fixed coils, 90° apart, and *a* movable element consisting of a simple, soft-iron core mounted on a shaft, with no control of any kind.

Resonant circuit meters, operating from circuits containing inductance and capacitance, can be made sensitive enough to indicate frequency variations of 0.01 Hz or less.

Precise frequency control is also accomplished with resonance techniques. Small-range indicators or recorders can be built as relays to monitor the frequency of a power system or generator, injecting an appropriate signal into a control system to restore frequency to a particular value. Such control may be made precise enough for use of the system frequency for electric-shock operation. Any tendency to frequency drift may be detected and corrected at the source by comparing an electric clock with a precise pendulum clock or one driven by a quartz-crystal oscillator.

Radio frequencies may be measured directly or indirectly. Direct measurement may be made with a wavemeter, an instrument with a tunable circuit and an ammeter to indicate the resonance frequency by a current maximum. In the indirect method, the unknown-frequency signal is introduced into a circuit with a precisely known frequency, and the beat frequency is counted. Quartz crystals maintained in temperature-regulated ovens will control the frequency of an oscillator to much better than 1 part in 10^6. Such a crystal-controlled oscillator, serving as a local reference standard of frequency, can be monitored against the very precise *standard* frequencies continuously broadcast by the NIST from its low-frequency station WWVL, operated at 60 kHz, or its high-frequency stations WWV and WWVH, which broadcast at a large number of higher frequencies. These broadcast frequencies are controlled by crystals operating under conditions that are most favorable to stability and are, in turn, monitored against the frequency of an atomic-beam resonator. The transmitted frequencies, as sent from the bureau stations, are accurate to about 1 part in 10^{12}. Frequencies from these broadcasts are modified somewhat in transmission by diurnal and moment-to-moment variations in the ionosphere, and their accuracy as received may be reduced by more than an order of magnitude.

Audio frequencies can be measured with a frequency-sensitive bridge, such as the Wien bridge with parallel- and series-connected capacitance-resistance arms, or they can be conveniently observed with a cathode-ray oscilloscope, if a known reference frequency is available. One set of plates of the oscilloscope is excited by the known- and the other set by the unknown-frequency signals. If the two frequencies have an exact, simple fractional relation, the Lissajous figure formed on the screen is stationary. For a 1/1 relationship, the pattern is an ellipse; for other fractional relationships, the pattern is more complicated, the relationship being determined from the number of loops. If the relationship cannot be represented by a simple fraction, the pattern will change continuously, and a count of the beat frequency is made over a measured time interval.

Electronic counters are widely used for frequency measurements. They work by counting the number of cycles of an input signal, or events, which occur in a very accurately known time interval (gate time). The gate time is based on the output of an internal standard oscillator (clock) or, optionally, on a reference-frequency signal input to the counter. Most counters of laboratory quality also can be used to measure the period of low-frequency signals, time intervals, the ratio of the frequencies of two input signals, and a total number of events. They also afford control of triggering, thus enabling the user to set trigger levels and slopes, noise rejection levels, and input attenuation levels. Output is via digital display, ranging from six to nine digits, and (usually) high-speed digital computer interface. Accuracies of frequency measurements are usually stated by the manufacturer to be ± clock accuracy ± 1 count. Most laboratory-grade counters can be equipped with high-stability crystal-based clocks, mounted in temperature-controlled ovens, and are stated to have drift rates as low as 2×10^{-8} per month. The frequency ranges covered are from nearly dc, directly or via period measurements, to as high as 500 MHz directly and to over 30 GHz using heterodyning techniques.

3.1.19 Slip Measurements

The *slip* of a rotating ac machine is the difference between its speed and the synchronous speed, divided by the synchronous speed; slip is usually expressed as a percentage. It may be computed from the measured speed of the machine and the synchronous speed, but direct methods are more accurate.

Millivoltmeter Method. If sufficient stray field is produced by the current in the secondary of an induction motor, a dc millivoltmeter connected to an adjacent coil of wire or across the motor shaft or frame will oscillate at slip frequency, each swing being one pole slip. In motors with wire-wound rotors, the millivoltmeter may be connected across the rotor slip rings.

Stroboscopic Method. In Fig. 3-38, a black disk with white sectors, equal in number to the number of poles of the induction motor, is attached to the induction-motor shaft. It is observed through another disk having an equal number of sector-shaped slits and carried on the shaft of a small self-starting synchronous motor, in turn fitted with a revolution counter which can be thrown in and out of gear at will. If n is the number of passages of the sectors, then $100n/n_s n_r$ = slip in percent, where n_s is the number of sectors and n_r is the number of revolutions recorded by the counter during the interval of observation. For large values of slip, the observations can be simplified by using only one sector ($n_s = 1$); then n = slip in revolutions.

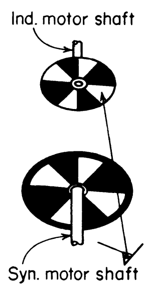

FIGURE 3-38 Slip measurement by stroboscopic method.

With a *synchronous light source* to illuminate the target on the induction-motor shaft, the synchronous motor is no longer necessary. An arc lamp connected across the ac supply may be used, but the carbons must be readjusted from time to time. A neon lamp makes a satisfactory source of light when the general illumination is not too bright. A portable stroboscope may consist of a gaseous discharge tube backed by a parabolic reflector to concentrate the light beam and an adjustable-frequency voltage source to trigger the flashlamp synchronously. The flash also can be triggered externally. Light output measured 1 m from the lamp may exceed 10^6 candela and flash duration may be as low as 0.5 μs.

Synchronizing. In order to connect any synchronous machine in parallel with another machine or system, the two voltages must be made equal and the machines must be synchronized, that is, the speed so adjusted that corresponding instantaneous values on the two waves are reached at the same instant, when they will be in exact phase. Furthermore, with polyphase machines, the direction of phase rotation must assuredly be the same. This, however, is usually made right once and for all when the machines are installed, the phases being so connected to the switches that the phase rotation will always be correct.

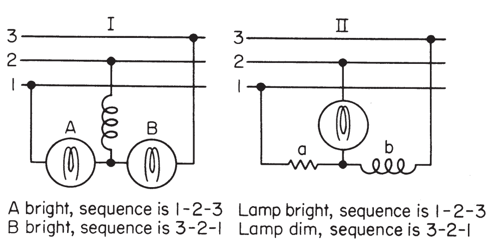

FIGURE 3-39 Phase-sequence indicators.

The *phase sequence of a 3-phase system* is often desired. Figure 3-39 shows two lamp methods. In I, two lamps and a highly reactive coil, such as the potential coil of a watthour meter, are used. The bright lamp indicates the particular phase sequence. In arrangement II, a noninductive resistance and a reactive coil of equal impedance are used in conjunction with a lamp, the brightness of which indicates the sequence.

3.1.20 Magnetic Measurements

The two classes of magnetic measurements are *field measurements,* such as the earth's field or the field in the air gap of a magnet, and *measurements to determine the characteristics* of magnetic materials.

Magnetic field measurements are commonly made by induction methods in which a coil is placed with its plane perpendicular to the field. Removing the coil to a point of zero flux or reversing the coil will induce in it an emf that can be measured by the ballistic deflection of a galvanometer in terms of its flux-linkage sensitivity (when operating in a circuit having the resistance of the search-coil circuit). In this measurement, $\int e\,dt = \mathrm{N}\,\Delta\phi 10^8$, where ϕ is the flux in maxwells enclosed by the coil and N is search-coil turns. The flux density B, in gauss, is ϕ/a, where a is the coil area in square centimeters.

The flux-linkage sensitivity of the galvanometer under the operating condition can be determined with the aid of a mutual inductor, with the galvanometer in the secondary circuit and a known current reversed in the inductor primary. Here, $\int e\,dt = 2MI$ volt-seconds, where M is mutual inductance in henrys and I is primary current in amperes. A Grassot-type fluxmeter can be used in place of a ballistic galvanometer. This is essentially a ballistic instrument in which restoring torque is reduced substantially to zero so that the deflection remains steady after the change in flux linkages.

Low field measurements are also made with magnetometers. This instrument uses a strip of high-permeability, low-coercive-force material (usually supermalloy) with an ac excitation coil that drives the material into saturation each half cycle at a frequency of a few kilohertz. A second-harmonic detector coil on the same strip will sense a bias field to which the assembly is exposed. A third coil on the strip supplies a measured offset ampere-turns to return the detector to zero, providing a very sensitive field measurement device. This is widely used in earth's field and other low-level field measurements. A portable flux-gate magnetometer, in which the vector-magnetic-field component at the sensor is neutralized by a current in a solenoid surrounding the sensor, has a resolution of 1 gamma at the neutralizing control. The magnitude (in gamma) of the neutralizing field is indicated on manually operated digital dials, and any difference between ambient field-vector component and neutralizing field is indicated on a meter whose range may be selected between 25 and 10^4 gammas. A nondirectional magnetometer system is based on proton gyromagnetic ratio and the functional relation between ambient field and resonance frequency in the sensor. This type of magnetometer is also used to sense small variations in the local earth's field.

Measurement of higher fields (20 to 20,000 G) and fields in spaces too confined for search coils are frequently made with Hall-effect gaussmeters. In a thin strip or film of a metal having a large Hall-effect coefficient and carrying a current, two points on opposite sides of the strip can be found between which there is no potential difference. If a magnetic field is then applied at a right angle to the plane of the strip, a potential will exist between these points which is proportional to the field. Germanium, bismuth, indium antimonide, and indium arsenide are the common materials for such probes, and they may be as small as 0.15×1.2 mm. Response of many of these instruments is fast enough to allow operation up to midrange audio frequencies.

In another type of gaussmeter, a small permanent magnet is suspended between taut bands. It will attempt to line up with any external field, and an attached pointer and scale can be calibrated in kilogausses. Such a device can be made to indicate both direction and magnitude of the external field to a somewhat limited accuracy.

DC magnetic materials testing is done either by providing a complete closed path of the sample material on which exciting and sensing windings can be placed or by utilizing a "yoke" type of apparatus to furnish excitation to a small sample with its own sensing winding. Closed-loop samples may be a toroid composed of a stack of punched rings, a toroid made by wrapping tape into a spiral, or a closed loop made by stacks of strip samples assembled with overlapped ends in an Epstein frame.

This arrangement, in the form of a square, has an excitation winding and a sensing winding distributed along the four sides of the square to enclose the sample. The geometry and construction of these coils is detailed in ASTM Standard A343, part 44 of the *Annual Book of ASTM Standards*. Punched-ring samples are not usually considered satisfactory for oriented materials, while either spiral-wrapped tape toroids or Epstein strip samples can be used in either oriented or nonoriented materials. In any of these closed-loop samples, the excitation can be determined in terms of the ampere-turns that supply it. If the mean diameter of the sample is large compared with its radial width, the excitation is calculated as $H = 0.4\pi NI/l$ oersteds, where N is the number of turns in the magnetizing winding, I is the current in amperes, and l is the mean path length of the ring in centimeters. In using Epstein samples, it is necessary to make an assumption as to the actual magnetic-path length. This is normally taken as 94 cm in the 25-cm Epstein frame. A mutual inductor is included for calibrating the ballistic galvanometer, the series and parallel resistors in the galvanometer circuit permit adjustment to make the system direct-reading in appropriate units while preserving a desired galvanometer damping; resistors in the excitation circuit permit reversal or step changes at a desired ampere-turn level. Both excitation and test windings on the sample should be uniformly distributed.

Permeameters are used for small samples and for "hard" magnetic materials which cannot be driven to a sufficiently high excitation by readily applied turns on closed-loop specimens. Basically, all types of permeameters utilize heavy coils and large-cross-section yokes to provide a high excitation level in small samples.

There is increasing use of complete plotting systems for drawing magnetization curves and dc hysteresis loops. Such systems use a magnet assembly with tapered pole pieces adjustable with a screw drive for excitation of the sample.

Magnetic susceptibility testing designates those measurements which require much more sensitive apparatus than the methods described above. Such tests are made by measuring the minute mechanical forces experienced when the sample is in a nonuniform field. All these systems—the Gouy, the Faraday, and the Thorpe-Senftle method—consist of a strong field in which the sample is placed and weighed. They differ in the method of obtaining a calculable nonuniform field.

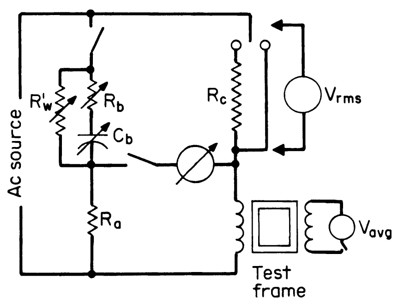

FIGURE 3-40 Modified Hay bridge.

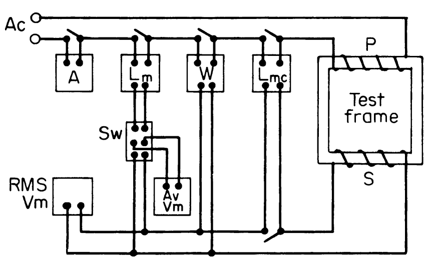

FIGURE 3-41 Voltmeter-wattmeter core-loss test system.

AC magnetic materials testing consists commercially in the determination of ac permeability and core loss in sheet materials. Substantially, all such testing is done either in Epstein-frame samples or in EI-type laminations. Up to an induction of 6000 G, measurements are made with the modified Hay bridge of Fig. 3-40. Above this level, measurements are made by the voltmeter-wattmeter method; Fig. 3-41 shows the circuit of such a test system. *A* is an ammeter of low impedance, *W* is a wattmeter with low-current circuit impedance and designed for low-power-factor use, rms V_m and av V_m are, respectively, rms responding and average responding voltmeters of very high impedance, L_m is a mutual inductance used with av V_m to read I_{peak} currents, and L_{mc} is a mutual inductance to compensate for the empty-frame mutual inductance of the Epstein frame. In operation, the flux density *B* is set using the average-responding voltmeter and calculating from the equation $4.444ANfB_{\max}/10^8 = 1.11\ E_{\text{av}}$, where $B_{\max}$ is the maximum induction in gauss, *A* is the cross section of the sample, *N* is the number of turns in the secondary (700 for the standard Epstein frame), and *f* is frequency in hertz. The value of *H* is determined by the formula $0.4NI_{\text{peak}}/L = H$ oersteds, where *N* is the number of turns in the magnetizing winding (700 for Epstein frame), I_{peak} is the peak current in amperes (derived from the reading of the voltmeter on the secondary of L_m), and *L* is the magnetic path length (94 cm for the 25-cm Epstein frame).

Core loss is calculated from the wattmeter reading divided by the active weight of the sample. Cross section is determined by weight of sample rather than an actual measurement of lamination thickness, with corrections for density of the material and assumed path length. Voltmeter-wattmeter measurements of core loss and ac permeability ($B_{\max}/H_{\text{peak}}$) are made with the actual instruments in the simple system. Commercial units for high-level production follow the basic circuit and include computation circuits to provide readings directly in the desired units, with printout of the data optional.

Magnetic amplifier material testing is a specialized procedure for materials to be used in amplifiers. There are a number of special tests in use on a supplier-user agreement basis that have no universal acceptance. ASTM Bulletin A598-69 specifies a number of recommended test points for various materials. These tests have the largest acceptance of any presently in use, and most suppliers are equipped to furnish material based on this type of testing. Test frequencies most commonly used are 60, 400, and 1600 Hz.

3.2 MECHANICAL POWER MEASUREMENTS

3.2.1 Torque Measurements

Torque is best measured with dynamometers, of which there are two classes: absorption and transmission. Absorption dynamometers absorb the total power delivered by the machine being tested, whereas transmission dynamometers absorb only that part represented by friction in the dynamometer itself. Made in a wide variety of forms, typical forms are described in the following paragraphs.

The Prony brake is the most common type of *absorption dynamometer*. The torque developed by the machine to overcome the friction is determined from the product of force required to prevent rotation of the brake and the lever arm. The load is applied by tightening the brake band or adding weights.

The *energy dissipated* in the brake appears in the form of heat. In small brakes, natural cooling is sufficient, but in large brakes, special provisions have to be made to dissipate the heat. Water cooling is the usual method, one common scheme employing a pulley with flanges at the edges of the rim which project inward. Water from a hose is played on the inside surface of the pulley and collected again by means of a suitable scooping arrangement. About 100 in^2 of rubbing surface of brake should be allowed with air cooling or about 25 to 50 in^2 with water cooling per horsepower.

The *Westinghouse turbine brake* employs the principle of the water turbine and is capable of absorbing several thousand horsepower at very high speeds.

In the *magnetic brake,* a metallic disk on the shaft of the machine being tested is rotated between the poles of magnets mounted on a yoke which is free to move. The pull due to the eddy currents induced in the disk is measured in the usual manner by counteracting the tendency of the yoke to revolve. This form of brake can be made in very small sizes and is therefore convenient for very small motors.

The principal forms of *transmission dynamometers* are the torsion and the cradle types. In *torsion dynamometers,* the deflection of a shaft or spiral spring, which mechanically connects the driving and driven machines, is used to measure the torque. The spring or shaft can be calibrated statically by noting the angular twist corresponding to a known weight at the end of a known lever arm perpendicular to the axis. When in use, the angle can be measured by various electrical and optical methods. The *cradle dynamometer* is a convenient and accurate device which is extensively used for routine measurements of the order of 100 hp or less. An electric generator is mounted on a “cradle” supported on trunnions and mechanically connected to the machine being tested. The pull exerted between the armature and field tends to rotate the field. This torque is counterbalanced and measured with weights moved along an arm in the usual manner.

3.2.2 Speed Measurements

Tachometers, or *speed indicators,* indicate the speed directly and thus include the time element. The principal types are centrifugal, liquid, reed, and electrical. In the *centrifugal type,* a revolving weight on the end of a lever moves under the action of centrifugal force in proportion to the speed, as in a flyball governor. This movement is indicated by a pointer which moves over a graduated scale. In the *portable* or *hand type,* the tachometer shaft is held in contact with the end of the shaft being measured, and in the *stationary type,* the instrument is either geared or belted. In the *liquid tachometer* of the Veeder type, a small centrifugal pump is driven by a belt consisting of a light cord or string.

This pump discharges a colored liquid into a vertical tube, the height of the column being a measure of the speed.

Reed tachometers are similar to reed-type frequency indicators, the reeds being set in resonant vibration corresponding to the speed of the machine. The instrument may be set on the bed frame of the machine, where any slight vibration due to the unbalancing of the reciprocating or evolving member will set the corresponding reed in vibration. Some forms are belted to the revolving shaft and the vibrations imparted by a mechanical device. *Electrical tachometers* may be either reed instruments operated electrically from small alternators geared or belted to the machine being measured or ordinary voltmeters connected to small permanent-magnet dc generators driven by the machine being tested.

Chronographs are speed-recording instruments in which a graphic record of speed is made. In the usual forms, the record paper is placed on the surface of a drum which is driven at a certain definite and exact speed by clockwork or weights, combined with a speed-control device so that 1 in on the paper represents a definite time. The pens which make the record are attached to the armature of electromagnets. With the pens in contact with the paper and making a straight line, an impulse of current causes the pen to make a slight lateral motion and, therefore, a sharp indication in the record. This impulse can be sent automatically by a suitable contact mechanism on the shaft of the machine or by a key operated by hand. The time per revolution is then determined directly from the distance between marks.

Stroboscopic methods are especially suitable for measuring the speed of small-power rotating machines where even the small power required to drive an ordinary speed counter or tachometer would change the speed, also for determining the speed of machine parts which are not readily accessible or where it is not practicable to use mechanical methods or where the speed is variable.

One convenient form of stroboscopic tachometer employs a neon lamp connected to an oscillating circuit supplied from a 60-Hz circuit, which is adjusted to “flash” the neon lamp at the frequency necessary to make the moving part that the lamp illuminates appear to stand still. Speeds from a few hundred to many thousands of revolutions per minute can be very conveniently measured.

3.3 TEMPERATURE MEASUREMENT

Temperature Scale. There is an international temperature scale, ITS-90 (International Temperature Scale of 1990), that came into effect on January 1, 1990 and superseded the IPTS-68 (International Practical Temperature Scale of 1968). All temperature measurements should be referred to the ITS-90. This scale extends upward from 0.65 K. The scale is defined in terms of ^{3}He and ^{4}He vapor pressure versus temperature relations, an interpolating constant-volume gas thermometer that is calibrated according to a specified procedure at designated fixed points to which temperature values have been assigned and that is used for interpolation according to specified equations, a set of defining fixed points to which temperature values have been assigned, and platinum resistance thermometers that are calibrated at specified sets of those fixed point and used for interpolation between those points according to designated reference and deviation functions, and Planck’s radiation law referenced to any one of three fixed points to which temperature values have been assigned. Temperatures on the ITS-90 were in as close agreement with Kelvin thermodynamic temperatures as possible at the time the scale was adopted. The scale is maintained in the United States by the National Institute of Standards and Technology (NIST), and any laboratory may obtain calibrations from NIST based on this scale. In the region from 0.65 to 25 K, rhodium-iron resistance thermometers and/or germanium resistance thermometers are calibrated on the ITS-90 to an uncertainty of $\pm$0.001 K or less; in the range from 13.8 to 934 K, standard platinum resistance thermometers (SPRTs) are calibrated to an uncertainty of $\pm$0.001 K or less; in the range from 273 to 1235 K, high-temperature SPRTs (HTSPRTs) are calibrated to an uncertainty of $\pm$0.002 K. Above 1235 K, the ITS-90 is realized by means of Planck’s radiation law, usually by calibrating a radiation thermometer, or pyrometer, at the freezing-point temperature of silver (1235 K), gold (1337 K), or copper (1358 K) and extrapolating to higher temperatures. The accuracy of the ITS-90 and the procedures used to calibrate the thermometers just described may be found in the references in the Bibliography. The remainder of this section on thermometry will be devoted to thermometry at a less accurate but more practical level.

Thermoelectric Thermometers (Thermocouples). By far the most commonly used thermometer in practical situations is the thermocouple. It consists of a pair of dissimilar electrical conductors (usually wires) joined at two junctions. One junction is maintained at a reference temperature t_0 (usually the melting point of ice), while the other is maintained at the unknown temperature t. The temperature difference produces a thermal emf which is measured by a potentiometer or a precise digital voltmeter. The latter is especially appealing because it is automatic (i.e., self-balancing), of sufficient resolution, and may easily be interfaced to an automatic data acquisition system.

Metals Used for Thermocouples. There are eight combinations of metal and alloys most extensively used, and they are designated as type B, E, J, K, N, R, S and T. Table 3-2 gives their nominal composition, temperature range, and highest suitable temperature for short-term use without significant degradation in performance.

Types R and S may be used for temperatures up to 1480°C and type B to 1700°C. It is recommended that the wire diameters exceed 0.5 mm if the thermocouple is to be used for long times at the upper temperature. These thermocouples are recommended for use in air because they are made from noble metals which are resistant to oxidation. They are easily degraded by other conditions, however, so they should be enclosed in a protective sheath. Type J may be used in a vacuum, inert, oxidizing, or reducing atmosphere. Again, a large-diameter wire (at least 3 mm) is necessary for use at long times in an oxidizing atmosphere. Types K and N are used up to 1200°C in inert or oxidizing atmospheres. Type E thermocouples are especially suitable for cryogenic use and may be used in vacuums, inert, oxidizing, or reducing atmospheres. Type T thermocouples may be used in the same atmospheres as type E, but they should not be used above 370°C under oxidizing conditions.

Temperature-EMF Relations for Various Thermocouples. Standard emf versus temperature tables, based on the ITS-90, have been developed and are published for the standardized thermocouples in NIST Monograph 175. Most manufacturers produce wires of sufficient quality so that a thermocouple may be fabricated from the materials given in Table 3-2, and their emf-t relation will deviate only slightly from that given in NIST monograph 175.

It must be understood that performance will degrade with use. There are a number of factors which cause decalibration, such as the atmosphere to which they are held at temperature and the highest temperature used. These effects are discussed in detail in the Bibliography.

Reference Junction Corrections. The values cited are appropriate for the situation in which the reference junction is maintained at the ice point ($t_0 = 0$°C). If the reference junction is not

maintained at that temperature, an emf correction must be applied to the measured emf to account for this. Refer to ANSI-MC96.1 for a discussion of this correction.

Extension (or Compensating) Wires. In many situations, it may be necessary for the reference junctions to be very distant (as much as several hundred feet) from the junction measuring T. Since most of the total emf in the thermocouple is generated by the short section at elevated temperatures, very little measurement error will occur if the remaining length at room temperature is replaced by thermocouple “extension” wires. Extension wires are made from materials having nearly the same thermal emf properties as the original thermocouple but which can be made at considerably less cost. For types E, J, K, N, and T thermocouples, the extension wires are made from the same alloy as the thermocouple wire but with less stringent requirements for the composition. For types R and S thermocouples, copper wire is used for one arm of the thermocouple, while a Cu–Ni alloy wire is used for the other.

Thermocouples: Summary. Thermocouples are relatively inexpensive, small, have rapid thermal response, and produce a signal (i.e., the emf) which is easily measured by a digital voltmeter. Spools of the thermocouple wire may be purchased, and many thermocouples may be made from them. Furthermore, each thermocouple will have an emf versus temperature given to within specified tolerance of the standard table so that in many instances calibration is not necessary. There are disadvantages to thermocouples, however; the emf is sensitive to the temperature distribution along the wire, strains, thermal history, and degradation at elevated temperatures. If these latter problems outweigh the advantages, other thermometers described below may be more appropriate.

Liquid-in-Glass Thermometry. A liquid-in-glass (LIG) thermometer consists of a reservoir of liquid and a stem with a temperature scale marked on it. The liquid has a very large thermal expansion compared with the reservoir and stem, and thus small temperature changes cause the liquid to expand into the stem where the length indicates T. A wide variety of liquids and glasses are used, but the most common liquid is mercury enclosed in borosilicate glass. If properly treated, LIG thermometers are capable of repeatedly measuring T to within 0.03°C. The major cause of catastrophic failure is breakage; of noncatastrophic failure, heating the thermometer beyond its specified range. LIG thermometers are used widely throughout industry because they are inexpensive and easy to read with the human eye. They are not amenable to automation or continuous monitoring, however. In many applications, they are being replaced by thermocouples or resistance thermometers, commonly called *resistance temperature detectors* (RTDs).

Resistance Temperature Detectors. Since resistance is a physical property that is easy to measure and automate with modern instrumentation, RTDs are finding more general acceptance in temperature measurement. The two major classes of resistors with strong temperature dependence are thermistors and platinum resistors.

Thermistors. Thermistors are made by sintering mixtures of oxides of Mn, Fe, Co, Cu, Mg, or Ti, bonding two electrical leads to the sintered material, and enclosing the unit in a protective coating. The devices are made in a wide variety of shapes (beads, disks, rods, and flakes), are very inexpensive, and are very compact (one bead type commercially available is only 0.07 mm in diameter). The resistance of the device is generally high (1 to 100 kΩ), so lead resistance is not a significant source of measurement error. If glass-encapsulated bead-type thermistors are used below 150°C, they are quite stable. (Commercial units are available which drift by no more than 0.01°C per year.)

Thermistors are semiconducting devices whose resistance depends exponentially on temperature. This means that the thermistor is very sensitive to temperature, but it also means that its temperature range is limited (i.e., if T becomes too low, the resistance becomes too high to measure; if T is too high, the resistance becomes too low to measure). Thermistors may be chosen for use with temperatures as low as 4 K, while others may be used in the region near 900 K. A technique, referred to as *linearization,* may be used to extend the operating range of a thermistor. This consists of connecting a temperature-independent resistor R in parallel with the thermistor. If the value of the resistor is equal to that of the thermistor in the center of its operating range, the resistance of the circuit will be roughly linear in temperature rather than exponential.

Thermistor-based measurement systems with digital readouts which read directly in temperature are widely available. These consist of a sensor, a digital ohmmeter, and a logic unit, generally a microprocessor. The microprocessor is used to perform resistance-to-temperature conversion and perhaps integration, control timing, run a display, and provide digital output for computer analysis.

Platinum Resistance Thermometers (PRTs). The resistance of platinum is roughly linear in temperature over a very wide temperature range, and thus PRTs may be used over a greater temperature range than thermistors. Precision-type PRTs can be very reproducible and are capable of high accuracy. They are, however, more sensitive to mechanical shock and less sensitive to temperature change than are thermistors.

For the highest-accuracy temperature measurements, three types of "standard" PRTs are used. From 83.8 to 693 or 934 K, a well-characterized, fine Pt wire is supported by insulators and enclosed in a fused silica glass casing. The assembled unit is 600 mm long and 7 mm in diameter. From 13 to 84 or 273 K, a "capsule" version 60 mm long, 6 mm in diameter, with similar internal construction, is used. A third type, called a *high-temperature standard PRT* (HTSPRT), is constructed of larger wire and typically has a resistance of about 0.25 or 2.5Ω at 273 K. That wire is wound on fused silica formers, and the overall length of the unit is about 24 in. When properly used (see NIST Technical Note 1265), PRTs may be used to measure temperature with an imprecision not exceeding ±0.001 K over the range 13 to 934 K. Such standard PRTs are used to realize the ITS-90 over the range 13 to 1235 K. Since great care must be exercised in measuring and handling these devices in order to achieve this performance, standard PRTs are generally restricted to the primary standards laboratory of any organization.

Thermal Radiation. Radiant flux, in the form of photons or electromagnetic waves, emitted by a surface solely as a consequence of its temperature is known as *thermal radiation*. Its wavelength range extends from about 100 nm (far ultraviolet) through the visible to about 1 mm (far infrared).

Blackbody Radiation. A surface which absorbs all incident radiation, regardless of wavelength or direction, is known as a *blackbody*. For a given temperature and wavelength, such a surface will emit the maximum possible thermal radiation. The thermal power emitted by an element of area into an element of solid angle surrounding the given direction of propagation (the *radiance*) is independent of direction for a blackbody. The spectral radiance distribution of a blackbody, $L_b(\lambda, T)$, is described by the Planck equation:

$$L_b(\lambda, T) = \frac{c_1}{\lambda^5(e^{c2/\lambda T} - 1)}$$

where λ is the wavelength of the emitted flux, T is the thermodynamic temperature of the blackbody, c_1 is the first radiation constant (3.741832×10^{-16} W · m^2), and c_2 is the second radiation constant (1.438786×10^{-2} m · K). A blackbody does not exist, but it can be closely approximated by a very small opening in a uniformly heated hollow opaque enclosure.

Stefan-Boltzmann Law. The relation between the total power per unit area emitted by a blackbody M_b and its thermodynamic temperature T is expressed by the equation

$$M_b = \sigma T^4$$

where σ is the Stefan-Boltzmann constant (5.67032×10^{-8} W · m^{-2} · K^{-4}). This equation is obtained by integration of the Planck equation over the wavelength range zero to infinity.

A real surface can never emit more thermal power than a blackbody. It is often convenient to express the total thermal power emitted by a real surface per unit area, M_s, to that emitted by a blackbody at the same temperature by the equation

$$M_s = \epsilon M_b = \epsilon \sigma T^4$$

where ϵ is the total hemispherical emissivity (note that $\epsilon < 1$).

Radiation Thermometer (Pyrometer), Wide-Band. In a wide-band radiation thermometer, thermal radiation from the source is focused on the sensor by means of a lens or concave mirror. The sensor might typically be a thermopile, a pyroelectric, or a solid-state photodiode detector. The fraction of the total thermal radiation received from the source is limited by the spectral transmission/reflection characteristics of the components in the optical path as well as the spectral response of the sensor itself. For measurement of the temperature of a blackbody source, the relation between the output of the sensor S and the temperature of source T_s can be approximated by the equation

$$S = a\sigma T_s^b$$

where a and b are instrumental constants obtained through calibration. With suitable linearization circuitry, the output of the instrument can indicate temperature.

Radiation Thermometer (Pyrometer), Spectral-Band. In a spectral-band radiation thermometer, thermal radiation from the source is typically focused on the sensor by means of a lens. The bandwidth of the thermal radiation reaching the sensor is defined by a transmission filter placed in the optical path within the instrument. The sensor found in most instruments is a solid-state photodiode detector. For measurement of the temperature of a blackbody source, the output of the detector is approximately proportional to the Planck equation.

With suitable linearization circuitry, the output of the instrument can indicate temperature. Many narrow-band instruments have a control which can be adjusted by the operator to compensate for the emissivity of the source.

3.4 ELECTRICAL MEASUREMENT OF NONELECTRICAL QUANTITIES

A *transducer* is a device in which variations in energy of one form produce corresponding variations in energy of another form. In common usage, either the input or output of a transducer is electrical. Thermocouples and thermistors fall into that category, as does the *thermal converter,* whose electrical output (dc millivolts) is derived from a thermal effect that represents an electrical quantity (ac volts, current, watts, vars) that differs in nature from the output. A variety of methods is often available for the measurement of a specific variable. "Frequently, operational considerations will indicate the choice of transducer; for instance, piezoelectric transducers may not perform well if long cables are required; capacitive devices, although quite sensitive, may require intermediate electronic circuitry; and magnetic transducers should not be used in the presence of strong magnetic fields."

Mechanical displacement may be converted into an electrical variable by the simple expedient of adjusting resistance in an electric circuit. A slide-wire resistor, having a movable contact attached to the part whose displacement is to be measured, may be connected through a 2-conductor circuit to a steady-voltage source in series with an ammeter (or milliammeter) calibrated in terms of the displacement. If the resistor is connected as a voltage divider, the need for a regulated supply is eliminated, and with a 3-conductor circuit the display instrument may be a ratio meter or a potentiometer. Such combinations are common and are available for both dc and ac operation. Where deflections are small—less than 0.1 in—measurement may be made by use of a differential transformer.

In the *strain gage,* microscopic relative displacements are electrically magnified and are displayed on an indicating or a recording meter or on an oscillograph. Modern resistance-type strain gages comprise fine-wire windings arranged to be more or less elongated when subjected to deformation. The units may be used singly, in pairs, or in sets of four constituting a complete Wheatstone bridge. There are two main classes of wire-wound strain gages, (1) bonded and (2) unbonded.

1. The *bonded strain gage* is composed of fine wire, wound and cemented on a resilient insulating support, usually a wafer unit. Such units may be mounted on or incorporated in mechanical elements or structures whose deformations under stress are to be determined. While there are no limits to the basic values which may be selected for strain-gage resistances, a typical example may be taken as of the order of 100 to 500 Ω.

2. In the *unbonded strain gage,* the resistance structure comprises a fine-wire winding stretched between insulating supports mounted alternately on the two members between which displacement is to be measured (Fig. 3-42). These wires comprise the four arms of a Wheatstone-bridge network of which two opposite arms are tightened and the other two are slackened by the displacement. While a bonded gage tends to respond to the average strain in the surface to which it is cemented, the unbonded form measures displacement between the two points to which the respective supports are attached. Unbonded wire strain gages are usually operated on input potentials ranging up to 35 V direct or alternating current. Under conditions of extreme unbalance, corresponding to full operating range, the open-circuit emf may be of the order of 8 to 10 mV and the closed-circuit current up to 100 μA.

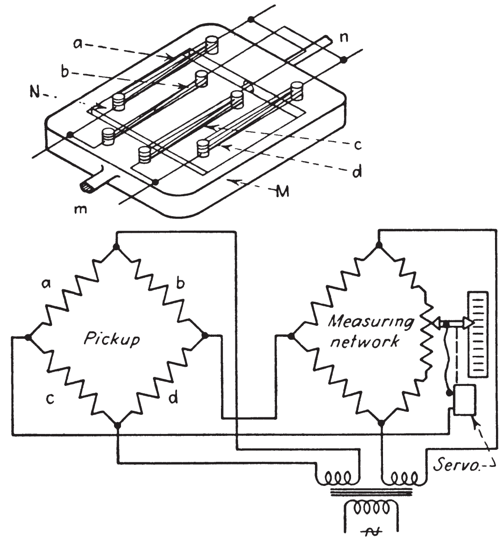

FIGURE 3-42 Diagram of unbonded wire strain gage. Supports *M* and *N* are attached by rods *m* and *n*, respectively, to points between which displacement is to be measured. Pickup and measurement networks are energized from similar but isolated sources. Unbalance originating in the pickup is detected and balanced by a servo-actuated measuring network, providing a reading of strain on a graduated scale.

Recently developed types of conductive rubber are used in resistive transducers capable of wider ranges of deformation than are those using wire or foil. Where the strain gage must operate over a temperature range, dummy gages exposed to the temperature but not the strain may be employed for temperature compensation, or alloys having a low temperature coefficient of resistance may be used. Piezoelectric strain gages are also available for applications in pressure, force, torque, and displacement measurement. Strain gages for use on ac circuits are supplied in both capacitive and inductive forms, wherein the corresponding characteristics of ac circuit components are varied by the displacements to be measured.

A popular means for measuring *small displacements* in the range from a millimeter to a micron is the *linear,* or *differential, transformer*. This device is generally produced with a single primary winding and two secondaries, all disposed along a common axis and having in the common magnetic circuit a movable iron core longitudinally displaceable with the motion to be measured. The secondaries may be connected additively or differentially and may be included in the circuit of a null-type instrument balanced either by shifting the core of a similar transformer excited from the same source or by the use of a slide-wire potentiometer. Linear transformers are regularly supplied for operation at all frequencies up to 30,000 Hz. The sensitivity, of course, increases with the frequency. Linear transformers may be interconnected in a great variety of arrangements to perform computations or to express desired mathematical functions of measured variables.

Strain gages permanently attached to diaphragms, tubes, and other pressure-sensitive elements find wide applications as components of *electrically actuated pressure gages*. By electrically combining simultaneous measurements of torque and velocity, continuous determination of mechanical power may be obtained, the combination becoming an electrical-transmission dynamometer.

Vibration may be determined by a strain gage, but the fact that this magnitude involves motion renders it generally preferable to utilize alternating potentials developed by periodic change in the geometry of the measuring circuit. This may be embodied in either a *capacitor* or an *inductive device*. In a recently developed apparatus, there are no moving parts except the object being shaken, and the vibration displacement is sensed by its effect on an electrostatic field between the pickup and the moving part. *Piezoelectric crystals* are particularly adapted to the measurement of vibration. The emf so obtained is proportional to the amplitude of deflection multiplied by the frequency squared.

Air velocities and the *flow of gases* in general may be measured by the *hot-wire anemometer*. In its simplest form, this device utilizes the cooling effect of the gas stream to establish a temperature difference between exposed and protected bridge arms. Where the flow is in an enclosed conduit, a heating element may be introduced and the volume of flow determined by the amount of heat transferred between the heater and the temperature-sensitive bridge wires.

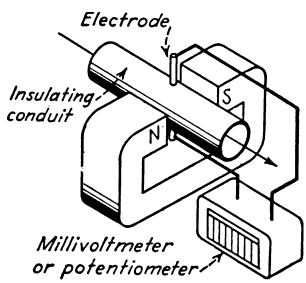

FIGURE 3-43 Electromagnetic flowmeter.

Flow of an electrically conducting liquid may be determined by measuring the emf developed between a pair of electrodes set in opposite sides of an insulating conduit due to the movement of the liquid through a magnetic field established transversely of the conduit and perpendicular to both the flow and the line joining the electrodes (Fig. 3-43). By using an alternating field, the effects of electrode polarization may be eliminated. Null measurement of the generated voltage renders the apparatus independent of the resistance of the liquid.

Liquid level may be expressed electrically by the use of a transducer responsive to the verticalposition of a float or by a pressure-sensitive strain gage immersed in the liquid below its lowest level. Variation in resistance of an immersed conductor is a widely accepted principle, especially in fuel tanks. If the liquid is an electrical insulator and of constant characteristics, its depth may be determined by its dielectric effect between a pair of vertically disposed capacitor plates. On the other hand, if the liquid is a conductor and very small changes in level are to be detected or regulated, the liquid may be made one electrode of a capacitor whose other electrode is a horizontal plate positioned above the surface.

Levels of corrosive liquids or those operating under extreme pressures, temperatures, or other conditions rendering them inaccessible for measurement by conventional means may be determined by the use of *gamma radiation*. Several gamma-ray sources are spaced at equal vertical intervals in the tank or reactor containing the liquid to be measured but are positioned so that none of them obstructs the line of sight of a Geiger counter tube placed at the top of the container. The response of the Geiger tube depends on the depth of the process material, and the output is measured on a null-type recording instrument.

Vacuum may be measured by determining either *energy dissipation* or electron emission in the space under test. The former principle provides the basis of the *Pirani gage*, wherein two similar heated filaments forming arms of a bridge are located, respectively, in a reference bulb and a bulb connected to the evacuated space. Heat dissipation will vary with the degree of evacuation, while conditions in the reference bulb remain constant. The electrical condition of the bridge then provides a continuous measure of the vacuum. The normal range of operation of the Pirani gage is from 10^{-7} to 5 torr. Since the performance of a thermionic tube is highly responsive to the degree of vacuum, its action under controlled electrical conditions is a criterion of internal atmosphere. This principle forms the basis of a number of *electronic vacuum gages*. The normal range of operation lies between 10^{-7} and 10^{-3} torr.

Electrical methods for *analyzing gases,* while essentially thermal in their nature, are made practicable only by the application of electrical principles in determining thermal relationships. In the *thermal-conductivity method,* as best exemplified in the CO_2 recorder, two cells or sections of conduit containing, respectively, a standard sample and the gas under test have in them adjacent arms of a bridge network composed of wires having known resistance variation with temperature and carrying sufficient current to raise their temperatures appreciably above their surroundings. As more or less heat is dissipated in the test cell as compared with the reference cell, the relative resistance of the bridge arms varies, providing an electrical basis for measurement of the gas composition.

The *catalytic-combustion method* is especially adapted to *detection of flammable gases* or determination of explosibility. The arrangement of cells and bridge wires may be similar to that of the thermal-conductivity type, but the filament is usually composed of activated platinum and is operated at a temperature sufficient to ignite the gas when a critical proportion is attained. The increased heating of the bridge wire due to combustion abruptly disturbs the balance and provides a positive indication of explosibility. In some forms of this instrument, the temperature rise is determined by thermocouples. The catalytic-combustion method is useful in determining mixtures containing such gases as propane, acetone vapor, carbon disulfide, and carbon monoxide. The equipment finds use in (1) solvent-recovery processes, (2) solvent-evaporating ovens, (3) combustible-gas storage rooms, (4) storage vaults, (5) gas-generating plants, (6) refineries, and (7) mines.

In determining the *oxygen content of gases,* both the conventional thermal-conductivity method and the catalytic combustion method are applicable. In addition to these, use is made of the *magnetic susceptibility* of oxygen as a basis of operation. In one such instrument, a hot-wire bridge similar to that of a CO_2 recorder is employed, one of the gas chambers being placed in a strong magnetic field. This stimulates the flow of oxygen-containing gas through that chamber, thereby unbalancing the bridge by a measurable amount. In the other magnetic analyzer, a test chamber contains a small magnetic member rotatable in a distorted field whose conformation depends upon the amount of oxygen present. The resultant angular displacement of the test member may be used similarly to that of a galvanometer in either a direct-deflecting or a null-type instrument.

An analyzer especially suited to measurement of *toxic ionizable gases* or vapors to and beyond the toxic limits utilizes the electrical conductivity of an aqueous solution of the gas. The vapor under test is bubbled through distilled water at a fixed rate, and the conductivity of the solution becomes a measure of gas concentration. A typical use is the continuous recording of small quantities of substances like sulfur dioxide, hydrogen sulfide, chlorine, and carbon disulfide in the air.

Atmospheric contamination may be determined by an *electronic leak detector,* utilizing emission of positive ions from an incandescent filament exposed to the air. The filament is enclosed in an open inner cylinder and heated by alternating current. The atmosphere under test is forced through the annular space between the inner and an outer cylinder at a predetermined rate, and the electron flow due to a dc potential maintained between the cylinders is measured as an index of the amount of contaminant. Presence of extremely small proportions of halogen vapor compounds, of which Freon, chloroform, and carbon tetrachloride are good examples, greatly increases the emission. At room temperatures, the device does not respond to Pyranol, but if this material is heated sufficiently to give off vapor, a response is obtained. It also responds to solid particles of the halogens and therefore will detect *smoke* from burning materials containing these elements. The instrument is also available as a recorder and/or a controller.

Relative humidity is determinable electrically by methods involving either of the two basic principles: (1) variation of electrical conductivity or of dielectric constant of a hydrophilic element and (2) computation based on "dry-bulb" and "wet-bulb" temperatures of the atmosphere whose moisture content is to be determined. The most common embodiment of the former method consists of an insulating card, plate, or cylinder carrying a bifilar winding of conductive wire and having a relatively large surface exposed to the atmosphere. The two strands of wire are bridged by a coating of material such as lithium chloride or colloidal graphite, having a high affinity for moisture. This material quickly assumes a water content corresponding to that of the atmosphere, and the electrical resistance between the conductors becomes a function of the humidity to be measured. A similar principle is used in determining the moisture content of hygroscopic materials such as wood, grain, or pulp. In such applications, a resistance-measuring circuit terminates in electrodes or probes which are pressed against or inserted into the material to be tested.

Moisture content of material in a web or sheet form, such as paper, may be continuously determined by passing the web between the plates of a capacitor, and thus obtaining a measurement determined by the dielectric constant of the material as affected by its water content.

Electrical determination of humidity by the wet-and-dry-bulb method requires somewhat intricate computing circuits which for accurate results must take account of absolute temperature and barometric pressure.

Determination of dew point, or the temperature at which condensation takes place on a polished surface, as a function of absolute humidity, employs essentially a thermal and optical method of measuring, but such a system may be rendered continuous and automatic by photoelectrically observing the conditions of a polished surface in the tested atmosphere utilizing a servo system to regulate its temperature and thus obtaining an indication or a record of the dew point.

The two most popular types of *electric micrometers* are (1) that utilizing the magnified output of a strain gage and (2) that based on precise determination of capacitance between two electrodes whose spacing corresponds to the measured dimension.

Ultrasonic thickness gages may be used to measure steel walls ranging in thickness from ⅛ in to 1 ft, utilizing the fact that sound vibrations tend to establish standing waves within the mass of the material upon which they are impressed. This device combines a variable-frequency oscillator with a piezoelectric crystal which is pressed against the wall to be tested. The circuit is tuned until the metal oscillates, causing a sharp increase in the loading. The frequency of this resonance indicates the thickness of the material.

Selection of a method for determining the *thickness of sheet material* in process will depend primarily on the inherent electrical conductivity of that material. If it is essentially a nonconductor, such as rubber, plastic, or paper, measurement may be continuously performed by passing the sheet or web between the plates of a capacitor. (In such measurements on hygroscopic materials, moisture content may become a dominating factor.)

Sheet thickness in sheet materials, whether conducting or insulating, may be measured by the *beta-ray gage.* In this device, a stream of beta rays passes through the sheet to a pickup head whose response is amplified and continuously recorded and, if desired, made the controlling influence in automatic regulation. Provision is made for the combined radiation source and pickup to traverse the strip of material and scan its whole width.

Thickness of coatings, such as varnish or lacquer, on conducting materials may be determined by a continuous measurement of capacitance between the base and a reference electrode, the coating being included as a dielectric. With a magnetic base, such measurement may be performed effectively by determining the effect of the coating on the gap in a magnetic circuit.

Surface roughness may be determined either on an absolute basis or by comparison with a "standard" surface. A common method involves passing a small stylus systematically over the surface, similarly to a phonograph needle, and measuring the resulting vibration. The stylus may be attached to a strain gage, piezoelectric crystal, or a magnetic pickup. The resulting alternating emf may be amplified and displayed on an oscillograph, or it may be rectified and measured with a millivoltmeter. A basis for quantitative determination of surface roughness is found in USAS B46.2.

An absolute method of determining roughness uses the electrical capacitance of the tested surface in contact with an electrolyte as compared with that of an ideal (mercury) surface. On the assumption that the capacitance varies as the surface area, the comparison provides a figure representing the ratio of the tested surface to one of perfect smoothness.

Transparency (or opacity) determination of materials and continuous monitoring of smoke density involve passing the substance to be examined through the path of a light beam directed upon a photocell. Uninterrupted measurement is made by means of a potentiometer or a bridge, according to the class of cell employed.

Viscosity measurement is essentially mechanical in its nature, and the application of electrical methods consists of determination of stress or displacement set up in the measuring apparatus owing to the characteristic of the fluid. One method involves measuring the electrical input to a small motor driving an impeller or stirrer in the fluid. Another method is based on electrical determination of the angle of lag (torque measurement) in a resilient mechanism through which an impeller is driven. A further method utilizes *magnetostriction* to produce longitudinal oscillations in a steel rod carrying a diaphragm immersed in the liquid. Determination of the electrical loading on the exciting circuit provides a measure of viscosity.

Electrical measurement has superseded many of the older methods of quantitative determination of *chemical magnitudes*. The two best-known methods are based, respectively, on the electrical *conductivity* of solutions and on the *voltaic effect* in specific cells. The basic principles of these measurements are wholly different, as are their applications. In the *conductivity* cell, every precaution must be observed to avoid electrolytic effects, the prime requisite being that the respective electrodes be of identical material. Even then, the passage of current or the application of the potential tends to produce internal polarization emf in the cell. This undesirable effect may be almost wholly eliminated by measuring electrolytic resistance with alternating current, and the highly sensitive ac detectors now available enable such tests to be made with precision. Outstanding among the uses of the resistance cell is determination of the *purity of water* for domestic and industrial purposes. Conductivity of water solutions usually increases in proportion to the amount of dissolved electrolytic material. Perfectly pure water has a specific resistivity of 18 to 20 million Ω/cm^3, but in practice, such values are virtually unobtainable. Only by careful distillation or deionization is it possible to obtain water of 400,000 to 800,000 specific Ω at a reference temperature of 20°C. Continuously operating water-conductivity recorders are supplied for use with commercial ac power supply, and a typical range is 100,000 specific Ω to infinity.

Electrolytic cells utilize measurement of emf developed between a standard combination of electrodes by the solution under test. Development of the principle has reached its highest refinement in the measurement of pH, or hydrogen-ion concentration, which is a criterion of the activity with which the solution will enter as an acid into a chemical reaction. The pH value is a logarithmic function of the emf developed with a given strength of the solution in a specified cell. For pure water, which is "neutral" in its reaction, lying midway between the acids and the bases, the pH value is 7. The pH measurement is essential in practically every industry involving any chemical process, as well as in waterworks, sewage systems, biological laboratories, and agricultural experiment stations.

3.5 TELEMETERING

Telemetering is measurement with the aid of intermediate means which permit the measurement to be interpreted at a distance from the primary detector. The distinctive feature of telemetering is the nature of the translating means, which includes provision for converting the measurand into a representative quantity of another kind that can be transmitted conveniently for measurement at a distance. The actual distance is irrelevant.

Electric telemetering is telemetering performed by deriving from the measurand or from an end device a quantitatively related separate electrical quantity or quantities as a translating means. A *measurand* is a physical quantity, property, or condition which is to be measured.

Telemetering has been practiced many years in the central-station industry and in the transmission and distribution of electric power but until lately only to a limited extent in the nonelectrical fields. With the phenomenal expansion of pipelines for gas and for oil, the need has vastly increased, and electric telemetering installations have become indispensable in the remote measurement, totalization, regulations, and dispatching of these utilities. Telemetering also has found wide application in extensive industrial plants, such as refineries, steel mills, and large chemical plants, and in these installations it often forms an essential part of remote regulating apparatus.

There has been a rapidly increasing use of telemetering in aircraft, meteorology, ordnance, and guided missiles. This has led to a sharp demarcation of telemetering philosophies and techniques into two classes, *mobile* and *stationary*. In the former, the apparatus is expected to operate for a very short period of time—often only a matter of seconds. The transmitting unit at least must be considered as expendable, and the combination is generally subject to an overall calibration for each isolated test in which it is used. Obviously, there can be no interconnecting physical circuit, and a radio link is an essential part of the system.

Stationary systems in general involve transmitting and receiving units at fixed locations. These are usually of a permanent nature and are intended for operation over extended periods of time. Signal transmission between the stations usually involves a physical circuit, and even where radio principles are utilized, the most common practices require guiding of the signal by means of a more or less continuous conducting path.

A *telemetering system* incorporates the same three essential elements as are required in a system for measurement of nonelectrical quantities by electrical means, namely, a *transmitting unit* (transducer or pickup), a *receiving unit* (an instrument for measuring an electrical variable), and an *interconnecting circuit* or channel by which the electrical variable (signal) originating at the transmitter is carried to and impressed upon the receiver.

In transmission of measurement over considerable distances, the *circuit* or *channel* may become the predominating factor in the system. In the ideal telemetering system, the terminal apparatus would be inherently self-compensating so that variations in circuit conditions would not adversely modify the signal. Merit of a telemetering system is directly related to the degree to which it approaches this ideal. Distance criterion of a telemetering system is not so much the number of feet or miles over which it will operate as it is the nature and magnitude of circuit impedance through which its signals will maintain their identity and proportionality. Since the data have been determined for specific types of circuits and channels, such magnitudes generally may be expressed in units of distance. A continually increasing proportion of telemetering is being carried out over circuits and channels leased from communication companies. With information available respecting the type of signal to be transmitted, the telephone or telegraph company provides a suitable circuit and assumes responsibiltiy for its operation. Where privately owned circuits are used for telemetering, their maintenance and protection correspond to those for comparable communication circuits.

In *classifying telemetering systems,* the ANSI has adopted a grouping recommended by the AIEE and based on the nature of the electrical variable transmitted through the interconnecting circuit or channel. The names of the five classes are more or less self-explanatory and are as follows: *current, voltage, frequency, position,* and *impulse* types. In each of the first three of these classes, the corresponding characteristic of the electrical output of the transducer comprising the transmitting unit is varied with variations in the measurand. In the *position* system, the quantitative ratio, or the phase relationship, between two electric voltages or currents determines the nature of the transmitted signal, usually requiring a circuit of three or more conductors. There are several *impulse* systems, in all of which the transmitting instrument acts to "key" a signal impressed on the circuit, producing a series of successive pulses which, according to their nature, are interpreted by the receiving instrument and expressed in terms of the measurand.

Telemetering systems are not always mutually exclusive. A single installation may represent a combination of several of the named systems. In some instances, it becomes difficult to decide into which of the specified classes a particular method of telemetering may fall.

Telemetering of electrical quantities, such as volts, watts, and vars (volt-amperes reactive power) presents a problem owing to the inherently low torque of direct-deflecting instruments, whereas devices for measuring such quantities as position, flow, and liquid level are not subject to such restrictions. Accordingly, where measurements of electric units are to be transmitted, practice favors those systems which place a minimum of burden on the primary measuring instruments and preferably those adapted to transmitters having no moving parts. Thus, photoelectric, thermoelectric, and capacitive transmitters have found considerable favor in the electric industry.

In transmitting measurements originating in *integrating meters,* such as watthour or varhour meters, the mechanism of the meter, either by photoelectric or electronic means or by a contact arrangement, is caused to develop a series of electrical pulses whose frequency of occurrence is proportional to the instantaneous value of the measured load. By a simple electronic network including capacitors charged and discharged at the frequency of the pulses, there is produced a direct current whose value is proportional to that frequency, the telemetering system being thus placed in the *current* class. On the other hand, the pulses may be directly impressed on the communication channel, whereupon the system falls into the *frequency* group.

Where the basic measurement is performed by a low-torque instrument of the direct-deflecting class, such as a wattmeter, common telemetering practice involves either *balancing the torque* or matching the deflection of the instrument by the effect of an automatically regulated direct current in the winding of a permanent-magnet moving-coil mechanism. This current, remaining proportional to the instrument torque, is transmitted through a metallic circuit for measurement at the receiving station and, if desired, may be included with other and similar currents in a load totalization.

A most flexible method for the transmission and totalization of electric power measurements involves the use of a *thermal converter*. The several commercial forms of this device operate on a long-known but only recently applied principle combining the circuit of the thermal wattmeter with that of the thermocouple. In the former, the temperatures of two resistors are caused to assume values differing by an amount proportional to the power in the measured circuit. In the latter, there is developed an emf proportional to the temperature difference or to the *power* in the measured circuit, irrespective of power factor, frequency, or waveform. Thermal converters are supplied in single-element, two-element, and three-element forms, and the ac input circuits may be wired into the instrument-transformer secondaries on any conventional polyphase power system. The output from the dc terminals is either measured directly or interconnected with that of other converters to provide totals of measured loads. The full-load potentials are usually rated at 50 or 100 mV, according to make and type, and measurement is preferably made with a self-balancing potentiometer. For best results, thermal-converter output circuits, which, of course, must be wholly metallic, should be well shielded from parasitic electrical effects and preferably should be in a sheathed cable. An advantage of thermal-converter installations, even for relatively short distances within the plant, is that the seven or eight conductors necessary for connecting instrument-transformer secondaries to wattmeters or varmeters are replaced by two small wires operating at a negligible power level. Furthermore, physical damage to the output wiring, whether in the nature of an open circuit or a short circuit, is not hazardous to equipment or personnel, and on restoration of the circuit, normal operation will be resumed without loss of accuracy.

Electrical impulses may be used as signals for telemetering in a number of ways, the most important in stationary installations being that based on *frequency* and that based on *duration* of successive impulses. Impulse systems are to telemetering what telegraphy is to other forms of communication. The function of the transmitting instrument is essentially one of “keying” a circuit. Since the significance of the transmitted signal is based on time only, it follows that the method is most nearly immune to circuit conditions, such as voltage variation, impedance changes, attenuation, poor connections, and pickup from adjacent disturbing influences. Impulses whose frequency represents the measured variable may be transmitted as such, then falling into the category of the *frequency system of telemetering,* or they may be converted into a proportional direct current and be classified with the *current* systems.

Impulse-Duration Telemetering. Signals recur at uniform intervals, and each has a duration corresponding to the then existing value of the measured magnitude. The transmitting instrument includes a constantly running cam or scroll plate having a spiral trailing edge and operating in the plane of the pointer but perpendicular to the line of excursion. At a fixed point in each revolution of the cam, the pointer is engaged and brought against the cam face until subsequently released by the trailing edge. With engagement and disengagement, the pointer is slightly deflected perpendicular to its line of travel and actuates a contact in a signal circuit. Because of the spiral form of the trailing edge, the length of the signal depends on the position of the pointer and thus represents the measured variable.

The receiving unit includes the equivalent of a pair of electromagnetic clutches continuously driven by a constant-speed motor. These clutches are actuated by the incoming signals, one in an “upscale” and the other in a “downscale” sense, according to whether the transmitter pointer is on or off the cam. The receiver pointer or pen is frictionally retained in position and is “nudged” alternately toward one end or the other of its range by impellers or “dogs” carried by the clutches and, respectively, reset to zero as the corresponding clutch is released. Thus, with each signal, the receiver pointer finds or maintains a position corresponding to that of the transmitter pointer.

Position Telemetering. In the *position system* of telemetering, the characteristic signal involves the relationship between two electrical quantities of a similar nature, that is, two voltages or two currents. Unless carrier is used, position systems (with one exception) require an interconnecting circuit of three or more conductors. The simplest position-telemetering arrangements are those of the rheostatic, or bridge, type, either direct or alternating current. Mechanical attachment of the measuring element to a voltage-dividing resistor provides a transmitting unit wherein the relative value of two voltages may be made proportional to the measured quantity. The receiving instrument may take the form of a ratio meter or may be a self-balancing bridge. The accuracy of such systems is affected by the impedance of the interconnecting circuit, but by maintaining this value small in comparison with that of the terminal instruments, the error may be made negligible for considerable lengths of line.

Selsyn. The inductive type of position system is best exemplified in the “selsyn” position motor or any one of its several equivalents. The transmitting and receiving units may be identical in structure. Each involves a stator and a rotor, one being provided with a single-phase and the other with a polyphase winding. The single-phase windings are excited from a common ac source, and the polyphase windings are interconnected. The rotors of the two units will tend to assume duplicate angular positions so that if one is attached to a measuring element, the other will provide a remote indication of its position. This system requires three line conductors in addition to the pair comprising the common power supply. The versatility and flexibility of the *differential transformer* render it particularly adaptable to telemetering of mechanical displacements.

Totalization of power loads and of other measured quantities may readily be effected in the current or voltage systems by connecting the outputs of the respective transmitters in parallel or in series, as the case may be. Subtotals and other mathematical functions also may be obtained. Telemetering, especially totalization and retransmission, is greatly facilitated by the power and flexibility of servo-actuated potentiometers and bridges. With these instruments available, there is practically no limit to the possibilities of telemetering, not only in the electrical-utility field but, also in association with pipelines and large industrial plants. By *multiplexing* the circuits, it is possible for several telemetering transmitters and receivers to share a common communication channel. The most common systems of multiplexing are those based on *frequency* and those based on *time*. The frequency method transmits the signals on carriers having a specific frequency allotted to each transmitter and receiver combination. Time multiplexing involves the use of a multiple-point switch at each end of the circuit. These switches are progressively advanced at definite intervals, providing connection successively between each receiver and its corresponding transmitter. After a predetermined number of operations, a distinct synchronizing signal checks and, if necessary, adjusts the relative position of the switches at the transmitting and the receiving stations.

3.6 MEASUREMENT ERRORS

The complete statement of any measurement result has three elements: the *unit* in terms of which the result is stated; a *numeric* which states the magnitude of the result in terms of the chosen unit; and its *uncertainity,* the experimenter's estimate of the range within which the result may differ from the actual value of the quantity. Any physical measurement is uncertain to some extent, and errors are present in all phases of the measurement process, including the standards used to calibrate the system. Values assigned to local reference standards have uncertainties accumulated from the entire measurement chain extending back to the national reference standards that maintain a common measurement base. These national reference standards are themselves the experimental realization of the units defined in terms of the seven base units of the International System of Units (SI), and their assignments include an uncertainty estimate.

The Measurement Base. In most measurements, we are concerned only with their conformity within the technical community in which we work; our error chain stops at the national reference standards which maintain the *legal* units of the country, and our uncertainty estimates are based on these legal units. Rarely, when our concern is with the international measurement community or with basic science, must our uncertainty also include that of the maintained national unit.

Sources of Error. In addition to uncertainties in the calibration of a measurement system (which must be accepted as systematic errors in its operation), there are a number of error sources (some systematic and some random) in its operation. These operational error sources include noise, response time, design limitations, energy required by the system, signal transmission, system deterioration, and ambient influences.

Noise is any signal that does not convey measurement information. Disturbances generated within the system or coming from outside make up the background against which the desired signal must be read. Noise signals may be picked up by electrical or mechanical coupling between an external source and an element of the system, and may be amplified within the system. Under the most favorable circumstances, where noise has been minimized by filtering, by component selection, and by shielding and isolation of the system, there are still certain sources of noise present, resulting from the granular nature of matter and energy; the structure of phenomena is not infinitely fine-grained.

These fluctuations may be small compared with the total energy transfer involved in most measurements, yet they do give rise to a noise background that limits the ultimate sensitivity to which a measurement can be carried. Such sensitivity-limiting mechanisms include the brownian motion of a mechanical system, the Johnson noise in a resistance element, the Barkhausen effect in a magnetic element, and others.

The *response time* of a measuring system may contribute to measurement error. If the measured signal is not constant, lag in response results in an indication that depends on a sequence of values over a previous time interval.

Design limitations which contribute to measurement uncertainty include friction and resolution. Because a certain minimum force is needed to overcome friction and initiate motion, there results uncertainty in the rest position of an indicator. Resolution is the ability of the observer to distinguish between nearly equal quantities.

In an optical system, resolution is stated as the smallest angle at which points can be distinguished as separate. If the components of the optical train were perfect, resolution would be limited by the effective aperture of the system and the wavelength of the light used. If a scale is to be read to determine magnitudes, resolution is limited to the smallest fraction of a scale division that can be read with certainty. Most observers will attempt to estimate tenths of a division, but they generally have individual bias patterns that make a reading uncertain by 0.1 to 0.2 division.

Energy extracted from the measurand to operate the system alters the measurand to some extent, and if the available energy is small, this contributes to error in the result. Where energy is supplied from an auxiliary source, coupling or feedback may alter the measurement result. In the *transmission* of information from sensor to indicator, the signal may be distorted by selective attenuation or resonance in a communication channel, or it may suffer loss by leakage. Physical or chemical *deterioration* or other alterations of elements in the system can contribute to measurement error. Of the *ambient influences* affecting a measurement, temperature is the most pervasive. Other influences, not so universally important, include humidity, smoke and other air contaminants, barometric pressure, and the effect of gravity on an unbalanced system.

Classes of Errors. In estimating the uncertainty of a measurement result, two classes of error must be considered: systematic (which bias the result) and random (which produce scatter). *Systematic errors* are those which are repeated consistently with repetition of the measurement. Errors in the calibration of the system are systematic; uncertainty in the assigned value of a standard used in calibration must be accepted by the user as systematic. Changes of components through aging or deterioration produce systematic errors, as does failure to take into account energy extracted from a low-level source by the system. In attempting to search out and evaluate systematic errors, repetition of the measurement with definite, known changes in those parameters that are under the operator's control can be helpful, as is the use of different instrumentation or a different method. In some instances, it is possible to measure something similar to the measurand, which is independently and accurately known.

Random errors are accidental, fluctuating in an unpredictable manner. In any repetitive measurement, observations are influenced by many factors, the parameters that the observer cannot control and the residue of those he or she attempts to control. It is reasonable that combinations of these influences that add to produce large excursions are less frequent than those which partly compensate to produce small excursions, since each is equally likely to produce a positive or a negative departure. In effect, the results of a repetitive measurement process approximate a probability distribution, and it is convenient to treat the scatter of such a process as though it followed the laws of probability.

Evaluation Data. Assuming that the data from a repetitive measurement approximate a normal statistical distribution, we say that (excluding systematic errors) the mean of a group observations of a measurand is the *best approximation* of its actual value we can make from those data. Further, we estimate the imprecision of the result by certain statistical procedures. These procedures have validity only for random errors; systematic errors are not amenable to statistical treatment.

Standard Deviation. A measure of the dispersion of a set of observations is the root mean square of the deviations of individual observations from the mean of the set, $s = \sqrt{\Sigma d_m^2/(n - 1)}$, where n is the number of observations and d_m is the departure of an individual from the group mean. If the number is large, the standard deviation is $\sigma = \sqrt{\Sigma d_m^2/n}$. If the number of observations is small, a reasonable approximation of s can be calculated easily and quickly from the range r, the difference between the largest and smallest observation of the set $s \cong r/\sqrt{n}(3 \leq n \leq 12)$.

Probable Error. The probable error (pe) of an observation is that deviation from the mean for which the chances are equal that it will or will not be exceeded. If the number of observations is large, pe $= \pm 0.6745\sigma$. While this figure correctly expreses the range in which the chances are equally good that the actual value of the measurand will or will not be found (excluding systematics), it actually has no more significance as a precision index than the standard deviation from which it is derived. Thus, pe has fallen into disuse in current practice, although it was much used in the earlier literature as an index of precision. The pe of the mean of a set of observations is the amount by which the group mean can be expected to differ from the actual value of the measurand (excluding systematics) with a 50% probability. It may be calculated as $\pm\ 0.6745\sigma/\sqrt{n}$.

Confidence Intervals. Probable error is a special case of a broader concept. A *confidence interval* is the range of deviation from the mean within which a certain fraction of the observed values may be expected to lie, and the probability that the value of a randomly selected observation will lie within this range is called the *confidence level*.

4.1 CONDUCTOR MATERIALS

4.1.1 General Properties

Conducting Materials. A *conductor of electricity* is any substance or material which will afford continuous passage to an electric current when subjected to a difference of electric potential. The greater the density of current for a given potential difference, the more efficient the conductor is said to be. Virtually, all substances in solid or liquid state possess the property of electric conductivity in some degree, but certain substances are relatively efficient conductors, while others are almost totally devoid of this property. The metals, for example, are the best conductors, while many other substances, such as metal oxides and salts, minerals, and fibrous materials, are relatively poor conductors, but their conductivity is beneficially affected by the absorption of moisture. Some of the less-efficient conducting materials such as carbon and certain metal alloys, as well as the efficient conductors such as copper and aluminum, have very useful applications in the electrical arts.

Certain other substances possess so little conductivity that they are classed as nonconductors, a better term being insulators or dielectrics. In general, all materials which are used commercially for conducting electricity for any purpose are classed as conductors.

Definition of Conductor. A *conductor* is a body so constructed from conducting material that it may be used as a carrier of electric current. In ordinary engineering usage, a conductor is a material of relatively high conductivity.

Types of Conductors. In general, a conductor consists of a solid wire or a multiplicity of wires stranded together, made of a conducting material and used either bare or insulated. Only bare conductors are considered in this subsection. Usually the conductor is made of copper or aluminum, but for applications requiring higher strength, such as overhead transmission lines, bronze, steel, and various composite constructions are used. For conductors having very low conductivity and used as resistor materials, a group of special alloys is available.

Definition of Circuit. An *electric circuit* is the path of an electric current, or more specifically, it is a conducting part or a system of parts through which an electric current is intended to flow. Electric circuits in general possess four fundamental electrical properties, consisting of resistance, inductance, capacitance, and leakage conductance. That portion of a circuit which is represented by its conductors will also possess these four properties, but only two of them are related to the properties of the conductor considered by itself. Capacitance and leakage conductance depend in part on the external dimensions of the conductors and their distances from one another and from other conducting bodies, and in part on the dielectric properties of the materials employed for insulating purposes. The inductance is a function of the magnetic field established by the current in a conductor, but this field as a whole is divisible into two parts, one being wholly external to the conductor and the other being wholly within the conductor; only the latter portion can be regarded as corresponding to the magnetic properties of the conductor material. The resistance is strictly a property of the conductor itself. Both the resistance and the internal inductance of conductors change in effective values when the current changes with great rapidity as in the case of high-frequency alternating currents; this is termed the *skin effect*.

In certain cases, conductors are subjected to various mechanical stresses. Consequently, their weight, tensile strength, and elastic properties require consideration in all applications of this character. Conductor materials as a class are affected by changes in temperature and by the conditions of mechanical stress to which they are subjected in service. They are also affected by the nature of the mechanical working and the heat treatment which they receive in the course of manufacture or fabrication into finished products.

4.1.2 Metal Properties

Specific Gravity and Density. Specific gravity is the ratio of mass of any material to that of the same volume of water at 4°C. Density is the unit weight of material expressed as pounds per cubic inch, grams per cubic centimeter, etc., at some reference temperature, usually 20°C. For all practical purposes, the numerical values of specific gravity and density are the same, expressed in g/cm^3.

Density and Weight of Copper. Pure copper, rolled, forged, or drawn and then annealed, has a density of 8.89 g/cm^3 at 20°C or 8.90 g/cm^3 at 0°C. Samples of high-conductivity copper usually will vary from 8.87 to 8.91 and occasionally from 8.83 to 8.94. Variations in density may be caused by microscopic flaws or seams or the presence of scale or some other defect; the presence of 0.03% oxygen will cause a reduction of about 0.01 in density. Hard-drawn copper has about 0.02% less density than annealed copper, on average, but for practical purposes the difference is negligible.

The international standard of density, 8.89 at 20°C, corresponds to a weight of 0.32117 lb/in^3 or 3.0270×10^{-6} lb/(cmil)(ft) or 15.982×10^{-3} lb/(cmil)(mile). Multiplying either of the last two figures by the square of the diameter of the wire in mils will produce the total weight of wire in pounds per foot or per mile, respectively.

Copper Alloys. Density and weight of copper alloys vary with the composition. For hard-drawn wire covered by ASTM Specification B105, the density of alloys 85 to 20 is 8.89 g/cm^3 (0.32117 lb/in^3) at 20°C; alloy 15 is 8.54 (0.30853); alloys 13 and 8.5 is 8.78 (0.31720).

Copper-Clad Steel. Density and weight of copper-clad steel wire is a mean between the density of copper and the density of steel, which can be calculated readily when the relative volumes or cross sections of copper and steel are known. For practical purposes, a value of 8.15 g/cm^3 (0.29444 lb/in^3) at 20°C is used.

Aluminum Wire. Density and weight of aluminum wire (commercially hard-drawn) is 2.705 g/cm^3 (0.0975 lb/in^3) at 20°C. The density of electrolytically refined aluminum (99.97% Al) and of hard-drawn wire of the same purity is 2.698 at 20°C. With less pure material there is an appreciable decrease in density on cold working. Annealed metal having a density of 2.702 will have a density of about 2.700 when in the hard-drawn or fully cold-worked conditions (see *NBS Circ*. 346, pp. 68 and 69).

Aluminum-Clad Wire. Density and weight of aluminum-clad wire is a mean between the density of aluminum and the density of steel, which can be calculated readily when the relative volumes or cross sections of aluminum and steel are known. For practical purposes, a value of 6.59 g/cm^3 (0.23808 lb/in^3) at 20°C is used.

Aluminum Alloys. Density and weight of aluminum alloys vary with type and composition. For hard-drawn aluminum alloy wire 5005-H19 and 6201-T81, a value of 2.703 g/cm^3 (0.09765 lb/in^3) at 20°C is used.

Pure Iron and Galvanized Steel Wire. Density and weight of pure iron is 7.90 g/cm^3 [2.690 $\times$ 10^{-6} lb/(cmil)(ft)] at 20°C. Density and weight of galvanized steel wire (EBB, BB, HTL-85, HTL-135, and HTL-195) with Class A weight of zinc coating are 7.83 g/cm^3 (0.283 lb/in^3) at 20°C, with Class B are 7.80 g/cm^3 (0.282 lb/in^3), and with Class C are 7.78 g/cm^3 (0.281 lb/in^3).

Percent Conductivity. It is very common to rate the conductivity of a conductor in terms of its percentage ratio to the conductivity of chemically pure metal of the same kind as the conductor is primarily constituted or in ratio to the conductivity of the international copper standard. Both forms of the conductivity ratio are useful for various purposes. This ratio also can be expressed in two different terms, one where the conductor cross sections are equal and therefore termed the *volume-conductivity ratio* and the other where the conductor masses are equal and therefore termed the *mass-conductivity ratio*.

International Annealed Copper Standard. The International Annealed Copper Standard (IACS) is the internationally accepted value for the resistivity of annealed copper of 100% conductivity. This standard is expressed in terms of mass resistivity as 0.5328 $\Omega \cdot$ g/m^2, or the resistance of a uniform round wire 1 m long weighing 1 g at the standard temperature of 20°C. Equivalent expressions of the annealed copper standard in various units of mass resistivity and volume resistivity are as follows:

0.15328	$\Omega \cdot$ g/m^2
875.20	$\Omega \cdot$ lb/mi^2
1.7241	$\mu\Omega \cdot$ cm
0.67879	$\mu\Omega \cdot$ in at 20°C
10.371	$\Omega \cdot$ cmil/ft
0.017241	$\Omega \cdot$ mm^2/m

The preceding values are the equivalent of $^1/_{58}$ $\Omega \cdot$ mm^2/m, so the volume conductivity can be expressed as 58 S $\cdot$ mm^2/m at 20°C.

Conductivity of Conductor Materials. Conductivity of conductor materials varies with chemical composition and processing.

Electrical Resistivity. *Electrical resistivity* is a measure of the resistance of a unit quantity of a given material. It may be expressed in terms of either mass or volume; mathematically,

Mass resistivity:
$$\delta = \frac{Rm}{l^2} \tag{4-1}$$

Volume resistivity:
$$\rho = \frac{RA}{l} \tag{4-2}$$

where R is resistance, m is mass, A is cross-sectional area, and l is length.

Electrical resistivity of conductor materials varies with chemical composition and processing.

Effects of Temperature Changes. Within the temperature ranges of ordinary service there is no appreciable change in the properties of conductor materials, except in electrical resistance and physical dimensions. The change in resistance with change in temperature is sufficient to require consideration in many engineering calculations. The change in physical dimensions with change in temperature is also important in certain cases, such as in overhead spans and in large units of apparatus or equipment.

Temperature Coefficient of Resistance. Over moderate ranges of temperature, such as 100°C, the change of resistance is usually proportional to the change of temperature. Resistivity is always expressed at a standard temperature, usually 20°C (68°F). In general, if R_{t_1} is the resistance at a temperature t_1

and α_{t_1} is the temperature coefficient at that temperature, the resistance at some other temperature t_2 is expressed by the formula

$$R_{t_2} = R_{t_1}[1 + \alpha_{t_1}(t_2 - t_1)] \tag{4-3}$$

Over wide ranges of temperature, the linear relationship of this formula is usually not applicable, and the formula then becomes a series involving higher powers of t, which is unwieldy for ordinary use.

When the temperature of reference t_1 is changed to some other value, the coefficient also changes. Upon assuming the general linear relationship between resistance and temperature previously mentioned, the new coefficient at any temperature t within the linear range is expressed

$$\alpha_t = \frac{1}{(1/\alpha_{t_1}) + (t - t_1)} \tag{4-4}$$

The reciprocal of α is termed the *inferred absolute zero of temperature*. Equation (4-3) takes no account of the change in dimensions with change in temperature and therefore applies to the case of conductors of constant mass, usually met in engineering work.

The *coefficient for copper of less than standard (or 100%) conductivity* is proportional to the actual conductivity, expressed as a decimal percentage. Thus, if n is the percentage conductivity (95% = 0.95), the temperature coefficient will be $\alpha'_t = n\alpha_t$, where α_t is the coefficient of the annealed copper standard.

The coefficients are computed from the formula

$$\alpha_t = \frac{1}{[1/n(0.00393)] + (t_1 - 20)} \tag{4-5}$$

Copper Alloys and Copper-Clad Steel Wire. Temperature-resistance coefficients for copper alloys usually can be approximated by multiplying the corresponding coefficient for copper (100% IACS) by the alloy conductivity expressed as a decimal. For some complex alloys, however, this relation does not hold even approximately, and suitable values should be obtained from the supplier. The temperature-resistance coefficient for copper-clad steel wire is 0.00378/°C at 20°C.

Aluminum-Alloy Wires and Aluminum-Clad Wire. Temperature-resistance coefficients for aluminum-alloy wires are for 5005 H19, 0.00353/°C, and for 6201-T81, 0.00347/°C at 20°C. Temperature-resistance coefficient for aluminum-clad wire is 0.0036/°C at 20°C.

Typical Composite Conductors. Temperature-resistance coefficients for typical composite conductors are as follows:

Type	Approximate temperature coefficient per °C at 20°C
Copper–copper-clad steel	0.00381
ACSR (aluminum-steel)	0.00403
Aluminum–aluminum alloy	0.00394
Aluminum–aluminum-clad steel	0.00396

Reduction of Observations to Standard Temperature. A table of convenient corrections and factors for reducing resistivity and resistance to standard temperature, 20°C, will be found in Copper Wire Tables, *NBS Handbook* 100.

Resistivity-Temperature Constant. The *change of resistivity per degree* may be readily calculated, taking account of the expansion of the metal with rise of temperature. The proportional relation between temperature coefficient and conductivity may be put in the following convenient form for reducing *resistivity* from one temperature to another. *The change of resistivity of copper per degree Celsius is a constant, independent of the temperature of reference and of the sample of copper. This "resistivity-temperature constant" may be taken, for general purposes, as* 0.00060 Ω *(meter, gram), or* 0.0068 μΩ · *cm.*

Details of the calculation of the resistivity-temperature constant will be found in Copper Wire Tables, *NBS Handbook* 100; also see this reference for expressions for the temperature coefficients of resistivity and their derivation.

Temperature Coefficient of Expansion. *Temperature coefficient of expansion* (linear) of pure metals over a range of several hundred degrees is not a linear function of the temperature but is well expressed by a quadratic equation

$$\frac{L_{t_2}}{L_{t_1}} = 1 + [\alpha(t_2 - t_1) + \beta(t_2 - t_1)^2] \tag{4-6}$$

Over the temperature ranges for ordinary engineering work (usually 0 to 100°C), the coefficient can be taken as a constant (assumed linear relationship) and a simplified formula employed

$$L_{t_2} = L_{t_1}[1 + \alpha_{t_1}(t_2 - t_1)] \tag{4-7}$$

Changes in linear dimensions, superficial area, and volume take place in most materials with changes in temperature. In the case of linear conductors, only the change in length is ordinarily important.

The coefficient for changes in superficial area is approximately twice the coefficient of linear expansion for relatively small changes in temperature. Similarly, the volume coefficient is 3 times the linear coefficient, with similar limitations.

Specific Heat. Specific heat of electrolytic tough pitch copper is 0.092 cal/(g)(°C) at 20°C (see *NBS Circ.* 73). Specific heat of aluminum is 0.226 cal/(g)(°C) at room temperature (see *NBS Circ.* C447, Mechanical Properties of Metals and Alloys). Specific heat of iron (wrought) or very soft steel from 0 to 100°C is 0.114 cal/(g)(°C); the true specific heat of iron at 0°C is 0.1075 cal/(g)(°C) (see *International Critical Tables,* vol. II, p. 518; also ASM, *Metals Handbook*).

Thermal Conductivity of Electrolytic Tough Pitch Copper. Thermal conductivity of electrolytic tough pitch copper at 20°C is 0.934 cal/(cm^2)(cm)(s)(°C), adjusted to correspond to an electrical conductivity of 101% (see *NBS Circ.* 73).

Thermal-Electrical Conductivity Relation of Copper. The Wiedemann-Franz-Lorenz law, which states that the ratio of the thermal and electrical conductivities at a given temperature is independent of the nature of the conductor, holds closely for copper. The ratio $K/\lambda T$ (where K = thermal conductivity, λ = electrical conductivity, T = absolute temperature) for copper is 5.45 at 20°C.

Thermal Conductivity.

Copper Alloys.

	Thermal conductivity (volumetric) at 20°C	
ASTM alloy (Spec. B105)	Btu per sq ft per ft per h per °F	Cal per sq cm per cm per sec per °C
8.5	31	0.13
15	50	0.21
30	84	0.35
55	135	0.56
80	199	0.82
85	208	0.86

Aluminum. The determination made by the Bureau of Standards at 50°C for aluminum of 99.66% purity is 0.52 cal/(cm^2)(cm)(s)(°C) (*Circ*. 346; also see *Smithsonian Physical Tables and International Critical Tables*).

Iron. Thermal conductivity of iron (mean) from 0 to 100°C is 0.143 cal/(cm^2)(cm)(s)(°C); with increase of carbon and manganese content, it tends to decrease and may reach a figure of approximately

0.095 with about 1% carbon, or only about half of that figure if the steel is hardened by water quenching (see *International Critical Tables,* vol. II, p. 518).

Copper. Copper is a highly malleable and ductile metal of reddish color. It can be cast, forged, rolled, drawn, and machined. Mechanical working hardens it, but annealing will restore it to the soft state. The density varies slightly with the physical state, 8.9 being an average value. It melts at 1083°C (1981°F) and in the molten state has a sea-green color. When heated to a very high temperature, it vaporizes and burns with a characteristic green flame. Copper readily alloys with many other metals. In ordinary atmospheres it is not subject to appreciable corrosion. Its electrical conductivity is very sensitive to the presence of slight impurities in the metal.

Copper, when exposed to ordinary atmospheres, becomes oxidized, turning to a black color, but the oxide coating is protective, and the oxidizing process is not progressive. When exposed to moist air containing carbon dioxide, it becomes coated with green basic carbonate, which is also protective. At temperatures above 180°C it oxidizes in dry air. In the presence of ammonia it is readily oxidized in air, and it is also affected by sulfur dioxide. Copper is not readily attacked at high temperatures below the melting point by hydrogen, nitrogen, carbon monoxide, carbon dioxide, or steam. Molten copper readily absorbs oxygen, hydrogen, carbon monoxide, and sulfur dioxide, but on cooling, the occluded gases are liberated to a great extent, tending to produce blowholes or porous castings. Copper in the presence of air does not dissolve in dilute hydrochloric or sulfuric acid but is readily attacked by dilute nitric acid. It is also corroded slowly by saline solutions and sea water.

Commercial grades of copper in the United States are electrolytic, oxygen-free, Lake, fire-refined, and casting. *Electrolytic copper* is that which has been electrolytically refined from blister, converter, black, or Lake copper. *Oxygen-free copper* is produced by special manufacturing processes which prevent the absorption of oxygen during the melting and casting operations or by removing the oxygen by reducing agents. It is used for conductors subjected to reducing gases at elevated temperature, where reaction with the included oxygen would lead to the development of cracks in the metal. *Lake copper* is electrolytically or fire-refined from Lake Superior native copper ores and is of two grades, low resistance and high resistance. *Fire-refined copper* is a lower-purity grade intended for alloying or for fabrication into products for mechanical purposes; it is not intended for electrical purposes. *Casting copper* is the grade of lowest purity and may consist of furnace-refined copper, rejected metal not up to grade, or melted scrap; it is exclusively a foundry copper.

Hardening and Heat-Treatment of Copper. There are but two well-recognized methods for hardening copper, one is by mechanically working it, and the other is by the addition of an alloying element. The properties of copper are not affected by a rapid cooling after annealing or rolling, as are those of steel and certain copper alloys.

Annealing of Copper. Cold-worked copper is softened by annealing, with decrease of tensile strength and increase of ductility. In the case of pure copper hardened by cold reduction of area to one-third of its initial area, this softening takes place with maximum rapidity between 200 and 325°C. However, this temperature range is affected in general by the extent of previous cold reduction and the presence of impurities. The greater the previous cold reduction, the lower is the range of softening temperatures. The effect of iron, nickel, cobalt, silver, cadmium, tin, antimony, and tellurium is to lower the conductivity and raise the annealing range of pure copper in varying degrees.

Commercial grade	ASTM Designation	Copper content, minimum %
Electrolytic	B5	99.900
Oxygen-free electrolytic	B170	99.95
Lake, low resistance	B4	99.900
Lake, high resistance	B4	99.900
Fire-refined	B216	99.88
Casting	B119	98

Alloying of Copper. Elements that are soluble in moderate amounts in a solid solution of copper, such as manganese, nickel, zinc, tin, and aluminum, generally harden it and diminish its ductility but improve its rolling and working properties. Elements that are but slightly soluble, such as bismuth and lead, do not harden it but diminish both the ductility and the toughness and impair its hot-working properties. Small additions (up to 1.5%) of manganese, phosphorus, or tin increase the tensile strength and hardness of cold-rolled copper.

Brass is usually a binary alloy of copper and zinc, but brasses are seldom employed as electrical conductors, since they have relatively low conductivity through comparatively high tensile strength. In general, brass is not suitable for use when exposed to the weather, owing to the difficulty from stress-corrosion cracking; the higher the zinc content, the more pronounced this becomes.

Bronze in its simplest form is a binary alloy of copper and tin in which the latter element is the hardening and strengthening agent. This material is rather old in the arts and has been used to some extent for electrical conductors for past many years, especially abroad. Modern bronzes are frequently ternary alloys, containing as the third constituent such elements as phosphorus, silicon, manganese, zinc, aluminum, or cadmium; in such cases, the third element is usually given in the name of the alloy, as in phosphor bronze or silicon bronze. Certain bronzes are quaternary alloys, or contain two other elements in addition to copper and tin.

In bronzes for use as electrical conductors, the content of tin and other metals is usually less than in bronzes for structural or mechanical applications, where physical properties and resistance to corrosion are the governing considerations. High resistance to atmospheric corrosion is always an important consideration in selecting bronze conductors for overhead service.

Commercial Grades of Bronze. Various bronzes have been developed for use as conductors, and these are now covered by ASTM Specification B105. They all have been designed to provide conductors having high resistance to corrosion and tensile strengths greater than hard-drawn copper conductors. The standard specification covers 10 grades of bronze, designated by numbers according to their conductivities.

Copper-Beryllium Alloy. *Copper-beryllium alloy* containing 0.4% of beryllium may have an electrical conductivity of 48% and a tensile strength (in 0.128-in wire) of 86,000 lb/in^2. A content of 0.9% of beryllium may give a conductivity of 28% and a tensile strength of 122,000 lb/in^2. The effect of this element in strengthening copper is about 10 times as great as that of tin.

Copper-Clad Steel Wire. *Copper-clad steel wire* has been manufactured by a number of different methods. The general object sought in the manufacture of such wires is the combination of the high conductivity of copper with the high strength and toughness of iron or steel. The principal manufacturing processes now in commercial use are (*a*) coating a steel billet with a special flux, placing it in a vertical mold closed at the bottom, heating the billet and mold to yellow heat, and then casting molten copper around the billet, after which it is hot-rolled to rods and cold-drawn to wire, and (*b*) electroplating a dense coating of copper on a steel rod and then cold drawing to wire.

Aluminum. *Aluminum* is a ductile metal, silver-white in color, which can be readily worked by rolling, drawing, spinning, extruding, and forging. Its specific gravity is 2.703. Pure aluminum melts at 660°C (1220°F). Aluminum has relatively high thermal and electrical conductivities. The metal is always covered with a thin, invisible film of oxide which is impermeable and protective in character. Aluminum, therefore, shows stability and long life under ordinary atmospheric exposure.

Exposure to atmospheres high in hydrogen sulfide or sulfur dioxide does not cause severe attack of aluminum at ordinary temperatures, and for this reason, aluminum or its alloys can be used in atmospheres which would be rapidly corrosive to many other metals.

Aluminum parts should, as a rule, not be exposed to salt solutions while in electrical contact with copper, brass, nickel, tin, or steel parts, since galvanic attack of the aluminum is likely to occur. Contact with cadmium in such solutions results in no appreciable acceleration in attack on the aluminum, while contact with zinc (or zinc-coated steel as long as the coating is intact) is generally beneficial, since the zinc is attacked selectively and it cathodically protects adjacent areas of the aluminum.

Most organic acids and their water solutions have little or no effect on aluminum at room temperature, although oxalic acid is an exception and is corrosive. Concentrated nitric acid (about 80% by weight) and fuming sulfuric acid can be handled in aluminum containers. However, more dilute solutions of these acids are more active. All but the most dilute (less than 0.1%) solutions of hydrochloric and hydrofluoric acids have a rapid etching action on aluminum.

Solutions of the strong alkalies, potassium, or sodium hydroxides dissolve aluminum rapidly. However, ammonium hydroxide and many of the strong organic bases have little action on aluminum and are successfully used in contact with it (see *NBS Circ.* 346).

Aluminum in the presence of water and limited air or oxygen rapidly converts into aluminum hydroxide, a whitish powder.

Commercial grades of aluminum in the United States are designated by their purity, such as 99.99, 99.6, 99.2, 99.0%. Electrical conductor alloy aluminum 1350, having a purity of approximately 99.5% and a minimum conductivity of 61.0% IACS, is used for conductor purposes. Specified physical properties are obtained by closely controlling the kind and amount of certain impurities.

Annealing of Aluminum. Cold-worked aluminum is softened by annealing, with decrease of tensile strength and increase of ductility. The annealing temperature range is affected in general by the extent of previous cold reduction and the presence of impurities. The greater the previous cold reduction, the lower is the range of softening temperatures.

Alloying of Aluminum. Aluminum can be alloyed with a variety of other elements, with a consequent increase in strength and hardness. With certain alloys, the strength can be further increased by suitable heat treatment. The alloying elements most generally used are copper, silicon, manganese, magnesium, chromium, and zinc. Some of the aluminum alloys, particularly those containing one or more of the following elements—copper, magnesium, silicon, and zinc—in various combinations, are susceptible to heat treatment.

Pure aluminum, even in the hard-worked condition, is a relatively weak metal for construction purposes. Strengthening for castings is obtained by alloying elements. The alloys most suitable for cold rolling seldom contain less than 90% to 95% aluminum. By alloying, working, and heat treatment, it is possible to produce tensile strengths ranging from 8500 lb/in^2 for pure annealed aluminum up to 82,000 lb/in^2 for special wrought heat-treated alloy, with densities ranging from 2.65 to 3.00.

Electrical conductor alloys of aluminum are principally alloys 5005 and 6201 covered by ASTM Specifications B396 and B398.

Aluminum-clad steel wires have a relatively heavy layer of aluminum surrounding and bonded to the high-strength steel core. The aluminum layer can be formed by compacting and sintering a layer of aluminum powder over a steel rod, by electroplating a dense coating of aluminum on a steel rod, or by extruding a coating of aluminum on a steel rod and then cold drawing to wire.

Silicon. *Silicon* is a light metal having a specific gravity of approximately 2.34. There is lack of accurate data on the pure metal because its mechanical brittleness bars it from most industrial uses. However, it is very resistant to atmospheric corrosion and to attack by many chemical reagents. Silicon is of fundamental importance in the steel industry, but for this purpose it is obtained in the form of ferrosilicon, which is a coarse granulated or broken product. It is very useful as an alloying element in steel for electrical sheets and substantially increases the electrical resistivity, and thereby reduces the core losses. Silicon is peculiar among metals in the respect that its temperature coefficient of resistance may change sign in some temperature ranges, the exact behavior varying with the impurities.

Beryllium. *Beryllium* is a light metal having a specific gravity of approximately 1.84, or nearly the same as magnesium. It is normally hard and brittle and difficult to fabricate. Copper is materially strengthened by the addition of small amounts of beryllium, without very serious loss of electrical conductivity. The principal use for this metal appears to be as an alloying element with other metals such as aluminum and copper. Beryllium is also toxic. Reference should be made to Material Safety Data Sheets for precautions in handling.

Sodium. *Sodium* is a soft, bright, silvery metal obtained commercially by the electrolysis of absolutely dry fused sodium chloride. It is the most abundant of the alkali group of metals, is extremely reactive, and is never found free in nature. It oxidizes readily and rapidly in air. In the presence of water (it is so light that it floats) it may ignite spontaneously, decomposing the water with evolution of hydrogen and formation of sodium hydroxide. This can be explosive. Sodium should be handled with respect, since it can be dangerous when handled improperly. It melts at 97.8°C, below the boiling point of water and in the same range as many fuse metal alloys. Sodium is approximately one-tenth as heavy as copper and has roughly three-eighths the conductivity; hence 1 lb of sodium is about equal electrically to 3½ lb of copper.

4.1.3 Conductor Properties

Definitions of Electrical Conductors

Wire. A rod or filament of drawn or rolled metal whose length is great in comparison with the major axis of its cross section. The definition restricts the term to what would ordinarily be understood by the term *solid wire*. In the definition, the word *slender* is used in the sense that the length is great in comparison with the diameter. If a wire is covered with insulation, it is properly called an *insulated wire,* while primarily the term *wire* refers to the metal; nevertheless, when the context shows that the wire is insulated, the term *wire* will be understood to include the insulation.

Conductor. A wire or combination of wires not insulated from one another, suitable for carrying an electric current. The term *conductor* is not to include a combination of conductors insulated from one another, which would be suitable for carrying several different electric currents. Rolled conductors (such as bus bars) are, of course, conductors but are not considered under the terminology here given.

Stranded Conductor. A conductor composed of a group of wires, usually twisted, or any combination of groups of wires. The wires in a stranded conductor are usually twisted or braided together.

Cable. A stranded conductor (single-conductor cable) or a combination of conductors insulated from one another (multiple-conductor cable). The component conductors of the second kind of cable may be either solid or stranded, and this kind of cable may or may not have a common insulating covering. The first kind of cable is a single conductor, while the second kind is a group of several conductors. The term *cable* is applied by some manufacturers to a solid wire heavily insulated and lead covered; this usage arises from the manner of the insulation, but such a conductor is not included under this definition of *cable*. The term *cable* is a general one, and in practice, it is usually applied only to the larger sizes. A small cable is called a *stranded wire* or a *cord,* both of which are defined below. Cables may be bare or insulated, and the latter may be armored with lead or with steel wires or bands.

Strand. One of the wires of any stranded conductor.

Stranded Wire. A group of small wires used as a single wire. A *wire* has been defined as a slender rod or filament of drawn metal. If such a filament is subdivided into several smaller filaments or strands and is used as a single wire, it is called *stranded wire*. There is no sharp dividing line of size between a stranded wire and a cable. If used as a wire, for example, in winding inductance coils or magnets, it is called a *stranded wire* and not a cable. If it is substantially insulated, it is called a *cord,* defined below.

Cord. A small cable, very flexible and substantially insulated to withstand wear. There is no sharp dividing line in respect to size between a cord and a cable, and likewise no sharp dividing line in respect to the character of insulation between a cord and a stranded wire. Usually the insulation of a cord contains rubber.

Concentric Strand. A strand composed of a central core surrounded by one or more layers of helically laid wires or groups of wires.

Concentric-Lay Conductor. Conductor constructed with a central core surrounded by one or more layers of helically laid wires.

Rope-Lay Conductor. Conductor constructed of a bunch-stranded or a concentric-stranded member or members, as a central core, around which are laid one or more helical layers of such members.

N-Conductor Cable. A combination of *N* conductors insulated from one another. It is not intended that the name as given here actually be used. One would instead speak of a "3-conductor cable," a "12-conductor cable," etc. In referring to the general case, one may speak of a "multiple-conductor cable."

N-Conductor Concentric Cable. A cable composed of an insulated central conducting core with *N*-1 tubular-stranded conductors laid over it concentrically and separated by layers of insulation. This kind of cable usually has only two or three conductors. Such cables are used in carrying alternating currents. The remark on the expression "*N* conductor" given for the preceding definition applies here also. (Additional definitions can be found in ASTM B354.)

Wire Sizes. Wire sizes have been for many years indicated in commercial practice almost entirely by gage numbers, especially in America and England. This practice is accompanied by some confusion because numerous gages are in common use. The most commonly used gage for electrical wires, in America, is the *American wire gage*. The most commonly used gage for steel wires is the *Birmingham wire gage*.

There is no legal standard wire gage in this country, although a gage for sheets was adopted by Congress in 1893. In England, there is a legal standard known as the *Standard wire gage*. In Germany, France, Austria, Italy, and other continental countries, practically no wire gage is used, but wire sizes are specified directly in millimeters. This system is sometimes called the *millimeter wire gage*. The wire sizes used in France, however, are based to some extent on the old Paris gage (*jauge de Paris de 1857*) (for a history of wire gages, see *NBS Handbook* 100, Copper Wire Tables; also see *Circ.* 67, Wire Gages, 1918).

There is a tendency to *abandon gage numbers* entirely and specify wire sizes by the *diameter in mils* (thousandths of an inch). This practice holds particularly in writing specifications and has the great advantages of being both simple and explicit. A number of wire manufacturers also encourage this practice, and it was definitely adopted by the U.S. Navy Department in 1911.

Mil is a term universally employed in this country to measure wire diameters and is a unit of length equal to one-thousandth of an inch. *Circular mil* is a term universally used to define cross-sectional areas, being a unit of area equal to the area of a circle 1 mil in diameter. Such a circle, however, has an area of 0.7854 (or $\pi/4$) mil^2. Thus a wire 10 mils in diameter has a cross-sectional area of 100 cmils or 78.54 mils^2. Hence, a cmil equals 0.7854 mil^2.

American wire gage, also known as the *Brown & Sharpe gage,* was devised in 1857 by J. R. Brown. It is usually abbreviated AWG. This gage has the property, in common with a number of other gages, that its sizes represent approximately the successive steps in the process of wire drawing. Also, like many other gages, its numbers are retrogressive, a larger number denoting a smaller wire, corresponding to the operations of drawing. These gage numbers are not arbitrarily chosen, as in many gages, but follow the mathematical law upon which the gage is founded.

Basis of the AWG is a simple mathematical law. The gage is formed by the specification of two diameters and the law that a given number of intermediate diameters are formed by geometric progression. Thus, the diameter of No. 0000 is defined as 0.4600 in and of No. 36 as 0.0050 in. There are 38 sizes between these two; hence the ratio of any diameter to the diameter of the next greater number is given by this expression

$$\sqrt[39]{\frac{0.4600}{0.0050}} = \sqrt[39]{92} = 1.122\,932\,2 \tag{4-8}$$

The square of this ratio = 1.2610. The sixth power of the ratio, that is, the ratio of any diameter to the diameter of the sixth greater number, = 2.0050. The fact that this ratio is so nearly 2 is the basis of numerous useful relations or shortcuts in wire computations.

There are a number of approximate rules applicable to the AWG which are useful to remember:

1. An increase of three gage numbers (e.g., from No. 10 to 7) doubles the area and weight and consequently halves the dc resistance.
2. An increase of six gage numbers (e.g., from No. 10 to 4) doubles the diameter.
3. An increase of 10 gage numbers (e.g., from No. 10 to 1/0) multiplies the area and weight by 10 and divides the resistance by 10.
4. A No. 10 wire has a diameter of about 0.10 in, an area of about 10,000 cmils, and (for standard annealed copper at 20°C) a resistance of approximately 1.0 Ω/1000 ft.
5. The weight of No. 2 copper wire is very close to 200 lb/1000 ft (90 kg/304.8 m).

Steel wire gage, also known originally as the *Washburn & Moen gage* and later as the *American Steel & Wire Co.'s gage,* was established by Ichabod Washburn in 1830. This gage, with a number of its sizes rounded off to thousandths of an inch, is also known as the *Roebling gage*. It is used exclusively for steel wire and is frequently employed in wire mills.

Birmingham wire gage, also known as *Stubs' wire gage* and *Stubs' iron wire gage,* is said to have been established early in the eighteenth century in England, where it was long in use. This gage was used to designate the Stubs soft-wire sizes and should not be confused with Stubs' steel-wire gage. The numbers of the Birmingham gage were based on the reductions of size made in practice by drawing wire from rolled rod. Thus, a wire rod was called "No. 0," "first drawing No. 1," and so on. The gradations of size in this gage are not regular, as will appear from its graph. This gage is generally in commercial use in the United States for iron and steel wires.

Standard wire gage, which more properly should be designated *(British) Standard wire gage,* is the legal standard of Great Britain for all wires adopted in 1883. It is also known as the *New British Standard gage,* the *English legal standard gage,* and the *Imperial wire gage*. It was constructed by so modifying the Birmingham gage that the differences between consecutive sizes become more regular. This gage is largely used in England but never has been used extensively in America.

Old English wire gage, also known as the *London wire gage,* differs very little from the Birmingham gage. Formerly it was used to some extent for brass and copper wires but is now nearly obsolete.

Millimeter wire gage, also known as the *metric wire gage*, is based on giving progressive numbers to the progressive sizes, calling 0.1 mm diameter "No. 1," 0.2 mm "No. 2," etc.

Conductor-Size Designation. America uses, for sizes up to 4/0, mil, decimals of an inch, or AWG numbers for solid conductors and AWG numbers or circular mils for stranded conductors; for sizes larger than 4/0, circular mils are used throughout. Other countries ordinarily use square millimeter area.

Conductor-size conversion can be accomplished from the following relation:

$$\text{cmils} = \text{in}^2 \times 1{,}273{,}200 = \text{mm}^2 \times 1973.5 \tag{4-9}$$

Measurement of wire diameters may be accomplished in many ways but most commonly by means of a micrometer caliper. Stranded cables are usually measured by means of a circumference tape calibrated directly in diameter readings.

Stranded Conductors. Stranded conductors are used generally because of their increased flexibility and consequent ease in handling. The greater the number of wires in any given cross section, the greater will be the flexibility of the finished conductor. Most conductors above 4/0 AWG in size are stranded. Generally, in a given concentric-lay stranded conductor, all wires are of the same size and the same material, although special conductors are available embodying wires of different sizes and materials. The former will be found in some insulated cables and the latter in overhead stranded conductors combining high-conductivity and high-strength wires.

The flexibility of any given size of strand obviously increases as the total number of wires increases. It is a common practice to increase the total number of wires as the strand diameter increases in order to provide reasonable flexibility in handling. So-called flexible concentric strands for use in insulated cables have about one to two more layers of wires than the standard type of strand for ordinary use.

Number of Wires in Standard Conductors. Each successive layer in a concentrically stranded conductor contains six more wires than the preceding one. The total number of wires in a conductor is

For 1-wire core constructions (1, 7, 19, etc.),

$$N = 3n(n + 1) + 1 \tag{4-10}$$

For 3-wire core constructions (3, 12, etc.),

$$N = 3n(n + 2) + 3 \tag{4-11}$$

where n is number of layers over core, which is not counted as a layer.

Wire size in stranded conductors is

$$d = \sqrt{\frac{A}{N}} \tag{4-12}$$

where A is total conductor area in circular mils, and N is total number of wires.

Copper cables are manufactured usually to certain cross-sectional sizes specified in total circular mils or by gage numbers in AWG. This necessarily requires individual wires drawn to certain prescribed diameters, which are different as a rule from normal sizes in AWG (see Table 4-10).

Diameter of stranded conductors (circumscribing circle) is

$$D = d(2n + k) \tag{4-13}$$

where d is diameter of individual wire, n is number of layers over core, which is not counted as a layer, k is 1 for constructions having 1-wire core (1, 7, 19, etc.), and 2.155 for constructions having 3-wire core (3, 12, etc.).

For standard concentric-lay stranded conductors, the following rule gives a simple method of determining the outside diameter of a stranded conductor from the known diameter of a solid wire of the same cross-sectional area: *To obtain the diameter of concentric-lay stranded conductor, multiply the diameter of the solid wire of the same cross-sectional area by the appropriate factor as follows*:

Number of wires	Factor	Number of wires	Factor
3	1.244	91	1.153
7	1.134	127	1.154
12	1.199	169	1.154
19	1.147	217	1.154
37	1.151	271	1.154
61	1.152		

Area of stranded conductors is

$$A = Nd^2 \text{ cmils} = \tfrac{1}{4}\,\pi N d^2 \times 10^{-6} \text{ in}^2 \tag{4-14}$$

where N is total number of wires, and d is individual wire diameter in mils.

Effects of Stranding. All wires in a stranded conductor except the core wire form continuous helices of slightly greater length than the axis or core. This causes a slight increase in weight and electrical resistance and slight decrease in tensile strength and sometimes affects the internal inductance, as compared theoretically with a conductor of equal dimensions but composed of straight wires parallel with the axis.

Lay, or Pitch. The axial length of one complete turn, or helix, of a wire in a stranded conductor is sometimes termed the *lay,* or *pitch*. This is often expressed as the *pitch ratio,* which is the ratio of the length of the helix to its *pitch diameter* (diameter of the helix at the centerline of any individual wire or strand equals the outside diameter of the helix minus the thickness of one wire or strand). If there are several layers, the pitch expressed as an axial length may increase with each additional layer, but when expressed as the ratio of axial length to pitch diameter of helix, it is usually the same for all layers, or nearly so. In commercial practice, the pitch is commonly expressed as the ratio of axial length to outside diameter of helix, but this is an arbitrary designation made for convenience of usage. The *pitch angle* is shown in Fig. 4-1, where *ac* represents the axis of the stranded conductor and l is the axial length of one complete turn or helix, *ab* is the length of any individual wire $l + \Delta l$ in one complete turn, and *bc* is equal to the circumference of a circle corresponding to the pitch diameter d of the helix. The angle *bac,* or θ, is the pitch angle, and the pitch ratio is expressed by $p = l/d$. There is no standard pitch ratio used by manufacturers generally, since it has been found desirable to vary this depending on the type of service for which the conductor is intended. Applicable lay lengths generally are included in industry specifications covering the various stranded conductors. For bare overhead conductors, a representative commercial value for pitch length is 13.5 times the outside diameter of each layer of strands.

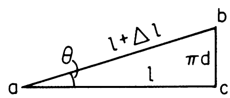

FIGURE 4-1 Pitch angle in concentric-lay cable.

Direction of Lay. The direction of lay is the lateral direction in which the individual wires of a cable run over the top of the cable as they recede from an observer looking along the axis. *Right-hand lay* recedes from the observer in clockwise rotation or like a right-hand screw thread; *left-hand lay* is the opposite. The outer layer of a cable is ordinarily applied with a right-hand lay for bare overhead conductors and left-hand lay for insulated conductors, although the opposite lay can be used if desired.

Increase in Weight Due to Stranding. Referring to Fig. 4-1, the increase in weight of the spiral members in a cable is proportional to the increase in length

$$\frac{l + \Delta l}{l} = \sec\theta = \sqrt{1 + \tan^2\theta}$$

$$= \sqrt{1 + \frac{\pi^2}{p^2}} = 1 + \frac{1}{2}\frac{\pi^2}{p^2} - \frac{1}{8}\left(\frac{\pi^2}{p^2}\right)^2 + \cdots \qquad (4\text{-}15)$$

As a first approximation this ratio equals $1 + 0.5(\pi^2/p^2)$, and a pitch of 15.7 produces a ratio of 1.02. This correction factor should be computed separately for each layer if the pitch p varies from layer to layer.

Increase in Resistance Due to Stranding. If it were true that no current flows from wire to wire through their lineal contacts, the proportional increase in the total resistance would be the same as the proportional increase in total weight. If all the wires were in perfect and complete contact with each other, the total resistance would decrease in the same proportion that the total weight increases, owing to the slightly increased normal cross section of the cable as a whole. The contact resistances are normally sufficient to make the actual increase in total resistance nearly as much, proportionately, as the increase in total weight, and for practical purposes they are usually assumed to be the same.

Decrease in Strength Due to Stranding. When a concentric-lay cable is subjected to mechanical tension, the spiral members tend to tighten around those layers under them and thus produce internal compression, gripping the inner layers and the core. Consequently, the individual wires, taken as a whole, do not behave as they would if they were true linear conductors acting independently. Furthermore, the individual wires are never exactly alike in diameter or in strength or in elastic properties. For these reasons, there is ordinarily a loss of about 4% to 11% in total tensile efficiency, depending on the number of layers. This reduction tends to increase as the pitch ratio decreases. Actual tensile tests on cables furnish the most dependable data on their ultimate strength.

Tensile efficiency of a stranded conductor is the ratio of its breaking strength to the sum of the tensile strengths of all its individual wires. Concentric-lay cables of 12 to 16 pitch ratio have a normal tensile efficiency of approximately 90%; rope-lay cables, approximately 80%.

Preformed Cable. This type of cable is made by preforming each individual wire (except the core) into a spiral of such length and curvature that the wire will fit naturally into its normal position in the cable instead of being forced into that shape under the usual tension in the stranding machine. This method has the advantage in cable made of the stiffer grades of wire that the individual wires do not tend to spread or untwist if the strand is cut in two without first binding the ends on each side of the cut.

Weight. A uniform cylindrical conductor of diameter d, length l, and density δ has a total weight expressed by the formula

$$W = \delta l \frac{\pi d^2}{4} \tag{4-16}$$

The weight of any conductor is commonly expressed in pounds per unit of length, such as 1 ft, 1000 ft, or 1 mi. The weight of stranded conductors can be calculated using Eq. (4-16), but allowance must be made for increase in weight due to stranding. Rope-lay stranding has greater increase in weight because of the multiple stranding operations.

Breaking Strength. The maximum load that a conductor attains when tested in tension to rupture.

Total Elongation at Rupture. When a sample of any material is tested under tension until it ruptures, measurement is usually made of the total elongation in a certain initial test length. In certain kinds of testing, the initial test length has been standardized, but in every case, the total elongation at rupture should be referred to the initial test length of the sample on which it was measured. Such elongation is usually expressed in percentage of original unstressed length and is a general index of the ductility of the material. Elongation is determined on solid conductors or on individual wires before stranding; it is rarely determined on stranded conductors.

Elasticity. All materials are deformed in greater or lesser degree under application of mechanical stress. Such deformation may be either of two kinds, known, respectively, as *elastic deformation* and *permanent deformation.* When a material is subjected to stress and undergoes deformation but resumes its original shape and dimensions when the stress is removed, the deformation is said to be *elastic*. If the stress is so great that the material fails to resume its original dimensions when the stress is removed, the permanent change in dimensions is termed *permanent deformation* or *set*. In general, the stress at which appreciable permanent deformation begins is termed the *working elastic limit*. Below this limit of stress the behavior of the material is said to be *elastic,* and in general, the deformation is proportional to the stress.

Stress and Strain. The *stress* in a material under load, as in simple tension or compression, is defined as the total load divided by the area of cross section normal to the direction of the load, assuming the load to be uniformly distributed over this cross section. It is commonly expressed in pounds per square inch. The *strain* in a material under load is defined as the total deformation measured in

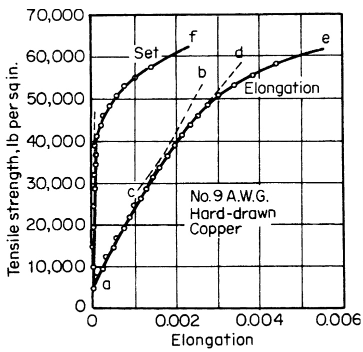

FIGURE 4-2 Stress-strain curves of No. 9 AWG hard-drawn copper wire. (Watertown Arsenal test).

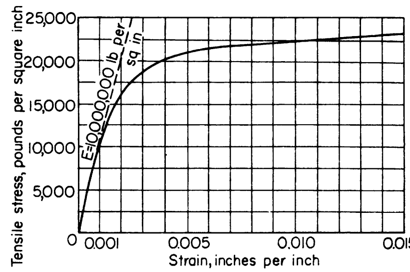

FIGURE 4-3 Typical stress-strain curve of hard drawn aluminum wire.

the direction of the stress, divided by the total unstressed length in which the measured deformation occurs, or the deformation per unit length. It is expressed as a decimal ratio or numeric.

In order to show the complete behavior of any given conductor under tension, it is customary to make a graph in terms of loading or stress as the ordinates and elongation or strain as the abscissas. Such graphs or curves are useful in determining the elastic limit and the yield point if the loading is carried to the point of rupture. Graphs showing the relationship between stress and strain in a material tested to failure are termed *load-deformation* or *stress-strain curves.*

Hooke's law consists of the simple statement that the stress is proportional to the strain. It obviously implies a condition of perfect elasticity, which is true only for stresses less than the elastic limit.

Stress-Strain Curves. A typical stress-strain diagram of hard-drawn copper wire is shown in Fig. 4-2, which represents No. 9 AWG. The curve *ae* is the actual stress-strain curve; *ab* represents the portion which corresponds to true elasticity, or for which Hooke's law holds rigorously; *cd* is the tangent *ae* which fixes the Johnson elastic limit; and the curve *af* represents the set, or permanent elongation due to flow of the metal under stress, being the difference between *ab* and *ae*. A typical stress-strain diagram of hard-drawn aluminum wire, based on data furnished by the Aluminum Company of America, is shown in Fig. 4-3.

Modulus (or Coefficient) of Elasticity. *Modulus (or coefficient) of elasticity* is the ratio of internal stress to the corresponding strain or deformation. It is a characteristic of each material, form (shape or structure), and type of stressing. For deformations involving changes in both volume and shape, special coefficients are used. For conductors under axial tension, the ratio of stress to strain is called *Young's modulus.*

If F is the total force or load acting uniformly on the cross section A, the stress is F/A. If this magnitude of stress causes an elongation e in an original length l, the strain is e/l. Young's modulus is then expressed

$$M = \frac{Fl}{Ae} \tag{4-17}$$

If a material were capable of sustaining an elastic elongation sufficient to make e equal to l, or such that the elongated length is double the original length, the stress required to produce this result would equal the modulus. This modulus is very useful in computing the sags of overhead conductor spans under loads of various kinds. It is usually expressed in pounds per square inch.

Stranding usually lowers the Young's modulus somewhat, rope-lay stranding to a greater extent than concentric-lay stranding. When a new cable is subjected initially to tension and the loading is carried up to the maximum working stress, there is an apparent elongation which is greater than the subsequent elongation under the same loading. This is apparently due to the removal of a very slight slackness in the individual wires, causing them to fit closely together and adjust themselves to the conditions of tension in the strand. When a new cable is loaded to the working limit, unloaded, and then reloaded, the value of Young's modulus determined on initial loading may be on the order of one-half to two-thirds of its true value on reloading. The latter figure should approach within a few percent of the modulus determined by test on individual straight wires of the same material.

For those applications where elastic stretching under tension needs consideration, the stress-strain curve should be determined by test, with the precaution not to prestress the cable before test unless it will be prestressed when installed in service. Commercially used values of Young's modulus for conductors are given in Table 4-1.

*For stranded cables the moduli are usually less than for solid wire and vary with number and arrangement of strands, tightness of stranding, and length of lay. Also, during initial application of stress, the stress-strain relation follows a curve throughout the upper part of the range of stress commonly used in transmission-line design.

†Final modulus is the ratio of stress to strain (slope of the curve) obtained after fully prestressing the conductor. It is used in calculating design or final sags and tensions.

‡Virtual initial modulus is the ratio of stress to strain (slope of the curve) obtained during initial sustained loading of new conductor. It is used in calculating initial or stringing sags and tensions.

Young's Modulus for ACSR. The permanent modulus of ACSR depends on the proportions of steel and aluminum in the cable and on the distribution of stress between aluminum and steel. This latter condition depends on temperature, tension, and previous maximum loadings. Because of the interchange of stress between the steel and the aluminum caused by changes of tension and temperature, computer programs are ordinarily used for sag-tension calculations.

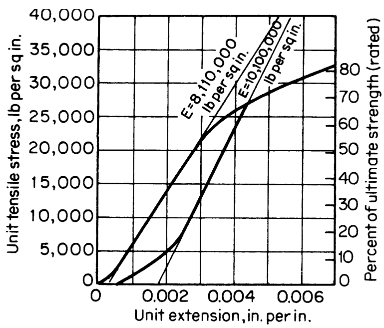

FIGURE 4-4 Repeated stress-strain curve, 795,000 cmil ACSR; 54 × 0.1212 aluminum strands, 7 × 0.1212 steel strands.

Because ACSR is a composite cable made of aluminum and steel wires, additional phenomena occur which are not found in tests of cable composed of a single material. As shown in Fig. 4-4, the part of the curve obtained in the second stress cycle contains a comparatively large "foot" at its base, which is caused by the difference in extension at the elastic limits of the aluminum and steel.

Elastic Limit. This is variously defined as the limit of stress beyond which permanent deformation occurs or the stress limit beyond which Hooke's law ceases to apply or the limit beyond which the stresses are not proportional to the strains or the *proportional limit*. In some materials, the elastic limit occurs at a point which is readily determined, but in others it is quite difficult to determine because the stress-strain curve deviates from a straight line but very slightly at first, and the point of departure from true linear relationship between stress and strain is somewhat indeterminate.

Dean J. B. Johnson of the University of Wisconsin, well-known authority on materials of construction, proposed the use of an arbitrary determination referred to frequently as the *Johnson definition of elastic limit*. This proposal, which has been quite largely used, was that an *apparent elastic limit* be employed, defined as that point on the stress-strain curve at which the rate of deformation is 50% greater than at the origin. The apparent elastic limit thus defined is a practical value, which is suitable for engineering purposes because it involves negligible permanent elongation.

The *Johnson elastic limit* is that point on the stress-strain curve at which the natural tangent is equal to 1.5 times the tangent of the angle of the straight or linear portion of the curve, with respect to the axis of ordinates, or *Y* axis.

Yield Point. In many materials, a point is reached on the stress-strain diagram at which there is a marked increase in strain or elongation without an increase in stress or load. The point at which this occurs is termed the *yield point*. It is usually quite noticeable in ductile materials but may be scarcely perceptible or possibly not present at all in certain hard-drawn materials such as hard-drawn copper.

Prestressed Conductors. In the case of some materials, especially those of considerable ductility, which tend to show permanent elongation or "drawing" under loads just above the initial elastic limit, it is possible to raise the working elastic limit by loading them to stresses somewhat above the elastic limit as found on initial loading. After such loading, or prestressing, the material will behave according to Hooke's law at all loads less than the new elastic limit. This applies not only to many ductile materials, such as soft or annealed copper wire, but also to cables or stranded conductors, in which there is a slight inherent slack or looseness of the individual wires that can be removed only under actual loading. It is sometimes the practice, when erecting such conductors for service, to prestress them to the working elastic limit or safe maximum working stress and then reduce the stress to the proper value for installation at the stringing temperature without wind or ice.

Resistance. *Resistance* is the property of an electric circuit or of any body that may be used as part of an electric circuit which determines for a given current the average rate at which electrical energy is converted into heat. The term is properly applied only when the rate of conversion is proportional to the square of the current and is then equal to the power conversion divided by the square of the current. A uniform cylindrical conductor of diameter d, length l, and *volume resistivity* ρ has a total resistance to continuous currents expressed by the formula

$$R = \frac{\rho l}{\pi d^2/4} \tag{4-18}$$

The resistance of any conductor is commonly expressed in ohms per unit of length, such as 1 ft, 1000 ft, or 1 mi. When used for conducting alternating currents, the effective resistance may be higher than the dc resistance defined above. In the latter case, it is a common practice to apply the proper factor, or ratio of effective ac resistance to dc resistance, sometimes termed the *skin-effect resistance ratio*. This ratio may be determined by test, or it may be calculated if the necessary data are available.

Magnetic Permeability. *Magnetic permeability* applies to a field in which the flux is uniformly distributed over a cross section normal to its direction or to a sufficiently small cross section of a nonuniform field so that the distribution can be assumed as substantially uniform. In the case of a cylindrical conductor, the magnetomotive force (mmf) due to the current flowing in the conductor varies from zero at the center or axis to a maximum at the periphery or surface of the conductor and sets up a flux in circular paths concentric with the axis and perpendicular to it but of nonuniform distribution between the axis and the periphery. If the permeability is nonlinear with respect to the mmf, as is usually true with magnetic materials, there is no correct single value of permeability which fits the conditions, although an apparent or equivalent average value can be determined. In the case of other forms of cross section, the distribution is still more complex, and the equivalent permeability may be difficult or impossible to determine except by test.

Internal Inductance. A uniform cylindrical conductor of nonmagnetic material, or of unit permeability, has a constant magnitude of internal inductance per unit length, independent of the conductor diameter. This is commonly expressed in microhenrys or millihenrys per unit of length, such as 1 ft, 1000 ft, or 1 mi. When the conductor material possesses magnetic susceptibility, and when the magnetic permeability μ is constant and therefore independent of the current strength, the internal inductance is expressed in absolute units by the formula

$$L = \frac{\mu l}{2} \tag{4-19}$$

In most cases, μ is not constant but is a function of the current strength. When this is true, there is an effective permeability, one-half of which ($\mu/2$) expresses the inductance per centimeter of length, but this figure of permeability is virtually the ratio of the effective inductance of the conductor of susceptible material to the inductance of a conductor of material which has a permeability of unity. When used for conducting alternating currents, the effective inductance may be less than the inductance with direct current; this is also a direct consequence of the same skin effect which results in an increase of effective resistance with alternating currents, but the overall effect is usually included in the figure of effective permeability. It is usually the practice to determine the effective internal inductance by test, but it may be calculated if the necessary data are available.

Skin Effect. *Skin effect* is a phenomenon which occurs in conductors carrying currents whose intensity varies rapidly from instant to instant but does not occur with continuous currents. It arises from the fact that elements or filaments of variable current at different points in the cross section of a conductor do not encounter equal components of inductance, but the central or axial filament meets the maximum inductance, and in general the inductance offered to other filaments of current decreases as the distance of the filament from the axis increases, becoming a minimum at the surface or periphery of the conductor. This, in turn, tends to produce unequal current density over the cross section as a whole; the density is a minimum at the axis and a maximum at the periphery. Such distribution of the current density produces an increase in effective resistance and a decrease in effective internal inductance; the former is of more practical importance than the latter. In the case of large copper conductors at commercial power frequencies and in the case of most conductors at carrier and radio frequencies, the increase in resistance should be considered.

Skin-Effect Ratios. If R' is the effective resistance of a linear cylindrical conductor to sinusoidal alternating current of given frequency and R is the true resistance with continuous current, then

$$R' = KR \quad \text{ohms} \tag{4-20}$$

where K is determined from Table 4-2 in terms of x. The value of x is given by

$$x = 2\pi a \sqrt{\frac{2f\mu}{\rho}} \tag{4-21}$$

where a is the radius of the conductor in centimeters, f is the frequency in cycles per second, μ is the magnetic permeability of the conductor (here assumed to be constant), and ρ is the resistivity in abohm-centimeters (abohm $= 10^{-9}\ \Omega$).

For practical calculation, Eq. (4-21) can be written

$$x = 0.063598\sqrt{\frac{f\mu}{R}} \tag{4-22}$$

where R is dc resistance at operating temperature in ohms per mile.

If L' is the effective inductance of a linear conductor to sinusoidal alternating current of a given frequency, then

$$L' = L_1 + K'L_2 \tag{4-23}$$

where L_1 is external portion of inductance, L_2 is internal portion (due to the magnetic field within the conductor), and K' is determined from Table 4-2 in terms of x. Thus, the total effective inductance per unit length of conductor is

$$L' = 2\ln\frac{d}{a} + K'\frac{\mu}{2} \tag{4-24}$$

The inductance is here expressed in abhenrys per centimeter of conductor, in a linear circuit; a is the radius of the conductor, and d is the separation between the conductor and its return conductor, expressed in the same units.

Values of K and K' in terms of x are shown in Table 4-2 and Figs. 4-5 and 4-6 (see *NBS Circ*. 74, pp. 309–311, for additional tables, and *Sci. Paper* 374).

Value of μ for nonmagnetic materials (copper, aluminum, etc.) is 1; for magnetic materials, it varies widely with composition, processing, current density, etc., and should be determined by test in each case.

Alternating-Current Resistance. For small conductors at power frequencies, the frequency has a negligible effect, and dc resistance values can be used. For large conductors, frequency must be taken into account in addition to temperature effects. To do this, first calculate the dc resistance at the operating temperature, then determine the skin-effect ratio K, and finally determine the ac resistance at operating temperature.

AC resistance for copper conductors *not* in close proximity can be obtained from the skin-effect ratios given in Tables 4-2 and 4-3.

AC Resistance for Aluminum Conductors. The increase in resistance and decrease in internal inductance of cylindrical aluminum conductors can be determined from data. It is not the same as for copper conductors of equal diameter but is slightly less because of the higher volume resistivity of aluminum.

AC Resistance for ACSR. In the case of ACSR conductors, the steel core is of relatively high resistivity, and therefore its conductance is usually neglected in computing the total resistance of such strands. The effective permeability of the grade of steel employed in the core is also relatively small. It is approximately correct to assume that such a strand is hollow and consists exclusively of its aluminum wires; in this case, the laws of skin effect in tubular conductors will be applicable. Conductors having a single layer of aluminum wires over the steel core have higher ac/dc ratios than those having multiple layers of aluminum wires.

Inductive Reactance. Present practice is to consider inductive reactance as split into two components: (1) that due to flux within a radius of 1 ft including the internal reactance within the conductor of radius r and (2) that due to flux between 1 ft radius and the equivalent conductor spacing D_s or geometric mean distance (GMD). The fundamental inductance formula is

$$L = 2 \ln \frac{D_s}{r} + \frac{\mu}{2} \qquad \text{abH/(cm)(conductor)} \tag{4-25}$$

This can be rewritten

$$L = 2 \ln \frac{D_s}{1} + 2 \ln \frac{1}{r} + \frac{\mu}{2} \tag{4-26}$$

where the term $2 \ln (D_s/1)$ represents inductance due to flux between 1 ft radius and the equivalent conductor spacing, and $2 \ln (1/r) + (\mu/2)$ represents the inductance due to flux within 1 ft radius [$2 \ln (1/r)$ represents inductance due to flux between conductor surface and 1 ft radius, and $\mu/2$ represents internal inductance due to flux within the conductor].

By definition, *geometric mean radius* (GMR) of a conductor is the radius of an infinitely thin tube having the same internal inductance as the conductor. Therefore,

$$L = 2 \ln \frac{D_s}{1} + 2 \ln \frac{1}{\text{GMR}} \tag{4-27}$$

Since inductive reactance $= 2\pi fL$, for practical calculation Eq. (4-27) can be written

$$X = 0.004657 f \log \frac{D_s}{1} + 0.004657 f \log \frac{1}{\text{GMR}} \qquad \Omega\text{/(mi)(conductor)} \tag{4-28}$$

In the conductor tables in this section, inductive reactance is calculated from Eq. (4-28), considering that

$$X = x_a + x_d \tag{4-29}$$

Inductive reactance for conductors using steel varies in a manner similar to ac resistance.

Capacitive Reactance. The capacitive reactance can be considered in two parts also, giving

$$X = \frac{4.099}{f} \log \frac{D_s}{1} + \frac{4.099}{f} \log \frac{1}{r} \qquad \text{M}\Omega\text{/(mi)(conductor)} \tag{4-30}$$

In the conductor tables in this section, capacitive reactance is calculated from Eq. (4-30), it being considered that

$$X' = x'_a + x'_d \tag{4-31}$$

It is important to note that in capacitance calculations the conductor radius used is the actual physical radius of the conductor.

Capacitive Susceptance

$$B = \frac{1}{x_a' + x_d'} \qquad \mu\text{S(mi)(conductor)} \tag{4-32}$$

Charging Current

$$I_C = eB \times 10^{-3} \qquad \text{A/(mi)(conductor)} \tag{4-33}$$

where e is voltage to neutral in kilovolts.

Bus Conductors. *Bus conductors* require that greater attention be given to certain physical and electrical characteristics of the metals than is usually necessary in designing line conductors. These characteristics are current-carrying capacity, emissivity, skin effect, expansion, and mechanical deflection. To obtain the most satisfactory and economical designs for bus bars in power stations and substations, where they are used extensively, consideration must be given to choice not only of material but also of shape. Both copper and aluminum are used for bus bars, and in certain outdoor substations, steel has proved satisfactory. The most common bus bar form for carrying heavy current, especially indoors, is flat copper bar. Bus bars in the form of angles, channels, and tubing have been developed for heavy currents and, because of better distribution of the conducting material, make more efficient use of the metal both electrically and mechanically. All such designs are based on the need for proper current-carrying capacity without excess bus bar temperatures and on the necessity for adequate mechanical strength.

Hollow (Expanded) Conductors. Hollow (expanded) conductors are used on high-voltage transmission lines when, in order to reduce corona loss, it is desirable to increase the outside diameter without increasing the area beyond that needed for maximum line economy. Not only is the initial corona voltage considerably higher than for conventional conductors of equal cross section, but the current-carrying capacity for a given temperature rise is also greater because of the larger surface area available for cooling and the better disposition of the metal with respect to skin effect when carrying alternating currents.

Air-expanded ACSR is a conductor whose diameter has been increased by aluminum skeletal wires between the steel core and the outer layers of aluminum strands creating air spaces. A conductor having the necessary diameter to minimize corona effects on lines operating above 300 kV will, many times, have more metal than is economical if the conductor is made conventionally.

Composite Conductors. *Composite conductors* are those made up of usually two different types of wire having differing characteristics. They are generally designed for a ratio of physical and electrical characteristics different from those found in homogeneous materials. *Aluminum conductors, steel reinforced (ACSR)* and *aluminum conductors, aluminum alloy reinforced (ACAR)* are types commonly used in overhead transmission and distribution lines.

Cables of this type are particularly adaptable to long-span construction or other service conditions requiring more than average strength combined with liberal conductance. They lend themselves readily to economical, dependable use on transmission lines, rural distribution lines, railroad electrification, river crossings, and many kinds of special construction.

Self-damping ACSR conductors are used to limit aeolian vibration to a safe level regardless of conductor tension or span length. They are concentrically stranded conductors composed of two layers of trapezoidal-shaped wires or two layers of trapezoidal-shaped wires and one layer of round wires of 1350 (EC) alloy with a high-strength, coated steel core. The trapezoidal wire layers are self-supporting, and separated by gaps from adjacent layers (Fig. 4-7). Impact between layers during aeolian vibration causes damping action.

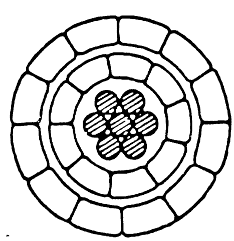

FIGURE 4-7 Self-damping ACSR conductor.

ACSR/TW is similar to self-damping ACSR in its use of trapezoidal-shaped wires, but does not have the annular gaps between layers. ACSR/TW has a smaller diameter and smoother surface than conventional round-wire ACSR of the same area, and thus may have reduced wind loading.

T2 conductors are fabricated by twisting two conventional conductors together with a pitch of about 9 ft (2.7 m). Severity of wind-induced galloping when the conductor is coated with ice is reduced because an ice profile that is uniform along the conductor length cannot form on the variable profile presented by the conductor.

Steel-supported aluminum conductors (SSAC) are similar to conventional ACSR but employ an aluminum alloy in the annealed condition. The annealed aluminum has increased electrical conductivity, and the conductor has improved sag-tension characteristics for high-temperature service.

4.1.4 Fusible Metals and Alloys

Fusible alloys having melting points in the range from about 60 to 200°C are made principally of bismuth, cadmium, lead, and tin in various proportions. Many of these alloys have been known under the names of their inventors (see index of alloys in *International Critical Tables*, vol. 2).

Fuse metals for electric fuses of the open-link enclosed and expulsion types are ordinarily made of some low-fusible alloy; aluminum also is used to some extent. The resistance of the fuse causes dissipation of energy, liberation of heat, and rise of temperature. Sufficient current obviously will melt the fuse, and thus open the circuit if the resulting arc is self-extinguishing. Metals which volatilize readily in the heat of the arc are to be preferred to those which leave a residue of globules of hot metal. The rating of any fuse depends critically on its shape, dimensions, mounting, enclosure, and any other factors which affect its heat-dissipating capacity.

Fusing currents of different kinds of wire were investigated by W. H. Preece, who developed the formula

$$I = ad^{3/2} \tag{4-34}$$

where I is fusing current in amperes, d is diameter of the wire in inches, and a is a constant depending on the material. He found the following values for a:

Copper	10,244	Iron	3,148
Aluminum	7,585	Tin	1,642
Platinum	5,172	Alloy (2Pb-1Sn)	1,318
German silver	5,230	Lead	1,379
Platinoid	4,750		

Although this formula has been used to a considerable extent in the past, it gives values that usually are erroneous in practice because it is based on the assumption that all heat loss is due to radiation. A formula of the general type

$$I = kd^n \tag{4-35}$$

can be used with accuracy if k and n are known for the particular case (material, wire size, installation conditions, etc.).

Fusing current-time for copper conductors and connections may be determined by an equation developed by I. M. Onderdonk

$$33\left(\frac{I}{A}\right)^2 S = \log\left(\frac{T_m - T_a}{234 + T_a} + 1\right) \tag{4-36}$$

$$I = A\sqrt{\frac{\log\left(\frac{T_m - T_a}{234 + T_a} + 1\right)}{33S}} \tag{4-37}$$

where I is current in amperes, A is conductor area in circular mils, S is time current applied in seconds, T_m is melting point of copper in degrees Celsius, and T_a is ambient temperature in degrees Celsius.

4.1.5 Miscellaneous Metals and Alloys

Contact Metals. *Contact metals* may be grouped into three general classifications:

Hard metals, which have high melting points, for example, tungsten and molybdenum. Contacts of these metals are employed usually where operations are continuous or very frequent and current has nominal value of 5 to 10 A. Hardness to withstand mechanical wear and high melting point to resist arc erosion and welding are their outstanding advantages. A tendency to form high-resistance oxides is a disadvantage, but this can be overcome by several methods, such as using high-contact force, a hammering or wiping action, and a properly balanced electric circuit.

Highly conductive metals, of which silver is the best for both electric current and heat. Its disadvantages are softness and a tendency to pit and transfer. In sulfurous atmosphere, a resistant sulfide surface will form on silver, which results in high contact-surface resistance. These disadvantages are overcome usually by alloying.

Noncorroding metals, which for the most part consist of the noble metals, such as gold and the platinum group. Contacts of these metals are used on sensitive devices, employing extremely light pressures or low current in which clean contact surfaces are essential. Because most of these metals are soft, they are usually alloyed.

The metals commonly used are tungsten, molybdenum, platinum, palladium, gold, silver, and their alloys. Alloying materials are copper, nickel, cadmium, iron, and the rarer metals such as iridium and ruthenium. Some are prepared by powder metallurgy.

Tungsten. *Tungsten* (W) is a hard, dense, slow-wearing metal, a good thermal and electrical conductor, characterized by its high melting point and freedom from sticking or welding. It is manufactured in several grades having various grain sizes.

Molybdenum. *Molybdenum* (Mo) has contact characteristics about midway between tungsten and fine silver. It often replaces either metal where greater wear resistance than that of silver or lower contact-surface resistance than that of tungsten is desired.

Platinum. *Platinum* (Pt) is one of the most stable of all metals under the combined action of corrosion and electrical erosion. It has a high melting point and does not corrode and surfaces remain clean and low in resistance under most adverse atmospheric and electrical conditions. *Platinum alloys* of iridium (Ir), ruthenium (Ru), silver (Ag), or other metals are used to increase hardness and resistance to wear.

Palladium. *Palladium* (Pd) has many of the properties of platinum and is frequently used as an alternate for platinum and its alloys. *Palladium alloys* of silver (Ag), ruthenium (Ru), nickel (Ni), and other metals are used to increase hardness and resistance to wear.

Gold. *Gold* (Au) is similar to platinum in corrosion resistance but has a much lower melting point. Gold and its alloys are ductile and easily formed into a variety of shapes. Because of its softness, it is usually alloyed. *Gold alloys* of silver (Ag) and other metals are used to impart hardness and improve resistance to mechanical wear and electrical erosion.

Silver. *Silver* (Ag) has the highest thermal and electrical conductivity (110%, IACS) of any metal. It has low contact-surface resistance, since its oxide decomposes at approximately 300°F. It is available commercially in three grades:

Grade	Typical composition, %	
	Silver	Copper
Fine silver	99.95+	
Sterling silver	92.5	7.5
Coin silver	90	10

Fine silver is used extensively under low contact pressure where sensitivity and low contact-surface resistance are essential or where the circuit is operated infrequently.

Sterling and coin silvers are harder than fine silver and resist transfer at low voltage (6 to 8 V) better than fine silver. Since their contact-surface resistance is greater than that of fine silver, higher contact-closing forces should be used.

Silver alloys of copper (Cu), nickel (Ni), cadmium (Cd), iron (Fe), carbon (C), tungsten (W), molybdenum (Mo), and other metals are used to improve hardness, resistance to wear and arc erosion, and for special applications.

Selenium. *Selenium* is a nonmetallic element chemically resembling sulfur and tellurium and occurs in several allotropic forms varying in specific gravity from 4.3 to 4.8. It melts at 217°C and boils at 690°C. At 0°C, it has a resistivity of approximately 60,000 Ω · cm. The dielectric constant ranges from 6.1 to 7.4. It has the peculiar property that its resistivity decreases on exposure to light; the resistivity in darkness may be anywhere from 5 to 200 times the resistivity under exposure to light.

4.2 MAGNETIC MATERIALS

4.2.1 Definitions

The following definitions of terms relating to magnetic materials and the properties and testing of these materials have been selected from ASTM Standard. Terms primarily related to magnetostatics are indicated by the symbol * and those related to magnetodynamics are indicated by the symbol **. General (nonrestricted) terms are not marked.

***AC Excitation N_1I/l_1.* The ratio of the rms ampere-turns of exciting current in the primary winding of an inductor to the effective length of the magnetic path.

***Active (Real) Power P.* The product of the rms current I in an electric circuit, the rms voltage E across the circuit, and the cosine of the angular phase difference θ between the current and the voltage.

$$P = EI\cos\theta \tag{4-38}$$

NOTE: The portion of the active power that is expended in a magnetic core is the total core loss P_c.

Aging, Magnetic. The change in the magnetic properties of a material resulting from metallurgical change. This term applies whether the change results from a continued normal or a specified accelerated aging condition.

NOTE: This term implies a deterioration of the magnetic properties of magnetic materials for electronic and electrical applications, unless otherwise specified.

Ampere-turn. Unit of magnetomotive force in the rationalized mksa system. One ampere-turn equals 4π/10, or 1.257 gilberts.

Ampere-turn per Meter. Unit of magnetizing force (magnetic field strength) in the rationalized mksa system. One ampere-turn per meter is $4\pi \times 10^{-3}$, or 0.01257 oersted.

Anisotropic Material. A material in which the magnetic properties differ in various directions.

Antiferromagnetic Material. A feebly magnetic material in which almost equal magnetic moments are lined up antiparallel to each other. Its susceptibility increases as the temperature is raised until a critical (Neél) temperature is reached; above this temperature the material becomes paramagnetic.

**Apparent Power P_a.* The product (volt-amperes) of the rms exciting current and the applied rms *terminal* voltage in an *electric* circuit containing inductive impedance. The components of this impedance due to the winding will be linear, while the components due to the magnetic core will be nonlinear.

**Apparent Power; Specific, $P_{a(B,f)}$.* The value of the apparent power divided by the active mass of the specimen (volt-amperes per unit mass) taken at a specified maximum value of cyclically varying induction B and at a specified frequency f.

Coercive Force H_c. The (dc) magnetizing force at which the magnetic induction is zero when the material is in a symmetrically cyclically magnetized condition.

Coercive Force, Intrinsic, H_{ci}. The (dc) magnetizing force at which the intrinsic induction is zero when the material is in a symmetrically cyclically magnetized condition.

Coercivity H_{cs}. The maximum value of coercive force.

**Core Loss; Specific, $P_{c(B,f)}$.* The active power (watts) expended per unit mass of magnetic material in which there is a cyclically varying induction of a specified maximum value B at a specified frequency f.

**Core Loss (Total) P_c.* The active power (watts) expended in a magnetic circuit in which there is a cyclically alternating induction.

NOTE: Measurements of core loss are normally made with sinusoidally alternating induction, or the results are corrected for deviations from the sinusoidal condition.

Curie Temperature T_c. The temperature above which a ferromagnetic material becomes paramagnetic.

Demagnetization Curve. That portion of a normal (dc) hysteresis loop which lies in the second or fourth quadrant, that is, between the residual induction point B_r and the coercive force point H_c. Points on this curve are designated by the coordinates B_d and H_d.

Diamagnetic Material. A material whose relative permeability is less than unity.

NOTE: The intrinsic induction B_i, is oppositely directed to the applied magnetizing force H.

Domains, Ferromagnetic. Magnetized regions, either macroscopic or microscopic in size, within ferromagnetic materials. Each domain per se is magnetized to intrinsic saturation at all times, and this saturation induction is unidirectional within the domain.

**Eddy-Current Loss, Normal, P_e.* That portion of the core loss which is due to induced currents circulating in the magnetic material subject to an *SCM* excitation.

Energy Product B_dH_d. The product of the coordinate values of any point on a demagnetization curve.

Energy-Product Curve, Magnetic. The curve obtained by plotting the product of the corresponding coordinates B_d and H_d of points on the demagnetization curve as abscissa against the induction B_d as ordinates.

NOTE 1: The maximum value of the energy product $(B_dH_d)_m$ corresponds to the maximum value of the external energy.

NOTE 2: The demagnetization curve is plotted to the left of the vertical axis and usually the energy-product curve to the right.

**Exciting Power, rms, P_z.* The product of the rms exciting current and the rms voltage induced in the exciting (primary) winding on a magnetic core.

NOTE: This is the apparent volt-amperes required for the excitation of the magnetic core only. When the core has a secondary winding, the induced primary voltage is obtained from the measured open-circuit secondary voltage multiplied by the appropriate turns ratio.

**Exciting Power, Specific* $P_{z(B,f)}$. The value of the rms exciting power divided by the active mass of the specimen (volt-amperes/unit mass) taken at a specified maximum value of cyclically varying induction B and at specified frequency f.

Ferrimagnetic Material. A material in which unequal magnetic moments are lined up antiparallel to each other. Permeabilities are of the same order of magnitude as those of ferromagnetic materials, but are lower than they would be if all atomic moments were parallel and in the same direction. Under ordinary conditions, the magnetic characteristics of ferrimagnetic materials are quite similar to those of ferromagnetic materials.

Ferromagnetic Material. A material that, in general, exhibits the phenomena of hysteresis and saturation, and whose permeability is dependent on the magnetizing force.

Gauss (Plural Gausses). The unit of magnetic induction in the cgs electromagnetic system. The gauss is equal to 1 maxwell per square centimeter or 10^{-4} T. See *magnetic induction (flux density)*.

Gilbert. The unit of magnetomotive force in the cgs electromagnetic system. The gilbert is a magnetomotive force of $10/4\pi$ ampere-turns. See *magnetomotive force*.

**Hysteresis Loop, Intrinsic.* A hysteresis loop obtained with a ferromagnetic material by plotting (usually to rectangular coordinates) corresponding dc values of intrinsic induction B_i for ordinates and magnetizing force H for abscissas.

**Hysteresis Loop, Normal.* A closed curve obtained with a ferromagnetic material by plotting (usually to rectangular coordinates) corresponding dc values of magnetic induction B for ordinates and magnetizing force H for abscissas when the material is passing through a complete cycle between equal definite limits of either magnetizing force $\pm H_m$ or magnetic induction $\pm B_m$. In general, the normal hysteresis loop has mirror symmetry with respect to the origin of the B and H axes, but this may not be true for special materials.

**Hysteresis-Loop Loss* W_h. The energy expended in a single slow excursion around a normal hysteresis loop is given by the following equation:

$$W_h = \int \frac{HdB}{4\pi} \qquad \text{ergs} \tag{4-39}$$

where the integrated area enclosed by the loop is measured in gauss-oersteds.

***Hysteresis Loss, Normal,* P_h.

1. The power expended in a ferromagnetic material, as a result of hysteresis, when the material is subjected to an *SCM* excitation.

2. The energy loss/cycle in a magnetic material as a result of magnetic hysteresis when the induction is cyclic (but not necessarily periodic).

Hysteresis, Magnetic The property of a ferromagnetic material exhibited by the lack of correspondence between the changes in induction resulting from increasing magnetizing force from decreasing magnetizing force.

Induction B. See *magnetic induction (flux density)*.

**Induction, Intrinsic,* B_i. The vector difference between the magnetic induction in a magnetic material and the magnetic induction that would exist in a vacuum under the influence of the same magnetizing force. This is expressed by the equation

$$B_i = B - \Gamma_m H \tag{4-40}$$

NOTE: In the cgs-em system, $B_i/4\pi$ is often called *magnetic polarization*.

Induction Maximum

*__1.__ B_m—the maximum value of B in a hysteresis loop. The tip of this loop has the magnetostatic coordinates H_m, B_m, which exist simultaneously.

**__2.__ B_{max}—the maximum value of induction, in a flux-current loop.

NOTE: In a flux-current loop, the magnetodynamic values B_{max} and H_{max} do not exist simultaneously; B_{max} occurs later than H_{max}.

**Induction, Normal, B.* The maximum induction in a magnetic material that is in a symmetrically cyclically magnetized condition.

NOTE: Normal induction is a magnetostatic parameter usually measured by hallistic methods.

**Induction, Remanent, B_d.* The magnetic induction that remains in a magnetic circuit after the removal of an applied magnetomotive force.

NOTE: If there are no air gaps or other inhomogeneities in the magnetic circuit, the remanent induction B_r will equal the residual induction B_r; if air gaps or other inhomogeneities are present, B_d will be less than B_r.

**Induction, Residual, B_r.* The magnetic induction corresponding to zero magnetizing force in a magnetic material that is in a symmetrically cyclically magnetized condition.

**Induction, Saturation, B_r.* The maximum intrinsic induction possible in a material.

**Induction Curve, Intrinsic (Ferric).* A curve of a previously demagnetized specimen depicting the relation between intrinsic induction and corresponding ascending values of magnetizing force. This curve starts at the origin of the B_i and H axes.

**Induction Curve, Normal.* A curve of a previously demagnetized specimen depicting the relation between normal induction and corresponding ascending values of magnetizing force. This curve starts at the origin of the B and H axes.

Isotropic Material. Material in which the magnetic properties are the same for all directions.

Magnetic Circuit. A region at whose surface the magnetic induction is tangential.

NOTE: A practical magnetic circuit is the region containing the flux of practical interest, such as the core of a transformer. It may consist of ferromagnetic material with or without air gaps or other feebly magnetic materials such as porcelain and brass.

Magnetic Constant (Permeability of Space) Γ_m. The dimensional scalar factor that relates the mechanical force between two currents to their intensities and geometrical configurations. That is,

$$dF = \Gamma_m I_1 I_2 dl_1 \times \frac{dl_2 \times r_1}{nr^2} \tag{4-41}$$

where Γ_m = magnetic constant when the element of force dF of a current element $I_1\ dl_1$ on another current element $I_2\ dl_2$ is at a distance r

r_1 = unit vector in the direction from dl_1 to dl_2

n = dimensionless factor, the symbol n is unity in unrationalized systems and 4π in rationalized systems

NOTE 1: The numerical values of Γ_m depend on the system of units employed. In the cgs-em system, $\Gamma_m = 1$; in the rationalized mksa system, $\Gamma_m = 4\pi \times 10^{-7}$ h/m.

NOTE 2: The magnetic constant expresses the ratio of magnetic induction to the corresponding magnetizing force at any point in a vacuum and therefore is sometimes called the permeability of space μ_r.

NOTE 3: The magnetic constant times the relative permeability is equal to the absolute permeability:

$$\mu_{abs} = \Gamma_m \mu_r \tag{4-42}$$

Magnetic Field Strength H. See *magnetizing force.*

Magnetic Flux ϕ. The product of the magnetic induction B and the area of a surface (or cross section) A when the magnetic induction B is uniformly distributed and normal to the plane of the surface.

$$\phi = BA \tag{4-43}$$

where ϕ = magnetic flux
B = magnetic induction
A = area of the surface

NOTE 1: If the magnetic induction is not uniformly distributed over the surface, the flux ϕ is the surface integral of the normal component of B over the area:

$$\phi = \iint_s B\, dA \tag{4-44}$$

NOTE 2: Magnetic flux is scalar and has no direction.

Magnetic Flux Density B. See *magnetic induction (flux density).*

Magnetic Induction (Flux Density) B. That magnetic vector quantity which at any point in a magnetic field is measured either by the mechanical force experienced by an element of electric current at the point, or by the electromotive force induced in an elementary loop during any change in flux linkages with the loop at the point.

NOTE 1: If the magnetic induction B is uniformly distributed and normal to a surface or cross section, then the magnetic induction is

$$B = \phi/A \tag{4-45}$$

where B = magnetic induction
ϕ = total flux
A = area

NOTE 2: B_{in} is the instantaneous value of the magnetic induction and B_m is the maximum value of the magnetic induction.

Magnetizing Force (Magnetic Field Strength) H. That magnetic vector quantity at a point in a magnetic field which measures the ability of electric currents or magnetized bodies to produce magnetic induction at the given point.

NOTE 1: The magnetizing force H may be calculated from the current and the geometry of certain magnetizing circuits. For example, in the center of a uniformly wound long solenoid,

$$H = C(NI/l) \tag{4-46}$$

where H = magnetizing force
C = constant whose value depends on the system of units
N = number of turns
I = current
l = axial length of the coil

If I is expressed in amperes and l is expressed in centimeters, then $C = 4\pi/10$ in order to obtain H in the cgs = em unit, the oersted. If I is expressed in amperes and l is expressed in meters, then $C = 1$ in order to obtain H in the mksa unit, ampere-turn per meter.

NOTE 2: The magnetizing force H at a point in air may be calculated from the measured value of induction at the point by dividing this value by the magnetic constant Γ_m.

***Magnetizing Force, AC.* Three different values of dynamic magnetizing force parameters are in common use:

1. H_L—an assumed peak value computed in terms of peak magnetizing current (considered to be sinusoidal).
2. H_x—an assumed peak value computed in terms of measured rms exciting current (considered to be sinusoidal).
3. H_p—computed in terms of a measured peak value of exciting current, and thus equal to the value H'_{max}.

***Magnetodynamic.* The magnetic condition when the values of magnetizing force and induction vary, usually periodically and repetitively, between two extreme limits.

Magnetomotive Force F. The line integral of the magnetizing force around any flux loop in space.

$$F = \oint H\,dl \tag{4-47}$$

where F = magnetomotive force
H = magnetizing force
dl = unit length along the loop

NOTE: The magnetomotive force is proportional to the net current linked with any closed loop of flux or closed path

$$F = CNI \tag{4-48}$$

where F = magnetomotive force
N = number of turns linked with the loop
I = current in amperes
C = constant whose value depends on the system of units. In the cgs system, $C = 4\pi/10$. In the mksa system, $C = 1$

**Magnetostatic.* The magnetic condition when the values of magnetizing force and induction are considered to remain invariant with time during the period of measurement. This is often referred to as a dc (direct-current) condition.

Magnetostriction. Changes in dimensions of a body resulting from magnetization.

Maxwell. The unit of magnetic flux in the cgs electromagnetic system. One maxwell equals 10^{-8} weber. See *magnetic flux.*

NOTE:

$$e = -N\frac{d\phi}{dt} \times 10^{-8} \tag{4-49}$$

where e = induced instantaneous emf volts
$d\phi/dt$ = time rate of change of flux, maxwells per second
N = number of turns surrounding the flux, assuming each turn is linked with all the flux

Oersted. The unit of magnetizing force (magnetic field strength) in the cgs electromagnetic system. One oersted equals a magnetomotive force of 1 gilbert/cm of flux path. One oersted equals $100/4\pi$ or 79.58 ampere-turns per meter. See *magnetizing force (magnetic field strength).*

Paramagnetic Material. A material having a relative permeability which is slightly greater than unity, and which is practically independent of the magnetizing force.

***Permeability, AC.* A generic term used to express various dynamic relationships between magnetic induction B and magnetizing force H for magnetic material subjected to a cyclic excitation by alternating or pulsating current. The values of ac permeability obtained for a given material depend fundamentally on the excursion limits of dynamic excitation and induction, the method and conditions of measurement, and also on such factors as resistivity, thickness of laminations, frequency of excitation, etc.

NOTE: The numerical value for any permeability is meaningless unless the corresponding B or H excitation level is specified. For incremental permeabilities, not only the corresponding dc B or H excitation level must be specified but also the dynamic excursion limits of dynamic excitation range (ΔB or ΔH).

AC permeabilities in common use for magnetic testing are

1. ***Impedance (rms) permeability* μ_z. The ratio of the measured peak value of magnetic induction to the value of the apparent magnetizing force H_z calculated from the measured rms value of the exciting current, for a material in the *SCM* condition.

NOTE: The value of the current used to compute H_z is obtained by multiplying the measured value of rms exciting current by 1.414. This assumes that the total exciting current is magnetizing current and is sinusoidal.

2. ***Inductance permeability* μ_L. For a material in an *SCM* condition, the permeability is evaluated from the measured inductive component of the electric circuit representing the magnetic specimen. This circuit is assumed to be composed of paralleled linear inductive and resistive elements ωL_1 and R_1.

3. ***Peak permeability* μ_p. The ratio of the measured peak value of magnetic induction to the peak value of the magnetizing force H_p, calculated from the measured peak value of the exciting current, for a material in the *SCM* condition.

Other ac permeabilities are:

4. *Ideal permeability* μ_a. The ratio of the magnetic induction to the corresponding magnetizing force after the material has been simultaneously subjected to a value of ac magnetizing force approaching saturation (of approximate sine waveform) superimposed on a given dc magnetizing force, and the ac magnetizing force has thereafter been gradually reduced to zero. The resulting ideal permeability is thus a function of the dc magnetizing force used.

NOTE: Ideal permeability, sometimes called anhysteretic permeability, is principally significant to feebly magnetic material and to the Rayleigh range of soft magnetic material.

5. ***Impedance, permeability, incremental*, $\mu_{\Delta z}$. Impedance permeability μ_z obtained when an ac excitation is superimposed on a dc excitation, *CM* condition.

6. ***Inductance permeability, incremental*, $\mu_{\Delta L}$. Inductance permeability μ_L obtained when an ac excitation is superimposed on a dc excitation, *CM* condition.

7. ***Initial dynamic permeability* μ_{0d}. The limiting value of inductance permeability μ_L reached in a ferromagnetic core when, under *SCM* excitation, the magnetizing current has been progressively and gradually reduced from a comparatively high value to zero value.

NOTE: This same value, μ_{0d}, is also equal to the initial values of both impedance permeability μ_x and peak permeability μ_p.

8. ***Instantaneous permeability (coincident with* B_{max}*)* μ_t. With *SCM* excitation, the ratio of the maximum induction B_{max} to the instantaneous magnetizing force H_t, which is the value of apparent magnetizing force H' determined at the instant when B reaches a maximum.

9. ***Peak permeability, incremental*, $\mu_{\Delta p}$. Peak permeability μ_p obtained when an ac excitation is superimposed on dc excitation, *CM* condition.

**Permeability, DC.* Permeability is a general term used to express relationships between magnetic induction B and magnetizing force H under various conditions of magnetic excitation. These relationships are either (1) absolute permeability, which in general is the quotient of a change in magnetic induction divided by the corresponding change in magnetizing force, or (2) relative permeability, which is the ratio of the absolute permeability to the magnetic constant Γ_m.

NOTE 1: The magnetic constant Γ_m is a scalar quantity differing in value and uniquely determined by each electromagnetic system of units. In the unrationalized cgs system, Γ_m is 1 gauss/oersted and in the mksa rationalized system $\Gamma_m = 4\pi \times 10^{-7}$ H/m.

NOTE 2: Relative permeability is a pure number which is the same in all unit systems. The value and dimension of absolute permeability depend on the system of units employed.

NOTE 3: For any ferromagnetic material, permeability is a function of the degree of magnetization. However, initial permeability μ_0 and maximum permeability μ_m are unique values for a given specimen under specified conditions.

NOTE 4: Except for initial permeability μ_0, a numerical value for any of the dc permeabilities is meaningless unless the corresponding B or H excitation level is specified.

NOTE 5: For the incremental permeabilities μ_Δ and $\mu_{\Delta i}$, a numerical value is meaningless unless both the corresponding values of mean excitation level ($\bar{B}$ or $\bar{H}$) and the excursion range (ΔB or ΔH) are specified.

The following dc permeabilities are frequently used in magnetostatic measurements primarily concerned with the testing of materials destined for use with permanent or dc excited magnets:

1. **Absolute permeability* μ_{abs}. The sum of the magnetic constant and the intrinsic permeability. It is also equal to the product of the magnetic constant and the relative permeability.

$$\mu_{\text{abs}} = \Gamma_m + \mu_i = \Gamma_m \mu_r \tag{4-50}$$

2. **Differential permeability* μ_d. The absolute value of the slope of the hysteresis loop at any point, or the slope of the normal magnetizing curve at any point.

3. **Effective circuit permeability* μ_{eff}. When a magnetic circuit consists of two or more components, each individually homogeneous throughout but having different permeability values, the effective (overall) permeability of the circuit is that value computed in terms of the total magnetomotive force, the total resulting flux, and the geometry of the circuit.

NOTE: For a symmetrical series circuit in which each component has the same cross-sectional area, reluctance values add directly, giving

$$\mu_{\text{eff}} = \frac{l_1 + l_2 + l_3 + \cdots}{l_1/\mu_1 + l_2/\mu_2 + l_3/\mu_3 + \cdots} \tag{4-51}$$

For a symmetrical parallel circuit in which each component has the same flux path length, permeance values add directly, giving

$$\mu_{\text{eff}} = \frac{\mu_1 A_1 + \mu_2 A_2 + \mu_3 A_3 + \cdots}{A_1 + A_2 + A_3 + \cdots} \tag{4-52}$$

4. **Incremental intrinsic permeability* $\mu_{\Delta i}$. The ratio of the change in intrinsic induction to the corresponding change in magnetizing force when the mean induction differs from zero.

5. **Incremental permeability* μ_Δ. The ratio of a change in magnetic induction to the corresponding change in magnetizing force when the mean induction differs from zero. It equals the slope of a straight line joining the excursion limits of an incremental hysteresis loop.

NOTE: When the change in H is reduced to zero, the incremental permeability μ_Δ becomes the reversible permeability μ_{rev}.

6. **Initial permeability* μ_0. The limiting value approached by the normal permeability as the applied magnetizing force H is reduced to zero. The permeability is equal to the slope of the normal induction curve at the origin of linear B and H axes.

7. **Intrinsic permeability* μ_i. The ratio of intrinsic induction to the corresponding magnetizing force.

8. **Maximum permeability* μ_m. The value of normal permeability for a given material where a straight line from the origin of linear B and H axes becomes tangent to the normal induction curve.

9. **Normal permeability* μ *(without subscript)*. The ratio of the normal induction to the corresponding magnetizing force. It is equal to the slope of a straight line joining the extrusion limits of a normal hysteresis loop, or the slope of a straight line joining any point (H_m, B_m) on the normal induction curve to the origin of the linear B and H axes.

10. **Relative permeability* μ_r. The ratio of the absolute permeability of a material to the magnetic constant Γ_m giving a pure numeric parameter.

NOTE: In the cgs-em system of units, the relative permeability is numerically the same as the absolute permeability.

11. *Reversible permeability* μ_{rev}. The limit of the incremental permeability as the change in magnetizing force approaches zero.

12. *Space permeability* μ_o. The permeability of space (vacuum), identical with the magnetic constant Γ_m.

***Reactive Power (Quadrature Power)* P_q. The product of the rms current in an electric circuit, the rms voltage across the circuit, and the sine of the angular phase difference between the current and the voltage.

$$P_q = EI \sin \theta \tag{4-53}$$

where P_q = reactive power, vars
E = voltage, volts
I = current, amperes
θ = angular phase by which E leads I

NOTE: The reactive power supplied to a magnetic core having an *SCM* excitation is the product of the magnetizing current and the voltage induced in the exciting winding.

**Remanence* B_{dm}. The maximum value of the remanent induction for a given geometry of the magnetic circuit.

NOTE: If there are no air gaps or other inhomogeneities in the magnetic circuit, the remanence B_{dm} is equal to the retentivity B_{rs}; if air gaps or other inhomogeneities are present, B_{dm} will be less than B_{rs}.

**Retentivity* B_{rs}. That property of a magnetic material which is measured by its maximum value of the residual induction.

NOTE: Retentivity is usually associated with saturation induction.

Symmetrically Cyclically Magnetized Condition, SCM. A magnetic material is in an *SCM* condition when, under the influence of a magnetizing force that varies cyclically between two equal positive and negative limits, its successive hysteresis loops or flux-current loops are both identical and symmetrical with respect to the origin of the axes.

Tesla. The unit of magnetic induction in the mksa (Giorgi) system. The tesla is equal to 1 Wb/m^2 or 10^4 gausses.

Var. The unit of reactive (quadrature) power in the mksa (Giorgi) and the practical systems.

Volt-Ampere. The unit of apparent power in the mksa (Giorgi) and the practical systems.

Watt. The unit of active power in the mksa (Giorgi) and the practical systems. One watt is a power of 1 J/s.

Weber. The unit of magnetic flux in the mksa and in the practical system. The weber is the magnetic flux whose decrease to zero when linked with a single turn induces in the turn a voltage whose time integral is 1 v/s. One weber equals 10^8 maxwells. See *magnetic flux*.

4.2.2 Magnetic Properties and Their Application

The relative importance of the various magnetic properties of a magnetic material varies from one application to another. In general, properties of interest may include normal induction, hysteresis, dc permeability, ac permeability, core loss, and exciting power. It should be noted that there are various means of expressing ac permeability. The choice depends primarily on the ultimate use.

Techniques for the magnetic testing of many magnetic materials are described in the ASTM standards. The magnetic and electric circuits employed in magnetic testing of a specimen are as free as possible from any unfavorable design factors which would prevent the measured magnetic data from being representative of the inherent magnetic properties of the specimen. The flux "direction" in the specimen is normally specified, since most magnetic materials are magnetically anisotropic. In most ac magnetic tests, the waveform of the flux is required to be sinusoidal.

As a result of the existence of unfavorable conditions, such as those listed and described below, the performance of a magnetic material in a magnetic device can be greatly deteriorated from that which would be expected from magnetic testing of the material. Allowances for these conditions, if present, must be made during the design of the device if the performance of the device is to be correctly predicted.

Leakage. A principal difficulty in the design of many magnetic circuits is due to the lack of a practicable material which will act as an insulator with respect to magnetic flux. This results in magnetic flux seldom being completely confined to the desired magnetic circuit. Estimates of leakage flux for a particular design may be made based on experience and/or experimentation.

Flux Direction. Some magnetic materials have a very pronounced directionality in their magnetic properties. Failure to utilize these materials in their preferred directions results in impaired magnetic properties.

Fabrication. Stresses introduced into magnetic materials by the various fabricating techniques often adversely affect the magnetic properties of the materials. This occurs particularly in materials having high permeability. Stresses may be eliminated by a suitable stress-relief anneal after fabrication of the material to final shape.

Joints. Joints in an electromagnetic core may cause a large increase in total excitation requirements. In some cores operated on ac, core loss may also be increased.

Waveform. When a sinusoidal voltage is applied to an electromagnetic core, the resulting magnetic flux is not necessarily sinusoidal in waveform, especially at high inductions. Any harmonics in the flux waveform cause increases in core loss and required excitation power.

Flux Distribution. If the maximum and minimum lengths of the magnetic path in an electromagnetic core differ too much, the flux density may be appreciably greater at the inside of the core structure than at the outside. For cores operated on ac, this can cause the waveform of the flux at the extremes of the core structure to be distorted even when the total flux waveform is sinusoidal.

4.2.3 Types of Magnetism

Any substance may be classified into one of the following categories according to the type of magnetic behavior it exhibits:

1. Diamagnetic
2. Paramagnetic
3. Antiferromagnetic
4. Ferromagnetic
5. Ferrimagnetic

Substances that fall into the first three categories are so weakly magnetic that they are commonly thought of as *nonmagnetic*. In contrast, ferromagnetic and ferrimagnetic substances are strongly magnetic and are thereby of interest as *magnetic materials*. The magnetic behavior of any ferromagnetic or ferrimagnetic material is a result of its spontaneously magnetized magnetic domain structure and is characterized by a nonlinear normal induction curve, hysteresis, and saturation.

The pure elements which are ferromagnetic are iron, nickel, cobalt, and some of the rare earths. Ferromagnetic materials of value to industry for their magnetic properties are almost invariably alloys of the metallic ferromagnetic elements with one another and/or with other elements.

Ferrimagnetism occurs mainly in the ferrites, which are chemical compounds having ferric oxide (Fe_2O_3) as a component. In recent years, some of the magnetic ferrites have become very important in certain magnetic applications. The magnetic ferrites saturate magnetically at lower inductions than do the great majority of metallic ferromagnetic materials. However, the electrical resistivities of ferrites are at least several orders of magnitude greater than those of metals.

Commercial Magnetic Materials. *Commercial magnetic materials* are generally divided into two main groups, each composed of ferromagnetic and ferrimagnetic substances:

1. Magnetically "soft" materials
2. Magnetically "hard" materials

The distinguishing characteristic of "soft" magnetic materials is high permeability. These materials are employed as core materials in the magnetic circuits of electromagnetic equipment. "Hard" magnetic materials are characterized by a high maximum magnetic energy product BH_{max}. These materials are employed as permanent magnets to provide a constant magnetic field when it is inconvenient or uneconomical to produce the field by electromagnetic means.

4.2.4 "Soft" Magnetic Materials

A wide variety of "soft" magnetic materials have been developed to meet the many different requirements imposed on magnetic cores for modern electrical apparatus and electronic devices. The various soft magnetic materials will be considered under three classifications:

1. Materials for solid cores.
2. Materials for laminated cores.
3. Materials for special purposes.

4.2.5 Materials for Solid Cores

These materials are used in dc applications such as yokes of dc dynamos, rotors of synchronous dynamos, and cores of dc electromagnets and relays. Proper annealing of these materials improves their magnetic properties. The principal magnetic requirements for the solid-core materials are high saturation, high permeability at relatively high inductions, and at times, low coercive force.

Wrought iron is a ferrous material, aggregated from a solidifying mass of pasty particles of highly refined metallic iron, into which is incorporated, without subsequent fusion, a minutely and uniformly distributed quantity of slag. The better types of wrought iron are known as *Norway iron* and *Swedish iron* and are widely used in relays after being annealed to reduce coercive force and to minimize magnetic aging.

Cast irons are irons which contain carbon in excess of the amount which can be retained in solid solution in austenite at the eutectic temperature. The minimum carbon content is about 2%, while the practical maximum carbon content is about 4.5%. Cast iron was used in the yokes of dc dynamos in the early days of such machines.

Gray cast iron is a cast iron in which graphite is present in the form of flakes. It has very poor magnetic properties, inferior mechanical properties, and practically no ductility. It does lend itself well to the casting of complex shapes and is readily machinable.

Malleable cast iron is a cast iron in which the graphite is present as temper carbon nodules. It is magnetically better than gray cast iron.

Ductile (nodular) cast iron is a cast iron with the graphite essentially spheroidal in shape. It is magnetically better than gray cast iron. Ductile cast iron has the good castability and machinability of gray cast iron together with much greater strength, ductility, and shock resistance.

4.2.6 Carbon Steels

Carbon steels may contain from less than 0.1% carbon to more than 1% carbon. The magnetic properties of a carbon steel are greatly influenced by the carbon content and the disposition of the carbon. Low-carbon steels (less than 0.2% carbon) have magnetic properties which are similar to those of wrought iron and far superior to those of any of the cast irons.

Wrought carbon steels are widely used as solid-core materials. The low-carbon types are preferred in most applications.

Cast carbon steels replaced cast iron many years ago as the material used in the yokes of dc machines, but have since largely been supplanted in this application by wrought (hot-rolled) carbon-steel plates of welding quality.

4.2.7 Materials for Laminated Cores

The materials most widely employed in wound or stacked cores in electromagnetic devices operated at the commercial power frequencies (50 and 60 Hz) are the electrical steels and the specially processed carbon steels designated as *magnetic lamination steels*. The principal magnetic requirements for these materials are low core loss, high permeability, and high saturation. ASTM publishes standard specifications for these materials. On a tonnage basis, production of these materials far exceeds that of any other magnetic material.

Electrical steels are flat-rolled low-carbon silicon-iron alloys. Since applications for electrical steels lie mainly in energy-loss-limited equipment, the core losses of electrical steels are normally guaranteed by the producers. The general category of electrical steels may be divided into classifications of (1) nonoriented materials and (2) grain-oriented materials.

Electrical steels are usually graded by high-induction core loss. Both ASTM and AISI have established and published designation systems for electrical steels based on core loss.

The ASTM core loss type designation consists of six or seven characters. The first two characters are 100 times the nominal thickness of the material in millimeters. The third character is a code letter which designates the class of the material and specifies the sampling and testing practices. The last three or four characters are 100 times the maximum permissible core loss in watts per pound at a specified test frequency and induction.

The AISI designation system has been discontinued but is still widely used. The AISI type designation for a grade consisted of the letter M followed by a number. The letter M stood for magnetic material, and the number was approximately equal to 10 times the maximum permissible core loss in watts per pound for 0.014-in material at 15 kG, 60 Hz in 1947.

Nonoriented electrical steels have approximately the same magnetic properties in all directions in the plane of the material (see Figs. 4-8 and 4-9). The common application is in punched laminations for large

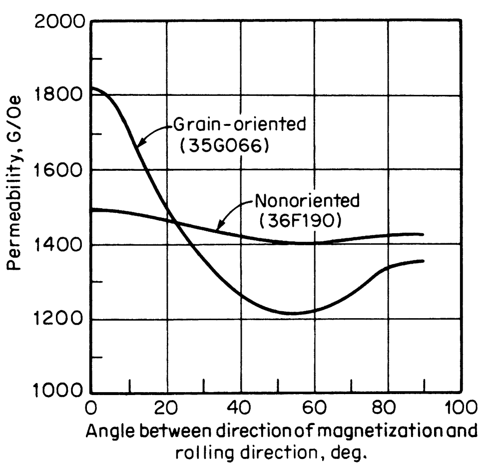

FIGURE 4-8 Effect of direction of magnetization on normal permeability at 10 Oe of fully processed electrical steels.

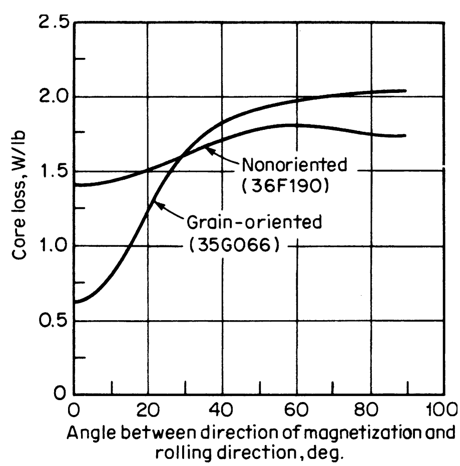

FIGURE 4-9 Effect of direction of magnetization on core loss at 15 kG, 60 Hz or fully processed electrical steel.

and small rotating machines and for small transformers. Today, nonoriented materials are always cold-rolled to final thickness. Hot rolling to final thickness is no longer practiced. Nonoriented materials are available in both fully processed and semiprocessed conditions.

Fully processed nonoriented materials have their magnetic properties completely developed by the producer. Stresses introduced into these materials during fabrication of magnetic cores must be relieved by annealing to achieve optimal magnetic properties in the cores. In many applications, however, the degradation of the magnetic properties during fabrication is slight and/or can be tolerated, and the stress-relief anneal is omitted. Fully processed nonoriented materials contain up to about 3.5% silicon. Additionally, a small amount (about 0.5%) of aluminum is usually present. The common thicknesses are 0.014, 0.0185, and 0.025 in.

Semiprocessed nonoriented materials do not have their inherent magnetic properties completely developed by the producer and must be annealed properly to achieve both decarburization and grain growth. These materials are used primarily in high-volume production of small laminations and cores which would require stress-relief annealing if made from fully processed material. Semiprocessed nonoriented materials contain up to about 3% silicon. Additionally, a small amount (about 0.5%) of aluminum is usually present. The carbon content may be as high as 0.05% but should be reduced to 0.005% or less by the required anneal. The common thicknesses of semiprocessed nonoriented materials are 0.0185 and 0.025 in.

Grain-oriented electrical steels have a pronounced directionality in their magnetic properties (Figs. 4-8 and 4-9). This directionality is a result of the "cube-on-edge" crystal structure achieved by proper composition and processing. Grain-oriented materials are employed most effectively in magnetic cores in which the flux path lies entirely or predominantly in the rolling direction of the material. The common application is in cores of power and distribution transformers for electric utilities.

Grain-oriented materials are produced in a fully processed condition, either unflattened or thermally flattened, in thicknesses of 0.0090, 0.0106, 0.0118, and 0.0138 in. Unflattened material has appreciable coil set or curvature. It is used principally in making spirally wound or formed cores. These cores must be stress-relief annealed to relieve fabrication stresses. Thermally flattened material is employed principally in making sheared or stamped laminations. Annealing of the laminations to remove both residual stresses from the thermal-flattening and fabrication stresses is usually recommended. However, special thermally flattened materials are available which do not require annealing when used in the form of wide flat laminations.

Two types of grain-oriented electrical steels are currently being produced commercially. The regular type, which was introduced many years ago, contains about 3.15% silicon and has grains about 3 mm in diameter. The high-permeability type, which was introduced more recently, contains about 2.9% silicon and has grains about 8 mm in diameter. In comparison with the regular type, the high-permeability type has better core loss and permeability at high inductions.

Some characteristics and applications for electrical steels are shown in Table 4-4.

Surface insulation of the surfaces of electrical steels is needed to limit the interlaminar core losses of magnetic cores made of electrical steels. Numerous surface insulations have been developed to meet the requirements of various applications. The various types of surface insulations have been classified by AISI.

Annealing of laminations or cores made from electrical steels is performed to accomplish either stress relief in fully processed material or decarburization and grain growth in semiprocessed material. Both batch-type annealing furnaces and continuous annealing furnaces are employed. The former is best suited for low-volume or varied production, while the latter is best suited for high-volume production.

Stress-relief annealing is performed at a soak temperature in the range from 730 to 845°C. The soak time need be no longer than that required for the charge to reach soak temperature. The heating and cooling rates must be slow enough so that excessive thermal gradients in the material are avoided. The annealing atmosphere and other annealing conditions must be such that chemical contamination of the material is avoided.

Annealing for decarburization and grain growth is performed at a soak temperature in the range from 760 to 870°C. Atmospheres of hydrogen or partially combusted natural gas and containing water vapor are often used. The soak time required for decarburization depends not only on the

temperature and atmosphere but also on the dimensions of the laminations or cores being annealed. If the dimensions are large, long soak times may be required.

Magnetic lamination steels are cold-rolled low-carbon steels intended for magnetic applications, primarily at power frequencies. The magnetic properties of magnetic lamination steels are not normally guaranteed and are generally inferior to those of electric steels. However, magnetic lamination steels are frequently used as core materials in small electrical devices, especially when the cost of the core material is a more important consideration than the magnetic performance.

Usually, but not always, stamped laminations or assembled core structures made from magnetic lamination steels are given a decarburizing anneal to enhance the magnetic properties. Optimal magnetic properties are obtained when the carbon content is reduced to 0.005% or less from its initial value, which may approach 0.1%. The soak temperature of the anneal is in the range from 730 to 790°C. The atmosphere most often used at the present time is partially combusted natural gas with a suitable dew point. Soak time depends to a considerable degree on the dimensions of the laminations or core structures being annealed.

Three types of magnetic lamination steels are produced. Type 1 is usually made to a controlled chemical composition and is furnished in the full-hard or annealed condition without guaranteed magnetic properties. Type 2 is made to a controlled chemical composition, given special processing, and furnished in the annealed condition without guaranteed magnetic properties. After a suitable anneal, the magnetic properties of Type 2 are superior to those of Type 1. Type 2S is similar to Type 2, but the core loss is guaranteed.

4.2.8 Materials for Special Purposes

For certain applications of soft or nonretentive materials, special alloys and other materials have been developed, which, after proper fabrication and heat treatment, have superior properties in certain ranges of magnetization. Several of these alloys and materials will be described.

Nickel-Iron Alloys. Nickel alloyed with iron in various proportions produces a series of alloys with a wide range of magnetic properties. With 30% nickel, the alloy is practically nonmagnetic and has a resistivity of 86 $\mu\Omega$/cm. With 78% nickel, the alloy, properly heat-treated, has very high permeability. These effects are shown in Figs. 4-10 and 4-11. Many variations of this series have been

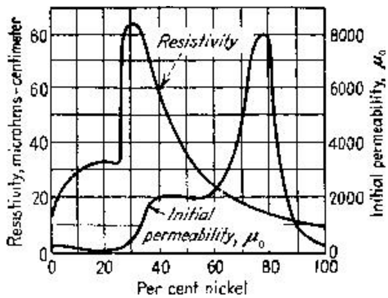

FIGURE 4-10 Electrical resistivity and initial permeability of iron-nickel alloys with various nickel contents.

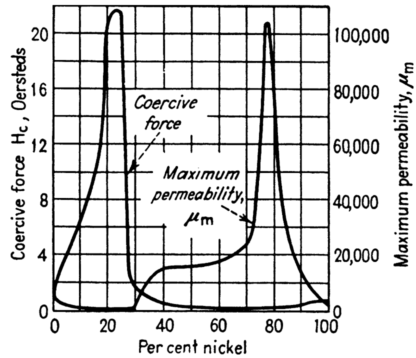

FIGURE 4-11 Maximum permeability and coercive force of iron-nickel alloys with various nickel contents.

developed for special purposes. Table 4-5 lists some of the more important commercial types of nickel-iron alloys, with their approximate properties. These alloys are all very sensitive to heat treatment, so their properties are largely influenced thereby.

Permalloy. This is a term applied to a number of nickel-iron alloys developed by the Bell Laboratories, each specified by a prefix number indicating the nickel content. The term is usually associated with the 78.5% nickel-iron alloys, the important properties of which are high permeability and low hysteresis loss in relatively low magnetizing fields. These properties are obtained by a unique heat treatment consisting of a high-temperature anneal, preferably in hydrogen, with slow cooling followed by rapid cooling from about 625°C. The alloy is very sensitive to mechanical strain, so it is desirable to heat-treat the alloy in its final form. The addition of 3.8% chromium or molybdenum increases the resistivity from 16 to 65 and 55 $\mu\Omega \cdot$ cm, respectively, without seriously impairing the magnetic quality. In fact, low-density permeabilities are better with these additions. These alloys have found their principal application as a material for the continuous loading of submarine cables and in loading coils for landlines.

By special long-time high temperature treatments, maximum permeability values greater than 1 million have been obtained. The double treatment required by the 78% Permalloy is most effective when the strip is thin, say, under 10 mils. For greater thicknesses, the quick cooling from 625°C is not uniform throughout the section, and loss of quality results.

Deltamax	50 Ni	15,500	85,000	–0.10		45

A 48% nickel-iron was developed for applications requiring a moderately high-permeability alloy with higher saturation density than 78 Permalloy. The same general composition is marketed under many names, such as Hyperm 50, Hipernik, Audiolloy, Allegheny Electric Metal, 4750, and Carpenter 49 alloy. Annealing is recommended after all mechanical operations are completed. These alloys have found extensive use in radio, radar, instrument, and magnetic-amplifier components.

Deltamax. By the use of special techniques of cold reduction and annealing, the 48% nickel-iron alloy develops directional properties resulting in high permeability and a square hysteresis loop in the rolling direction. A similar product is sold under the name of Orthonic. For optimal properties, these materials are rapidly cooled after a 2-h anneal in pure hydrogen at 1100°C. They are generally used in wound cores of thin tape for applications such as pulse transformers and magnetic amplifiers.

Iron-Nickel-Copper-Chromium. The addition of copper and chromium to high-nickel-iron alloys has the effect of raising the permeability at low flux density. Alloys of this type are marketed under the names of Mumetal, 1040 alloy, and Hymu 80. For optimal properties, they are annealed after cutting and forming for 4 h at 1100°C in pure hydrogen and cooled slowly. Important applications are as magnetic shielding for instruments and electronic equipment and as cores in magnetic amplifiers.

Constant-Permeability Alloys. *Constant-permeability alloys* having a moderate permeability which is quite constant over a considerable range of flux densities are desirable for use in circuits in which waveform distortion must be kept at a minimum. Isoperm and Conpernik are two alloys of this type. They are nickel-iron alloys containing 40% to 55% nickel which have been severely cold-worked. Perminvar is the name given to a series of cobalt-nickel-iron alloys (e.g., 50% nickel, 25% cobalt, 25% iron) which also exhibit this characteristic of constant permeability over a low (~800 G) density range. When magnetized to higher flux densities, they give a double loop constricted at the origin so as to give no measurable remanence or coercive force. The characteristics of the alloys in this group vary greatly with the chemical content and the heat treatment. A sample containing approximately 45 Ni, 25 Co, and 30 Fe, baked for 24 h at 425°C and slowly cooled, had hysteresis losses as follows: At 100 G, 214×10^{-4} erg/(cm^3)(cycle); at 1003 G, 15.27 ergs; at 1604 G, 163 ergs; at 4950 G, 1736 ergs; and at 13,810 G, 4430 ergs. Over the range of flux densities in which the permeability is constant (from 0 to 600 G), the hysteresis loss is very small, or on the order of the foregoing figure for 100 G. The resistivity of the sample was 19.63 $\mu\Omega \cdot$ cm.

Monel. *Monel metal* is an alloy of 67% nickel, 28% copper, and 5% other metals. It is slightly magnetic below 95°C.

Iron-Cobalt Alloys. The addition of cobalt to iron has the effect of raising the saturation intensity of iron up to about 36% cobalt (Fe_2Co). This alloy is useful for pole pieces of electromagnets and for any application where high magnetic intensity is desired. It is workable hot but quite brittle cold. *Hyperco* contains approximately ⅓ Co, ⅔ Fe, plus 1% to 2% "added element." Total core loss is about 2.5 W/lb at 15 kG and 0.010 in thick. It is available as hot-rolled sheet, cold-rolled strip, plates, and forgings. The 50% cobalt-iron alloy Permendur has a high permeability in fields up to 50 Oe and, with about 2% vanadium added, can be cold-rolled.

Iron-Silicon Aluminum Alloys. Aluminum in small percentages, usually under 0.5%, is a valuable addition to the iron-silicon alloy. Its principal function appears to be as a deoxidizer. Masumoto has investigated soft magnetic alloys containing much higher percentages of aluminum and found several that have high permeabilities and low hysteresis losses. Certain compositions have very low magnetostriction and anisotropy, high initial permeability, and high electrical resistivity. An alloy of 9.6% silicon and 6% aluminum with iron has better low-flux-density properties than the Permalloys. However, poor ductility has limited these alloys to dc applications in cast configurations or in insulated pressed-powder cores for high-frequency uses. These alloys are commonly known as Sendust. The material has been prepared in sheet form by special processes.

Temperature-Sensitive Alloys. Inasmuch as the Curie point of metal may be moved up or down the temperature scale by the addition of other elements, it is possible to select alloys which lose their ferromagnetism at almost any desired temperature up to 1115°C, the change point in cobalt. Iron-based alloys are ordinarily used to obtain the highest possible permeability at points below the Curie temperature. Nickel, manganese, chromium, and silicon are the most effective alloy elements for this purpose, and most alloys made for temperature-control applications, such as instruments, reactors, and transformers, use one or more of these. The Carpenter Temperature Compensator 30 is a nickel-copper-iron alloy which loses its magnetism at 55°C and is used for temperature compensation in meters.

Heusler's Alloys. *Heusler's alloys* are ferromagnetic alloys composed of "nonmagnetic" elements. Copper, manganese, and aluminum are frequently used as the alloying elements. The saturation induction is about one-third that of pure iron.

4.2.9 High-Frequency Materials Applications

Magnetic materials used in reactors, transformers, inductors, and switch-mode devices are selected on the basis of magnetic induction, permeability, and associated material power losses at the design frequency. Control of eddy currents becomes of primary importance to reduce losses and minimize skin effect produced by eddy-current shielding. This is accomplished by the use of high-permeability alloys in the form of wound cores of thin tape, or compressed, insulated powder iron alloy cores, or sintered ferrite cores.

Typically, the thin magnetic strip material is used in applications where operating frequencies range from 400 Hz to 20 kHz. Power conditioning equipment frequently operates at 10 kHz and up, and the magnetic materials used are compressed, powdered iron-alloy cores or sintered ferrite cores. Power losses in magnetic materials are of great concern, especially so when operated at high frequencies.

3% Silicon-Iron Alloys. *3% Silicon-iron alloys* for high-frequency use are available in an insulated 0.001- to 0.006-in-thick strip that exhibits high effective permeability and low losses at relatively high flux densities. This alloy, as well as other rolled-to-strip soft magnetic alloys, is used to make laminated magnetic cores by various methods, including (1) the wound-core approach for winding toroids and C and E cores, (2) stamped or sheared-to-length laminations for laid-up transformers, and (3) stamped laminations of various configurations (rings E, I, F, L, DU, etc.) for assembly into transformer cores. Laminated core materials usually are annealed after all fabricating and stamping operations have been completed in order to develop the desired magnetic properties of the material. Subsequent forming, bending, or machining may impair the magnetic characteristics developed by the anneal.

Amorphous Metal Alloys. *Amorphous metal alloys* are made using a new technology which produces a thin (0.001 to 0.003 in) ribbon from rapidly quenched molten metal. The alloy solidifies before the atoms have a chance to segregate or crystallize, resulting in a glasslike atomic structure material of high electrical resistivity, 125 to 130 $\mu\Omega \cdot$ cm. A range of magnetic properties may be developed in these materials by using different alloying elements. Amorphous metal alloys may be used in the same high-frequency applications as the cast, rolled-to-strip, silicon-iron, and nickel-iron alloys.

Nickel-Iron Powder Cores. *Nickel-iron powder cores* are made of insulated alloy powder, which is compressed to shape and heat-treated. The alloy composition most widely used is 2-81 Permalloy powder composed of 2% molybdenum, 81% nickel, and balance iron. Another less widely used powder, Sendust, is made of 7% to 13% silicon, 4% to 7% aluminum, and balance iron. Prior to pressing, the powder particles are thinly coated with an inorganic, high-temperature insulation which can withstand the high compacting pressures and the high-temperature (650°C) hydrogen atmosphere anneal. The insulation of the particles lowers eddy-current loss and provides a distributed air gap which can be controlled to provide cores in a range of permeabilities. The 2-81 Permalloy cores are commercially available in permeability ranges of 14 to 300, and Sendust cores have permeabilities ranging from 10 to 140.

These types of nickel-iron powder cores find use in applications where inductance must remain relatively constant when the magnetic component experiences changes in dc current or temperature. Additional stability over temperature can also be achieved by the addition of low-Curie-temperature powder materials to neutralize the naturally positive permeability-temperature coefficient of the alloy powder. Some applications are in telephone loading coils or filter chokes for power conditioning equipment where output voltage ripple must be minimized. Other uses are for pulse transformers and switch-mode power supplies where low power losses are desired. Operating frequencies can range from 1.0 kHz for 300 permeability materials to 500 kHz for the 14 permeability materials.

Powdered-Iron Cores. *Powdered-iron cores* are manufactured from various types of iron powders whose particle sizes range from 2 to 100 μm. The particles are electrically insulated from one another using special insulating materials. The insulated powder is blended with phenolic or epoxy binders and a mold-release agent. The powder is then dry-pressed in a variety of shapes including toroids, E cores, threaded tuning cores, cups, sleeves, slugs, bobbins, and other special shapes. A low-temperature bake of the pressed product produces a solid component in which the insulated particles provide a built-in air gap, reducing eddy-current losses, increasing electrical Q, and thus allowing higher operating frequencies. The use of different iron powder blends and insulation systems provides a range of permeability, from 4 to 90, for use over the frequency spectrum of 50 Hz to 250 MHz. Applications include high-frequency transformers, tuning coils, variable inductors, rf chokes, and noise suppressors for power supply and power control circuits.

Ferrite Cores. *Ferrite cores* are molded from a mixture of metallic oxide powders such that certain iron atoms in the cubic crystal of magnetite (ferrous ferrite) are replaced by other metal atoms, such as Mn and Zn, to form manganese zinc ferrite, or by Ni and Zn to form nickel zinc ferrite. Manganese zinc ferrite is the material most commercially available and is used in devices operating below 1.5 MHz. Nickel zinc ferrites are used mainly for filter applications above that frequency. They resemble ceramic materials in production processes and physical properties. The electrical resistivities correspond to those of semiconductors, being at least 1 million times those of metals. Magnetic permeability μ_0 may be as high as 10,000. The Curie point is quite low, however, in the range 100 to 300°C. Saturation flux density is generally below 5000 G (Fig. 4-12). Ferrite materials are available in several compositions which, through processing, can improve one or two magnetic parameters (magnetic induction, permeability, low hysteresis loss, Curie temperature) at the expense of the other parameters. The materials are fabricated into shapes such as toroids; E, U, and I cores; beads; and self-shielding pot cores. Ferrite cores find use in filter applications up to 1.0 MHz, high-frequency power transformers operating at 10 to 100 kHz, pulse transformer delay lines, adjustable-air-gap inductors, recording heads, and filters used in high-frequency electronic circuits.

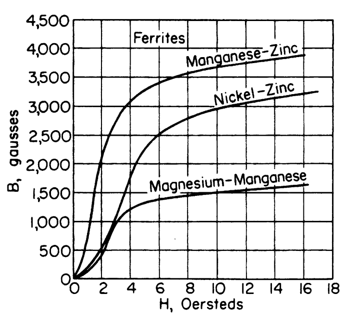

FIGURE 4-12 Typical normal-induction curves for *soft* ferrites.

Permanent-Magnet Materials. *Permanent-magnet materials* that are commercially available may be grouped into five classes as follows:

1. Quench-hardened alloys
2. Precipitation-hardened cast alloys
3. Ceramic materials
4. Powder compacts and elongated single-domain materials
5. Ductile alloys

4.2.10 Quench-Hardened Alloys

Early permanent magnets were made of low-carbon steel (1% C) that was hardened by heat treatment. Later developments saw improvements in the magnetic properties through the use of alloying elements of tungsten, chromium, and cobalt. The chrome steels are less expensive than the cobalt steels, and both find use in hysteresis clutch and motor applications.

Ceramic Magnet Material. *Ceramic magnet material* usage is increasing yearly because of improved magnetic properties and the high cost of cobalt used in metallic alloy magnets. The basic raw material used in these magnets is iron oxide in combination with either strontium carbonate or barium carbonate. The iron oxide and carbonate mixture is calcined, and then the aggregate is ball-milled to a particle size of about 1.0 μm. The material is compacted in dies using the dry powder or a water-based slurry of the powder. High pressures are needed to press the parts to shape. In some ceramic grades, a magnetic field is applied during pressing to orient the material in order to obtain a preferred magnetic orientation. Parts are sintered at high temperatures and ground to finished size using diamond grinding wheels with suitable coolants. Ceramic magnets are hard and brittle, exhibit high electrical resistivities, and have lower densities than cast magnet alloys.

Made in the form of rings, blocks, and arcs, ceramic magnets find use in applications for loudspeakers, dc motors, microwave oven magnetron tubes, traveling wave tubes, holding magnets, chip collectors, and magnetic separator units. Ceramic magnet arcs find wide use in the auto industry in engine coolant pumps, heating-cooling fan motors, and window lift motors. As with other magnets, they are normally supplied nonmagnetized and are magnetized in the end-use structure using magnetizing fields of the order of 10,000 Oe to saturate the magnet. The brittleness of the material necessitates proper design of the magnet support structure so as not to impart mechanical stress to the magnet.

Rare Earth Cobalt Magnets. *Rare earth cobalt magnets* have the highest energy product and coercivity of any commercially available magnetic material. Magnets are produced by powder metallurgy techniques from alloys of cobalt (65% to 77%), rare earth metals (23% to 35%), and sometimes copper and iron. The rare earth metal used is usually samarium, but other metals used are praseodymium, cerium, yttrium, neodymium, lathanum, and a rare earth metal mixture called *misch metal.* The rare earth alloy is ground to a fine particle size (1 to 10 μm), and the powder is then die-compacted in a strong magnetic field. The part is then sintered and abrasive-ground to finish tolerances.

Although this material uses comparatively expensive raw materials, the high value of coercive force (5500 to 9500 Oe) leads to small magnet size and good temperature stability. These magnets find use in miniature electronic devices such as motors, printers, electron beam focusing assemblies, magnetic bearings, and traveling wave tubes. Plastic-bonded rare earth magnets are also being made, but the magnetic value of the energy product is only a fraction of the sintered product.

Ductile Alloys. *Ductile alloys* include the materials Cunife, Vicalloy, Remalloy, chromium-cobalt-iron (Cr-Co-Fe), and in a limited sense, manganese-aluminum-carbon (Mn-Al-C). They are sufficiently ductile and malleable to be drawn, forged, or rolled into wire or strip forms. A final heat treatment after forming develops the magnetic properties. Cunife has a directional magnetism developed as a result of cold working and finds wide use in meters and automotive speedometers. Vicalloy has been used as a high-quality and high-performance magnetic recording tape and in hysteresis clutch applications. Remalloy has been used extensively in telephone receivers but is now being replaced by a newer, less costly magnetic material.

New permanent-magnet materials that are now being produced are the Cr-Co-Fe alloy and the Mn-Al-C alloy. The Cr-Co-Fe alloy family contains 20% to 35% chromium and from 5% to 25% cobalt. This alloy is unique among permanent-magnet alloys due to its good hot and cold ductility, machinability, and excellent magnetic properties. The heat treatment of the alloy involves a rapid cooling from approximately 1200°C to a spinoidal decomposition phase occurring at about 600°C. The magnetic phase developed in the spinoidal decomposition process may be oriented by a heat treatment in a magnetic field, or the material may be magnetically oriented by "deformation aging" as would be accomplished in a wire-drawing operation. The magnetic properties that can be developed are comparable with those of Alnico 5 and are superior to those of the other ductile alloys,

Cunife, Vicalloy, and Remalloy. Western Electric has introduced a Cr-Co-Fe alloy which replaces Remalloy in the production of telephone receiver magnets and at a lower cost due to reduced cobalt.

The Mn-Al-C Alloy. *The Mn-Al-C alloy* achieves permanent-magnetic properties (B_r, 5500 G; H_c, 2300 Oe; Mg · Oe energy product, 5 Mg · Oe) when mechanical deformation of the alloy takes place at a temperature of about 720°C. Mechanical deformation may be performed by warm extrusion. Magnet size is limited by the amount of deformation needed to develop and orient the magnetic phase in the alloy. The alloying elements are inexpensive, but the tooling and equipment needed in the deformation process is expensive and may be a factor in the economical production of this magnet alloy. Magnets of this alloy would find use in loudspeakers, motor applications, and microwave oven magnetron tubes. The low density, 5.1 g/cm^3, is desirable for motors where reduced inertia and weight savings are important. The low Curie temperature, 320°C, limits the use of this alloy to applications where the ambient temperature is less than 125°C.

Permanent-Magnet Design. *Permanent-magnet design* involves the calculation of magnet area and magnet length to produce a specific magnetic flux density across a known gap, usually with the magnet having the smallest possible volume. Designs are developed from magnet material hysteresis loop data of the second quadrant, commonly called *demagnetization curves*.

Other considerations are the operating temperature of the magnetic assembly, magnet weight, and cost. Also, care should be exercised in the calculation of any steel return path cross section to ensure that it is adequate to carry the flux output of the magnet. Table 4-6 illustrates the range of magnetic characteristics that may be considered in the design. Detailed magnetic and material specifications may be obtained from the magnet manufacturer.

4.3 INSULATING MATERIALS

4.3.1 General Properties

Electrical Insulation and Dielectric Defined. Electrical insulation is a medium or a material which, when placed between conductors at different potentials, permits only a small or negligible current in phase with the applied voltage to flow through it. The term *dielectric* is almost synonymous with electrical insulation, which can be considered the applied dielectric. A perfect dielectric passes no conduction current but only capacitive charging current between conductors. Only a vacuum at low stresses between uncontaminated metal surfaces satisfies this condition.

The range of resistivities of substances which can be considered insulators is from greater than $10^{20}\ \Omega \cdot$ cm downward to the vicinity of $10^6\ \Omega \cdot$ cm, depending on the application and voltage stress. There is no sharp boundary defined between low-resistance insulators and semiconductors. If the voltage stress is low and there is little concern about the level of current flow (other than that which would heat and destroy the insulation), relatively low-resistance insulation can be tolerated.

Circuit Analogy of a Dielectric or Insulation. Any dielectric or electrical insulation can be considered as equivalent to a combination of capacitors and resistors which will duplicate the current-voltage behavior at a particular frequency or time of voltage application. In the case of some dielectrics, simple linear capacitors and resistors do not adequately represent the behavior. Rather, resistors and capacitors with particular nonlinear voltage-current or voltage-charge relations must be postulated to duplicate the dielectric current-voltage characteristic.

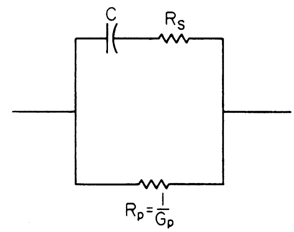

FIGURE 4-13 Equivalent circuit of a dielectric.

The simplest circuit representation of a dielectric is a parallel capacitor and resistor, as shown in Fig. 4-13 for $R_S = 0$. The perfect dielectric would be simply a capacitor. Another representation of a dielectric is a series-connected capacitor and resistor as in Fig. 4-13 for $R_p = \infty$, while still another involves both R_S and R_p.

The ac dielectric behavior is indicated by the phase diagram (Fig. 4-14). The perfect dielectric capacitor has a current which leads the voltage by 90°, but the imperfect dielectric has a current which leads the voltage by less than 90°. The dielectric phase angle is θ, and the difference, $90° - \theta = \delta$, is the loss angle. Most measurements of dielectrics give directly the tangent of the loss angle tan δ (known as the *dissipation factor*) and the capacitance C. In Fig. 4-13, if $R_p = \infty$, the series $R_s - C$ has a tan $\delta = 2\pi f C_s R_s$, and if $R_s = 0$, the parallel $R_p - C$ has a tan $\delta = 1/2\pi f C_p R_p$.

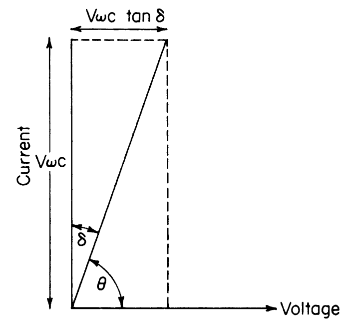

FIGURE 4-14 Current-voltage phase relation in a dielectric.

The ac power or heat loss in the dielectric is $V^2 2\pi f C$ tan δ watts, or VI sin δ watts, where sin δ is known as the power factor, V is the applied voltage, I is the total current through the dielectric, and f is the frequency. From this it can be seen that the equivalent parallel conductance of the dielectric σ (the inverse of the equivalent parallel resistance ρ) is $2\pi f C$ tan δ. The ac conductivity is

$$\sigma = (5/9) f \epsilon' \tan \delta \times 10^{-12}\ \Omega^{-1}\ \text{cm}^{-1} = 1/\rho \tag{4-54}$$

where ϵ' is the permittivity (or relative dielectric constant) and f is the frequency. (The IEEE now recommends the symbol ϵ' for the dielectric constant relative to a vacuum. The literature on dielectrics and insulation also has used κ [kappa] for this dimensionless quantity or ϵ'_r. In some places, ϵ' has been used to indicate the absolute dielectric constant, which is the product of the relative dielectric constant and the dielectric constant of a vacuum ϵ_0, which is equal to 8.85×10^{-12} F/m.) κ_0 also has been used to represent the dielectric constant of a vacuum. While the ac conductivity theoretically increases in proportion to the frequency, in practice, it will depart from this proportionality insofar as ϵ' and tan δ change with frequency.

Capacitance and Permittivity or Dielectric Constant. The capacitance between plane electrodes in a vacuum (with fringing neglected) is

$$C = \epsilon' \epsilon_0 A/t = 0.0884 \times 10^{-12} A/t \qquad \text{farads} \tag{4-55}$$

where ϵ_0 is the dielectric constant of a vacuum, A is the area in square centimeters, and t is the spacing of the plates in centimeters. ϵ_0 is 0.225×10^{-12} F/in when A and t are expressed in inch units.

When a dielectric material fills the volume between the electrodes, the capacitance is higher by virtue of the charges within the molecules and atoms of the material, which attract more charge to the capacitor planes for the same applied voltage. The capacitance with the dielectric between the electrodes is

$$C = \epsilon' \epsilon_0 A/t \tag{4-56}$$

where ϵ' is the relative dielectric constant of the material. The capacitance relations for several other commonly occurring situations are

Coaxial conductors: $$C = \frac{2\pi\epsilon'\epsilon_0 L}{\ln(r_2/r_1)} \quad \text{farads} \tag{4-57}$$

Concentric spheres: $$C = \frac{4\pi\epsilon'\epsilon_0 r_1 r_2}{r_2 - r_1} \quad \text{farads} \tag{4-58}$$

Parallel cylindrical conductors: $$C = \frac{2\pi\epsilon'\epsilon_0 L}{\cosh^{-1}(D/2r)} \quad \text{farads} \tag{4-59}$$

In these equations, L is the length of the conductors, r_2 and r_1 are the outer and inner radii, and D is the separation between centers of the parallel conductors with radii r. For dimensions in centimeters, ϵ_0 is 0.0884 F/cm.

The value of ϵ' depends on the number of atoms or molecules per unit volume and the ability of each to be polarized (i.e., to have a net displacement of their charge in the direction of the applied voltage stress). Values of ϵ' range from unity for vacuum to slightly greater than unity for gases at atmospheric pressure, 2 to 8 for common insulating solids and liquids, 35 for ethyl alcohol and 91 for pure water, and 1000 to 10,000 for titanate ceramics (see Table 4-7 for typical values).

The relative dielectric constant of materials is not constant with temperature, frequency, and many other conditions and is more appropriately called the *dielectric permittivity*. Refer to the volume by Smyth (1955) for a discussion of the relation of ϵ' to molecular structure and to von Hippel (1954) and other tables of dielectric materials from the MIT Laboratory for Insulation Research. The permittivity of many liquids has been tabulated in *NBS Circ.* 514. The *Handbook of Chemistry and Physics* (Chemical Rubber Publishing Co.) also lists values for a number of plastics and other materials.

The permittivity of many plastics, ceramics, and glasses varies with the composition, which is frequently variable in nominally identical materials. In the case of some plastics, it varies with degree of cure and in the case of ceramics with the firing conditions. Plasticizers often have a profound effect in raising the permittivity of plastic compositions.

There is a force of attraction between the plates of a capacitor having an applied voltage. The stored energy is $\frac{1}{2} CV^2$ J. The force equals the derivative of this energy with respect to the plate separation: $(\frac{1}{2})\, \epsilon'\epsilon_0 E^2 \times 10^2$ N/cm² or $(\frac{1}{2})\, \epsilon'\epsilon_0 E^2 \times 10$ bar, where E is the electric field in volts per centimeter. The force increases proportionally to the capacitance or permittivity. This leads to a force of attraction of dielectrics into an electric field, that is, a net force which tends to move them toward a region of high field. If two dielectrics are present, the one with higher permittivity will displace the one with lower permittivity in the higher-field region. For example, air bubbles in a liquid are repelled from high-field regions. Correspondingly, elongated dielectric bodies are rotated into the direction of the electric field. In general, if the voltage on a dielectric system is maintained constant, the dielectrics move (if they are able) to create a higher capacitance.

Resistance and Resistivity of Dielectrics and Insulation. The measured resistance R of insulation depends on the geometry of the specimen or system measured, which for a parallel-plate arrangement is

$$R = \rho t/A \quad \text{ohms} \tag{4-60}$$

where t is the insulation thickness in centimeters, A is the area in square centimeters, and ρ is the dielectric resistivity in ohm-centimeters. If t and A vary from place to place, the effective "insulation resistance" will be determined by the effective integral of the t/A ratio over all the area under stress, on the assumption that the material resistivity ρ does not change. If the material is not homogeneous and materials of different resistivities appear in parallel, the system can be treated as parallel

resistors: $R = R_aR_b/(R_a + R_b)$. In this case, the lower-resistivity material usually controls the overall behavior. But if materials of different resistivities appear in series in the electric field, the higher-resistivity material generally will control the current, and a majority of the voltage will appear across it, as in the case of series resistors.

The resistance of dielectrics and insulation is usually time-dependent and (for the same reason) frequency-dependent. The dc behavior of dielectrics under stress is an extension of the low-frequency behavior. The ac and dc resistance and permittivity can, in principle, be related for comparable times and frequencies.

Current flow in dielectrics can be divided into parts: (*a*) the true dc current, which is constant with time and would flow indefinitely, is associated with a transport of charge from one electrode into the dielectric, through the dielectric, and out into the other electrode, and (*b*) the polarization or absorption current, which involves, not charge flow through the interface between the dielectric and the electrode, but rather the displacement of charge within the dielectric. This is illustrated in Fig. 4-15, where it is shown that the displaced or absorbed charge is responsible for a reverse current when the voltage is removed.

Polarization current results from any of the various forms of limited charge displacement which can occur in the dielectric. The displacement occurring first (within less than nanoseconds) is the electronic and intramolecular charged atom displacement responsible for the very high frequency permittivity.

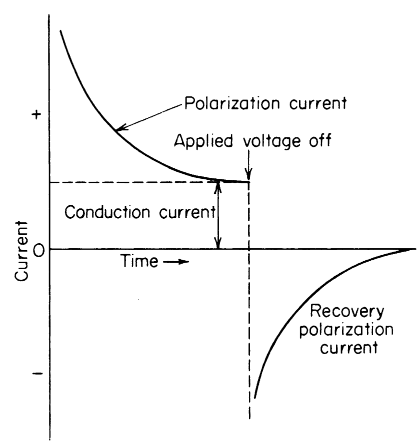

FIGURE 4-15 Typical dc dielectric current behavior.

The next slower displacement is the rotation of dipolar molecules and groups which are relatively free to move. The displacement most commonly observed in dc measurements, that is, currents changing in times of the order of seconds and minutes, is due to the very slow rotation of dipolar molecules and ions moving up to internal barriers in the material or at the conductor surfaces. When those slower displacement polarizations occur, the dielectric constant declines with increasing frequency and approaches the square of the optical refractive index η^2 at optical frequencies.

In composite dielectrics (material with relatively lower resistance intermingled with a material of relatively higher resistance), a large interfacial or Maxwell-Wagner type of polarization can occur. A circuit model of such a situation can be represented by placing two of the circuits of Fig. 4-13 in series and making the parallel resistance of one much lower than the other. To get the effect, it is necessary that the time constant R_pC be different for each material.

A simple model of the polarization current predicts an exponential decline of the current with time: $I_p = Ae^{-\alpha t}$, similar to the charging of a capacitor through a resistor. Composite materials are likely to have many different time constants, $\alpha = 1/RC$, superimposed. It is found empirically that the polarization or absorption current decreases inversely as a simple negative exponent of the time

$$I = At^{-n} \tag{4-61}$$

The ratio of the current at 1 min to that at 10 min has been called the *polarization index* and is used to indicate the quality of composite machine insulation. A low polarization index associated with a low resistance sometimes indicates parallel current leakage paths through or over the surface of insulation (e.g., in adsorbed water films).

The level of the conduction current which flows essentially continuously through insulation is an indication of the level of the ionic concentration and mobility in the material. Frequently, as with salt in water, the ions are provided by dissolved, absorbed, or included impurity electrolytes in the material rather than by the material itself. Purifying the material will therefore often raise the resistivity. If it is liquid, purification can be done with adsorbent clays or ion-exchange resins.

The conductivity of ions in an insulation is given by the equation

$$\sigma = \mu ec \qquad \Omega^{-1}\cdot\text{cm}^{-1} \tag{4-62}$$

where μ is the ion mobility, e is the ionic charge in coulombs, and c is the ionic concentration per cubic centimeter. The mobility, expressed in centimeters per second-volt per centimeter, decreases inversely with the effective internal viscosity and is very low for hard resins, but it increases with temperature and with softness of the resin or fluidity of liquids. The ionic conductivity also varies widely with material purity. Among the polymers and resins, nonpolar resins such as polyethylene are likely to have high resistivities, on the order of 10^{16} or greater, since they do not readily dissolve or dissociate ionic impurities. Harder or crystalline polar resins have higher resistivity than do similar softer resins of similar dielectric constant and purity. Resins and liquids of higher dielectric constant usually have higher conductivities because they dissolve ionic impurities better, and the impurities dissociate to ions much more readily in a higher dielectric constant medium. Ceramics and glasses have lower resistivity if they contain alkali ions (sodium and potassium), since these ions are highly mobile.

Water is particularly effective in decreasing the resistivity by increasing the ionic concentration and mobility of materials, on the surface as well as internally. Water associates with impurity ions or ionizable constituents within or on the surface or interfaces. It helps to dissociate the ions by virtue of its high dielectric constant and provides a local environment of greater mobility, particularly as surface water films.

The ionic conductivity σ, exclusive of polarization effects, can be expected to increase exponentially with temperature according to the relation

$$\sigma = \sigma_0 e^{-B/T} \tag{4-63}$$

where T is the Kelvin temperature and σ_0 and B are constants. This relation, log σ versus $1/T$, is shown in Fig. 4-16. It is often observed that at lower temperatures, where the resistivity is higher, the resistivity tends to be lower than the extrapolated higher temperature line would predict. There are at least two possible reasons for this: the effect of adsorbed moisture and the contribution of a very slowly decaying polarization current.

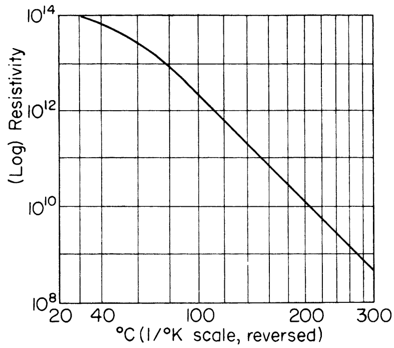

FIGURE 4-16 Typical dielectric resistivity-temperature dependence. (*Corning*.)

Variation of Dielectric Properties with Frequency. The permittivity of dielectrics invariably tends downward with increasing frequency, owing to the inability of the polarizing charges to move with sufficient speed to follow the increasing rate of alternations of the electric field. This is indicated in Fig. 4-17. The sharper decline in permittivity is known as a *dispersion region.* At the lower frequencies, the ionic-interface polarization declines first; next, the molecular dipolar polarizations decline. With some polar polymers, two or more dipolar dispersion regions may occur owing to different parts of the molecular rotation.

Figure 4-17 is typical of polymers and liquids but not of glasses and ceramics. Glasses, ceramics, and inorganic crystals usually have much flatter permittivity-frequency curves, similar to that shown for the nonpolar polymer, but at a higher level, owing to their atom-ion displacement polarization, which can follow the electric field usually up to infrared frequencies.

The dissipation factor–frequency curve indicates the effect of ionic migration conduction at low frequency. It shows a maximum at a frequency corresponding to the permittivity dispersion region. This maximum is usually associated with a molecular dipolar rotation and occurs when the rotational mobility is such that the molecular rotation can just keep up with frequency of the applied field. Here it has its maximum movement in phase with the voltage, thus contributing to conduction current. At lower frequencies, the molecule dipole can rotate faster than the field and contributes more to permittivity. At higher frequencies it cannot move fast enough. Such a dispersion region can also occur because of ionic migration and interface polarization if the interfaces are closely spaced and if the frequency and mobility have the required values.

The frequency region where the dipolar dispersion occurs depends on the rotational mobility. In mobile, low-viscosity liquids, it is in the 100- to 10,000-MHz range. In viscous liquids, it occurs in the region of 1 to 100 MHz. In soft polymers it may occur in the audio-frequency range, and with hard polymers it is likely to be at very low frequency (indistinguishable from dc properties). Since the viscosity is affected by the temperature, increased temperature shifts the dispersion to higher frequencies.

Variation of Dielectric Properties with Temperature. The trend in ac permittivity and conductivity, as measured by the dissipation factor, is controlled by the increasing ionic migrational and dipolar molecular rotational mobility with increasing temperature. This curve, which is indicated

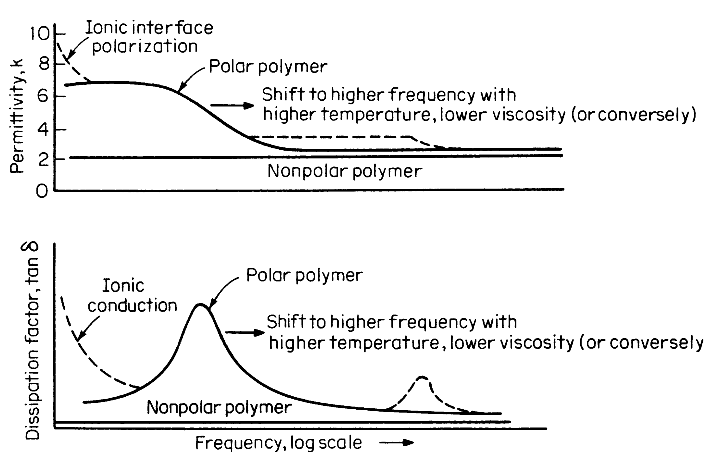

FIGURE 4-17 Typical variation in dielectric properties with frequency.

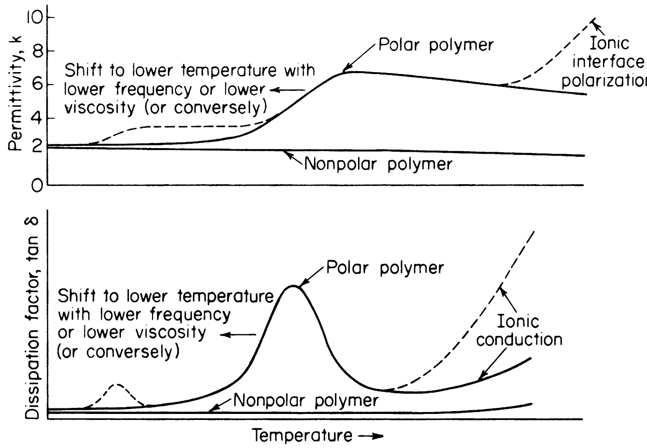

FIGURE 4-18 Typical variation in dielectric properties with temperature.

in Fig. 4-18, is in most respects a mirror image of the frequency trend shown in Fig. 4-17, since the two effects are interrelated.

The permittivity-dispersion and dissipation factor maximum region occurs below room temperature for viscous liquids and still lower for mobile liquids. In fact, mobile liquids may crystallize before they would show dispersion, except at high frequencies. With polymers, the dissipation factor maxima is likely to occur, at power frequencies, at a temperature close to a softening-point or internal second-order transition-point temperature. Dielectric dispersion and mechanical modulus dispersion usually can be correlated at the same temperature for comparable frequencies.

Composite Dielectrics. The dielectric properties of composite dielectrics are generally a weighted average of the individual component properties, unless there is interaction, such as dissolving (as opposed to intermixing) of one material in another, or chemical reaction of one with another. Interfaces created by the mixing present a special factor, which often can lead to a higher dissipation factor and lower resistivity as a result of moisture and/or impurity concentration at the interface.

The ac properties of sheets of two dielectrics of dielectric constant k_1 and k_2 and of thickness t_1 and t_2 placed in series are related to the properties of the individual materials by the series of capacitance and impedance relation

$$C = \frac{k_0 k_1 k_2 A}{k_1 t_2 + k_2 t_1} \tag{4-64}$$

$$\tan\delta = \frac{(t_1/t_2)\epsilon'_2 \tan\delta_1 + \epsilon'_1 \tan\delta_2}{\epsilon'_1 + \epsilon'_2 (t_1/t_2)} \tag{4-65}$$

Similarly, the properties of two dielectrics in parallel are

$$C = \epsilon_0 \left(\frac{\epsilon'_1 A_1}{t_1} + \frac{\epsilon'_2 A_2}{t_2} \right) \tag{4-66}$$

$$\tan\delta = \frac{t_2 \epsilon'_1 A_1 \tan\delta_1 + t_1 \epsilon'_2 A_2 \tan\delta_2}{t_2 \epsilon'_1 A_1 + t_1 \epsilon'_2 A_2} \tag{4-67}$$

With steady dc voltages, the resistivities control the current. With equal-area layer dielectrics in series,

$$R = R_1 + R_2 = \frac{1}{A}(\rho_1 t_1 + \rho_2 t_2) \tag{4-68}$$

When the dielectrics are in parallel and of equal thickness t,

$$R = \frac{R_1 R_2}{R_1 + R_2} = \frac{\rho_1 \rho_2 t}{\rho_1 A_2 + \rho_2 A_1} \tag{4-69}$$

Potential Distribution in Dielectrics. The maximum potential gradient in dielectrics is of critical significance insofar as the breakdown is concerned, since breakdown or corona is usually initiated at the region of highest gradient. In a uniform-field arrangement of conductors or electrodes, the maximum gradient is simply the applied voltage divided by the minimum spacing. In divergent fields, the gradient must be obtained by calculation (which is possible for some simple arrangements) or by field mapping.

A common situation is the coaxial geometry with inner and outer radii R_1 and R_2. The gradient at radius r (centimeters) with voltage V applied is given by the equation

$$E = \frac{V}{r \ln (R_2/R_1)} \qquad \text{V/cm} \tag{4-70}$$

The gradient is a maximum at $r = R_1$.

When different dielectrics appear in series, the greater stress with ac fields is on the material having the lower dielectric constant. This material will frequently break down first unless its dielectric strength is much higher

$$\frac{E_1}{E_2} = \frac{\epsilon'_2}{\epsilon'_1} \quad \text{and} \quad E_1 = \frac{V}{t_1 + t_2 \epsilon'_1 / \epsilon'_2} \tag{4-71}$$

The effect of the insulation thickness and dielectric constant (as well as the sharpness of the conductor edge) to create sufficient electric stress for local air breakdown (partial discharges) is shown in Fig. 4-19. With dc fields, the stress distributes according to the resistivities of the materials, the higher stress being on the higher-resistivity material.

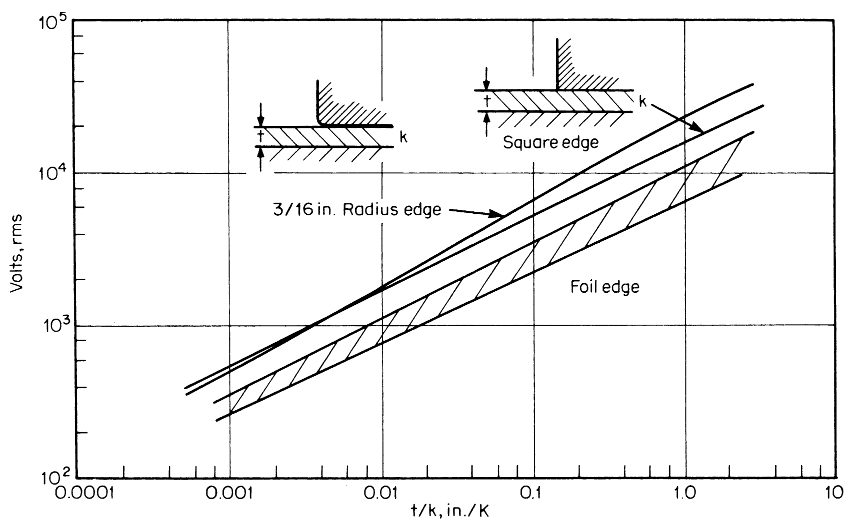

FIGURE 4-19 Corona threshold voltage at conductor edges in air as a function of insulation thickness.

Dielectric Strength. This is defined by the ASA as the maximum potential gradient that the material can withstand without rupture. Practically, the strength is often reported as the breakdown voltage divided by the thickness between electrodes, regardless of electrode stress concentration.

Breakdown appears to require not only sufficient electric stress but also a certain minimum amount of energy. It is a property which varies with many factors such as thickness of the specimen, size and shape of electrodes used in applying stress, form or distribution of the field of electric stress in the material, frequency of the applied voltage, rate and duration of voltage application, fatigue with repeated voltage applications, temperature, moisture content, and possible chemical changes under stress.

The practical dielectric strength is decreased by defects in the material, such as cracks, and included conducting particles and gas cavities. As will be shown in more detail in later sections on gases and liquids, the dielectric strength is quite adversely affected by conducting particles.

To state the dielectric strength correctly, the size and shape of specimen, method of test, temperature, manner of applying voltage, and other attendant conditions should be particularized as definitely as possible.

ASTM standard methods of dielectric strength testing should be used for making comparison tests of materials, but the levels of dielectric strength measured in such tests should not be expected to apply in service for long times. It is best to test an insulation in the same configuration in which it would be used. Also, the possible decline in dielectric strength during long-time exposure to the service environment, thermal aging, and partial discharges (corona), if they exist at the applied service voltage, should be considered. ASTM has thermal life test methods for assessing the long-time endurance of some forms of insulation such as sheet insulation, wire enamel, and others. There are IEEE thermal life tests for some systems such as random wound motor coils.

The dielectric strength varies as the time and manner of voltage application. With unidirectional pulses of voltage, having rise times of less than a few microseconds, there is a time lag of breakdown, which results in an apparent higher strength for very short pulses. In testing sheet insulation in mineral oil, usually a higher strength for pulses of slow rise time and somewhat higher strength for dc voltages is observed.

The trend in breakdown voltage with time is typical of many solid insulation systems.

With ac voltages, the apparent strength declines steadily with time as a result of partial discharges (in the ambient medium at the conductor or electrode edge). These penetrate the solid insulation. The discharges result from breakdown of the gas or liquid prior to the breakdown of the solid. Mica in particular, as well as other inorganic materials, is more resistant to such discharges. Organic resins should be used with caution where the ac voltage gradient is high and partial discharges (corona) may be present. Since the presence of partial discharges on insulation is so important to the long-time voltage endurance, their detection and measurement have become very important quality control and design tools. If discharges continuously strike the insulation within internal cavities or on the surface, the time to failure usually varies inversely as the applied frequency, since the number of discharges per unit time increases almost in direct proportion to the frequency. But in some cases, ambient conditions prevent continuous discharges.

When organic resin insulation is fabricated to avoid partial discharges using conductors or electrodes intimately bonded to the insulation, as in extruded polyethylene cables with a plastic semiconducting interface between the resin and the coaxial inner and outer metal conductors, respectively, the voltage endurance is greatly extended. Imperfections, however, in this "semicon"-resin interface, or at conducting particle inclusions in the resin, can lead to local discharges and the development of "electrical tree" growth. Vacuum impregnating and casting electrodes or conductors into resin also tend to avoid cavities and surface discharges and greatly improve the voltage endurance at high stresses.

The dc strength of solid insulation is usually higher and declines much less with time than the ac strength, since corona discharges are infrequent.

The dielectric strength is much higher where surface discharges are avoided and when the electric field is uniform. This can be achieved with solid materials by recessing spherical cavities into the material and using conducting paint electrodes.

The "intrinsic" electric strength of solid materials measured in uniform fields, avoiding surface discharges, ranges from levels on the order of 0.5 to 1 MV/cm for alkali halide crystals, which are about the lowest, upward to somewhat more than 10 MV/cm. Polymers and some inorganic materials, such as mica and aluminum oxide, have strengths of 2 to 20 MV/cm for thin films. The strength decreases with increasing thickness and with temperature above a critical temperature (which is usually from 1 to 100°C), below which the strength has a level value or a moderate increase with increasing temperature. Below the critical temperature, the breakdown is believed to be strictly electronic in nature and is constant or increases slightly with temperature. Above this temperature, it declines owing to dielectric thermal heating.

The breakdown voltage of thin insulation materials containing defects, which give the minimum breakdown voltage, declines as the area under stress increases. The effect of area on the strength can be estimated from the standard deviation S of tests on smaller areas by applying minimum value statistics: $V_1 - V_2 = 1.497\, S \log(A_1/A_2)$, where V_1 and V_2 are the breakdown voltages of areas A_1 and A_2.

If the ac or dc conductivity of a dielectric is high or the frequency is high, breakdown can occur as a result of dielectric heating, which raises the temperature of the material sufficiently to cause melting or decomposition, formation of gas, etc. This effect can be detected by measuring the conductivity as a function of applied electric stress. If the conductivity rises with time, with constant voltage, and at constant ambient temperature, this is evidence of an internal dielectric heating. If the heat transfer to the electrodes and ambient surroundings is adequate, the internal temperature eventually may stabilize, but if this heat transfer is inadequate, the temperature will rise until breakdown occurs. The criterion of this sort of breakdown is the heat balance between dielectric heat input and loss to the surroundings.

The dielectric heat input is given by the equation

$$\sigma E^2 = (5/9\, \epsilon' f \tan \delta \times 10^{-12}) E^2 \qquad \text{W/cm}^3 \tag{4-72}$$

where E is the field in volts per centimeter. When this quantity is on the order of 0.1 or greater, dielectric heating can be a problem. It is much more likely to occur with thick insulation and at elevated temperatures.

Water Penetration. Water penetration into electrical insulation also degrades the dielectric strength by several mechanisms. The effect of water to increase the insulation conductivity contributes thereby to a decreased dielectric strength, probably by a thermal breakdown mechanism. Another effect noticed recently, particularly in polyethylene cables, is the development of "water" or "electrochemical trees." Water (and/or a similar high dielectric constant chemical) can diffuse through polyethylene and collect at tiny hygroscopic inclusion sites, where the water or chemical is adsorbed. Then the electric field causes an expansion and growth of the adsorbed water or chemical in the electric field direction. This may completely bridge the insulation or possibly increase the local electric stress at the site so as to produce an electric tree and eventual breakdown.

Ionizing Radiation. Ionizing radiation, as from nuclear sources, may degrade insulation dielectric strength and integrity by causing polymer chain scission, and cracking of some plastics, as well as gas bubbles in liquids. Also, the conductivity levels in solids and liquids are increased.

Arc Tracking of Insulation. High-current arc discharges between conductors across the surface of organic resin insulation may carbonize the material and produce a conducting track. In the presence of surface water films, formed from rain or condensation, etc., small arc discharges form between interrupted parts of the water film, which is fairly conducting, and conducting tracks grow progressively across the surface, eventually bridging between conductors and causing complete breakdown. Materials vary widely in their resistance to tracking, and there are a variety of dry and wet tests for this property. With proper fillers, some organic resins can be made essentially nontracking. Some resins such as polymethyl methacrylate and polymethylene oxide burst into flame under arcing conditions.

Thermal Aging. Organic resinous insulating materials in particular are subject in varying degrees to deterioration due to thermal aging, which is a chemical process involving decomposition or modification of the material to such an extent that it may no longer function adequately as the intended insulation. The aging effects are usually accelerated by increased temperature, and this characteristic is used to make accelerated tests to failure or to an extent of deterioration considered dangerous. Such tests are made at appreciably higher than normal operating temperatures, if the expected life is to be several years or more, since useful accelerated tests reasonably should be completed in less than a year.

Frequently, other environmental factors influence the life in addition to the temperature. These include presence or absence of oxygen, moisture, and electrolysis. Mechanical and electrical stress may reduce the life by setting a required level of performance at which the insulation must perform. If this level is high, less deterioration of the insulation is required to reach this level.

Sometimes a complete apparatus is life-tested, as well as smaller specimens involving only one insulation material or a simple combination of these in a simple model. New tests are being devised continually, but there has been some standardization of tests by the IEEE and ASTM and internationally by the IEC.

It is important to note that frequently materials are assigned temperature ratings based on tests of the material alone. Often that material, combined with others in an apparatus or system, will perform satisfactorily at appreciably higher temperatures. Conversely, because of incompatibility with other materials, it may not perform at as high a temperature as it would alone. For this reason, it is considered desirable to make functional operating tests on complete systems. These can also be accelerated at elevated temperatures and environmental exposure conditions such as humidification, vibration, cold-temperature cycling, etc. introduced intermittently. The basis for temperature rating of apparatus and materials is discussed thoroughly in *IEEE Standard Publ.* 1. Tests for determining ratings are described in *IEEE Publs.* 98, 99, and 101.

Application of Electrical Insulation. In applying an insulating material, it is necessary to consider not only the electrical requirements but also the mechanical and environmental conditions of the application. Mechanical failure often leads to electrical failure, and mechanical failure is frequently the primary cause for failure of an aged insulation.

The initial properties of an insulation are frequently more than adequate for the application, but the effects of aging and environment may degrade the insulation rapidly to the point of failure. Thus, the thermal and environmental stability should be considered of equal importance. The effects of moisture and surface dirt contamination should be particularly considered, if these are likely to occur.

4.3.2 Insulating Gases

General Properties of Gases. A gas is a highly compressible dielectric medium, usually of low conductivity and with a dielectric constant only a little greater than unity, except at high pressures. In high electric fields, the gas may become conducting as a result of impact ionization of the gas molecules by electrons accelerated by the field and by secondary processes which produce partial breakdown (corona) or complete breakdown. Conditions which ionize the gas molecules, such as very high temperatures and ionizing radiation (ultraviolet rays, x-rays, gamma rays, high-velocity electrons, and ions such as alpha particles), will also produce some conduction in a gas.

The gas density d (grams per liter) increases with pressure p (torrs or millimeters of mercury) and gram-molecular weight M and decreases inversely with the absolute temperature T (degrees Celsius + 273) according to the relation

$$d = \frac{M}{22.4}\frac{p}{760}\frac{273}{T} \qquad \text{g/L} \tag{4-73}$$

The preceding relation is exact for ideal gases but is only approximately correct for most common gases.

If the gas is a vapor in equilibrium with a liquid or solid, the pressure will be the vapor pressure of the liquid or solid. The logarithm of the pressure varies as $-\Delta H/RT$, where ΔH is the heat of vaporization in calories per mole and R is the molar gas constant, 1.98 cal/(mol)(°C). This relation also applies to all common atmospheric gases at low temperatures, below the points where they liquify.

Dielectric Properties at Low Electric Fields

Dielectric Constant. The dielectric constant k of gases is a function of the molecular electrical polarizability and the gas density. It is independent of magnetic and electric fields except when a significant number of ions is present.

Conduction. The conductivity of a pure molecular gas at moderate electric stress and moderate temperature can be assumed, in the absence of any ionizing effect such as ionizing radiation, to be practically zero. Ionizing radiation induces conduction in the gas to a significant extent, depending on the amount absorbed and the volume of gas under stress. The energy of the radiation must exceed, directly or indirectly, the ionization energy of the gas molecules and thus produce an ion pair (usually an electron and positive ion). The threshold ionization energy is on the order of 10 to 25 electronvolts (eV)/molecule for common gases (10.86 eV for methyl alcohol, 12.2 for oxygen, 15.5 for nitrogen, and 24.5 for helium). Only very short wavelength ultraviolet light is effective directly in photoionization, since 10 eV corresponds to a photon of ultraviolet with a wavelength of 1240 Å. Since the photoelectric work function of metal surfaces is much lower (2 to 6 eV; e.g., copper about 4 eV), the longer-wavelength ultraviolet commonly present is effective in ejecting electrons from a negative conductors surface. Such cathode-ejected electrons give the gas apparent conductivity.

High-energy radiation from nuclear disintegration is a common source of ionization in gases. Nuclear sources usually produce gamma rays on the order of 10^6 eV energy. Only a small amount is absorbed in passing through a low-density gas. A flux of 1 R/h produces ion pairs corresponding to a saturation current (segment *ab* of Fig. 4-20) of 0.925×10^{-13}A/cm^3 of air at 1 atm pressure if all the ions formed are collected at the electrodes. The effect is proportional to the flux and the gas density.

At a voltage stress below about 100 V/cm, some of the ions formed will recombine before being collected, and the current will be correspondingly less (segment *oa* of Fig. 4-20). Higher stresses do not increase the current if all the ions formed are collected. A very small current, on the order of 10^{-21}A/cm^3 of air, is attributable to cosmic rays and residual natural radioactivity.

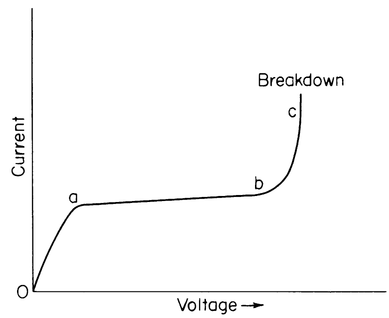

FIGURE 4-20 Current-voltage behavior of a lightly ionized gas.

Electrons (beta rays) produce much more ionization per path length than gamma rays, because they are slowed down by collisions and lose their energy more quickly. Correspondingly, the slower alpha particles (positive helium nuclei) produce a very dense ionization in air over a short range. For example, a 3-million-eV (MeV) alpha particle has a range in air of 1.7 cm and creates a total of 6.8×10^5 ion pairs. A beta particle (an electron) of the same energy creates only 40 ion pairs per centimeter and has a range of 13 m in air.

It should be noted that ionizing radiation of significant levels has only a small effect on gas dielectric strength. For example, the ionization current produced by a corona discharge from a needle point is typically much higher than that produced by a radiation flux of significant level, 10^{11} gamma photons per square centimeter.

At temperatures increasing above 600°C, it has been shown that thermionic electron emissions from negative conductor surfaces produce significant currents compared with levels typical of electrical insulation.

Since the rate of production of ions by the various sources mentioned above is limited, the current in the gas does not follow Ohm's law, unless the rate of collection of the ions at the electrodes is small compared with the rate of production of these ions, as in the initial part of segment *oa* in Fig. 4-20.

Dielectric Breakdown

Uniform Fields. The dielectric breakdown of gases is a result of an exponential multiplication of free electrons induced by the field. It is generally assumed that the initiation of breakdown

TABLE 4-8 Relative Dielectric Strengths of Gases (0.1-in gap)

Air	0.95	CF_4	1.1

requires only one electron. However, if only a few electrons are present prior to breakdown, it is not easily possible to measure the trend of current shown in Fig. 4-20. If the breakdown is completed between metal electrodes, the spark develops extremely rapidly into an arc, involving copious emission of electrons from the cathode metal and, if the necessary current flow is permitted, vaporization of metal from the electrodes. Table 4-8 gives the dielectric strength of typical gases.

In uniform electric fields, breakdown occurs at a critical voltage which is a function of the product of the pressure p and spacing d (Paschen's law).

It would be more accurate to consider the gas density-spacing product, since the dielectric strength varies with the temperature only as the latter affects the gas density. It will be noted that the electric field at breakdown decreases as the spacing increases. This is typical of all gases and is due to the fact that a minimum amount of multiplication of electrons must occur before breakdown occurs. A single electron accelerated by the field creates an avalanche which grows exponentially as $e^{\alpha}x$, where x is the distance and α is the Townsend ionization coefficient (electrons formed by collision per centimeter), which increases rapidly with electric field. At small spacings, α and the field must be higher for sufficient multiplication. In divergent electric fields or large spacings, it has been found that when the integral *int*$\alpha_E\,dx$ increases to about 18.4 (10^8 electrons), sufficient space charge develops to produce a streamer type of breakdown. It seems to be apparent that the final step in gas breakdown before arc development is the development of a branched filamentary streamer which proceeds more easily from the positive electrode toward the negative electrode.

Relative Dielectric Strengths of Gases. The relative dielectric strength, with few exceptions, tends upward with increasing molecular weight. There are a number of factors other than molecular or atomic size which influence the retarding effect on electrons. These include ability to absorb electron energy on collision and trap electrons to form negative ions. The noble atomic gases (helium, argon, neon, etc.) are poorest in these respects and have the lowest dielectric strengths. Table 4-8 gives the relative dielectric strengths of a variety of gases at 1 atm pressure at a $p\,.\,d$ value of 1 atm × 0.25 cm. The relative strengths vary with the $p\,.\,d$ value, as well as gap geometry, and particularly in divergent fields where corona begins before breakdown. It is best to consult specific references with regard to divergent field breakdown values.

Corona and Breakdown in Nonuniform Fields between Conductors. In nonuniform fields, when the ratio of spacing to conductor radius of curvature is about 3 or less, breakdown occurs without prior corona. The breakdown voltage is controlled by the integral of the Townsend ionization coefficient α across the gap. At larger ratios of spacing to radius of curvature, corona discharge occurs at voltage levels below complete gap breakdown.

Corona in air at atmospheric pressure occurs before breakdown when the ratio of outer to inner radius of coaxial electrodes exceeds 2.72 or where the ratio of gap to sphere radius between spheres exceeds 2.04. These discharges project some distance from the small-radii conductor but do not continue out into the weaker electric field region until a higher voltage level is reached.

Such partial breakdowns are often characterized by rapid pulses of current and radio noise. With some conductors at intermediate voltages between onset and complete breakdown, they blend into a pulseless glow discharge around the conductor. When corona occurs before breakdown, it creates an ion space charge around the conductor, which modifies the electric field, reducing the stress at sharp conductor points in the intermediate voltage range. At higher voltages, streamers break out of the space-charge region and cross the gap.

The surface voltage stress at which corona begins increases above that for uniform field breakdown stress, since the field to initiate breakdown must extend over a finite distance. An empirical relation developed by Peek is useful for expressing the maximum surface stress for corona onset in air for several geometries of radius r cm:

$$\text{For concentric cylinders: } E = 31\delta\left(1 + \frac{0.308}{\sqrt{\delta r}}\right) \quad \text{kV/cm} \tag{4-74}$$

$$\text{For parallel wires: } E = 29.8\delta\left(1 + \frac{0.301}{\sqrt{\delta r}}\right) \quad \text{kV/cm} \tag{4-75}$$

$$\text{For spheres: } E = 27.2\delta\left(1 + \frac{0.54}{\sqrt{\delta r}}\right) \quad \text{kV/cm} \tag{4-76}$$

where δ is the density of air relative to that at 25°C and 1 atm pressure.

Corona Discharges on Insulator Surfaces. It has been shown by a number of investigators that the discharge-threshold voltage stress on or between insulator surfaces is the same as between metal electrodes. Thus, the threshold voltage for such discharges can be calculated from the series dielectric-capacitance relation for internal gaps of simple shapes, such as plane and coaxial gaps, insulated conductor surfaces, and hollow spherical cavities.

The corona-initiating voltage at a conductor edge on a solid barrier depends on the electric stress concentration and generally on the ratio of the barrier thickness to its dielectric constant, except with low surface resistance. Any absorbed water or conducting film raises the corona threshold voltage by reducing stress concentration at the conductor edge on the surface.

It is sometimes possible to overvolt such gaps considerably prior to the first discharge, and the offset voltage may be below the proper voltage due to surface-charge concentration. With ac voltages, pulse discharges occur regularly back and forth each half cycle, but with dc voltage, the first discharge deposits a surface charge on the insulator surface which must leak away before another discharge can occur. Thus, corona on or between insulator surfaces is very intermittent with steady dc voltages, but discharges occur when the voltage is raised or lowered.

Flashover on Solid Surfaces in Gases. As has been mentioned in the previous section on partial discharges, the breakdown in gases is influenced by the presence of solid insulation between conductors. This insulation increases the electric stress in the gas. A particular case of this is the complete breakdown between conductors across or around solid insulator surfaces. This can occur when the conductors are on the same side of the insulation or on opposite sides. A significant reduction in flashover voltage can occur whenever a significant part of the electric field passes through the insulation. The reduction is influenced by the percentage of electric flux which passes through the solid insulation and the dielectric constant of the insulation.

4.3.3 Insulating Oils and Liquids

General Considerations. Typical insulating liquids are natural or synthetic organic compounds and frequently consist of mixtures of essentially isomeric compounds with some range of molecular weight. The mixture of very similar but not exactly the same molecules, with a range of molecular size and with chain and branched hydrocarbons, prevents crystallization and results in a low freezing point, together with a relatively high boiling point. Typical insulating liquids have permittivities (dielectric constants) of 2 to 7 and a wide range of conductivities depending on their purity. The dc conductivity in these liquids is usually due to dissolved impurities, which are ionized by dissociation. Higher ionized impurity and conductivity levels occur in liquids having higher permittivities and lower viscosities.

The function of insulating liquids is to provide electrical insulation and heat transfer. As insulation, the liquid is used to displace air in the system and provide a medium of high electric strength to fill pores, cracks, and gaps in insulation systems. It is usually necessary to fill and impregnate systems with liquid under vacuum so that all air bubbles are eliminated. If air is completely displaced in all high-electric-field regions, the corona threshold voltage and breakdown voltage for the system are greatly increased. The viscosity selected for a liquid insulation is often a compromise to provide the best balance between electrical insulation and heat transfer and other limitations such as flammability, solidification at low temperatures, and pressure development at high temperatures in sealed systems.

The most commonly used insulating liquids are natural hydrocarbon mineral oils refined to give low conductivity and selected viscosity and vapor-pressure levels for transformer, circuit-breaker, and cable applications. A number of synthetic fluids are also used for particular applications where the higher cost above that of mineral oil is warranted by the requirements of the application or by the improved performance in relation to the apparatus design.

Mineral Insulating Oils. Mineral insulating oils are hydrocarbons (compounds of hydrogen and carbon) refined from crude petroleum deposits from the ground. They consist partly of aliphatic compounds with the general formula $C_nH_{2n} + 2$ and C_nH_2n, comprising a mixture of straight- and branched-chain and cyclic or partially cyclic compounds. Many oils also contain a sizable fraction of aromatic compounds related to benzene, naphthalene, and derivatives of these with aliphatic side chains. The ratio of aromatic to aliphatic components depends on the source of the oil and its refining treatment. The percentage of aromatics is of importance to the gas-absorption or evaluation characteristics under electrical discharges and to the oxidation characteristics.

The important physical properties of a mineral oil (as for other insulating liquids as well) are listed in Table 4-9 for three types of mineral oils. In addition to these properties, mineral oils which are exposed to air in their application have distinctive oxidation characteristics which vary with type of oil and additives and associated materials.

Many manufacturers now approve the use of any of several brands of mineral insulating oil in their apparatus provided that they meet their specifications which are similar to ASTM D1040, (values from which are tabulated in Table 4-9). Low values of dielectric strength may indicate water or dirt contamination. A high neutralization number will indicate acidity, developed very possibly from oxidation, particularly if the oil has used been already. Presence of sulfur is likely to lead to corrosion of metals in the oil.

The solubility of gases and water in mineral oil is of importance in regard to its function in apparatus. Solubility is proportional to the partial pressure of the gas above the oil

$$S = S_0(p/p_0) \tag{4-77}$$

where S is the amount dissolved at pressure p if the solubility is expressed as the amount S_0 dissolved at pressure p_0.

The solubility is frequently expressed in volume percent of the oil. Values for solubility of some common gases in transformer oil at atmospheric pressure (760 torr) and 25°C are air 10.8%, nitrogen 9.0%, oxygen 14.5%, carbon dioxide 99.0%, hydrogen 7%, and methane 30% by volume. The solubilities of all the gases, except CO_2, increase slightly with increasing temperature. Water is dissolved in new transformer oil to the extent of about 60 to 80 ppm at 100% relative humidity and 25°C. The amount dissolved is proportional to the relative humidity. Solubility of water increases with oxidation of the oil and the addition of polar impurities, with which the water becomes associated. Larger quantities of water can be suspended in the oil as fine droplets.

Dielectric Properties of Mineral Oils. The permittivity of mineral insulating oils is low, since they are essentially nonpolar, containing only a few molecules with electric dipole moments. Some oils possess a minor fraction of polar constituents, which have not been identified. These contribute a dipolar character to the dielectric properties at low temperature and/or high frequency. A typical permittivity for American transformer oil at 60 Hz is 2.19 at 25°C, declining almost linearly to 2.11 at 100°C. At low temperatures and high frequencies, values of permittivity as high as 2.85 have been noted in oils with a relatively high level of polar constituents.

The dc conductivity levels of mineral oils range from about $10^{-15}\ \Omega^{-1} \cdot \text{cm}^{-1}$ for pure new oils up to $10^{-12}\ \Omega^{-1} \cdot \text{cm}^{-1}$ for contaminated used oils. This conductivity is due to dissociated impurity ions or ions developed by oil oxidation. It increases approximately exponentially with temperature about 1 decade in 80°C.

Alternating-current dissipation-factor values are nearly proportional to the dc conductivity $10^{-13}\ \Omega^{-1}$, corresponding to a tan δ of 0.008. If no electrode polarization or interfacial polarization effects at solid barrier surface are present, the dc conductivity σ should be related to the ac conductivity (tan δ) by $\sigma = \frac{5}{9}\epsilon' f \tan\delta \times 10^{-12}$ where ϵ' is the dielectric permittivity (Table 4-7) and f is the frequency.

Corona or partial breakdown can occur in mineral oil, as with any liquid or gas, when the electric stress is locally very high and complete breakdown is limited by a solid barrier or large oil gap (as with a needle point in a large gap). Such discharges produce hydrogen and methane gas, and sometimes carbon with larger discharges. Dissolved air is also sometimes released by the discharge. If the gas bubbles formed are not ejected away from the high field, they will reduce the subsequent discharge threshold voltage to as much as 80%. The resistance of insulating oils to partial discharges is measured by two ASTM gassing tests: D2298 (Merrill test) and D2300 (modified Pirelli test). These tests measure the amount of decomposition gas evolved under specified conditions of exposure to partial discharges. A minimum amount of gas is, of course, preferred, particularly in applications for cables or capacitors. In fact, conventional mineral oils are inadequate in this respect for application in modern 60-Hz power capacitor designs.

Deterioration of Oil. Deterioration of oil in apparatus partially open or "breathing" is subject to air oxidation. This leads to acidity and sludge. There is no correlation between the amount of acid and the likelihood of sludging or the amount of sludge. Sludge clogs the ducts, reduces the heat transfer, and accelerates the rate of deterioration. ASTM tests for oxidation of oils are D1904, D1934, D1313, and D1314. Copper and lead and certain other metals accelerate the oxidation of mineral oils. Oils are considerably more stable in nitrogen atmospheres.

Inhibitors are now commonly added both to new and to used oils to delay the oxidation. Ditertiary butyl paracresol (DBPC) is the inhibitor most commonly used at present.

Servicing, Filtering, and Treating. Oil in service is usually maintained by testing for acidity, dielectric strength, inhibitor content, interfacial tension, neutralization number, peroxide number, pour point, power factor, refractive index and specific optical dispersion, resistivity, saponification, sludge, corrosive sulfur, viscosity, and water content, as outlined in ASTM D117. These properties indicate various types of contamination or deterioration which might affect the operation of the insulating oil.

Depending on the voltage rating of the apparatus, the oil is maintained above 16 to 22 kV (ASTM test D877). The usual contaminants are water, sludge, acids, and in circuit-breaker oils, carbon. The centrifuge is best suited for removing large quantities of water, heavier solid particles, etc. The blotter filter press is used for the removal of minute quantities of water, fine carbon, etc. In another method, after removing the larger particles, the oil is heated and sprayed into a vacuum chamber, where the water and volatile acids are removed. Sludge and very fine solids are then taken out by a blotter filter press. All units are assembled together so that the process is completed in a single pass. Some work has been done in reclaiming oil by treating it to reduce acidity. One process is similar to the later stages in refining. Another treatment uses activated alumina, Fuller's earth, or silica gel. The IEEE Guide for Maintenance of Insulating Oil is published as *IEEE Standards Publ*. 64.

It has been found that analysis of the dissolved gas in oil or above the oil in oil-insulated transformers and cables is a good diagnostic tool to detect electrical faults, particularly, or deterioration, generally. For example, continuing or intermittent partial discharges produce hydrogen and low-molecular-weight hydrocarbons such as methane, ethane, and ethylene which accumulate in the oil and can be measured accurately to assess the magnitude of the fault. Higher-current arc faults produce acetylene in addition to H_2 and other low-molecular-weight hydrocarbons. Thermal deterioration of cellulosic or paper insulation is indicated by elevated concentrations of CO and CO_2 in the oil.

Synthetic Liquid Insulation. Synthetic chlorinated diphenyl and chlorinated benzene liquids (askarels) have been used widely from the mid-1930s up to the mid-1970s and are still in service in many power capacitors and transformers, where they were adopted for their nonflammability as well as good electrical characteristics. Since the mid-1970s, their use has been banned in most countries due to their alleged toxicity and resistance to biodegradation in the environment. Now, when apparatus containing these fluids, which are commonly referred to as *PCBs*, are taken out of service, environmental regulations in the United States require that the fluid not be released into the environment. Waste fluid should be incinerated at high temperature with HCl reactive absorbent scrubbers in the stack, since this acid gas is a product of the combustion.

New synthetic fluids have been developed and are now widely applied in power capacitors where the electrical stresses are very high. These fluids include aromatic (containing benzene rings) hydrocarbons, some of which have excellent resistance to partial discharges. They are not fire-resistant, however.

Very high boiling, low-vapor-pressure, high-flash-point (>300°C) hydrocarbon oils are being tried for power transformers with some fire resistance. Methods for assessing the risk of fire with such liquids, as well as with silicones, are still being debated.

Perchlorethylene (tetrachloroethylene), a nonpolar liquid, is now in use in sealed medium-power transformers, where nonflammability is required. With a boiling point at atmospheric pressure of 121°C, this fluid is completely nonflammable. It is also widely used in dry cleaning. Other important classes of synthetic insulating fluids are discussed in the following sections.

Fluorocarbon Liquids. A number of nonpolar nonflammable perfluorinated aliphatic compounds, in which the hydrogen has been completely replaced by fluorine, are available with different ranges of viscosity and boiling point from below room temperature to more than 200°C. These compounds have low permittivities (near 2.0) and very low conductivity. They are inert chemically and have low solubilities for most other materials. The chemical formula for these compounds is one of the following: C_nF_{2n}, C_nF_{2n+2}, or $C_nF_{2n}O$. The presence of the oxygen in the latter formula does not seem to reduce the stability. These compounds have been used for filling electronic apparatus and large transformers to give high heat-transfer rates together with high dielectric strength. The vapors of these liquids also have high dielectric strengths.

Silicone Fluids. These fluids, chemically formed from Si—O chains with organic (usually methyl) side groups, have a high thermal stability, low temperature coefficient of viscosity, low dielectric losses, and high dielectric strength. They can be obtained with various levels of viscosity and correlated vapor pressures. Rated service temperatures extend from –65 to 200°C, some having short-time capability up to 300°C. Their permittivity is about 2.6 to 2.7, declining with increasing temperature. These fluids have a tendency to form heavier carbon tracks than other insulating liquids when breakdown occurs. They cannot be considered fireproof but will reduce the risk of fire due to their low vapor pressure.

Ester Fluids. There are a few applications, mostly for capacitors, where organic ester compounds are used. These liquids have a somewhat higher permittivity, in the range of about 4 to 7, depending on the ratio of ester groups to hydrocarbon chain lengths. Their conductivities are generally somewhat higher than those of the other insulating liquids discussed here. The compounds are easily subject to hydrolysis with water to form acids and alcohols and should be kept dry, particularly if the temperature is raised. Their thermal stability is poor. Specifically, dibutyl sebacate has been used in high-frequency capacitors and castor oil in energy-storage capacitors.

4.3.4 Insulated Conductors

Insulated conductors vary from those carrying only a few volts to those carrying thousands of volts. They range from low-voltage bell wire with conductor gage of 22 to 24 to power cables with conductors of 2000 kcmil or 1013 mm^2 in cross-sectional area. The conductors can be round, rectangular, braided, or stranded. They can be of aluminum or copper. The insulation can be thin as in magnet wire or thick as in underground or marine cables. The insulation system can vary with functional application. It can be extruded or taped. It can be thermoplastic or thermoset. It can be a polymer in combination with cotton or glass cloth. There can be several different layers with different functional roles. Some of the applications for insulated conductors are communications, control, bell, building, hookup, fixture, appliance, and motor lead. The insulation technology for magnet wire and for power cables has been studied extensively because of the severe stresses seen by these insulation systems.

Flexible Cords. Flexible cords and cables cover appliance and lamp cords, extension cords for home or industrial use, elevator traveling cables, decorative-lighting wires and cords, mobile home wiring, and wiring for appliances that get hot (e.g., hot plates, irons, cooking appliances). The requirements for these cables vary a great deal with application. They must be engineered to be water-resistant, impact-resistant, temperature-tolerant, flex-tolerant, linearly strong, and flame-resistant and have good electrical insulation characteristics.

Magnet Wire Insulation. The term *magnet wire* includes an extremely broad range of sizes of both round and rectangular conductors used in electrical apparatus. Common round-wire sizes for copper are AWG No. 42 (0.0025 in) to AWG No. 8 (0.1285 in). A significant volume of aluminum magnet wire is produced in the size range of AWG No. 4 to AWG No. 26. Ultrafine sizes of round wire, used in very small devices, range as low as AWG No. 60 for copper and AWG No. 52 for aluminum.

Approximately 20 different “enamels” are used commercially at present in insulating magnet wire. Magnet wire insulations are high in electrical, physical, and thermal performance and best in space factor. The most widely used polymers for film-insulated magnet wire are based on polyvinyl acetals, polyesters, polyamideimides, polyimides, polyamides, and polyurethanes. Many magnet wire constructions use different layers of these polymer types to achieve the best combination of properties. The most commonly used magnet wire is NEMA MW-35C, Class 200, which is constructed with a polyester basecoat and a polyamideimide topcoat. Polyurethanes are employed where ease of solderability without solvent or mechanical striping is required. The thermal class of polyurethane insulations has been increased up to Class 155 and even Class 180. Magnet wire products also are produced with fabric layers (fiberglass or Dacron-fiberglass) served over bare or conventional film-insulated magnet wire. Self-bonding magnet wire is produced with a thermoplastic cement as the outer layer, which can be heat-activated to bond the wires together.

Power Cables. Insulated power cables are used extensively in underground residential distribution. There has been extensive replacement of PILC, or paper in lead cable, with extruded polymer-insulated cables. Although PILC is still dominant for underground transmission cables, extruded polymeric cables are also beginning to be used for these high-voltage applications. Typical cable sizes with the cross section of the conductor are shown in the Table 4-10.

TABLE 4-10 Typical Cable Sizes

Cable size	Conductor cross section, mm^2
AWG 2	33.6
AWG 1	42.4
AWG 1/0	53.5
AWG 2/0	67.4
AWG 3/0	85.0
AWG 4/0	107.2
500 kcmil	253.5
750 kcmil	379.5
1000 kcmil	507.0
2000 kcmil	1013.0

Typically, a cable rated at 15 kV will have insulation of wall thickness 175 mil (4.45 mm); one rated at 35 kV will have a wall thickness of 345 mil (8.76 mm); one rated at 69 kV will have insulation thickness of 650 mil (16.5 mm); and a 138-kV cable will have insulation of wall thickness 850 mil (21.6 mm). A cable construction includes the conductor shield, insulation, and insulation shield. In addition, most cables these days have a jacket to diminish moisture penetration into the insulation.

The conductor shield is a semiconductive material applied to the conductor to smooth out the stress. Since the conductors, especially the stranded conductors, have "bumps" that can enhance the field, the role of the semiconductor is to present an even voltage stress to the insulation. The insulation shield fulfills a similar role on the outer surface of the insulation. Grit, or especially metal particles, can be sites where breakdown begins. A clean interface and a semiconductive material prevent such sites from forming. The formulation of the conductor shield and the insulation shield is different. The formulation also depends on the insulating material used. A number of different materials have been used as the matrix material for semiconductive shields. These include low-density polyethylene (LDPE), ethylene–ethyl acrylate (EEA), ethylene–vinyl acetate (EVA), ethylene–propylene rubber (EPR), ethylene–propylene diene monomer (EPDM), butyl rubber, and various proprietary formulations. These materials, in themselves, are not conducting. They are made conducting by loading the polymer with carbon.

There are two insulations in use for power cables. One is cross-linked polyethylene (XLPE) and the other is ethylene–propylene rubber (EPR). These insulating materials will be described in greater detail in the following paragraphs.

Most of the cables being installed in the latter part of the 1990s are jacketed. The jacket provides protection against oil, grease, and chemicals. However, the primary role played by the jacket is to slow down the ingress of moisture, since moisture in the presence of an electric field causes the insulation to degrade by a process called *treeing*. One of the materials used extensively as a jacket material is linear low-density polyethylene (LLDPE). Jackets are approximately 50 mil (1.27 mm) thick. The discussion thus far has not described the chemistry of each of these insulating materials. The terms *thermoset* and *thermoplastic* are used without explanation. Material names such as PE, PTFE, PVC, and silicones are used without characterizing the chemistry or structure.

A *thermoplastic* resin is one with a melting point. With rising temperature, a thermoplastic resin first undergoes a glass-transition temperature (T_g) and then a crystalline melting point (T_m). Below the glass-transition temperature, a polymer is rigid and exhibits properties associated with the crystalline state. Above the glass-transition temperature, the material becomes plastic and viscous, and the material starts to slowly approach the structure of the liquid state. The glass-transition state can be detected by plotting the dielectric constant, refractive index, specific heat, coefficient of expansion, or electrical conductivity as a function of temperature.

There is one characteristic slope below the glass-transition state and another steeper slope above the glass-transition temperature. Approximate values for T_g and T_m for polyethylene are –128 and 115°C, and for polystyrene they are 80 and 240°C. It is difficult to give exact values for a given generic polymer. This is so because the exact value will depend a great deal on the variation in the character of a particular polymer, with all the variations being grouped together and called by a common name. For example, for polyethylene, the molecular weight (the degree of polymerization) of the resin, the degree of branching, and the size or length of the branches will affect both T_g and T_m. With polyvinyl chloride, the steroregularity, copolymerization, and plasticization all will affect T_g and T_m.

A *thermoset* resin does not exhibit a visible melting point. An epoxy or a phenolic resin has a three-dimensional network structure. The three-dimensional structure results in a rigid framework that cannot be made fluid without breaking a large number of bonds. The thermoplastic resins, on the other hand, are linear. They might be thought of as strands of spaghetti. The strands can slip by one another and can be fluid. The analogy to a bowl of spaghetti can be used in understanding how a thermoset material can be formed by cross-linking a thermoplastic polymer such as polyethylene. The cross-linking reaction forms bonds between the linear strands of polyethylene to form a three-dimensional structure. To visualize the cross-linking, an analogy that can be used is that of the bowl of spaghetti left in a refrigerator overnight. Once the strands of spaghetti stick together, the mass is no longer fluid. The mass can be taken out of the bowl, and it will retain the shape of the bowl. The only way to fluidize this spaghetti is to break most or all the bonds formed between the individual strands.

Some of the insulation materials used for insulated conductors are polyethylene (PE), ethylene–propylene rubber (EPR), polyvinyl chloride (PVC), fluorinated ethylene propylene (FEP), ethylene chlorotrifluoroethylene, polytetrafluoroethylene (PTFE), butyl rubber, neoprene, nitrile–butadiene rubber (NBR), latex, polyamide, and polyimide.

Polyethylene is made by polymerizing ethylene, a gas with a boiling point of –104°C. A reaction carried out at high temperature (up to 250°C) and high pressure (between 1000 and 3000 atm) produces low-density polyethylene. The reason for the low density is that the short and long branches on the long chains prevent the chains from packing efficiently into a crystalline mass. The use of Ziegler-Natta catalysts results in high-density polyethylene. The use of the catalyst results in less branching and thereby a polymer that can pack more efficiently into crystalline domains. Recently, shape-selective catalysts have become available that produce polyethylene polymers that can be made with designer properties. Even though polyethylene consists of chains of carbons, the properties can vary depending on molecular weight and molecular shape. Polyethylene sold for insulating purposes has only small amounts of additives. There is always some antioxidant. For cross-linked polyethylene, the residues of the cross-linking agent are present. Additives to inhibit treeing are added.

Ethylene–propylene rubber is a copolymer made from ethylene and propylene. The physical properties of the neat polymer are such that it is not useful unless compounded. The finished compounded product has as much as 40 to 50% filler content. Fillers consist of clays, calcium carbonate, barium sulfate, or various types of silica. In addition to the filler, EPR is compounded with plasticizer, antioxidants, flame retardants, process aids, ion scavengers, coupling agents, a curing coagent, and a curative.

Polyvinyl chloride is a polymer made from vinyl chloride, a gas boiling at –14°C. It is partially syndiotactic; that is, the stereochemistry of the carbons on which the chlorines are attached is more or less alternating. By being only partially syndiotactic, the crystallinity is low. However, the polymer is still fairly rigid, and for use where flexibility is desired, the polymer must be plasticized.

Dibutylphthalate is often used as a plasticizer. In addition to plasticizers, PVC contains heat and light stabilizers. Oxides, hydroxides, or fatty acid salts of lead, barium, tin, or cadmium are typical stabilizers.

Polytetrafluoroethylene (or Teflon) is a polymer made from tetrafluoroethylene, a nontoxic gas boiling at –76°C. It is a linear polymer consisting of chains made of CF_2 units. Its crystallinity is quite high, and its crystalline melting point is 327°C. It is resistant to almost all reagents, even up to the boiling point of the reagent. It is attacked only by molten alkali metals or the alkali metal dissolved in liquid ammonia. Polytetrafluoroethylene exhibits excellent electrical properties. It has a low dielectric constant and a low loss factor. These electrical properties do not change even when the polymer is kept at 250°C for long periods of time.

Fluorinated ethylene propylene is a copolymer made from tetrafluoroethylene and hexafluoropropylene. It compares in toughness, chemical inertness, and heat stability to polytetrafluoroethylene (PTFE).

Polychlorotrifluoroethylene has performance properties that are surpassed only by PTFE and FEP. The crystalline melting point is 218°C, as compared with 327°C for PTFE. It retains useful properties to 150°C, as opposed to 250°C for PTFE. The advantage for polychlorotrifluoroethylene is that its melt viscosity is so low enough that molding and extrusion become more feasible than for PTFE and FEP.

Polyamides or Nylons are long-chain linear polymers made by molecules linked by amide linkages. Nylon 66 is made from hexamethylene diamine and adipic acid. Nylon 66 exhibits high strength, elasticity, toughness, and abrasion resistance. Nylon 6 is made from caprolactam, a cyclic amide. To form a polymer, the caprolactam opens and the amine group and carboxylic acid group form intermolecular amide links rather than the intramolecular amide link in the cyclic compound.

Polyimides are polymers connected by imide bonds. An amide is formed when the OH group of a carboxylic acid is replaced by the NH of an amine. An imide is a related structure formed when the noncarbonyl oxygen of an acid anhydride is replaced by a nitrogen of an amine. A polyimide is usually formed from an aromatic diamine and an aromatic dianhydride. The aromatic nature of the polyimide imparts thermal stability.

Rubbers used for electrical insulation can be either natural rubber or one of the synthetic rubbers. Natural rubber is obtained from the latex of different plants. The primary commercial source is the tree *Hevea brasiliensis*. Natural rubber is an isoprenoid compound wherein the isoprene (2-methyl-1,3-butadiene) is the unit of a high-molecular-weight polymer with a degree of polymerization of around 5000. Rubber without processing is too gummy to be of practical use. It is vulcanized (cross-linked) by reaction with sulfur. Natural rubber is flexible and elastic and exhibits good electrical characteristics.

Butyl rubbers are synthetic rubbers made by copolymerizing isobutylene (2-methyl-1-propene) with a small amount of isoprene. The purpose of isoprene is to introduce a double bond into the polymer chain so that it can be cross-linked. Butyl rubbers are mostly amorphous, with crystallization taking place on stretching. They are characterized by showing a low permeability to gases, thus making them the material of choice for inner tubes of automobile tires. They are reasonably resistant to oxidative aging. Butyl rubbers have good electrical properties.

Polychloroprene or *neoprene* is a generic term for polymers or copolymers of chloroprene (2-chloro-1,3-butadiene). Neoprene is an excellent rubber with good oil resistance. It has resistance to oxidative degradation, and is stable at high temperatures. Its properties are such that it would make excellent automobile tires, but the cost of the polymer makes it noncompetitive for this market. Its desirable properties are exploited for wire and cable insulations.

Nitrile rubbers are polymers of butadiene and acrylonitrile. Nitrile rubbers are used where oil resistance is needed. The degree of oil resistance varies with acrylonitrile content of the copolymer. With 18% acrylonitrile content, the oil resistance is only fair. With 40% acrylonitrile content, the oil resistance is excellent. The oil resistance is characterized by retention of low swelling, good tensile strength, and good abrasion resistance after being immersed in gasoline or oil. Nitrile rubbers can be used in contact with water or antifreeze. For use in wire insulation where oil resistance is needed, nitrile rubber is slightly better than neoprene.

4.3.5 Thermal Conductivity of Electrical Insulating Materials

One of the general characteristics of electrical insulating materials is that they are also good thermal insulating materials. This is true, in varying degrees, for the entire spectrum of insulating materials, including air, fluids, plastics, glasses, and ceramics. While the thermal insulating properties of electrical insulating materials are not especially important for electrical and electronic designs which are not heat sensitive, modern designs are increasingly heat sensitive. This is often because higher power levels are being dissipated from smaller part volumes, thus tending to raise the temperature of critical elements of the product design. This results in several adverse effects, including degradation of electrical performance and degradation of many insulating materials, especially insulating papers and plastics. The net result is reduced life and/or reduced reliability of the electrical or electronic part. To maximize life and reliability, much effort has been devoted to data and guidelines for gaining the highest possible thermal conductivity, consistent with optimization of product design limitations such as fabrication, cost, and environmental stresses. This section will present data and guidelines which will be useful to electrical and electronic designers in selection of electrical insulating materials for best meeting thermal design requirements. Also, methods of determining thermal conductivity K will be described.

Basic Thermal-Conductivity Data. The thermal-conductivity values for a range of materials commonly used in electrical design are shown in Table 4-11. These data show the ranking of the range of materials, both conductors and insulating materials, from high to low. The magnitude of the differences in conductor and plastic thermal-conductivity values can be seen. Note that one ceramic, 95% beryllia, has a higher thermal-conductivity value than some metals—thus making beryllia highly considered for high-heat-dissipating designs which allow its use. Thermal conductivity is variously reported in many different units, and convenient conversions are shown in Table 4-12.

Values of thermal conductivity do not change drastically up to 100°C or higher, and hence only a single value is usually given for plastics. For higher-temperature applications, such as with ceramics, the temperature effect should be considered. In addition to bulk insulating materials, insulating coatings are frequently used.

Thermal-Conductivity Measurements. The recognized primary technique for measuring thermal conductivity of insulating materials is the guarded-hot-plate method (ASTM C177). A schematic of the apparatus is shown in Fig. 4-21. The purpose of the guard heater is to prevent heat flow in all but the axial (up and down in the schematic) direction by establishing isothermal surfaces on the specimen's hot side. With this condition established and by measuring the temperature difference across the sample, the electrical power to the main heater area and the sample thickness, the K factor, can be calculated as

$$K = \frac{QX}{2A\,\Delta T} \tag{4-78}$$

Instruments are available for this test which use automatic means to control the guard temperature and record the sample ΔT. Unfortunately this test is fairly expensive.

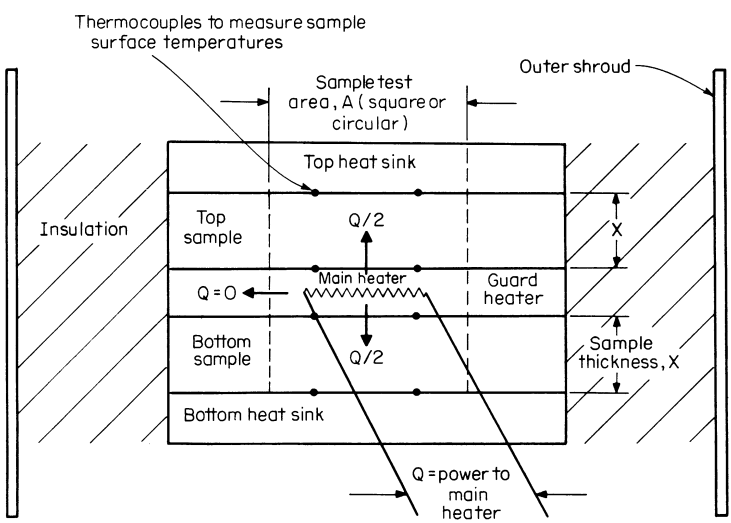

FIGURE 4-21 Schematic assembly of guarded hot plate.

Another technique uses a heat-flow sensor, which is a calibrated thermopile, in series with the heater, specimen, and cold sink. This method avoids the guard heater and requires only one specimen. This secondary technique is described in ASTM C518.

4.4 STRUCTURAL MATERIALS

4.4.1 Definitions of Properties

Stress. *Stress* is the intensity at a point in a body of the internal forces or components of force that act on a given plane through the point. Stress is expressed in force per unit of area (pounds per square inch, kilograms per square millimeter, etc.). There are three kinds of stress: tensile, compressive, and shearing. *Flexure* involves a combination of tensile and compressive stress. *Torsion* involves shearing stress. It is customary to compute stress on the basis of the original dimensions of the cross section of the body, though "true stress" in tension or compression is sometimes calculated from the area of the time a given stress exists rather than from the original area.

Strain. *Strain* is a measure of the change, due to a force, in the size or shape of a body referred to its original size or shape. Strain is a nondimensional quantity but is frequently expressed in inches per inch, etc. Under tensile or compressive stress, strain is measured along the dimension under consideration. *Shear strain* is defined as the tangent of the angular change between two lines originally perpendicular to each other.

Stress-Strain Diagram. A *stress-strain diagram* is a diagram plotted with values of stress as ordinates and values of strain as abscissas. Diagrams plotted with values of applied load, moment, or torque as ordinates and with values of deformation, deflection, or angle of twist as abscissas are sometimes referred to as stress-strain diagrams but are more correctly called *load-deformation diagrams*. The stress-strain diagram for some materials is affected by the rate of application of the load, by cycles of previous loading, and again by the time during which the load is held constant at specified values; for precise testing, these conditions should be stated definitely in order that the complete significance of any particular diagram may be clearly understood.

Modulus of Elasticity. The *modulus of elasticity* is the ratio of stress to corresponding strain below the proportional limit. For many materials, the stress-strain diagram is approximately a straight line below a more or less well-defined stress known as the *proportional limit*. Since there are three kinds of stress, there are three moduli of elasticity for a material, that is, the modulus in tension, the modulus in compression, and the modulus in shear. The value in tension is practically the same, for most ductile metals, as the modulus in compression; the modulus in shear is only about 0.36 to 0.42 of the modulus in tension. The modulus is expressed in pounds per square inch (or kilograms per square millimeter) and measures the elastic *stiffness* (the ability to resist elastic deformation under stress) of the material.

Elastic Strength. To the user and the designer of machines or structures, one significant value to be determined is a *limiting stress below which the permanent distortion of the material is so small that the structural damage is negligible and above which it is not negligible*. The amount of plastic distortion which may be regarded as negligible varies widely for different materials and for different structural or machine parts. In connection with this limiting stress for elastic action, a number of technical terms are in use; some of them are

1. *Elastic Limit*. The greatest stress which a material is capable of withstanding without a permanent deformation remaining on release of stress. Determination of the elastic limit involves repeated application and release of a series of increasing loads until a set is observed upon release of load. Since the elastic limit of many materials is fairly close to the proportional limit, the latter is sometimes accepted as equivalent to the elastic limit for certain materials. There is, however, no fundamental relation between elastic limit and proportional limit. Obviously, the value of the elastic limit determined will be affected by the sensitivity of apparatus used.

2. *Proportional Limit*. The greatest stress which a material is capable of withstanding without a deviation from proportionality of stress to strain. The statement that the stresses are proportional to strains below the proportional limit is known as *Hooke's Law*. The numerical values of the proportional limit are influenced by methods and instruments used in testing and the scales used for plotting diagrams.
3. *Yield Point*. The lowest stress at which marked increase in strain of the material occurs *without increase in load*. If the stress-strain curve shows no abrupt or sudden yielding of this nature, then there is no yield point. Iron and low-carbon steels have yield points, but most metals do not, including iron and low-carbon steels immediately after they have been plastically deformed at ordinary temperatures.
4. *Yield Strength*. The stress at which a material exhibits a specified limiting permanent set. Its determination involves the selection of an amount of permanent set that is considered the maximum amount of plastic yielding which the material can exhibit, in the particular service condition for which the material is intended, without appreciable structural damage. A set of 0.2% has been used for several ductile metals, and values of yield strength for various metals are for 0.2% set unless otherwise stated. On the stress-strain diagram for the material (Fig.4-22) this arbitrary set is laid off as *q* along the strain axis, and the line *mn* drawn parallel to *OA*, the straight portion of the diagram. Since the stress-strain diagram for release of load is approximately parallel to *OA*, the intersection *r* may be regarded as determining the stress at the yield strength. The yield strength is generally used to determine the elastic strength for materials whose stress-strain curve in the region *pr* is a smooth curve of gradual curvature.

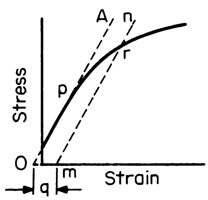

FIGURE 4-22 Yield strength of a material having no well-defined yield point.

Ultimate Strength. *Ultimate strength (tensile strength* or *compressive strength)* is the maximum stress which a material will sustain when slowly loaded to rupture. Ultimate strength is computed from the maximum load carried during a test and the original cross-sectional area of the specimen. For materials that fail in compression with a shattering fracture, the compressive strength has a definite value, but for materials that do not fracture, the compressive strength is an arbitrary value depending on the degree of distortion which is regarded as indicating complete failure of the material. In tensile tests of many materials, especially those having appreciable ductility, failure does not occur at the stress corresponding to the ultimate strength. For such materials, localized deformation, or necking, occurs and the nominal stress decreases because of the rapidly decreasing cross-sectional area until failure occurs.

Shearing Strength. *Shearing strength* is the maximum shearing stress which a material is capable of developing. The remarks in the preceeding paragraph regarding methods of failure are also applicable to failures in shear. Owing to experimental difficulties of obtaining true shearing strength, the values of modulus of rupture in torsion are usually reported as indicative of the shearing strength.

Modulus of Rupture. *Modulus of rupture* in flexure (or torsion) is the term applied to the computed stress, in the extreme fiber of a specimen tested to failure under flexure (or torsion), when computed by the arbitrary application of the formula for stress with disregard of the fact that the stresses exceed the proportional limit. Hence, the modulus of rupture does not give the true stress in the member but is useful only as a basis of comparison of relative strengths of materials.

Ductility. *Ductility* is that property of a material which enables it to acquire large permanent deformation and at the same time develop relatively large stresses (as drawing into a wire). Although ductility is a highly desirable property required by almost all specifications for metals, the quantitative amount needed for structural applications is not entirely clear but probably does not exceed about 3% elongation after the structure is fabricated. The commonly used measures of ductility are

1. *Elongation* is the ratio of the increase of length of a specimen, after rupture under tensile stress, to the original gage length; it is usually expressed in percent. The percentage of elongation for any given material depends upon the gage length, which should always be specified.
2. *Reduction of area or contraction of area* is the ratio of the difference between the original and the fractured cross section to the original cross-sectional area; it is usually expressed as a percentage.
3. *Bend test* measures the angle through which a given specimen of material can be bent, at a specified temperature, without cracking. In some cases, the maximum angle through which the specimen can be bent around a certain diameter or the number of bendings back and forth through a stated angle are measured. In other cases, the elongation in a given gage length across the crack on the tension side of the bend specimen is measured.

Plasticity. *Plasticity* permits a material to assume permanent deformations under loads without recovery of the strain when the loads are removed. Plasticity permits shaping of metal parts by plastic deformation; plastic materials deform instead of fracturing under load.

Brittleness. *Brittleness* is defined as the ability of a material to fracture under stress with little or no plastic deformation. Brittleness implies a lack of plasticity.

Resilience. *Resilience* is the amount of strain energy (or work) which may be recovered from a stressed body when the loads causing the stresses are removed. Within the elastic limit, the work done in deforming the bar is completely recovered upon removal of the loads; the total amount of work done in stressing a unit volume of the material to the elastic limit is called the *modulus of resilience*.

Toughness. *Toughness* is the ability to withstand large stresses accompanied by large strains before fracture. The toughness is usually measured by the total work done in stressing a unit volume of the material to complete fracture and may be interpreted as the total area under the stress-strain curve. Ductility differs from toughness in that it deals only with the ability of the material to deform, whereas toughness is measured by the energy-absorbing capacity of the material.

Impact Resistance. The ability of a material to resist impact or energy loads without permanent distortion is measured by the modulus of resilience. The ultimate resistance to impact before fracture is measured by the toughness of the material. For members with abrupt changes of section (holes, keyways, fillets, etc.), the resistance to a rapidly applied load depends greatly on the *notch sensitivity* (the resistance to the formation and spread of a crack); above certain critical velocities of loading and below certain critical temperatures, the impact strength is greatly reduced. Relative notch sensitivity under repeated loads is not the same as that in a single-blow notched-bar test. Impact values are influenced by speed of straining, shape and size of specimen, and type of testing machine.

Charpy or *Izod* impact bend tests measure the energy required to fracture small notched specimens (1 cm^2) under a single blow. These tests are used as an indication of toughness, a property that is very sensitive to the composition and thermal-mechanical history of the material. Tests should be carried out over a range of temperatures to determine the temperature at which the alloy fails by brittle rather than ductile failure.

Fracture Mechanics. Three primary factors have been identified that control the susceptibility of a structure to brittle failure: material toughness (affected by composition and metallurgical structure as well as temperature, strain rate, and constraints to plastic yielding), flaw size (internal discontinuities such as porosity or small cracks from welding, fatigue, and fabrication), and stress level (applied or residual). Fracture mechanics attempt to interrelate these variables in order to predict the occurrence of brittle fracture on a quantitative design basis rather than depend on qualitative relationships between experience and results of impact tests such as Izod and Charpy. Fracture mechanics has had excellent success when applied to high-strength materials. The material parameter defined, called the *fracture toughness* K_C, can be measured experimentally and used to specify safe loading conditions in the presence of a given size and geometry of flaw.

Hardness. *Hardness* is the resistance which a material offers to small, localized plastic deformations developed by specific operations such as scratching, abrasion, cutting, or penetration of the surface. Hardness does not imply brittleness, as a hard steel may be tough and ductile. The standard Brinell hardness test is made by pressing a hardened steel ball against a smooth, flat surface under certain standard conditions; the Brinell hardness number is the quotient of the applied load divided by the area of the surface of the impression. A different method of test is employed in the Shore scleroscope, in which a small, pointed hammer is allowed to fall from a definite height onto the material, and the hardness is measured by the height of the rebound, which is automatically indicated on a scale. The Rockwell hardness machine measures the depth of penetration in the metal produced by a definite load on a small indenter of spherical or conical shape. Vickers or Tukon hardness machines measure hardness on a microscopic scale. The dimensions of the impression of a lightly loaded diamond pyramid indenter on a polished surface are related to hardness number.

Fatigue Strength. *Fatigue strength (fatigue limit)* is a limiting stress below which no evidence of failure by progressive fracture can be detected after the completion of a very large number of repetitions of a definite cycle of stress. The fatigue limits usually reported are those for completely reversed cycles of flexural stress in polished specimens. For stress cycles in which an alternating stress is superimposed on a steady stress, the endurance limit (based on the maximum stress in the cycle) is somewhat higher. Most ferrous metals have well-defined limits, whereas the fatigue strength of many nonferrous metals is arbitrarily listed as the maximum stress that is just insufficient to cause fracture after some definite number of cycles of stress, which should always be stated. The fatigue strength of actual members containing notches (holes, fillets, surface scratches, etc.) is greatly reduced and depends entirely on the "stress-raising" effect of these discontinuities and the sensitivity of the material to the localized stresses at the notch.

Composition and Structure. Chemical analysis is employed to determine whether component elements are present within specified amounts and impurity elements are held below specified limits. Mechanical and physical properties, however, depend on the size, shape, composition, and distribution of the crystalline constituents that make up the structure of the alloy. Chemical analysis does not reveal these features of the structure. Metallographic techniques, which involve examination of carefully polished and etched surfaces by optical and electron microscopy or x-ray methods, are required to provide this vital information. Nondestructive testing (NDT) methods are useful in detecting the presence of flaws of various kinds in finished parts and structures. These techniques depend on the interference of the defect with some easily measured physical property, such as x-ray absorption, magnetic susceptibility, propagation of acoustical waves, or electrical conductivity. NDT techniques have particular application where defects are difficult to detect and quite likely to occur (as in welded structures), and where high-integrity performance requires 100% inspection.

Aging. *Aging* is a spontaneous change in properties of a metal with time after a heat-treatment or a cold-working operation. Aging tends to restore the material to an equilibrium condition and to remove the unstable condition induced by the prior operation, and usually results in increased strength of the metal with corresponding loss of ductility. The fundamental action involved is generally one of precipitation of hardening elements from the solid solution, and the process can usually be hastened by slight increase in temperature. This is a very important strengthening mechanism in a variety of ferrous and nonferrous alloys, for example, high-strength aluminum alloys.

Corrosion Resistance. There is no universal method of determining corrosion resistance, because different types of exposures ordinarily produce entirely dissimilar results on the same material. In general, the subject of corrosion is rather complicated; in some cases, corrosive attack appears to be chiefly chemical in nature, while in others the attack is by electrolysis. Owing to the great diversity of materials exposed to corrosive influences in service and the wide range of service conditions, it is impracticable to formulate any universal measure of corrosion resistance. If the service life is likely to be determined by corrosion resistance, the degree of impairment which marks the end of usefulness ordinarily will be established by considerations of safety and reliability or perhaps of appearance. Corrosion testing is conducted in general by two methods: (1) normal exposure in service with periodic observations of corrosive action as it progresses under such conditions, and (2) some type of artificially accelerated test, which may serve merely to obtain comparative results or, again, may simulate the conditions of service exposure.

Powder Metallurgy. Many alloys and metallic aggregates having unusual and very valuable properties are being produced commercially by mixing metal powders, pressing in dies to desired shapes, and sintering at high temperatures. Parts may be produced to close dimensional tolerance, and the process enables the mixing of dissimilar materials which will not normally alloy or which cannot be cast because of insolubility of the constituents. Wide use of powder metallurgy is made in producing copper-molybdenum alloys for contact electrodes for spot welding, extremely hard cemented tungsten carbide tips for use in metal cutting tools, and copper-base alloys containing either graphite particles or a controlled dispersion of porosity for bearings of the “oilless” or oil-retaining types. Silver-nickel and silver-molybdenum alloys (tungsten or graphite may be added) for contact materials having high conductivity but good resistance to fusing can be produced by the method. Powdered iron is being used to manufacture gears and small complex parts where the savings in weight of metal and machining costs are able to offset the additional cost of metal and processing in the powdered form. Small Alnico magnets of involved shape which are exceedingly difficult to cast or machine can be produced efficiently from metallic powders and require little or no finishing. Solid mixtures of metals and nonmetals, such as asbestos, can be produced to meet special requirements. The size and shape of powder particles, pressing temperature and pressure, sintering temperature and time, all affect the final density, structure, and physical properties.

4.4.2 Structural Iron and Steel

Classification of Ferrous Materials. Iron and steel may be classified on the basis of composition, use, shape, method of manufacture, etc. Some of the more important ferrous alloys are described in the sections below.

Ingot iron is commercially pure iron and contains a maximum of 0.15% total impurities. It is very soft and ductile and can undergo severe cold-forming operations. It has a wide variety of applications based on its formability. Its purity results in good corrosion resistance and electrical properties, and many applications are based on these features. The average tensile properties of Armco ingot iron plates are tensile strength 320 MPa (46,000 lb/in^2); yield point 220 MPa (32,000 lb/in^2); elongation in 8 in, 30%; Young’s modulus 200 GPa (29×10^6 lb/in^2).

Plain carbon steels are alloys of iron and carbon containing small amounts of manganese (up to 1.65%) and silicon (up to 0.50%) in addition to impurities of phosphorus and sulfur. Additions up to 0.30% copper may be made in order to improve corrosion resistance. The carbon content may range from 0.05% to 2%, although few alloys contain more than 1.0%, and the great bulk of steel tonnage contains from 0.08% to 0.20% and is used for structural applications. Medium-carbon steels contain around 0.40% carbon and are used for constructional purposes—tools, machine parts, etc. High-carbon steels have 0.75% carbon or more and may be used for wear and abrasion-resistance applications such as tools, dies, and rails. Strength and hardness increase in proportion to the carbon content while ductility decreases. Phosphorus has a significant hardening effect in low-carbon steels, while the other components have relatively minor effects within the limits they are found. It is difficult to generalize the properties of steels, however, since they can be greatly modified by cold working or heat treatment.

High-strength low-alloy steels are low-carbon steels (0.10% to 0.15%) to which alloying elements such as phosphorus, nickel, chromium, vanadium, and niobium have been added to obtain higher strength. This class of steel was developed primarily by the transportation industry to decrease vehicle weight, but the steels are widely used. Since thinner sections are used, corrosion resistance is more important, and copper is added for this purpose.

Free-Machining Steels. Additions of manganese, phosphorus, and sulfur greatly improve the ease with which low-carbon steels are machined. The phosphorus hardens the ferrite, and the manganese and sulfur combine to form nonmetallic inclusions that help form and break up machining chips. The improvement in machinability is gained at some loss of mechanical properties, and these steels should be used for noncritical applications. Small amounts of lead also improve machining characteristics of steel by helping break up chips as well as providing a self-lubricating effect. Lead is more often added to higher-carbon steels where the effect on mechanical properties is less detrimental than that caused by sulfide inclusions.

Alloy Steels. When alloying ingredients (in addition to carbon) are added to iron to improve its mechanical properties, the product is known as an *alloy steel*. Heat treatment is a necessary part of the manufacture and use of alloy steels; only through proper quenching and tempering can the full beneficial effects of the alloys be obtained. The chief advantages obtained from the addition of alloys to steel are (1) to increase the depth of hardening on quenching, thus making it possible to produce more uniform properties throughout thick sections with a minimum of distortion, and (2) to form chemical compounds which when properly distributed develop desirable properties in the steel, that is, extreme hardness, corrosion or heat resistance, and high strength without excessive brittleness.

The most commonly used alloy steels have been classified by the American Iron and Steel Institute and the Society of Automotive Engineers and are identified by a nomenclature system that is partially descriptive of the composition. The system of steel designations and the approximate strengths of several alloy steels after specific heat treatments are available from various manufacturers. Mechanical properties of the alloy steels vary over a wide range depending on size, composition, and thermomechanical treatment.

Cast Iron. Iron ore is reduced to the metallic form in a blast furnace, yielding a product of molten iron saturated in carbon (about 4%). Most commonly, this "hot metal" is immediately processed to steel by a refining process without allowing it to solidify. Occasionally, it is cast into bars; this product is called *pig iron*. Cast iron is made by remelting pig iron and/or scrap steel in a cupola or electric furnace and casting it into molds to the desired shape of the finished part. Cast iron has a much higher carbon content than steel, usually between 2.5% and 3.75%.

Gray Cast Iron. In gray cast iron, the excess carbon beyond that soluble in iron is present as small flake-shaped particles of graphite. The flakes of graphite account for some of the unique properties of gray iron, in particular, its low tensile strength and ductility, its ability to absorb vibrational energy (damping capacity), and its excellent machinability. Cast iron is easy to cast because it has a lower melting point than steel, and the formation of the low-density graphite offsets solidification shrinkage so that minimal dimensional changes occur on freezing. Other elements in the composition of ordinary gray cast iron are important chiefly insofar as they affect the tendency of carbon to form as graphite rather than in chemical combination with the iron as iron carbide (Fe_3C). Silicon is most effective in promoting the formation of graphite. Slower cooling rates during freezing also favor the formation of graphite as well as increase the size of the flakes. Cooling rate also affects the mode of decomposition of the carbon retained in solution during freezing. Slow cooling favors complete precipitation as graphite, leaving a soft ferrite matrix, while fast cooling produces a stronger matrix containing Fe_3C (as pearlite). The tensile strength of gray cast iron typically ranges from 140 to 410 MPa (20,000 to 60,000 lb/in^2). Corresponding compressive strengths are 575 to 1300 MPa (85,000 to 190,000 lb/in^2). Young's modulus may range from 70 to 150 GPa (10×10^6 to 20×10^6 lb/in^2), depending on the microstructure.

White Cast Iron. Careful adjustment of composition and cooling rate can cause all the carbon in a cast iron to appear in the combined form as pearlite or free carbide. This structure is very hard and brittle and has few engineering applications beyond resistance to abrasion. This product does serve, however, as an intermediate product in the production of malleable cast iron described in the following paragraph.

Malleable Cast Iron. By annealing white cast iron at about 950°C, the combined carbon will decompose to graphite. This graphite grows in a spheroidal shape rather than the flake-like shape that forms during the freezing of gray cast iron. Because of this difference in graphite shape, malleable iron is much tougher and stronger. If the castings are slowly cooled from the malleabilizing temperature, the matrix can be converted to ferrite, with all the carbon appearing as graphite; this is a very tough product. Faster cooling will yield a pearlitic matrix with greater strength and hardness. It is also possible to quench and temper malleable iron for optimum combinations of strength and toughness. By careful control of composition, the malleabilizing cycle can be carried out in 8 to 20 h.

Nodular Cast Iron. *Nodular cast iron* has the same carbon content as gray iron; however, the addition of a few hundreds of 1% of either magnesium or cerium causes the uncombined carbon to form spheroidal particles during solidification instead of graphite flakes. Strength properties comparable with those of steel may be achieved in the pearlitic iron. The softer ferritic and pearlitic as-cast irons exhibit considerable ductility, 10% elongation or more. As the hardness and strength are increased by appropriate heat treatment or the thickness of the casting decreased below approximately $^1/_4$ in, the ductility decreases. An austenitic form of nodular iron may be obtained by adding various amounts of silicon, nickel, manganese, and chromium. For many purposes, nodular iron exhibits properties superior to those of either gray or malleable cast iron.

Chilled Cast Iron. *Chilled cast iron* is made by pouring cast iron into a metallic mold which cools it rapidly near the surfaces of the casting, thus forming a wear-resisting skin of harder material than the body of the metal. The rapid cooling decreases the proportion of graphite and increases the combined carbon, resulting in the formation of white cast iron.

Alloy Cast Iron. *Alloy cast iron* contains specially added elements in sufficient amount to produce measurable modification of the physical properties. Silicon, manganese, sulfur, and phosphorus, in quantities normally obtained from raw materials, are not considered alloy additions. Up to about 4% silicon increases the strength of pure iron; greater content produces a matrix of dissolved silicon that is weak, hard, and brittle. Cast irons with 7% to 8% silicon are used for heat-resisting purposes and with 13% to 17% silicon form acid- and corrosion-resistant alloys, which, however, are extremely brittle. Manganese up to 1% has little effect on mechanical properties but tends to inhibit the harmful effects of sulfur. Nickel, chromium, molybdenum, vanadium, copper, and titanium are commonly used alloying elements. The methods of processing or of making the alloy additions to the iron influence the final properties of the metal; hence, a specified chemical analysis is not sufficient to obtain required qualities. Heat treatment is also employed on alloy irons to enhance the physical properties.

Density of Cast Iron. *Density of cast iron* varies considerably depending on the carbon content and the proportion of the carbon that is present as graphite. Using the density of pure iron, 7.86, as a reference, the density of cast iron may range from 7.60 for white cast iron to as low as 6.80 for gray cast iron.

Thermal Properties of Cast Iron. Thermal properties vary somewhat with the composition and the proportions of graphitic carbon. The average specific heat from 20 to 110°C is 0.119; thermal conductivity, 0.40 W/(cm^3)(°C); coefficient of linear expansion, 0.0000106/°C at 40°C.

Values of modulus of elasticity for ferrous metals may be assumed approximately as shown in Table 4-13. The values for all steels are fairly constant, whereas for cast irons the modulus increases somewhat with increased strength of material. Alloy steels have practically the same modulus as plain carbon steels unless large amounts, say, 10%, of alloying material are added; for large percentages of alloying elements, the modulus decreases slightly. The modulus of steels is not affected by heat treatment.

Heat Treatment of Steel. The properties of steels can be greatly modified by thermal treatments, which change the internal crystalline structure of the alloy. *Hardening* of steel is based on the fact that iron undergoes a change in crystal structure when heated above its "critical" temperature. Above this critical transformation temperature, the structure is called *austenite*, a phase capable of dissolving carbon up to 2%. Below the critical temperature, the steel transforms to *ferrite*, in which carbon is insoluble and precipitates as an iron carbide compound, Fe_eC (sometimes called *cementite*). If a steel is cooled rapidly from above the critical temperature, the carbon is unable to diffuse to form cementite, and the austenite transforms instead to an extremely hard metastable constituent called *martensite,* in which the carbon is held in supersaturation. The hardness of the martensite depends sensitively on the carbon content. Low-carbon steels (below about 0.20%) are seldom quenched, while steels above about 0.80% carbon are brittle and liable to crack on quenching. Plain carbon steels must be quenched at very fast rates in order to be hardened. Alloying elements can be added to decrease the necessary cooling rates to cause hardening; some alloy steels will harden when cooled in air from above the critical temperature. It should be noted, however, that it is the amount of carbon that primarily determines the properties of the alloy; the alloying elements serve to make the response to heat treatment possible.

Normalizing is a treatment in which the steel is heated over the critical temperature and allowed to cool in still air. The purpose of normalizing is to homogenize the steel. The carbon in the steel will appear as a fine lamellar product of cementite and ferrite called pearlite.

Annealing is similar to normalizing, except the steel is very slowly cooled from above the critical. The carbides are now coarsely divided and the steel is in its softest state, as may be desired for cold-forming or machining operations.

Process annealing is a treatment carried out below the critical temperature designed to recrystallize the ferrite following a cold-working operation. Metals become hardened and embrittled by plastic deformation, but the original state can be restored if the alloy is heated high enough to cause new strain-free grains to nucleate and replace the prior strained structure. This treatment is commonly applied as a final processing for low-carbon steels where ductility and toughness are important, or as an intermediate treatment for such products as wire that are formed by cold working.

Stress-relief annealing is a thermal treatment carried out at a still lower temperature. No structural changes take place, but its purpose is to reduce residual stresses that may have been introduced by previous nonuniform deformation or heating.

Tempering is a treatment that always follows a hardening (quenching) treatment. After hardening, steels are extremely hard, but relatively weak owing to their brittleness. When reheated to temperatures below the critical, the martensitic structure is gradually converted to a ferrite-carbide aggregate that optimizes strength and toughness. When steels are tempered at about 260°C, a particularly brittle configuration of precipitated carbides forms; steels should be tempered above or below this range. Another phenomenon causing embrittlement occurs in steels particularly containing chromium and manganese that are given a tempering cycle that includes holding at or cooling through temperatures around 567 to 621°C. Small molybdenum additions retard this effect, called *temper brittleness*. It is believed to be caused by a segregation of trace impurity elements to the grain boundaries.

Manganese Steels. Manganese is present in all steels as a scavenger for sulfur, an unavoidable impurity; otherwise, the sulfur would form a low-melting constituent containing FeS, and it would be impossible to hot work the steel. The manganese content should be about 5 times the sulfur to provide protection against this "hot shortness." Beyond this amount, manganese increases the hardness of the steel and also has a strong effect on improving response to hardening treatment, but increases susceptibility to temper brittleness. Manganese can be specified up to 1.65% without the steel being classified as an alloy steel. The alloy containing 12% to 14% Mn and around 1% carbon is called *Hadfield's manganese steel*. This alloy can be quenched to retain the austenite phase and is quite tough in this condition. When deformed, this austenite transforms to martensite, which confers exceptional wear and abrasion resistance. Applications for this unique steel include railroad switches, crushing and grinding equipment, dipper bucket teeth, etc.

Vanadium Steels. In amounts up to 0.01%, vanadium has a powerful strengthening effect in microalloyed high-strength, low-alloy steels. In alloy steels, 0.1% to 0.2% vanadium is used as a deoxidizer and carbide-forming addition to promote fine-grained tough steels with deep hardening characteristics. Vanadium accentuates the benefits derived from other alloying elements such as manganese, chromium, or nickel, and it is used in a variety of quaternary alloys containing these elements. Vanadium in amounts of 0.15% to 2.50% is an important element in a large number of tool steels.

Silicon Steels. Silicon is present in most constructional steels in amounts up to 0.35% as a deoxidizer to enhance production of sound ingot structures. Silicon increases the hardenability of steel slightly and also acts as a solid solution hardener with little loss of ductility in amounts up to 2.5%. Silicon in amounts of about 4.5% is a major ingredient in electrical steel sheets. Silicon improves the magnetic properties of iron, but even more important, these steels can be fabricated to produce controlled grain size and orientation. Since permeability depends on crystal orientation, exceptionally small core losses are obtained by using grain-oriented silicon steel in motors and transformers. Alloys containing 12% to 14% Si are exceptionally resistant to corrosion by acids. This alloy is too brittle to be rolled or forged, but it can be cast and is widely used as drainpipe in laboratories and for containers of mineral acids.

Nickel Steels. Nickel is used as a ferrite strengthener and improves the toughness of steel, especially at low temperatures. Nickel also improves the hardenability and is particularly effective when used in combination with chromium. Nickel acts similarly to copper in improving corrosion resistance to atmospheric exposure. Certain iron-nickel alloys have particularly interesting properties and are used for special applications: *Invar* (36% Ni) has a very low temperature coefficient of expansion; *Platinite* (46% Ni) has the same expansion coefficient as platinum; and the 39% Ni alloy has the same coefficient as low-expansion glasses. These alloys are useful as gages, seals, etc. *Permalloys* (45% and 76% Ni) have exceptionally high permeability and are used in transformers, coils, relays, etc.

Chromium Steels. In constructional steels, chromium is used primarily as a hardener. It improves response to heat treatment and also forms a series of complex carbide compounds that improve wear and high-temperature properties. For these purposes, the amount of chromium used is less than 2%. Alloys containing around 5% Cr retain high hardness at elevated temperatures, and have applications as die steels and high-temperature processing equipment. Alloys containing more than 11% Cr have exceptional resistance to atmospheric corrosion and form the basis of the stainless steels.

Stainless Steels. Iron-base alloys containing between 11% and 30% chromium form a tenacious and highly protective chrome oxide layer that gives these alloys excellent corrosion-resistant properties. There are a great number of alloys that are generally referred to as *stainless steels*, and they fall into three general classifications.

Austenitic stainless steels contain usually 8% to 12% nickel, which stabilizes the austenitic phase. These are the most popular of the stainless steels. With 18% to 20% chromium, they have the best corrosion resistance and are very tough and can undergo severe forming operations. These alloys are susceptible to embrittlement when heated in the range of 593 to 816°C. At these temperatures, carbides precipitate at the austenite grain boundaries, causing a local depletion of the chromium content in the adjacent region, so this region loses its corrosion resistance. Use of "extra low carbon" grades and grades containing stabilizing additions of strong carbide-forming elements such as niobium minimizes this problem. These alloys are also susceptible to stress corrosion in the presence of chloride environments.

Ferritic stainless steels are basically straight Fe-Cr alloys. Chromium in excess of 14% stabilizes the low-temperature ferrite phase all the way to the melting point. Since these alloys do not undergo a phase change, they cannot be hardened by heat treatment. They are the least expensive of the stainless alloys.

Martensitic stainless steels contain around 12% Cr. They are austenitic at elevated temperatures but ferritic at low; hence they can be hardened by heat treatment. To obtain a significant response to heat treatment, they have higher carbon contents than the other stainless alloys. Martensitic alloys are used for tools, machine parts, cutting instruments, and other applications requiring high strength. The austenitic alloys are nonmagnetic, but the ferritic and martensitic grades are ferromagnetic.

Heat-Resistant Alloys. Heat-resistant alloys are capable of continuous or intermittent service at temperatures in excess of 649°C. There are a great number of these alloys; they are best considered by class. *Iron-chromium alloys* contain between 10% and 30% chromium. The higher the chromium, the higher is the service temperature at which they can operate. They are relatively low-strength alloys and are used primarily for oxidation resistance. *Iron-chromium-nickel alloys* have chromium in excess of 18%, nickel in excess of 7%, and always more chromium than nickel. They are austenitic alloys and have better strength and ductility than the straight Fe-Cr alloys. They can be used in both oxidizing and reducing environments and in sulfur-bearing atmospheres. Iron-nickel-chromium alloys have more than 10% Cr and more than 25% Ni. These are also austenitic alloys and are capable of withstanding fluctuating temperatures in both oxidizing and reducing atmospheres. They are used extensively for furnace fixtures and components and parts subjected to nonuniform heating. They are also satisfactory for electric resistance-heating elements. *Nickel-base alloys* contain about 50% Ni, and also contain some molybdenum. They are more expensive than iron-base alloys, but have better high-temperature mechanical properties. *Cobalt-base alloys* contain about 50% cobalt and have especially good creep and stress-rupture properties. They are widely used for gas-turbine blades. Most of these alloys are available in both cast and wrought form; the castings usually have higher carbon contents and often small additions of silicon and/or manganese to improve casting properties.

4.4.3 Steel Strand and Rope

Iron and Steel Wire. Annealed wire of iron or very mild steel has a tensile strength in the range of 310 to 415 MPa (45,000 to 60,000 lb/in^2); with increased carbon content, varying amounts of cold drawing, and various heat treatments, the tensile strength ranges all the way from the latter figures up to about 3450 MPa (500,000 lb/in^2), but a figure of about 1725 MPa (250,000 lb/in^2) represents the ordinary limit for wire for important structural purposes. For example, see the following paragraph on bridge wire. Wires of high carbon content can be tempered for special applications such as spring wire. The yield strength of cold-drawn steel wire is 65% to 80% of its ultimate strength. For examples showing the effects of drawing and carbon content on wire, see *Making, Shaping, and Treating of Steel*, U.S. Steel.

Galvanized-Steel Bridge Wire. The manufacture of high-strength bridge wire like that used for the cables and hangers of suspension bridges such as the San Francisco–Oakland Bay Bridge, the Mackinac Bridge in Michigan, and the Narrows Bridge in New York is an excellent example of careful control of processing to produce a quality material. The wire is a high-carbon product containing 0.75% to 0.85% carbon with maximum limits placed on potentially harmful impurities. Rolling temperatures are carefully specified, and the wire is subjected to a special heat treatment called *patenting*. The steel is transformed in a controlled-temperature molten lead bath to ensure an *optimal* microstructure. This is followed by cold drawing to a minimum tensile strength of 1550 MPa

(225,000 lb/in^2) and a 4% elongation. The wire is given a heavy zinc coating to protect against corrosion. Joints or splices are made with cold-pressed sleeves which develop practically the full strength of the wire. Fatigue tests of galvanized bridge wire in reversed bending indicate that the endurance limit of the coated wire is only about 345 to 415 MPa (50,000 to 60,000 lb/in^2).

Wire Rope. Wire rope is made of wires twisted together in certain typical constructions and may be either flat or round. Flat ropes consist of a number of strands of alternately right and left lay, sewed together with soft iron to form a band or belt; they are sometimes of advantage in mine hoists. Round ropes are composed of a number of wire strands twisted around a hemp core or around a wire strand or wire rope. The standard wire rope is made of six strands twisted around a hemp core, but for special purposes, four, five, seven, eight, nine, or any reasonable number of strands may be used. The hemp is usually saturated with a lubricant, which should be free from acids or corrosive substances; this provides little additional strength but acts as a cushion to preserve the shape of the rope and helps to lubricate the wires. The number of wires commonly used in the strands are 4, 7, 12, 19, 24, and 37, depending on the service for which the ropes are intended. When extra flexibility is required, the strands of a rope sometimes consist of ropes, which in turn are made of strands around a hemp core. Ordinarily, the wires are twisted into strands in the opposite direction to the twist of the strands in the rope. The makeup of standard hoisting rope is 6×19; extrapliable hoisting rope is 8×19 or 6×37; transmission or haulage rope is 6×7; hawsers and mooring lines are 6×12 or 6×19 or 6×24 or 6×37, etc.; tiller or hand rope is 6×7; highway guard-rail strand is 3×7; galvanized mast-arm rope is 9×4 with a cotton center. The tensile strength of the wire ranges, in different grades, from 415 to 2415 MPa (60,000 to 350,000 lb/in^2), depending on the material, diameter, and treatment. The maximum tensile efficiency of wire rope is 90%; the average is about 82.5%, being higher for 6×7 rope and lower for 6×37 construction. The apparent modulus of elasticity for steel cables in service may be assumed to be 62 to 83×10^6 kPa (9 to 12×10^6 lb/in^2) of cable section. Grades of wire rope are (from historic origins) referred to as traction, mild plow, plow, improved plow, and extra improved plow steel. The most common finish for steel wire is "bright" or uncoated, but various coatings, particularly zinc (galvanized), are used.

4.4.4 Corrosion of Iron and Steel

Principles of Corrosion. Corrosion may take place by direct chemical attack or by electrochemical (galvanic) attack; the latter is by far the most common mechanism. When two dissimilar metals that are in electrical contact are connected by an electrolyte, an electromotive potential is developed, and a current flows. The magnitude of the current depends on the conductivity of the electrolyte, the presence of high-resistance "passivating" films on the electrode surfaces, the relative areas of electrodes, and the strength of the potential difference. The metal that serves as the anode undergoes oxidation and goes into solution (corrodes).

When different metals are ranked according to their tendency to go into solution, the galvanic series, or electromotive series, is obtained. Metals at the bottom will corrode when in contact with those at the top; the greater the separation, the greater the attack is likely to be. Table 4-14 is such a ranking, based on tests by the International Nickel Company, in which the electrolyte was seawater. The nature of the electrolyte may affect the order to some extent. It also should be recognized that very subtle differences in the nature of the metal may result in the formation of anode-cathode galvanic cells: slight differences in composition of the electrolyte at different locations on the metal surface, minor segregation of impurities in the metal, variations in the degree of cold deformation undergone by the metal, etc. It is possible for anode-cathode couples to exist very close to each other on a metal surface. The electrolyte is a solution of ions; a film of condensed moisture will serve.

Corrosion Prevention. An understanding of the mechanism of corrosion suggests possible ways of minimizing corrosion effects. Some of these include (1) avoidance of metal combinations that are not compatible, (2) electrical insulation between dissimilar metals that have to be used together, (3) use of a sacrificial anode placed in contact with a structure to be protected (this is an expensive technique but can be justified in order to protect such structures as buried pipelines and ship hulls),

(4) use of an impressed *emf* from an external power source to buck out the corrosion current (called *cathodic protection*), (5) avoiding the presence of an electrolyte—especially those with high conductivities, and (6) application of a protective coating to either the anode or the cathode. The problems of corrosion control are complex beyond these simple concepts, but since the use of protective coatings on iron and steel is extensive, this subject is treated in the following sections.

Protective Coatings. Protective coatings may be selected to be inert to the corrosive environment and insolate the base metal from exposure, or the coating may be selected to have reasonable resistance to attack but act sacrificially to protect the base metal. Protective coatings may be considered in four broad classes: paints, metal coatings, chemical coatings, and greases. Painting is commonly used for the protection of structural iron and steel but must be maintained by periodic renewal. Metal coatings take various ranks in protective effectiveness, depending on the metal used and its characteristics as a coating material. A wide variety of metals are used to coat steels: zinc, tin, copper, nickel, chromium, cobalt, lead, cadmium, and aluminum; coatings of gold and silver are also used for decorative purposes. Coatings may be applied by these principal methods: hot dipping, cementation, spraying, electroplating, and vapor deposition. The latter may involve simply evaporation and condensation of the deposited metal or may include a chemical reaction between the vapor and the metal to be coated.

Zinc coatings are more widely used for the protection of structural iron and steel than coatings of any other type. The hot-dip process is the earliest type known and is very extensively used at the present time; two improvements, the Crapo process and the Herman, or "galvannealed," process, are used in galvanizing wire. The cementation, or sherardizing, process consists of heating the articles for several hours in a packing of zinc dust in a slowly rotating container. Electroplating is also employed, and heavier coatings can be obtained than are usual with the hot-dip process, but adherence is difficult to obtain, and this process is not often used. See ASTM specifications for zinc-coated iron and steel products.

Aluminum coatings are applied by a cementation process which is commercially known as *calorizing*. The articles to be coated are packed in a drum in a mixture of powdered aluminum, aluminum oxide, and a small amount of ammonium chloride. The articles are then slowly rotated and heated in an inert atmosphere, usually of hydrogen. Such coatings are very resistant to oxidation and sulfur attack at high temperatures. Aluminum coatings also can be applied by the hot-dipping method and then are heat-treated to improve the alloy bond. Aluminum also can be applied by spraying. Aluminum-coated steel is used extensively for oxidation protection, for example, for heat ducts and automobile mufflers. Aluminum-zinc coatings, applied by hot dipping, have been developed that combine the high-temperature protection of aluminum with the sacrificial protection of zinc.

Almost all *tin coatings* are now applied by electrolytic deposition methods. The accurate control obtained by electrolytic deposition is important because of the high cost of tin. Unlike zinc, tin is electropositive to iron. The coating must remain intact; once penetrated, corrosion of the iron will be accelerated. If a zinc coating is penetrated, the zinc will still sacrifically protect the adjacent exposed iron. Tin has good corrosion resistance, is nontoxic, readily bonds to steel, is easily soldered, and is extensively utilized by the container industry for food and other substances.

The objective of *lead coating* of steel is to obtain an inexpensive corrosion-resistant coating. Lead alone will not alloy with iron; so it is necessary to add *tin* to the lead to obtain a smooth, continuous, adherent coating. Originally, about 25% tin (called *terne metal*) was used, but the tin content has been reduced as the price of tin has increased. Since corrosion protection is less effective in this case terne-coated steel is not used extensively. Applications include uses where corrosion is not too critical or likely, such as gasoline tanks and roofing sheets, or where the lubricating properties of the soft lead surface help forming operations.

Metal-spray coatings are applied by passing metal wire through a specially constructed spray gun which melts and atomizes the metal to be used as coating. The surface to be sprayed must be roughened to afford good adhesion of the deposited metal. Nearly all the commonly used protective metals can be applied by spraying, and the process is especially useful for coating large members or repairing coatings on articles already in place. Sprayed coatings can also be applied that will resist wear and can be used to build up worn parts such as armature shafts and bearing surfaces or to apply copper coatings to carbon brushes and resistors.

Chromium coatings can be applied by cementation or electroplating. In electroplating, the best results are secured by first plating on a base coating of nickel or nickel copper to receive the chromium. The great hardness of chromium gives it important applications for protection against wear or abrasion; it will also take and retain a high polish. Very thin coatings have a tendency to be inefficient as a result of the presence of minute pinholes.

Electroplating is employed in the application of coatings of nickel, brass, copper, chromium, cadmium, cobalt, lead, and zinc. Only cadmium, chromium, and zinc are electronegative to iron. The other metals mentioned are employed because of their own corrosion-resistant properties and because they afford surface finishes having certain desirable characteristics.

Protective Paints. Protective paints are extensively employed to protect heavily exposed structures of iron and steel, such as bridges, tanks, and towers. The protection is not permanent but gradually wears away under weather exposure and must be reviewed periodically. Various specially prepared paints are used for protecting the surface from dampness, oxidizing gases, and smoke. No one paint is suitable for all purposes but the choice depends on the nature of the corrosive influence present. Asphaltum and tar protect the surface by formation of an impervious film. A chemical protective action is exerted by paints containing linseed oil as the vehicle and red lead as the pigment; linseed oil absorbs oxygen from the atmosphere and forms a thick elastic covering, a formation hastened by adding salts of manganese or lead to the oil. All dryers, vehicles, and pigments used in paint must be inert to the steel; otherwise, corrosion will be hastened instead of prevented. Graphite- and aluminum-flake pigments give very impermeable films but do not show the inhibitive action of red lead or zinc when the films are scratched. Aluminum has the advantage of reflecting both infrared and ultraviolet rays of the sun; hence, it protects the vehicle from a source of deterioration and is used to paint gasoline-storage tanks to prevent excessive heating due to the sun's rays. A large number of new protective coatings have been developed recently from synthetic materials such as silicones, artificial rubbers, and phenolic plastics. Many of these are tightly adhering compounds in the form of paints or varnishes which offer rather good protection against a wide variety of chemical attacks. The majority of these new coatings, however, are sensitive to abrasion, and many of them must be baked on to secure full effectiveness.

Corrosion-Resistant Ferrous Alloys. Corrosion-resistant ferrous alloys such as rustless or stainless iron and steel have come into use for both structural and ornamental purposes but on account of their chromium and nickel contents are relatively expensive in comparison with the ordinary structural steels. Copper-bearing iron and steel, containing about 0.15% to 0.25% copper, are used extensively; the copper content tends to retard corrosion slightly but does not prevent it, and some protective coating is usually necessary. Some structural uses have been made of these steels without applying special protective coatings. A tightly adherent brown oxide surface film forms from weathering to serve as the future "protective coating."

Copperweld. A series of steel products, including wire, wire rope, bars, clamps, ground rods, and nails, that contain a copper-clad surface are made by the Copperweld process. The copper coating is intimately bonded to the steel by pouring a ring of molten copper about a heated steel billet fastened in the center of a refractory mold. The solidified composite ingot is then hot-rolled to bar stock and subsequently cold drawn to the various wire sizes. The thickness of the copper coating on wire is 10% to 12½% of the wire radius and produces a high-strength steel wire with a resistance to corrosion similar to that of a solid copper wire. Their increased electrical conductivity over that of a solid steel wire or rod makes the Copperweld products suitable for high-strength conductors, ground rods, aerial cable messengers, etc.

4.4.5 Nonferrous Metals and Alloys

Copper. Numerous commercial "coppers" are available. The standard product is *tough-pitch* copper, which contains about 0.04% oxygen. If it has been electrolytically refined, it is called *electrolytic tough pitch.* This copper cannot be heated in reducing atmospheres because the oxygen will react with hydrogen and severely embrittle the alloy. Various deoxidized varieties are made. When deoxidized with phosphorus, there is some loss of electrical conductivity depending on the amount of residual phosphorus and the extent to which other impurities are reduced and redissolve in the metal. As a general principle, alloying elements that dissolve in copper reduce conductivity sharply; those that are insoluble have little effect.

Copper castings are improved by using special deoxidizers such as Boroflux and silicocalcium copper alloy. By the use of these deoxidizers, the castings are improved structurally, and the electrical conductivity can be increased to about 80% to 90% of standard annealed copper. Boroflux is a mixture of boron suboxide, boric anhydride, magnesia, and magnesium; for data on its use, see publications of the General Electric Company.

Oxygen-free high-conductivity copper is deoxidized with carbon, and thus is free of residual oxide or deoxidizer. It is a more expensive product but does not suffer the potential embrittlement of tough pitch and is capable of more severe cold-forming operations at the cost of a slight loss of electrical conductivity. Free-machining copper contains lead or tellurium that drops conductivity from 3% to 5%. Since copper is a very difficult material to machine, this may be a small sacrifice for certain applications. Small amounts of silver improve resistance to elevated-temperature softening with no loss of physical or mechanical properties.

Brass. Brasses are alloys of copper and zinc; commercial brasses contain from 5% to 45% zinc. A wide variety of properties are obtainable in the brasses. In general, the alloys have excellent corrosion resistance, good mechanical properties, colors ranging from red to gold to yellow to white, and are available in a wide variety of cast and wrought shapes. The alloy of 30% zinc has an optimum combination of strength and ductility. It is called "cartridge brass," since an early application was drawing of cartridge shells. It is the most commonly used brass alloy.

Muntz metal contains nominally 40% zinc and is a two-phase alloy that is readily hot-worked in the high-temperature form and develops good strength when cooled. It is used for extruded shapes and for bolts, fasteners, and other high-strength applications. The properties of brass can be modified by small additions of numerous alloying elements; those commonly used include silicon, aluminum, manganese, iron, lead, tin, and nickel. The addition of 1% tin to cartridge brass results in an alloy called *Admiralty brass*, which has very good corrosion resistance and is extensively used in heat exchangers.

Brasses, especially the high zinc-bearing alloys, are subject to a corrosion phenomenon called *dezincification.* It involves a selective loss of zinc from the surface and the formation of a spongy copper layer accompanied by deterioration of mechanical properties. It is more likely to occur with the high-zinc brasses in contact with water containing dissolved CO_2 at elevated temperatures. Like many other metals, the brasses are susceptible to stress-corrosion craking—an embrittlement due to the combined action of stress and a selective corrosive agent. In the case of brass, the particular agent responsible for stress-corrosion cracking is ammonia and its compounds. Brass products that might be exposed to such environments should be stress-relief annealed before being placed in service. For details on compositions and properties of brasses, see the appropriate ASTM specifications and the publications of brass producers.

Bronze, or Copper-Tin, Alloys. Bronze is an alloy consisting principally of copper and tin and sometimes small proportions of zinc, phosphorus, lead, manganese, silicon, aluminum, magnesium, etc. The useful range of composition is from 3% to 25% tin and 95% to 75% copper. Bronze castings have a tensile strength of 195 to 345 MPa (28,000 to 50,000 lb/in^2), with a maximum at about 18% of tin content. The crushing strength ranges from about 290 MPa (42,000 lb/in^2) for pure copper to 1035 MPa (150,000 lb/in^2) with 25% tin content. *Cast bronzes* containing about 4% to 5% tin are the most ductile, elongating about 14% in 5 in. Gunmetal contains about 10% tin and is one of the strongest bronzes. Bell metal contains about 20% tin. *Copper-tin-zinc alloy* castings containing 75% to 85% copper, 17% to 5% zinc, and 8% to 10% tin have a tensile strength of 240 to 275 MPa (35,000 to 40,000 lb/in^2), with 20% to 30% elongation. *Government bronze* contains 88% copper, 10% tin, and 2% zinc; it has a tensile strength of 205 to 240 MPa (30,000 to 35,000 lb/in^2), yield strength of about 50% of the ultimate, and about 14% to 16% elongation in 2 in; the ductility is much increased by annealing for ½ h at 700 to 800°C, but the tensile strength is not materially affected. *Phosphor bronze* is made with phosphorus as a deoxidizer; for malleable products such as wire, the tin should not exceed 4% or 5%, and the phosphorus should not exceed 0.1%. *United States Navy bronze* contains 85% to 90% copper, 6% to 11% tin, and less than 4% zinc, 0.06% iron, 0.2% lead, and 0.5% phosphorus; the minimum tensile strength is 310 MPa (45,000 lb/in^2), and elongation at least 20% in 2 in. *Lead bronzes* are used for bearing metals for heavy duty; an ordinary composition is 80% copper, 10% tin, and 10% lead, with less than 1% phosphorus. *Steam or valve bronze* contains approximately 85% copper, 6.5% tin, 1.5% lead, and 4% zinc; the tensile strength is 235 MPa (34,000 lb/in^2), minimum, and elongation 22% minimum in 2 in (ASTM Specification B61). The bronzes have a great many industrial applications where their combination of tensile properties and corrosion resistance is especially useful.

Beryllium-Copper Alloys. Beryllium-copper alloys containing up to 2.75% beryllium can be produced in the form of sheet, rod, wire, and tube. The alloys can be hardened by a heat treatment consisting of quenching from a dull red heat, followed by reheating to a low temperature to hasten the precipitation of the hardening constituents. Depending somewhat on the heat treatment, the alloy of 2.0% to 2.25% beryllium has a tensile strength of 415 to 650 MPa (60,000 to 193,000 lb/in^2), elongation 2.0% to 10.0% in 2 in, modulus of elasticity 125 × GPa (18 × 10^6 lb/in^2), and endurance limit of about 240 to 300 MPa (35,000 to 44,000 lb/in^2). An outstanding quality of this alloy is its high endurance limit and corrosion resistance; it can be hardened by heat treatment to give great wear resistance and has high electrical conductivity. Typical applications include nonsparking tools for use where serious fire or explosion hazards exist and many electrical accessories such as contact clips and springs or instrument and relay parts. Beryllium is a toxic substance, and care should be taken to avoid ingesting airborne particles during such operations as machining and grinding. For details on properties and uses of beryllium bronzes, see publications of Kawecki Berylco Industries, New York.

Nickel. Nickel is a brilliant metal which approaches silver in color. It is more malleable than soft steel and when rolled and annealed is somewhat stronger and almost as ductile. The tensile strength ranges from 415 MPa (60,000 lb/in^2) for cast nickel to 795 MPa (115,000 lb/in^2) for cold-rolled full-hard strip; yield strength 135 to 725 MPa (20,000 to 105,000 lb/in^2); elongation in 2 in, 2% when full hard to about 50% when annealed; modulus in tension is about 205 GPa (30 × 10^6 lb/in^2). Nickel takes a good polish and does not tarnish or corrode in dry air at ordinary temperatures. It has various industrial uses in sheets, pipes, tubes, rods, containers, and the like, where its corrosion resistance makes it especially suitable.

The greatest tonnage use of nickel is as an alloying element in steels, principally stainless and heat-resisting steels. There are also a variety of copper-nickel alloys whose main applications are based on their excellent corrosion resistance, for example, condenser tubes. Additions of aluminum and titanium to nickel-base alloys result in age-hardening characteristics, and they can be heat-treated to exceptionally high strengths that are retained to high temperatures. The International Nickel Company publishes an extensive list of bulletins describing the characteristics of nickel and nickel alloys.

Monel Metal. Monel metal is a silvery-white alloy containing approximately 66% to 68% nickel, 2% to 4% iron, 2% manganese, and the remainder copper. It can be cast, forged, rolled, drawn, welded, and brazed, and is easily machined. It melts at 1360°C and has a density of 8.80, coefficient of expansion of 14 × 10^{-6} per degree Celsius, thermal conductivity of 0.06 cgs unit, specific heat of 0.127 cal/(g)(°C), and modulus of 175 GPa (25 × 10^6 lb/in^2). The tensile strength ranges from 450 MPa (65,000 lb/in^2) for cast monel metal to 860 MPa (125,000 lb/in^2) in cold-rolled full-hard strip; yield strength 175 to 725 MPa (25,000 to 115,000 lb/in^2). It is highly resistant to corrosion and the action of seawater or mine waters. The industrial uses for it include many applications where its combination of physical properties and corrosion resistance gives it special advantages.

Magnesium Alloys. The outstanding feature of magnesium alloys is their light weight (specific gravity of about 1.8). Alloys containing thorium and rare-earth additions have been developed that retain good strength at temperatures between 260 and 371°C. The correspondingly high strength/weight ratio makes them particularly useful to the aircraft industry. Less exotic alloys, based mainly on alloying with aluminum (up to 10%) and zinc (up to 6%), still have excellent strengths and are heat-treatable. These alloys have many uses where low density is desired: portable tools, ladders, structural members for trucks and buses, housings, etc. Magnesium alloys are available as castings, forgings, extrusions, and rolled-mill products in a variety of shapes. Their thermal coefficient of expansion is about 0.000029/°C, and their melting point is about 620°C. Tensile strengths of castings range from 145 to 235 MPa (21,000 to 34,000 lb/in^2), yield strengths from 62 to 150 MPa (9,000 to 22,000 lb/in^2), and elongation from 1% to 10% in 2 in. Forged or extruded alloys have tensile strengths of 225 to 300 MPa (33,000 to 43,000 lb/in^2), yield strengths 125 to 205 MPa (18,000 to 30,000 lb/in^2), and elongations of 5% to 17% in 2 in. The Brinell hardness ranges from 35 to 78, and the endurance limit from 40 to 115 MPa (6,000 to 17,000 lb/in^2) depending on the alloy and heat treatment. Since magnesium is highly anodic to other common metals, care must be taken in designing with this metal. Protective coatings are used, and care must be taken to avoid forming galvanic couples. Finely divided magnesium will burn but massive sections are safely melted and welded.

Lead. Lead is a heavy, soft, malleable metal with a blue-gray color; it shows a metallic luster when freshly cut, but the surface is rapidly oxidized in moist air. It can be easily rolled into thin sheets and foil or extruded into pipes and cable sheaths but cannot be drawn into fine wire. Although in an ordinary tensile test lead may develop a tensile strength of 17 MPa (2400 lb/in^2), it may creep at ordinary room temperatures at stresses as low as 0.34 MPa (50 lb/in^2). Owing to this tendency to creep, it may fracture under long-continued load at stresses as low as 5.5 MPa (800 lb/in^2), and the ordinary static tensile properties do not have much significance. The resistance of pure lead to corrosion makes it useful in the form of sheets, pipes, and cable coverings, and large quantities of lead are used in the manufacture of various alloys, particularly in alloys for bearings. Common alloys of lead for cable sheatings contain (approximately) 0.04% Cu, 0.75% Sb, or 0.03% Ca. The greatest use of metallic lead is in the manufacture of storage batteries.

Tin. Tin is a silvery-white, lustrous metal, very soft and malleable and of very low tensile strength. It has a density of about 7.3 and melts at 232°C. In ductility it equals soft steel. The tensile strength varies with the speed of testing. As a metal it has few uses except in sheets, but large quantities of it are used in various industrial alloys. Its chief uses are in tin- and terneplate, solder, babbitt and other bearing metals, brass, and bronze. Tin is very resistant to atmospheric corrosion, and water hardly affects it at all; however, it is electronegative to iron and therefore is not an efficient protective coating under atmospheric exposures.

Zinc. Zinc is a bluish-white metal which has a metallic luster on a new fracture. The density of cast zinc ranges from 7.04 to 7.16. At ordinary temperature it is brittle, but in the range of about 100 to 150°C it becomes malleable and can be rolled into sheets and drawn into wire. At 200°C, it becomes so brittle that it can be pulverized. The tensile strength of cast zinc ranges from about 55 to 95 MPa (8000 to 14,000 lb/in^2) in an ordinary testing-machine test and that of drawn zinc from about 150 to 200 MPa (22,000 to 30,000 lb/in^2); it has a poorly defined proportional limit of about 35 MPa (5000 lb/in^2) and exhibits a certain amount of creep at room temperatures; hence, it may fracture in service under constant stresses below its testing-machine strength. It strongly resists atmospheric corrosion but is readily attacked by acids. The principal industrial uses for it are for galvanizing iron and steel, for plates and sheets for roofing and other applications, and for alloying with copper, tin, and other metals; very large quantities are used in the various types of brass. Next to galvanizing, the greatest use of zinc is in the production of die castings. Because of its moderate melting point, good mechanical properties, and especially because it does not attack steel melting pots and dies, it is the most popular die-casting material (although closely rivaled by aluminum). Zinc alloys for die casting contain some aluminum, copper, and magnesium; all ingredients must be very pure or the casting will have poor corrosion resistance and dimensional stability.

Titanium and Titanium Alloys. Titanium alloys are important industrially because of their high strength-weight ratio, particularly at temperatures up to 427°C. The density of the commercial titanium alloys ranges from 4.50 to 4.85 g/cm^3, or approximately 70% greater than aluminum alloy and 40% less than steel. The purest titanium currently produced (99.9% Ti) is a soft, white metal. The mechanical strength increases rapidly, however, with an increase of the impurities present, particularly carbon, nitrogen, and oxygen. The commercially important titanium alloys, in addition to these impurities, contain small percentages (1% to 7%) of (1) chromium and iron, (2) manganese, and (3) combinations of aluminum, chromium, iron, manganese, molybdenum, tin, or vanadium. The thermal conductivity of the titanium alloys is low, about 15 W/m · K at 25°C, and the electrical resistivity is high, ranging from 54 $\mu\Omega \cdot$ cm for the purest titanium to approximately 150 $\mu\Omega \cdot$ cm for some of the alloys. The coefficient of thermal expansion of the titanium alloys varies from 2.8 to 3.6 $\times$ 10^{-6} per degree Celsius, and the melting-point range is from 1371 to 1704°C for the purest titanium. The tensile modulus of elasticity varies between 100 to 120 GPa (15 to 17 $\times$ 10^6 lb/in^2). The mechanical properties, at room temperature, for annealed commercial alloys range approximately as follows: yield strength 760 to 965 MPa (110,000 to 140,000 lb/in^2); ultimate strength 800 to 1100 MPa (116,000 to 160,000 lb/in^2); elongation 5% to 18%; hardness 300 to 370 Brinell. On the basis of the strength-weight ratio many of the titanium alloys exhibit superior short-time tensile properties as compared with many of the stainless and heat-resistant alloys up to approximately 427°C. However, at the same stress and elevated temperature, the creep rate of the titanium alloys is generally higher than that of the heat-resistant alloys. Above about 482°C, the strength properties of titanium alloys decrease rapidly. The corrosion resistance of the titanium alloys in many media is excellent; for most purposes, it is the equivalent or superior to stainless steel.

Aluminum. Aluminum is an important commercial metal possessing some very unique properties. It is very light (density about 2.7) and some of its alloys are very strong, so its strength-weight ratio makes it very attractive for aeronautical uses and other applications in which weight saving is important. Aluminum, especially in the pure form, has very high electrical and thermal conductivities and is used as an electrical conductor in heat exchangers, etc. Aluminum has good corrosion resistance, is nontoxic, and has a pleasing silvery-white color; these properties make it attractive for applications in the food and container industry, architectural, and general structural fields.

Aluminum is very ductile and easily formed by casting and mechanical forming methods. Aluminum owes its good resistance to atmospheric corrosion to the formation of a tough, tenacious, highly insulating, thin oxide film, in spite of the fact that the metal itself is very anodic to other metals. In moist atmospheres, this protective oxide may not form, and some caution must be taken to maintain this film protection. Although aluminum can be joined by all welding processes, this same oxide film can interfere with the formation of good bonds during both fusion and resistance welding, and special fluxing and cleaning must accompany welding operations.

Commercially pure aluminum (99+%) is very weak and ductile: tensile strength of 90 MPa (13,000 lb/in^2), yield strength of 34.5 MPa (5000 lb/in^2), and shearing strength of 62 MPa (9500 lb/in^2). Extrapure grades (electrical conductor grade) are 99.7+% pure, and are even weaker, but have better conductivity.

Heat Treatment of Aluminum Alloys. Alloys of the 1000, 3000, and 5000 series cannot be hardened by heat treatment. They can be hardened by cold working and are available in annealed (recrystallized) and cold-worked tempers. The 5000-series alloys are the strongest non-heat-treatable alloys and are frequently used where welding is to be employed, since welding will generally destroy the effects of hardening heat treatment. The remaining wrought alloys can be hardened by controlled precipitation of alloy phases. The precipitation is accomplished by first heating the alloy to dissolve the alloying elements, followed by quenching to retain the alloy in supersaturation. The alloys are then "aged" to develop a controlled size and distribution of precipitate that produces the desired level of hardening. Some alloys naturally age at room temperature; others must be artificially aged at elevated temperatures.

4.4.6 Stone, Brick, Concrete, and Glass Brick

Building Stone. Stone is any natural rock deposit or formation of igneous, sedimentary, and/or metamorphic origin, in either its original or its altered form. Building stone is the quarried product of such deposit or formation, which is suitable for structural and ornamental purposes. Igneous or volcanic rock, such as granite or basalt, is rock of plutonic or volcanic origin, formed from a fused condition and crystalline in structure. Sedimentary rock, such as limestone, dolomite, and sandstone, is formed by the deposition of particles from water and laminated in structure. Metamorphic rock, such as gneiss, marble, and slate, is rock formation which, in the natural ledge, has undergone marked change in microstructure or character due to heat, pressure, or moisture and therefore exists in form different from the original.

Portland Cement. *Portland cement* is produced by sintering a proportional mixture of lime and clay, which is subsequently ground with the addition of gypsum (to retard the rate of setting). The properties of the clay and limestone determine the principal characteristics: fineness, soundness, time of set, and strength. Strength is measured from briquettes made of a mortar of 1 part cement to 3 parts sand, and measured under specified conditions. Minimum tensile strengths are 2 MPa (275 1b/in^2) at 7 days, and 2.6 MPa (350 1b/in^2) at 28 days.

Mortar. *Mortar* is a mixture of sand, screenings, or similar inert particles with cement and water, which has the capacity of hardening into a rocklike mass. The inert particles are usually less than $1/4$ in in size. The proportions of cement to sand range all the way from 1:0 to 1:4 for various purposes.

Concrete. *Concrete* is a mixture of crushed stone, gravel, or similar inert material with a mortar. The maximum size of inert particles is variable but usually less than 2 in. These inert constituents of mortar and concrete are known as the *aggregate.* In making good concrete, the properties of the aggregate are as important as those of the cement. The fine aggregates consist of sand, screenings, mine tailings, pulverized slag, etc., with particle sizes less than $1/4$ in; the coarse aggregates consist of crushed stone, gravel, cinders, slag, etc. Rubble concrete is made by embedding a considerable proportion of boulders or stone blocks in concrete. The proportions by volume of cement, sand, and coarse aggregate range all the way from 1:1:2 for high compressive strength to 1:4:8 for structures requiring mass more than strength. In general, the strength of concrete increases with the density and richness of mix (proportion of cement) but is decreased in proportion to the amount of mixing water that is added beyond that required to produce a plastic workable mixture. In controlling the quality of a concrete of given mix, the ratio of the volume of mixing water to the volume of cement (water-cement ratio) is often used as a criterion of the strength. For proper curing, the concrete should be kept moist for at least a week after placing, and care should be taken to prevent its freezing in cold weather during the early stages of curing. Freshly poured concrete gains strength very slowly in cold weather. Various admixtures are often added in small amounts to modify pouring characteristics and setting time as well as physical characteristics such as resistance to freezing and thawing cycles, wear, abrasion, and permeability.

For concrete of common proportions cured under good conditions, 25% to 40% of the 2-year strength is developed in 7 days, 50% to 65% in 1 month, and 70% to 90% in 6 months. The tensile strength of concrete is very low (about one-tenth its compressive strength), and hence in structural members the concrete is usually designed to resist the compressive stresses only, the tensile strength of the concrete being considered negligible. For flexural members, steel reinforcing bars are usually inserted on the tensile side of the beam to resist the tensile stresses.

4.5 WOOD PRODUCTS

By PHILIP MASON OPSAL

Wood Scientist—Consultant, Wood Science, LLC. This author's perception at the outset of the effort to construct this Section is that very few, if any, engineers of any specialty in the last 20 years have received any course work dealing with the subject of wood materials as a construction material. This is due to a number of reasons, including the evolution of course requirements at institution of higher learning to include newer and more modern construction materials, and the advent of the computer causing the need to use significant amounts of time for classes devoted to the teaching of engineers to be computer-wise, effectively providing the basic skills to accomplish all sorts of engineering design functions modeling, simulations, etc., significantly reducing time required for those tasks and increasing productivity for the professional engineer. It is thus that this Chapter is designed to be very basic in wood, not aiming at making professional electrical engineers into wood scientists, but rather to assist in the building of a knowledge base in wood to enable a better understanding of the material made in trees by natural forces. It is therefore purposeful that the bibliography has a considerable array of the old proven and very reliable textbooks of wood science/wood technology to allow the lessor experienced electrical engineer without such experience and/or even without any prior training that even opened up the subject of wood material. For those electrical engineers with more experience and knowledge, the best way to consider proceeding with this chapter to increase and/or enhance the current knowledge base may well be to reference the more contemporary of the references shown and then pursue a course looking for keywords of phrases through the listed references that are to be found in each of those references following along possible avenues to larger more detailed and technical sources to the more current research.

4.5.1 Sources/Trees

The material known as *wood* has as its source *trees*. Natural in origin, the quality of this construction material is based primarily on the availability of the factors that contribute to tree growth, viz, sunlight, moisture, and nutrients. The best quality wood fiber results when these basic factors are at their optimum quantities. Wood materials of the best strength result from the selection of quality species, good forest management during the growing cycle, selective harvesting of only acceptable trees for a use such as utility poles, and then making certain that none of those hand-picked trees are damaged during any of the handling, hauling, and/or processing methods of operations. There are many species of trees present on the earth and on a broad basis are separated into *hardwoods* and *softwoods;* but these names do not truly reflect the relative "hardness" or "softness" of the wood resulting from the trees in either group inasmuch as balsa wood is in the hardwood category and is very lightweight and very weak wood, while a species such as *Douglas-fir*, a wood used in very large quantities as a strong structural member, is classified as a softwood. Generally, the hardwoods have leaves of fairly good size, such as maples, oaks, and elms, and are those trees which have a spreading configuration and are seen typically in yards, parks, and in some cities, lining the streets and avenues where in those locations and for such uses they appear as what are termed *ornamentals*. In hardwood forest stands, however, where, due to the density of the forest, with many trees per acre, natural pruning tends to occur and the tree trunks then grow more pole like with less branch remnants, allowing less deviated grain to from in the outer wood of the tree trunk as growth proceeds in height and circumference. Such was true of the American Chestnut, *Castenea dentata*, from which long tall poles were harvested and subsequently fabricated for use in utilities as supporting structures for conductor, crossarms, insulators, transformers, guys and anchors, regulators, OCRs, etc. Of course chestnut was prized and processed into wood products for many other applications as well. Unfortunately, the chestnut blight found its way from Europe and this organism severely devastated the majority of trees in the United States. Chestnut trees were known for their resistance to decay due to the heartwood section containing a high content of the organic chemicals called *tannins*.

Softwood are also known as *conifers* and most are evergreens keeping their leaves, which are usually "needle-like", all year long (exceptions are Eastern larch and Western larch, respectively, *Larix laricina* and *Larix occidentalis*, which drop their leaves in the fall and grow new leaves each spring). The normal "form class" of the softwood trees is a long tapering trunk extending up to a crown of branches, which originate each year at the top of the tree in a "whorl" or sort of in a circle or sometimes a helical pattern around the circumference of the tree. Knots (earlier in the life of the tree its branches) cause the grain to deviate by the growth of the tree having to grow around the circular or elliptically shaped pattern of braches. It must be remembered that straight grain is the strongest while the greater the deviation of the grain is from straight the weaker the wood is. The configuration of knot whorls in clusters of closely adjacent knots can form a significant weakened section of a wood pole and, as well, weaken structural timbers such as crossarms and crossbraces. It is extremely important to require all wood products to be 100% inspected, examined, and assessed to ensure the receipt at destination of only quality wood capable of safely functioning to support the structure for which their use was designed by the professional electrical engineer.

4.5.2 Wood Structure

Gross wood structure may be used to differentiate between the hardwood and softwood classes and to identify species within each group. The cross section of a log shows several well-defined features from the outer bark, through the wood, to the central pith. The purpose of the bark is to protect the inner living tissues from injury. The inner portion of the bark is a conductive tissue that transports foodstuffs from the leaves to the living cells. The wood portion of the tree has outer sapwood and inner heartwood regions, which often are distinguishable by a difference in color. The lighter-colored sapwood is a living tissue. The darker-colored heartwood consists of entirely dead cells and serves primarily for mechanical support in the tree. The heartwood contains deposits of gums, oils, and other organic infiltrations in the cells. These materials are called *extractives* and import the darker color (ranging from light brown to black) to heartwood. Other differences include durability and permeability. Sapwood of all species is readily destroyed by insects and the decay fungi. The heartwoods of many species are also nondurable, but others are very durable (e.g., cypress, the cedars, and redwood). Sapwood is usually more permeable to liquids, owing largely to the absence of extractives. For this reason, sapwood is more easily treated with preservatives. Wood near the center of the tree is often characterized by fast growth and is termed *juvenile wood*. The properties of juvenile wood are inferior to those of normal heartwood. The strength properties of heartwood and sapwood are the same.

Annual Rings. In temperate zones, the tree increases in diameter and height by division of cells in a singular cell layer, called the *cambium*, capable of dividing and simultaneously supplying a new cell both in the direction of the bark and in the direction of the mass of the tree. The growth increment for each year is called the *annual ring*. The trees of North America have well-defined annual rings due to the production of cellular structure differing during the spurt of growth in the spring, when the tree growth surges and the wood cells produced by such fast growth are very thin-walled and are structurally weaker than those produced later in the growing season as the growth slows and the cells produced tend to be thicker-walled and thus are stronger structurally. These growth patterns have been termed *earlywood* (*Springwood*) and/or *latewood (Summerwood)* and show up as distinctive sections in the annual ring produced in each growing season. Because of this, the age of the tree can be determined by simply counting the rings beginning just inside the bark of the tree and continuing into the pith, the name given to the very center of each tree. (Note: Inasmuch as trees do not always grow in symmetry with purely concentric rings, the growth on two or more sides of the tree may have to be averaged.) Counting the rings and determining the percent of the latewood in the rings is often used as a tool in an attempt to roughly define the strength of wood to be used in a structural capacity. Tropical woods, producing growth nearly continuously, do not usually display seasonal growth rings.

Minute Wood Structure. Minute wood structure differs for hardwood and softwood species. The conifers are composed primarily of long hollow fibers oriented with their long axis parallel to the length of the tree. The ends of these fibers are tapered and the adjacent ends overlapping. The size, shape, and structure of these fibers vary considerably from one species to another, which accounts for much of the variation in properties of the respective wood. Given wood's O*rthotropic* nature, having three distinctly different axes, the longitudinal, the radial, and the tangential, the characteristics of each such as shrinkage are significantly different with a very small amount of shrinkage longitudinally followed by the radial and then by the tangential exhibiting the greatest amount, respectively less than 1% approximately 0.1% to 0.2%, radial 2% to 8%, and tangentially 4% to 14%. The individual fibers, primarily tracheids, are composed of multilayer cell wall enclosed within a central hollow void, much like a soda straw.

Chemical Composition. Chemically, wood consists of approximately 70% cellulose, 25% lignin, and about 5% extractives. The strength of wood may be attributed almost entirely to the cellulose and lignin present in the cell wall. The extractives do not contribute to the cell wall structure but do contribute to such properties as color, odor, taste, and resistance to decay.

Specific Gravity. Specific gravity is a measure of the amount of material contained in a piece of wood. It is calculated by dividing the weight of a given volume of wood by the weight of an equal volume of water. Specific gravity varies according to the amount of water present in wood. For this reason, the ovendry weight of wood is usually used for reported values of specific gravity. The specific gravity of some commercially imported woods is listed in Table 4-15. For clear, straight-grained

wood at a known moisture content, specific gravity is positively correlated with several important properties, including strength and stiffness in bending, tension, and compression. Approximate functions for predicting the mechanical properties of wood for known average and/or specific gravity ranges are given in the *Wood Handbook*. When wood contains natural growth characteristics and/or imperfections, the relationship between properties and specific gravity may be less pronounced due to the disruption of the structural continuity and/or integrity of straight-grained wood known to be the strongest.

4.5.3 Moisture in Wood

Wood is a hygroscopic material. Moisture in wood occurs in three forms: water vapor in airspaces in the cell cavities, capillary water in the cell cavities, and water molecules bound to the hydroxyl groups of the cellulose in the cell wall. In most end-use conditions, when wood is not in contact with water, nearly all the moisture present is bound water and is usually between 3% and 30% of the dry weight of the wood. Since this bound water tends to be at equilibrium with the vapor pressure of the surrounding atmosphere, the maximum amount of bound water in wood occurs in a saturated atmosphere. Any increase in moisture content above this maximum is due to capillary water, acquired from contact with liquid water.

The moisture content of wood is expressed as a percentage of the ovendry weight of wood. It can be measured by weighing a wood sample before and after drying to constant weight at 103°C ± 3°C (217.4°F) using the relationship:

$$\text{Moisture content,\%} = \frac{\text{moist weight–dry weight}}{\text{dry weight}} \times 100$$

When moist wood dries, the liquid water present in the cell capillaries evaporates before the bound water leaves the cell wall. The *fiber-saturation point* is defined as the moisture content of wood at that point at which the cell walls are saturated and there is no free water in the cell cavities. It is at this point that the moisture content is approximately 30%, varying somewhat among species.

Volumetric Changes. Below the fiber-saturation point, water that evaporates from wood results in a reduction in wood volume in the percentages cited earlier in the three directions, longitudinal, radial, and tangential. The amount of volumetric change is positively related to the changes in moisture content and density and due to the orthotropic nature of the wood results in unequal shrinkage. In general, the shrinkage increases with density. Some representative shrinkage values are given Table 4-15. In round wood members, shrinkage results as the wood dries internal stresses develop until reaching the point that relief occurs manifested in the wood checks and splits taking place as to serve to eliminate the stresses. As wood poles dry out, shrinkage in circumference approximates 1% to 2% depending on size.

Wood Seasoning. Most wood products are dried prior to use to remove the large amount of moisture present in freshly cut wood. Wood that has been dried offers a number of advantages including reduced weight and shrinkage, an increase in strength, and durability compared to green wood. Drying may be accomplished by one of several procedures. Two of the most common are air drying and kiln drying. A number of defects may develop during drying if the process is not carefully controlled. These defects are the result of drying stresses due to unequal shrinkage. Most kiln-drying procedures include moisture-equalizing and conditioning treatments to improve moisture uniformity throughout the thickness of the wood product, and to relieve residual stresses. Improper drying may result in warping, checking, or more severe defects.

4.5.4 Thermal Properties of Wood

Temperature affects several properties of wood. As wood is heated, it expands. The coefficient of thermoexpansion for wood averages near 1.1×10^{-6} per degree Celsius for most native species. Wood is a good insulator and does not respond very fast to a change in environmental temperature. The coefficient of thermoconductivity for wood ranges from 0.4 to 0.7 Btu/(h)(°C) for a 1 ft^2 area 1 in in thickness at a moisture content of 12%. The thermoconductivity of wood increases with increasing specific gravity and moisture content.

4.5.5 Electrical Properties of Wood

Three important electrical properties of wood are resistivity, dielectric constant, and power factor. Wood is an excellent insulator. The resistivity of dry wood to the flow of direct current is high, approximately $3 \times 10^{17}\ \Omega \cdot \text{cm/cm}^3$ parallel to the grain. The presence of moisture lowers resistivity. The dielectric constant for wood determines the amount of stored electric potential energy when it is placed in a high-frequency alternating current. The dielectric constant for wood varies over a range from 2.0 for dry wood to 8 for wood above the fiber-saturation point. The dielectric constant is affected by density and grain direction. The power factor determines the amount of energy that is dissipated as heat when wood absorbs power in a high-frequency dielectric field. The power factor for wood is about 2% to 6% at low moisture contents for frequencies between 2 and 15 Hz.

4.5.6 Strength of Wood

Effect of Moisture on Strength. Clear wood generally increases in strength and stiffness as it dries below the fiber-saturation point. The change in strength resulting from a 1% change in moisture content, is approximately 4 for modulus of rupture, 2 for modulus of elasticity, and 5 for compression parallel to the grain.

For structual lumber, the increase in strength of the clear wood is partly offset by the development of seasoning defects such as checks and splits. For this reason, the properties in the green condition are generally used as the base for the development of design stresses for wood. For lumber that is nominally 5 cm (2 in) in thickness, the design stress is increased by up to 25% in bending, 20% in modulus of elasticity, and 37.5% in compression parallel to grain when the moisture content is at or less than 15%.

Effect of Temperature on Strength. In general, heating reduces and cooling increases the mechanical properties of wood. The change is immediate and irreversible for temperatures remaining above 66°C(150°F) for any appreciable period of time. The adverse effect of high temperature is more pronounced at high moisture contents. For elevated temperatures below 66°C(150°F), the immediate loss of strength is recovered when the wood is cooled to ambient conditions. When wood is repeatedly exposed to high temperature, the adverse effect on properties is cumulative leading to creep and ultimate failure without any in ovease in loading.

Mechanical Properties. The mechanical properties of the commercially important woods of the United States have been evaluated in accordance with ASTM Standard D143, which specifies small, clear test specimens to eliminate the influence of naturally occurring physical defects in the wood. Tables 4-16 and 4-17 show some mechanical properties for wood in the green condition and at 12% moisture content, respectively. The green properties are obtained from specimens at essentially the same moisture content as in the living tree, well above the fiber-saturation point. The data in these tables include several of the more important hardwood and softwood species and the mechanical properties of each, which are likely to be uniquely important for specific uses encountered in electrical engineering applications. Adjustments to the values of strength determined for small, clear green test specimens are shown in ASTM Standard D245.

4.5.7 Decay and Preservatives

Decay and Its Prevention. At ordinary temperatures, wood is very stable and, unless attacked by living organisms, remains the same for centuries, either in air or under water. Fungi are the chief enemies of wood, and they thrive best with warmth and abundance of moisture and air, for example, in contact with the ground. Higher temperatures near the surface of the ground, together with adequate air and a greater prevalence of fungi, cause decay to progress faster near the ground line than at several feet below. Proper seasoning, together with protection against the entrance of moisture and impregnating with fungus-inhibiting compounds, which prevent fungi from feeding on the wood, is the best means of preservation. The heartwood of some species is resistant to decay whereas the sapwood of all species is nondurable to decay and insects and the preservative treatment, if done properly, substantially increases the safe service life of wood members.

Wood Preservatives. For a nominal cost, the service life of wood can be greatly increased by the use of preservative treatment. Creosote is extensively used for the protection of poles and crossarms. Southern yellow pine, because of its thick sapwood, requires a pressure treatment. Species with intermediate sapwood thickness such as Douglas-fir, lodgepole pine, and jack pine are treated by either pressure or nonpressure processes. Thin sapwood species such as western red cedar and larch are generally treated by nonpressure processes. The American Wood-Preservers' Association Standards are used to specify preservative chemicals and treatment methods for wood products. The AWPA introduced the "Use-Category System" in 1999, where selection of products based on use and relative exposures to environmental conditions become the main bases of choice of products. After a period of 5 years of experience with the "Use-Category System", the 2004 AWPA Standards have been completely rearranged to offer a more discerning, practical, and understood array of products fitted and custom-tailored by the industry to usage.

Wood preservatives fall into two main classes: (1) oil-borne preservatives and (2) water-borne metallic salts. The former may be further subdivided into (a) coal-tar creosote with and without the mixture of cheaper materials such as petroleum or coal tar and (b) solutions of toxic organic chemicals such as pentachlorophenol dissolved in petroleum oils. Oil-type preservatives are used extensively for products that are exposed to ground contact, whereby resistance to leaching is an important requirement of the preservative. These products include poles, crossties, crossarms, crossbraces, piling, bridge timbers, fence posts, and highway barrier posts. Water-borne preservatives are used mainly for the treatment of lumber. Wood treated with a water-borne preservative is clean, paintable, and odorless.

Creosote is a distillate of coal tar formed during the coking of coal during the steel-making process. Creosote has historically been a most important preservative significant in the preservation of wood members placed in contact with the ground, such as railroad ties, utility poles, piles, and timbers, for application to structures in coastal waters where significant destruction is inflicted on wharves and docks by marine organisms.

Pentachlorophenol, appearing in crystalline form much like sugar and/or table salt must be dissolved in aromatic-type petroleum oils for best solubility to accomplish movement into the wood cells during the treating process. Low-boiling solvents like mineral spirits are used as a carrier for penta when cleanliness is required for products such as millwork where no contact with the ground is anticipated. Water repellents are added to millwork treatments to both minimize dimensional changes as well as to provide greater stability and permanence to the treated products. Other oil-borne preservatives such as copper napthenate, copper-8-quinolinolate, tri-butylin oxide, and other recent additional are commercially in use.

Water-borne preservatives are generally mixtures of several inorganic salts, the most important of which are salts of copper, chromium arsenic and zinc. Boron is an inorganic water becoming more widely used some of these preservatives give good protection to wood exposed to wet conditions while others are not recommended for such use. Wood treated with water-borne preservatives is clear and paintable after drying to below 25% moisture content.

Several supplemental wood preservatives are used to bolster the original wood preservatives of in-service wood poles, which over time have changed due to leaching and oxidation and thus no longer are protecting those poles as occurred during the earlier years in service. These supplemental preservatives come in the form of (1) bandages containing grease formulations for exterior applications, (2) liquids containing common preservatives like creosote, penta-in-oil, and sodium flouride to treat internal decay, and (3) another liquid for the same purpose which on contact with water changes form into a vapor (gas) becoming a *fumigant* and moving both up-and downward in the wood cells effectively killing decay present and offering lasting protection for extended periods of time.

Paints, varnishes, and stains are used for decorative effects, but they also attord surface protection by retarding moisture changes and thus decreasing checking, warping, and weathering. Such protection is only superficial and they are not wood preservatives.

Fire-retardant chemicals such as ammonium phosphate and sulfate and salts of zinc and boron are used to decrease the flammability of wood. Some fire-retardant formulations may give protection against decay.

Methods of Treating Wood. The methods of preservative treatment are divided into two categories, *pressure* and *nonpressure*. Pressure methods are very effective in the treating of difficult to treat woods such as Douglas-fir, and the processing usually takes much less time if the seasoning does not need to be accomplished in the cylinder than the nonpressure processes, which rely on vacuum, diffusion, and/or temperature differentials to treat the wood. The pressure is conducted in an air-tight cylinder with the preservative liquids being forced into the products, while the nonpressure methods such as dipping, soaking, brushing, and/or spraying are less effective and are not recommended for products requiring trouble-free long service lives or installation into ground exposures. The *vacuum process* can achieve better results and the *thermal process* is capable of treating wood poles for specifications requiring adequate retention and penetration into the wood, sufficient to protect wood for inground installation. The thermal process (formerly the “hot-cold” bath process) accomplishes the required penetration and retention of preservative by first covering the wood with a “hot” liquid at about 112.8°C (23°F), increasing the temperature of the air in the wood cells causing expansion, and then allowing the preservative to either cool down or pumping the hot oil out of the tank and pumping relatively cold preservative into the tank at about 66°C (150°F), which effectively cools the wood cells and the air to contract and form a vacuum pulling the preservative into the cells.

There are several modifications of the pressure process. The full-cell process is used for the treatment of marine piling, which requires high retention of creosote for protection against wood-boring animals. The process is also used commonly in the treatment of lumber with water-borne presevatives. An initial vacuum removes the air from the cell lumens providing maximum penetration and retention into those spaces and the cell walls. Much wood for land use is treated with oil-type preservatives by one of the so-called empty-cell methods, whereby it is possible to increase the depth of penetration obtained with a limited retention of preservative. In the Rueping process, air is first injected to create within the wood a pressure greater than atmospheric. The cylinder is filled with preservative in such a way that the injected air is trapped in the wood. The pressure is then increased to force preservative into the wood. After the pressure is released and the cylinder drained, the compressed air in the wood expands to expel some of the preservative. The recovered preservative is called *kickback.* The Lowry process differs from the Rueping process in that no initial air pressure is applied. In this process, the air normally present in the cells is compressed during the pressure cycle and produces some kickback when pressure is released.

The conditioning of the wood prior to treatment is an important step. Air seasoning, kiln drying, and various processes of cylinder conditioning are employed. The latter include steaming plus vacuum, boiling in oil under vacuum, and vapor drying, in which green wood is surrounded by hot vapors of distillates of coal tar or petroleum.

When oil preservatives are applied by simple soaking methods, the wood should be well-seasoned in order to provide airspaces sans water into which the oil may move. Oil preservatives of low viscosity are preferable. The results attainable vary greatly with the species of wood.

Diffusion methods depend on the diffusion of water-soluble chemicals into the moisture present in green wood. Here again, the species of wood is an important factor, but the results are affected by other factors such as the nature of the chemical, the concentration of the solution, and the duration of the soaking period.

Applications of Preservative Treatment. Preservative treatments are applied to many wood products including poles, crossties, lumber, structural timbers such as crossarms and crossbraces, fence posts, and piling.

Advantages of Preservative Treatment. In addition to the conservation of a natural resource, preservative treatment results in economic savings due to increased service life and reduced maintenance costs. This has been recognized for many years by railroad companies, utility companies, and other large users of wood products. Because of demonstrated savings, practically all crossties and poles are now given a preservative treatment before installation. There has been a gradual increase in the volume of lumber treated annually, due to more widespread knowledge of the need for such treatment when the wood is to be used under conditions favorable to attack by decay or insects. For best performance, it is desirable that all machining operations be completed before treatment.

Strength of Treated Lumber. The effect of a preservative such as creosote or pentachlorophenol, in and of itself, on the strength of treated lumber appears to be negligible. It may be necessary, however, in establishing design stress values, to take into account possible reductions in strength that may result from temperatures or pressures used in the conditioning or treating processes. Results of tests of treated wood show reductions of stress in extreme fiber in bending and compression perpendicular to grain, ranging from a few percent up to 25%, depending on the processes used. Compression parallel to grain is affected less and modulus of elasticity very little. The effect on resistance to horizontal shear can be estimated by inspection for shakes and checks after treatment. Strength reductions for wood poles agreed on in formulating fiber-stress recommendations in American Standard Specifications and Dimensions for Wood Poles, ANSI 05.1, range from 0% to 15% in various species, depending on the conditioning and treating processes. Treating conditions specified by the American Wood-Preservers' Association should never be exceeded. Reductions of strength can be minimized by restricting temperatures, heating periods, and pressures as much as is consistent with obtaining the absorption and penetration required for proper treatment.

Effect of Preservative Treatment on Electrical Resistivity. The electrical resistivity of wood depends on its moisture content to a much greater degree than any other single variable. Ovendry wood is an excellent insulator, but as the wood absorbs moisture, its resistivity decreases rapidly. Wood in normal use, however, where its moisture content may range from about 6% to 14%, is still a good enough insulator for many electrical applications.

When wood has been treated with salts for preservative or fire-retardant purposes, its electrical resistivity may be markedly reduced. The effect of such salt treatment is small when the wood moisture is below about 8% but increases rapidly as the moisture content exceeds about 10%. Treatment with creosote or pentachlorophenol has practically no effect on the resistivity of wood, just as long as no excess water is the treating solution. The resistivity of wood decreases by about a factor of 2 for each increase of 10°C in the temperature and is about half as great for current flow along the grain as across the grain.

4.5.8 American Lumber Standards

Voluntary Product Standard PS 20-99, American softwood Lumber Standard is a voluntary standard of manufacturers, distributors, and users promulgated in cooperation with the U.S. Department of Commerce. It provides for use classifications of (1) yard lumber, (2) structural lumber, and (3) factory and shop lumber. Different grading rules apply to each class. Size standards and generalized grade descriptions are part of PS 20-99, but details of grading rules are left to the organized agencies of the lumber manufacturing industry. The grades and working stresses for structural lumber are referred by PS 20-99 to the authority of ASTM D245, Methods for Establishing Structural Grades of Lumber, or D2018, Recommended for Determining Design Stresses for Load-Sharing Lumber Members.

Standard Commercial Names. Standard commercial names of the most commonly used structural softwood from ASTM D1165, Standard Nomenclature of Domestic Hardwood and Softwoods, are as follows:

- Cedar
  - Alaska cedar
  - Port Orford cedar
  - Western red cedar
- Fir
  - Douglas-fir
  - White fir
- Hemlock
  - Eastern hemlock
  - Western hemlock
- Larch, Western
- Pine
  - Jack pine
  - Lodgepole pine
  - Norway pine
  - Ponderosa pine
  - Southern yellow pine
- Redwood
- Spruce
  - Eastern spruce
  - Engelmann spruce
  - Sitka spruce

Standard Structural Grades. Detailed descriptions of the standard structural grades are published and promulgated in the grading rule books of the organized regional agencies of the lumber manufacturing industry. These are subject to review for compliance with the general requirements of PS 20–99, American softwood Lumber Standard. The principal-use classes of structural lumber are: (1) *joists and planks*, pieces of rectangular cross section 5 to 10 cm (2 to 4 in) thick and 10 cm (4 in) or more wide (nominal dimensions), graded primarily for bending strength edgewise or flatwise, (2) *beams and stringers*, pieces of rectangular cross section 12.7 by 20.3 cm (5 by 8 in) (nominal dimensions) and up, graded for strength in bending when loaded on the narrow face, and (3) *posts and timbers*, pieces of square or nearly square cross section, 12.7 by 12.7 cm (5 by 5 in) (nominal dimensions) and larger, graded primarily for use as posts and columns.

Working Stresses. Working stresses recommended by the lumber industry for their structural grades are found with the detailed grade descriptions in the grading rule books of the organized regional agencies of the industry. A complete listing of all structural grades and their working stresses is found in the *National Design Specification for Wood Construction,* published by ANSI/AF&PAssn. Values for a few typical grades are shown in Table 4-18. Working stresses vary according to the grades and sizes of lumber and their condition with respect to moisture content. Stresses are adjustable also for duration of load and for special conditions such as extreme temperature. Stress increases are provided for "load-sharing/repetitive members" in which the safety of the structure

*__LUMBER DIMENSIONS__. Tabulated design values are applicable to lumber that will be used under dry conditions such as in most covered structures. For 5″ and thicker lumber, the GREEN dressed sizes shall be permitted to be used (see Table 1A) because design values have been adjusted to compensate for any loss in size by shrinkage which may occur. (Tabulated design values are for normal load duration and dry service conditions, unless specified otherwise. See NDS 4.3 for a comprehensive description of design value adjustment factors.)

Source: Compiled from *National Design Specification for Wood Construction* ANSI/AF$P ASSN.-1 depends upon the strength of the assemblage of members rather than upon the lowest strength value for any single member. These stress modifications are described in ASTM standards.

Allowable working stresses for the structural grades of lumber are also a part of certain use specifications, such as the Minimum Property Standards of the Federal Housing Administration, the *American Railway Engineering Association Manual*, and various local or regional building codes. These allowable values may or may not coincide with the lumber industry stress recommendations for the same species and grade.

Wood-Base Panel Materials. Included in this category are insulating board, hardboard, particle board, waferboard, plywood, and several engineered-wood products. Plywood, normally fabricated by bonding an odd number of layers of veneers together with the grain direction in adjacent piles at right angles to each other, is more dimensionally stable and more uniform in strength in the plane of the sheet than wood. Qualities of glue line and veneer permitted are set by the various commercial standards for plywood and determine the grades under which plywood is sold. In general, glue-line quality determines whether plywood is classed as being suitable for interior or exterior use.

U.S. Product Standard PS1-83 covers the basic specifications for the manufacture of construction plywood. Decorative hardwood plywood is described by U.S. Product Standard PS51(5.2). Plywood manufactured according to this standard will carry a grade trademark of a qualified testing agency. Testing is conducted under PS2-92 and ASTM D1037.

Insulation boards and hardboards are panel products made by reducing wood substance to particles or fiber and reconstituting the fiber into stiff panels 1.2 by 2.4 m (4 by 8 ft) in area or larger. Insulation board is of either interior or water-resistant quality, and is usually manufactured for use where combinations of thermal and sound-insulating properties and stiffness and strength are desired. Hardboard with a density of 50 lb/ft^3 or more is used in many applications where a relatively thin, hard, uniform panel material is required. Of great importance in the electrical field are special high-density hardboard products expressly manufactured with high dielectric properties. Medium-density fiberboards have a density between that of insulation board and hardboard.

Particle boards are panel products made by gluing small pieces of wood in a form such as flakes (this product is called waferboard) and shavings into relatively thick, rigid panels. Thermosetting resins are used to provide bonds of either interior or water-resistant quality. Standards ASTM C208 and ANSI A208.1 and PS58 govern minimum qualities of regular insulation board, particle board, and hardboard. The important physical and strength properties of various board products are indicated by Table 4-19.

There are many engineered-wood products now available for structural use. In addition to plywood, which has already been discussed, they include glued-laminated timber, wood I-joists,oriented-strand board (OSB), laminated-veneer lumber (LVL), parallel-strand lumber (PSL), and laminated-strand lumber (LSL). All these products require structural engineering input in their design, manufacture, and end use. There are many advantages in using these products compared with solid wood.

4.5.9 Wood Poles and Crossarms

Douglas-fir (Coast) and Southern pine as a group of four species, loblolly, longleaf, shortleaf, and slash pine, are the most commonly used in the United States to support electric supply and communication lines, cables, and equipment. In the Northeast part of the country, there are still some chestnut and also Northern white cedar poles in service, but these species are no longer available for purchase. Western red cedar, lodgepole and ponderosa pines, and Western larch are used to a limited extent in the Western states. Other species are shown in the ANSI 05.1 Specification size/class tables, but many of those are not provided for orders due to lack of supply or lack of fabricating and treating sources.

4.5.10 Standards for Wood Poles

The ANSI specifications for wood poles serve as a basis for purchasing and use. The ANSI specifications cover fiber stresses, dimensions, defect limitations, and manufacturing requirements. The fiber stresses approved by the ANSI and contained in its Standard 05.1 are as shown in Tables 4-20, 4-21, 4-22, and 4-23. These tables cover all species of poles normally used in communication and electrical power construction.

Notes: Classes and lengths for which circumferences at 6 ft (1.83 m) from the butt are listed in boldface type are the preferred standard sizes. Those shown in light type are included for engineering purposes only.

1 in = 2.54 cm; 1 ft = 0.3048 m; 1 lb/in^2 = 6.895 kPa.

*The figures in this column are intended for use only when a definition of ground line is necessary in order to apply requirements relating to scars, straightness, etc.

Pole Dimensions. The circumference at "6 ft (1.8 m) from butt" in ANSI Standard 05.1 is based on the following principles:

a. The classes from the lowest to the highest were arranged in approximate geometric progression, the increments in breaking load between classes being about 25%.

b. The dimensions were specified in terms of circumference in inches at the top and circumference in inches at 6 ft from the butt for poles of the respective classes and lengths, except for three classes having no requirement for butt circumference.

c. All poles of the same class and length were to have, when new, approximately equal strength or, in more precise terms, equal moments of resistance at the ground line.

d. All poles of different lengths within the same class were of sizes suitable to withstand approximately the same breaking load, on the assumption that the load is applied 0.6 m (2 ft) from the top and that the break (failure) would occur at the ground line.

Notes: Classes and lengths for which circumferences at 6 ft (1.83 m), from the butt are listed in boldface type are the preferred standard sizes. Those shown in light type are included for engineering purposes only.

1 in = 2.54 cm; 1 ft = 0.3048 m; 1 lb/in^2 = 6.895 kPa.

*The figures in this column are intended for use only when a definition of ground line is necessary in order to apply requirements relating to scars, straightness, etc.

The breaking loads referred to in (d) above for the classes for which 6 ft (1.8 m) from butt circumferences are given are as follows: Class 1, 4,500 lb; Class 2, 3,700 lb; Class 3, 3,000 lb; Class 4, 2,400 lb; Class 5, 1,900 lb; Class 6, 1,500 lb; Class 7, 1,200 lb; Class 9, 740 lb; Class 10,370 lb.

Minimum top circumferences and minimum circumferences at 6 ft (1.8 m) from butt are given in Tables 4-20, 4-21, 4-22, and 4-23.

Length. Poles under 50 ft (15.2 m) in length should not be more than 3 in shorter or 6 in longer than nominal length. Poles 50 ft (15.2 m) or over in length should not be more than 6 in shorter or 12 in longer than nominal length. Length should be measured between the extreme ends of the pole.

Circumference. The minimum circumference at 6 ft (1.8 m) from the butt and at the top, for each length and class of pole, is listed in the tables of dimensions. The circumference at 6 ft (1.8 m) from the butt of poles should be not more than 7 in (17.8 cm) or 20% larger than the specified minimum, whichever is greater. The top dimensional requirement should apply at a point corresponding to the minimum length permitted for the pole.

Classification. The true circumference class should be determined as follows: Measure the circumference at 6 ft (1.8 m) from the butt. This dimension will determine the true class of the pole, provided that its top (measured at the minimum length point) is large enough. Otherwise, the circumference at the top will determine the true class, provided that the circumference at 6 ft (1.8 m) from the butt does not exceed the specified minimum by more than 7 in (17.8 cm) or 20%, whichever is greater. The preceding information relating to the pole standards approved by the ANSI does not constitute the complete standards. For further information, consult the standards, which may be obtained at a nominal charge.

Machine shaving of poles has increased as a practice of producers. Some producers also turn the pole down in the process, thereby obtaining a straighter pole with a specific taper. The machine-processed poles season more rapidly, which is particularly important with species like Southern pine which is susceptible to fungus attack before treatment. Machine shaving makes for easier detection of defects and provides a pole of improved appearance. If poles having normally thin sapwood (such as Western red cedar and larch) are to be full-length when treated with preservative, it is undesirable to reduce the thickness of the sapwood more than necessary to obtain a dressed pole.

Inspection. Poles are inspected prior to treatment for physical defects and decay and after treatment for penetration and retention of preservative and for cleanliness. Inspection is most effective when made at vendors' plants, because defects that may be hidden by preservative are detected and freight is saved on rejects. Commercial inspection agencies are available at most producing locations, and it is normally economical to utilize their services. Quantity users may have their own trained inspectors. *Crossarm inspection* is important because safety of linemen is a consideration in addition to quality of timber. As with poles, inspection should be made before treatment for defects and after treatment for penetration, retention, and cleanliness. Inspection should be done by qualified timber specialists.

Conductivity. Conductivity is of concern to many electric-utility companies. Pole resistance varies greatly with moisture content. Dry wood of all species exhibits high resistance. Surface absorption of rainwater by untreated wood may vary the resistance over a wide range. Full-length treated poles thoroughly dried before treatment generally show only moderate reduction in resistance following a rain. A rough correlation between resistance and moisture will show that 500,000 Ω over a 20-ft length of pole between contacts driven $3\frac{1}{2}$ in deep corresponds to a moisture content of about 25%. Other average points on the curve band are 50,000,000 Ω 15% moisture and 20,000 Ω 40% moisture.

Depth of Pole Setting. The values in the column headed "Ground-line distance from butt" in Tables 4-20 to 4-23 may be accepted as a guide for a satisfactory depth of pole settings in ordinary firm soil. In marshy soil and at unguyed angles in lines, setting depths should be increased 1 to 2 ft (0.3 to 0.6 m). In rock, the indicated settings may be reduced one-half for that part of the pole set in rock. Rock backfill in ordinary earth locations is not considered as set in rock.

Pole Stubbing. Pole stubbing frequently can be employed to effect substantial money savings. An otherwise good pole that is decayed at or below the ground line is fastened securely to a new preservative-treated stub set in the ground alongside it. The major part of the savings resulted from avoidance of transferring wires and equipment.

Salvaging. Poles removed for any reason can frequently be salvaged for future use. Users of large quantities can economically do this. The following operations must be employed: if defective cut off top, butt and retreat, remove old hardware, peel off saprot, reframe, and retreat as required.

Kinds of Timber for Crossarms. Two kinds of timber are in general use for crossarms, Douglas-fir and Southern pine. All pine crossarms are treated with creosote or pentachlorophenol. Crossarms must be treated to achieve long service life.

Most Douglas-fir arms used for communication and power-distribution lines are manufactured from timber selected for the purpose. Dense and close-grain lumber is used. Publication 17 of the West Coast Lumber Inspection Bureau sets forth grading and dressing requirements.

TABLE 4-24 Bending Load and Crushing Strength of Crossarms

Note: 1 in = 2.54 cm; 1 lb = 0.4536 kg; 1 lb/in^2 = 6.895 kPa.

There is no grade of Southern pine timber designated as crossarm stock, and crossarm users depend on the limitations set forth in their specifications to obtain a satisfactory quality of product. Pine arms are usually small boxed heart timbers.

Large transmission-line structures are treated round poles and over the past 20 years, laminated towers, arms and braces have more frequently been selected.

Crossarm Specifications. The most widely used specifications for power-line crossarms have been promulgated by ANSI 05.3 as "Solid Sawn-Wood Crossarms and Braces—Specifications and Dimensions" and by the Transmission and Distribution Committee of the Edison Electric Institute. For fir crossarms: Specification TD-90, which combines both dense and close-grain grades; Specification TD-92, Heavy-Duty Douglas-Fir Crossarms; Specification TD-93, Heavy-Duty Douglas-Fir Braces. For pine crossarms: Specification TD-91, Dense Southern Pine Crossarms Preservative Treated. Widely used specifications for communication crossarms are American Telephone and Telegraph Co. Specification AT-7298. Crossarms. Sawn crossarms are treated with preservatives by pressure processes following AWPA Standard C25 laminated structures must confirm with the standards of AITC (American Institute of Timber Construction).

Strength of Crossarms. The most reliable source of information on the strength comes from tests made under conditions to simulate crossarms in service. Some tests have been made, and others are under consideration. Theoretical considerations, treating a crossarm as a beam, are valuable if those factors which control the actual strength are taken into account. Tests made several years ago on 84 six-pin, 3$3\frac{1}{4}$ by 4$3\frac{1}{4}$-in by 6-ft communication crossarms, with a uniformly distributed vertical load, gave average results shown in Table 4-24 (*U.S. Forest Service Circ.* 204, by T. R. C. Wilson). The maximum bending load is the total distributed vertical load. The maximum crushing strength is under compression parallel to the grain. Methods of tests are covered by the appropriate ASTM standards.

5.1 FOSSIL-FUELED PLANTS

5.1.1 Introduction

America—and much of the world—is becoming increasingly electrified. In 2005, more than half of the electricity generated in the United States came from coal. For the foreseeable future, coal will continue to be the dominant fuel used for electric power production. The low cost and abundance of coal is one of the primary reasons why consumers in the United States benefit from some of the lowest electricity rates of any free-market economy.

The key challenge to keeping coal viable as a generation fuel is to remove the environmental objections to the use of coal in power plants. New technologies are being developed that could virtually eliminate the sulfur, nitrogen, and mercury pollutants released when coal is burned. It may also be possible to capture greenhouse gases that are emitted from coal-fired power plants and prevent them from contributing to global warming concerns.

Research is also underway to increase the fuel efficiency of coal-fueled power plants. Today's plants convert only one-third of coal's energy potential to electricity. New technologies could nearly double efficiency levels in the next 10 to 15 years.

Natural gas is the fastest growing fuel for electricity generation. More than 90% of the power plants to be built in the next 20 years will likely be fueled by natural gas. Natural gas is also likely to be a primary fuel for distributed power generators—mini-power plants that could be sited close to where the electricity is needed.

Natural gas-powered fuel cells are also being developed for future distributed generation applications. Fuel cells use hydrogen that can be extracted from natural gas, or perhaps in the future from biomass or coal.

5.1.2 Thermodynamic Cycles

Rankine Cycle. The cornerstone of the modern steam power plant is a modification of the Carnot cycle proposed by W. J. M. Rankine, a distinguished Scottish engineering professor of thermodynamics and applied mechanics. The temperature-entropy and enthalpy-entropy diagrams of Fig. 5-1 illustrate the state changes for the Rankine cycle. With the exception that compression terminates (state *a*) at boiling pressure rather than the boiling temperature (state *á*), the cycle resembles a Carnot

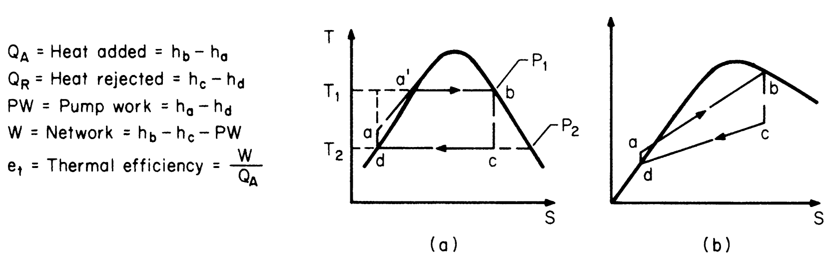

FIGURE 5-1 Simple Rankine cycle (without superheat): (*a*) temperature-entropy; (*b*) enthalpy-entropy (Mollier).

cycle. The triangle bounded by *a-á* and the line connecting to the temperature-entropy curve in Fig. 5-1*a* signify the loss of cycle work because of the irreversible heating of the liquid from state *a* to saturated liquid. The lower pressure at state *a*, compared to *á*, makes possible a much smaller work of compression between *d-a*. For operating plants, it amounts to 1% or less of the turbine output.

This modification eliminates the two-phase vapor compression process, reduces compression work to a negligible amount, and makes the Rankine cycle less sensitive than the Carnot cycle to the irreversibilities bound to occur in an actual plant. As a result, when compared with a Carnot cycle operating between the same temperature limits and with realistic component efficiencies, the Rankine cycle has a larger network output per unit mass of fluid circulated, smaller size, and lower cost of equipment. In addition, because of its relative insensitivity to irreversibilities, its operating plant thermal efficiencies will exceed those of the Carnot cycle.

Regenerative Rankine Cycle. Refinements in component design soon brought power plants based on the Rankine cycle to their peak thermal efficiencies, with further increases realized by modifying the basic cycle. This occurred through increasing the temperature of saturated steam supplied to the turbine, by increasing the turbine inlet temperature through constant-pressure superheat, by reducing the sink temperature, and by reheating the working vapor after partial expansion followed by continued expansion to the final sink temperature. In practice, all of these are employed with yet another important modification. The irreversibility associated with the heating of the compressed liquid to saturation by a finite temperature difference is the primary thermodynamic cause of lower thermal efficiency for the Rankine cycle. The regenerative cycle attempts to eliminate this irreversibility by using as heat sources other parts of the cycle with temperatures slightly above that of the compressed liquid being heated.

This procedure of transferring heat from one part of a cycle to another in order to eliminate or reduce external irreversibilities is called "regenerative heating," which is basic to all regenerative cycles.

The scheme shown in Fig. 5-2 is a practical approach to regeneration. Extraction or "bleeding" of steam at state *c* for use in the "open" heater avoids excessive cooling of the vapor during turbine expansion; in the heater, liquid from the condenser increases in temperature by ΔT. (Regenerative cycle heaters are called "open" or "closed" depending on whether hot and cold fluids are mixed directly to share energy or kept separate with energy exchange occurring by the use of metal coils.)

The extraction and heating substitute the finite temperature difference ΔT for the infinitesimal dT used in the theoretical regeneration process. This substitution, while failing to realize the full potential of regeneration, halves the temperature difference through which the condensate must be heated in the basic Rankine cycle. Additional extractions and heaters permit a closer approximation to the maximum efficiency of the idealized regenerative cycle, with further improvement over the simple Rankine cycle shown in Fig. 5-1.

Reducing the temperature difference between the liquid entering the boiler and that of the saturated fluid increases the cycle thermal efficiency. The price paid is a decrease in net work produced per pound of vapor entering the turbine and an increase in the size, complexity, and initial cost of the plant. Additional improvements in cycle performance may be realized by continuing to accept the consequences of increasing the number of feedwater heating stages. Balancing cycle thermal efficiency against plant size, complexity, and cost for production of power at minimum cost determines the optimum number of heaters.

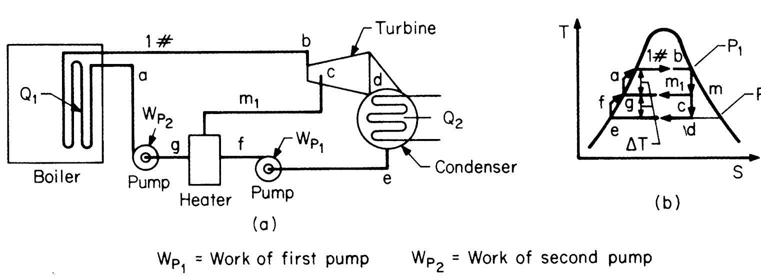

FIGURE 5-2 Single extraction regenerative cycle: (*a*) flow diagram; (*b*) temperature-entropy diagram.

Reheat Cycle. The use of *superheat* offers a simple way to improve the thermal efficiency of the basic Rankine cycle and reduce vapor moisture content to acceptable levels in the low-pressure stages of the turbine. But with continued increase of higher temperatures and pressures to achieve better cycle efficiency, in some situations available superheat temperatures are insufficient to prevent excessive moisture from forming in the low-pressure turbine stages.

The solution to this problem is to interrupt the expansion process, remove the vapor for *reheat* at constant pressure, and return it to the turbine for continued expansion to condenser pressure. The thermodynamic cycle using this modification of the Rankine cycle is called the "reheat cycle." Reheating may be carried out in a section of the boiler supplying primary steam, in a separately fired heat exchanger, or in a steam-to-steam heat exchanger. Most present-day utility units combine superheater and reheater in the same boiler.

Usual central-station practice combines both regenerative and reheat modifications to the basic Rankine cycle. For large installations, reheat makes possible an improvement of approximately 5% in thermal efficiency and substantially reduces the heat rejected to the condenser cooling water. The operating characteristics and economics of modern plants justify the installation of only one stage of reheat except for units operating at supercritical pressure.

Figure 5-3 shows a flow diagram for a 600-MW fossil-fueled reheat cycle designed for initial turbine conditions of 2520-lb/in^2 (gage) and 1000°F steam. Six feedwater heaters are supplied by exhaust steam from the high-pressure turbine and extraction steam from the intermediate and low-pressure turbines. Except for the deaerating heater (third), all heaters shown are closed heaters. Three pumps are shown: (1) the condensate pump, which pumps the condensate through oil and hydrogen gas coolers, vent condenser, air ejector, first and second heaters, and deaerating heater; (2) the condensate booster pump, which pumps the condensate through fourth and fifth heaters; and (3) the boiler feed pump, which pumps the condensate through the sixth heater to the economizer and boiler. The mass flows noted on the diagram are in pounds per hour at the prescribed conditions for full-load operation.

5.1.3 Reheat Steam Generators

The boiler designer must proportion heat-absorbing and heat-recovery surfaces to make best use of the heat released by the fuel. Waterwalls, superheaters, and reheaters are exposed to convection and radiant heat, whereas convection heat transfer predominates in air heaters and economizers.

The relative amounts of such surfaces vary with the size and operating conditions of the boiler. A small low-pressure heating plant with no heat-recovery equipment has quite a different arrangement from a large high-pressure unit operating on a reheat regenerative cycle and incorporating heat-recovery equipment.

Factors Influencing Boiler Design. In addition to the basics of unit size, steam pressure, and steam temperature, the designer must consider other factors that influence the overall design of the steam generator.

Fuels. Coal, although the most common fuel, is also the most difficult to burn. The ash in coal consists of a number of objectionable chemical elements and compounds. The high percentage of ash that can occur in coal has a serious effect on furnace performance.

At the high temperatures resulting from the burning of fuel in the furnace, fractions of ash can become partially fused and sticky. Depending on the quantity and fusion temperature, the partially fused ash may adhere to surfaces contacted by the ash-containing combustion gases, causing objectionable buildup of slag on or bridging between tubes. Chemicals in the ash may attack materials such as the alloy steel used in superheaters and reheaters.

In addition to the deposits in the high-temperature sections of the unit, the air heater (the coolest part) may be subject to corrosion and plugging of gas passages from sulfur compounds in the fuel acting in combination with moisture present in the flue gas.

Furnace. Heat generated in the combustion process appears as furnace radiation and sensible heat in the products of combustion. Water circulating through tubes that form the furnace wall lining absorbs as much as 50% of this heat, which, in turn, generates steam by the evaporation of part of the circulated water.

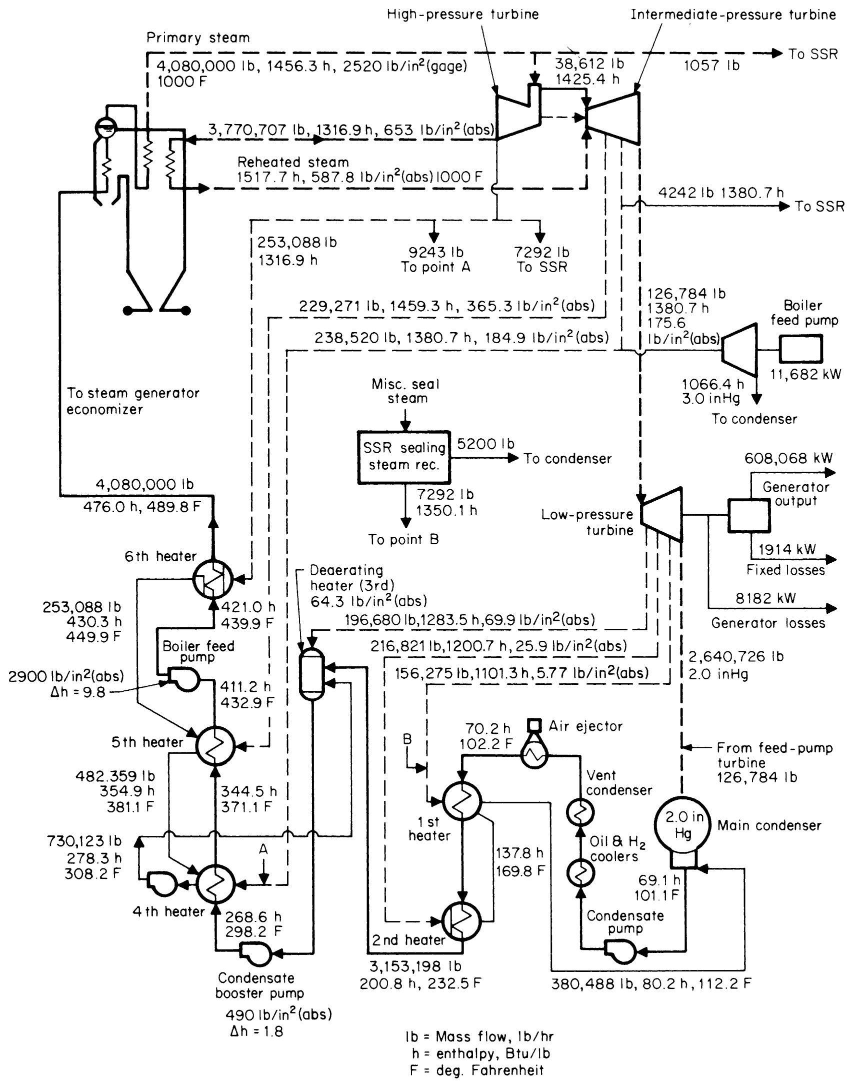

FIGURE 5-3 Reheat regenerative cycle, 600-MW subcritical-pressure fossil-fuel power plant.

Furnace design must consider water heating and steam generation in the wall tubes as well as the processes of combustion. Practically, all large modern boilers have walls comprising water-cooled tubes to form complete metal coverage of the furnace enclosure. Similarly, areas outside the furnace which form enclosures for sections of superheaters, reheaters, and economizers also use either water- or steam-cooled tube surfaces. Present practice is to use tube arrangements and configurations which permit practically complete elimination of refractories in all areas that are exposed to high-temperature gases.

Waterwalls usually consist of vertical tubes arranged in tangent or approximately so, connected at top and bottom to headers. These tubes receive their water supply from the boiler drum by means of downcomer tubes connected between the bottom of the drum and the lower headers. The steam, along with a substantial quantity of water, is discharged from the top of the waterwall tubes into the upper waterwall headers and then passes through riser tubes to the boiler drum. Here the steam is separated from the water, which together with the incoming feedwater is returned to the waterwalls through the downcomers.

Tube diameter and thickness are of concern from the standpoints of circulation and metal temperatures. Thermosyphonic (also called thermal or natural) circulation boilers generally use larger-diameter tubes than positive (pumped) circulation or once-through boilers. This practice is dictated largely by the need for more liberal flow area to provide the lower velocities necessary with the limited head available. The use of small-diameter tubes is an advantage in high-pressure boilers because the lesser tube thicknesses required result in lower outside tube-metal temperatures. Such small-diameter tubes are used in recirculation boilers in which pumps provide an adequate head for circulation and maintain the desired velocities.

Superheaters and Reheaters. The function of a superheater is to raise the boiler steam temperature above the saturated temperature level. As steam enters the superheater in an essentially dry condition, further absorption of heat sensibly increases the steam temperature.

The reheater receives superheated steam which has partly expanded through the turbine. As described earlier, the role of the reheater in the boiler is to re-superheat this steam to a desired temperature.

Superheater and reheater design depends on the specific duty to be performed. For relatively low final outlet temperatures, superheaters solely of the convection type are generally used. For higher final temperatures, surface requirements are larger and, of necessity, superheater elements are located in very high gas-temperature zones. Wide-spaced platens or panels, or wall-type superheaters or reheaters of the radiant type, can then be used. Figure 5-4 shows an arrangement of such platen and panel surfaces. A relatively small number of panels are located on horizontal centers of 5 to 8 ft to permit substantial radiant heat absorption. Platen sections, on 14- to 28-in centers, are placed downstream of the panel elements; such spacing provides high heat absorption by both radiation and convection.

Economizers. Economizers help to improve boiler efficiency by extracting heat from flue gases discharged from the final superheater section of a radiant/reheat unit (or the evaporative bank of an industrial boiler). In the economizer, heat is transferred to the feedwater, which enters at a temperature appreciably lower than that of saturated steam. Generally, economizers are arranged for downward flow of gas and upward flow of water.

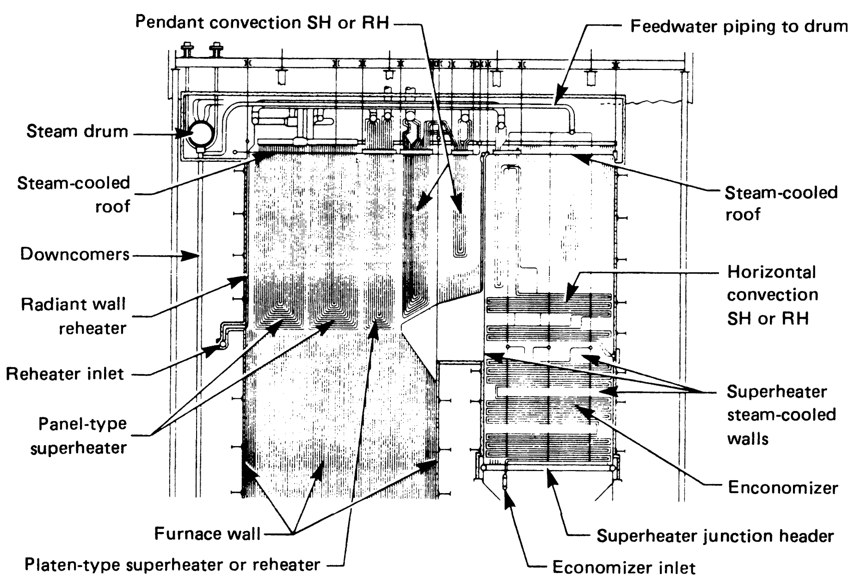

FIGURE 5-4 Arrangement of superheater, reheater, and economizer of a large coal-fired steam generator.

Water enters from a lower header and flows through horizontal tubing constituting the heating surface. Return bends at the ends of the tubing provide continuous tube elements, whose upper ends connect to an outlet header that is in turn connected to the boiler drum by means of tubes or large pipes.

As shown in Fig. 5-4, economizers of a typical utility-type boiler are located in the same pass as the primary or horizontal sections of the superheater, or superheater and reheater, depending on the arrangement of the surface. Tubing forming the heating surface is generally low-carbon steel. Because steel is subject to corrosion in the presence of even extremely low concentrations of oxygen, it is necessary to provide water that is practically 100% oxygen free. In central stations and other large plants, it is a common practice to use deaerators for oxygen removal.

Air Heaters. Steam-generator air heaters have two important and concomitant functions: they cool the gases before they pass to the atmosphere, thereby increasing fuel-firing efficiency; at the same time, they raise the temperature of the incoming air of combustion. Depending on the pressure and temperature cycle, the type of fuel, and the type of boiler involved, one of the two functions will have prime importance.

For instance, in a low-pressure gas- or oil-fired industrial or marine boiler, combustion-gas temperature can be lowered in several ways—by a boiler bank, by an economizer, or by an air heater. Here, an air heater has principally a gas-cooling function, as no preheating is required to burn the oil or gas. If the boiler is a high-pressure reheat unit burning a high-moisture subbituminous or lignitic coal, high preheated-air temperatures are needed to evaporate the moisture in the coal before ignition can take place. Here, the air-heating function becomes primary. Without exception, then, large pulverized-coal boilers either for industry or electric power generation use air heaters to reduce the temperature of the combustion products from the 600 to 800°F level to final exit-gas temperatures of 275 to 350°F. In these units, the combination air is heated from about 80°F to between 500 and 750°F, depending on coal calorific value and moisture content.

In theory, only the primary air must be heated; that is, air used to actually dry the coal in the pulverizers. Ignited fuel can burn without preheating the secondary and tertiary air. However, there is considerable advantage to the furnace heat-transfer process from heating *all* the combustion air; it increases the rate of burning and helps raise adiabatic temperature.

5.1.4 Fossil Fuels

Fossil fuels used for steam generation in utility and industrial power plants may be classified into solid, liquid, and gaseous fuels. Each fuel may be further classified as a natural, manufactured, or by-product fuel. Not mutually exclusive, these classifications necessarily overlap in some areas. Obvious examples of natural fuels are coal, crude oil, and natural gas.

Of all the fossil fuels used for steam generation in electric-utility and industrial power plants today, coal is the most important. It is widely available throughout much of the world, and the quantity and quality of coal reserves are better known than those of other fuels.

5.1.5 Classification of Coal

Coals are grouped according to rank. For the purposes of the power-plant operator, there are several suitable ranks of coal:

Anthracite
Bituminous
Subbituminous
Lignite

The following description of coals by rank gives some of their physical characteristics.

Anthracite. Hard and very brittle, anthracite is dense, shiny black, and homogeneous with no marks or layers. Unlike the lower-rank coals, it has a high percentage of fixed carbon and a low percentage of

*This classification does not include a few coals, principally nonbanded varieties, which have unusual physical and chemical properties and which come within the limits of fixed carbon or calorific value of the high-volatile bituminous and subbituminous ranks. All of these coals either contain less than 48% dry, mineral-matter-free fixed carbon or have more than 15,500 moist, mineral-matter-free Btu per pound.

†Moist refers to coal containing its natural inherent moisture but not including visible water on the surface of the coal.

‡If agglomerating, classify in low-volatile group of the bituminous class.

§Coals having 69% or more fixed carbon on the dry, mineral-matter-free basis shall be classified by fixed carbon, regardless of calorific value.

¶It is recognized that there may be nonagglomerating varieties in these groups of the bituminous class, and there are notable exceptions in the high-volatile C bituminous group.

volatile matter. Anthracites include a variety of slow-burning fuels merging into graphite at one end and into bituminous coal at the other. They are the hardest coals on the market, consisting almost entirely of fixed carbon, with the little volatile matter present in them chiefly as methane, CH_4. Anthracite is usually graded into small sizes before being burned on stokers. The "metaanthracites" burn so slowly as to require mixing with other coals, while the "semianthracites," which have more volatile matter, are burned with relative ease if properly fired. Most anthracites have a lower heating value than the highest-grade bituminous coals. Anthracite is used principally for heating homes and in gas production.

Some semianthracites are dense, but softer than anthracite, shiny gray, and somewhat granular in structure. The grains have a tendency to break off in handling the lump, and produce a coarse, sand-like slack. Other semianthracites are dark gray and distinctly granular. The grains break off easily in handling and produce a coarse slack. The granular structure has been produced by small vertical cracks in horizontal layers of comparatively pure coal separated by very thin partings. The cracks are the result of heavy downward pressure, and probably shrinkage of the pure coal because of a drop in temperature.

Bituminous. By far the largest group, bituminous coals derive their name from the fact that on being heated they are often reduced to a cohesive, binding, sticky mass. Their carbon content is less than that of anthracites, but they have more volatile matter. The character of their volatile matter is more complex than that of anthracites, and they are higher in calorific value. They burn easily, especially in pulverized form, and their high volatile content makes them good for producing gas. Their binding nature enables them to be used in the manufacture of coke, while the nitrogen in them is utilized in processing ammonia.

The low-volatile bituminous coals are grayish-black and distinctly granular in structure. The grain breaks off very easily, and handling reduces the coal to slack. Any lumps that remain are held together by thin partings. Because the grains consist of comparatively pure coal, the slack is usually lower in ash content than are the lumps.

Medium-volatile bituminous coals are the transition from high-volatile to low-volatile coal and, as such, have the characteristics of both. Many have a granular structure, are soft, and crumble easily. Some are homogeneous with very faint indications of grains or layers. Others are of more distinct laminar structure, are hard, and stand handling well.

High-volatile A bituminous coals are mostly homogeneous with no indication of grains, but some show distinct layers. They are hard and stand handling with little breakage. The moisture, ash, and sulfur contents are low, and the heating value is high.

High-volatile B bituminous coals are of distinct laminar structure; the layers of black, shiny coal alternate with dull, charcoal-like layers. They are hard and stand handling well. Breakage occurs generally at right angles and parallel to the layers, so that the lumps generally have a cubical shape.

High-volatile C bituminous coals are of distinct laminar structure, are hard, and stand handling well. They generally have high moisture, ash, and sulfur contents and are considered to be free-burning coals.

Subbituminous. These coals are brownish black or black. Most are homogeneous with smooth surfaces, and with no indication of layers. They have high moisture content, as much as 15% to 30%, although appearing dry. When exposed to air they lose part of the moisture and crack with an audible noise. On long exposure to air, they disintegrate. They are free-burning, entirely noncoking, coals.

Lignite. Lignites are brown and of a laminar structure in which the remnants of woody fibers may be quite apparent. The word *lignite* comes from the Latin word *lignum* meaning wood. Their origin is mostly from plants rich in resin, so they are high in volatile matter. Freshly mined lignite is tough, although not hard, and it requires a heavy blow with a hammer to break the large lumps. But on exposure to air, it loses moisture rapidly and disintegrates. Even when it appears quite dry, the moisture content may be as high as 30%. Owing to the high moisture and low heating value, it is not economical to transport it long distances.

Unconsolidated lignite (B in Table 5-1) is also known as "brown coal." Brown coals are generally found close to the surface, contain more than 45% moisture, and are readily won by strip mining.

5.1.6 Impact of Fuel on Boiler Design

The most important item to consider when designing a utility or large industrial steam generator is the fuel the unit will burn. The furnace size, the equipment to prepare and burn the fuel, the amount of heating surface and its placement, the type and size of heat-recovery equipment, and the flue-gas-treatment devices are all fuel dependent.

The major differences among those boilers that burn coal or oil or natural gas result from the ash in the products of combustion. Firing oil in a furnace results in relatively small amounts of ash; there is no ash from natural gas. For the same output, because of the ash, coal-burning boilers must have larger furnaces and the velocities of the combustion gases in the convection passes must be lower. In addition, coal-burning boilers need ash-handling and particulate-cleanup equipment that costs a great deal and requires considerable space.

Table 5-2 lists the variation in calorific values and moisture contents of several coals, and the mass of fuel that must be handled and fired to generate the same electrical-power output. These values are important because the quantity of fuel required helps determine the size of the coal-storage yard, as well as the handling, crushing, and pulverizing equipment for the various coals.

Furnace Sizing. The most important step in coal-fired unit design is to properly size the furnace. Furnace size has a first-order influence on the size of the structural-steel framing, the boiler building and its foundations, as well as on the sootblowers, platforms, stairways, steam piping, and duct work. The fuel-ash properties that are particularly important when designing and establishing the size of coal-fired furnaces include

The ash fusibility temperatures (both in terms of their absolute values and the spread or difference between initial deformation temperature and fluid temperature)

The ratio of basic to acidic ash constituents

The iron/calcium ratio

The fuel-ash content in terms of pounds of ash per million British thermal units

The ash friability

These characteristics and others translate into the furnace sizes in Fig. 5-5, which are based on the six coal ranks shown in Table 5-2. This size comparison illustrates the philosophy of increasing the furnace plan area, volume, and the fuel burnout zone (the distance from the top fuel nozzle to the furnace arch), as lower-grade coals with poorer ash characteristics are fired.

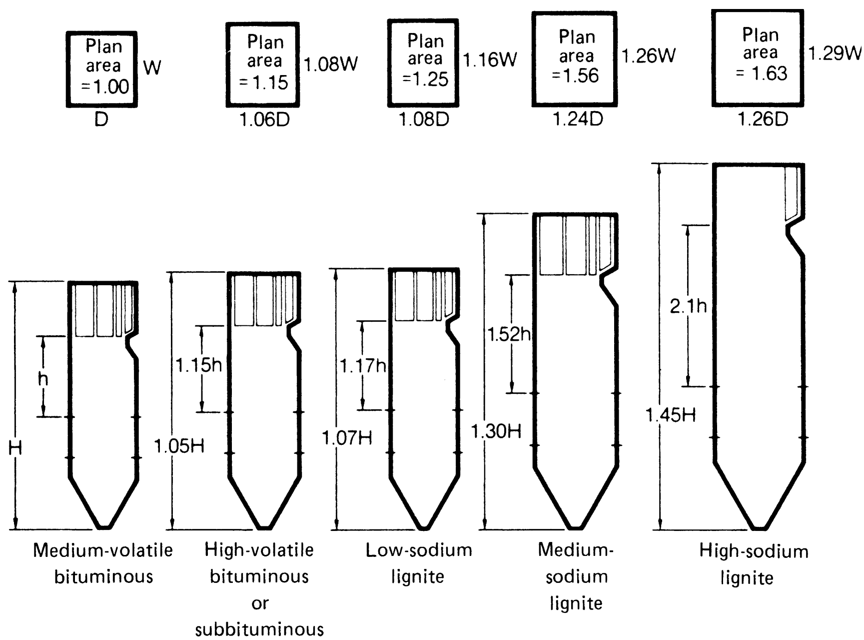

FIGURE 5-5 Effect of coal rank on furnace sizing (constant heat output).

Figure 5-5 is a simplified characterization of actual furnaces built to burn the fuels listed in Table 5-2. Wide variations exist in fuel properties within coal ranks, as well as within several subclassifications (e.g., subbituminous A, B, C), each of which may require a different size furnace.

Among the most important design criteria in large pulverized-fuel furnaces are net heat input in British thermal units per hour per square foot of furnace plan area (NHI/PA) and the vertical distance from the top fuel nozzle to the furnace arch. Furnace dimensions must be adequate to establish the necessary furnace retention time to properly burn the fuel as well as to cool the gaseous combustion products. This is to ensure that the gas temperature at the entrance to the closely spaced convection surface is well below the ash-softening temperature of the lowest-quality coal burned. Heat-absorption characteristics of the walls are maintained using properly placed wall blowers to control the furnace outlet gas temperature by removing ash deposited on the furnace walls below the furnace outlet plane.

5.1.7 Environmental Considerations

Concerns for the control of air quality have probably had the largest single impact on power plant site selection, design, operation, and cost. The three classes of emissions which are of major concern are nitrogen oxides, sulfur oxides, and particulate matter.

Nitrogen Oxides. In the United States, nitrogen oxides can be controlled within federal, state, and local regulatory limits by in-furnace and postcombustion techniques. With respect to firing systems, each steam-generator manufacturer has developed specific design concepts for reducing nitrogen oxides. The common characteristics of all of these designs, however, included a careful regulation of the fuel/air ratio in the firing zone where the major fraction of the fuel nitrogen compounds are liberated and control of the heat-liberation pattern in the furnace. Postcombustion reduction methods utilizing reagents with or without catalysts are somewhat similar in concept among the steam-generator suppliers.

Particulate Control. The traditional particulate control device in power plant applications has been the electrostatic precipitator. In recent years, fabric filters (also called "baghouses") have become increasingly popular.

In electrostatic precipitation, suspended particles in the gas are electrically charged, then driven to collecting electrodes by an electrical field; the electrodes are rapped to cause the particles to drop into collecting hoppers. This process differs from mechanical or filtering processes in which forces are exerted directly on the particulates rather than the gas as a whole. Effective separation of particles can be achieved with lower power expenditure, with negligible draft loss, and with little or no effect on the composition of the gas.

The principle of electrostatic precipitation is relatively simple. The process applies an electrostatic charge to dust particles with a corona discharge and passes them through an electric field where the particles are attracted to a collecting surface. The basic elements of a precipitator include a source of unidirectional voltage, corona or discharge electrodes, collecting electrodes, and a means of removing the collected matter.

Single-stage (Cottrell-type) precipitators combine the ionizing and collecting step. In the more common plate type, the electrodes are suspended between plates on insulators connected to a high-voltage source. A voltage differential created between the discharge and collecting electrodes develops a strong electric field between them. The flue gas is passed through the field and a unipolar discharge of gas ions, from the discharge electrode, is attached to the particulate matter.

5.1.8 Fabric Filtration

Fabric filters, or baghouses, have a long history of applications in both dry and wet filtration processes to recover chemicals or control stack emissions. Available materials limited early baghouse installations to temperatures below 250°F, and air dilution was frequently used ahead of the baghouse. In addition, the chemical-resistance characteristics of the bags also curtailed fabric filtration. These two limitations retarded its development for many years, particularly as available precipitator equipment met the existing regulations.

Serious consideration of this technology began after 1970; interest heightened as installations on large coal-fired boilers demonstrated good operating characteristics and high particulate-removal efficiencies.

5.1.9 Flue-Gas Desulfurization Systems

Flue-gas desulfurization (FGD) began in England in 1935. The technology remained dormant until the mid-1960s when it became active primarily in the United States and Japan. Since then, over 50 FGD processes have been developed, differing in the chemical reagents and the resultant end products.

The most common FGD system is a lime/limestone wet scrubber. After the flue gas has been treated in the precipitation (or baghouse), it passes through the induced fans and enters the SO_2 scrubber. If the required SO_2 removal efficiency is less than 85%, a fraction of the flue gas can be treated while bypassing the rest to mix with and reheat the saturated flue gas leaving the scrubber.

For higher-sulfur fuels requiring SO_2 removal efficiencies of 90% or greater, the entire flue-gas stream must be treated. Upon leaving the SO_2 absorption section, the flue gas is passed through entrainment separators to remove any slurry droplets mixed with the gas. The saturated flue gas is then reheated approximately 25 to 50°F above the water dewpoint before it is vented to the stack.

For low- to medium-sulfur fuels, an alternate scrubbing technology is dry scrubbing. This process minimizes water consumption and eliminates the requirement for flue-gas reheating but requires more expensive additives than the wet limestone systems.

The typical dry SO_2 absorber is a cocurrent classifying spray dryer. Flue gas enters the top of the absorber through inlet assemblies containing swirl vanes. The absorbent is injected pneumatically into the center of each swirler assembly by ultrasonic atomizing nozzles that require an air pressure of about 60 lb/in^2 (gage). Slurry feed pressures are 10 to 15 lb/in^2 (gage). The compressed air induces primary dispersion of the absorbent slurry by mechanical shear forces produced by the two fluid streams. Final dispersion is accomplished by shattering the droplets with ultrasonic energy produced by the compressed air used with a proprietary nozzle design. Then ultrasonic nozzles generate extremely fine droplets, which have diameters that range from 10 to 50 μm, as shown by photographic studies.

The flue-gas outlet design requires that effluent gases make a 180° turn before leaving the absorber. Besides eliminating product accumulation in the outlet duct, the abrupt directional change also allows the larger particles to drop out in the absorber product hopper. This design curtails the particulate loading to the fabric filter. Consequently, the number of cleaning cycles as well as abrasion of the filter medium are reduced.

As compared with ordinary fly-ash collection applications, fabric filters together with dry scrubbing offer a broader choice of design options. In conventional fly-ash collection applications, the fabric filter experiences flue-gas temperatures about 100 to 150°F higher than encountered in dry scrubbing. Filter media unsuitable at the higher temperatures can be used when the fabric filter follows a dry absorber. In particular, acrylic fibers become attractive because of their strength and flex characteristics, as well as their ability to support more vigorous cleaning methods like mechanical shaking.

5.1.10 Advanced Methods of Using Coal

Coal, which is the most abundant and economically stable fossil fuel in the United States, continues to grow in use while under pressure to meet the most stringent federal and local emissions requirements. This trend has added to the cost and complexity of coal combustion technologies.

Emission-control methods that facilitate the use of coal in power plants can be classified as

Precombustion processes

In situ combustion processes

Postcombustion processes

Precombustion processes include methods to clean the coal of sulfur-bearing compounds by wet separation, coal gasification, and coal liquefaction techniques. Coal gasification involves the partial oxidation of coal to produce a clean gas or by production of a "clean fuel" through coal liquefaction. Sulfur and ash are removed in these processes. The use of coal to produce a gas is not a new idea; it has been used to produce "town gas" for over 200 years. But its use in the United States had almost disappeared by 1930, because natural gas was abundant and low in cost. Concerns about the availability and economic stability of gas supplies, along with environmental trends, have renewed interest in coal gasification to produce substitute natural gas (SNG) and low- and medium-heat-content (LBTU and MBTU) gas for chemical feedstock or power plant fuel. Coal gasification in the combined-cycle mode has been well established as a viable technology for producing power with very low emissions both in the United States and Europe. New plants are using technologies such as high-temperature gas turbines, hot-gas cleanup to remove 99% of the sulfur (H_2S), and higher-pressure combined steam cycles to achieve overall efficiencies of greater than 40%. New integrated gasification combined-cycle (IGCC) plants of as much as 250 MWe are available. IGCC technology produces very low emissions per kilowatt of power and is therefore very attractive for the production of power. Likewise, coal liquefaction is not a new technology, but is only in limited commercial use in the United States. South Africa is the largest producer of synthetic liquid fuels from coal. Large-scale production of synthetic liquid fuels from coal began in 1910 in Germany with the Fischer-Tropsch process, which is used to produce a variety of fuels.

In fluidized-bed combustion, an in situ combustion-emission-control process, 90% to 95% of the SO_2 is captured during combustion by a sorbent (limestone). In this process, the NO_x production is low because of the low temperature at which the combustion reaction takes place. NO_x levels well fired below 0.25 lb/MBtu have been achieved with certain coals. Fluidized-bed combustion was developed in the 1950s and is now available for electric power plants of up to 300-MWe size. The technology has three distinct types of units: bubbling bed, hybrid velocity, and circulating fluidized bed (CFB). CFB technology is the most popular fluidized-bed process and has evolved as a low-emission technology with excellent fuel flexibility for the production of power. Bubbling and hybrid-velocity fluidized-bed technologies have demonstrated low emissions while burning low-rank coals, waste fuels such as petroleum coke, and renewable fuel such as wood and peat. Hybrid-velocity fluidized-bed combustion can be readily retrofit to many older boilers that need pollution-control technology. Pressurized fluidized-bed combustion is used to achieve low sulfur and NO_x emissions of fluidized-bed combustion integrated with a gas turbine to achieve high cycle efficiency, and therefore make more efficient use of coal.

Postcombustion control processes are widely used for the capture of sulfur and particulate. Lime-based scrubbers for SO_2 removal and equipment for particulate control were described in Sec. 5.1.9.

Processes and equipment for removal of NO_x from flue gases leaving boilers have been widely used in Europe and are being applied in the United States. In situ control of NO_x by modifications to firing technology and over-fire air can reduce NO_x as much as 50%. Selective noncatalytic control (SNCR) involves ammonia or urea sprayed in the proper place in the boiler to reduce NO_x. More NO_x reduction can be achieved by selective catalytic reduction (SCR), which uses ammonia in a postcombustion control system. SCR can reduce NO_x levels well below those from a conventional pulverized-coal boiler.

Coal gasification is an efficient way to produce electric power while minimizing the emissions from the combustion of coal. Coal gasification can achieve cycle efficiencies above 40% when the gas turbine cycle is completely integrated with the steam cycle. This is referred to as the *integrated gasification combined cycle* (IGCC) (Fig. 5-6). In an IGCC plant, the gas from the gasification process is burned in a boiler or gas turbine for the generation of electric power. The process also uses the heat from the gas turbine exhaust to produce electric power from a steam cycle.

In the gasification process, coal is partially reacted with a deficiency of air to produce low-heating-value fuel gas. The gas is cleaned of particulate and then sulfur compounds in a hot-gas cleanup system. Elemental sulfur is disposed of or sold.

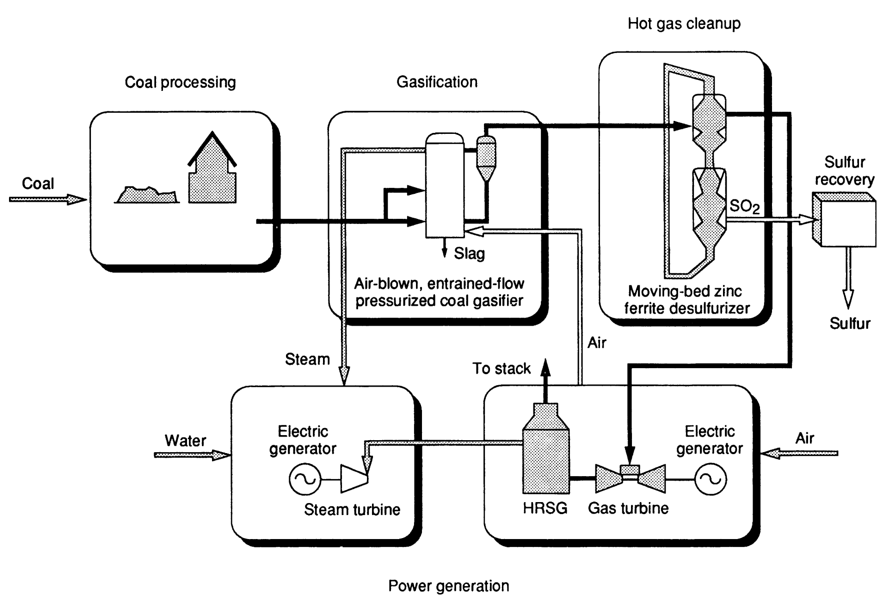

FIGURE 5-6 Integrated combined-cycle power plant.

5.1.11 Fluidized-Bed Combustion

For decades, fluidized-bed reactors have been used in noncombustion reactions in which the thorough mixing and intimate contact of the reactants in a fluidized bed result in high product yield with improved economy of time and energy. Although conventional methods of burning coal can also generate energy with very high efficiency, fluidized-bed combustion can burn coal efficiently at a temperature low enough to avoid many of the problems of conventional combustion.

The outstanding advantage of fluidized-bed combustion (FBC) is its ability to burn high-sulfur coal in an environmentally acceptable manner without the use of flue-gas scrubbers. A secondary benefit is the formation of lower levels of nitrogen oxides compared to other combustion methods.

5.1.12 Circulating Fluidized-Bed Steam Generators

Figure 5-7 shows a typical CFB steam generator. Crushed fuel and sorbent are fed mechanically or pneumatically to the lower portion of the combustor. Primary air is supplied to the bottom of the combustor through an air distributor, with secondary air fed through one or more elevations of air ports in the lower combustor. Combustion takes place throughout the combustor, which is filled with bed material. Flue gas and entrained solids leave the combustor and enter one or more cyclones where the solids are separated and fall to a seal pot. From the seal pot, the solids are recycled to the combustor. Optionally, some solids may be diverted through a plug valve to an external fluidized-bed heat exchanger (FBHE) and back to the combustor. In the FBHE, tube bundles absorb heat from the fluidized solids.

Bed temperature in the combustor is essentially uniform and is maintained at an optimum level for sulfur capture and combustion efficiency by heat absorption in the walls of the combustor and in the FBHE (if used). Flue gas leaving the cyclones passes to a convection pass, air heater, baghouse, and induced-draft (ID) fan. Solids inventory in the combustor is controlled by draining hot solids through an ash cooler.

5.2 NUCLEAR POWER PLANTS

By GEORGE H. MILEY

5.2.1 Nuclear Energy

Introduction. The United states is the world's largest supplier of commercial nuclear power. In 2005, there were 104 U.S. commercial nuclear generating units that were fully licensed to operate. One reactor, however, Brown's Ferry unit 1 has been shut down since 1985. Therefore, some sources cite only 103 units. Together, they provide about 20% of the nation's electricity—second only to coal as a fuel source.

The Energy Information Administration (EIA) reports that the U.S. nuclear industry generated 788,556 million kilowatt hours of electricity in 2004 (Fig. 5-8), a new U.S. (and international) record. Although no new U.S. nuclear power plants have come on line since 1996, this is the industry's fifth annual record since 1998.

General. Applying the nuclear process for electrical production involves consideration of characteristics substantially different from those associated with the use of fossil fuels. With fossil fuels or with hydro, the amount of energy source (fuel) supplied to the power plant is proportional to the power demanded at that time. With nuclear power, however, the fuel for a substantial amount of energy output is physically located in the converter at any time. A second important characteristic of the nuclear process is the energy density. The thermal energy density in a typical fossil boiler (heated volume or core volume) is in the range of 0.20 kW/L; in a typical nuclear power generator it is in

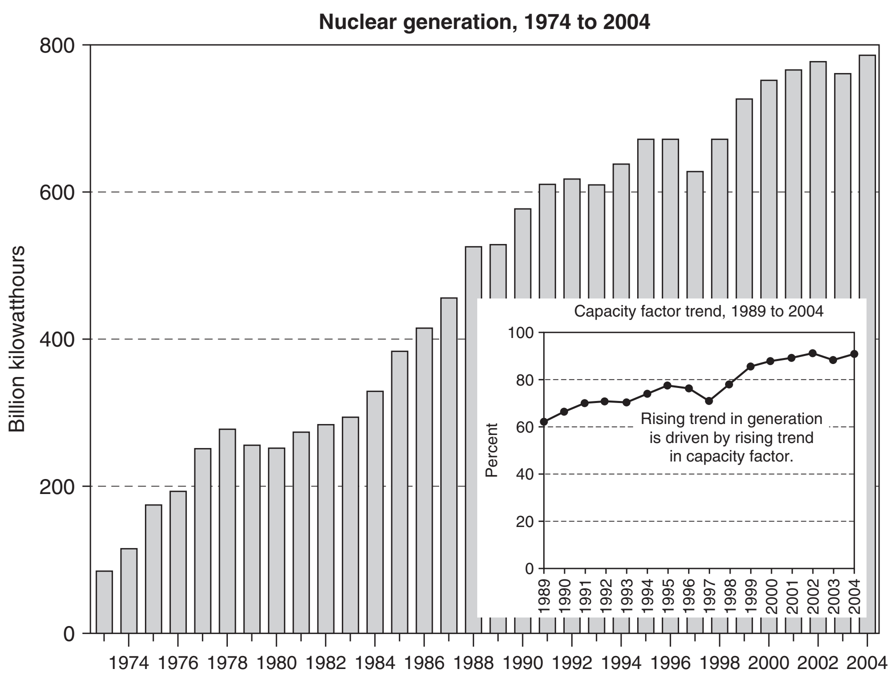

FIGURE 5-8 U.S. nuclear power generation. (***Source:*** Energy Information Administration, *Monthly Energy Review.*)

the range of 80 kW/L. A third important difference is that of continued low-level heat generation (decay heat) when the nuclear process is shut down following power operation. A fourth important difference is that of emanations. The fossil process requires the intake of large volumes of air and fuel and the corresponding exhaust of large volumes of waste gas, including CO_2, SO_3, NO_2, etc., some particulate matter, and in the case of coal-fired boilers, substantial quantities of ash. The nuclear process, however, requires only the input of the material placed in the core; its output is fuel-element materials plus radioactive "waste" products from the fission process. This residue includes small quantities of gases which may be released or may be stored and solids which are contained within the fuel.

These and other more subtle aspects introduce many new considerations in the equipping and regulation of the nuclear process.

5.2.2 Mass-Energy Relationships

One of the first applications of the special theory of relativity proposed by Einstein in 1905 was the interrelation between mass and energy, expressed by the equation $E = mc^2$. Thus, a change in nuclear mass appears as energy. If the mass m is expressed in kilograms and the velocity of light c in meters per second, the energy E is in joules.

$$\begin{aligned} E(\text{J}) &= \text{mass(kg)} \times (2.998 \times 10^8 \text{ m/s})^2 \\ &= \text{mass(kg)} \times 8.99 \times 10^{16} \text{ m}^2\text{s}^2 \end{aligned} \tag{5-1}$$

The amounts of energy involved in single nuclear events are usually very small. Thus, for convenience, the electronvolt (the energy acquired by any charged particle carrying a unit electronic charge falling through a potential of 1 V) is often used. One electronvolt (eV) $= 1.602 \times 10^{-19}$ J and, correspondingly, 1 keV $= 1.602 \times 10^{-16}$ J. One MeV $= 1.602 \times 10^{-13}$.

The mass-energy relationships become

$$\begin{aligned} E(\text{eV}) &= \text{mass(kg)} \times \frac{8.99 \times 10^{16} \text{ m}^2/\text{s}^2}{1.602 \times 10^{-19} \text{ J/eV}} \\ &= \text{mass(kg)} \times 5.61 \times 10^{35} \text{ eV/kg} \\ E(\text{keV}) &= \text{mass(kg)} \times 5.61 \times 10^{32} \text{ keV/kg} \\ E(\text{MeV}) &= \text{mass(kg)} \times 5.61 \times 10^{29} \text{ MeV/kg} \end{aligned}$$

where $1 \text{ J} = 1 \text{ m}^2 \cdot \text{kg/s}^2$.

It is often convenient to use the energy corresponding to 1 atomic mass unit (amu). One amu $= 1.657 \times 10^{-27}$ kg (1 amu $= {}^1/_{12}$ of the mass of a neutral atom of ^{12}C).

$$\begin{aligned} E_{\text{amu}} &= 1.66 \times 10^{-27} \text{ kg} \times 5.61 \times 10^{29} \text{ MeV/kg} \\ &= 931 \text{ MeV/amu} \end{aligned} \tag{5-2}$$

The atomic mass of a nuclide can be evaluated in terms of the masses of its constituent particles and the *binding energy* (Fig. 5-9). The mass of the nuclide is less than the sum of its constituent particles in the free state. If ΔM is the decrease in mass when a number of protons, neutrons, and electrons combine to form an atom, then the mass-energy equivalence principle states that an amount of energy equal to $\Delta E = c^2 \Delta M$ is released in the process. The difference in mass ΔM is called the *mass defect*; it is the amount of mass which would be converted to energy if a particular atom or nuclide were to be assembled from the requisite number of protons, neutrons, and electrons. The same amount of energy would be needed to break the atom into its constituent particles, and the energy equivalent of the mass defect is therefore a measure of the binding energy of the nuclei. The mass of

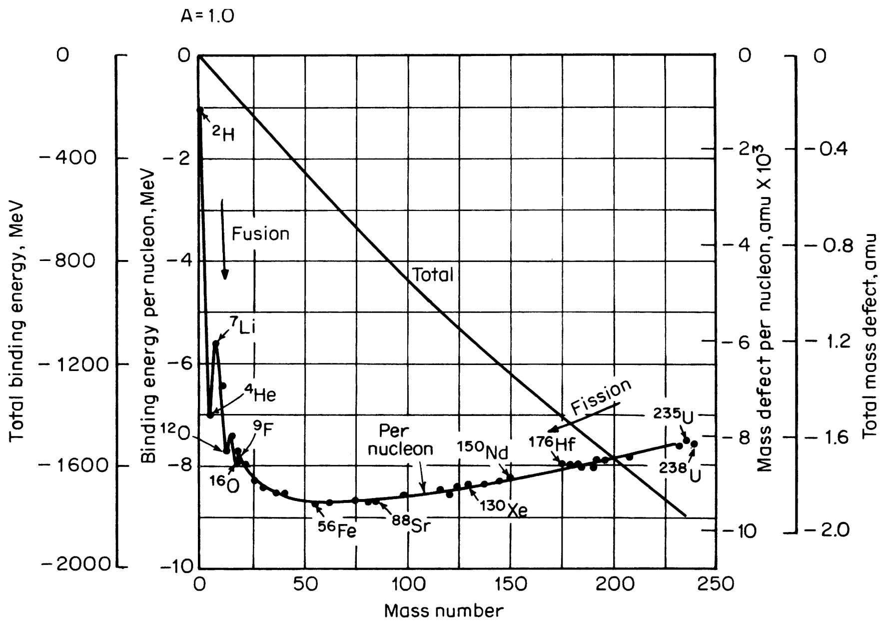

FIGURE 5-9 Mass defects and binding energies of nuclei.

the constituent particles is the sum of Z proton masses, Z electrons, and $A - Z$ neutrons, where A refers to the mass number of the element. Pairs of protons and electrons can be represented by hydrogen atoms; the loss in mass which accompanies the formation of the hydrogen atom from the proton and an electron is negligible. The mass defect can then be written $\Delta M = ZM_H + (A - Z)M_n - M_{ZA}$, where M_H is the mass of the hydrogen atom, 1.008142 amu; M_n is the mass of the neutron, 1.008982 amu; and M_{ZA} is the mass of nuclide of concern.

Figure 5-9 provides an approximate picture of the nuclear binding energy. In the higher mass numbers, the actual binding energy is not the same for each particle in the nucleus. After the maximum of the curve, almost every successive particle (proton or neutron) is bound less tightly than those already present, and the overall average decreases. The binding energy represented, however, is sufficiently accurate for engineering evaluations.

5.2.3 The Fission Process

In the higher mass numbers, several of the naturally occurring elements are radioactive or have a characteristic which enables them to emit nuclear particles and be transmuted to different elements as a function of time. The various naturally occurring series are designated the thorium, uranium, and actinium series. These designations are related to the elements at or near the head of the series and can be expressed as multiples of a number N, where N is an integer. The series are indicated by $4N$, $4N + 2$, and $4N + 3$, respectively. There is no naturally occurring $4N + 1$ element; such an element has been created in the process of artificial nuclear transmutation. This element is designated neptunium and has the mass characteristic of $4N + 1$. It, too, heads a radioactive series. The four radioactive series are shown in Fig. 5-10.

A number of elements with high mass numbers, both natural and artificially produced, undergo a process of nuclear fission. In the fission process, a nucleus absorbs a neutron and the resulting compound nucleus is so unstable that it immediately breaks up into parts. As shown by the arrow labeled "fission" in Fig. 5-9, the fission products have a lower mass and larger binding energy, resulting in

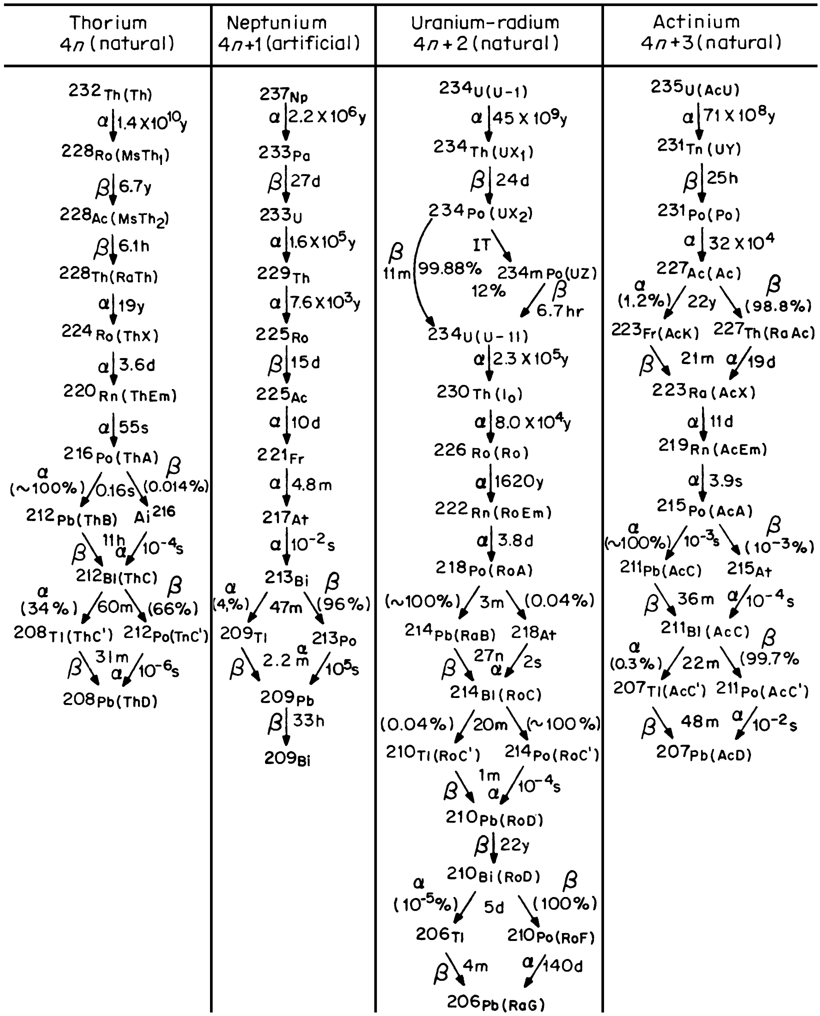

FIGURE 5-10 The four radioactive series.

a release of energy in the form of kinetic energy of the products. (Also note in Fig. 5-9 that the arrow for "fusion" shows lighter elements fusing together to create higher mass products, again with a release of energy by emission of high-speed products. Many of the heavy nuclides can be induced to fission, but most only with neutrons of high energy. Naturally occurring heavy nuclides that fission with neutrons of energy in the range of the neutrons produced by the fission are uranium isotopes ^{235}U and ^{238}U and thorium 232. In addition, artificially produced nuclides ^{233}U and ^{239}Pu, produced by (n, β) reactions in ^{232}Th and ^{238}U, respectively, are capable of fission. The fission process, in a nuclear reactor, is initiated by neutrons which are generated as part of the process. The general fission process may be expressed by

$$^{m}F + {}^{1}n \rightarrow {}^{x}A + {}^{m-(x+C)}B + C\,{}^{1}n \qquad (5\text{-}3)$$

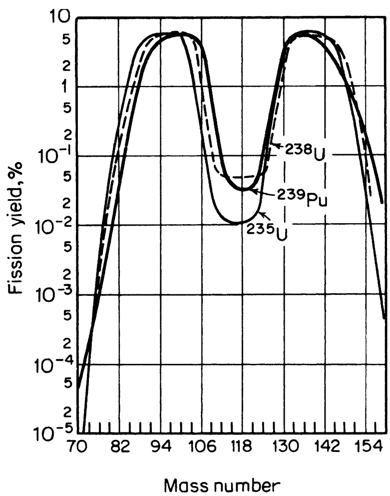

FIGURE 5-11 Fission yield.

where F = fuel nuclide, mass number m
n = neutron
A, B = fragment nuclides
C = number of neutrons produced
x = atomic number

The percentage of nuclide production as a function of mass number is shown in Fig. 5-11.

A typical example is the fission of ^{235}U with the production of two most likely fission fragments.

$$^{235}\text{U} + {}^{1}n \rightarrow {}^{95}A + {}^{139}B + 2\,{}^{1}n \qquad (5\text{-}4)$$

The mass balances of this equation are

Before fission		After fission	
^{235}U	– 235.124 amu	^{95}A	–94.945 amu
^{1}n	1.009 amu	^{139}B	138.955 amu
		$2\,{}^{1}n$	2.018 amu
236.133 amu			235.918 amu

TABLE 5-3 Distribution of Fission Energy

Energy	MeV
Kinetic energy of fission fragments	168 ± 5
Instantaneous gamma-ray energy	5 ± 1
Kinetic energy of fission neutrons	5 ± 0.5
Beta particles from fission products	7 ± 1
Gamma rays from fission products	6 ± 1
Neutrinos	~10
Total fission energy	201 ± 6

The mass change resulting from fission is 236.133 − 235.918 = 0.215 amu, which by the relationship of mass to energy is equivalent to E(J) = mass(amu) × 1.49 × 10^{-10} J/amu, which represents ~3.2 × 10^{-11} J/fission or approximately 200 MeV/fission (or 3.2 × 10^{-11} W · s/fission).

The major portion of this energy is released immediately as kinetic energy of the fission fragments, the fission neutrons, and instantaneous gamma rays. A portion of the energy is released gradually from the decay of the fission fragments. Table 5-3 shows the distribution of fission energy. For practical purposes, the neutrino energy, because of the low probability of interaction of neutrinos with matter, is not recoverable. (This leaves about 190 MeV, or 3.0 × 10^{-11} J, recoverable per fission.)

5.2.4 Neutron Interaction

Each neutron interacting with a nucleus does not always result in fission; some are scattered and some are involved in radiative capture, that is, initiate the radiation of other particles and/or photons to reduce the target atom to a stable state. The neutron-absorption probability for a given nuclide is referred to as its cross section and is expressed in units of area. Since very small areas are involved, the special unit for cross section is the barn, equal to 10^{-24} cm^2.

The cross section for a neutron interaction varies with energy. An explanation is that, quantum mechanically, the wavelength λ of the neutron is inversely proportional to its energy E or velocity, and may be expressed by

$$\lambda = \frac{2.86 \times 10^{-8}}{\sqrt{E(\text{ev})}} \quad \text{mm} \qquad (5\text{-}5)$$

For fast neutrons (about 1 MeV), λ is of the order of 10^{211} mm, and for thermal neutrons (about 0.03 MeV), λ is about 1.7 3 10^{27} mm. The slower neutrons behave as though they had a diameter approaching that of the atom, and thus have a larger probability of interaction.

5.2.5 Radiation

Nuclide Composition. The elements of the periodic table, both naturally occurring and artificial, are composed of protons (except for hydrogen), neutrons, and electrons. Many of the elements have two or more isotopic forms, states which have the same atomic number but a different atomic mass because of a different number of neutrons in the nucleus.

Most of the naturally occurring elements are stable, that is, do not eject particles to change to a different isotope or a different element. However, some naturally occurring elements, as indicated in Fig. 5-10, are conditionally stable and have a probability for transmutation. Out of the total number of atoms present, the probability indicates that a certain number of the atoms will, by ejecting a particle, change to an isotope or a new element. The mode of decay for a given isotope is predictable. The pattern is sometimes complex and follows a decay chain.

Radioactive Transmutation. For every radioactive material, there are characteristic quantities that may be used to describe the process. Each radioactive nuclide has a definite probability of decaying in unit time. This decay probability has a constant value, characteristic of the particular radioisotope. In a given sample, the rate of decay at any instant is proportional to the number of radioactive atoms present at that time. If N is the number of radioactive atoms present at time t and λ is the decay constant, the decay rate is given by $dn/dt = -\lambda N$ for a simple decay scheme. Integrating this over the interval N_0 to N gives

$$N = N_0 e^{-\lambda t} \tag{5-6}$$

where N = number of atoms remaining unchanged at any time t
N_0 = initial number of atoms
λ = disintegration constant

The reciprocal of the decay constant 1/λ is the mean or average life of the radioactive species = t_m. A more widely used quantity for quantifying radioactive decay is the half-life, that period of time during which half the atoms originally present are transmuted. If N is set equal to $\frac{1}{2}N_0$ and the above equation is solved for t, the value becomes

$$t_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.6931}{\lambda} \tag{5-7}$$

In a radioactive species, a nuclide may undergo successive decay before reaching the ground state. For a compound decay scheme involving two states A and B, the net rate of change of B with time is given by

$$\frac{dN_b}{dt} = \lambda_A N_A - \lambda_B N_B \tag{5-8}$$

where the solution is $N = [\lambda_A N_{A0}/(\lambda_B - \lambda_A)]\,(e^{-\lambda_A t} - e^{-\lambda_B t})$. The first term on the right represents the production of B from the decay of A; the second term is the decay of B. N_{A0} is the number of parent atoms at time $t = 0$. Sample decay curves in Fig. 5-12 show both a simple decay and a compound two-stage decay.

If the radiation occurs by the emission of a quantity of energy (photon), the nuclide retains its atomic weight and number. If the decay occurs by emission of a particle, the nuclide changes to an isotope (same atomic number), an isobar (same mass number), or a different element.

Artificial elements, including those resulting from the fission process, are very likely to be radioactive. In some cases, this activity results in the emission of a photon of energy to allow the atom to reach a lower energy state. In other cases, a particle is emitted; the particle emitted for some decaying nuclides is a neutron. These delayed neutrons are important to the regulation of the fission process.

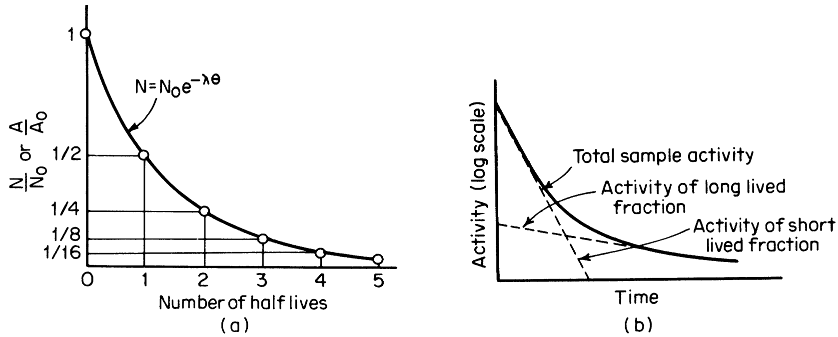

FIGURE 5-12 (*a*) Radioactive decay of a single radionuclide as a function of half-life; (*b*) decay of mixture of independent radionuclides.

Types of Radiation. There are three categories of radiation emanations of biological concern in nuclear power. The first category is that of charged particles, principally alpha particles and beta particles. The second is that of uncharged particles, chiefly neutrons. The third is that of photons or gamma rays. The charged particles directly produce ionization by collision with neutral atoms. Neutrons and photons indirectly produce ionization by liberating directly ionizing particles or by initiating nuclear transformations.

In radioactivity, a conventional unit is the curie, that quantity of any radioactive material giving 3.7×10^{10} disintegrations/s. For small quantities of radiation, the millicurie and the microcurie, 3.7×10^{7} and 3.7×10^{4} disintegrations/s, respectively, are frequently used. The rutherford (rd), equal to 10^{6} disintegrations/s, is sometimes used. The SI unit of radioactivity is the becquerel [1 curie (Ci) = 3.7×10^{10} becquerel (Bq)].

The radioactivity, the decay constant, and the weight are related by

$$\frac{dN}{dt} = \lambda N = \frac{\lambda W_A}{G_w} \tag{5-9}$$

where λ = decay constant, disintegrations/s
W = weight of the material, g
A = Avogadro's number = 6.02×10^{23} atoms/mol
G_w = gram atomic weight of the material, g/mol
N = number of atoms

This equation shows that a given amount of radioactivity may occur from a large mass with a small decay rate or a small mass which has a high decay rate.

Radiation dosage is expressed in four ways:

1. *Absorbed dose* (D), which is the energy absorbed per unit mass at a specific place in a material. The standard of absorbed dose is the gray; 1 Gy = 1 J/kg. The special unit of absorbed dose is the rad = 0.01 J/kg = 0.01 Gy. A subset is the absorbed-dose index, which is the maximum absorbed dose, at a point, within a 300-mm-diameter sphere centered at the point and consisting of material equivalent to soft tissue with a density of 1 g/cm^3.
2. *Dose equivalent* (H). In general, the biological equivalent of a given absorbed dose depends on the type of radiation and the irradiation conditions. The product of modifying factors, assigned to weigh the effect on a given organ, and the absorbed dose is the dose equivalent. The special unit of H is the rem (where D is in rads, H is in rems). A subset of this is the dose-equivalent index, which is the maximum dose equivalent, at a point, within a 300-mm-diameter sphere centered at the point and consisting of material equivalent to soft tissue with a density of 1 g/cm^3.

3. *Kerma* (K), which is the sum of the initial kinetic energies of the charged particles produced by indirectly ionizing radiation per unit mass of the material in which the interaction takes place. The units of K are grays or rads.
4. *Exposure* (X) is the measure of a particular field of electromagnetic radiation (x- or gamma rays) to ionize air. The special unit of exposure is the roentgen (R) $= 2.58 \times 10^{-4}$ coulombs (C)/kg of air.

5.2.6 Nuclear Plant Safety

The nuclear-powered steam supply system characteristics of substantial energy potential present in the reactor, radiation production during the fission process, and continued radiation production and heat generation after shutdown require that special safety precautions be taken in design and operation of a nuclear plant. The health and welfare of the public depends on both the continuation of the plant's power production and the avoidance of any incident which would endanger the environment. In order to achieve the latter goal and to aid the former, special regulations relating to nuclear plants have been formulated.

Workers in power plants are covered by federal regulations, with special attention being devoted to radiation protection. A guiding principle applied throughout the industry is known as ALARA. This directs management and workers to seek *as low an exposure as is reasonably achievable*. Application of ALARA requires careful planning and a balance between minimizing exposure versus work requirements.

5.2.7 Federal Regulations

Title 10 of the Code of Federal Regulations (10 CFR) has the following parts which are of primary importance to nuclear power facilities:

Part 20, Standards for Protection against Radiation

Part 50, Licensing of Production and Utilization Facilities

Part 55, Operators' Licenses

Part 70, Special Nuclear Material

Part 100, Reactor Site Criteria

There are several other parts of 10 CFR which relate to the usage or handling of radioactive material. Most of the parts previously listed have appendixes which treat requirements for specific subjects. Authority for regulation of commercial, nuclear-powered plants is vested with the U.S. Nuclear Regulatory Commission. This authority includes the licensing of new facilities and the surveillance of operating facilities. An applicant for a nuclear-powered plant is required to apply for a license to construct and operate the facility. Such application includes the submission of Safety Analysis Reports which describe the design bases, the design, and the analyses performed to show that plant performance and conditions will be within established limits.

5.2.8 Standards

Appendix A of 10 CFR Part 50 provides general design criteria for nuclear power plants. Criterion 1 requires that structures, systems, and components important to safety be designed, fabricated, erected, and tested to quality standards. The nuclear standards program of the American National Standards Institute has developed a sizable group of standards for this requirement. The principal design, systems, and operation standards are those developed by ASME, IEEE, ANS, and ISA.

Many other documents providing criteria, standard practices, or guidance are available. In the nuclear area, specific designs have not been repeated frequently enough to accumulate a significant backlog of experience. As a result, many of the "standards" are developed to provide leadership in addressing given areas.

The Nuclear Regulatory Commission provides guidance in many areas of design, construction, and operation through Regulatory Guides. Individual guides may cite a standard as an acceptable method of addressing the area concerned.

5.2.9 Quality Assurance

The best defense against incidents which endanger the public is to prevent them. In a similar way, the best system performance is effected when malfunctions are eliminated. Reliability is the interface between quality assurance and safety. Reliability can neither be tested nor legislated into equipment; it must be built in. High quality in design, procurement, installation, and operation will lead to a system that has high availability, good reliability, and a low probability of incurring an accident. Quality assurance is a total systems approach to achieving these aims. Quality assurance does represent an increase in costs; this increase must be balanced against safer operation and savings resulting from less time lost, fewer repairs, and better control. The prime responsibility for an effective quality assurance program lies with the owner/operator of the plant, who may delegate portions of the program to major suppliers.

5.2.10 Nuclear Energy System

Reactor-System Assembly. To achieve a self-sustaining, but regulated fission process, and for the energy released to be extracted and converted to electricity, a reactor system is constructed.

The nuclear fuel, usually uranium, is fabricated into fuel elements. The typical design for the fuel of a light-water power reactor involves the fuel in oxide form. Where the fuel is uranium, the uranium dioxide is fabricated into pellets, right circular cylinders approximately 19 mm high and 8 mm in diameter.

In light-water reactors, the uranium dioxide material is typically enriched to a low value, approximately 3% to 7%, in the fissionable isotope ^{235}U. This enrichment is necessary because light water has an appreciable neutron-absorption cross section. The extra neutrons available from the added fissile material compensate for the absorption in the moderator. The fuel-pellet material is usually of a ceramic nature (e.g., UO_2); the pellets are dished at both ends to allow for differential thermal expansion and fuel volumetric growth with burnup.

The pellets are inserted into fuel tubes, typically thin-walled tubes of stainless steel or Zircalloy. An open space (with the column of pellets spring-loaded) at the top of the tube is provided to accommodate generation of gases during the fission process. The tubes are sealed top and bottom and are assembled into a configuration involving fixed spacing in a fuel assembly. A representative fuel assembly is shown in Fig. 5-13. This assembly has an overall length of approximately 4.5 m with an active length of approximately 3.8 m.

Plutonium, ^{239}Pu, is produced in the fuel elements during power operation by the absorption of neutrons in the ^{238}U. This material is fissionable and may be recovered during fuel reprocessing and fabricated into new fuel elements. However, to date, regulations in the United States have prevented fuel reprocessing, largely due to concerns about proliferation of materials for use in weapons. Consequently, spent fuel from U.S. plants is currently being stored, awaiting future decisions about reprocessing. In contrast, reprocessing plants have been constructed in Europe.

In gas-cooled reactors in the United States, the fuel-element design differs from that of light-water reactors. The recent gas-cooled reactor elements are hexagonal graphite blocks into which blind longitudinal holes are drilled to receive rods of fuel particles. The fissile material is enriched uranium carbide, UC_2. Kernels of this material are coated with a pyrolytic carbon–silicon carbide–pyrolytic carbon sandwich. Fertile material in the form of thorium oxide, ThO_2, kernels is also used. A fertile material is one which, by absorption of neutrons, is changed to a material which can be fissioned. In this case, ^{232}Th is converted to ^{233}U, which has superior characteristics for fission reactions. The kernels are coated with two layers of pyrolitic carbon. The two types of fuel particles are mixed in the proper proportions and are formed with a carbon matrix into fuel “rods” about 15.6 mm in diameter and about 60 mm long. These rods are inserted into the holes in the graphite blocks. Through holes are provided in the block for the helium coolant flow. These loaded graphite blocks or “fuel assemblies” form the basic module for the core of the gas reactor.

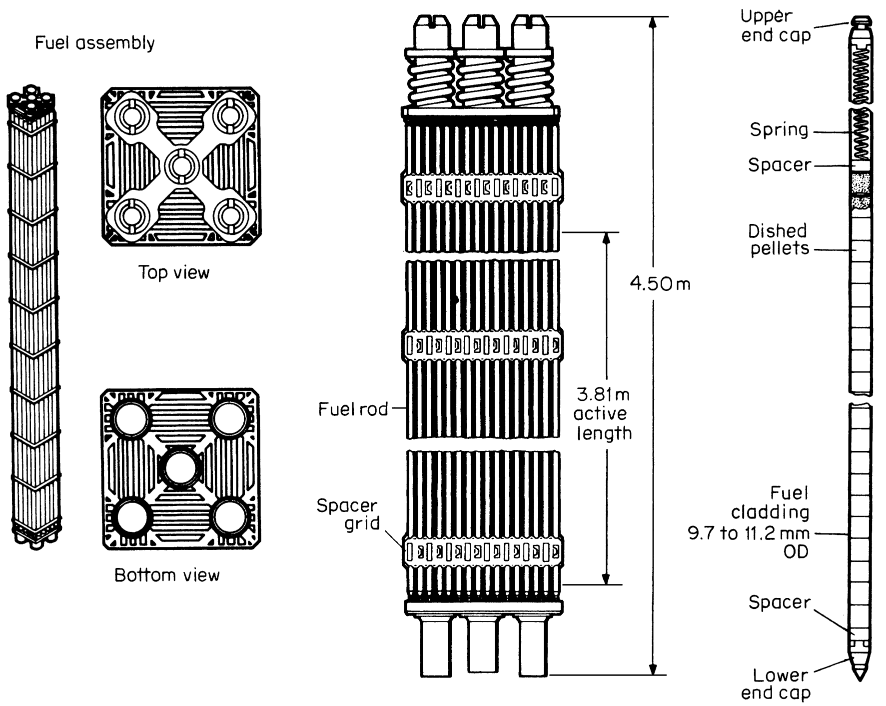

FIGURE 5-13 PWR fuel assembly.

The required number of fuel assemblies to produce a power output desired for the reactor plant are assembled into a reactor-core configuration approximating a right circular cylinder. This configuration provides a high volume-to-surface ratio which minimizes the neutron leakage and conserves the neutrons produced for further fission action. For a 1300-MW (electrical) light-water nuclear plant, a representative core assembly might involve 241 fuel assemblies each weighing approximately 660 kg, for a core equivalent diameter of 3.6 m, a core height of approximately 5 m, and a total core weight of approximately 160 metric tons.

Control-Element Assemblies. In each fuel assembly, several holes are shown. These open holes are spaces into which control elements are inserted for regulation of the fission process. The individual control elements may be grouped typically into control-element assemblies. Control elements for current Pressurized Water Reactors (PWRs) (Fig. 5-22) are located in the fuel elements in this fashion. Control elements of Boiling Water Reactors (BWRs) are blade-type cruciform units. These units are inserted into or withdrawn from the spaces between the fuel assemblies. The control-element assemblies are selected from a material which absorbs neutrons; therefore, by insertion into the fuel assembly or withdrawal from the fuel assembly, the amount of neutrons available for fission production can be reduced or increased, respectively, as required for reactor-system performance. These control-element assemblies are inserted or withdrawn by electromechanical or hydraulic drive mechanisms.

Moderator and Heat-Transfer Medium. The thermal energy released from the core must be conveyed to the electric generator at a rate and in a fashion which meets the requirements. Some consideration has been given to the use of a reactor core to heat gas which is supplied to a magnetohydrodynamic generator. However, commercial systems for the present and near future will continue to use steam turbines as the motive power for the generator.

If fuel of low enrichment (e.g., 3% to 4%) in ^{235}U or other fissile isotope is used, a moderator is needed to take advantage of the larger cross section at thermal neutron energy. If enrichments greater than 20% are used, sufficient fissile material is present to overcome the nonfission capture effects of ^{238}U, and a moderator is not needed. In this case, the reactor is said to be "fast" (referring to the neutron velocity), and liquid metals (selected for low neutron absorption) are used as a coolant.

5.2.11 Plant Arrangement

Primary-System Configuration. The fuel elements, assembled into the core arrangement, are positioned within a reactor vessel by support structures also referred to as reactor internals. The reactor vessel also contains, guides, and directs the primary coolant. Elementary configurations are shown in Fig. 5-14.

In the BWRs, the reactor vessel also contains the steam-separation apparatus, since the coolant is converted to steam in the core. Steam is piped from the reactor vessel to the turbine and condensate

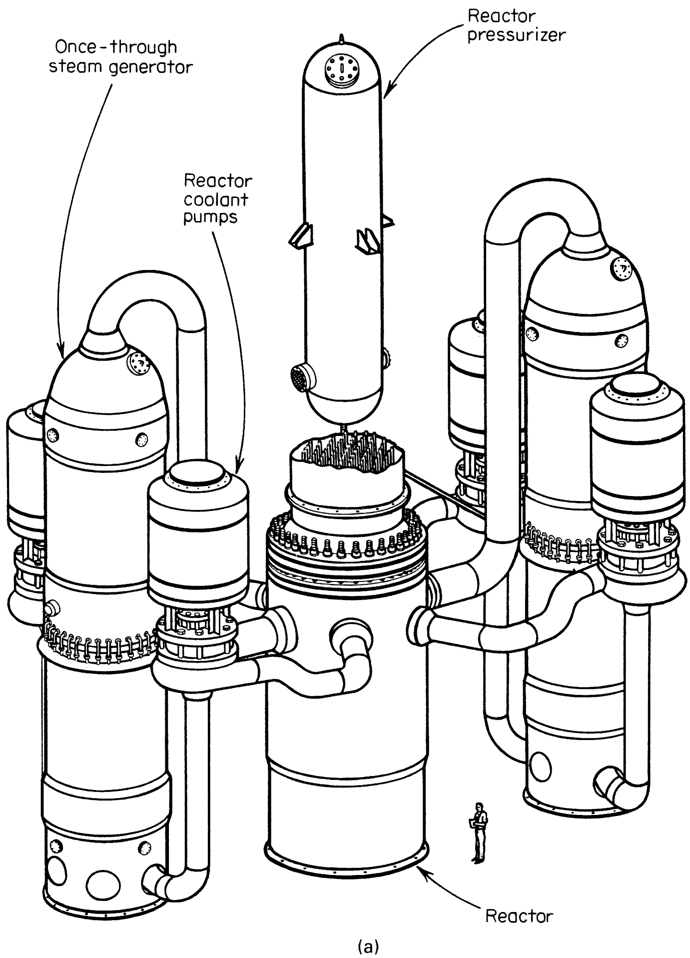

FIGURE 5-14 (*a*) PWR arrangement with once-through steam generators; (*b*) BWR arrangement. (*General Electric Co.*)

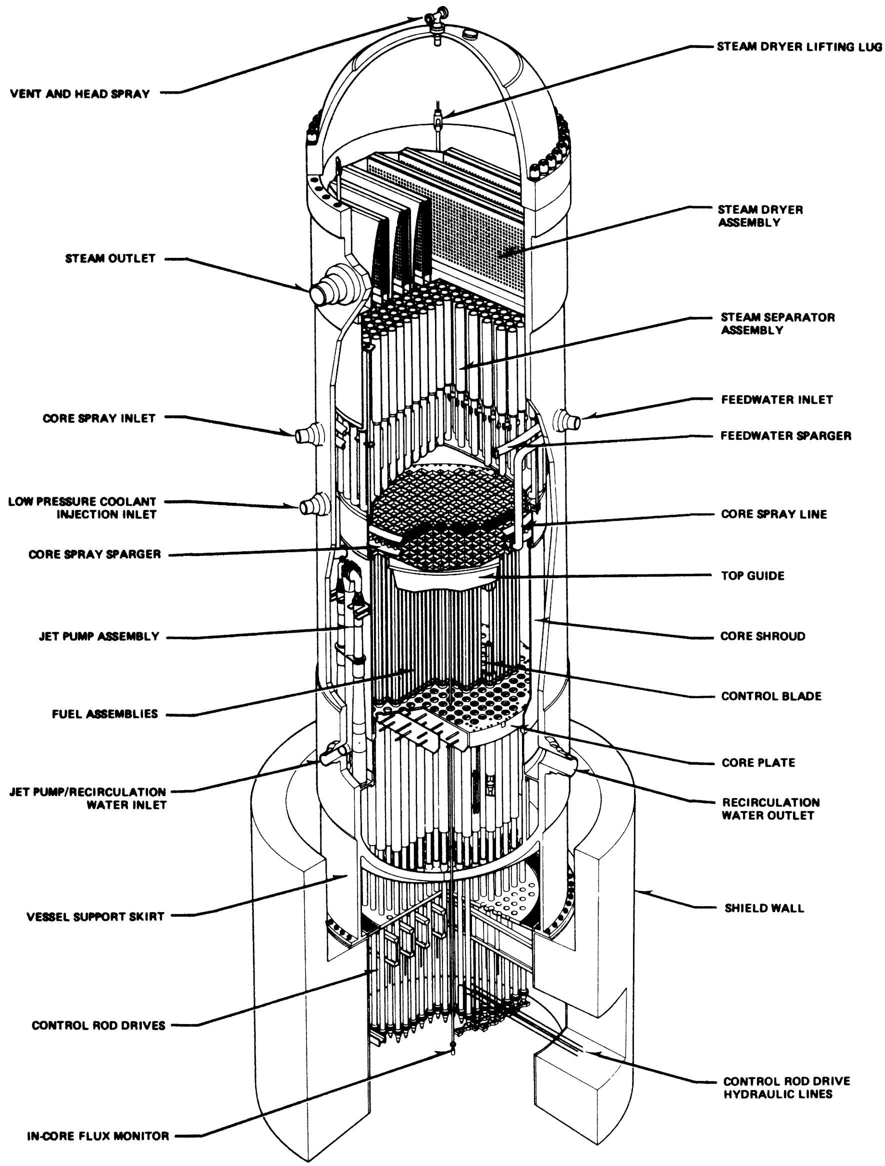

(b)

FIGURE 5-14 (*Continued*)

is returned from the hotwell through feedwater systems to the reactor vessel. Recirculation loops on the reactor vessel increase the recirculation ratio to effect better steam separation and provide better control of void fraction within the core (reactivity control). Access to the core for control rods and for in-core instrumentation is provided from the bottom of the reactor vessel to avoid the steam-separation area at the top.

In PWRs, the primary system is maintained at a subcooled condition by operating at a pressure greater than saturation. Conventionally this pressure is in the range of 12 to 16 MPa. This pressure is maintained by a pressurizer connected to the primary piping. A steam-water interface is maintained in the pressurizer by the action of electric resistance heaters which boil water to raise the pressure or spray flow to quench steam and lower the pressure. The reactor vessel is connected, by heavy piping, to one or more steam generators, and coolant is circulated through this primary system by large pumps. On the secondary side of the steam generator are located the customary steam piping complex, the turbine condenser, and feedwater system.

In liquid-metal reactors, the concerns associated with coolant metal–water reaction in the event of leakage and the induced activity in the primary metal sometimes direct the design to an intermediate heat-exchange system between the primary-metal coolant and the steam system.

Containment Structure. To provide a secondary barrier for radioactivity in the fluid systems and a fourth barrier for the activity in the fuel (the fuel matrix or ceramic, the fuel sheath, and the primary-system boundary are the other three), the primary-system components are located within a containment structure. This structure is designed to confine gases and materials that might occur in the event of an inadvertent release from the primary barrier(s).

The principal types of containments that have been used are

1. The steel sphere made of sections of steel sheet welded together
2. The "inverted lightbulb" of the BWR, which is a concrete cavity in the shape described with a pressure-retaining steel liner
3. The domed cylinder for the PWR; the cylinder of reinforced concrete with an impervious internal steel membrane
4. The cylindrical prestressed-concrete reactor vessel (PCRV) for the GCRs

These structures serve to provide isolation and shielding for the primary-system components. Instrumentation, control, and electric power conductors must pass through the pressure seal while maintaining its integrity. To provide this capability, banks of containment penetrations are provided. The requirements for these items are described by IEEE 317, *Electric Penetration Assemblies in Containment Structures for Nuclear Power Generating Stations.*

5.2.12 Plant Operations

Nuclear Plant Costs. A large amount of equipment and capital investment is required for a nuclear plant. A nuclear steam-supply system (NSSS) is arranged and equipped to initiate, sustain, and regulate the fission process in the reactor fuel, transfer heat from the fuel to the steam generators, and produce steam to supply a turbine. Auxiliary fluid systems to provide chemical cleaning and conditioning of the primary-system fluid, control of chemical shim (if used), supply and purification of secondary water (if required), and processing of radioactive effluents (liquid and gas) are associated with the NSSS. Equipment for instrumentation, control, protection, and electric power distribution is included. Typical equipment supplied in a nuclear steam-supply package is shown in Table 5-4.

This large investment in equipment encourages the development of nuclear plants of large capacity to reduce the per megawatt cost. Plants in the current generation have been from 500 to 1300 MW in electrical capacity. Depending on the size of the system, a single nuclear plant can represent 10% to 20% or more of the system operating capacity. This large size, the high capital investment, plus a low fuel cost of the nuclear plant direct the base loading of the nuclear plant.

Performance Evaluation. Evaluating the nuclear steam-supply system for performance as a source of steam energy often requires that the system be modeled, that is, the system equations be developed. The principal components whose characteristics are important for transient analysis are the reactor fission process and thermal process and the primary coolant piping and the steam generator(s) in a PWR along with the associated control and protection systems.

The functions of these components, in combination, are (1) the reactor core through the fission process converts potential energy in the uranium atoms to thermal energy in the fuel elements; (2) in a

PWR, GCR, LMFBR, the primary coolant piping conveys the thermal energy to the steam generator(s) and the steam generator(s) transfer the energy from the primary fluid to the secondary fluid. Since the secondary fluid is maintained at a lower pressure, boiling is introduced and steam is generated; (3) in a BWR, the directly produced steam is separated; (4) the PWR pressurizer maintains pressure on the primary coolant to assure that the primary thermal process takes place in a subcooled condition; and (5) the BWR recirculation system maintains a circulation of primary fluid sufficient to ensure adequate steam separation and to regulate the void fraction in the core (reactivity control).

Neutron Multiplication. The description of performance of the reactor begins with the neutron kinetics, the time behavior of the fission neutrons. A generation of neutrons begins with a neutron flux density from the previous generation (or from the source). A fuel nuclide absorbs a neutron and probably undergoes fission. A small percentage of absorbed neutrons do not cause fission; so the number of neutrons released per capture of a neutron is given by

$$\eta = \nu \frac{\Sigma_f}{\Sigma_u} \tag{5-10}$$

where η = number of neutrons released per capture
ν = number of neutrons released per fission
Σ_f = cross section of the fuel for fission
Σ_u = absorption cross section (fission and nonfission) in the fuel

In a reactor assembly where the fissions are initiated principally by thermal neutrons, some fissioning will be introduced by the fast neutrons before they have been thermalized. The ratio of the total number of fast neutrons produced by neutrons of all energies to the number produced by thermal neutrons is given by ϵ.

During the slowing-down (thermalizing) process, some neutrons are captured in nonfission processes; the fraction escaping such capture is ρ. When the neutrons have been thermalized, they will diffuse in the core region until absorbed in the fuel or in some other material, structure, moderator, poison, etc. The fraction absorbed in the fuel is given by

$$f = \frac{\text{thermal neutrons absorbed in fuel}}{\text{total thermal neutrons absorbed}}$$

If n neutrons are present in one generation (in an infinite system), the multiplication factor, k_{inf}, or the ratio of the neutrons in one generation to those in the next generation, is given by

$$k_{inf} = \frac{n\eta\,\epsilon p f}{n} = \eta\,\epsilon p f$$

This is also known as the four-factor formula.

In a reactor system of finite dimensions, there is also leakage out of the system, so that the infinite multiplication factor must be adjusted to provide for leakage. Considering the diffusion process and the boundary conditions, it is evident that for a reactor of finite physical dimensions, there will be some leakage (loss) of neutrons from the boundary. In describing the process of slowing down the neutrons, two quantities are developed. The first of these is the diffusion length L, which is equal to one-sixth of the net vector distance that a monoenergetic neutron travels from its source to the point where it is absorbed by a nucleus. A second quantity is the buckling B, which represents the "bending" or appreciable reduction of the value of neutron flux at any point in the reactor.

These quantities may be used to develop two factors which take into account the finite size of the reactor and the leakage which occurs. For the first factor, the term $e^{-B^2L_s}$ represents the nonleakage probability of the neutrons as they slow down, where L_s is a slowing-down length. The algebraic loss, by diffusion, of thermal neutrons in a volume element is $-D\nabla^2\phi = DB^2\phi$. The ratio of thermal leakage to thermal absorption is

$$\frac{\text{Thermal leakage}}{\text{Thermal absorption}} = \frac{DB^2\phi}{\Sigma_\alpha\phi} = L^2B^2 \quad \text{so } \frac{D}{\Sigma_\alpha} = L^2 \tag{5-11}$$

Adding the thermal absorption to the thermal leakage, effectively adding unity to both sides of the equation, and inverting, gives, for the second factor, the ratio

$$\frac{\text{Thermal absorption}}{\text{Thermal leakage} + \text{thermal absorption}} = \frac{1}{1 + L^2B^2}$$

which accounts for the nonleakage probability at thermal energy.

For a finite reactor then, the effective multiplication factor may be expressed by a combination of these two factors:

$$k_{eff} = k_{inf}\frac{e^{-B^2L_s}}{1 + L^2B^2} \tag{5-12}$$

When fission occurs, more than 99% of the resulting neutrons are produced within 10^{-3} s. The remaining neutrons are produced during the decay of the fission fragments. The time required for their production varies; they may be separated into groups for convenience. These delayed neutrons are essential to the regulation of the fission process.

Reactor Kinetics. For development of control equations, a single delayed group model (Fig. 5-15) may be used for approximation of the neutron production.

The production of neutrons for fission initiation including generation and thermalization is given by $K_{inf}\Sigma_\alpha\phi e^{-B^2L_s}$, where ϕ is the neutron population, Σ_α is the absorption cross section, and $e^{-B^2L_s}$ is the nonleakage probability during thermalization.

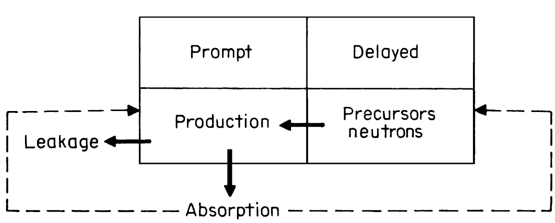

FIGURE 5-15 Single-neutron delayed group model.

The leakage of neutrons is $D\nabla^2\phi = -DB^2\phi$. Assuming β is the fraction of neutrons delayed, the neutron balance for the main group is

$$\dot{n} = (1 - \beta)k_{\text{inf}}\Sigma_\alpha \phi e^{-B^2L_s} + \lambda C - DB^2\phi - \Sigma_\alpha \phi \tag{5-13}$$

where λ = decay constant of the delayed neutron precursors
C = population of delayed neutron precursors
ϕ = neutron fluence rate (flux)

Since $\phi = n\nu$, the equation becomes

$$\dot{n} = n\left[(1 - \beta)k_{\text{inf}}\,\nu\Sigma_\alpha e^{-B^2L_s} - \nu DB^2 - \nu\Sigma_\alpha\right] + \lambda C$$

But

$$k_{\text{eff}} = \frac{k_{\text{inf}}\,e^{-B^2L_s}}{1 + L^2B^2}\frac{1}{\bar{l}} = \nu\Sigma_\alpha(1 + L^2B^2)$$

and $D = \Sigma_\alpha L^2$, where $\bar{l}$ is the average lifetime of the neutrons.

Substituting for k_{inf} and D gives

$$\dot{n} = n[(1 - \beta)k_{\text{eff}}\nu\Sigma_\alpha(1 + L^2B^2) - \nu\Sigma_\alpha(1 + L^2B^2)] + \lambda C$$

Substituting $1/\bar{l}$ for $\nu\Sigma_\alpha(1 + L^2B^2)$ gives

$$\dot{n} = n\left[(1 - \beta)\frac{k_{\text{eff}}}{\bar{l}}\frac{1}{\bar{l}}\right] + \lambda C$$

$$= n\frac{(1 - \beta)k_{\text{eff}} - 1}{\bar{l}} + \lambda C$$

The balance equation for the delayed group is

$$\dot{c} = n(\beta k_{\text{inf}}\,\nu\Sigma_\alpha e^{-B^2L_s}) - \lambda c \tag{5-14}$$

Substituting

$$\frac{k_{\text{inf}}\,e^{-B^2L_s}}{1 + L^2B^2} = k_{\text{eff}}$$

gives

$$\dot{c} = n[\beta k_{\text{eff}}\,\nu\Sigma_\alpha(1 + L^2B^2)] - \lambda c$$

and substituting $1/\bar{l} = \nu\Sigma_\alpha(1 + L^2B^2)$ gives

$$\dot{c} = n\frac{\beta k_{\text{eff}}}{\bar{l}} - \lambda c$$

Rearranging the equation for $\dot{n}$ gives

$$\dot{n} = n\frac{(k_{\text{eff}} - 1) - \beta k_{\text{eff}}}{\bar{l}} - \lambda\dot{C} = n\frac{k_{\text{eff}}(1 - \beta) - 1}{\bar{l}} - \lambda C$$

Since k_{eff} is very close to 1, $\beta k_{\text{eff}} \approx \lambda\beta$ and reactivity ρ is the ratio of the excess multiplication factor to the effective multiplication or

$$\rho = \frac{k_{\text{eff}} - 1}{k_{\text{eff}}} = \frac{k_{\text{ex}}}{k_{\text{eff}}} \quad \text{or} \quad \frac{\delta k}{k_{\text{eff}}}$$

Where the deviations from criticality are small, $k_{eff} \approx 1$ and

$$\rho \approx k_{ex} = k_{eff} - 1 = \delta k \qquad \text{so } \dot{n} = n[(\delta k - \beta)/\bar{l}] - \lambda C$$

The power level P is proportional to the neutron concentration. There are typically six delayed neutron groups. The balance equations then become

$$\dot{P} = \frac{P(\delta k - \beta)}{\bar{l}} + \sum_{j=1}^{\phi} \lambda_j C_j \tag{5-15}$$

$$\dot{C}_j = P\beta_j/\bar{l} - \lambda_{jC_j} \tag{5-16}$$

where j represents the delayed neutron group and β_j, λ_j, C_j are the fraction, decay constant, and concentration of delayed neutrons, respectively, of the jth group.

The balance equations show that, in the steady state, the effective multiplication factor is equal to 1. If the K_{eff} increases above 1, the multiplication will increase with time; if K_{eff} decreases below 1, the multiplication will decrease below 1. If $k_{eff}(1 - \beta) - 1$ increases to a value of 1 or greater, the reactor is said to be prompt critical and the rate of power increase depends on the ratio of $k_{eff}(1 - \beta) - 1$ to l. Since l is so small (about 10^{-4} s or less for a thermal reactor; 10^{-7} s or less for a fast reactor), P increases very rapidly with time for any appreciable value of $k_{eff}(1 - \beta) - 1$. Regulation of the process at these rates with conventional apparatus is very difficult. For this reason, k_{eff} in power reactors is kept below the value $1/(1 - \beta)$ when the reactor is operating.

Reactivity Control. The reactivity is affected by neutron absorption. The absorption occurs principally from control-element-type absorbers, dissolved-chemical control absorbers, resonance absorption in the fuel, absorption in the moderator, and absorption by fission products. The absorption initiated by the control elements and the chemical shim are varied by the operators and are characterized by δk_c.

The reactivity effect from the fuel is caused by the widening of the resonance peaks (Fig. 5-16) with temperature, which increases the nonfission capture of neutrons. With cores containing large amounts of ^{238}U and ^{232}Th, this Doppler effect is negative; that is, increasing the power level introduces a reactivity change which opposes the increase. The Doppler coefficient varies with coolant and fuel temperature and with moderator voids. Typical values of the Doppler coefficient are shown in Fig. 5-16. The curves may be approximated by the equation

$$\delta k_F = AT_F - BT_F^2 \tag{5-17}$$

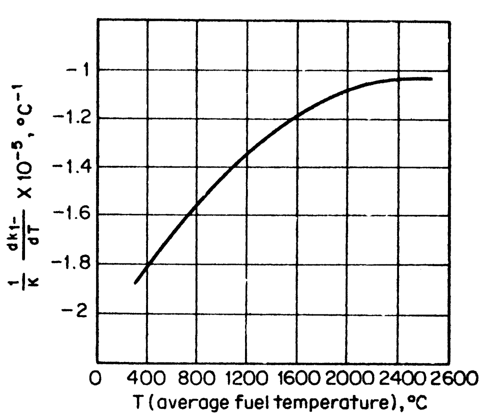

FIGURE 5-16 Values of the Doppler coefficient of reactivity. (*General Electric Co.*)

The reactivity effect of the moderator depends on the type of moderator and the type of reactor. In water-cooled and moderated reactors, the reactivity effects are initiated by changes in density which affect the slowing-down power and the absorption. Boiling-water reactors are operated at a relatively constant pressure and saturated conditions, which correspond to a relatively constant temperature. Density changes due to temperature are small. The steam production varies with power level so that density variation by voids is appreciable. In a pressurized-water reactor, the coolant in the core is subcooled and voids are suppressed. Coolant temperature may be varied with power, which would cause density changes as a function of temperature.

A reactivity change from the moderator based on the density change also occurs if there is dissolved neutron absorber (chemical shim) in the moderator. A density decrease causes less of the absorber to be present in a given volume and a decrease in neutron absorption with increasing temperature.

The reactivity effect of voids and of temperature change of the water, therefore, is to oppose a change in power while the reactivity effect, due to temperature change, of dissolved chemical shim is to aid a change in power. Since it is desirable (for safety reasons) to have a negative moderator temperature coefficient of reactivity, that is, a coefficient that with decreasing moderator density acts to retard the fission process, the amount of dissolved chemical shim is usually limited to that which will do no more than reduce the temperature coefficient of reactivity to zero.

Another reactivity effect is produced by the buildup of fission products. Some of these are neutron absorbers and will act as a retardant of the fission process by removing active neutrons. Two of the strongest absorbers are xenon, ^{135}Xe, and samarium, ^{149}Sm, whose absorption cross sections are 3×10^6 barns and 5×10^4 barns, respectively. ^{135}Xe is produced directly as a fission fragment (fission yield 0.3%), and in the decay chain of the fission fragment ^{135}Te (fission yield 5.6%) is

$$^{135}\text{Te} \xrightarrow[1\text{ min}]{} {^{135}\text{I}} \xrightarrow[6.7\text{ h}]{} {^{135}\text{Xe}} \xrightarrow[9.2\text{ h}]{} {^{135}\text{Cs}} \xrightarrow[2.1 \times 10^6\text{ yr}]{} {^{135}\text{Ba}}$$

On neutron absorption, ^{135}Xe is converted to ^{136}Xe, which is stable and has a low neutron cross section. ^{135}Xe, therefore, has two modes of production and two modes of elimination. This can be represented by the equation

$$\frac{dX}{dt} = (\lambda_x \Sigma_f - \sigma_x X)\phi + \lambda_x I - \lambda_x X$$
$$\frac{dI}{dt} = \gamma_I \Sigma_f \phi - \lambda_1 I \qquad (5\text{-}18)$$

where X = number of atoms of ^{135}Xe present per cubic centimeter (cm^3) at any time t
γ_x = fractional yield of xenon as a direct fission product
σ_x = microscopic thermal-neutron absorption cross section of ^{135}Xe
ϕ = thermal neutron flux
λ_1 = decay constant of ^{135}I
I = number of atoms of ^{135}I present per cm^3 at any time t
λ_x = decay constant of ^{135}Xe
Σ_f = macroscopic fission cross section of fuel in reactor
γ_1 = fractional yield of ^{135}I from direct fission process

The concentration reaches an equilibrium value during steady-state operation of the reactor but undergoes transients as the power changes. Of special concern to reactor regulation is the variation that occurs when the core is made subcritical following a power history. With the resulting large decrease in Xe removal by neutron absorption, the concentration of Xe increases because the difference in the ^{135}I decay and the ^{135}Xe decay allows a buildup. The peak concentration of ^{135}Xe is proportional to the preshutdown power level, as shown in Fig. 5-17. This absorbing effect must be overridden by control rods or elements if start-up is to occur.

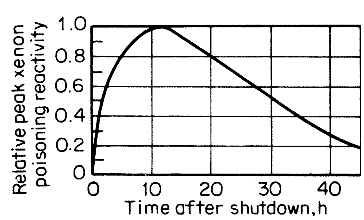

FIGURE 5-17 Relative peak xenon-poisoning reactivity.

Thermal Reaction. The heat from the core is generated in the fuel material as a result of the fissions initiated by the impinging neutrons. Although the center of a fuel element is subject to self-shielding, the fuel-element radial temperature distribution can be obtained by assuming a uniform volumetric heat source in a conduction problem. The gradient from the centerline of the fuel element through the gas gap and cladding to the coolant might be as shown in Fig. 5-18*a*. The power distributions (Fig. 5-18*b* and *c*) axially and radially in the core also vary, generally being highest in the center and decreasing toward the top and bottom and outside.

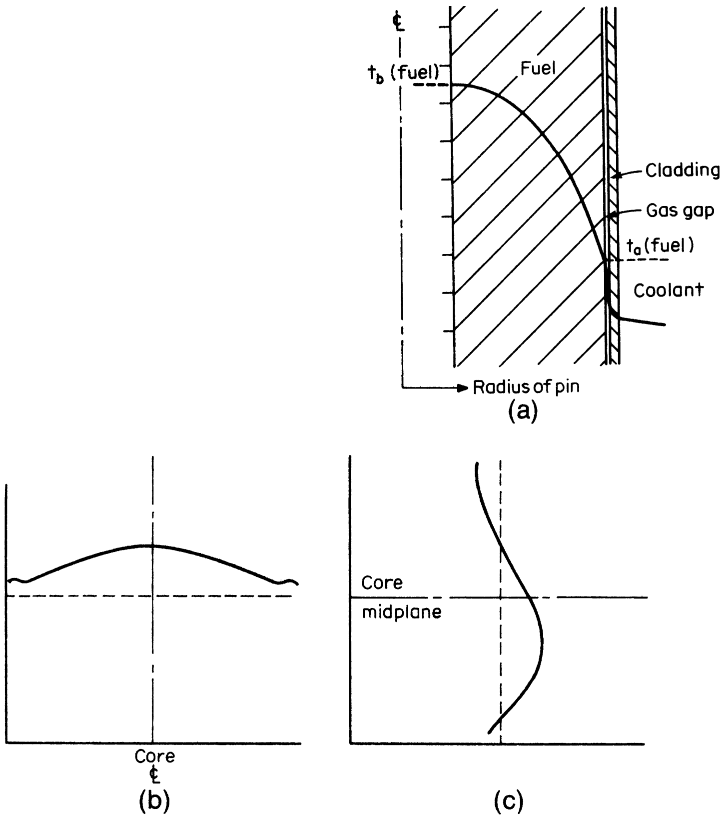

FIGURE 5-18 (*a*) Temperature distribution in fuel rod; (*b*) radial power profile; (*c*) axial power profile.

Control elements are adjusted to provide some degree of flattening. This makes a higher average power possible from the reactor for a given peak power.

For instrumentation and control purposes, the fuel may be considered to be mathematically represented by a series of time lags. These lags are important because the protection and control are strongly dependent on the time involved in transferring the heat out of the fuel. Since the elements are very long compared with their radius, conduction of heat in the axial direction can be neglected. In cylindrical coordinates, the Laplace equation for heat flow (neglecting the Z direction) is

$$\frac{\partial^2 T}{\partial \gamma^2} + \frac{1}{\gamma}\frac{\partial T}{\partial \gamma} + \frac{1}{\gamma^2}\frac{\partial^2 T}{\partial \phi^2} = \frac{\rho C}{k}\frac{\partial T}{\partial t} \tag{5-19}$$

where T = temperature, °C
t = time, s
k = thermal conductivity, W/(m)(°C)
C = specific heat, J/(kg)(°C)
ρ = density, kg/m^3
γ and ϕ = cylindrical coordinates, m

Solving this equation and assuming that the heat capacity of the cladding and the thermal resistance from the surface of the fuel pellet to the cooling channel can be neglected, gives the fuel-element transfer function

$$G(s) = (1 - \gamma) \sum_{\eta=1}^{4} \frac{F_n}{1 + \tau_n S} + \gamma \tag{5-20}$$

where $G(s)$ = fuel transfer function
γ = fraction of heat produced by photons
F_n = gain of nth term
τ_n = time constant of the nth term

Application of Performance Equations. The equations of performance for the various portions of the NSSS may be used for mathematical analyses or for development of simulations. Simulation of an NSSS is frequently desired. Such simulation enables (1) evaluation of system performance to assure that plant performance requirements are met, (2) performance evaluation of monitoring or control equipment, and (3) analyses of protection action to assure protective-system adequacy.

The simulation may be performed with an analog, a digital, or a hybrid computer; selection of the appropriate method should be based on the equipment to be simulated and the objectives of the tests to be performed.

The level of detail of the simulation also varies with the objectives of the test. For instance, modeling of the reactor core may be one node for gross thermal input to another component or be multinode to evaluate the performance of in-core instrumentation; 1-, 4-, 7-, and 38-node models are examples of core simulations that have been found to be useful.

Since commercial power-reactor systems are large and are oriented to power production, it is inconvenient to encumber them with apparatus and operations directed to obtaining their time-response characteristics, which interferes with normal operation. It has been found that the discrete nature of neutrons and the statistical nature of the fission process give rise to random fluctuations in neutron population or "reactor noise." The production, absorption, and leakage of neutrons can be considered analogous to the random flow, from emitter to collector, of electrons in a diode. Using power-spectral-density techniques, the reactor transfer function can be developed from an analysis of reactor noise.

5.2.13 Control Systems

Fission Regulation. The fission process is regulated by the absorption, in a controlled manner, of some of the neutrons which cause fission. The controlled absorption may be provided by the control rods or control elements which are mechanically inserted into, or withdrawn from, the reactor core or by absorber material dissolved within the reactor coolant. Because steam is produced directly from the coolant in a BWR, dissolved poisons are usually not used in normal operation of the BWR. In a gas-cooled reactor where the coolant gas is either helium or carbon dioxide, it is not feasible to provide dissolved absorbers in the coolant. Dissolved poisons, therefore, are used principally in PWRs. Where dissolved poisons or fixed poisons within the core are used, they are generally used for the purpose of accommodating core burnup. Changes in the reactivity for normal operation, initial start-up, planned shutdown, and restart are normally accomplished by control rods or control elements. Since the rate of change available from dissolved poisons or fixed burnable poisons is normally quite slow, the mechanically inserted control rods or control elements are also used for emergency shutdown.

Considerations involved in determining the characteristics of the control rods or elements are the amount of reactivity that has to be controlled, the position accuracy (which corresponds to the minimum increment of the reactivity) to be provided, the rate of reactivity that must be provided for operation, and the reliability of components. The reactivity requirements of a nuclear system are based on the planned rate of fuel depletion, the fission-product buildup, including the principal poisons xenon and samarium, inherent reactivity effects such as temperature or void changes, and the control range necessary for maneuvering to which the plant may be subjected.

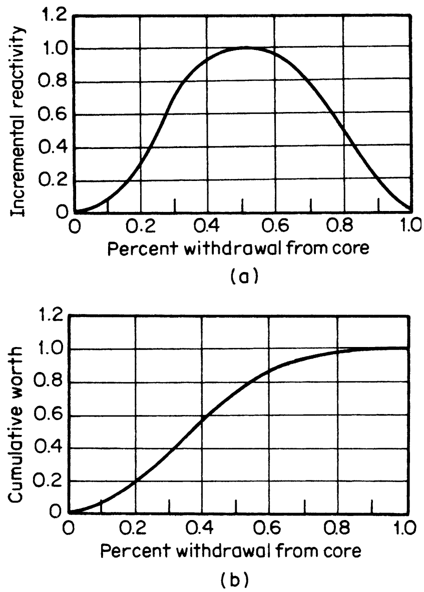

FIGURE 5-19 (*a*) Incremental reactivity versus core withdrawal; (*b*) cumulative worth versus core withdrawal.

The control rods or elements are also used to flatten the power developed radially and axially within the reactor to raise the average power and increase the output from the system. To accomplish this purpose, the rods or elements are normally assigned to groups or banks which are operated together. The capability of a rod or element to perform its neutron absorption or the worth of the control unit is dependent on the position of the element within the core. As the element progresses from the bottom, its worth increases from a low value to a peak and then decreases again to a low value as it is withdrawn from the top of the core. The typical incremental worth and the cumulative worth of an assembly are shown in Fig. 5-19. (Individual worths are affected by core power distribution.)

Emergency Shutdown. In order to provide an emergency shutdown capability, the control rods or elements are normally provided with a fast-insertion capability. This characteristic, also referred to as scram, is provided for control drives mounted on top of the reactor by a delatching capability with the rods or elements free-falling into the reactor core. With rods or elements that are mounted on the bottom of the reactor, a capability is provided to drive the rods rapidly up to their full insertion position. The latter mechanism is typically hydraulically actuated. Since the position of the control rods or elements is an important information in determining core power distribution and it represents a knowledge of the rate at which the fission process is proceeding, it is desirable to provide indication of the position of the control elements and to provide input from the rod-position sensors to core-power-distribution calculations. Position indication can be provided by analog meters, digital indicators, analog presentations on a cathode-ray tube, position logged by a digital computer with printout, or other types of display. Because of the importance of the position of the control element in reactor regulation and reactor shutdown, two systems of indication for the control elements are normally provided.

Controlling Fluid Processes. The primary system of most U.S. reactors involves either light water or helium as a coolant. Other fluid systems are provided to supply makeup, effect cleanup, process waste, etc. Conventional instrumentation is used to monitor these variables, and control signals in accordance with preselected control program are applied to appropriate actuator elements.

The special requirements of nuclear systems for continuity of cooling may require that extra care be used in the application of control equipment to assure high reliability. Establishment of set points and alarm points should also be done with due care.

Protection Systems. The high specific power of nuclear reactor sources coupled with the potential for the release of radioactivity, which might be a hazard to human beings, requires that additional systems be provided for regulation. In addition to the instrumentation provided for the control of the fission and fluid processes, systems are specifically supplied to initiate protective action in the event that preselected limits are exceeded. The relation of protection systems to other instrumentation and control systems is shown in Fig. 5-20.

Basically, a protection system must provide a functional capability to initiate action in the event of a design-basis event which, if unchecked, could lead to unacceptable consequences. Because of this requirement, the protection system must operate when required and must operate correctly. The development of functional and reliability requirements is very important in this arrangement.

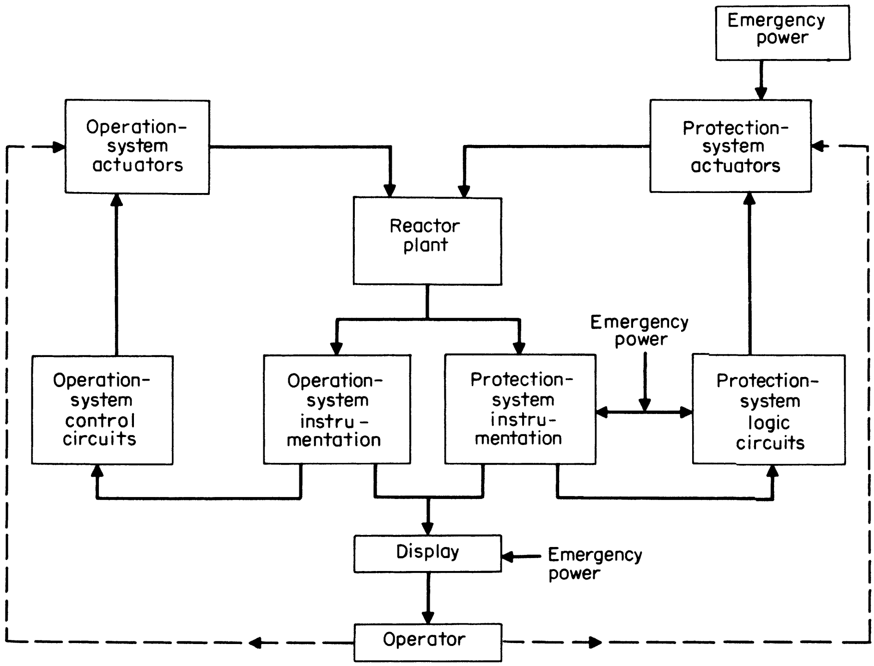

FIGURE 5-20 Relation of protection system to other instrumentation and control system.

The consequence of the greatest concern associated with a nuclear system is the release of radioactivity. The nuclear fuel itself has multiple barriers between the fuel material and the outside boundaries for the public. These barriers are the fuel matrix, the fuel jacket or cladding, the primary system, and the containment structure. For any given condition, it is the duty of the protection systems to prevent a situation which would lead to an excessive release of radioactivity from occurring past a given boundary.

The protection systems therefore include the reactor shutdown system and other systems that effect the containment of the radioactivity such as emergency core cooling, containment isolation, containment pressure reduction, emergency power sources, and air filtration. A protection system itself includes the instruments, logic systems, actuators, protective interlocks, and mechanisms which carry out the necessary functions. That system which effects reactor shutdown, normally referred to as the reactor protection system, includes all electrical and mechanical devices and circuits used to initiate a reduction of the fission process below criticality. The engineered safety features or engineered safeguards systems include everything else associated with protection except the reactor protection system.

In order to accomplish a high availability, that is, the capability to act when needed, it is necessary to provide multiple channels to perform the same action. The probability of any one channel not being able to act at a given time, therefore, is offset by having other channels capable of performing the action. In order to avoid spurious action, that is, initiation of a protection when none is required, it is usually the practice to provide a logic arrangement and initiate action only when there is a coincidence of two or more channels. The consequences of spurious action, for example, loss of a power source, in a large system can also be rather severe in terms of impact not only at the plant site but also in the area of public usage of the plant output, and such false action should therefore be precluded. Conventional protection systems have used a logic arrangement involving three or four channels and requiring the coincidence of two of three or two of four in order to initiate action.

In the selection of the plant variables that are sensed by the protection system, it is usual to evaluate those plant conditions which could occur as a result of some event. In some cases, such as those involved with protection of the clad integrity, the variables cannot be measured directly and an inferred or computed variable must be used to initiate the protective action. Such plant variables used to evaluate the fuel design limits are the departure from nucleate boiling (DNB) ratio in the case of PWRs and minimum critical heat-flux ratio (MCHFR) in the case of BWRs. In order to maintain these critical values below safety limits, it is necessary to monitor the observable parameters which affect DNB or MCHFR such as thermal power, coolant flow, coolant temperature, coolant pressure, and core power distribution (from the nuclear instrumentation and control-element-position sensors). These values are translated into systems relating to desired protection, and reactor shutdown is initiated if the measured variables approach boundaries of regions established by these systems. The earlier nuclear plants utilized parameters directly and the shutdown values or limits were set on the basis of calculated values relating to a set of curves. Current nuclear plants involve, to a certain degree, the use of online digital calculators permitting the protection system to provide continual computations of the relation of the variables. Shutdown limits are initiated as a function of the instantaneous value of the measured variables.

In order to avoid the possibility of disabling of the protection system by some common initiating mechanism, a principle of diversity of sensing and operation is suggested. The diversity relates to a different type of equipment or a different mode of operation to effect protection action from a given condition. Types of diversity that have been considered include equipment, functional, operational administrative, and design administrative diversity. Therefore, an evaluation should be made of the utilization of diversity in order to assure that (1) a definite objective may be obtained, (2) the additional complexity introduced by added equipment will not result in a degradation of the system, and (3) typical relations will be maintained between the primary action and the diverse action provided.

Nuclear Instrumentation. Since the fission process involves a neutron fluence where the fluence rate (flux) is proportional to power, it is essential to measure the fluence rate. Such measurement, for the large-core commercial reactors, involves special consideration, including the following:

Measurement over 10 to 13 orders of magnitude may be required.

There may be important spatial variations.

The measurement is of uncharged nuclear particles (neutrons).

The measurements have to be made in a background of substantial gamma radiation.

In addition to the monitoring of neutrons, a nuclear steam system involves the monitoring of radiation, principally gamma, from process lines and fuel.

Ex-Core Neutron Monitoring. Ex-core, or out-of-core, detectors are those which are located external to the reactor core and usually external to the primary pressure boundary. The fast-neutron flux leaking from the core provides a neutron flux spectrum for some distance beyond the vessel wall. This flux, proportional to a spatially average core power, becomes thermalized in the shielding, usually hydrogenous material surrounding the reactor.

The environment in which the detectors are located involves, typically, neutron fluxes from up to 10^{11} neutrons/(cm^2)(s), gamma dose rate up to 10^7 R/h, and temperatures to 200°C.

The detectors used are devices which produce a current pulse when subjected to the passage of a nuclear emission. The incident radiation drops some or all of its energy within the detector, causing ions to be produced. The ions produced are attracted to electrodes, within the detector, by the effect of voltage across the electrodes. The number of ions collected is a function of applied voltage. The chambers are filled with a gas selected to enhance the performance for a particular type of operation. The chambers are operated with voltages between the electrodes to effect the collection of charged particles as pulses or current (continuous pulses). Operation for ex-core ion-chamber detectors is normally in the flat or plateau region. The "knee" at the left of the curve moves to the right with increasing ambient radiation, so the selected voltage operating point must be sufficiently high so as to remain on the plateau for all conditions.

The chambers can be made sensitive to neutrons by coating the electrodes with a film of material containing an element with which neutrons interact, such as ^{235}U or ^{10}B. Enrichment of the isotope can be selected to effect desired performance in the range of neutron flux. In addition to pulses from incident neutrons, there are pulses from other incident ionizing radiation such as gamma rays. The contribution from gamma rays can be countered or compensated for by supplying two identical volumes, one with neutron-sensitive coating and one without, and subtracting their output. Since the neutron fluence rate and the gamma level do not increase together, that is, maintain the same ratio, this compensation can be completely canceled only at a given power level. Over the range of operation, about 97% to 98% compensation can be effected. The compensated ion chambers (CIC) can be used in a fluence rate about two decades below that of the uncompensated ion chambers (UIC). Ion chambers are applied for both in-core and ex-core monitoring.

Low neutron fluence rates produce currents too low to be accurately measured with an ion chamber. Proportional counters operating in a pulse-counting mode are conventionally used in this application. These detectors are filled with a gas, such as BF_3, which interacts with incident neutrons to produce ionized particles. Gas amplification is used to increase the output for a given event. Voltage applied is typically in the center of the proportional range. A well-regulated voltage supply is necessary.

Ion chambers using a sensitive coating involving ^{235}U absorb neutrons and undergo fission which generates the ions. Because of the substantial energy imparted to the ions by the fission process, these detectors are used satisfactorily for both current and pulse generation. Operation over 10 decades of neutron fluence rate may be satisfactorily achieved.

Reliability. Selection and procurement of the equipment must include consideration of minimum maintenance and low-failure-rate characteristics. The steps taken to achieve quality levels include good design practices, quality control, qualification testing, calibration, and system testing.

Independence. The equipment is to be installed so that independence of redundant channels is preserved. This requires that (1) components and circuits be electrically separated to prevent the propagation of electrical faults, (2) components and circuits be physically protected from destructive factors such as missiles and water or steam jets, and (3) steps be taken to avoid loss of protective action in the event of common-mode events such as fire or high temperature.

Signal Validation. The equipment design and arrangement is to be such that there are means of verifying that the signal represents the actual condition of the variable monitored. Such verification may include

1. Calibration
2. Cross checking between channels
3. Introducing and measuring known perturbation in the variable

Maintenance. In order to assure high system availability, redundant parts of the systems must be both repairable and adjustable. Special consideration must be given to access, bypassing, removal of modules, and calibration.

Information Readout. The system readouts are to be designed to provide operators with accurate, complete, and timely information. Consideration must be given to sequence and trend indication and to indication of related conditions.

Emergency Power Systems. Because of the need for protective action to be available at all times when the reactor is operating and the need for continued cooling and monitoring when the reactor is shut down, systems must be provided to assure high availability of electric power.

Primary Coolant Circulators. The largest single plant load is the drives for primary coolant circulation. Since it is important to maintain coolant circulation and since these drives are generally too large to be supplied by engine-driven sources, provisions should be made to supply the coolant circulator drives from two or more sources. Frequently, arrangements are made for the main generator to supply two or more power lines. Provisions in the switchyard enable the plant distribution system to be supplied from the plant generator or from one or more of the outside lines.

In spite of possible connection of plant loads to multiple external power sources, it is possible to lose all external lines, for instance, by a tornado. In this event, a local source of power to supply critical ac loads is required. For these purposes, engine (diesel)-driven generators are usually used. Credit can sometimes be taken for local hydro generators or gas-turbine generators if these sources can meet the requirements. These power systems must be designed so that they provide power to the station following a design-basis event. An ac power system (generation and distribution), a dc power

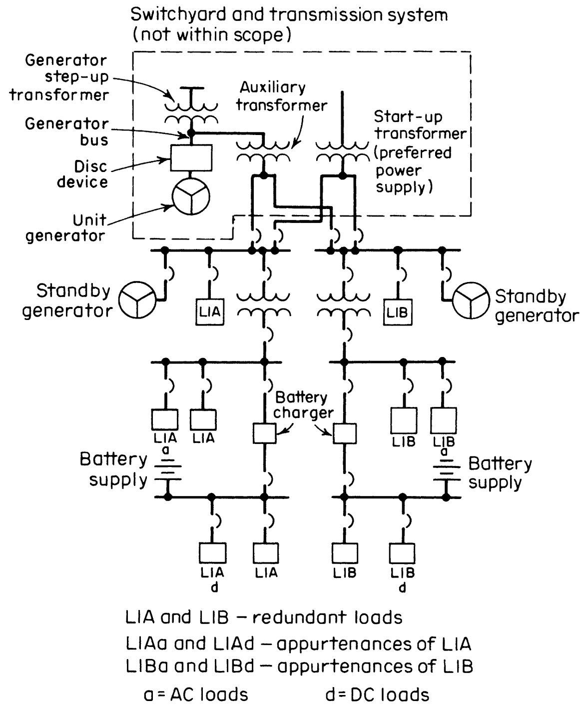

FIGURE 5-21 Class 1E power system for single unit.

system, and a vital instrumentation and control power system are provided. An example of a safety-grade power system is shown in Fig. 5-21.

In the ac system, each of the redundant load groups must have access to both a preferred and a standby power supply. The units of the standby supply must have sufficient independence from the preferred supply and from one another to preclude a common failure mode. Load assignment must be such that the safety actions of each group are redundant and independent. Protective devices must be provided to limit the degradation of the system and maintain the power quality (voltage and frequency) within acceptable limits. Following a demand for the standby power supply, it must be available within a time consistent with the requirements of the engineered safeguards features and the shutdown systems.

In the dc system, batteries, distribution equipment, and load groups are arranged to supply critical dc loads and switching and control power. Redundant load groups, and corresponding battery sections, must be sufficiently independent to preclude common failure modes. Each of the redundant load groups must have access to one or more battery chargers; the batteries are to be kept charged. The battery supplies must be sized to be able to start and operate their assigned loads in the expected loading sequence for a length of time commensurate with the protection provided.

Battery chargers supplying the redundant load groups must have sufficient capacity to restore the battery from its design minimum charge to its fully charged state while supplying normal and postaccident loads. Each charger supply must have a disconnecting device in its ac feeder and one in its dc output line. The dc system must be equipped with surveillance equipment to monitor its status and to indicate actions.

The vital instrument system is provided to power the instrumentation needed for reactor protection and engineered safety features. Since there may be considerable variation in the instrumentation in various plants, the vital system may be required to supply ac or dc or both. To preserve freedom from common-mode failure, the vital supply must be divided into redundant and independent systems with adequate status indication. Provisions for testing, adjustment, and repair should be included in the parts of the emergency power systems to improve reliability and availability.

5.2.14 Radioactive Waste Disposal

There are two broad categories of radioactive wastes, low-level wastes (LLWs) and high-level wastes (HLWs). Nuclear power plants produce significant quantities of both. (Other important sources include defense [military] labs and various commercial/university/hospital labs using radioisotopes, research reactors, etc.) Their safe and economic handling represents a key objective if nuclear power is to remain competitive in the future. Issues related to radioactive wastes are exceedingly complex, involving both intense political-societal-legal interactions and technology. Here we will briefly discuss various technical issues, but caution the reader that sociopolitical factors are, in many cases to date, overriding.

The principal Nuclear Regulatory Commission (NRC) regulation for LLWs is 10 CFR 61. It defines three classes of radioactive waste—A, B, and C—depending both on the isotope's half-life and on the specific activity in curies per cubic meter, class A representing the shortest half-life and less specific activity and class C being the highest. Ideally, the classification would be hazard-based, but for practical reasons and ease of enforcement, it is based largely on the process of the industry that generated the waste. 10 CFR 61 provides a quantitative evaluation for all radionuclides involved. All power-reactor fuel elements are automatically classified as HLWs while resin, sludges, contaminated clothing, materials, etc. are LLWs.

An LLW disposal facility can be licensed either by a state (if qualified by the NRC) or by the NRC itself for use by a commercial operator. The site is selected from appropriate candidate land when extensive facts about the geology, water flow patterns, and nearby population are known or developed. After 20 to 50 years, the site is closed, and ownership is transferred to the state or federal agency, which then continues to monitor the site for the period of institutional control (100 years). Then the license is terminated and no further maintenance is needed, but the design should have assured protection for a period of 500 years.

The disposal of HLWs is controlled by the Nuclear Regulatory Commission, following regulations 10 CFR 60. Some important provisions in this lengthy regulation are as follows:

The facility should not pose an unreasonable risk to the health and safety of the public; the allowed radiation dose limit is a small fraction of that from natural background.

A multiple barrier approach is to be used, including the waste form, the containers, and the site geology.

A thorough site characterization is required with features such as great geologic stability and slow water movement regarded as favorable.

The location should not have attractive resources, should be far from population centers, and under federal or state control.

HLWs are to be retrievable for up to 50 years.

Packaged wastes should be secure for at least 300 years; groundwater travel time to any source of public water should be at least 1000 years.

The annual release of radionuclides must be less than $10^{-3}\%$ (in radioactivity) present 1000 years after the repository is closed.

Predictions of safety must be made with conservative assumptions and by calculations that take account of uncertainties, using expert opinion.

In principle, prior to storage/disposal of radioactive isotopes, power reactor fuel elements could be reprocessed (e.g., by chemical solution followed by separation) to recycle fissile and some structural material so that only the radioactive fission products and activated substances are sent to disposal. However, by presidential decision, based on a concern that reprocessing might enable nuclear proliferation, the United States has not permitted reprocessing. (Other countries, e.g., France, have reprocessing plants.) The only actual reprocessing of commercial wastes done was by Nuclear Fuel Services, Inc., at West Valley, New York, in the period 1966 to 1972. This plant was shut down because it was uneconomical to operate, compared to the cost of producing fuel from uranium ore. Thus, since 1972, spent fuel has been accumulating at nuclear power plants.

Another distinction among radioactive wastes involves transuranic elements. Transuranic (TRU) wastes are those containing isotopes above uranium in the periodic table of chemical elements. They are the by-products of fuel assembly and weapons fabrication and of reprocessing operations. Their radioactivity level generally is low, but since they contain several long-lived isotopes, they must be managed separately. This classification includes isotopes with half-lives greater than 20 years with a total activity greater than 100 nanocuries per gram of waste material. Isotopes include plutonium-239, americium-241, americium-243, cirium-244, neptunium-237, and curium-245.

Transuranic wastes give off very little heat, and most of them can be handled by ordinary methods not requiring remote control. Since 1970, they have been placed in retrievable storage.

Another special category of wastes involved with the power reactor fuel cycle consists of mill tailings. These wastes are the residue from the physical and chemical processing of uranium ore to obtain uranium. They are stored and disposed of separately due to the enormous volume of material involved.

Another waste category must be considered along with "pure" radioactive materials. "Mixed wastes" are those containing both hazardous chemicals and radioactive substances. The disposal of hazardous wastes is regulated by the Environmental Protection Agency (EPA), while radioactive wastes are controlled by the NRC. Thus, it has been necessary to establish consistent dual rules by agreement between agencies. This overlap of agency control results in many complications, which have caused difficulty in handling of mixed wastes, and has led to most such waste being chemically processed to eliminate the chemical hazard, followed by disposal as LLRW.

What to do with spent fuel has been an important challenge for the United States since the early 1970s, and will continue to be well into the twenty-first century. It is estimated that about 80,000 metric tons of spent fuel elements will have to be stored by the year 2020, assuming, of course, that no reprocessing is done.

Several materials have been candidates for the host geologic medium for a disposal site. Regions containing deposits of rock salt, basalt, granite, tuff, and argillaceous materials (clay and shale) have been involved in several levels of investigation. The Yucca Mountain region in Nevada has been selected for detailed evaluation. A facility located deep beneath the surface of the tuff-type mountainous range would be employed. Tuff is a compacted and hardened ash that has come from volcanoes. Yucca Mountain is composed of a welded tuff, formed by a flow of ash into sheets, that has become solid through pressure from material above. The Yucca Mountain site would use the mined cavity method for storage (see the general concept illustrated in Fig. 5-22). A shaft would extend from the earth's surface down to a series of horizontal tunnels. Canisters containing spent fuel would be placed in holes drilled in the tunnel floor. Then the openings would be backfilled. In addition to the geological safety achieved, this method has the advantage of using conventional mining techniques. After a lengthy legal battle with the state of Nevada concerning the government's right to characterize the Yucca Mountain site, plus delays due to various citizens' protests about issues such as possible water seepage into the mine structure, the DOE recently resumed work to characterize and evaluate the site.

A large volume of wastes classified as high-level defense waste, including some mixed with toxic chemical liquids, is now stored in underground tanks and bins at three main government sites—Hanford, Idaho Falls, and Savannah River.

We see from the foregoing that there is one radioactive waste problem but three key disposal challenges: defense wastes; spent fuel; and low-level wastes.

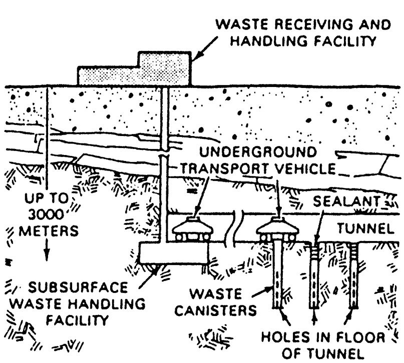

FIGURE 5-22 Emplacement of waste canisters in a mined cavity.

Modern reactors use uranium that has a higher percentage of ^{235}U (3%) than is found in nature (0.7%). The enriched fuel is typically in the form of uranium dioxide (UO_2) as small pellets about $^3/_{16}$ in in diameter and $^3/_8$ in long.

During the $1^1/_2$ to 3 years that a fuel element typically stays in the reactor, neutron irradiation has consumed some of the uranium and produced some new materials. The content of ^{235}U is reduced to about 1%, while ^{238}U has gone down from 97% to 94%. A new fissile isotope, ^{239}Pu, has been produced. It has a half-life of around 24,000 years, emitting an alpha particle of 5.1-MeV energy. As noted earlier, a small quantity of other transuranic elements are also produced. By successive neutron absorption ^{239}Pu becomes ^{240}Pu, fissile ^{241}Pu, ^{242}Pu, and short-lived ^{243}Pu. (Light-water reactors are sometimes called "converters" because they transform some of the ^{238}U into plutonium isotopes.) Figure 5-23 shows the before and after composition of spent fuel. Note that the spent fuel still has most of its original ^{238}U and a fairly high fissile fuel content.

The volume of a typical assembly is less than 7 ft^3 with about 60 assemblies removed per year from each reactor, a total of around 400 ft^3 of spent fuel must be handled. From the 100 reactors in the United States, the annual spent fuel volume would thus be around 40,000 ft^3, corresponding to less than 1-ft depth in a standard football field.

The actual amount of radioactive materials in the spent fuel is considerably smaller than the total volume quoted above. If the fuel were reprocessed, these would be extracted, as would most of the plutonium isotopes. The uranium would be cleaned up in preparation for reuse. For each 1200-lb assembly, there would be only around 35 lb of fission product waste. For 60 assemblies discharged per reactor per year, this is about 1 ton. The actual volume would be only 3.4 ft^3, which is 18 in on a side. However, most wastes could not be stored or disposed of in such a concentrated form because its radioactivity would produce intense heat.

If, as at present, fuel is not reprocessed, two choices are open: store it indefinitely or dispose of it by burial or other isolation technique. These options do not seem optimum in view of the value of the fissile elements in the fuel elements and the reduction in volume that reprocessing could achieve. The decision to avoid storage was based on the Pu-239 content and nuclear proliferation concerns. However, trade-offs among options must be constantly reevaluated with changes in both technology and international politics.

5.2.15 Prior and Present Trends in Nuclear-Fueled Plant Development

The development of nuclear-fueled steam-electric plants underwent substantial change in the 1970s. At the beginning of the decade, orders for nuclear-fueled plants were increasing to a peak of 38 per year. Following the oil crisis of 1973 to 1974, changes in the economy began to affect the cost of, and consequently the demand for, electric power. Opposition to the use of nuclear energy for electric power production increased; litigation was frequently employed. Near the end of the decade, sociopolitical aspects of nuclear-fueled plants became as involved and time-consuming as the technical aspects. In order to participate effectively in the design, construction, and operation of nuclear-fueled plants, one must be familiar with the energy perspective; the concerns about the use of nuclear energy; and the functions of advocates, intervenors, and regulators.

With the maturity of the nuclear-fueled plants, more emphasis was placed on project management (Pederson 1978). Siting of the plants became a major task (Winter and Conner 1978). Because of the reduced demand for electric power, the increased cost of money, and the difficulty of resolving the objections raised, orders for nuclear-fueled plants began to decrease sharply after the middle of the decade. Some orders were canceled. Then in March 1979, a major accident occurred at the Three Mile Island plant, causing serious damage to the plant. This event raised questions about the operation of nuclear-fueled plants and a review of the value of nuclear energy (Rubenstein 1979). At the end of the decade, orders for new nuclear-fueled plants had been reduced to zero and a sizable number of plant orders had been canceled.

The beginning of the decade of the 1980s saw reinforcement of the need for commercial use of nuclear energy (Greenhalgh 1980), but also heralded changes in the safety, control, and maintenance systems. In the electrical area, the most notable changes were the redesign of control rooms and stations and the increased use of computers in more sophisticated safety systems (Hanes et al. 1982). The study of incidents and malfunctions by means of computers has provided another means to inform and guide operators and to evaluate possible trouble spots (Kaplan 1983). The availability and capability of the microprocessor has provided new ways to improve the safety and performance of plant instrumentation, control, and safety systems.

With fewer new nuclear plants being built worldwide than originally anticipated, much attention has been on methods to achieve "life extension" of present plants (retrofitting to allow operation beyond the traditional 20-year life cited for power plants). At the same time, procedures for decontamination and decommissioning of plants being shut down are being refined. The NRC is simultaneously developing streamlined procedures for licensing new plants, with the anticipation that utilities may turn to nuclear energy in the future in the form of the new passive-safe type reactors. This effort, the deregulation of the utility industry in the United States, plus the possible emphasis on nuclear energy as a way to meet goals for reduction of CO_2 greenhouse gases (Schmidt 1998), could have a profound effect on the evolution of the nuclear industry.

There has been a growing belief in recent years that a 'rebirth" of nuclear energy has begun. This has been driven by the rapid increase in oil process coupled with a desire by countries like the U.S. to achieve energy independence, while future energy needs will be met by a combination of conservation plus use of a wide range of energy sources (solar, wind, bio renewable energy sources). There is a growing opinion that nuclear is needed to fill the future needs for central plant energy production. The new "Generation-IV" reactor concepts being developed by DOE offer many attractive features to fit into this need, including competitive costs, passive safety, improved efficiency, reduced maintenance down time and costs, and they also eliminate greenhouse gas emission. The main obstacle remaining is gaining of public acceptance of radioactive waste disposal techniques.

5.3 NUCLEAR POWER FOR THE FUTURE

By GEORGE H. MILEY

Development in nuclear power for the future is following three main paths: the extension of present reactor designs to create advanced concepts with passive safety features and improved economics; the development of breeder reactors to extend the supply of fissionable fuel; and the development of a new nuclear energy source, fusion. Each of these paths is considered in turn in the following sections.

5.3.1 Advanced Concepts with Passive Safety Features

Recent progress in advanced nuclear power development reveals a high potential for nuclear reactor systems that are smaller and easier to operate than the present generation. Passive, or intrinsic, characteristics are applied to ensure continued cooling of the fuel and its containment systems even in the advent of a major breakdown of the normal cooling/control functions. This substantially reduces the chance of a severe accident. The reactor design concepts that are emerging are simpler, more rugged, have a longer lifespan, and place less burden on equipment and operating personnel. Modular design concepts and design standardization are envisioned to reduce construction time and engineering costs.

Common Development Goals. The primary thrust in U.S. advanced reactor development is to incorporate design improvements to achieve five primary objectives:

Assured safety with features to minimize negative consequences of human error, especially a reduction in the probability of severe core damage.

A significantly simpler design, with increased safety and performance margin in key operational parameters.

High reliability throughout a lifetime of about 60 years.

Reduction in costs to meet the economic competition.

A standardized design which is predictably licensable.

Common generic technical features (passive stability, simplification, ruggedness, ease of operation, and modularity) are being developed to respond to these goals for each of the principal nuclear power systems—the light-water reactor (LWR), the liquid-metal reactor (LMR), and the high-temperature gas-cooled reactor (HTGR). These features, coupled with standardization and assurance that the plant is licensable, should ensure future economic competitiveness.

Light-Water Reactor with Passive Safety Factors. An effort to develop a passively stable LWR in the United States is jointly sponsored by the Electric Power Research Institute (EPRI) and the Department of Energy (DOE) with substantial contributions from several major U.S. suppliers.

Conceptual designs have been developed for passive versions of both a boiling water reactor (BWR) and a pressurized water reactor (PWR). A 600-MWe unit output is proposed to provide the utilities the option of a smaller nuclear power plant and to make it easier and less costly to incorporate passive cooling features.

PWR with Passive Safety Features. An advanced PWR, called AP-600 uses proven technology: a UO_2-fueled core and field-proven plant components. The burden on systems has been reduced by increasing design margins through reductions in coolant temperature, flow rate, and core power density and by selecting higher-quality materials and more robust components.

Passive cooling is provided by a passive emergency core cooling system (ECCS) and a passive containment cooling system. The ECCS consists of a combination of cooling water sources: gravity drain of water and water ejected from two accumulator tanks under nitrogen pressure. Additionally, the system can be depressurized to permit an even larger amount of water to enter the system. If a feedwater accident disables the steam generators, core decay heat is removed through a passive residual heat exchanger. This transfers core decay heat to the refueling water by natural circulation.

Containment integrity is ensured by cooling the containment shell by evaporating water that is gravity-fed from a large storage tank; heat is removed by a natural-circulation air system. Only automatic valve operations are required to provide emergency core cooling and containment cooling after a major energy release.

It is estimated that the use of a modular design for the AP-600 will reduce construction time to 3 or 4 years. The simplified design combined with the shorter construction time should counter the loss of economy of scale that previously favored larger plants.

The Passively Stable BWR. A passively stable BWR design uses fully proven components and systems operating at reduced burdens: lower power density and increased thermal margin. The reactor operates at full power under natural circulation, which eliminates the need for recirculation pumps while reducing the amount of piping, valves, and controls used in present BWRs.

A passive containment cooling system (PCCS), which consists of three condenser units, provides the capability for removal of the decay heat for a period of 3 days. In the event of a LOCA, the steam discharged from the break and noncondensibles from the dry well flow through the condensers to the wet well. The steam is condensed and the condensate is returned to the gravity-driven cooling system pools. Isolation condensers are used to remove decay heat during reactor isolation events. The condensed steam from the reactor is returned to the reactor vessel, maintaining vessel inventory and limiting the pressure increase without the need to open safety/relief valves. Both the isolation condensers and the passive cooling condensers are located in a large interconnected pool of water on top of the containment building.

The Advanced Liquid-Metal Reactor (LMR). The LMR development work is focused on a modular, passively stable reactor concept called S-PRISM (stable power reactor inherently safe module).

The principal parameters of PRISM are thermal power, 4000 MWt, from four nuclear modules; electric output, 1500 MWe, from two turbine generators; net efficiency, 37.5%; steam conditions, 864°F/2400 lb/in^2 (absolute); exit sodium temperature, 950°F; core power density, 199 W/cm^3; and equilibrium fuel burnup, 150 MW · day/kg. The two reactor modules in each power block provide heated sodium to a single sodium-to-water heat exchanger that generates steam for a single 750-MWe turbine generator. A commercial S-PRISM plant is envisioned to consist of a series of three such 465-MWe power packs, each of which would be functionally independent of the other two.

The reactor vessel auxiliary cooling system (RVACS) provides for emergency core cooling after any incident that causes a loss of the normal emergency heat-conversion systems. The residual-heat removal path consists of radiant-heat transfer from the reactor vessel to the containment vessel where the heat is removed by natural circulation of air between the containment vessel and the biological shield. This combination of passive reactor stability and passive cooling provides assurance of residual-heat removal without operator action.

The reference fuel for the S-PRISM concept is a uranium-plutonium-zirconium alloy with plutonium concentrations of about 25%. An important feature potentially achievable with this fuel is use of a metallurgical processing method for the separation of uranium, plutonium, and the transuranic elements from the fission products. Thus, long-lived transuranics can be recycled in the LMR rather than sent to a disposal site. This approach is basic to the integral fast reactor (IFR) concept pioneered by the Argonne National Laboratory (ANL). The S-PRISM concept is also capable of using standard oxide fuel in the event that the development promise of the metal fuel is not realized.

ANL has applied its experience in metal fuels operation, fabrication, and reprocessing to develop the IFR concept, which envisions a colocated nuclear power plant, fuel fabrication, and fuel reprocessing center where S-PRISM could function as the power plant. Although such a collocated concept is not essential to S-PRISM, or vice versa, this would provide for greater proliferation resistance because plutonium-bearing materials would not have to be transported outside the security boundaries of the site. The burning of the long-lived actinides via the colocated plant would also significantly ease the waste storage problem.

Advanced Modular Gas-Cooled Reactor. The modular high-temperature gas-cooled reactor (MHTGR) has been the primary focus in advanced gas-cooled reactor development. Its principal parameters are thermal power, 1400 MWt, from four nuclear modules; electric output, 538 MWe from two turbine generators; net efficiency, 38.4%; steam conditions, 1005°F [2515 lb/in^2 (abs)]; core exit coolant temperature, 1268°F ; core power density, 5.9 W/cm^3; and equilibrium fuel burnup, 92.200 MW · day/ton.

The reactor core is composed of hexagonal blocks of graphite-fuel elements in an annular array. The fuel is in the form of coated particles of low-enriched uranium oxycarbide and thorium oxide. This fuel and the graphite moderator arrangement have been termed a "prismatic fuel." It provides an essential barrier to fission product release during an accident. Test data have shown that essentially no failure of the refractory coatings occurs if the fuel is maintained below 1800°C. Even if all active cooling systems were unavailable, decay heat is dissipated by conduction and radiation to the reactor cavity cooling system in the reactor enclosure. This limits the maximum fuel temperatures in accidents to about 600°C, well below the fuel failure temperature.

Tests at a German gas-cooled reactor demonstrated this passive cooling capability after a loss of all coolant flow with no intervention by the operator. The conceptual design of the MHTGR is presently under review by the U.S. Nuclear Regulatory Commission to assess licensability.

Other Advanced Reactor Design Projects. The major industrial countries outside the United States also have advanced nuclear power development programs, several of them larger than those in the United States. The largest programs are in France and the United Kingdom, where the LWR and LMR are under development; and in Germany and Japan, where all three types of reactors are studied. ASEA Brown Boveri in Sweden has proposed a passive LWR, called the process inherent ultimate safety (PIUS) reactor, a concept originating from studies of reactor systems suitable for central heating applications. PIUS is a 640-MWe PWR plant; its core is enclosed in a large prestressed concrete vessel. A fluidic valve is located at the bottom of the core. It introduces, through intrinsic thermal-hydraulic properties, emergency core cooling from the pool of water surrounding the reactor. The concept reduces active equipment beyond the level of U.S. passive designs discussed here.

The Canadian nuclear industry is continuing its development of the 600-MWe heavy-water-cooled reactor called CANDU. This reactor has achieved a superior performance record thus far. A 300-MWe CANDU is being developed to provide a smaller-size system for the utilities.

Conclusion. The advanced reactor approach to next-generation reactors will require a substantial development program to verify the safety and cost objectives of the advanced designs. This includes detailed design, licensing review, cost estimates, extensive testing of the LWR and SBWR passive-cooling features, and prototype operations of the modular LMR and HTGR advanced systems. While a variety of concepts have been proposed, they all involve systems that increase the use of passive systems (versus active equipment) to protect against accidents; that is, systems that reduce the dependence on rapid operator response to abnormal conditions, systems that are simple and rugged, and systems that perform reliably without requiring high performance of equipment.

5.3.2 Breeder Reactors

The breeder reactor is able to create more fissionable material than it consumes. A fast breeder is designed to have more nuclear reactions created by neutrons in the high-energy region than by neutrons in the thermal-energy region, as used by the light-water reactors. This design is accomplished by not moderating, or slowing down, the energy of the neutrons created by one fission reaction prior to subsequent captures of, or fissions by, the neutrons created. In the light-water reactors previously described, the water coolant absorbs energy from the neutrons, creating a condition (called the thermal-energy region) in which more neutrons fission the $^{235}U_{92}$ isotopes than are captured by the $^{238}U_{92}$ isotopes. The capture of a neutron by the $^{238}U_{92}$ isotopes results in a decay chain that produces an atom of plutonium (see reaction chain following). The plutonium can be used to fuel nuclear reactors. Liquid-metal fast-breeder reactors (LMFBRs) operate in the "fast," or high-energy region, where more of the neutrons are captured by fertile material than cause fission in fissionable material, and where the average number of neutrons created in fission reactions by fast neutrons is greater than the average number created by thermal neutrons. These additional neutrons permit the breeder to produce more fuel by the following reaction chain than is consumed by the fission reactions.

$$^{1}n_0 + {}^{238}U_{92} \longrightarrow {}^{239}U_{92} \xrightarrow[23\text{ min}]{\beta^-} {}^{239}Np_{93} \xrightarrow[2.3\text{ days}]{\beta^-} {}^{239}Pu_{94}$$

This same reaction occurs in a light-water reactor, but, without the greater number of neutrons and higher ratio of capture cross section to fission cross section, less fuel is created than is consumed. Much of this bred fissionable material is fissioned in situ. For the excess fissionable material in a breeder to be of use in other reactors, or for refueling itself, the spent fuel and blanket assemblies require reprocessing to separate the fissionable material from the fission products created by the nuclear fissions. These fission products, and the damage to the material of the fuel tubes, also limit the life, or time, breeder fuel can remain in the core to produce power. The fission products compete for capture of the neutrons and eventually "poison" the fission reactions, shutting down the chain reaction.

Thermal breeder reactors are possible using a $^{233}U_{92}$ fuel. This isotope results from the decay chain started from the fertile material thorium, $^{232}Th_{90}$.

$$^{1}n_0 + {}^{232}Th_{90} \longrightarrow {}^{233}Th_{90} \xrightarrow[23\text{ min}]{\beta^-} {}^{233}Pa_{91} \xrightarrow[27\text{ days}]{\beta^-} {}^{233}U_{92}$$

Experimental thermal breeder reactors have been operated using a seed-and-blanket core with water coolant or a molten-salt homogeneous core. The helium-cooled graphite-moderated reactor can also theoretically perform as a breeder.

The present breeder reactor designs use a liquid metal (sodium) to cool the core without moderating the energy level of the neutrons. This liquid metal becomes radioactive (15.5 h half-life) but is isolated from the condensate-feedwater-steam by a secondary, or intermediate, liquid-metal coolant circuit. Thus, an additional heat exchanger and pump are necessary with the attendant impact on plant cost and operating complexity.

Because all fuel resources are finite, breeding of fuels will eventually be necessary to sustain the present use of power with an increasing population and diminishing reserve of fuel. Crude oil and natural gas fuels will be depleted for practical purposes in 100 years. Coal resources will be depleted in about 450 years. Other concerns, such as the greenhouse effects, may limit the use of coal. Without breeding, uranium will be depleted in less than 100 years, as only 0.7% of natural uranium is the fissionable isotope $^{233}U_{92}$. Breeders will permit most of the uranium and thorium resources to be used as fuel. Breeders can supply our energy needs for thousands of years while avoiding production of greenhouse-effect gases. At a growth rate of 3% per year in power utilization, breeder technology needs to double the fuel every 23 years. Present experimental LMFBRs have demonstrated that *even shorter* doubling times are attainable.

Present Status. In 1983, funds for completing the Clinch River breeder reactor, a power-demonstration fast-breeder reactor, were canceled. Subsequently, the U.S. breeder program has regrouped to focus on the advanced LMR development program described earlier. However, this program was also terminated in the mid-1990s. Russia, France, Germany, Great Britain, and Japan also continued their research and development support of breeder reactors until recent events caused curtailment (but not cancellation) of their efforts.

Breeder Reactor Developments in Europe. Breeder reactor technology is being developed in Europe by combining national with cooperative ventures. Two prototype pool-type plants of 250-MW capacity each, Phenix in France and PFR in the United Kingdom, have been operated. A loop-type plant, SNR 300, was built in Germany but was canceled and terminated. A commercial-size plant, Superphenix, has been in operation in France but is in danger of being decommissioned.

These projects, done on a national basis in the early 1980s, resulted in designs known as Superphenix 2, CDFR, and SNR 2 in France, the United Kingdom, and Germany, respectively. Since 1984, these countries have jointly focused on one single design, the European fast reactor (EFR), which should incorporate the best features from the various national designs.

Breeder Reactor Development in Japan. The LMFBR is being developed in Japan as a national development project. The goal is to develop large oxide-fueled LMFBRs. Japan plans to bring these plants to commercialization by 2020 to 2030.

Joyo, a 100-MWt experimental fast reactor, has been operating successfully since 1977. Monju, a 280-MWe prototype FBR plant, began construction in October 1985, and achieved initial criticality in 1993. The plant was shut down, however, following a 1996 accident.

A demonstration FBR plant, now planned to follow operational experience with Monju, is expected to demonstrate the prospect for commercialization of the LMFBR. A preliminary design study of the demo FBR is in progress in order to verify the technical feasibility of a top-entry loop-type FBR. The plant assumed for this study is to produce between 600 and 800 MWe.

In summary, the Japanese FBR development program is quite aggressive. The Joyo and Monju reactors provide valuable operational experience. A variety of advanced concepts are under active consideration for the next-step demonstration reactor scheduled for operation in the early 2000 time frame so that competitive commercial plants can be introduced by 2020 to 2030.

Breeder Reactor Development in Other Countries. In addition to the U.S., European, and Japanese programs, active work on liquid-metal fast breeders is in progress in the former Soviet Union and India.

Fast-reactor development began in the former Soviet Union in the 1950s. Two reactors, BN-350 and BN-600, are in operation. Design and development of future fast reactor concepts have been initiated with improved safety and better economics as prime goals.

Because natural uranium availability in India is limited, a FBR system has been chosen for increasing the supply of fissile material to meet future energy needs. The fast-breeder test reactor (FBTR) was the first major step in this direction and is to be followed by the construction of a 500-MWe liquid-sodium-cooled fast-breeder reactor, called *prototype fast-breeder reactor* (PFBR). Design and construction of PFBR is expected to be the beginning of the commercial deployment of such reactors.

The FBTR attained its first criticality in October 1985 and began producing electricity in 1991. The first core is small, producing only 16 MWt. The next core to be introduced will be close to the reference design of about 35 MWt. FBTR has served the purpose of a pilot plant and has also turned out to be a good investment for developing trained workers. This experience will lead to the next significant step: the 500 MWe PFBR.

Projections for future energy requirements have driven the India breeder program. It is estimated that India will need over 3000 billion units of electricity by 2040. The goal for FBRs is defined by the need to supply at least 1000 to 2000 billion units so as to significantly reduce the use of coal for electrical production. An installed capacity of 200 to 400 million kW in fast breeder reactors would be required to meet this goal. Starting with an annual feed of 3000 kg of plutonium produced from 10 million kW of PHWR capacity, the realizable growth for different fuel options is given in Table 5-5.

Thorium is not introduced in the fuel cycle in any significant way. Thus, the fast reactor program would be based on Pu–U-238 cycle as long as depleted uranium is available as a by-product of the first-stage heavy-water program. Preference for depleted uranium is based on higher growth potential of a Pu–U-238 fuel cycle.

Table 5-5 shows that a ternary metal alloy comes closest to meeting India's needs when the fuel is designed to give a specific power of about 0.3 MWe/kg of fissile material and a breeding ratio of 1.4 to 1.5, corresponding to an annual net breeding gain of 316 kg/GWe. Advances reported for the

development of the ternary metal alloy make the assumed figures appear realistic. Research and development for fuel development has therefore shifted from the mixed carbide to the ternary metal alloy.

The Indira Gandhi Center for Atomic Research and Nuclear Power Corporation of India Ltd. have created a new public sector company Bharitiya Nabhikiya Vidyut Nigam Ltd. to carry out the construction and operation of the India Department of Atomic Energy's first 500-MWe prototype fast breeder reactor.

5.4 NUCLEAR FUSION

By GEORGE H. MILEY and STEPHEN O. DEAN

The substantial, research effort now in progress aimed at controlling thermonuclear reactions to produce electric power at gigawatt levels is stimulated by the fact that the basic fuel consumed in fusion, deuterium, naturally occurs to the extent of one atom for every 6500 atoms of hydrogen, making ocean and lake water the basic fuel. This represents a virtually inexhaustible fuel source. Fusion liberates energy by combining two nuclei of light elements into one nucleus of a heavier element. The resulting mass is less than that of the fusing nuclei. Fission, results in splitting one atom of a heavy element into two atoms of lighter elements. The resulting mass, again, is less than that of the fissioning atoms. Each fusion reaction releases about 20 MeV of energy. Each fissioning reaction releases about 200 MeV of energy. (See also Sec. 5.4.)

Fusion will enable use of an extremely large fuel resource—the deuterium isotope, $^2D_1$, which exists as 1 part in 6500 parts of $^1H_1$ in natural hydrogen. The deuterium available from the ocean could fuel the power requirements of the world for billions of years—even until the Sun expands and envelops the Earth. However, research is still far from developing a commercial fusion reactor. Fission, solar energy and coal, other renewables, and nuclear fusion provide the means of avoiding severe shortages of electricity and other forms of power in the twenty-first century.

Many years will be required to develop a commercial fusion power plant. Current estimates for the introduction of commercial fusion plants are generally for sometime in the mid-twenty-first century. In fiscal year 2004, the Dept. of Energy outlay in support of civilian fusion research in the United States exceeded \$263 million. A larger budget, \$514 million, is provided by the National Nuclear Security Administration for inertial confinement fusion aimed at simulating nuclear weapons.

5.4.1 Fusion Reactions

The reactions of interest for fusion power occur when nuclei (ions) of elements of low atomic number are brought together in a plasma, at such temperature (i.e., velocity) as to give the nuclei sufficient speed to overcome the repulsive coulumbic barrier between them (and fuse), thereby transforming a part of their mass into kinetic energy. Because it is most reactive, the reaction generally favored for first-generation fusion plants involves deuterium, tritium, and lithium, in the so-called D-T-Li cycle.

This cycle involves two types of reactions. In the first, deuterium and tritium react to produce an alpha particle (helium-4 nucleus) and a high-energy neutron:

$$\mathrm{D} + \mathrm{T} \rightarrow {}^{4}\mathrm{He} + n$$

The helium-4 ion emerges with an energy of 3.5 MeV, and the neutron with 14.1 MeV.

The second reaction involves the production of tritium by lithium, which is contained in a "blanket" surrounding the plasma. Two neutron-induced reactions are involved in the production of tritium:

$$^{6}\mathrm{Li} + n \rightarrow \mathrm{T} + {}^{4}\mathrm{He}$$

and

$$^{7}\mathrm{Li} + n \rightarrow \mathrm{T} + {}^{4}\mathrm{He} + n \qquad (E_n \gtrsim 7\ \mathrm{MeV})$$

The tritium used in the D + T reaction is thereby regenerated by the lithium reactions in the "blanket" region external to the plasma. The power density produced by this reaction reaches a maximum when the kinetic temperature of the plasma is about 15 keV.

5.4.2 Advanced Fuels

A number of fusion reactions are possible at temperatures of potential interest for fusion (<1 MeV) that involve various light elements through boron. The principal advantages of seeking such "advanced fuels" include elimination of the need to breed tritium, reduced neutron fluxes (to reduce both materials damage and induced radioactivity in vessel and blanket structure), and an increased fraction of fusion energy carried by charged particles (making direct energy conversion attractive). Two general classes of fuels are of interest: deuterium-based and proton-based. Examples of the former include deuterium-deuterium (D-D) and deuterium-helium 3 (D-^{3}He) fusion while hydrogen- (proton)-boron 11 (p-^{11}B) is a frequently cited proton-based reaction. The deuterium-based reactions all involve neutron production to some degree due to D-D reactions whereas p-^{11}B represents a fairly ideal fuel since the primary product is helium ($p + {}^{11}\mathrm{B} \rightarrow 3\alpha$). The supply of hydrogen and boron 11 (from borax) is virtually as extensive as for deuterium; ^{3}He, however, must be bred, either via D-D reactions or through the decay of tritium (12-year half-life). Another potential source of plentiful ^{3}He that has gained considerable attention involves lunar mining. Bombardment of the lunar surface by the solar wind has resulted in the impregnation of the upper crust with a variety of gases, including ^{3}He.

Because of the relatively small fusion cross sections involved and the higher energies (plasma temperatures) required, all of the advanced fuels pose more stringent confinement requirements and offer lower power densities compared to D-T-Li fusion. Consequently, these fuels appear to be candidates for later-generation power plants. Still, the improved environmental compatibility they offer, combined with a significant reduction in neutron damage to structural materials, make this an important long range goal.

5.4.3 Power Production

The major part (about 80%) of the energy released by the D-T-Li cycle is carried by the high-energy neutrons. These, being chargeless, cannot interact with electric or magnetic fields, and hence cannot produce electric power directly. Rather, their power is converted to heat, which is extracted from the lithium blanket by thermal transfer. This heat (like that in fission- and fossil-fueled systems) must be converted to electricity by a thermal system, for example, one employing vapor (e.g., steam) or a working liquid (e.g., potassium).

The remaining 20% of the power generated involves charged alpha particles (helium-4 nuclei). This power remains in the plasma, thus sustaining its temperature. With a p-^{11}B cycle, the charged particle energy could be increased to nearly 100%, making direct conversion a more important avenue for energy extraction.

Energy Breakeven. In nuclear fission, the reaction is neutron-induced and self-sustaining when criticality is reached. In nuclear fusion, on the other hand, the strong mutual repulsion between the positively charged deuterium and tritium nuclei must be overcome to cause them to fuse. To do so, power must be supplied to start and heat the plasma to create reactions. The power derived from the fusion reactions must, of course, exceed the input power. Energy breakeven is the condition at which the fusion energy released just equals the energy input required to heat the plasma to the fusion temperature.

To achieve energy breakeven, the product $n\tau$ of the plasma density n and the time τ during which the plasma is confined must lie within a narrow range for a specific reaction. In the D + T reaction this product (i.e., $n\tau$) must be roughly 10^{14} ions/cm$^3 \cdot$ s (frequently called the "Lawson criterion"). Thus, if confinement is achieved for a few tenths to several seconds (typical of magnetic confinement), the plasma density required lies in the range of 10^{14} to 10^{16} ions/cm^3. If the confinement time is of the order of a thousandth of a microsecond (typical of inertial systems), much higher densities, of the order of 10^{26} ions/cm^3, must be achieved. In all cases, the plasma temperatures must be in the range of 10 to 15 keV.

Power Balance. To obtain useful amounts of power from fusion, not only must the output fusion power meet the conditions for power breakeven and all the other power inputs required by the reactor, but the fusion-released power must exceed this input power by a large amount, the difference being equal to the useful output. The power input to the auxiliaries of the fusion reactor, which heat and confine the plasma, is typically 10%–20% of the total power.

Since useful power output from a fusion reactor can be obtained only when substantial input power is provided, the reactor must be viewed as a power-amplifying device, the degree of power amplification differing according to the plasma-confinement scheme and the design of the lithium blanket, but typically is on the order of a few hundred.

5.4.4 Nonelectrical Applications

In addition to electrical production, fusion reactors can potentially be used for a variety of other important purposes. For example, neutrons from D-T (and other D-based fuels) can be employed very effectively in a fusion-fission hybrid to breed fissile fuel in the blanket region of the fusion device. A unique feature of these hybrids is that very high "support ratios" are conceivable; for example, with some concepts, as much as 20 times the energy production of the fusion plant can be provided in light-water fission plants. Fusion neutrons may also be used in conjunction with fission processes in hybrid systems and to accelerate the decay of fission wastes, that is, providing a fission waste burner. Several methods for chemical production by fusion plants have also been studied. These generally use the penetrating power of the high-energy neutron to create a high-temperature region in the blanket. This then appears well suited to various processes, for example, hydrogen production from water via either high-temperature electrolysis or thermochemical processes. The use of radiation, neutrons, or the plasma itself has also been considered for chemical processing, but this approach is not as straightforward (or as developed) as thermal processing.

Fusion driven propulsion units for deep space missions have also received serious attention. In this case, the fusion heated plasma can be exhausted through a magnetic nozzle to achieve directed thrust. This gives very high exhaust velocities (or high "specific impulses") making fusion propulsion extremely well suited for space missions to Mars and beyond where fast transit times are essential.

5.4.5 Plasma Confinement

The high temperatures and pressures of the fusion reaction preclude the use of a material vessel to confine the plasma during the reaction. Two primary approaches are now under investigation: magnetic and inertial confinement.

In the magnetic confinement scheme, intense magnetic fields are generated in the reactor, oriented with respect to the reaction space such that the plasma ions and electrons experience an inward pressure that resists the outward pressure of the hot plasma.

In inertial confinement, D-T-fueled targets (e.g., small plastic ampules) are bombarded by intense pulsed laser, x-rays, or charged-particle beams. Many beams are arranged to impinge symmetrically on the target from different directions; that is, beams are aimed at a common point at which the target is positioned. Each beam is pulsed and rapidly heats the surface of the target. A very high energy, exceeding a megajoule, is required in each pulse. Typically, each pulse lasts about 10^{-9} s and the pulse rate is about 1/s. The symmetrical heating at the surface of the pellet causes it to ablate. This creates a strong inward force such that the target's interior is compressed. Fusion then occurs at the center and the reaction burns outward. High-energy, heavy ions are considered to be potentially attractive for inertial confinement fusion, the key advantages being the high efficiency of these ion accelerators and improved coupling of the beam energy into the target compared to photons (lasers). Also, the potential for the scale-up of present accelerators to achieve economical, efficient, high-repetition-rate units seems good based on developing accelerator technology.

Magnetic Confinement. The principal means for magnetic confinement is the tokamak. Other approaches include, the reversed field pinch, the spheromak, the tandem mirror, and the stellarator. However, the level of support for research on alternative approaches is only a small fraction of that in tokamaks.

A measure for the performance of the magnetic confinement methods can be expressed by a parameter β, the ratio of the outward plasma kinetic pressure to the inward confining pressure of the magnetic field. This parameter denotes the efficiency of the magnetic confinement; that is, high-β systems make better use of the confining field than do the low-β systems. The parameter β is defined as

$$\beta = \text{constant} \times \frac{n(T_i + T_e)}{B^2}$$

where n is the plasma density, T_i and T_e the ion and electron kinetic temperatures, and B the confining magnetic field strength. High-β reactors are expected to operate with β greater than 0.8, and low-β designs at values below 0.2. The fusion power density varies as the square of β. Tokamaks are generally low-β devices. Spheromaks and reversed-field configurations are examples of high-β devices.

Inertial Confinement. Originally termed "laser fusion" this confinement method focuses a tremendous pulse of energy onto the surface of a sub- millimeter scale target containing fusionable fuel, e.g. D and T. This energy causes the outer layer of the target to be ablated away in "rocket exhaust" fashion. The resulting inward directed force causes compression of the target to ultra- high densities, approaching a thousand times solid density. In the process, compression heating raises the target fuel to fusion reaction conditions. A point is reached where the internal pressure of the hot, high density target just balances the internal compressive force. This results in a "stagnation" point in the inward trajectory of the target radius, followed by a rapid outward expansion. The time associated with this motion around a stagnation point can be viewed as the confinement time, τ. In effect the target dynamics is governed by the inertia of the individual target ions, hence the terminology "inertial confinement fusion". A rough estimate of τ is given by R/υ_{ith} where R is the compressed target radius and υ_{ith} is the average speed of the target ions. Then if R~10^{-6} m and υ_{ith}~10^3 m/sec, τ~10^{-9} sec. While very short, this confinement time proves to be adequate for net energy production.

The key point is that with the very high density, the fusion reaction rate is so large that this time is sufficient to produce more fusion energy than that required for the compression. In addition to lasers, it is now recognized that other pulsed energy sources (termed "drivers") such as x-ray producing Z-pinches and heavy ion accelerators can focus the required energy on these extremely small inertial confinement targets.

Other Confinement Methods. While magnetic and inertial confinement are the most widely considered approaches, a variety of other techniques have (or are being) considered. Examples include high speed acceleration of a target against a "wall" or another projectile, creating "impact" fusion. Electrostatic fields can not confine a plasma in steady state, but if directed ion motion is created, the ion inertia itself prevents directed plasma losses, providing Inertial Electrostatic Confinement (IEC). The replacement of an electron in liquid deuterium or tritium with a muon (i.e. a "heavy electron") results in a much smaller orbital radius for the muionic deuterium atom. This in tern allows atoms to approach each other at shorter distance than normal and thus permits fusion in the liquid (or in effect "cold fusion") without requiring the high ion velocities of a hot fusion. This is termed muon catalyzed fusion. These examples are far from being inclusive but they indicate the "richness" of the field.

5.4.6 Tokamaks

In tokamaks, the plasma-confinement space has closed, toroidal geometry, as shown in Fig. 5-24. A current in the toroidal field coils produces a toroidal field of the order of 100 kG, which confines the

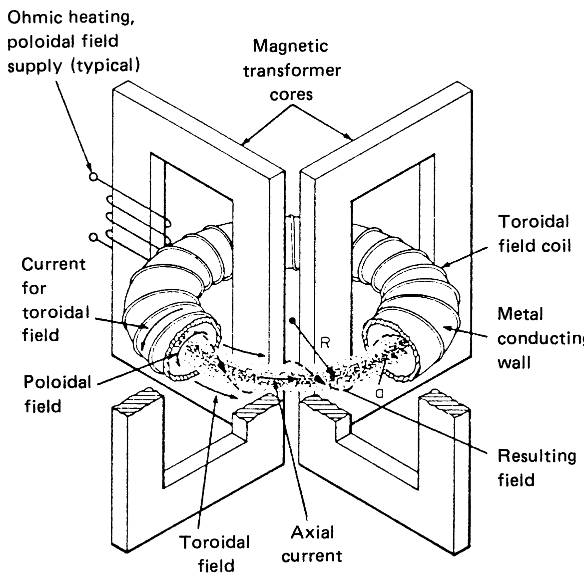

FIGURE 5-24 Elements of the tokamak reactor. Two magnetic fields (toroidal and poloidal) combine to produce a resulting field shown in the dashed line. This field both confines the plasma and causes its ions and electrons to move through the cavity. The ohmic heating of this axial current is one component of the heat required to achieve fusion of the plasma. Additional heating must also be supplied from an external source to maintain the fusion temperature in excess of 100 million degrees Kelvin.

plasma within the toroidal cavity. A second magnetic field, the poloidal field, is produced by external magnetic cores so that this field falls at right angles to the toroidal field everywhere within the cavity. The vector sum of the two fields (dashed line in Fig. 5-24) causes the plasma ions and electrons not only to be confined but to move through the torus, producing an axial current of tens of hundreds megaamperes. The ohmic heating associated with this current is an important source of power input for heating the plasma. However, in a tokamak, ohmic heating alone is insufficient to produce fusion temperatures. Additional plasma heating must be supplied by one of various methods, or combinations of them, such as radio-frequency (rf) heating, adiabatic compression, or the injection of high-energy beams of fuel particles.

A third, transverse, magnetic field is also needed to provide control of the position of the plasma column within the cavity. Additional magnetic coils may be involved to create a magnetic “divertor” which is used to scrape off the outer surface of the plasma and divert it into a “dump” vacuum pump region. The divertor serves three key functions: removal of impurity ions attempting to enter the plasma from the plasma chamber’s wall, removal of fuel and fusion products that diffuse to the outer surface of the plasma, and removal of heat carried by escaping plasma.

When operating in the burn cycle, the kinetic temperature of the plasma is expected to range from 10 to 30 keV; the latter figure is above 300 million degrees absolute. Several large experimental devices, for example, the JET tokamak in England and the TFTR tokamak at Princeton University, have achieved temperatures in the range of 10 keV, and near energy breakeven conditions. In pulsed operation of the tokamak, successive periods of plasma confinement will last several seconds or tens of seconds. The total burn time, prior to purging and reloading the reactor, will be of the order of several hundreds or thousands of seconds. Auxiliary heating power of 10 to 100 MW is required to produce a fusion power output of 1 to 5 GW. Recent studies have concentrated on the possibility of using rf or other techniques to provide a current drive which can ultimately permit steady-state rather than pulsed operation. Deuterium and tritium fuel would be injected at a rate of about 2 to 4×10^{22} atoms/s to provide a density of about 10^{14} ions/cm^3 in a low-β (3% to 10%) tokamak.

device began initial operation in December 1982. Since then, the TFTR has carried out a series of impressive experiments. Objectives have been to obtain improved confinement, a basic understanding and control of instabilities, improved heating and current drive, impurity control, and plasma-wall interactions. These results have been complemented by a number of other major tokamak experiments worldwide. These included D-III (San Diego, USA), JET (Culham, UK), JT-60 (Japan), and T-12 (Russia). A major step in this work involved the study of burning D-T plasmas in both TFTR and JET. This provided valuable experience with a fusion plasma where a major fraction of its heating comes from energetic fusion products (the 3.5-MeV alpha particle in the case of D-T fusion). It also provided experience with safe handling and control of tritium. Then, after several successful campaigns with D-T burns, Congress cut funding for TFTR stating it had met the design objectives. The experiment was then shut down in 1997.

The TFTR employed ~30 MW of neutral beam heating in a device with 12.48-m major radius (R) and a 0.85-m minor radius (a) and an on-axis toroidal field of 5.2 T. It produced plasmas with densities of 10^{13} particles/cm^3, plasma temperatures of 10 keV, and fusion power densities of the order of 1 MW/m^3. The JET experiment is still in operation.

5.4.7 World Facilities for Fusion Research and Reactor Concepts

A large number of both magnetic and inertial fusion research facilities are in operation worldwide. A complete list of institutes, ordered by country, city, and acronym, along with a listing of major equipment and scientific staff, is available from the International Atomic Energy Agency, Vienna (World Survey of Activities in Controlled Fusion Research, 2001 ed.).

Magnetic Confinement Facilities and Concepts

Operational Experience with Large Tokamaks. Extensive operational experiences have been obtained with hydrogen, deuterium, and D-T plasmas in major tokamaks around the world. Two—TFTR and JET—have used D-T plasmas. This experience, plus some data about prior operations, is provided here for these two major tokamak facilities.

TFTR operational experience is described in detail by von Halle (1998) and Johnson (1995).

In April 1997, the TFTR completed its final operating period, bringing to a close a highly successful phase of fusion research. The TFTR produced over 80,000 high-power plasmas since 1982 with the objectives of studying the plasma physics of large tokamaks, gaining experience in the solution of engineering problems associated with large fusion systems, and demonstrating fustian energy production from the burning, on a pulsed basis, of deuterium and tritium in a magnetically confined toroidal plasma system.

In 1993, TFTR became the first magnetic fusion device to study plasmas using nearly equal concentrations of deuterium and tritium. Since that time, over 1000 D-T experimental shots and over 23,000 D-D shots were carried out, demonstrating new regimes of plasma confinement, proof of alpha heating, and reactor-level fusion power densities by producing a plasma that yielded over 10 MW of fusion power at a corresponding central fusion power density of approximately 2.8 MWm^{-3} (Nazikian 1996, Bell 1997).

The TFTR technical systems routinely operated at or beyond the original design criteria throughout the period, maintaining an impressive machine availability of $>85\%$. This success continued through the final night of operations when a plasma with a record 7.7 MJ of stored energy was attained.

An important additional contribution from this work was the demonstration of safe operation of the tritium systems, with over 950 kCi of tritium processed within the constraints of a 50-kCi site limit and a 20-kCi machine limit. The tritium purification system "closed the loop" on the TFTR fuel cycle during the final operating campaign, processing >50 kCi of tritium at $>95\%$ purity back to the tritium storage and delivery system U-beds for further use on TFTR experiments.

JET operational experience is outlined by Bertolini and The JET Team (1997). JET started operation in June 1983, as the largest tokamak experiment of the coordinated fusion research program of the European Union. The global objective of JET was to produce and study plasmas of thermonuclear grade, in configurations suitable for extrapolation to a reactor. This led to the early choice of machine parameters with D-shaped toroidal coils, vacuum vessel, and plasma cross section. Great flexibility and suitable stress margins were included in the original JET design, to allow modifications and/or upgrading of the machine to follow the rapidly evolving requirements of the physics program (Keilhacker and The JET Team 1997).

Two major interventions took place between 1986 and 1989. The first involved increasing the plasma current capability from the design value of 4.8 to 7.0 MA in limiter configuration and from 3.0 to 5.0 MA in the *X*-point configuration. This work involved revising the design of the toroidal and poloidal coils, of the mechanical structure and of the vacuum vessel, by detailed finite element computer modeling and calculations, and fatigue tests on the prototype toroidal coil. Moreover, new power supplies had to be provided and plasma control also had to be improved, to cope with the enhanced vertical instability of the plasma ring. This upgrading was generated by initial experimental results, which showed a sharp decay of the energy-confinement time with heating. This could be counteracted by increasing the plasma current and by setting up an *X*-point configuration, which allowed H modes to be established.

The second change required progressively covering the inconel vessel walls with low-*Z* materials, specifically, graphite tiles ($Z = 6$) and later beryllium tiles ($Z = 4$), supplemented at first by wall carbonization and later by beryllium evaporation. This intervention was prompted by the need to substantially reduce Z_{eff} in order to decrease radiation losses.

At this point, the JET plasma could be maintained for only about 1 s, limited by a combination of MHD instabilities and accumulation of impurities in the *X*-point region. Active control of the impurities was therefore required, and was achieved by installing a pumped divertor to control impurity level and particle and energy exhaust and to enhance plasma energy confinement in H mode (Bertolini 1995). This represents the third major upgrading of the JET tokamak. The original features of the JET design allowed the basic structure of the machine to be maintained (viz., toroidal and poloidal coils, mechanical structure, and vacuum vessel). However, the necessity to install the divertor coils inside the vacuum vessel produced a loss of about 25% of the plasma volume, but it allowed plasma currents up to 6 MA to be accommodated.

Three divertor configurations (Mark I, Mark II, and Mark III Gas Box) have been designed, with progressively more closed configuration to enhance particle and impurity retention in the divertor chamber and to increase the amount of plasma energy released by radiation. The results of JET divertor studies are of great importance to finalize the ITER divertor design.

The full implementation of these measures led to the development of the hot-ion regime, showing a spectacular increase in overall plasma performance. The fusion triple product improved from

0.12 to 0.9 × 10^{21} m^{-3} (s · keV) and the equivalent energy gain Q_{DT} increased from 0.01 to 1.07. In separate pulses, an ion density of $n_D \sim 4 \times 10^{20}$ m^{-3}, an ion temperature T_D ~30 keV, and an energy-confinement time of $\tau_E \sim 1.8$ s, were obtained.

Finally, a $Z_{eff} \leq 2$ and a dilution factor $n_D/n_e \geq j0.9$ were reached. This level of global plasma parameters was sufficient to perform the first ever D-T experiment, which, in spite of using a mixture far from optimum (11% T–89% D), achieved a peak fusion power of 1.7 MW with >50% of thermalized neutrons, and a fusion energy of 2 MJ (The JET Team 1992). The additional heating power has been progressively increased up to 50 MW (20 MW of neutral beam injection, 20 MW on ion-cyclotron resonance heating, and 10 MW of lower hybrid). These results of internal plasma-wall components, especially the divertor, are under way with a new D-T experimental campaign planned for fall 1999 (The JET Team 1995).

A recent series of experiments with deuterium-tritium plasmas (DTE1) are of particular importance for fusion reactor developments (Stork and The JET Team 1997). These are the first plasma experiments with a 50:50 D-T mixture in a tokamak with a divertor.

Extensive work was undertaken to ensure that the JET machine and its major subsystems were able to safely carry out an extended period of D-T operation (Hemmerich 1989). This included adding the JET active-gas-handling system (AGHS) and its commissioning to full closed-cycle operation. As of 1998, the AGHS supplied around 40 g of tritium to the JET torus and neutral-beam injectors (NBIs) and reprocessed batches of tritium of over 11 g returned from the cryopumps of the torus and NBI.

Several modifications were required to bring the NBI system to full tritium compatibility (Stork and the JET Team 1997). The injection of tritium beams at energy up to 155 kV and total power of up to 11.3 MW has taken place.

Prior to D-T operation, JET was subjected to extensive deterministic analysis of design-basis accidents (DBAs) to establish changes required to protection systems and to satisfy the regulatory authorities.

A planned intervention to repair a small water leak in the tritium neutral injector was successfully undertaken during these operations (Stork and the Jet Team 1997). The exhaust detritiation system (EDS) was effective in keeping environmental discharges to below management limits throughout operations.

Other Major Tokamak Experiments. Although not all-inclusive, this section indicates the status and diversity of tokamak research worldwide.

The JT-60 tokamak, located at the Naka Fusion Research Establishment, Ibaraki-ken, Japan, is one of the world's largest tokamak experiments (Neyatani and The JT-60 Team 1995, Sakasai and The JT-60 Team 1997). To extend the earlier results from JT-60U, a superupgrade design (JT-60SU) has been developed. It has a superconducting toroidal field and poloidal field coil system with a pulse length of 2000 s or more. Figure 5-27 compares cross-sectional views of JT-60SU and JT-60U.

Typical operation parameters are shown in Table 5-7. The physics goal is a simultaneous achievement of stable steady-state full current drive plasma with high confinement and high bootstrap current fraction, together with a dense, cold, radiation-divertor function in reactor-relevant conditions.

For steady-state physics, the pulse length is set to exceed than 2000 s, which is sufficiently longer than the characteristic times of the particle saturation of the wall (30 to 60 s), current diffusion (100 to 400 s), and first-wall temperature (500 to 1000 s). Establishment of integrated physics, technology, and engineering for long-pulse operation under steady-state reactor-relevant conditions is also important for future steady-state reactors, such as developing superconducting coils, and high-heat-conductive secondary gamma-ray shielding. Progress in high-performance and steady-state experiments on JT-60U during 1995 to 1997 is summarized as follows:

> JT-60U research on the steady state with high fusion performance focused on contributions to ITER physics R&D. Experiments on negative-ion-based neutral beam injection (N-NBI) indicated a high neutralization efficiency of 60% at 370 keV and a high current drive efficiency of $\eta_{CD} = 8 \times 10^{18}$ $m^{-2} \cdot$ A/W.
>
> Toroidicity-induced Alfvén eigenmodes (TAE modes) excited by N-NBI were observed for the first time. The divertor was modified from the open divertor to the W-shaped pumped divertor in February to May 1997.

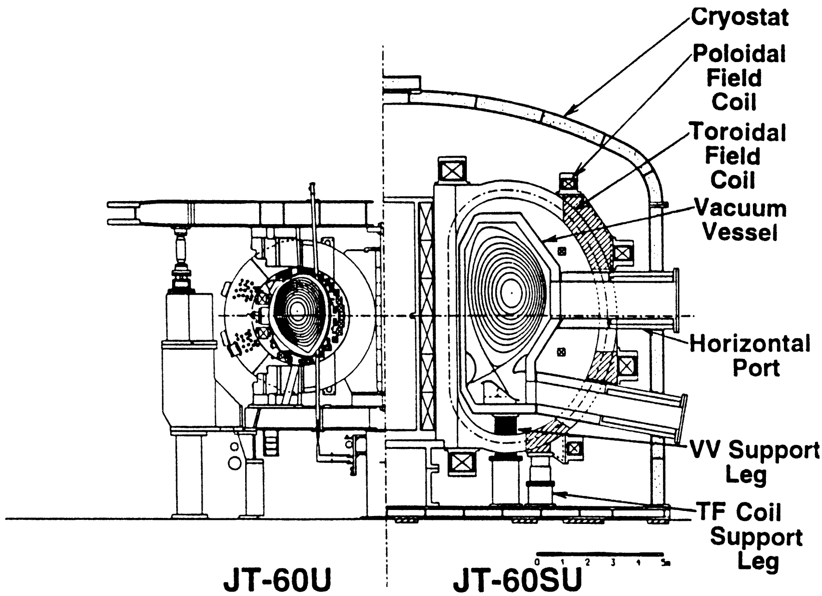

FIGURE 5-27 Cross-sectional views of JT-60SU and JT-60U.

In the new pumped divertor, radiative divertor by neon and deuterium injection with high recycling enhanced the divertor radiation with helium pumping in ELMy H-mode discharges.

Halo current was measured in the new divertor, and a new database was added for ITER. A high equivalent Q_{DT} of 1.05 was achieved in high-performance reversed magnetic-shear discharge.

Quasi-steady reversed-shear plasma with internal transport barrier and H-mode edge was sustained for 4.3 s. High-triangularity shaping was effective for improvement of the giant ELM limit and β_N. Steady-state high performance in the ELMy H mode was sustained for 9 s with the new divertor.

The DIII-D Tokamak. The mission of the DIII-D national program, centered at General Atomics in San Diego, Calif., is to establish the scientific basis for the optimization of the tokamak (Calis et al. 1989, Petersen and The DIII-D Team 1997). The research is carried out in four areas—transport, stability, boundary, and current drive and heating—in collaboration with a large number of national and international collaborators. The main goal is to optimize the performance of the tokamak through active control of the plasma shape and the plasma profiles. In the transport area, the emphasis has been on the study of the role of internal transport barriers in improving confinement. In the stability area, the emphasis has been on the study of neoclassical MHD, resistive wall stabilization, density limits, and disruption characterization and mitigation. In the boundary area, the emphasis has been on developing understanding of radiative divertor physics and the initiation of the new radiative

divertor, and in the current drive and heating area on the preparation of two 110 GHz gyrotrons. These areas will be discussed in more detail in the following sections.

This research program utilizes the DIII-D tokamark (Fig. 5-28), which is a midsized device operating at near-reactor-level plasma parameters. It has a D-shaped cross section with an aspect ratio of 2.5:1 and a major radius of 1.6 m, and is capable of producing a large variety of plasma shapes, including elongation up to 2.6 and triangularity to 1.0. The maximum toroidal field on axis is 2.1 T, and the maximum plasma current is 3 MA. The shaping flexibility is due to the 18 fielding shaping coils that are located close to the plasma and individually controlled. A divertor baffle and a cryopump are installed above the floor and at the ceiling of the DIII-D vessel to allow study of divertor physics and control the plasma density. The auxiliary heating of the plasma is provided by eight neutral beams producing 20 MW at 80 kV in deuterium, 1.5 MW (source) of 110 GHz electron cyclotron heating, and 6 MW (source) of fast-wave current drive.

More than 50 different diagnostics are used to probe the DIII-D plasma. The Thomson scattering system measures the electron temperature and density every 2 ms at 40 different locations including the divertor region. The rotational Stark effect diagnostic measures the local pitch angle of the magnetic field, and thereby of the plasma current density, and the radial electrical field. The charge exchange recombination diagnostic measures ion temperature, poloidal and toroidal rotation, impurity density, and radial electrical field. There are several diagnostics that measure fluctuations (beam emission spectroscopy, far infrared scattering, etc.). A digital control system is used to control the plasma shape, current, and density and the injection of auxiliary heating power.

Increasing electron cyclotron heating (ECH) has high priority. With the successful testing of the two gyrotrons and development of new diamond windows, it appears that long-pulse gyrotrons are now available. The ECH power will be used for current profile control, perturbation studies, and transport barrier control. An extension of the DIII-D pulse length can be obtained by installing a new return bus for the toroidal coil, with minor upgrades of the field-shaping coil supplies. A longer tokamak pulse duration is important for stability studies, extension of the advanced tokamak mode, and wall stabilization. Upgrade of the Thomson scattering system to include a central cord is important for transport and neutral density measurements, understanding of disruptions, and to aid active mode control of neoclassical MHD modes. The top divertor will be completed with inner and private flux baffles, which should help reduce core fueling of neutrals and thereby improve confinement and increase the electron temperature for a more efficient current drive. Later, the lower divertor will be upgraded for advanced tokamak operations.

Tore Supra. Among the large tokamaks in operation around the world, Tore Supra (Centre d' études de Cadarache, France) has the unique feature of a superconducting magnet which provides a permanent toroidal field. With its niobium-titanium coils operating at 1.8 K, the Tore Supra toroidal field is routinely set up for 4-T/(12-h/day) operation. Its main research directions are therefore concentrated on the control of multimegawatt plasmas during long duration, with the steady state as ultimate goal, ultimately involving steady-state operation of a large tokamak (R = 2.4 m, a = 0.8 m, I_p = 1.7 MA). Both lower hybrid and fast waves are used to drive the current. Enhanced performances related to current profile shaping have been intensively studied (Martin 1997). Consequently, the Tore Supra inner vessel is equipped with several water cooled elements which interact with the plasma to allow injection of several megawatts during several tens of seconds. A world record in injected energy was achieved in 1996 with 280 MJ during a 2-min shot. Very long evolution times were then put in evidence in plasma wall interaction physics.

On the basis of these results, an enhancement in the capability to handle large input powers and control the particles over long duration is now under way. This is the main motivation for the Composants Internes et Limiteur (CIEL) project, which consists mainly in an upgrading of the first wall components:

1. A new toroidal belt limiter in the lower part of the vessel, made from carbon fiber composite (CFC) brazed on copper tubes. This has been designed to remove continuously up to 15 MW of convective power.

2. A set of pumps to evacuate all types of gas species through the toroidal throat of this limiter, allowing improved density control.

3. A new water-cooled radiation screen to cover as much as possible of the inner vessel, to avoid uncooled parts interacting with the plasma.

The Alcator C-Mod Tokamak. The Alcator C-Mod, located at MIT, Cambridge, Mass., is a high-field, high-particle and high-power-density advanced divertor tokamak. It is one of the only five divertor experiments capable of plasma currents exceeding 1 MA. The primary research goals of the experimental program involve divertor research with reactor grade parameters, critical tests of both empirical and theory-based scaling laws for transport, and rf heating and current drive and their application to advanced tokamak research. Figure 5-29 shows a side view of the machine. Note that Alcator C-Mod is enclosed inside a cryostat so that the magnets can be cooled with liquid nitrogen (LN_2) to nearly 77 K. The liquid is circulated through the magnets and then drains back to a 300-ga sump, where it is recirculated.

The C-Mod vacuum vessel, unlike most other tokamaks, is used as a structural element designed to support the OH and EF coils. Since thick stainless steel construction is required, large currents can therefore flow. However, these currents have been successfully compensated for by the control system combined with an excellent set of magnet diagnostics. Table 5-8 lists some of the machine parameters currently obtained and also those expected over the next few years as upgrades are made to the first-wall hardware and rf systems are added.

KSTAR Tokamak. The KSTAR (Korea Superconducting Tokamak Advanced Research) project (Choi et al. 1979) is the major effort of the Korean National Fusion Program to design, construct, and operate a steady-state-capable superconducting tokamak. The project is led by Korea Basic Science Institute and shared by national laboratories, universities, and industry along with international collaboration. The key design features of KSTAR are major radius 1.8 m, minor radius 0.5 m, toroidal field 3.5 T, plasma current 2 MA, and flexible plasma shaping (elongation 2.0; triangularity 0.8; double-null poloidal divertor). Both the toroidal and the poloidal field magnets are superconducting

coils. The device is configured for upgrading for up to 300-s operation with noninductive current drive (Table 5-9).

The auxiliary heating and current drive systems consist of neutral beam, ICRF, lower hybrid, and ECRF. Deuterium operation is planned with a full radiation shielding. The KSTAR operational program is staged into two phases: the baseline and the upgrade. In phase I (2002 to 2005), inductively driven 20-s operation with the baseline auxiliary system (15 MW) is to be conducted, whereas 300-s operation with an upgraded auxiliary system (40 MW) for full noninductive current drive at high-beta regimes is planned for phase II (2006 to 2010).

The International Thermonuclear Experimental Reactor (ITER). The next major step expected in tokamak development has involved a massive international design effort. At the invitation of the director general of the IAEA, representatives of the world's four major fusion programs met in 1987 and developed a detailed proposal for a joint venture called the Conceptual Design Activity (CDA) for the proposed International Thermonuclear Experimental Reactor (ITER). The Director General then invited each interested party to cooperate in the CDA in accordance with the terms of reference developed at the meeting.

The ITER CDA, under the auspices of the IAEA, began in April 1988 and was successfully completed in December 1990. This work included two phases, the definition phase and the design phase. In 1988, the first phase produced a concept with a consistent set of technical characteristics and preliminary plans for coordinated R&D in support of ITER. The design phase produced a conceptual design, a description of site requirements, a preliminary construction schedule and cost estimate, and an ITER R&D plan. At the end of the design phase in 1998, however, global financial conditions forced a delay in the decision to proceed with construction of ITER. A reduced-size study produced a design for a smaller version at about half the cost.

The ITER design is based on a scientific knowledge base derived from the operation of dozens of tokamaks worldwide over the past decade. It also relies on the technical know-how flowing from the extensive fusion technology R&D programs of the four parties. The ITER tokamak is shown in Fig. 5-30. The principal parameters of the reduced-size version are listed in Table 5-10.

The main characteristics and parameters of ITER follow from its technical objectives which were derived to meet well-defined programmatic goals. Ignition requirements set the value of plasma current. Extended burn favors superconducting coil systems. The design goals for the first wall fluxes and fluence both dictate approximately the same minimum shield thickness. These requirements, combined with considerations of plasma stability, impurity control, and current drive, define the general features and approximate size of ITER. Nevertheless, within the freedom allowed by the technical objectives, the design philosophy has been to control size and minimize cost. Moreover, safety considerations are an integral part of the design activities.

The CDA defined both physics and technology R&D conducted in the various laboratories of the parties designed to validate the technical basis for the design. The physics R&D studies placed emphasis on reducing uncertainties in the divertor performance and energy confinement, extending the burn duration with noninductive current drive, and avoiding disruptions. The main categories of the technology R&D activities involved superconducting magnets, plasma-facing components, nuclear blankets and shields, remote maintenance, fueling systems, and heating and current drive systems.

The EDA phase lasted for 6 years and culminated in a well-documented basis for a decision on construction and siting. Construction would require about 8 years, followed by two "phases" of operation (physics and technology) totaling about 18 years, after which decommissioning would commence.

The EDA work involved about 1200 professional worker years with a team whose strength peaked at about 180 professionals. The cost of this design work, including full overhead and support personnel, was about $250 million.

The professional workerpower needed during the construction activities has been estimated to be about 2900 worker-years, primarily at the construction site. The actual construction cost of ITER has been estimated to be about $4.9 billion. During the construction phase, technology R&D would be needed (estimated to cost about $300 million). The cost of physics R&D directly attributable to ITER should be added to these costs, but this is difficult to separate out from generic fusion R&D in progress at the same time.

A central team of 300 professionals would be needed during the operation activities, including physicists and engineers, to operate the machine and supervise the testing program. The resulting

preliminary operating cost estimates amount to about $270 million per year. The cost of the experimental part of the ITER program would be in addition to this basic operational cost. Decommissioning costs have not been estimated.

In conclusion, the ITER project has been a pioneering program in both technology and international collaboration. The goal for ITER has been to provide the basis for a demonstration reactor intended to open the way to commercialization of fusion power through the "tokamak route." Proponents of alternative magnetic confinement approaches and inertial confinement fusion (ICF) have been critical of the size and cost of ITER. They propose alternative approaches which they claim are more attractive and faster to develop. However, the extensive worldwide effort on tokamaks combined with the large experimental database accumulated from the many tokamak experiments carried out thus far have provided the tokamak with the lead in this development to date.

ITER construction is scheduled for 2006 with initial operation in 2014. Two sites have been proposed, one in France and the other in Japan.

Alternative Magnetic Fusion Concepts. Table 5-11 summarizes a representative cross section of alternative fusion concepts (AFCs) that, in one way or the other, have been or are being considered for the production of electrical power, chemical process heat, and/or fissile material. Depending on the confinement scheme considered, systems studies of AFCs range from a simple physics analysis, based on Lawson-like criteria, to detailed conceptual designs. With few exceptions, most reactor studies of alternative concepts fall into the less formalized part of this spectrum. For this reason, a quantitative intercomparison and ranking is not possible.

The toroidal AFCs summarized in Table 5-11 are classified as quasi-steady-state, long-pulsed (10 to 100 s), and pulsed (~1 s). A sampling from each category is given.

National Spherical Torus Experiment (NSTX). The National Spherical Torus Experiment (Fig. 5-31) is designed to prove the scientific principle of the spherical torus (ST) plasma. The ST plasma is nearly spherical in shape; its minor radium is slightly smaller than its major radius, thus giving an aspect ratio close to 1. ST plasmas may have several advantageous features such as a higher pressure for a given magnetic field. Since the fusion power density is proportional to the square of the plasma pressure, the ST is an example of an innovative alternative fusion concept that could lead to smaller and more economical sources of fusion energy.

Princeton Plasma Physics Laboratory (PPPL) leads the project and operates the NSTX facility, located at PPPL. The design and construction of the NSTX is a joint project of PPPL, the Oak Ridge National Laboratory (ORNL), Columbia University, and the University of Washington. The NSTX will have modular components for ease of repair and upgrade.

A national research team will carry out the research program on NSTX, which will cover a broad range of fusion and plasma science topics. The ST plasma possesses features of tokamak and spheromak plasmas, as seen in Fig. 5-32. The magnetic-field line of the ST plasma resembles that of the tokamak plasma at the stable, inboard side and that of the spheromak at the unstable, outboard side. This leads to a number of attractive physics features of interest to fusion energy science, estimated according to our present understanding in toroidal fusion science. These include

- MHD-stable plasmas with very high average toroidal beta (plasma pressure divided by externally applied toroidal field pressure at the major radius) in the range of 25% to 50%.
- Nearly complete (greater than or equal to 90%) alignment of self-driven current profile with the required plasma current.
- Strong magnetic shear and magnetic well (~30%), which help stabilize plasma microinstabilities believed responsible for plasma turbulence and rapid energy loss.
- Increased flow shear (by up to two orders of magnitude beyond tokamaks), which tends to suppress the remaining plasma microinstabilities.
- High plasma dielectric constant that permits a new class of potentially efficient rf-heating and current drive techniques, such as the high-harmonic fast wave and the electron cyclotron wave conversion to electron Bernstein wave.

These interesting features indicate great opportunities for discovery, innovation, and advancement in fusion and plasma sciences. If verified, the ST plasma will open up new opportunities for attractive applications of magnetic fusion using compact devices.

Figure 5-33 indicates how the ST plasma, given successes in proof-of-principle and proof-of-performance tests, could lend itself to a pathway for developing fusion power.

The NSTX effort grew from successful pioneering experiments conducted worldwide since 1991. These include the START (small tight-aspect-ratio tokamak) at the United Kingdom Atomic Energy Authority-Fusion, UK; the CDX-U (current drive experiment—upgrade) at PPPL; the HIT (helicity injected tokamak) at the University of Washington; the TS-3 (Tokyo Spheromak-3) at the University of Tokyo, Japan; and the SPHEX (spheromak experiment) at the University of Manchester Institute of Science and Technology, UK.

The data from these experiments have shown that the ST concept is ready for proof-of-principle tests. The NSTX is one of the new generation of experiments for this purpose. Other experiments include the MAST (megaampere spherical tokamak) at the United Kingdom Atomic Energy

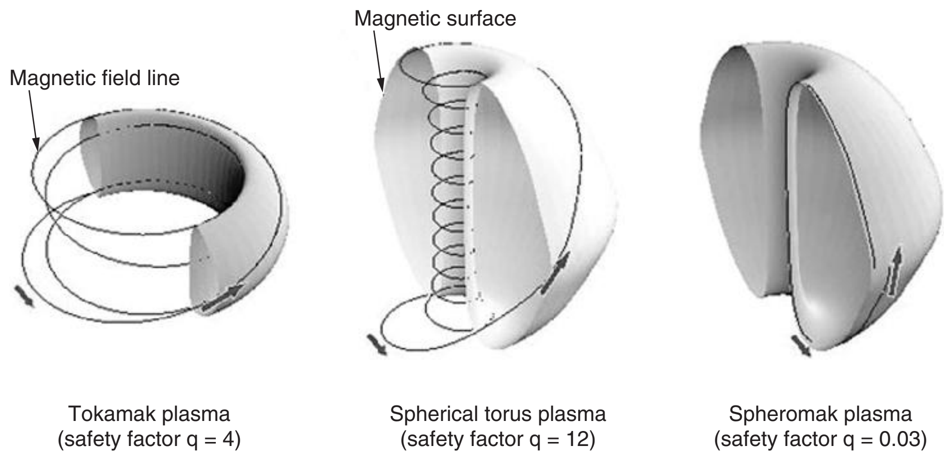

FIGURE 5-32 Spherical torus plasmas combine advantageous features of tokamak and spheromak plasmas.

Authority-Fusion, UK; the GLOBUS-Modified at the Ioffe Physical Technical Institute of St. Petersburg in the Russian Federation; and the Pegasus at the University of Wisconsin. These began experimentation during the second half of 1998.

These experiments will have strong complementary capabilities, and when combined, will permit investigations for plasma currents in the range of 1 MA, stability, toroidal β limits approaching

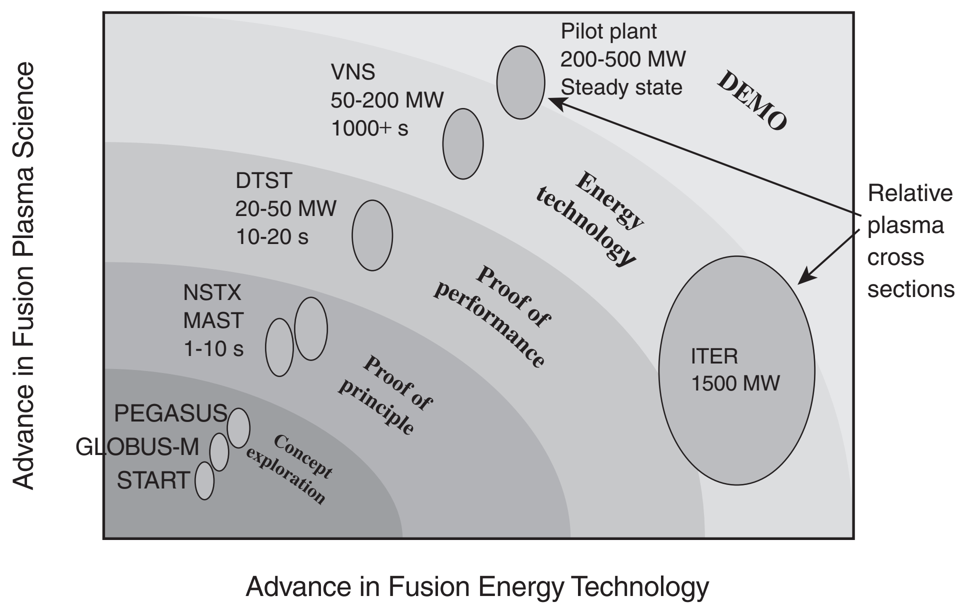

FIGURE 5-33 Schematic diagram of fusion science and technology advances.

50%, bootstrap currents approaching 90% of the plasma current, aspect ratios as small as 1.1, elongation as high as 4, and duration up to 5 s.

Plasma-heating and current-drive techniques to be tested cover neutral-beam injection, a full range of rf waves, and the more exotic noninductive start-up techniques.

The NSTX Research Program will investigate the fusion science principles of the ST plasma, covering

- Noninductive start-up, current sustainment, and profile control
- Confinement and transport
- Pressure limits and self-driven currents
- Scrape-off layer and divertor physics
- Stability and disruption resilience

These principles will be investigated in the scientifically interesting regimes that are relevant to near-term applications such as volume neutron sources (VNS) and fusion pilot and power plants of the future. Thus, the following regimes will be stressed:

- High average toroidal betas (25% to 45%)
- High pressure-gradient-driven current fractions (40% to 90%)
- Fully relaxed, noninductively sustained current profile
- Collisionless plasmas with high temperatures and densities
- Aspect ratios (major radius over minor radius) as small as 1.25 and elongation above 2

The NSTX device (Fig. 5-31) is designed to operate with the baseline parameters in Table 5-12 for plasmas with several forms of divertor and limiter configurations. The NSTX facility shall deliver to the plasma and handle the following power for start-up, heating, and current drive:

- 6 MW of high harmonic fast wave (HHFW) for up to 5 s
- 2 MJ of coaxial helicity injection (CHI) during 5 to 10 ms
- 20 kA of CHI injected current for up to 5 s
- 20 kW of electron-cyclotron heating (ECH) for up to 5 ms

The NSTX facility design will further account for the possibility of adding and handling 400 kW of ECH for up to 100 ms for noninductive start-up and 5 MW of neutral-beam injection (NBI) for up to 5 s for additional heating and current drive. The center stack of NSTX is highly compact to permit a plasma aspect ratio of as low as 1.25. It contains the inner legs of the toroidal field coils, a solenoid to provide full capability for inductive operation, a pair of poloidal field coils most effective in varying the plasma triangularity, the inboard vessel wall containing these components, the protective

graphite tiles, and the interface to the remainder of the device. The center stack is designed to be replaceable without affecting the rest of the device.

The vacuum vessel is 3.6 m in height and accommodates a plasma elongation of up to 2.2 and a triangularity of up to 0.6 for an aspect ratio of 1.25; a higher elongation of about 3 can be obtained for an aspect ratio of 1.4 by operating plasmas with a reduced minor radius.

Auxiliary heating and current drive for current profile control address another essential part of the NSTX mission. High harmonic fast-wave operation is expected to effectively accommodate the high-beta and high-bootstrap-current fraction plasma discharges and fully utilize rf power sources available on-site. A conducting shell, also protected by graphite tiles, will be placed near the outboard plasma edge to enable the investigation of maximized MHD stability limits in plasma beta and bootstrap current.

Mirrors. Mirror-type fusion reactors are characterized by open magnetic-field geometries; that is, magnetic flux passes through a mirror-type device and intersects material walls outside the reaction chamber. In order for such a device to be an adequate container of fusion plasma, it is essential that the end leakage of the plasma be strongly inhibited.

The earliest magnetic mirror configuration used a solenoid with increased magnetic-field strength near its end (Fig. 5-34). In this "simple" mirror, a charged particle travels in a helical orbit around an axially directed magnetic-field line. When traveling into a region of increasing magnetic-field strength, most particles are reflected, that is, their axial motion is stopped and reversed before they can penetrate to the high point of the mirror field. (Some particles with highly directed velocity may still escape. Strong magnets can reduce this leakage, but it cannot be completely eliminated.)

The plasma in a simple mirror is unstable to sideways motion because the magnetic field weakens in directions perpendicular to the coil axis. (The radial weakening of field is evidenced by the concave-inward surface of the magnetic flux bundle.) To solve this stability problem, the simple mirror configuration was replaced by the minimum-*B* mirror. From the center of this field—produced by a pair of

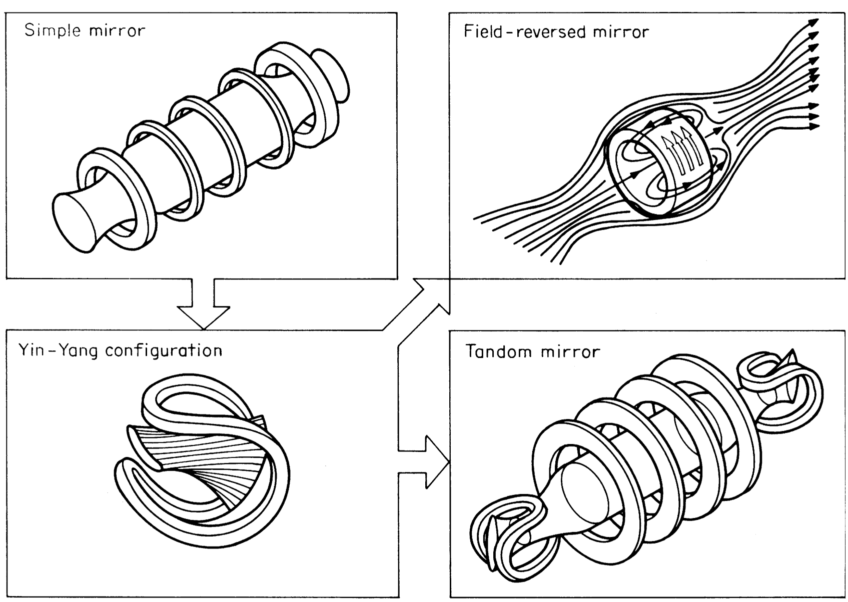

FIGURE 5-34 Evolution of mirror confinement concepts. The field-reversed mirror uses an internal ion ring (created by injection and by diamagnetic currents) to effectively create a torus configuration embedded inside the open mirror field. The tandem mirror uses electromagnetic fields created by ion injection to reduce the leakage from the ends of a solenoidal field.

solenoids and Ioffe bars, a baseball coil (shown in Fig. 5-34), or yin-yang coil—the field strength increases in all directions. However, by 1975, it was concluded from conceptual design studies of mirror reactors based on the minimum-B geometry that end losses from such a reactor would severely limit its plasma Q (fusion power divided by trapped injected power). The subsequent search for enhanced-Q mirror machines led to two new concepts: the field-reversed mirror and the tandem mirror.

In a field-reversed mirror (FRM), the confinement of plasma occurs through a toroidal region of closed magnetic-field lines generated by plasma currents in a nearly uniform background field (Fig. 5-34). The FRM offers the exciting possibility of fusion electric power reactors in small sizes. For example, conceptual design studies were carried out for both a multicell reactor producing 75 MW (electric) of net electric power and a single-cell pilot reactor producing ~11 MW (electric). However, following a series of initial experiments at the Lawrence Livermore National Laboratory (LLNL) that failed to build up sufficient plasma current for reversal, most of the LLNL effort shifted to the tandem mirror.

The tandem mirror confinement concept, invented in 1976, received strong study until cancellation of the U.S. program in 1985. The basic concept entails the improved axial confinement of a long cylindrical fusion plasma within a solenoid by means of strong electrostatic potentials at the ends, produced by mirror-confined, end-plug plasmas (Fig. 5-34). An improvement in the tandem mirror involved use of a *thermal barrier*. This concept uses enhancement of the confining electrostatic potential to establish a hotter electron population in the plugs than in the central cell. However, in the normal operation, electron flow between the plugs and central cell presents large temperature differences. Thus, a thermal barrier is necessary to reduce the passing of central-cell electrons into the plug. Basically, the thermal barrier consists of a region of much reduced magnetic field strength, plasma density, and plasma potential. This causes a depressed positive plasma potential which serves as an electrostatic barrier to electrons.

In order to maintain the thermal barrier, however, it is necessary to prevent the filling of the barrier region by thermal ions leaking from the central cell. Several methods of "barrier pumping" have been investigated. In one, the pumping is accomplished by trapped ions undergoing charge exchange interactions with axially directed neutral beams.

A preliminary conceptual design of a power reactor based on the tandem mirror has been carried out, including use of thermal barriers. The D-T fusion plasma is contained in the 56-m-long central cell and produces 1770 MW of fusion power. With $Q \simeq 10$, the reactor produces ~500 MW of net electricity. The central cell consists of twenty-eight 2-m-long modules, each containing an annular blanket region, a magnetic shield region, and two niobium-titanium solenoidal magnets. The entire central cell resides in a vacuum trench, which allows the module-to-module seal to be made by an annular metal inflatable cushion. The plug plasmas, contained in the plug yin-yang coils, are each sustained by a low-current, 400-keV neutral beam. A gyrotron tube system is used for microwave heating of the electrons on the plug side of the thermal barrier. Neutral beams on the end wall of the plug vacuum vessel provide charge-exchange pumping of the barrier and fueling of the central cell.

Advanced Toroidal Systems. Various "advanced" toroidal confinement systems are under active study. The spherical tokamak directed earlier represents one approach. Others include the stellarator, (and torsatron) and the helitron.

Stellarator-Torsatron. Unlike the tokamak, the nonaxisymmetric stellarator achieves equilibrium in a toroidal geometry by externally inducing a rotational transform in the confining magnetic field (Fig. 5-35); ideally, no axial currents need to be supported by the toroidal plasma column, as is required in a tokamak, although until very recently all stellarator experiments utilized such currents for ohmic heating. Implementation of a deformation (twist) into a simple toroidal field coil set allows the Torsatron magnetic geometry to be produced while eliminating the helical coil set in favor of a highly modular device (Fig. 5-36). In addition, more optimally oriented coil forces and lower stresses are anticipated for this modular Torsatron approach. These new advances have renewed interest in the reactor extrapolation of the stellarator-Torsatron concept, a renaissance that coincides with experimental success in heating a low-ohmic-current device, the latter being a prerequisite for eventual steady-state reactor operation.

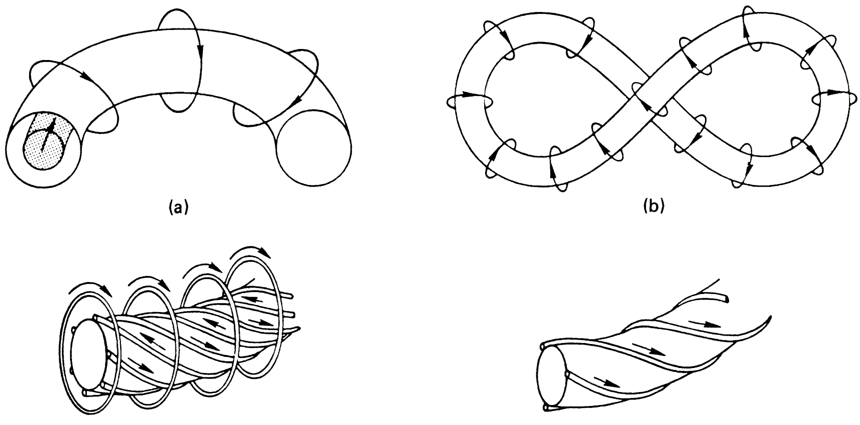

FIGURE 5-35 Toroidal configurations. (*a*) Tokamak: the main magnetic field is provided by poloidal coils with the poloidal field due mainly to a toroidal current in the plasma. Several external toroidal coils (which are not shown) provide a vertical magnetic field as well as drive the plasma current. (*b*) Figure-eight stellarator: only one set of solenoidal coils is needed. The rotational transform is generated by the torsion of the magnetic axis. (*c*) Classical stellarator: a set of 2*l* helical coils with current flowing in opposite directions inside the toroidal field coils provides the rotational transform. (*d*) Torsatron: a single set of *l* helical windings provides both the toroidal and poloidal fields. Usually, an additional set of toroidal coils (which are not shown) is necessary to provide an additional vertical field. The standard heliotron configuration is similar to this, but has an additional set of toroidal field coils.

Qualitative advantages that can be invoked for the Torsatron reactor concept include steady-state magnetic fields and burn, operation at ignition or high Q for low recirculating power, impurity and ash removal by means of a magnetic limiter and helical poloidal diverter that occur as a natural consequence of the topology, and no major plasma disruptions that could lead to an intense, local energy dump and no auxiliary position or field-shaping coils and moderate aspect ratio (>10), both of which ease maintenance access.

Stellarator Experiments. Next to tokamaks, the largest worldwide effort in magnetic fusion is focused on stellarator (Boozer et al. 1998, Wakatani 1998). The stellarator concept offers a potentially attractive alternative to the tokamak approach in magnetic confinement fusion. The magnetic field structure, which is required for equilibrium and stability of the confined plasma, is generated by external coil currents only and has an inherent steady-state capability. The rotational transform is generated in the classical approach by helical windings surrounding the plasma vessel. Plasma confinement under net current free operation has been demonstrated in experiments at Garshing, Germany. The net current free operation avoids disruptions.

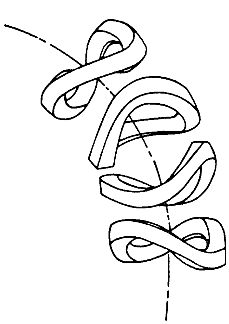

FIGURE 5-36 Coils in a typical modular stellarator.

Two small experiments are located in the United States; HSX at the University of Wisconsin and CAT at Auburn University (major radii of 1.2 and 0.5 m, respectively). Two new major stellarator experiments: LHD and W7-X will provide integrated tests of particular stellarator configurations using superconducting coils. Divertor, transport, and β-limit issues are being studied on CHS in Japan and W7-AS in Germany. TJ-II in Spain (1997) and H-1 in Australia focus on β-limit issues. Stellarator research is also being pursued in Russia and the Ukraine. The theory programs associated with the major stellarators are focused on support for the experiments. Longer-range projects include a better free-boundary package for the MHD stability codes, which is under development at Garching,

Germany. Studies are also starting on the implications of different stellarator configurations for a fusion power plant. A new stellarator, NCSX, in under construction at Princeton.

The Wendelstein 7-X (W7-X) Stellarator. The Wendelstein 7-X Stellarator (W7-X) is the next-step device in the stellarator line of the Institute for Plasma Physics (IPP) in Garching, Germany. A new branch of IPP is in Greifswald, Germany and will house the W7-X.

The stellarator line of IPP concentrates on low-shear devices, which exclude resonances with low rational numbers $n/m = {}^1/_3, {}^1/_2 \cdots$ from the confinement region and provide stability by a magnetic well rather than by strong shear. The classical stellarator approach such as W7-A, however, has enhanced neoclassical transport by trapped particles, which is not tolerable in reactor-scale devices. Furthermore, the β limit is too low for an economic power reactor, which requires a β value of typically 4% to 5%. The pressure-driven bootstrap current generates a significant contribution to the total rotational transform in classical stellarators, and thus contradicts the concept that the magnetic parameters can be controlled by external currents alone. These considerations have led to the next-step W7-X device. Some main parameters of the last three successive stellarators at IPP are shown in Table 5-13, where the stepwise development toward W7-X becomes obvious.

The coil and magnetic configuration for W7-X are depicted in Figure 5-37. Fifty nonplanar coils provide the confining magnetic configuration. The flux surfaces show a variation from a strong

indented elongated shape (bean shape) in the $\phi = 0°$ plane to a triangular shape in the $\phi = 36°$ plane. The standard configuration has a "built-in" profile of the rotational transform with $\tau = 0.86$ on axis and 1.0 at the edge. As is known from W7-AS experiments, the confinement depends strongly on the edge value of the rotational transform. For this reason, experimental flexibility is built into W7-X to allow the variation of the rotational transform and the profile in a wide range. A separate set of planar coils can be independently powered and allows a variation of the rotational transform from 0.75 to 1.01 on axis and 0.83 to 1.25 at the edge. Thus, both low- and high-shear configurations can be verified. The physics goals for W7-X include

1. Demonstration of quasi-steady-state operation in a reactor-relevant plasma parameter regime, with temperatures $T_e < 10$ keV, $T_I = 2$ to 5 keV, and densities $n_e = 0.1$ to 3×10^{20} m^{-3}
2. Demonstration of good plasma confinement to improve the database for reactor extrapolation
3. Demonstration of stable plasma equilibrium at a reactor-relevant plasma β of about 5%
4. Investigation and development of a divertor to control plasma density and impurities

W7-X does not aim at D-T operation, and provisions for remote handling in radioactive environments are not foreseen.

The Large Helical Device (LHD). The LHD at the National Institute for Fusion Science, Nagaya, Japan, is a superconducting (SC) toroidal fusion facility, is a heliotron-type device and has $l = 2$ SC continuous coils and three sets of SC poloidal coils. LHD has a maximum stored energy of 1.6 GJ at 4-T operation (Motojima 1993, 1995). The dumbbell-shaped vacuum chamber is installed in the inside of SC coils and a built-in helical divertor with the double-null structure functions for producing the steady-state plasma. The schematic view and basic parameters of LHD are shown in Fig. 5-38 and listed in Table 5-14. The volume and surface area of the vacuum chamber are 150 m^3 and 850 m^2, respectively.

To ascertain and realize the steady-state operation of LHD, several important issues concerned with both physics and technology should have been carefully considered and fixed during the design and construction phases. Of interest here are the major operations scenarios of steady-state plasmas based on both physics and technology aspects, especially divertor functions.

The LHD began operation in fall 1998. The objectives of steady-state experiments are to (1) satisfy the necessary condition for an economical fusion reactor by ensuring self-ignition, possibly taking advantage of the currentless plasma; (2) increase the knowledge of plasma boundary phenomena, plasma-wall interactions, plasma heating (burning), fueling, particle and impurity control, and ash-exhausting and confinement improvement; and (3) advance fusion technology including high-heat-flux components, cooling techniques, and pumping systems.

LHD explores a new parameter regime involving long pulses >1000 s. The level of the steady (continuous-wavelength [CW]) power is 3 MW at least, with the temperature of more than a few thousand electronvolts in the medium-density region.

The helical divertor is one of the most important design features for control of severe plasma-wall interactions, and for heat and particle fluxes. It is also installed for improving the confinement performance of the plasma.

Elmo Bumpy Torus (EBT). The EBT concept is a toroidal array of simple magnetic mirrors. The promise of a steady-state, high-β reactor that operates at or near D-T ignition emerges from this combination of simple mirrors and toroidal geometry. The creation of an rf-generated, low-density, and energetic electron ring at each position between mirror coils (i.e., midplane location) is needed to stabilize the bulk toroidal plasma against well-known instabilities associated with simple mirror confinement.

Following early experiments on the concept at Oak Ridge National Laboratory, studies of this approach ceased in the early 1990s because of a combination of technical and funding difficulties.

Toroidal Bicusp (Tormac). Like the tokamak and the stellarator and Torsatron designs, the Tormac is a toroidal device that confines plasma on combined poloidal and toroidal magnetic fields. By opening the outer poloidal field regions, however, the Tormac creates an absolute minimum-B configuration that is MHD-stable for large aspect ratio and plasma β. The resulting toroidal line cusps support plasma on both closed field lines (i.e., high-β bulk plasma) and open field lines; confinement of the latter plasma is enhanced by mirroring effects in the sheath region that separates regions of open and closed field lines. Few experimental studies of this concept have been pursued since an initial series of work in the late 1980s.

Surface Magnetically Confined Systems (Surmac). The Surmac concept represents one example of a general class of multipole configurations in which electrical conductors are arrayed in either a linear or toroidal geometry to create a surface magnetic configuration with low magnetic field in the bulk plasma volume. Figure 5-39 illustrates a toroidal version of this high-β, steady-state system. The Surmac can operate with considerably reduced synchrotron radiation emanating from the bulk plasma, and, therefore, this concept appears to be particularly suitable for confining the high-temperature advanced-fuel plasmas.

Long-Pulsed Toroidal Systems. In terms of power density, relative simplicity, and symbiosis with the basic confinement scheme, ohmic dissipation of toroidal plasma currents represents a very efficient heating scheme. Two long-pulsed toroidal concepts are described that propose ohmic heating as the sole means to obtain an ignited thermonuclear plasma: the Riggatron and the reversed-field pinch (RFP). A variation of the RFP would use an external helical winding to achieve a more controllable rotational transform in a reversed-field state; this concept is called the *ohmically heated toroidal experiment* (OHTE).

The High-Field Ohmically Heated Tokamak (Riggatron Ignitor). Although in principle a tokamak, the Riggatron represents a sufficient change in engineering approach and "conventional" tokamak physics to warrant classification as an alternative concept (Coppi et al. 1992, Carpignano et al. 1995).

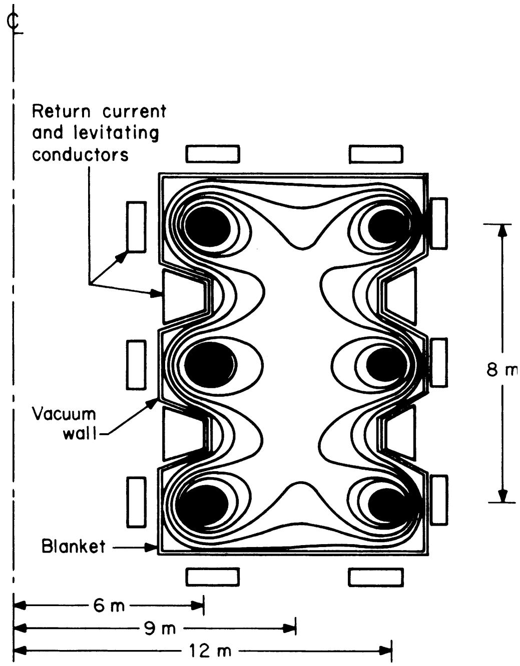

FIGURE 5-39 Schematic representation of the toroidal Surmac plasma and coil configuration.

The combined use of high toroidal current density (8 MA/m^2) and high toroidal field (16 to 20 T) copper coils positioned near the first wall allows net energy production in a relatively short burn period from a high-β, ohmically heated system. The severe thermal-mechanical environment necessarily dictates an engineered short life. The plasma chamber and the D_2O-cooled copper magnets would be small because of the increased plasma density (2 to 3 $\times$ 10^{21} m^{-3}) and high β (0.15 to 0.25). The 6- to 10-MA Riggatron would generate 1 to 2 GW (thermal); the fusion neutron power is recovered in a fixed lithium blanket located outside the magnet system. Recovery of joule and neutron heating in the copper coils is also an essential element of the overall power balance.

The Ignitor experiment involves an advanced compact high-magnetic-field machine, somewhat similar to the Riggatron concept. It employs normal conductor cryogenic magnets with the goal of investigating D-T fusion burning plasmas. The design and construction of the experiment is being carried out by an industrial-university consortium in Italy in collaboration with MIT scientists.

Reversed-Field Pinch (RFP). The RFP is similar to a tokamak in that a toroidal axisymmetrical configuration is used to confine a plasma with toroidal current by a combination of poloidal and toroidal magnetic fields. Using a passive conduction shell, the RFP relaxes inherent constraints on the magnetic-field profiles for a tokamak such that the variation of the magnetic shear need not exhibit a minimum in a region enclosed by a first-wall conducting shell. By removing this constraint, the RFP can operate with a current density that is sufficient for ignition by ohmic heating, an unrestricted aspect ratio, a higher β value, and an appreciably lower magnetic field at the superconducting windings. Consideration has also been given to the possibility of developing a compact reactor based on the RFP concept but using copper coils. The compact RFP reactor would have many operational features similar to those described above for the Riggatron.

Pulsed Toroidal Systems. The early quest on the part of fusion reactor designers to attain the economic advantages of high-β operation simultaneously with the physics advantages of toroidal confinement led to concepts like the reference theta-pinch reactor (RTPR) and the high-β stellarator (HBS). It was generally found that the fast-pulsed nature of the RTPR (i.e., ~1- to 2-μs shock heating, 30-ms adiabatic compression, ~0.5-s burn time) resulted in technological problems that may outweigh the high-β ($>$0.8) advantages for that particular system. Additionally, the absence of MHD stability without fast feedback for the particular field configurations then under experimental investigation indicated other reactor-related problems for both the RTP and the HBS, although the latter was eventually proposed for steady-state operation. A more recent variation is the belt-shaped screw pinch reactor (BSPR). While it is still heated by a fast radial implosion, a toroidal bias magnetic field is applied to reduce the final values of β and thereby enhance stability.

Compact Toroids. The generic name *compact toroid* (CT) has recently been applied to the class of toroidal plasma configurations in which no magnetic coil or material walls extend through the torus.

This closed-field plasmoid configuration is not new, as it was generated by a coaxial plasma gun a few decades ago. Interest in this configuration, as applied to a conceptual fusion reactor, however, began when the spheromak was proposed as a means to retain the developing physics base for tokamaks, while simultaneously shedding certain technological difficulties. Since the spheromak reactor was first proposed, the fusion community has identified the general area and potential of compact toroids; the spheromak is one element of the CT class of plasma configurations. Figure 5-40 summarizes the CT class of devices.

Although representing a great diversity of plasmoid formation, heating, and confinement schemes, the fundamental physics of particle and energy transport and stability and equilibrium are not well known for many subsets of the CT class. Two approaches that involve field reversal with smaller-orbit ions driving the plasma currents—the spheromak and the field-reversed theta pinch—are currently receiving the most study. The theta pinch-reversed field configuration, along with the field-reversed mirror, are normally classified as field-reversed configurations (FRCs).

The FRC and spheromak are closely related. A major difference is the lack of a torodial field component in the FRC, as its confinement properties derive solely from a polodial field.

FRC Reactor Studies. Various reactor studies (Momota et al. 1992, Choi et al. 1979, Miley 1988) have been performed to examine the potential advantages of FRCs. Both stationary designs and concepts where the plasma is passed through a linear burn chamber have been considered. The TRACT (triggered-reconnection adiabatically compressed toroid) reactor design for the stationary burn of a field-reversed theta pinch is a good example of these concepts. Table 5-15 also gives typical prototype reactor parameters for this ~1-Hz batch-burn system. Utilizing a longer burn period (~0.5 s) and modest magnetic fields (5.3 T), a hybrid superconducting (dc)/normal (ac) coil system would provide the required flux compression to achieve ignition in a plasmoid with an initial radius of 0.72 m. A first-wall copper coil cancels and subsequently reverses for a few milliseconds the field generated by an exoblanket superconducting coil, during which time a low-temperature

plasma is created. The superconducting flux is reestablished in two stages: a fast (shock) stage and a slower (adiabatic compression) stage. When the external field induced by the fast shock-heating power supply reaches a peak value, trigger coils are activated and field-line reconnection occurs. The resulting elongated FRC rapidly compresses axially to achieve an equilibrium; this compression provides the bulk of the heating. The resulting ~1.5-m-long plasmoid would attain ignition.

The TRACT approach leads to a relatively small pilot plant of moderate cost that may operate on the basis of near-term technology. A large commercial plant that distributes the power supply costs over several reactor modules benefits since the economy of scale for these systems predicts acceptable direct capital costs. An alternative pilot plant design, SAFFIRE, employed D-^{3}He fuel and neutral-beam injection for heating plus partial current drive. Pellet injection to maintain the desired radial density profile also contributed significant current drive in SAFFIRE. Reasonable costs for the commercial version would require cost savings by manufacturing of modular components in quantity.

The CTOR system designed at Los Alamos National Laboratory would use a field-reversed theta pinch to produce an FRC plasmoid external to the reactor that is subsequently translated through a linear burn chamber. Like SAFFIRE, in the CTOR design the plasmoid source and compressional heater are removed from the burn chamber to a less hostile environment. To minimize the technological requirements imposed by the plasmoid source and the associated pulsed power, a flared axial compressor would maintain the first-wall magnet coil close to the plasma for stability, while the translating plasmoid is adiabatically compressed to ignition prior to entering the linear burn chamber. Figure 5-41 shows a schematic view of this operation. Translation of the ignited plasmoid in the high-temperature burn chamber allows portions of the conducting shell that have not experienced flux diffusion to be continually "exposed." A nearly steady-state (thermal) operation of the first wall and blanket is possible by adjusting plasmoid speed and injection rate. Superconducting coils are located outside the blanket, conducting shell, and shield to provide a continuous bias field that is compressed between the conducting shell and the plasmoid; gross MHD stability would thereby be provided throughout the burn without requiring feedback stabilization. The plasmoid motion terminates in an end region where expansion directly converts internal plasma energy to electrical energy.

The most extensive FRC reactor design study is for a D-^{3}He system termed *Artemis.* This study, led by a design team at the National Institute for Fusion Science in Japan, was carried out for the purpose of examining its attractive characteristics and clarifying critical issues for commercial fusion reactors. The D-^{3}He-fueled FRC fusion reactor Artemis consists of a formation chamber, a burning chamber, and a pair of direct-energy converters, all of which are connected by magnetic lines of force (Fig. 5-42). An FRC plasma is produced at start-up by the conventional reverse-biased fast theta-pinch method in the formation chamber and then translated to the burning chamber.

A combination of deuterium NBI, fueling, and a slow magnetic compression in the burning chamber brings the volume, the temperature, and the number density of the plasma up to those for the D-^{3}He burning state. Most of the D-^{3}He fusion energy is carried by charged particles along the lines of force, which connect to a pair of direct-energy converters. A smaller fraction of the fusion energy is carried by neutrons and photons to the first wall of the burning chamber. This energy is converted to electricity by turbine generators.

The formation chamber is arranged symmetrically so as to reduce error fields. A fast-rising theta-pinch discharge with a one-turn voltage of 400 kV in the filling gas pressure of 0.05 Pa and bias field

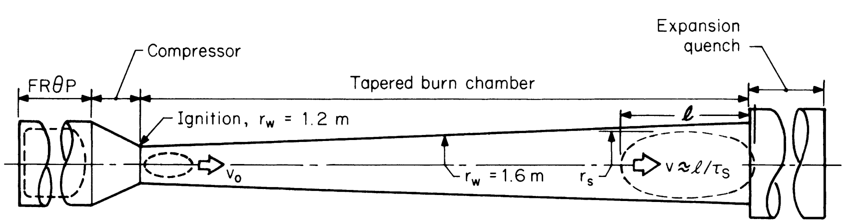

FIGURE 5-41 Schematic layout of a CTOR that would translate at an initial velocity ϑ_0 an FRC down a linear burn chamber of length *l*. The FRC would be formed externally to the reactor by an FRθP plasmoid source.

of 0.035 T produces an initial FRC plasma (Table 5-16 column a). The plasma is then translated to the burning chamber because of an unbalanced cusp magnetic field. During the translation, the FRC conserves particle numbers of respective species, the total energy, the trapped flux, and its "intelligence." Plasma parameters obtained at the burning chamber are listed in Table 5-16, column b.

In the burning chamber, the FRC plasma is heated by means of energetic deuterium NBI with a maximum power of 100 MW. A slow magnetic compression is also applied. The injected particles form an ion beam current that serves as the seed current needed to sustain or increase the trapped magnetic flux of an FRC. The plasma evolves in its volume, the density, and the temperature, forming a burning plasma. During the evolution, the ratio of the current carried by the energetic beam particles to the total plasma current is high enough to stabilize an FRC against macroscopic modes. The set of plasma parameters obtained in this way is tabulated in Table 5-16, column c.

In a D-^{3}He burning FRC plasma, the current drive due to the preferential trapping of fusion protons, assisted by a small amount of external beam injection, is sufficient to sustain an equilibrium in a steady burning state.

The concept of a traveling-wave direct-energy converter (TWDEC) was developed to extract the fusion energy carried by 14.7-MeV fusion protons. The technologies needed for this development are conventional. The lifetimes of existing structural ferritic steels are as long as the total reactor life of the Artemis, and no development of new materials is necessary. Fuel injection is accomplished by oscillating the FRC axially to "engulf" fuel pellets dropped into its path. Operation of large high-field magnetic coils is not required. Thus, the bases of technologies employed for Artemis design are conventional and have considerable technological flexibility that enables the design to accommodate a range of unknown parameters.

The estimated cost of electricity (COE) from Artemis is ~30 mill/kWh, which is low compared with a tokamak reactor or even an LWR. The COE depends only weakly on the fuel cost; thus, uncertainties in the cost of ^{3}He are not crucial. The high energy-conversion efficiency (~62% overall) obtained with the TWDEC and the modest cost of that unit are key factors in the competitive COE

obtained for Artemis. Low radioactivity, low tritium yields, and the inherent safety of the power plant should be readily acceptable socially and ecologically, representing an imporant advantage of this type of power plant.

Studies on issues such as stabilization of macroscopic modes by means of energetic particles must still be carried out, but the general characteristics of a D-^{3}He-fueled FRC fusion power plant offer a very attractive prospect for energy development for the twenty-first century.

A key issue in the use of a D-^{3}He reactor such as Artemis is the source of ^{3}He. In the design study, lunar mining was assumed and the corresponding cost factored into the COE cited. An alternative approach is to breed ^{3}He, either using a semicatalyzed D-D reactor or from production of excess tritium and subsequent decay to ^{3}He.

FRC Experiments: LSX. Reviews (Haruhiko et al. 1995, Hoffman 1996, Hoffman et al. 1993, Momota et al. 1992) of the research status of the FRC discuss small-scale experiments under way at the following laboratories worldwide: BN (TRINITI, Moscow), TL (TRINITI), TOR (TRINITI), NUCTE-3 (Nihon University), FIX (Osaka University), MRX (PPPL), STX (University of Washington), FIREX (Cornell University), and rotomak (Flinders University). Notable achievements include formation by a theta pinch and by counterhelicity injection, stabilization of the rotational mode, detection of global internal modes, tilting-mode theory, translation and acceleration, identification of transport anomalies, and reduction of convective thermal losses. Immediate issues include the need to demonstrate a long-lived, high-quality FRC, improved theories for global stability land kinetic physics, the development of a reactor-relevant start-up method and current drive, and a better understanding of the plasma energy-transport mechanism. Additional long-term issues include studies of flow stabilization and kinetic stabilization effects, rotating-magnetic-field current drive, and the concept of a traveling-wave direct-energy converter (TWDEC). FRC experiments have undergone a 5-year hiatus in the United States because of the 1990 DOE decision to halt alternative confinement fusion research in favor of concentrated tokamak development. The largest FRC facility, the Large *s* Experiment (LSX), was built during 1986 to 1990, but operated for only 1 year, after which it was converted to studies of plasmoid fueling tokamaks. Its parameters are shown in Table 5-17. A modified version of that facility was reinaugurated in 1998.

The LSX was constructed to explore the stability of FRCs as *s* (device radius/ion gyroradius) was increased beyond the value of 2 (produced in previous small experiments), where stabilizing kinetic effects are theoretically predicted to diminish. Stable, well-confined FRCs were produced with *s* values up to 4, with indications that higher-*s* FRCs would be stable if they could be successfully formed using the theta-pinch techniques. However, before the LSX program was halted, it became clear that theta-pinch formation was limited to flux values in the tens of milliwebers range, while webers of flux are required for a reactor. Thus, flux buildup represents a key area for future research.

The particle-confinement times measured on LSX and other FRC experiments indicate a strong correlation with the parameter $rs/\sqrt{\rho_i}$, where rs is the separatrix radius (see Fig. 5-40) and ρ_i is the gyroradius. The general form implies a confinement time scaling ($\tau_N = x_s\, a^2/D_\perp$) with a basic particle diffusivity [$D_\perp = 2/n^{1/2}$ (10^{21} m^2) m^2/s], where a is the minor radius of the toroid (Fig. 5-40) and n is the averaged plasma density. The factor x_s occurs here as a result of the increase in flux (lower beta) for a given radius FRC, and the dependence on density just reflects the $\rho_i \propto 1/n^{1/2}$ relationship for a high β plasma.

This empirical scaling is unfavorable for low-density operation, and thus low-power, steady-state operation. However, there is evidence from recent Japanese experiments (Haruhiko et al. 1995) that an improved low-density confinement mode may exist. Confinement may also improve when current sustainment techniques are applied. Then, the toroidal plasma current is carried either by large-orbit ions or gyrocenter drifts, rather than by simple diamagnetism.

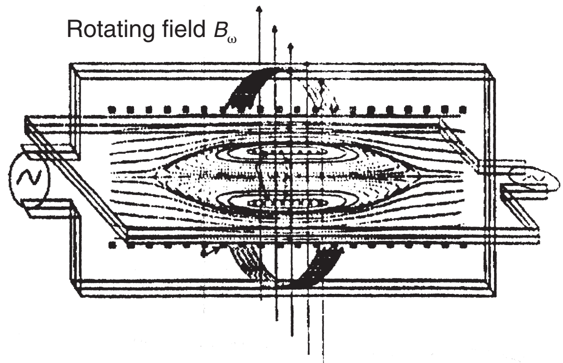

FIGURE 5-43 RMF current-drive schematic.

In order to build a steady-state FRC reactor it is essential to develop some form of flux buildup and current drive. The Artemis reactor design study described earlier assumed neutral beams resulting in large ion orbits (Momota et al. 1992). Large-orbit ions are theoretically effective in stabilizing compact toroids, but the technology is expensive and the large azimuthal ion-ring momentum may introduce ring-plasma instabilities. A simpler, but unproven current drive method for hot plasmas would be to directly drive the electrons using rotating magnetic fields (RMFs). Such a technique, sketched on Fig. 5-43, has been demonstrated on small-scale rotomak experiments.

The two antenna coils in Figure 5-43 are driven 90° out of phase to produce a rotating field $B_r = B_\omega \cos(\omega t - \theta), B_\theta = B_\omega \sin(\omega t - \theta) E_z = r\omega B_r$. If $\omega_{ci} < \omega << \omega_{ce}$, then the electrons, but not the ions, will be dragged along with the rotating field. Here ω_{ci} and ω_{ce} are the ion- and electron-cyclotron frequencies, respectively. The perpendicular B_ω field will prevent an axial current from flowing and shielding the plasma interior from the rotating field.

Spheromak Reactor Concepts. The spheromak lends itself to a reactor embodiment (Fowler et al. 1994, Hagenson and Krakowski 1985, Hooper and Fowler 1996, and Moir 1996) that shares many features with the FRC. However, fewer specific studies have been reported for the spheromak. Still it has been shown to potentially offer a comparatively simple fusion reactor with relatively low cost of electricity. The magnetic fields are generated primarily by plasma currents except for a vertical field, required to support the hoop stress, which is generated by a set of purely solenoidal coils. Current is driven by an external coaxial gun that generates linked toroidal and poloidal magnetic fluxes (helicity) that drive current in the core of the spheromak through a magnetic dynamo. The plasma-core current may return to the gun or be collected at the other end of the magnetic separatrix. It is anticipated that the ohmic heating from the plasma current will be sufficiently strong such that no auxiliary heating source will be required to reach reactor conditions.

Figure 5-44 shows the proposed magnetic-field configuration for a spheromak reactor. The fusion plasma is confined within a magnetic separatrix with toroidal, magnetic flux surfaces; thus, the geometry shown has two *X* points. Helicity injection is from a coaxial, electrostatic gun shown located above the upper *X* point; power flowing from the confinement region is diverted into the upper and lower coaxial regions, which act as divertors. It may be possible to unbalance the magnetic configuration so that most of the energy and particles flow to the lower region, thus separating the divertor from the gun, and potentially improving the power and particle handling characteristics of the reactor.

The blanket, located in the annular region surrounding the plasma, is envisioned to consist of liquid lithium or lithium salts, perhaps flowing vertically between the wall and the plasma; solid or other configurations are also possible. If ohmic ignition occurs, the spheromak will allow a blanket without radial port penetrations. Thus, it has been suggested that the simplicity of the configuration may make a liquid/NaK "potboiler" type of reactor possible.

5.4.9 Inertial Electrostatic Confinement

Instead of using magnetic fields for confinement, electrostatic fields can be employed (Miley 1997, Kulcinski et al. 1997, Miley et al. 1997, Sved 1997, Gu and Miley 1995, Miley et al. 1998). This requires a dynamic plasma, for instance, one where the inertia of high-energy ions becomes significant since, as proved by Earnshaw, pure electrostatic fields cannot be used alone to confine a plasma. Thus, electrostatic fields have generally been viewed as a way to "plug" plasma leakage routes in magnetic confinement systems, which has been widely considered (e.g., see the preceding discussion of the tandem mirror), and studies of electrostatic confinement have been limited. The best known concept, termed *inertial electrostatic confinement* (IEC), uses the inertia associated with recirculating ions to overcome Earnshaw's theorem. This concept traces back to Philo Farnsworth, the U.S. inventor of electronic television, who proposed and patented aspects of the concept in the 1960s. While some continuing research has been done ever since then, the first aggressive small-scale experimental projects were set up at the University of Illinois, Los Alamos Scientific Laboratory, University of Wisconsin, MC^2 Corporation, and the University of Kyoto.

A significant result of these efforts is that Daimler-Benz Aerospace Corporation initiated commercial production of a version of the University of Illinois unit. The commercial IEC unit is for use as a portable 2.5-MeV neutron source (D-D fusion) for industrial neutron activation analysis (NAA) and neutron tomography. While operating with a net power input well below energy breakeven ($Q \sim 10^{-6}$), this development represents the first commercial use of a confined fusing plasma.

The University of Illinois experiment is representative of present IEC research and will be briefly described here. For simplicity, it replaces the ion guns used in early Farnsworth-type experiments with a grid-produced plasma discharge. Operation employs the "star" mode, where ion beams formed in the discharge pass through grid openings, minimizing grid sputtering and erosion.

Both spherical and cylindrical versions have been developed. In the spherical design, illustrated in Fig. 5-45, the transparent grid biased at −60 kV acts as a cathode relative to the grounded vacuum vessel wall.

When a deuterium gas (or deuterium plus tritium or ^3He mixtures) discharge is used, D^+ ions are extracted from the plasma by the cathode grid, accelerated, and focused in the center where D-D fusion reactions occur. The grid provides recirculation of the D^+ ions, increasing the power efficiency. At high currents, a potential structure develops in the nonneutral plasma, creating virtual electrodes that further enhance ion containment and recirculation (Fig. 5-46).

Steady-state spherical IEC units typically produce 10^7 D-D n/s, while advanced pulsed versions extend to 10^{11} neutrons per second (n/s) (10^{13} n/s for DT).

The cylindrical version of the IEC (Fig. 5-47) uses a hollow electrode design where ions recirculate between two outer anodes producing a line-like neutron source within the hollow cathode region. This unit is most useful for applications requiring broad-area extended sources, such as luggage inspection, and NAA of materials, such as ores, on a conveyer belt.

Neutron yields from the cylindrical design are comparable to those from the spherical IEC, but the lack of three-dimensional virtual electrode formation limits its ultimate fusion rate.

The unique feature of the IEC is that it develops a fusion-grade plasma in a small volume (a few cubic centimeters) while avoiding bulky magnets, injectors, and the like. In addition, the star mode creates ion beams that reduce grid bombardment, which, combined with use of a "damage free" plasma target (the dense core of Fig. 5-46) provides long-lifetime units. Thus, the commercial IEC NAA units provide a first step in what could be a progression of uses for fusion-grade plasmas prior to actual fusion power plants.

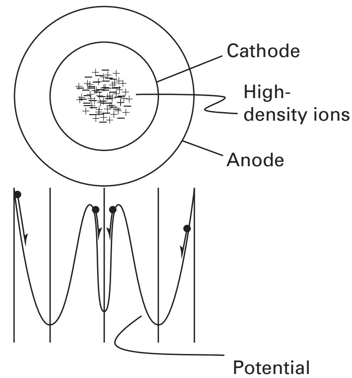

FIGURE 5-46 The potential structure in the dense plasma core of an IEC. The central "well" traps ions, providing efficient local recirculation.

In addition to NAA, the IEC has been proposed as a tunable x-ray source and as a plasma thruster for space applications. These applications generally require higher reaction rates, and present research is focused on that objective, largely via use of higher ion currents. If successful, the scale-up to a near-breakeven unit could be considered for neutron-irradiation applications such as neutron-damage studies. Development issues include the stability of the potential structure illustrated in Fig. 5-46 at high currents and technology such as grid survivability. Grid scale-up requires development of very efficient active cooling methods, or use of an alternative approach to eliminate grids. For example, a recent concept proposed by R. W. Bussard replaces the grid with a unique high-order cusp magnetic field.

5.4.9 Inertial Fusion Energy and Concepts

In the inertial confinement scheme, the surface of a small spherical target of a solid material containing deuterium-tritium fuel is symmetrically illuminated by very high energy laser or charged particle

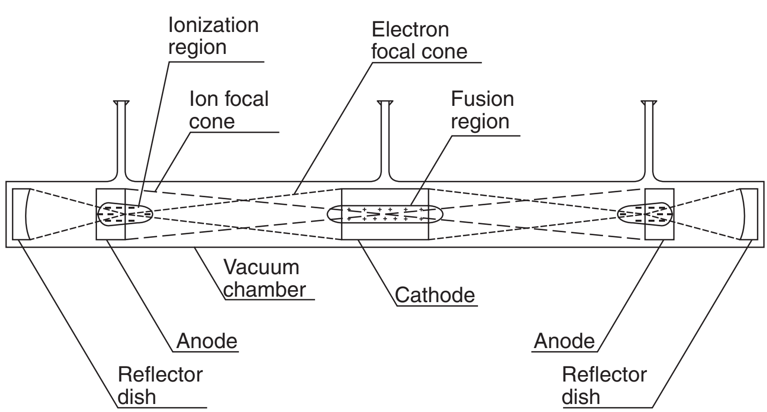

FIGURE 5-47 Cross section of the cylindrical version of the IEC. The ion-electron optics are designed to provide a central beam through the hollow cathode.

beams. The density of the nuclei in the target prior to illumination is typically ~10^{22} ions/cm^3. A thermal compression, caused by ablation as the beam energy impinges on the target, causes a further increase in density of up to 10^4 times, producing a density at the center of the pellet approaching 10^{26} ions/cm^3. At this density, a Lawson-type breakeven density-confinement time product of 10^{16} s/cm^3 can be achieved in a confinement time of only 1 ns (10^{-9} s) or less, which is achieved by the inertia of the fuel itself. If a central pocket of DT gas is left in the center of the target, as shown in Fig. 5-44, it will be adiabatically heated during compression to a temperature of 10^8°C, initiating a fusion burn. These density-confinement, time-temperature conditions are adequate for energy breakeven. Thus, the process is essentially one of a thermally induced implosion. The total laser energy which must be applied to the target to achieve useful fusion gains is estimated to be of the order of 5 MJ. With a target gain of 100, this would give a yield of 500 MJ. A pulse rate of 2 Hz would produce 1000 MW_t.

In terms of power plant design, the most important feature of inertial fusion is that the confinement of the plasma is decoupled from the functions of the reaction chamber, wall, and blanket. This is possible because the physics of energy absorption, implosion, ignition, and burn of this plasma are physically separable from the chamber conditions and structural requirements.

In inertial fusion power plant chamber design, the degree of freedom allowed by this separability is exploited by placing fluids (gases or liquids) or fields (magnetic deflection) inside the chamber to protect the wall from ablative material loss due to the energy deposition of the short-range fusion radiation (25% to 35% in soft x-rays and debris) and, in the case of thick liquid-metal walls, to provide protection from radiation damage due to deeply penetrating x-rays and neutrons. Similarly, the final optics of the driver can be protected by placing the final mirrors tens of meters away and protecting them by a gas, or in the case of an ion beam driver, by closing a rotating shutter in front of the ion beam ports to block the plasma debris.

The use of protective fluids, combined with the pulsed nature of the energy release, leads to new engineering constraints and techniques that are radically different from those of magnetic fusion. Understanding and manipulating the dynamic response of fluids and structures become of primary importance, and such factors as new materials development to resist neutron damage take less emphasis.

The HYLIFE System. The most detailed calculations and conceptual design for an inertial fusion power plant were performed at LLNL, in conjunction with a team of university and industrial contractors. The high-yield lithium injection fusion energy (HYLIFE) chamber shown in Fig. 5-48 is designed to operate with yields of a few thousands megajoules at rates of a few hertz. A lithium energy-conversion blanket, consisting of a dense array of 20-cm-diameter jets, is continuously injected into the chamber. This provides an effective blanket thickness of 1 m between the fusion pellet and the inner steel wall. The 14-MeV neutron flux is reduced by a factor of 200 by this lithium blanket, allowing a chamber with a 5-m-radius to operate for 21 full-power years (30 years at 70% availability), at an integrated neutron energy flux of 0.3 MW/m^2. Since the flux in the wall without lithium protection would be 5.7 MW/m^2 (including pellet effects), the power density within the reactor vessel is very high, approaching that of a fission reactor. A common low-alloy ferritic steel (2.25 Cr-1 Mo) is used throughout. The tritium-breeding ratio is controllable between 1.0 and 1.7 by adjusting one *G*/*i* enrichment in the lithium.

The chamber contains a hexagonal array (50% packing fraction) of 20-cm-diameter lithium jets, which gives an effective shock isolation from the effects of the fusion pulse. Since the hot gas merely blows through the array of jets, this configuration minimizes the wall stress due to the impact of lithium accelerated by high-pressure blowoff gas, caused by x-ray and debris energy deposition. A substantial fraction of the kinetic energy of expansion of fluid, resulting from the neutron absorption, is dissipated in the liquid-liquid interactions among colliding jets. Finally, the enormous surface area of the fluid acts as an effective condensation pump for the lithium vapor.

The HYLIFE power plant requires 16 pumps to inject the liquid lithium into the 5-m-radius chamber. The power necessary for the lithium recirculation pumping is 20 MW (electric), only 1.6% of the gross electric power, if mechanical pumps are used. The laser mirrors are located at the far ends of the containment building, 60 m from the microexplosion. They are protected from the soft x-rays and debris by 0.25 torr of xenon in a 30-m section of the passageway. The neutron flux on the

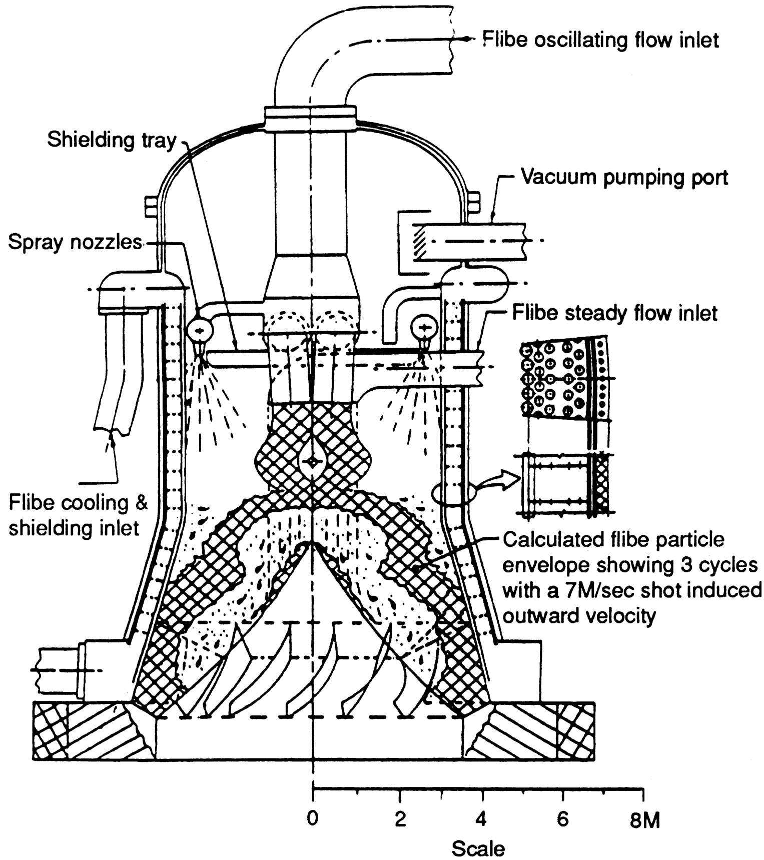

FIGURE 5-48 HYLIFE-II, oscillating flow combines wall protection and driver-beam access.

mirrors is 0.042 MW/m^2, low enough to assure substrate lifetimes of over a year. The power plant characteristics are summarized in Table 5-18.

HYLIFE-II. The HYLIFE-II reaction chamber, shown in Fig. 5-48, employed an oscillating flow scheme to permit beam injection while still protecting the chamber wall. HYLIFE-II avoids the fire hazard of lithium by using a molten salt composed of fluorine, lithium, and beryllium (LI_2BeF_4) called Flibe. Access for heavy-ion beams is provided.

A high repetition rate is employed in HYLIFE-II, requiring faster reestablishment of the jets after a shot. This is accomplished in part by decreasing the jet fall height and increasing the jet flow velocity. In addition, there is liquid splash that must be forcibly cleared because gravity is too slow at repetition rates higher than 1 Hz. Splash removal is accomplished in the central region by oscillating jet flows.

Flibe is compatible with 316-stainless steel or even better with Hastelloy N at a much higher temperature than lithium (923 vs. 770 K). Its heat-transfer properties, while different from lithium, are still suitable to remove heat and serve to protect the permanent structure from neutron damage and blast. Flibe, unlike lithium, dissociates. However, recombination is rapid enough to avoid affecting condensation; hence this does not limit the repetition rate. If the salt is maintained in a reduced state

by keeping the mole fraction of tritium fluoride (TF) low, corrosion from fluorine compounds formed during the evaporation process should be small. The salt is reduced by contacting it with beryllium or by use of a CeF_3/CeF_4 buffering agent.

To achieve a high repetition rate and short fall distance with splash clearing, the jet nozzles oscillate horizontally, as shown in Fig. 5-48.

"Cool" Flibe at 873 K is injected in a spray of droplets in the vicinity of the beam paths. This injected spray can provide a large condensation area. Thus, it is not necessary for the explosion itself to form a large number of small droplets for seeding the condensation process as is sometimes assumed.

Practically, all of the tritium gas emitted by exploding targets will be removed by the vacuum pumping system, but almost none of the tritium bred in the Flibe will diffuse out of the Flibe droplets while in the chamber. The reason is that tritium has a low solubility in Flibe so it tries to diffuse out of and not into the droplets. A vacuum disengager has been designed to remove the tritium from the molten salt coolant (see Fig. 5-49).

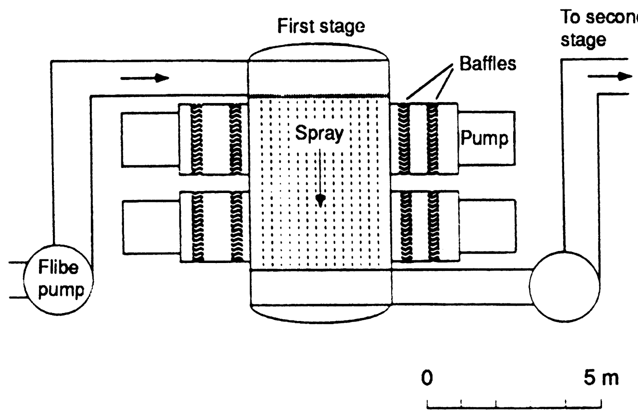

FIGURE 5-49 The vacuum disengager removes tritium from small Flibe droplets falling 5 m.

An outstanding feature of the HYLIFE-II reactor is its favorable safety characteristics. These include

Off-site dose from severe accident less than 2 Sv (200 rem) for passive safety

No N-stamp requirement for most components, thus requiring less than 0.25 Sv (25 rem) off-site dose

Working area dose rate less than 50 mSv/h (5 mrem/h) for a low occupational risk

Dose from routine atmospheric effluents less than 50 mSv/year (5 mrem/year)

Some of the key issues include verifying splash removal techniques, tritium removal effectiveness, condensation phenomena, heavy-ion accelerator technology, cost reduction, and beam propagation. Most importantly, to be competitive with future coal and light-water-reactor (LWR) nuclear power, the cost of electricity needs to be reduced by a factor of somewhat less than 2.

OFE Inertial Fusion Reactor Studies. There have been a number of ICF reactor studies such as HYLIFE with varying degrees of completeness (Miley and Campbell 1997). Recently, the Office of Fusion Energy (OFE) commissioned two studies to take advantage of the database through 1990, and we will briefly consider them. These studies take 1 GWe as the appropriate output electrical energy (a large power plant).

The OFE reactor studies have considered both heavy-ion and KrF laser drivers. Both approaches to ICF, namely, direct and indirect drive (qualitatively illustrated in Figs. 5-50 and 5-51), are considered. (Other studies are advancing the diode-pumped solid-state laser discussed earlier. A light-ion-beam driver study is also being advanced.) However, with at least thousands of active components, it is difficult to accurately assess the reliability and true costs of these conceived drivers. Figures 5-52 and 5-53 illustrate delivery of the driver energy in the Prometheus-H (heavy ion) and SOMBRERO (KrF laser) concepts that are taken as typical. Prometheus-H has a single accelerator, but 18 beamlets are generated, stored, delivered, and focused from two sides onto the indirectly driven target.

The SOMBRERO layout illustrates some of the issues for laser direct drive. Note that the building has a 55-m radius. The size of the building is dictated by the need to place laser optics far from the neutron source.

The ability to line up and consistently hit a target is a key issue. Figure 5-54 illustrates a delivery concept for the SOMBRERO case. The targets must be delivered accurately and, particularly in the case of indirect drive, they must also be precisely aligned. The OSIRIS reactor chamber concept (Fig. 5-55) has highly attractive features. The walls are wetted and continuously renewing. Liquid Flibe (500 to 600°C) is the wetting agent, the heat-removal agent, and the tritium-breeding agent.

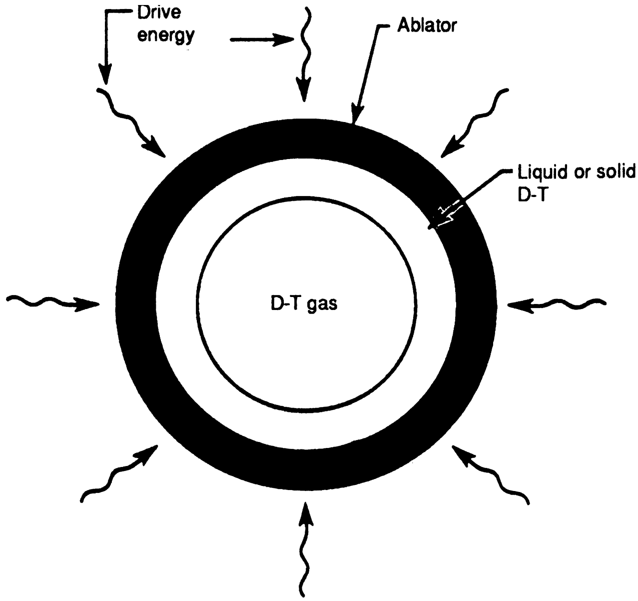

FIGURE 5-50 The basic concept of inertial fusion uses uniformly distributed radiation to drive the compression of a capsule containing deuterium and tritium. Direct drive applies the incident energy directly from a laser or ion beam.

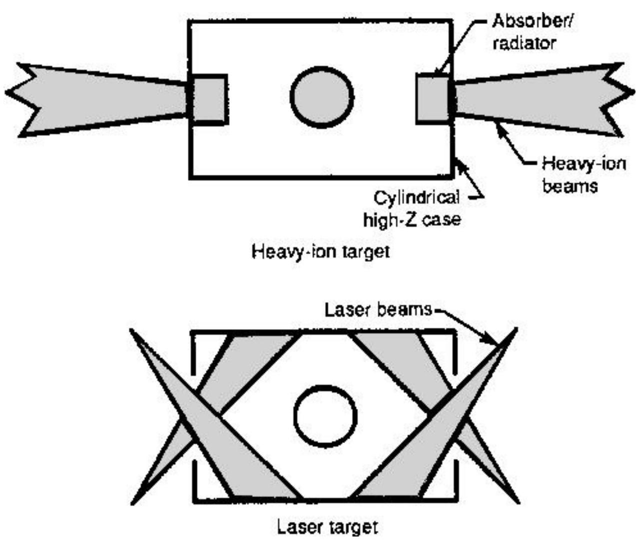

FIGURE 5-51 For indirect-drive targets, the incident ion beam or laser energy is focused onto a material surface where secondary radiation is generated, resulting in uniform radiation incident on the central, spherical capsule.

Fast Ignitor. In addition to research on direct- and indirect-drive targets for inertial confinement fusion (ICF), worldwide interest has developed the concept of "fast ignition" proposed in 1994 by researchers at LLNL (Tabak 1994). In this concept, the target is first "hit" by the main driver beam which compresses it to a high density. Almost simultaneously, it would be "hit" by a second beam from a Petawatt laser, which uses chirped-pulse amplification to achieve very high power, with short time pulses through a thousand-fold pulse compression in time (Perry et al. 1996).

When focused onto a solid target, the Petawatt laser pulse can generate a forward-traveling beam of high-energy electrons. The fast-ignitor concept is to use this electron beam to "bore a hole" through the outer region of a precompressed ICF target, igniting a small volume of fusion fuel near the center (equivalent to "spark ignition" by converging shock waves created by a time-shaped laser pulse in normal direct-drive ICF).

Fast ignition can reduce the driver-beam energy by 10 times or more for inertial fusion energy (IFE) by reducing the implosion velocity and energy for a given fuel compression ratio (Logan and Meier 1998). For any type of driver that can deliver the ignition energy fast enough, fast ignition increases the target gain compared to conventional targets. By reducing the fuel compression energy, velocity, and implosion convergence ratio, and by tolerating mixing in the DT core, fast ignition also reduces the degree of symmetry required both on the driver beam illumination as well as on the smoothness of capsule ablators and cryogenic DT fuel layers. In principle, these advantages of fast ignition can accrue to any type of driver used to compress the fuel, and to any driver type used to ignite the fuel after compression; that is, ion accelerators or lasers might be used for either or both

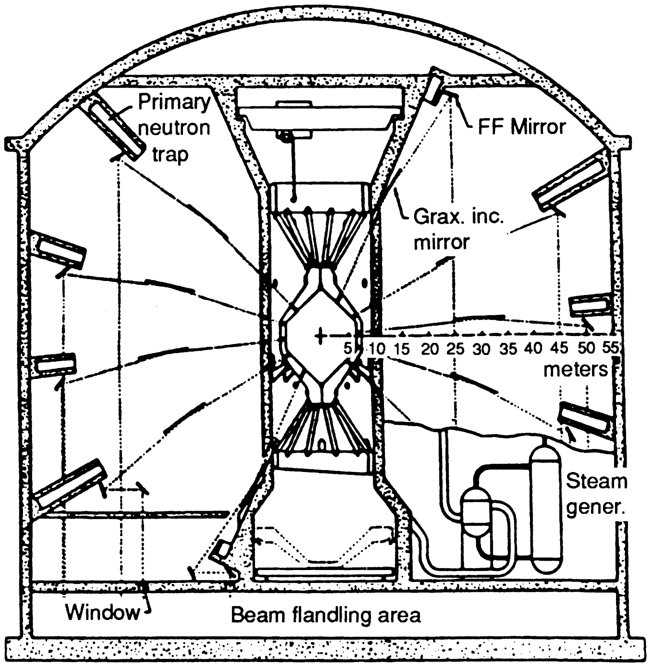

FIGURE 5-53 Side view of full reactor hall for the SOMBRERO KrF laser-driven concept. (*W. J. Schafer.*)

functions. With high peak beam power and small focal spots, fast ignition is more demanding of the driver than is fuel compression, despite lower-energy input required for ignition. Experiments with a Petawatt laser have demonstrated adequate conversion efficiency of light into hot electrons with the range needed to ignite DT cores in future experiments (Perry et al. 1996). Further experiments are required to determine if the laser light and ht electrons can channel deeply enough into the corona plasma of a preimploded capsule to heat a small portion of a >1000-fold liquid density compressed DT core to ignition. Ion-driven fast ignition, compared to laser-driven fast ignition, has the advantage of direct (*dE*/*dx*) deposition of beam energy to the DT, eliminating inefficiencies for conversion

into hot electrons. On the other hand, ion accelerators have not yet been demonstrated that can produce sufficient beam quality for high pulse compression ratios and small focal spot sizes for fast ignition. Accordingly, it is the accelerator and beam focusing, not the target coupling physics, that poses the main challenge to ion-driven fast ignition.

ICF Laser Facilities NIF. The NOVA laser at the Lawrence Livermore National Laboratory (LLNL) in California has served for years as the world's most powerful laser for inertial confinement fusion (ICF) research. It was shut down to make way for the National Ignition Facility (NIF). This facility has as its ultimate goal the demonstration of ignition and high-gain operation of ICF targets. To accomplish this, the NIF is designed to deliver over 2 MJ of 0.35-μm light to indirect-drive targets with a peak power of 500 to 1000 TW in a variety of pulse shapes.

For ICF, ignition is defined where the fusion alphas deposit sufficient energy locally to double the burn temperature in the hot spot of the fuel. This will occur in a DT target if the core is compressed to $\rho r > 0.3$ g/cm^2 and a preignition temperature of 5 keV. Then a thermonuclear burn will propagate into the remaining cold fuel, which is nearly isentropically compressed to high density. For a reactor, an energy gain of 100 or more would be desirable.

The National Ignition Facility. The National Ignition Facility (NIF) will contain the world's most powerful laser. The planned experiments to achieve ignition and high gain for the first time in a laboratory will have far-reaching implications for the future of national security, fusion energy, and a host of scientific and technological fields.

The NIF will focus 192 extremely powerful laser beams onto a pea-sized capsule of deuterium and tritium. Two kinds of targets are under study, both of which can be used in the NIF: *direct-drive targets*, in which a spherical capsule containing deuterium and tritium is struck directly by the laser beams; and *indirect-drive targets*, using a capsule inside a small, thin-walled cylindrical container made from high-atomic-number materials such as gold or lead. The container, called a *hohlraum*, converts the driver beams to x-rays which compress the fuel capsule.

The NIF will also be able to achieve more dramatic results in high-energy-density physics than have been possible with lasers to date. The key physics of certain types of stars, of supernovas, of fluid dynamics and the interior of a nuclear explosion can be revealed, allowing confirmation of computer models and answering questions of nuclear stockpile reliability, fusion energy, and astrophysics.

At a final cost of $2.0 billion, the football stadium–sized facility would be the centerpiece of the nation's inertial confinement fusion research community, leading a worldwide effort to understand the challenging world of high-energy-density physics and possible fusion-energy production. But leading the world into a nuclear testing-free world is also a vital element of the NIF. Its key role in what is described as *science-based stockpile stewardship* responds to a search for alternative means of maintaining confidence in our nuclear deterrent without nuclear testing. The NIF and other elements of the stewardship program allow researchers the insight to help maintain the stockpile in a safe and reliable fashion.

Answers to important energy questions will be possible with the NIF, as one of the key challenges in inertial fusion research is to achieve ignition of the deuterium-tritium fuel capsule, and further, to show a modest gain in the energy produced. Once researchers can show that they produce more energy than the lasers used to create ignition, the inertial confinement community will have vital information on which to base the next step in its fusion energy development.

Groundbreaking research has been under way at Lawrence Livermore National Laboratory using the Nova laser and at the University of Rochester with the Omega upgrade laser, but the boost in technology achieved by NIF (40 times more energy and 10 times the power of nova) will offer information on inertial fusion ignition and gain that is critical to the next era of ICF progress. It will determine the minimum drive energy (and cost) necessary to ignite an inertial fusion target, thus allowing evaluation of the viability of inertial fusion as an energy source. Since the NIF will be able to reproduce conditions that exist in stellar interiors, it will become an important new tool for laboratory astrophysics. It will also allow important experiments in other fundamental sciences.

Initial operation of the first four of 192 beams began in April 2003.

NIF Design Requirements. The design for NIF takes into account the requirements and requests of three main user communities. The top-level performance requirements for the NIF were driven by the indirect- (x-ray-) drive, ICF mission. Those requirements are as follows:

- 1.8 MJ of laser pulse energy on target
- Flexible pulse shaping (dynamic range >50)
- Peak power of 500 TW
- Pulse wavelength in the ultraviolet (0.35 μm)
- Beam power balance better than 8% over 2 ns
- Pointing accuracy $< 50\ \mu$m
- Compatibility with cryogenic and noncryogenic targets
- Ability to do 50 shots per year, each with a yield of 20 MJ, for a total 1200 MJ annual yield
- Maximum credible DT fusion yield of 45 MJ
- Ability to perform classified and unclassified experiments

In addition to these capabilities, weapons physics users desire the highest possible peak power for short pulses ($>$750 TW at 3ω for 1 ns) in order to reach high temperatures and a range of pulse lengths from 0.1 to 20 ns for a wide variety of experiments. These users want bright sources for experiments requiring x-ray backlighting, with small spots at high temperatures (half the energy in a 100-μm spot, and about 95% of the energy at 200 μm). The beams for these backlighters must be pointed a few centimeters away from the center of the main target chamber.

Weapons effects users want the ability to locate arrays of laser targets several tens of centimeters from the target chamber center, as well as 1ω and 2ω capability. Their other requirements include access to the chamber for large, heavy test objects, a well-shielded diagnostics area for testing electronic systems, and no residual light on the test objects.

The NIF target chamber will also have ports that allow the beams to be placed in the proper location for direct-drive ICF experiments and for tetrahedral hohlraums as well as for the baseline cylindrical

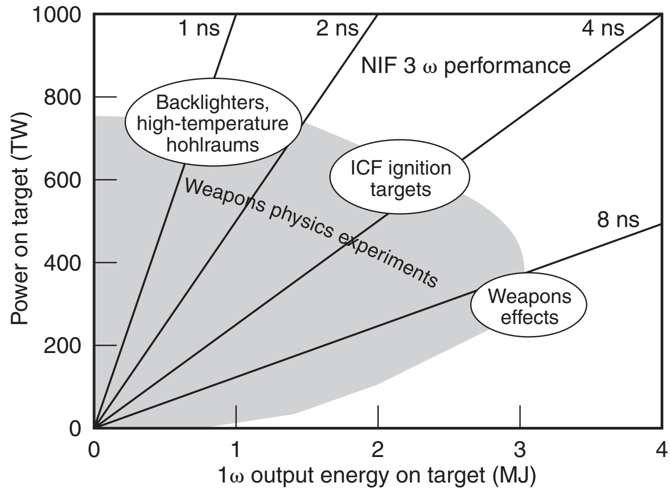

FIGURE 5-56 National Ignition Facility (NIF) users have identified important experiments spanning over a wide range of operating conditions.

hohlraums. All these requirements mean that the NIF must accommodate experiments spanning a wide range of operating conditions (see Fig. 5-56).

NIF Description. The NIF laser system provides routine operation at 1.8 MJ/500 TW in an ignition-target-shaped pulse and has a wide range of operation to meet other user requirements. The laser uses neodymium glass amplifier slabs, with 192 beams in a multipass architecture. Frequency conversion is to the third harmonic: 3ω (350 nm). The laser has adaptive optics (deformable mirrors) to control the beam quality and uses kinoforms and smoothing by spectral dispersion (SSD) to control the beam quality on the target.

Figure 5-57 shows the laser and target area building, as they appear in the Title I Design (submitted to DOE). The overall floor plan is U-shaped, with laser bays forming the legs of the U, and switchyards and the target area forming the connection. The NIF will contain 192 independent laser beams or "beamlets" measuring 40 × 40 cm each. Beamlets are grouped into 2 × 2 "quads," which are stacked two high in 4 × 2 "bundles" (thus eight beamlets per bundle). These bundles are grouped six each into four large "clusters," two in each laser bay, for a total of 192 beamlets (8 beamlets per bundle × 6 bundles per array × 4 clusters). The 192 laser beamlines will require more than 7000 discrete, large optical components (larger than 40 × 40 cm) and several thousand smaller optics. Beams from the laser will strike a series of mirrors, which will redirect them to the large target chamber shown on the right side of Fig. 5-57. The building for the NIF will be about 100 m wide (122 m including the capacitor bays), and about 170 m long.

In deciding how many beams for the NIF, two conditions have to be met. First, there has to be enough beam area facing the target to deliver the required energy. The maximum safe 3ω fluence for an ignition target pulse is about 9 J/cm^2. The maximum practical single beam area is about 1300 cm^2, which would deliver about 11 kJ/beam on the target. At 11 kJ per beam, at least 164 beams are required to put 1.8 MJ on target. Second, the conditions required by indirect- (x-ray-) drive targets are essential factors. These targets (cylindrically symmetric hohlraums) require twice as many beams in the outer cone as in the inner cone, illumination from two directions, and eight or more beam spots per cone. When we multiply these factors together, we find that the beam count must be divisible by 48. The smallest system that satisfies these two conditions is 4 × 48 = 192 beams.

It turns out that it is also very convenient to transport these beams in 48 (2 × 2) clusters, and that this configuration is also compatible with direct-drive uniformity requirements. Finally, 192 beams at 9 J/cm^2 provides 2.2 MJ, a full 20% margin for baseline operation of 1.8 MJ.

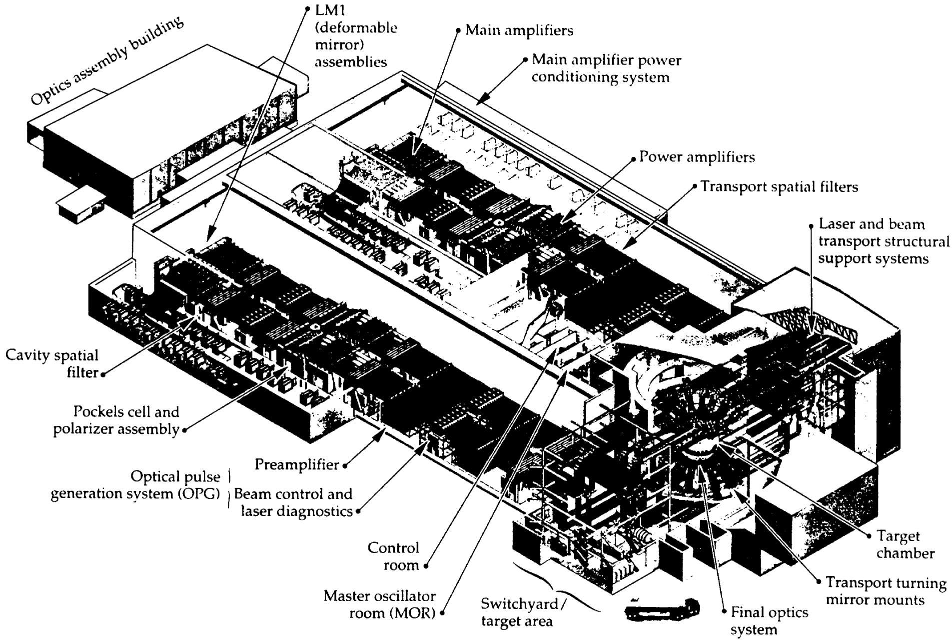

FIGURE 5-57 Layout of the laser and target area building. The two pairs of large beamlet clusters running the length of each laser bay are essentially identical to each other.

Master Oscillator System. The laser pulse is produced in the master oscillator room, where a fiber-ring oscillator generates a weak, single-frequency laser pulse. A phase modulator puts on bandwidth for smoothing by SSD and suppressing stimulated Brillouin scattering. Each pulse is then launched into an optical fiber system that amplifies and splits the pulse into 48 separate fibers. The optical fibers carry the pulses to 48 low-voltage optical modulators very similar to those used in high-bandwidth fiber communication systems. These modulators allow temporally and spectrally shaping of each pulse by computer control. An optical fiber then carries each nanojoule,1-μm pulse to a preamplifier module (PAM).

Preamplifier Module. Optical fibers carrying the pulses from the master oscillator room spread out to 48 preamplifier modules, located on a space frame beneath the transport spatial filters. Each preamplifier has a regenerative amplifier followed by a flashlamp-pumped four-pass rod amplifier. The preamplifier is a two-stage system, designed as a self-contained assembly, that can be pulled out and replaced as needed. The preamplifier brings the pulse to about 10 J, with the spatial intensity profile needed for injection into the main laser cavity. Before entering the main cavity, the output from the preamplifier is split four ways. These four pulses are injected into the four beams that form each of the 48-beam quad arrays.

Main Laser System. Figure 5-58 shows the layout of the main laser components of a NIF beamlet. These components take a laser pulse from the preamplifier to the final optics assembly. A laser pulse from the preamplifier enters the main laser cavity when it reflects from a small mirror labeled LM0. This mirror is located near the focal plane of the transport spatial filter. The 40-cm-diameter pulse exits the transport spatial filter, traveling to the left, and passes through the power amplifier, containing five amplifier slabs.

The beam then enters the periscope assembly, which contains two mirrors (LM2 and LM3) and a switch (a Pockels cell and a polarizer). The pulse reflects off LM3 and the polarizer before passing

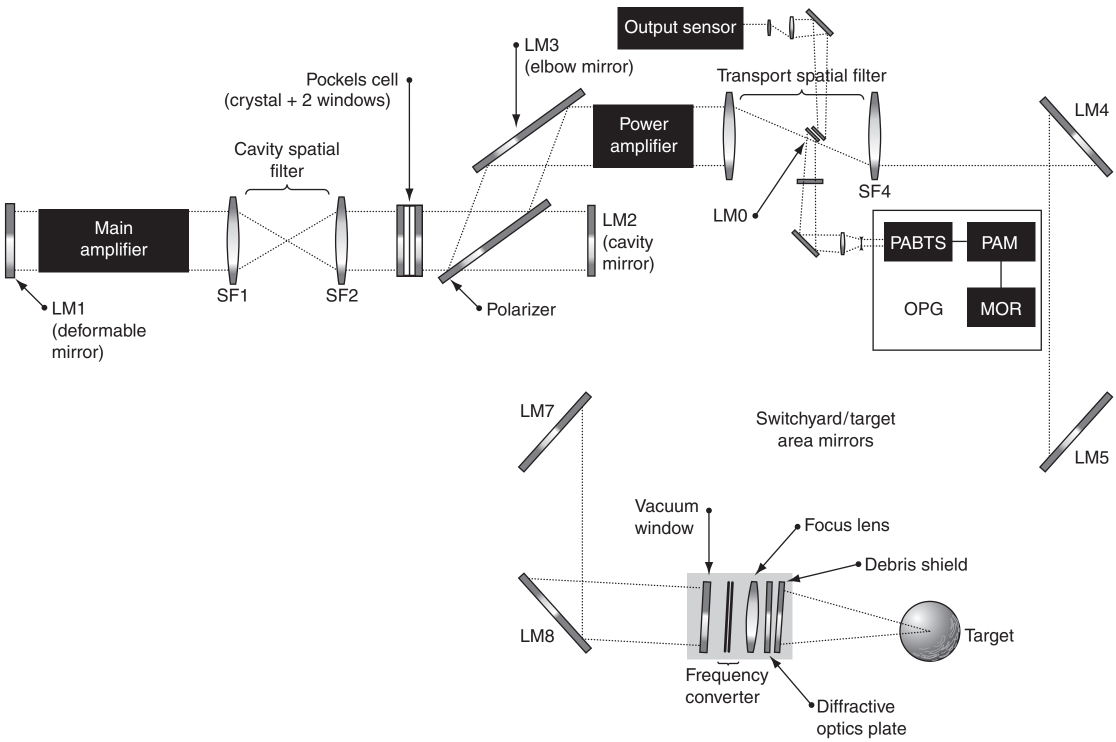

FIGURE 5-58 Schematic diagram of the NIF laser system.

through the Pockels cell. It goes through the cavity spatial filter and the 11-slab main amplifier, and then reflects from a deformable mirror with 39 actuators. After once again passing through the main amplifier, the beam comes back through the cavity spatial filter to the periscope assembly. Meanwhile, the Pockels cell has been fired to rotate the polarization, so the beam passes through the polarizer and strikes mirror LM2, which redirects it back through the cavity spatial filter for another double pass through the main amplifier. The beam returns to the periscope assembly, passes through the deenergized Pockels cell, reflects off the polarizer and LM3, and is further amplified by the power amplifier. Now the pulse passes through the transport spatial filter on a path slightly displaced from the input path. The output pulse just misses the injection mirror LM0 and enters the switchyard and beam transport area.

Switchyard and Beam Transport. Between the switchyards and the target chamber room, the beams are in two 2×2 arrays: the 4×2 bundles are split into 2×2 quads, moving up or down to one of the eight levels of the switchyard. Each pulse now travels through a long beam path, reflecting off of several transport mirrors before reaching the target chamber. The transport mirrors can be moved to create the beam configuration needed for direct- or indirect-drive experiments. For indirect drive, mirrors send the beams straight up or straight down to make the cones coming into the top and the bottom of the target chamber cylinder. For direct drive, 24 beams are directed to circumferential positions around the target chamber by moving two mirrors in each of these beamlines. Once the beams reach the target chamber, they enter the final optics assembly.

Final Optics Assembly. The final optics assemblies are mounted on the target chamber. Each assembly includes a vacuum window at 1ω, a cell that includes a frequency converter (two plates of potassium dihydrogen phosphate crystal) to convert the pulse to 3ω, and the final focusing lens. The cell tips and tilts to tune the frequency converter, and translates along the beam direction to focus the beam on the target. A debris-shield cassette includes the capability of diffractive optics for spot shaping. Once a pulse travels through this assembly, it proceeds to the target in the target chamber.

Other Laser Facilities. Other powerful lasers for ICF experiments include GEKKO XII at Osaka University in Japan, Omega at the University of Rochester in New York, and Nike at the Naval Research Laboratory in Washington, D.C. The GEKKO XII laser used ND: glass laser at 0.53 μm, and 12 beams with random-phase-plates implemented. The laser energy is 8 to 10 kJ with a nominally 1.7-ns (full width at half-maximum, [FWHM]) flat-top pulse with a rise time equivalent to a 1- to 1.3-ns Gaussian pulse (FWHM). Achievements at GEKKO XII include the generation of 10^{13} neutrons per shot, a 10-keV plasma with stagnation-free mode compression, and a density compression up to 600 times solid density using a plastic shell target implosion. An upgrade of the GEKKO system to double the output in blue laser light has been implemented. Further, it is envisioned that a solid-state laser could be ultimately developed for use in a power plant using laser diode (LD) pumping of the laser and advanced active cooling techniques. In addition to technical issues involved in this approach, the projected cost for the LD unit must be substantially reduced to achieve economic competitiveness.

LD-pumped solid-state lasers have advanced to driver candidate status due to the recent advances of AlGaAs LD arrays with power of ~4 kW/cm^2 (200-μs pulse duration), an efficiency of ~60%, and a lifetime of 10^{11} shots. A conceptual power plant design has been carried out for an LD system with 10-MJ blue output, 10% efficiency, and 10-Hz repetition rate. Also, additional constraints incorporated in the design include the following:

To prevent damage, the fluence of the laser beam in the amplifier was restricted to be 32 J/cm^2 at a pulse width of 10 ns.

To prevent parasitic oscillation in the laser disk material, the product of the largest dimension of the disk and the small signal gain coefficient was held $\lesssim 4$.

Cooling was added to keep the maximum temperature difference and the peak temperature in the disk below 10% and 30% of the transition or melting point of the laser material, respectively.

The maximum thermal stress in the disk was held to $\lesssim 20\%$ of the fracture strength to ensure optical quality and long-lifetime operation.

OMEGA Laser Facility. The OMEGA laser is housed in the Laboratory for Laser Energetics (LLE) at the University of Rochester, New York. This facility is part of the national laser fusion effort within the U.S. Department of Energy and has as its main mission direct-drive laser fusion research in support of the upcoming National Ignition Facility (NIF) at the Lawrence Livermore National Laboratory (LLNL). The OMEGA laser system has been operating since May 1994 (McCrory 1994, Seka et al. 1997, Sourers et al. 1996). This 60-beam UV laser facility can cover a wide variety of experiments related to ICF. The facility also supports indirect-drive laser fusion research under the direction of LLNL and the Los Alamos National Laboratory (LANL).

The OMEGA laser system (Boehly et al. 1992) is a Nd:glass laser system with frequency conversion to the third harmonic with a UV (351-nm) energy capability on target in excess of 30 kJ for pulse durations of ≤2 ns. The system's 60 beams (30-cm beam diameter) are arrayed symmetrically around the 3.3-m-diameter target chamber and are focused onto the target by 60 near-diffraction-limited *f*/6 lenses.

Laser pulses with a wide variety of predetermined, temporal UV output pulse shapes have been produced by a versatile pulse-shaping system. These shapes range from 1- to 3-ns flat-topped pulses to linear ramps (1 to 3 ns), Gaussians (0.2 to 1.2 ns), and a special 2-ns pulse designed for indirect-drive targets.

The demonstrated energy balance of the OMEGA system is ~2% rms for the IR part of the system, ~3% rms in the UV after the conversion crystals, and ~4% to 5% rms on target after the UV transport optics (two turning mirrors, a focusing lens, and a blast shield per beamline). The system's reproducibility is <1% rms excluding clearly identifiable flashlamp or PFN malfunctions. The measurement accuracy of the beam energies (including residual fundamental and second-harmonic output from the conversion crystals) is ~0.8% rms.

The OMEGA laser system has three complete driver lines with corresponding pulse-shaping systems. Any one or any combination of two of these driver lines can be used to drive the laser system. The laser system supports the propagation of two different pulse shapes: one for the main experiment (driver) and the other for a backlighter. In this case, one driver line feeds 40 beamlines, while the other feeds the remaining 20. The timing between these two groups of beams can be chosen freely.

Beam smoothing, an essential component for the success of direct-drive laser fusion, is implemented on OMEGA using smoothing by SSD pioneered at LLE. LLE's approach combines continuous-phase-plate technology with polarization rotators and two FM modulators with corresponding spectral dispersion in two dimensions (2-D SSD). Present capabilities are limited to 2- to 3-Å total bandwidth for the two modulators (3 and 3.3 GHz modulation frequency). In addition, a limited number of phase plates and polarization rotators are available primarily for planar target experiments. A full complement of phase plates is available for spherical irradiation experiments, and complete complement of polarization rotators is expected soon. At that time, increased bandwidth (~10 Å) and higher FM modulation frequencies (~10 GHz) will also be available, allowing an on-target frequency bandwidth of ~1 THz in the UV spectrum.

The pointing capability of the OMEGA laser system has been shown to be ~10 μm rms on target. This performance has been repeatedly verified with x-ray imaging using pinhole cameras and x-ray microscopes. The stability of the system is sufficient to maintain the above pointing accuracy without adjustments for at least a period of 1 day. Furthermore, beams can be placed in basically arbitrary locations within ~1 cm from the target chamber center with essentially the same accuracy (~20 mm without corrections; better accuracy is achievable with one iterative fine correction). This capability has been demonstrated on recent indirect-drive hohlraums of cylindrical (two laser entrance holes) and spherical shape ("tetrahedral" hohlraums with four laser entrance holes) with or without additional backlighter targets.

The present OMEGA experiments address irradiation uniformity, implosion physics, hydrodynamic instabilities, laser imprinting, and laser-plasma-interaction physics. In addition, there are experiments carried out by LLNL and LANL relating to indirect-drive laser fusion.

Liquid or solid layers of DT are required to minimize the drive requirements for high-performance, direct- and indirect-drive targets. In a collaboration involving LLNL, LANL, General Atomics (GA), and LLE, the technology required to conduct cryogenic-fuel-layer ICF experiments is being developed at the OMEGA facility (Sourers et al. 1996).

As part of the national effort on cryogenic target development, GA is currently designing a cryogenic target delivery system for OMEGA experiments. The system is shown schematically in Fig. 5-59.

Using this system, polymer shells will be filled with DT up to 1500-atm-pressure, room-temperature equivalent. The shells will be transferred to the vicinity of the OMEGA target chamber in a cold-transfer cryostat. Fuel layers up to 100 μm thick will be formed inside the 1-mm-diameter plastic shells. The capsules will then be inserted into the OMEGA chamber and irradiated by the 60-beam system. Liquid layering is expected to occur inside the chamber with in situ characterization just before the target is shot.

A $50 million upgrade to the OMEGA laser is planned for completion in 2007. It will add two high-energy Petawatt lasers for advanced fast-ignition experiments.

The NIKE KrF Laser. In order to achieve an attractive laser-driver for inertial fusion energy (IFE), a higher laser efficiency is needed than achieved with current flash-lamp-pumped Nd-glan lasers. One approach that combines a reasonably high laser efficiency (around 5%) and short wavelength (UV) is the KrF laser (Sethian et al. 1997).

NIKE is a multikilojoule krypton-fluoride (KrF) laser that has been built at the Naval Research Laboratory (NRL), Washington, D.C. to study the physics of direct-drive inertial confinement fusion. Both the two final amplifiers of the NIKE laser are electron-beam-pumped systems. This design places strong reliance on the pulsed electron beams to drive the amplifiers. The smaller of the two has a 20 × 20-cm aperture and produces an output laser-beam energy in excess of 100 J (Fig. 5-60).

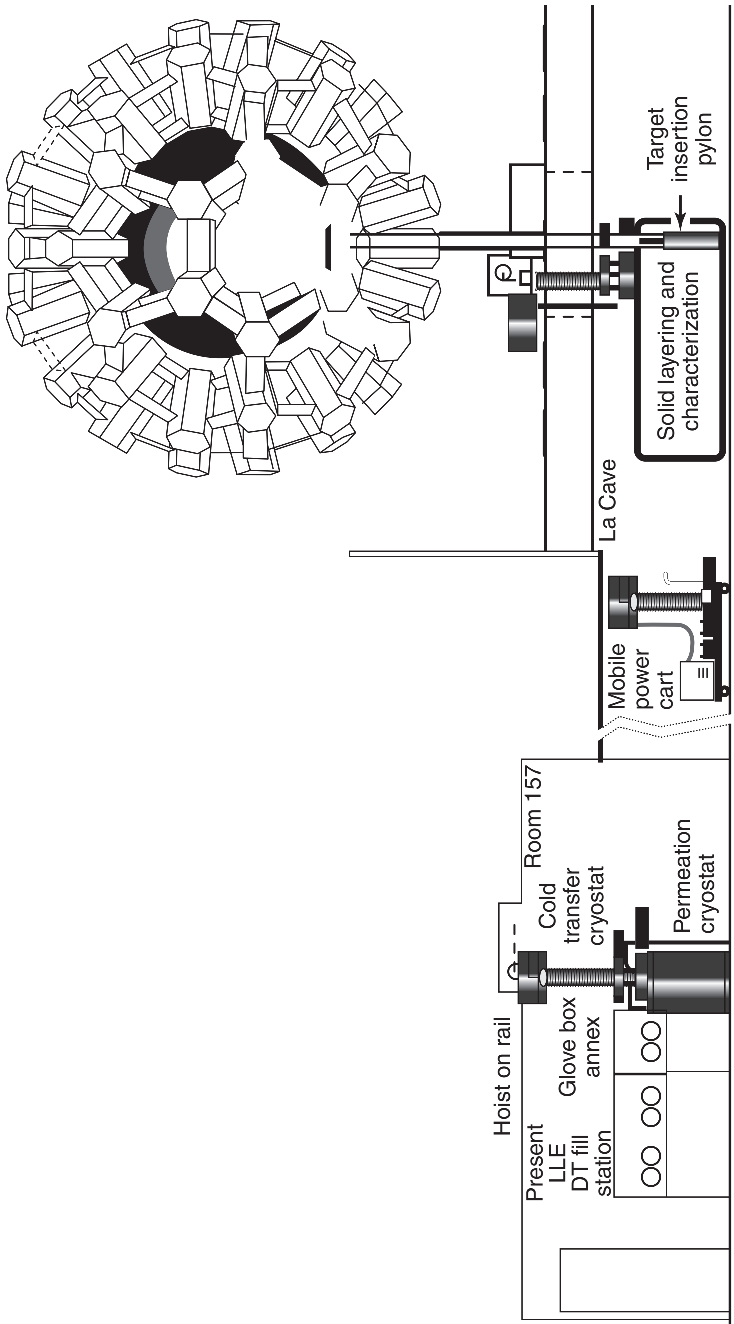

FIGURE 5-59 Schematic diagram of OMEGA cryogenic target system.

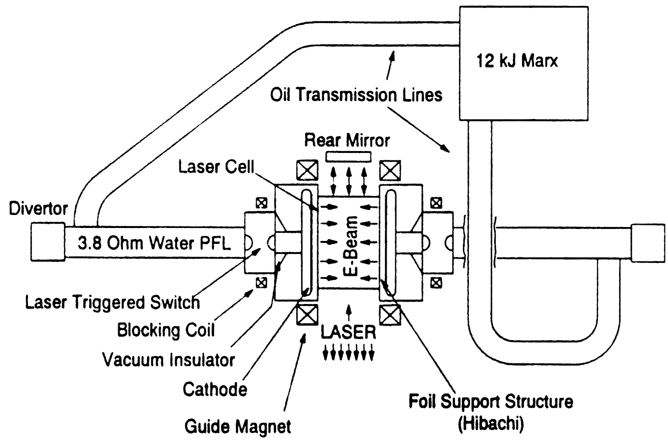

FIGURE 5-60 The NIKE 20-cm amplifier. The paths of the laser beam and electron beams are shown in this figure. The laser beam enters the laser cell (from the bottom of the figure), is amplified once, is reflected off the rear mirror, and is amplified again as it passes back through the cell. The 60-cm amplifier uses a similar concept.

This 20-cm amplifier uses a single 12-kJ Marx generator to inject two 300-kV, 75-kA, 140-ns flat-top electron beams into opposite sides of the laser cell. The larger amplifier in NIKE has a 60 × 60-cm aperture, and amplifies the laser beam up to 5 kJ. This 60-cm amplifier has two independent electron-beam systems. Each system has a 170-kJ Marx generator that produces a 670-kV, 540-kA, 240-ns flat-top electron beam. Both amplifiers are complete, are fully integrated into the laser, meet the NIKE system requirements, and are used routinely for laser-target experiments. To obtain sufficiently high target gains for a direct-drive fusion reactor, a KrF laser based on the NIKE concept must take advantage of three optimizations. First, the laser-beam illumination on the pellet has to be extremely uniform. High-mode beam nonuniformities in the range of 0.2% rms are required, along with low-mode nonuniformities of about 1%. These nonuniformity levels have already been achieved with NRL's KrF laser. Second, the rocket efficiency has to be maximized by depositing the laser energy deeply into the pellet. KrF, with 0.25-μm light, deposits at about twice the plasma density as a solid-state laser at 0.34 μm. Third, the target gain is optimized by "zooming" the laser beam inward during the implosion, thereby better matching the laser spot size to the pellet diameter. This optical zooming is achieved in a straightforward fashion with KrF lasers. There are also several engineering challenges in developing a laser of this type with sufficient energy, repetition rate, reliability, and economy for a practical reactor. Some of these challenges are the lifetime of the emitter and pressure foil in the electron-beam pumped amplifiers, the ability to clear the laser gas between pulses without sacrificing beam quality, and the overall efficiency of the system.

Accelerator and X-Ray Fusion. In addition to lasers, accelerators and x-rays are considered strong candidates for ICF drivers, especially for future reactors. We will consider both briefly here.

Light-Ion Accelerators. Pulsed-power-based light-ion particle accelerators (Bluhm et al. 1992, Mehlhorn 1997, Quintenz et al. 1996) have been under development as ICF drivers since 1972. The technology produces a beam that couples well to matter and is scalable to very high power levels. Light-ion ICF uses pulsed-power accelerators that compress electrical energy in both space and time, and then covert the energy into directed ion beams in a device called an *ion diode*. The ion power and focusability can be improved by using two acceleration gaps, in a device called a *two-stage diode*. Self-pinched transport is an attractive option for propagating the beam from the diode to the target. A stand-off distance of several meters is required to protect the diode from the fusion target blast. Finally, the

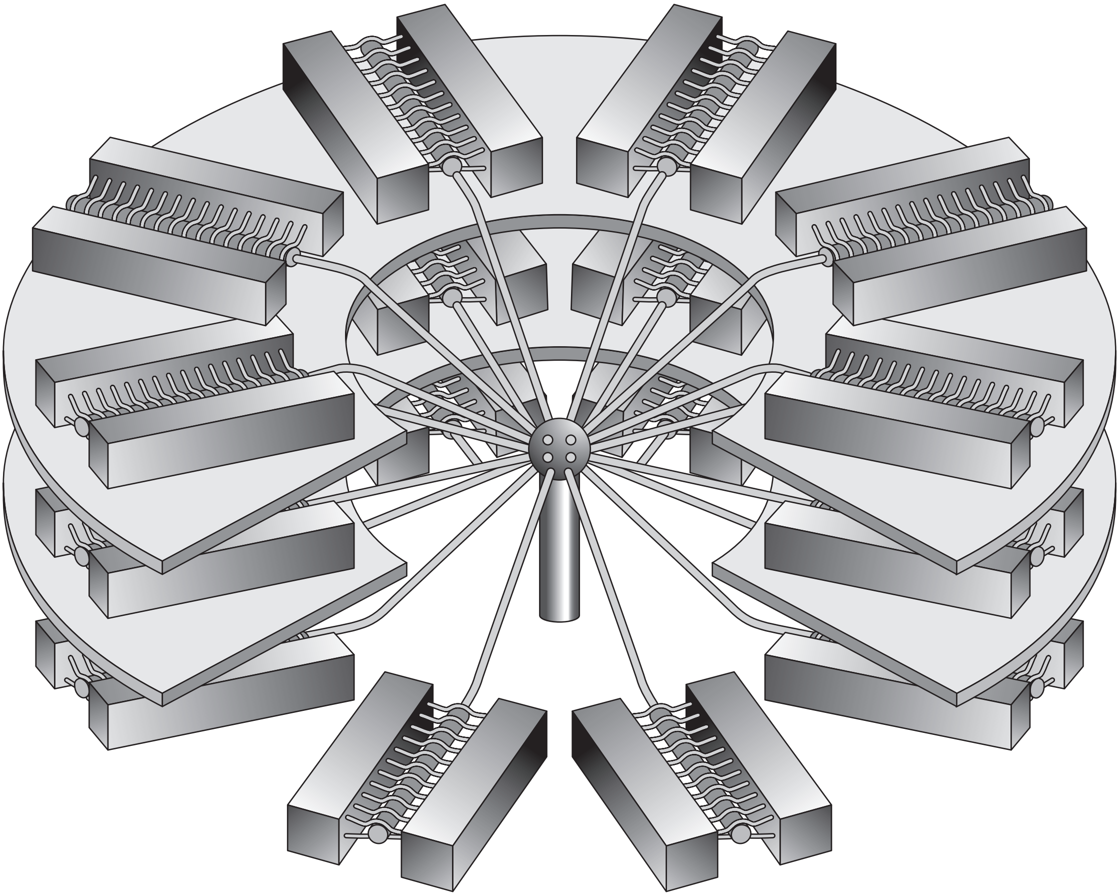

FIGURE 5-61 Z-facility showing modules arranged in three tiers.

light-ion driver beam is focused onto the ICF target, producing x-rays that drive the capsule to fusion conditions, resulting in a large fusion energy yield. Light-ion research is focused on developing the basic physics and technology scalings that could enable the construction of a high-yield facility (HYF) or engineering test facility (ETF) for IFE as shown schematically in Fig. 5-61. A light-ion IFE facility would comprise many modular pulsed-power accelerators that are compact, efficient, and low cost. Ion-beam divergence is the ratio of the transverse to longitudinal beam velocity, and is a measure of the focusability of a beam. Each module would have a two-stage ion diode comprising an injector section that accelerates lithium ions to $\leqslant$24 mrad at 9 MeV, a second stage of acceleration to reduce the divergence to $\leqslant$12 mrad at 35 MeV (by adding only longitudinal momentum), and a self-pinched transport channel that can propagate a 12-mrad lithium beam up to 4 m to the target. The ion beams from these modules would be focused onto a single target to supply the total power and energy requirements for ICF with sufficient uniformity to drive a symmetric implosion. Considerable progress in this technology has been made on accelerators at Sandia National Laboratory (SNL) in New Mexico and the Research Center Karlsruhe (FZK) in Karlsruhe, Germany. Proton beams have been focused to peak intensities of 1 TW/cm^2 at FZK and 5 TW/cm^2 at SNL, while SNL has focused a lithium beam to ~2 TW/cm^2. Focused lithium beams have heated a target to almost 70 eV at specific energy densities that are comparable to the initial pulse level of an HYF target. At present, the key technical challenges for the light-ion program are (1) developing low-emittance ion sources that can provide 1–2 kA/cm^2, (2) reducing total ion beam emittance, (3) increasing total ion beam brightness by two-stage acceleration, and (4) developing a simple robust ion beam transport system. The modularity of the light-ion approach provides a cost-effective development path for an HYF/ETF. The key technical issues can be studied on existing smaller accelerators such as SABRE at SNL and KALIF at FZK; the scaling of the results can be tested on existing larger accelerators such as HERMES-III at SNL, leading to the construction of a single HYF module and the eventual construction of a full HYF/ETF. This technology is now used to produce x-rays for inertial confinement fusion pellet implosions.

Z-Pinch X-Ray Fusion. Since October 1996, the Z-facility (previously known as PBFA-II) at Sandia National Laboratories (Albuquerque) has operated in a Z-pinch configuration to provide experimental data to the Stockpile Stewardship Program of the National Nuclear Security Administration (NNSA). In the new configuration, electrical energy is coupled into the kinetic energy of a magnetically-driven imploding plasma, formed by passing a large current through an annular array of wires. An intense, short pulse of soft x-rays is created when the imploding plasma stagnates on axis. These x-rays are then directed onto the surface of a fusion capsule, heating and compressing it. In a fusion power plant based on Z-pinch x-rays, an array of accelerators would deliver x-rays sequentially to a target chamber at about 0.1 Hz.

Work is proceeding on the design and testing of key systems for the refurbishment of the Z-facility (to be known as ZR) to be complete in 2006.

Heavy-Ion Accelerators for ICF. High-energy particle accelerators are considered as potential ignition devices for inertially driven fusion targets. Relativistic particle beams have the advantage that intrabeam forces are reduced by the cancellation of electric repulsion by magnetic attraction between two particles moving in quasiparallel paths near each other. Also, with large beam energies, huge peak powers can be achieved with relatively small currents. For instance, at 10 GeV, a peak power of 400 TW corresponds to a peak current of 40,000 A (or the combined effect of 40 beams each with 1000-A current), entirely within the realm of achievable currents for a variety of particles.

A key difficulty in the use of high-energy beams is the requirement of depositing most of the beam energy within the relatively thin outer shell of the target. To meet this goal, one can use heavy ions, which even at several GeV have a range smaller than ~1 g/cm^2 or, alternatively, use relativistic electrons, but with an intermediate, "energy-efficient" conversion into soft-x-ray photons (~0.1 to 1.0 keV). The x-rays then drive the target implosion (so-called indirect drive).

The key figure of merit in colliding-beam devices is *luminosity*. This requires high current densities and, in most designs, a large number of high-energy particles packed in a tight bunch. These requirements are not unrealistic, however. For instance, the high current reached many years ago in the CERN-ISR has spurred these ideas on. The energy stored in each beam of the ISR has now reached 5×10^6 J using a beam of 50 A at 31.5 GeV for the duration of 3.3 μs, roughly the correct order of magnitude of energy for ICF ignition. There are, however, two important differences when comparing ICF requirements with CERN-ISR: first, the beam duration for ICF should be $\leqslant$ns in order to achieve the instantaneous power required and second, protons must be replaced by heavier ions (e.g., lithium) in order to ensure a sufficiently short range. These extrapolations are by no means trivial.

To operate a large-scale ICF power station, beams with a total energy delivered to the target of several 10^7 J are required. Since the beam duration must follow the implosion time, the length of the pulse must be a few nanoseconds. Hence, the peak power will reach ~10^{15} to 10^{16} W, or several hundred TW. More detailed calculations with 10-GeV bismuth ions focused to a 2-mm radius target, show that an energy ~5 MJ and a peak power of 300 TW are appropriate for a gain G ~80, sufficient for a commercial-grade reactor.

Another difference between current accelerator experiments and ICF involves the environment in the vicinity of the final focus in ICF. While peak currents in excess of 10^3 A have been focused to submillimetric spots in colliders at hard vacuum without problems, the reactor vessel will have vacuum conditions of 1 to 10 torr. Also, the large amount of radiation emitted by the imploding pellet could "backfire" on the incoming beam.

We can now give a short description of the whole scheme (see Fig. 5-62). The initial acceleration of the singly ionized heavy ions uses a linac structure delivering about 50 mA of current during a

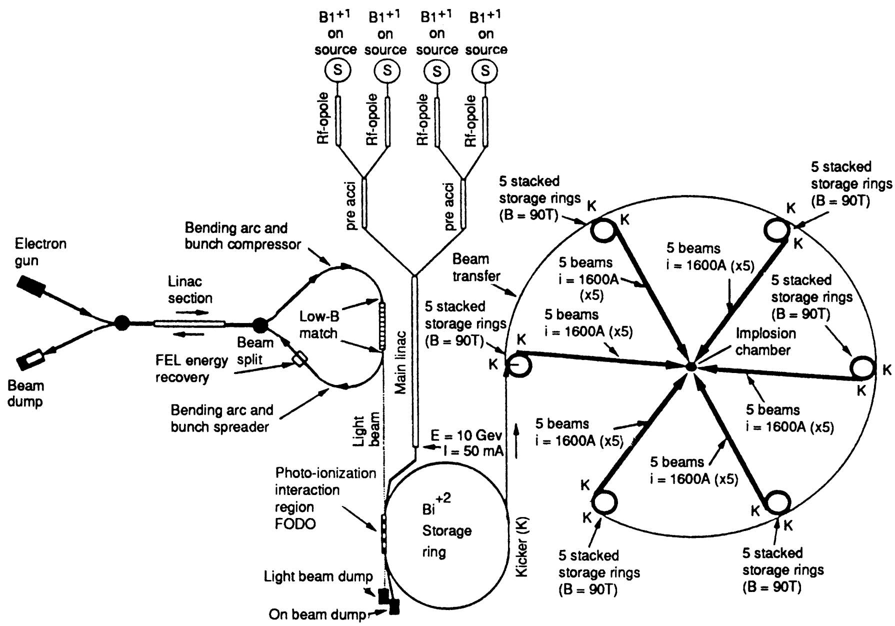

FIGURE 5-62 General layout of the heavy-ion pellet ignition scheme. This is an updated version of the basic HIBALL design.

filling burst of 12.8 ms. To achieve the required current, several sources and preaccelerators are merged. A linac accelerator is complicated and expensive, but compared to other types of accelerators, the single-pass linac appears to be a good choice. The linac pulse is optically dissociated into a doubly ionized beam, which is injected in a storage ring. Every 0.43 ms, the stored beam is dumped into a set of 30 superconducting rings which also act as beam-storage devices. The transfer is performed as a five-turn injection, and the field of these rings is maximized for high compression of the beam. The 30 beams are tightly bunched, extracted through the final focus and the compression channels, and then focused onto the target. At the final phase, each of the 30 beams carries about 1600 A in a pulse duration slightly less than 10 ns.

The U.S. Heavy Ion Fusion Program currently places great emphasis on cost reduction since high capital cost appears to be one of the disadvantages of this approach. The search for lower cost encompasses two main activities: (1) the exploration of new directions in beam physics, plasma physics, and target design (mostly scientific issues), and (2) development of improved materials, better hardware, and better fabrication techniques (mostly technological issues). As the understanding of the science of heavy-ion fusion continues to improve, several developments aid in cost reduction. One involves beam propagation in the target chamber. Recent numerical studies show that beam neutralization techniques will be effective. Beam neutralization allows a reduction in ion kinetic energy, leading to a significant reduction in accelerator cost. Target physics, including fast ignition, appears to be another scientific area where cost breakthroughs are likely. Important cost reductions in most areas of technology also appear feasible. A heavy-ion induction accelerator consists of a number of components: ion sources, an injector, ferromagnetic cores, insulators, magnetic and electric focusing lenses, pulsers, and diagnostics and controls. Although the ion sources by themselves are not costly, improved sources can lead to lower cost in the remainder of the accelerators; consequently, several new source technologies, including aluminosilicate, contact ionization, gas, laser, and spark sources, are being explored. The cost of ferromagnetic materials for the induction cores ranges from a few dollars per kilogram to more than $100/kg. Techniques are under study to insulate and anneal inexpensive materials to make them suitable for accelerator applications. Traditionally, insulators for accelerators are made from alumina.

The joints to metal are made by brazing. Large alumina insulators needed for fusion accelerators are costly, as is brazing. Thus, insulators that can be cast with metal attachments are being developed. Innovative superconducting magnetic lenses with an emphasis on designs that can be inexpensively fabricated are being developed. Conventional and advanced pulsers for heavy-ion fusion are also under study. In terms of conventional pulsers, most work is with thyratrons, exploring methods to optimize them for our application. Advanced pulsers employ solid-state devices and magnetic pulse compression. Finally, improved diagnostics and control systems are being developed. Improved ability to sense and control the beam leads to smaller less expensive accelerators.

Fusion Breeder. The physical basis of the fusion breeder (also called the fusion-fission hybrid) is the prolific production of high-energy neutrons in fusion reactions. These neutrons can be used to breed fertile fuel (plutonium and ^{233}U) for use in conventional fission reactors. Each D-T fusion reaction produces 14 MeV of total energy, or approximately 4 times as many neutrons per unit of energy as a fission event (~3 neutrons per 200 MeV). The 14-MeV fusion neutrons produce additional neutrons in the breeder blanket by neutron-multiplying nuclear reactions, by fast fissions in fertile materials, and/or by nonfissioning reactions such as (n, 2n) reactions in beryllium.

5.4.10 Breeder Types

Two different fusion breeder types based on these two methods of neutron multiplication have emerged. One uses a fast-fission blanket and the other uses a suppressed-fission blanket. In the former, the D-T fusion source is surrounded by a blanket of fertile material (^{238}U and/or ^{232}Th) and a lithium compound for tritium breeding as shown in Fig. 5-63. Fast fissions in the fertile material multiply both the fusion energy (3 to 10 times) and the neutrons (approximately two to four neutrons per fusion neutron). One of the neutrons is needed to breed tritium from lithium and the remainder are available for breeding fissile fuel.

In the suppressed-fission blanket (see Fig. 5-63), a nonfissioning, neutron-multiplying material such as beryllium replaces most of the fertile fuel in the blanket. Consequently, the fast-fission source of neutron multiplication is replaced with a nonfissioning source of neutrons. To further suppress the fissioning of the bred ^{233}U, its concentration is limited to about 1% or less of the fertile fuel. Thus, the breeding blanket must be designed to allow for online, or quick, low-cost removal and recovery of the bred fissile fuel. The low fission rate results in superior overall reactor safety characteristics. Also, a much lower fission product inventory and a lower decay afterheat results.

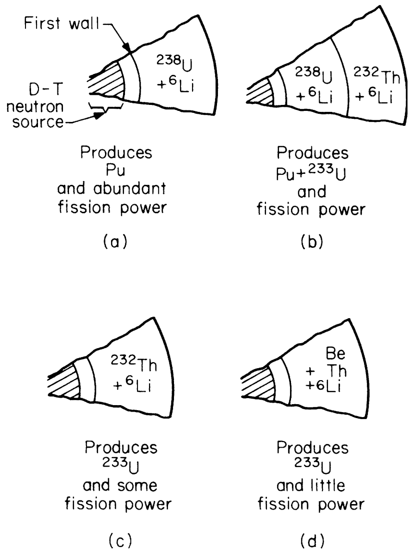

FIGURE 5-63 Methods of neutron multiplication: (*a*) ^{238}U fast-fission blanket; (*b*) ^{238}U + ^{238}Th fast-fission blanket; (*c*) ^{232}Th fast-fission blanket; (*d*) ^{9}Be fission-suppressed blanket.

Fuel Cycles. The suppressed-fission blanket can produce plutonium rather than ^{233}U by substituting uranium carbide for the thorium, but then the number of client LWRs that can be fueled is lower. For example, for a recent design with a 2100-MW fusion driver (4000 MW$_{nuclear}$), the suppressed fission design could support 14 LWRs or 4000 MW$_{nuclear}$ each when producing ^{233}U but only about 9 when producing plutonium. The advantages of higher LWR support motivate the desire for new fuel-reprocessing technologies for ^{233}U and thorium. Two technologies being considered are the conventional, aqueous THOREX reprocessing technology and a pyrochemical process that uses magnesium dissolution of the thorium leaving the ^{233}U as a precipitate.

Breeder Role. Fusion breeders are best understood in the context of a symbiotic fusion-breeder–fission-burner system that generates electricity. The fusion breeder would be incorporated into a fuel-cycle complex along with fuel-reprocessing plants, fuel-fabrication facilities, and possibly a waste-disposal facility—all in a safeguarded area. The fissile fuel produced in the fusion breeder is recovered by reprocessing, mixed with fertile fuel, fabricated into fuel rods, and shipped to the fission burner reactors. The spent fuel from the burner reactors is returned to the safeguarded fuel-cycle complex where the remaining fissile fuel is separated from the radioactive waste material.

Support Ratio. The thermal support ratio is defined as the nuclear (or thermal) power of the client fission reactor (e.g., LWR) divided by the nuclear power of the fusion breeder. A high thermal support ratio is advantageous because such a breeder could fuel a large number of fission reactors, thus having a large commercial impact. Also, for large support ratios, only a small fraction of the symbiotic system's cost and electricity generation is attributed to the addition of a fusion breeder into the existing electricity generation system (typically 15% of the overall capital cost and about 5% of the overall electricity generation). Because relatively little power would be produced within the safeguarded fuel-cycle park itself, the breeders could be in a remote location.

Thermal support ratios for fusion breeders range from 4 to 45, depending on the choice of fusion blanket and client thermal converter (e.g., LWRs or advanced converter reactors). The following support ratio estimates are typical: uranium fast-fission blankets produce enough plutonium to support 4 to 6 LWRs; thorium fast-fission blankets produce enough ^{233}U to support 8 to 12 LWRs, or 14 to 28 advanced converters; uranium suppressed-fission blankets produce enough plutonium to support 9 to 11 LWRs; thorium suppressed-fission blankets produce enough ^{233}U to support 12 to 16 LWRs, or 35 to 45 advanced converters.

The variations in these support-ratio estimates depend on the specifics of the fusion-blanket designs, the type of client fission reactor, and fuel-cycle choices.

These support ratios can be put in perspective by comparing them to the support ratios of a liquid-metal fast-breeder reactor (LMFBR). A typical LMFBR does not produce enough excess fissile fuel to support even one LWR of equivalent nuclear power. Furthermore, the LMFBR must also produce fissile fuel to satisfy the fissile inventory requirement of additional LMFBRs. Consequently, LWR support is not an effective mode of LMFBR operation. The fusion breeder, on the other hand, requires no initial fissile inventory, and its tritium inventory is quite low.

Performance Requirements. Fusion breeders can operate economically with significantly lower fusion performance and higher cost than fusion electric power plants. We consider two performance indicators for magnetic fusion devices: plasma energy gain Q and first-wall fusion neutron wall loading Γ. Q is defined as the ratio of the fusion energy produced to the input energy required to heat and sustain the plasma (supplied by relatively expensive beams of energetic neutral atoms and/or rf heating systems). The fusion neutron first-wall loading in megawatts per square meter is indicative of the blanket power density.

Several conceptual design studies of fusion reactors have shown that pure fusion power plants will require $Q > 20$ and $\Gamma > 3$ MW/m^2 to produce competitive electricity. Although high Q is preferred, fusion breeders will only require Q values from 2 to 6 and $\Gamma > 1$ MW/m^2 to economically produce fuel for LWRs. Fusion breeders with fast-fission blankets can operate in the lower-Q regime (i.e., Q from 2 to 4); with suppressed-fission blankets, Q values above 6 are required.

These performance requirements also apply to ICF systems. For example, ICF hybrid studies have shown that a driver-efficiency target gain product ($\eta_D G$) of about 6 is acceptable while an $\eta_D G$ product greater than 20 is required for fusion electric power generation. These lower performance requirements can allow relaxation of technology requirements.

5.4.11 Progress toward Attainment of Controlled Fusion

Figure 5-64 illustrates the progress of magnetic fusion toward the goal of controlled nuclear fusion. In this figure, the kinetic temperature of a pure deuterium-tritium plasma (ions and electrons taken to have the same temperature) is plotted against the density-confinement time product $n\tau$. In these coordinates, ignition occurs at any point on or above the locus (top of the diagram) at which the thermonuclear energy gain exceeds 30.

Loci of constant gain (fusion power density at 17.6 MeV per fusion, divided by the external power density required to maintain the plasma temperature against losses) are plotted over a wide range (from

The values of the operating areas of specific experiments are identified by the abbreviated symbols for several confinement devices. The highest attained kinetic temperature achieved is in mirror and certain pinch experiments where about 30 keV, equivalent to 300 million degrees absolute, has been achieved.

Unique Resource Requirements. Table 5-19 lists a number of materials needed to support a nuclear-fusion power economy capable of delivering a total power of a million megawatts (third column) compared with the forecast U.S. demand for these materials in the year 2000 and estimates of world reserves. According to this table, there appears to be no resource limitation that would prevent the extensive development of fusion power. However, the demands for certain materials (beryllium, copper, helium, lithium, vanadium, niobium, and molybdenum) would require additional production capacity, and exploration for new sources would be required for beryllium, lithium, vanadium, niobium, and molybdenum.

Many of these materials will require new fabrication technology and the development of measures against structural deterioration under neutron bombardment and other radiation effects.

Safety and Environmental Considerations. Fusion power has long been considered preferable to fission power from the viewpoints of safety and environmental impact. Fusion reactors, in large part because they are concerned with fuels and reaction products of low atomic number, have lower potential for the release of radioactive materials. Also, the fusion process does not inherently result in radioactive products that require long-time storage like the fission-product waste from fission reactors. But more detailed examination of the processes involved in fusion shows that there are several key points at which stringent radiation safety measures must be taken.

The principal environmental hazard of fusion reactors employing the D-T-Li cycle is the release of tritium during normal operation or in the event of an accident. The avenues of escape of tritium during normal operations are the lithium blanket and its associated containment structure, fluid piping, and heat-exchanger tubing. All these elements operate at extremely high temperatures, with corresponding high permeation rates.

Fusion safety standards have been developed that require tritium releases to be maintained below 10 Ci/day in routine operations and considerably higher values are proposed in the event of a severe accident. It is assumed, on the basis of experimental evidence, that essentially all elemental tritium escaping to the environment will become oxidized. Oxides are several thousand times more hazardous than the element itself.

In a 1000-MW fusion plant, the internal throughput of tritium of about 4×10^6 Ci/day would require a containment factor of 99.9999% to limit the escape to 10 Ci/day. While such a factor is feasible, its attainment at acceptable costs must be demonstrated before large-scale fusion plants employing tritium can be demonstrated to be cost effective.

Fusion neutrons will also cause activation of the first-wall and blanket materials. This radioactivity can be minimized by judicious selection of materials. The overall biological-hazard potential of a typical fusion blanket system is lower than that of a liquid-metal fast-breeder fission reactor by at least one order of magnitude. While this fact does not in itself demonstrate that fusion reactors are safer than fission reactors, it does indicate that the technical problems of ensuring fusion safety probably will be simpler. Both types of reactor require stringent design constraints in this respect.

The problems of an accidental or forced shutdown involve two major factors: (1) the afterheat associated with loss of coolant of the plasma-facing structure and in the lithium blanket and its structural elements, and (2) the energy storage of the magnets in the confinement system. The afterheat depends markedly on the structural materials (silicon carbide, vanadium, and ferrite steels are the three current candidates) associated with the blanket. The duration of the cooling period may vary from hours to years. These materials have biological-hazard potentials lower than plutonium, but still they are not negligible.

The forces associated with the large magnet structures at the high fields required for fusion are of large proportions. During normal opration, for example, in a typical tokamak reactor, the force tending to push the toroidal field coils toward the center is 10^8 lb per coil at a field of 150 kG.

The stored energy in the system can be as high as 10^{11} J. Uncontrolled quenching of the field can produce extremely high voltages, so the insulators associated with the magnetic system must have a high safety factor. Even in normal operation, when the field energy is purposely dissipated by passage through a resistance bank, a residual amount of the energy, of the order of 1%, may remain. This residue (10^9 J of energy) is still enormous by conventional standards.

The foregoing examples illustrate the nature and extent of the engineering problems that will remain to be solved after controlled fusion itself is demonstrated and reduced to practice.

5.5 INDUSTRIAL COGENERATION

5.5.1 Cogeneration Defined

Cogeneration is a highly efficient means of generating heat and electric power at the same time from the same energy source. Displacing fossil fuel combustion with heat that would normally be wasted in the process of power generation, it reaches efficiences that can triple, or even quadruple, conventional power generation. Although cogeneration has been in use for nearly a century, in the mid-1980s relatively low natural gas prices made it a widely attractive alternative for new power generation. In fact, gas-fired cogeneration is largely responsible for the decline in conventional power plant construction that occurred in North America during the 1980s. Cogeneration accounted for a large proportion of all new power plant capacity built in North America during much of the period in the late 1980s and early 1990s.

Cogeneration equipment can be fired by fuels other than natural gas. There are installations in operation that use wood, agricultural waste, peat moss, and a wide variety of other fuels, depending on local availability.

5.5.2 Siting Cogeneration Plants

Because it is impractical to transport heat over any distance, cogeneration equipment must be located physically close to its heat user. Cogeneration plants tend to be built smaller, and owned and operated by smaller and more localized companies than simple-cycle power plants. As a general rule, they are also built closer to populated areas, which cause them to be held to higher environmental standards.

In northern Europe, and increasingly in North America, cogeneration is at the heart of district heating and cooling systems. District heating combined with cogeneration has the potential to reduce human greenhouse gas emissions by more than any other technology except public transit.

5.5.3 Basic Concept of Cogeneration

Conventional power generation is based on burning a fuel to produce steam. It is the pressure of the steam that actually turns the turbines and generates power. This is an inherently inefficient process. Because of a basic principle of physics, no more than one-third of the energy of the original fuel can be converted to steam that generates electricity.

Cogeneration, in contrast, makes use of the excess heat, usually in the form of relatively low-temperature steam exhausted from the power generation turbines. Such steam is suitable for a wide range of heating applications, and effectively displaces the combustion of carbon-based fuels, with all their environmental implications.

In addition to cogeneration, there are a number of related technologies which make use of exhaust steam at successively lower temperatures and pressures. These are collectively known as combined-cycle systems. They are more efficient than conventional power generation, but not as efficient as cogeneration, which normally produces about 30% power and 70% heat. Combined cycle technologies can be financially attractive despite their lower efficiencies, because they can produce proportionately more power and less heat.

Cogeneration equipment recaptures the exhaust and water heat of power generation equipment and converts it into hot water, steam, space heat, process heat, air conditioning, and many other useful purposes. No additional fuel is used to provide this source of “free” energy. Figure 5-65 illustrates the process by which this “free” energy is captured and utilized.

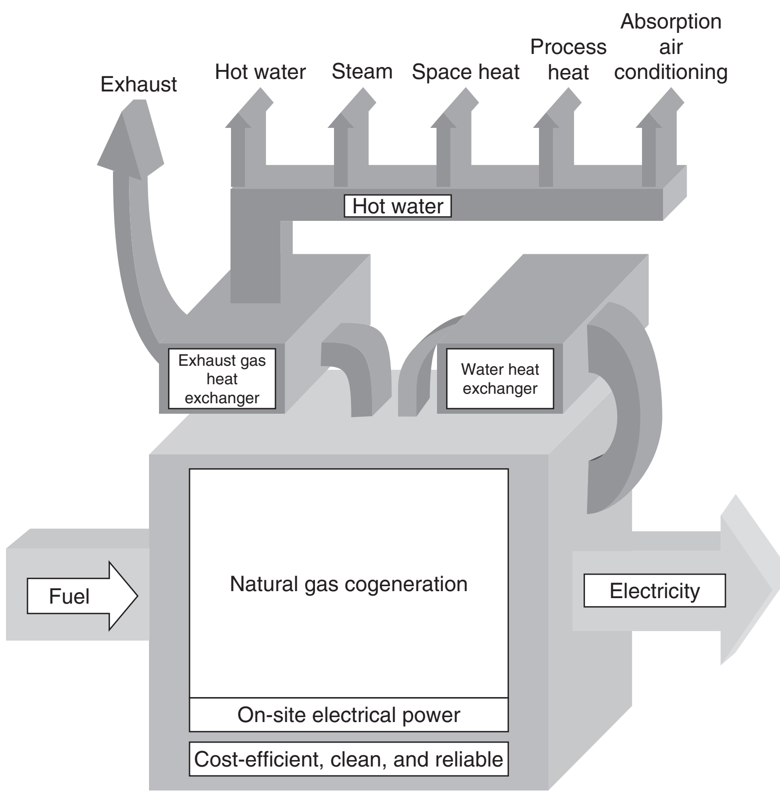

FIGURE 5-65 Diagram of the cogeneration process.

5.5.4 Advantages of Cogeneration

Cogeneration technology provides greater conversion efficiencies than traditional generation methods since it captures heat that would otherwise be wasted. This can result in more than doubling the thermal efficiency.

By recycling the waste heat, cogeneration systems achieve electrical efficiencies of 50% to 70%; a dramatic improvement over the average 33% efficiency of conventional fossil-fueled power plants. Higher efficiencies reduce air emissions and leading greenhouse gases, which are associated with climate change.

Environmental Issues. Carbon dioxide emissions will also be substantially reduced. Cogeneration systems predominantly use natural gas, a fuel source which emits less than half the greenhouse gas per unit of energy produced than the cleanest available thermal power station.

It is claimed by the Australian Cogeneration Association that cogeneration systems are more environmentally friendly, flexible, efficient, and can be more cost effective than traditional systems—especially when network costs and losses are taken into account.

Trigeneration provides even greater efficiency than cogeneration. Trigeneration is the conversion of a single fuel source into three useful energy products: electricity, steam or hot water, and chilled water. Trigeneration converts and distributes up to 90% of the energy contained in the fuel burned in a turbine or engine into usable energy. This is excellent efficiency compared to the 30% conversion that is typical for the standard electric generator.

5.5.5 Where Is Cogeneration Being Used?

A 1996 survey conducted by the International Cogeneration Alliance showed that the Netherlands was the world's leader of cogeneration use closely followed by two other Scandinavian countries—Denmark and Finland.

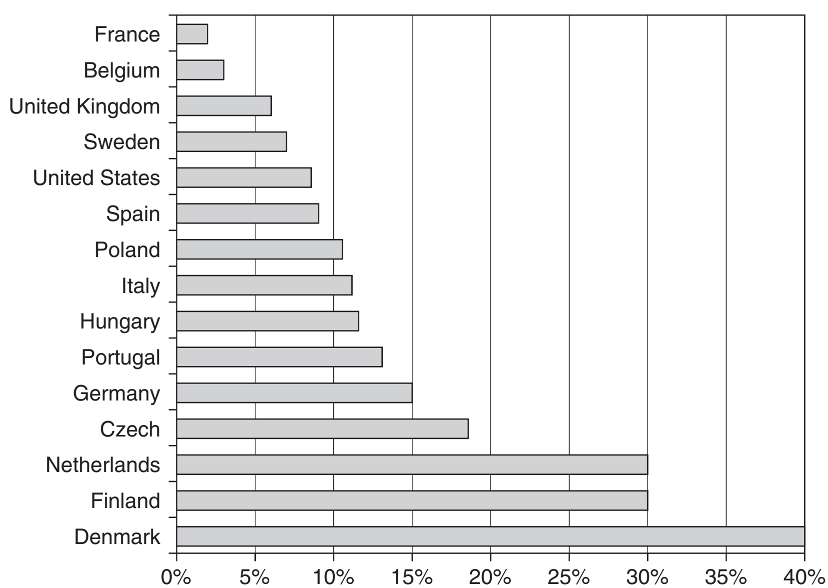

FIGURE 5-66 Percentage of national power production generated by cogeneration systems. ***Source:*** American Council for an Energy-Efficient Economy.

In 1900, half the electricity generated in the U.S. came from plants that also provided industrial steam or district heating. By the 1970s, cogeneration had fallen to less than 5%, but interest in this technology is being renewed.

The U.S. Department of Energy (DOE) set an initiative to double the use of combined heat and power systems in the United States by 2010. The U.S. National Energy Policy recommended that the president direct the U.S. Environmental Protection.

Agency (EPA) to take an active role in promoting cogeneration. While progress is slow, some states, along with EPA and DOE, are trying to lower regulatory hurdles for combined heat and power systems.

Figure 5-66 shows the percentage of national power production generated by cogeneration systems in 1997 in a variety of European countries, along with the United States.

As older power plants age and need to be replaced, and as competitive pressures to cut costs and reduce emissions of air pollutants and greenhouse gases increase, owners and operators of industrial and commercial facilities will be actively looking for ways to use energy more efficiently.

CONTENTS

6.1 STEAM PRIME MOVERS

6.1.1 Steam Engines and Steam Turbines

Steam prime movers are either reciprocating engines or turbines, the former being the older, dominant type until 1900. Reciprocating engines offer low speed (100 to 400 r/min), high efficiency in small sizes (less than 500 hp), and high starting torque. In the Industrial Revolution, they powered mills and steam locomotives. Steam turbines are a product of the twentieth century and have established a wide usefulness as prime movers. They completely dominate the field of power generation and are a major prime mover for variable-speed applications in ship propulsion (through gears), centrifugal pumps, compressors, and blowers. Single steam turbines can be built in greater capacities (over 1,000,000 kW) than any other prime mover. Turbines offer high speeds (1800 to 25,000 r/min) and high efficiencies (over 85% in larger units); require minimum floor space with relatively low weight; need no internal lubrication; and operate at high steam pressures (5000 lb/in^2 [gage]), high steam temperatures (1050°F), and low vacuums (0.5 inHg [abs]). Steam turbines have no reciprocating mass (with resulting vibrations) nor parts subject to friction wear (except bearings), and consequently provide very high reliability at low maintenance costs.

6.1.2 Steam-Engine Types and Application

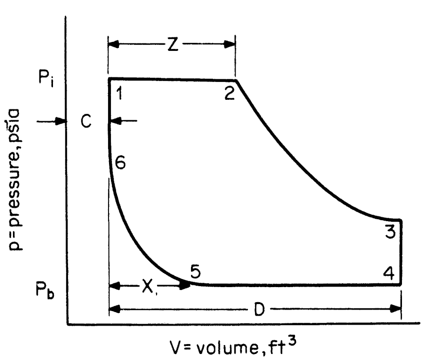
The former great diversity in engine types has been reduced so that (1) simple D-slide engines (less than 0.100 hp) are used for auxiliary drive and (2) single-cylinder counterflow and uniflow engines (less than 1000 hp), with Corliss or poppet-type valve gear, are used for generator or equipment drive in factories, office buildings, paper mills, hospitals, laundries, and process applications (where noncondensing by-product power operations prevail). Multiple-expansion, multicylinder constructions are largely obsolete except for some marine applications. Although engines as large as 7500 kW have been built and are still found in service, the field is generally limited to engines less than 500 kW in size. Engine governing is by flyball or flywheel types to (1) throttle steam supply or (2) vary cutoff.

6.1.3 Steam-Engine Performance

The basic thermodynamic cycle is shown in Fig. 6-1. The net work of the cycle is represented by the area enclosed within the diagram and is represented by the mean effective pressure (mep), that is, the net work (area) divided by the length of the diagram. The power output is computed by the "plan" equation:

$$\text{hp} = \frac{p_m Lan}{33{,}000} \tag{6-1}$$

where hp = horsepower; p_m = mep, pounds per square inch; L = length of stroke, feet; a = net piston area, square inches; and n = number of cycles completed per minute.



Where	Usual value
D = displacement	0.05–20 ft^2
C = clearance	0.03–0.2
Z = cutoff, fraction of D	0.1–0.6
X = compression, fraction of D	0.1–0.8
p_i = initial pressure	100–300 lb/in^2 (abs.)
p_b = back pressure	2–30 lb/in^2 (abs.)
p_m = mean effective pressure	50–125 lb/in^2 (abs.)

The theoretical mep and horsepower are larger than the actual indicated values and are customarily related by a diagram factor ranging between 0.5 and 0.95. The shaft or brake mep and horsepower are lower still, with mechanical efficiency ranging between 0.8 and 0.95.

6.1.4 Steam Turbines—General

1. *Expansion of steam through nozzles and buckets*. Basically, steam turbines are a series of calibrated nozzles through which heat energy is converted into kinetic energy which, in turn, is transferred to wheels or drums and delivered at the end of a rotating shaft as usable power.

2. *Impulse, reaction, and Curtis staging*. Turbines are built in two distinct types: (1) impulse and (2) reaction. *Impulse turbines* have stationary nozzles, and the total stage pressure drop is taken across them. The kinetic energy generated is absorbed by the rotating buckets at essentially constant static pressure. Increased pressure drop can be efficiently utilized in a single stage (at constant wheel speed) by adding a row of turning vanes or "intermediates" which are followed by a second row of buckets. This is commonly called a *Curtis* or 2-row stage.

In the *reaction* design, both the stationary and rotating parts contain nozzles, and an approximately equal pressure drop is taken across each. The pressure drop across the rotating parts of reaction-design turbines requires full circumferential admission and much closer leakage control.

To illustrate the variations in energy-absorbing capacities of an impulse stage, a 2-row impulse stage, and a reaction stage, one must start with the general energy equation as applied to a nozzle:

$$\frac{V_1^2}{2gJ} + H_1 = \frac{V_2^2}{2gJ} + H_2 \tag{6-2}$$

which is reduced to

$$\text{Jet velocity, ft/s} = 223.7\sqrt{\Delta H} \tag{6-3}$$

where V_1 is assumed to be zero, and ΔH is the enthalpy drop (isentropic expansion) in Btu per pound as obtained from the Mollier chart for steam (Fig. 6-2).

Assuming a typical wheel pitch line speed (W) of 550 ft/s and initial steam conditions of 400 lb/in^2 (abs.), 700°F (H_1 = 1363.4 Btu/lb), the optimum energy-absorbing capacities of each type can be derived.

Table 6-1 illustrates that the energy-absorbing capability of the Curtis stage is 4 times that of an impulse stage and 8 times that of a reaction stage.

Because of this capability, the 2-row Curtis stage has found many applications in the process industries for small mechanical-drive use (up to 1000 hp) where the inlet steam can be taken from one process header and the exhaust steam sent out to a lower-pressure process header. As energy costs increase, however, the lower efficiency attainable with these small-volume-flow single-stage units offsets some of the desirable features (e.g., speed control, low cost, etc.). All modern turbines over 1000 hp are multistage for good efficiency, varying from 3 to 4 stages on noncondensing units with a small pressure ratio up to 20 or more stages on large reheat condensing units. Reaction (Parsons) designs generally have more stages than impulse (Rateau) designs. All large units have an impulse (1- or 2-row) first stage because there is no pressure drop on the moving rows, which makes it more suitable for partial-arc admission.

3. *The control stage.* The first stage of the turbine must be designed to pass the maximum flow through the unit at rated inlet steam conditions. The pressure required at less than rated flow will decrease if the nozzle area is held constant, resulting in a throttling loss through the control valves of the unit at partial flows. Very early in the development of steam turbines, it was recognized that if full throttle pressure could be made available to the first-stage nozzles across the load range, the maximum isentropic energy that would be available for work and overall efficiency would be increased at part load. Most first stages now use sectionalized first-stage nozzle plates with 4, 6, or 8 separate ports (depending on steam conditions, unit size, and manufacturer).

Note: 1 ft/s = 0.3048 m/s; 1 lb/in^2 = 0.06895 bar; 1 Btu/lb = 2.326 kJ/kg.

The flow to each port is controlled by its own valve, and the valves are opened sequentially. As each valve is opened to its governing point, the full throttle pressure (minus stop-valve and control-valve pressure loss) becomes available to the arc of nozzles fed by that valve. The overall result is a greater availability of energy to do work.

4. *Steam-path design.* Condensing-turbine sizes increase with the development of longer last-stage buckets and, consequently, the last-stage dimensions (length and diameter) are the first to be determined; these dimensions fix the diameter of the L-1 stage and the optimum energy (pressure drop) which can be placed on that stage. This stage in turn defines the parameters of the L-2 stage and so on up to the first stage, and it can be said that steam paths of turbines are designed backward except for the first stage. In the 1970s, the largest-capacity single-flow condensing turbine was approximately 120,000 kW. Larger ratings are obtained by multiplying the number of exhaust stages (usually the last 5 to 7 stages are involved) by 2, 4, 6, or 8 times to satisfy the rating requirements. This practice is limited to the larger blades to round out a product line to well over 1,000,000 kW.

6.1.5 Turbine Efficiency

1. *Nozzle and bucket.* The turbine stage efficiency is defined as the actual energy delivered to the rotating blades divided by the ideal energy released to the stage in an isentropic expansion from P_1 to P_2 of the stage. The most important factors determining the stage efficiency are the relationship of the mean blade speed to the theoretical steam velocity, the aspect ratio (blade length/passage width), and the aerodynamic shape of the passages. Figure 6-3 describes the typical variation in nozzle and bucket efficiencies with velocity ratio and nozzle height.

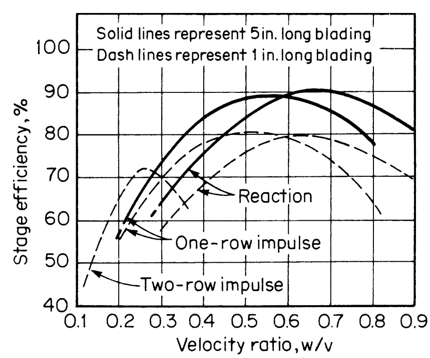

FIGURE 6-3 Approximate relative efficiencies of turbine stage types.

2. *Losses*

Clearance leakage. A 100% efficiency cannot be obtained because of friction in the blading and clearance between the stationary and rotating parts, and because the nozzle angle cannot be zero degrees. Axial clearance increases in the stages further from the thrust bearing to satisfy the need to maintain a minimum clearance at extreme operating conditions when the differential expansion between the light rotor and heavy casing is at its worst. To reduce this leakage, radial spillbands are used. These thin, metal-strip seals may be attached to the diaphragm or casing and extend close to the shroud bands covering the rotating blades. This clearance can be kept quite close (0.020 to 0.060 in), and axial changes in the rotor position do not affect the clearance since the spillbands ride over the shrouds. The need to control the clearance leakage area is especially important on reaction stages with small blade heights because of the pressure drop across the moving blades.

Nozzle leakage. Leakage around the nozzles between the bore of the blade ring or nozzle diaphragm and the drum or rotor must be kept to a minimum. This leakage is controlled through the use of a metallic labyrinth packing which consists of a single ring with multiple teeth arranged to change the direction of the steam as well as to minimize the leakage area. Labyrinth packings are also used at the shaft ends to step the pressure down at the high-pressure end and to seal the shaft at the vacuum end.

Rotation loss. Rotation of the rotor consist of losses due to the rotation of the disks, the blades, and shrouds. Partial-arc impulse stages have a greater windage loss within the idle buckets. Rotation losses vary directly with the steam density, the fifth power of the pitch diameter, and the third power of the rpm. In general, the windage loss amounts to less than 1% of stage output at normal rated output. At no-load conditions, windage loss for noncondensing turbines approximates 1.5% of the rating per 100 lb/in^2 exhaust pressure, and on condensing units approximates from 0.4% to 1.0% of the rating at 1.5 inHg (abs) exhaust pressure.

Carryover loss. A carryover loss (about 3%) occurs on certain stages when the kinetic energy of the steam leaving the rotating blades cannot be recovered by the following stage because of a difference in stage diameters or a large axial space between adjacent stages. Typically, this happens in control stages and in the last stages of noncondensing sections. The last stages of condensing turbines have the largest carryover losses (normally referred to as exhaust loss) because of the large variations in exhaust volumetric flow with exhaust pressure and the large variation of stage pressure ratio with load. Stages preceding the last operate with essentially a constant pressure ratio down to very low loads and consequently can be designed for peak efficiency at a wide range of loads.

Leaving loss. Condensing turbines are frequently “frame sized” by last-stage blade height. It is sometimes economical to size the unit with exhaust loss equal to 5% deterioration in overall turbine performance at the design point (valves wide-open throttle flow and 1.5 inHg [abs] exhaust pressure) when the normal expected exhaust pressure will be higher or the unit will be operating at part load for a large part of the time.

Nozzle end loss, partial arc. Control stages and partial-arc impulse stages are subject to end losses at the interface of the active and inactive portions of the blading as the stagnant steam within the idle bucket passages enters the active arc of nozzles and must be accelerated. There is also a greater turbulence in the steam jet at both ends of the active arc. In partial-arc impulse stages, the increase in efficiency due to larger blade heights (aspect ratio) is partially offset by increased rotation and end losses, and there is an optimum to this proportioning beyond which there is an overall loss.

Supersaturation and moisture loss. Moisture in the steam causes supersaturation and moisture losses in the stage. The acceleration of the moisture particles is less than that of the steam, causing a momentum loss as the steam strikes the particles. The moisture particles enter the moving blades (buckets) at a negative velocity relative to the blades, resulting in a braking force on the back of the blades. Supersaturation is a temporary state of supercooling as the steam is rapidly expanded from a superheated state to the wet region before any condensation has begun. The density is greater than when in equilibrium, resulting in a lower velocity as the steam leaves the nozzle. As soon as some condensation occurs at approximately 3.5% moisture, according to Yellot, a state of equilibrium is almost instantly achieved and supersaturation ceases.

3. *Turbine efficiency.* The internal used energy of the stage is obtained by multiplying the isentropic energy available to the stage by the stage efficiency. The sum of the used energies of all stages in the turbine represents the total used energy of the turbine. The internal efficiency of the turbine can be obtained by dividing the total used energy by the overall isentropic available energy from throttle pressure and temperature conditions to the exhaust pressure. (Note: The sum of the available energies of the stages is greater than the overall available energy and represents the reheat factor or gain attributable to the unused energy of preceding stages becoming available to following stages.) The use of overall available energy will automatically account for pressure-drop losses occurring in stop valves, control valves, exhaust hood, and piping between HP and LP elements. Other losses which must be accounted for to arrive at the turbine overall efficiency include valve-stem and shaft-end packing leakages and bearing and oil-pump losses. Determination of the overall efficiency of a turbine and its driven equipment must take into account the losses of gears or generators and their bearings as well.

6.1.6 Turbine Construction

Since the early 1900s, horizontal-shaft units have been universally used. Horizontal units may be single-shaft or double-shaft, with single, double, or triple steam cylinders on one shaft. These modern units may be throttle or multiple-nozzle governed, have one or more steam extraction points, and exhibit innumerable variations in construction. Figure 6-4 shows several of the more commonly used types of turbines in schematic cross sections.

Steam turbines may be classified into several broad categories, according to the basic purpose and design of the steam path: (1) straight condensing, (2) straight noncondensing, (3) uncontrolled extraction, (4) single, double, or triple controlled extraction, and (5) reheat. Various combinations of these features may be present in a typical unit, and occasionally unusual variations on the above types may be seen.

Figure 6-5 is a cross section of a modern automatic-extraction turbine, showing the details of construction. A steam turbine consists of the following basic parts: (1 to 3) steam path made up of rotating

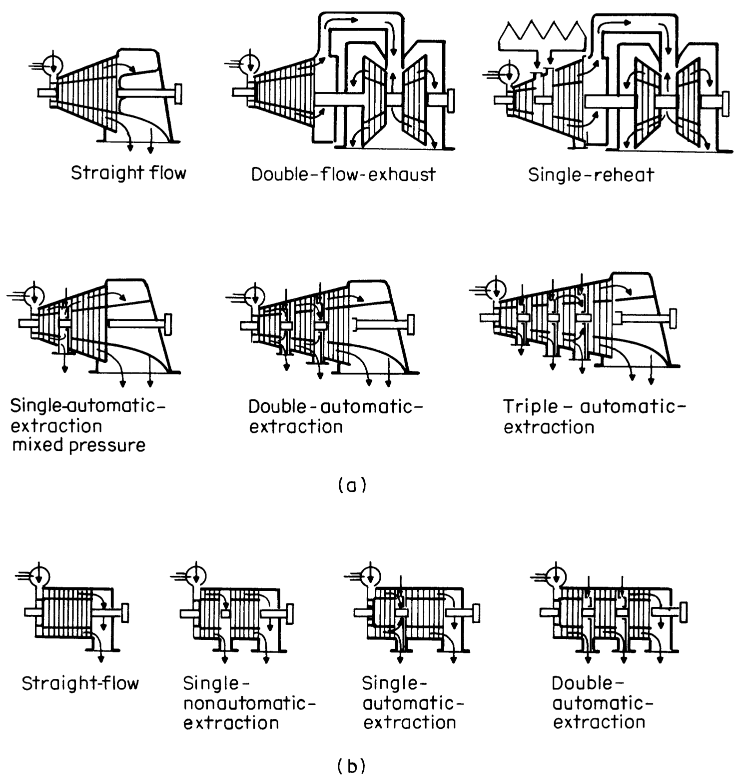

FIGURE 6-4 (a) Condensing turbines (exhaust at backpressures less than atmospheric); (b) noncondensing turbines (wide range of backpressures). (*General Electric.*)

and stationary blading (buckets and nozzles); (4) casing to contain the stationary parts and act as a steam pressure vessel; (5 to 8) controlling and protective valves, piping, and associated components to accept and control the steam admitted to the steam path; (9 and 10) packing and sealing arrangement to prevent steam from escaping into the surrounding area; (11) front standard which houses lubrication, control, and protective equipment and supports part of the casing; (12 to 14) set of journal and thrust bearings to support the rotating elements and absorb all static and dynamic rotor loads; (15) lubrication and hydraulic system for supplying bearing lubrication and (when applicable) generator seals, control, and protective oil requirements; (16) supporting foundation on which the major stationary parts rest; and (17 to 20) various accessory components, such as turning gear, control and protective components, drain valves, etc., as required by the specific application.

Turbines are constructed chiefly of carbon, alloy, and stainless steels. The rotor may be a single forging, fabricated from a shaft and separate wheels, or constructed of forged elements welded together. The buckets forming the rotating portion of the steam path are generally machined from solid stock and attached by pins, or grooves called "dovetails," to the wheels. The stationary steam path is built up of diaphragms with nozzles mounted in the heavy, two-piece casing (usually cast steel), which is bolted together on a horizontal joint. If the unit is condensing or has a low back pressure, the exhaust casing may be made up as a separate assembly and bolted to the main casing through a vertical joint. To minimize thermal stresses in high-temperature applications (950 to 1050°F), a double shell casing may be used. The rotor may sometimes be made in two pieces and coupled together, particularly in the case of the larger condensing double-flow units. A solid or flexible coupling may be used to connect the turbine rotor to its load.

Labyrinth-type packing rings, consisting of high and low teeth, are arranged at the ends of the steam path to inhibit steam from escaping into the surrounding area. (Similar packing is used at each diaphragm, and particularly at stages having control valves, to prevent excessive leakage from one stage to another within the steam path.) Associated with the external packing is a seal system which draws a vacuum to exhaust a mixture of leaking steam and air and thus prevents any steam from leaking into the surrounding room.

Bearings for supporting the turbine rotor are located in pedestals at either end and consist of journals and a thrust assembly. Normally, when steam flows through the turbine, thrust is developed in the direction of steam flow. However, unusual operating conditions or configurations often cause a thrust reversal. Therefore, it is usually necessary to provide an "active" thrust bearing for normal loading and an "inactive" thrust bearing for reverse loading.

The control-valve gear-activating equipment in a turbine usually is mounted on top of the turbine casing at the stage where steam is to be admitted. There are at least as many valve-gear assemblies as there are control stages, sometimes more if a lower valve-gear assembly is required for passing the flow. Protective or emergency valves are generally located off the machine, near the associated steam piping. Control, protective, and accessory components are often located in part in the front standard, at the pedestal housing the first journal and thrust bearing assemblies. The unit is usually supported on its foundation at the front standard and at the exhaust casing. The coupled generator shares similar foundation supports.

6.1.7 Turbine Control and Protective Systems

Steam turbines require a number of systems and components to provide control and protective capability. These may be divided into two functional categories: (1) primary control systems and (2) secondary and/or protective control systems.

Primary Control Systems. *Primary control systems* may be further subdivided into the following elements: control valves and associated operating gear, speed/load control, and pressure control. *Secondary or protective systems* consist of overspeed limiting devices, emergency valves, trip devices, and associated alarm devices.

Control-Valve Gear. Most modern turbine-generators use steam-admission control-valve designs which are as efficient as practical, in terms of pressure drop and throttling losses. Most popular are the ball-venturi valves used in the inlet stages of modern high-pressure units. The use of multiple valves, with the efficient venturi seat configuration and the tight-seating ball valves, permits partial-arc nozzle admission to the turbine with good part-load efficiency and a sequential opening action which produces nearly linear flow curves. These valves may be opened by one of two basic means: bar lift, with valves sequenced by stem lengths, or cam-operated by levers and rollers, to linearize the inherently nonlinear flow characteristics of ball-venturi valves. A common variation of the ball-venturi valve gear once widely used is the poppet-valve gear, with beveled valves and seats. This arrangement is not as efficient as a ball-venturi valve gear and is not presently very popular.

Another commonly employed valve gear, particularly on lower-pressure high-volume-flow applications, is the double-seated spool valve gear. This valve is not very efficient but passes high-volume flow and can be programmed to open in a manner similar to a ball-venturi valve.

A third scheme used somewhat in the past, but now less popular, is the grid valve, which consists of two plates with specially shaped holes arranged so that when one is rotated relative to the other, the flow area is developed as the holes coincide. High volume flow and short physical span are the grid valve's strong points, but its efficiency and accuracy are not good, and operating forces are high.

Speed/Load Control Systems. After a choice has been made from the types of valves available for steam admission to the turbine, a means must be provided for positioning these valves to obtain basic speed/load control. The primary requirement is the maintenance of an accurate, predetermined rotating speed, since all turbines are designed to operate at a specific speed or over a specific range of speeds. Every turbine, therefore, has some type of speed governor or, more generally, "speed/load control system." Its purpose is to maintain a relationship between actual turbine speed and some reference value, over a wide range of load torques.

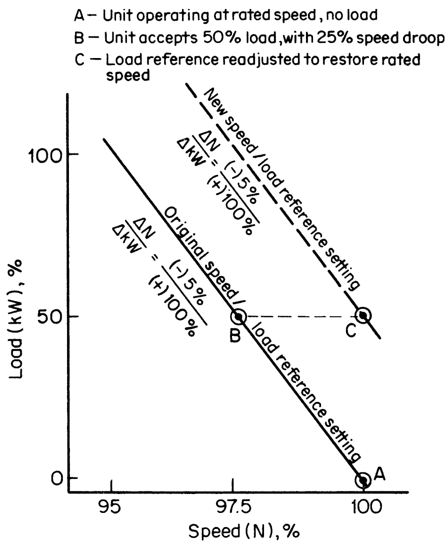

FIGURE 6-6 Steady-state speed/load regulation for a given reference setting in the speed/load system of a steam turbines. (*General Electric.*)

Land turbines used for power generation generally operate at a specific rated speed whereas marine and mechanical-drive turbines, because of the inherent coupling characteristics between rotating blades and fluids, operate over a range of speeds.

In most of the Western Hemisphere, the accepted operating frequency for turbine-generator machinery is 60 Hz. Such units having a 2-pole generator must, therefore, operate at 60 r/s, or 3600 r/min. A 4-pole unit operating at 60 Hz will rotate at half the speed of a 2-pole unit, or 1800 r/min. Most units in the United States operate at either 1800 or 3600 r/min. In most of the remainder of the world, the accepted electric frequency is 50 Hz, with common operating speeds of 1500 or 3000 r/min. In order to understand steam-turbine speed/load control, it is helpful to consider the example of constant-speed/load-based utility or industrial units.

Figure 6-6 shows the relationship designed into the speed/load control system of most such units built in the United States. The commonly accepted speed "droop," with load, for such a system is (–) 5% for 100% load change, based on a given speed/load reference setting. Note that speed droops proportionally with increasing load, on a steady-state basis. The system should be so designed that a steady-state error in speed is required to provide the command signal to move the control valve gear to accept the required load.

If such a unit operates independently, the speed/load characteristic will be as shown by the solid line in Fig. 6-6 (point *A*). If the unit is tied to a system much larger than itself, and the same system load change occurs, obviously the effect on the unit will be much less, and speed will not vary as much. The system is said to be "stiff" compared to the unit. Since speed accuracy is very important if the operating unit is isolated, any speed droop experienced with a load change (point *B*) must be corrected by changing the speed/load reference setting. This is illustrated by the dashed line of Fig. 6-6, where a 50% load change was followed by a reference correction to restore rated speed (point *C*). If an operating unit is tied to a "stiff" system, and it must accept more of the system load, a similar adjustment will cause it to pick up load with no change in speed, as the dashed line shows.

Manual speed/load reset, therefore, permits a unit, whether isolated or tied to a system, to be set to hold speed, or carry load, as the operator desires. However, if such a unit is to operate for long periods of time, and under varying load conditions, manual load reset is an inadequate solution to the problem of maintaining speed accuracy. In such cases, the use of an automatic reset device or "speed corrector" to provide isochronous control is common.

Figure 6-7 shows a very simple form of speed/load control system: a mechanical speed governor suitable for very small turbines. This type of governor uses a spring-load mechanical flyball mechanism connected to a throttling valve to directly control steam admission to the turbine. On larger units, where the forces required are too high for direct operation, a hydraulic relay governing system, as shown in Fig. 6-8, is used. In this arrangement a centrifugal flyball-type governor is connected through linkage to a double-spooled pilot valve. Oil is admitted to the pilot valve, so that when the valve moves, it ports fluid either into or out of an operating cylinder as required. The motion of the cylinder restores the pilot valve, through another linkage, to maintain a stable relationship between the pilot valve and its cylinder. Available force for operating the control valves is multiplied many times with this arrangement. On units larger than about 1000 kW, a mechanical hydraulic control system having two or more such hydraulic relays or amplifiers is used to multiply available force and to operate multiple control-valve gear systems.

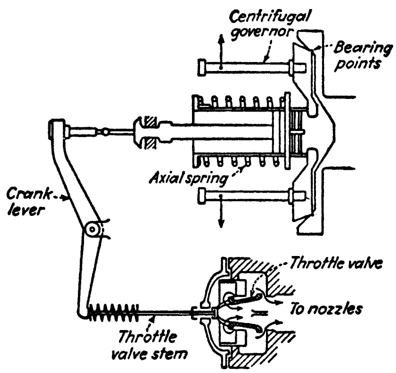

FIGURE 6-7 Mechanical governor for small turbines.

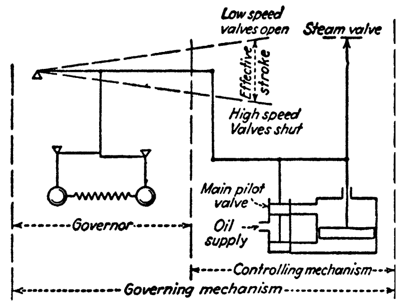

FIGURE 6-8 Governor with hydraulic power amplifier.

The electrohydraulic control system offers greater accuracy, higher operating forces, remote and centralized control capability, and more options and flexibility than any previous system. The speed/load control system in Fig. 6-9, consists of (1) a permanent magnet generator or digital-type reluctance pickup to provide a shaft-speed signal, (2) electronic circuitry for comparing the speed signal with a reference signal, (3) a high-gain servo valve to convert the resulting electric signal to a hydraulic signal, (4) a valve-gear power-actuator assembly capable of operating on high-pressure hydraulics on receipt of the servo-valve signal, (5) a feedback transducer on the power actuator to restore the servo valve to a stable condition when the desired valve position is reached, and (6) a high-pressure hydraulic system to provide the force required.

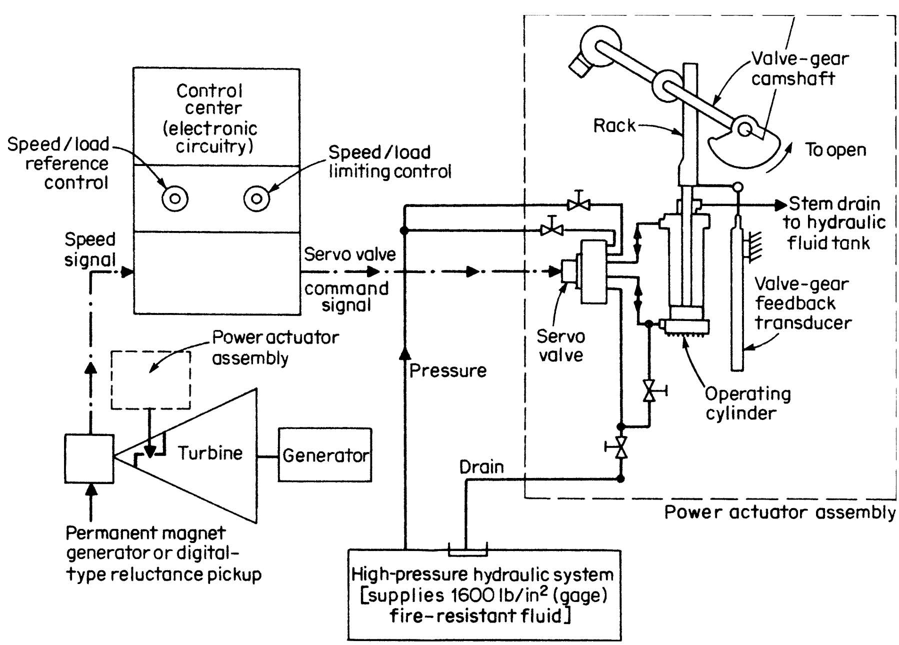

FIGURE 6-9 Schematic diagram of a basic electro-hydraulic speed/load control system. (*General Electric.*)

Other types of speed/load control systems have been applied to turbines from time to time. These include pneumatic, hydraulic, or electric devices. However, the two most common systems for turbine control are the mechanical hydraulic control (MHC) and electrohydraulic control (EHC) systems described. Another version of the EHC system was developed in the late 1960s to provide bridge control on marine turbine applications.

Pressure Control Systems. A second major area of control technology on steam turbines deals with process control. In industrial power plants particularly, it is often economical to generate and control several process flows, using steam from available steam turbines. As in the case of speed/load control, when a process is to be controlled, a definite relationship or "regulation" is established between the flow to be supplied by the turbine and the pressure. However, the possible options in process-pressure-control management are much greater than the speed/load control options described. The most common application control is for an extraction or exhaust flow from a turbine, which is to be controlled accurately in pressure and used in an industrial process. For this purpose, automatic-extraction and exhaust pressure control systems have been designed, using both the MHC and EHC technologies. Occasionally, particularly on waste-heat boiler applications, there is a need for initial pressure control as well.

Figure 6-10 is a greatly simplified schematic representation of a mechanical hydraulic control system on a single-automatic-extraction condensing turbine. The unit consists of two turbines, an HP and an LP section (each supplied by a separate valve gear), on one shaft. A flyball speed governor is used to move the two sets of valves to control speed, or load, and a bellows-type pressure governor is employed to sense process pressures and move the valves in opposite directions to control process flow and pressure. (Actual hardware required for these actions would, of course, include either mechanical hydraulic relays and linkage or electrohydraulic components.) The system is usually so designed that load and process flow variations can be satisfied at the same time with a minimum of interaction between the two variables.

Often the need exists as well for control of exhaust pressure on a noncondensing turbine-generator. In this case, since the number of variables which can be controlled is only equal to the number of control-valve stages, one variable must be sacrificed. Usually, the unit is tied to a "stiff" electrical

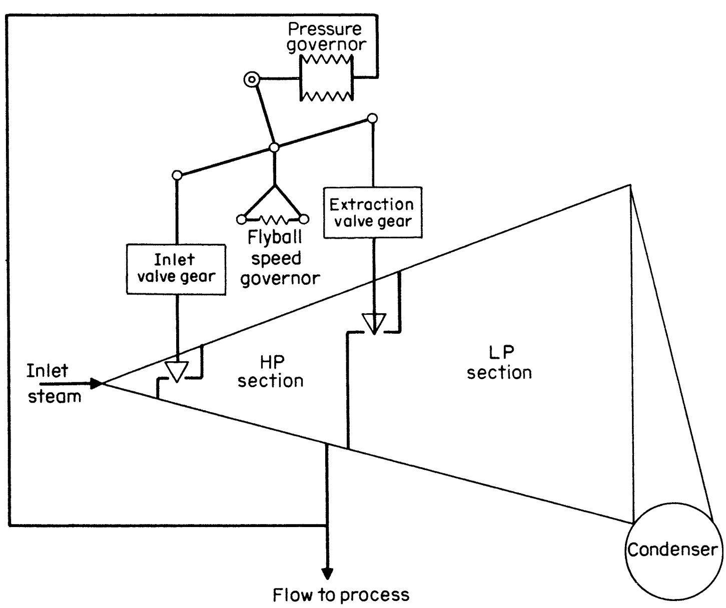

FIGURE 6-10 Simplified schematic diagram of a speed and pressure control system for a single-automatic-extraction condensing turbine. (*General Electric.*)

system, and speed/load control is sacrificed in favor of exhaust pressure control. Figure 6-11 shows a modern electrohydraulic control system for a single-automatic-extraction noncondensing turbine capable of controlling two process pressures for industrial needs.

6.1.8 Lubrication and Hydraulic Systems

Forced-feed lubrication of turbines and generator bearings is normally used on units above approximately 200 hp in size. On such units, the lubrication system is sometimes used to supply low-pressure seal oil for a hydrogen-cooled generator as well. Also, it often is used to supply the higher-pressure oil for the turbine control and protective systems. This is normally the case on units having a mechanical hydraulic control system and operating on turbine oil at a pressure of 250 lb/in^2 (gage) or less. On units having electrohydraulic control systems, operating at higher hydraulic pressures up to 3000 lb/in^2 (gage), and using fire-resistant fluids, a separate hydraulic-fluid power unit supplies all fluid for the control systems and usually for the protective systems as well.

6.1.9 Oil-Seal and Gas-Cooling Systems for Hydrogen-Cooled Generators

For steam turbine-generators rated up to about 40,000 kW, the electrical windings are generally cooled by air. However, above this size range, most units have hydrogen-cooled generators. Liquid cooling with hollow conductors is used on the largest units, above about 300,000 kW. Hydrogen cooling is employed because hydrogen has a thermal conductivity nearly 7 times that of air, and a density only one-fourteenth that of air. This permits reduction of windage losses and increased cooling, thereby increasing load-carrying capability for a given size of hardware.

A shaft sealing system is required to properly seal the hydrogen for cooling larger units. Oil is the sealing medium and is pressurized above hydrogen gas pressure so that it leaks across the seals to a cavity which is a receiving area for the hydrogen leaking out of the generator casing. The hydrogen-oil mixture is then scavenged through a dryer to a hydrogen control cabinet which monitors the pressure, temperature, and purity of the gas mixture, in order to maintain a safe hydrogen concentration in the generator.

6.1.10 Miscellaneous Steam-Turbine Components

In addition to the systems and components discussed in the earlier sections, steam turbines often have a number of accessory components which are important to their operation. A turning gear is provided on units rated larger than approximately 10 MW, to slowly rotate the turbine shaft before the unit is started and after it is shut down. This action helps prevent rotor bowing due to unequal heating or cooling of the rotor.

Another device of some importance is a lifting gear, for assembly and disassembly of the unit during installation and outages.

A set of turbine supervisory instruments is often included with a steam-turbine package. Typically monitored items are shaft vibration, differential thermal expansion between the casing and the rotor, expansion of the casing, eccentricity while on turning gear, thrust bearing position, speed of rotation, acceleration, control-valve position, and various other items as required by design and/or customer needs.

6.2 STEAM-TURBINE APPLICATIONS

6.2.1 Central-Station Turbines

A 60-MW, 3600-r/min *nonreheat steam turbine* is typical of those installed in smaller utility plants. Steam flows into the steam chest and through the control valves to the first-stage nozzle. After expanding through a Curtis-type, 2-row control stage, the steam flows through 16 more Rateau (impulse) stages to the exhaust. During the expansion, some steam is bled off at four or five extraction points for feedwater heating. Larger-rated units, such as those used in combined-cycle plants, require double flowing of the last five or six stages in order to provide the last-stage annulus area necessary to maintain a low leaving loss.

A 600- to 800-MW tandem-composed single-reheat steam turbine is typical of the type used in large fossil-fired central stations. Steam conditions are predominantly 2400 lb/in^2 (gage), 1000/1000°F, but some applications are at 3500 lb/in^2 (gage) and a few utilize double reheat as well. Steam enters the high-pressure turbine element through four pipes leading from the off chest-control valves to the nozzle box and the double-flow first stage. The flow is expanded through six more impulse stages before exiting from the HP casing to the reheater. The reheated steam enters at the center of the intermediate turbine and expands through seven double-flow intermediate stages before exhausting to the crossover pipe. The crossover feeds the steam to the four-flow LP elements where it is expanded to completion through six more stages before exhausting to the condenser.

A typical *nuclear steam turbine* has a capacity of 1000 to 1300 MW. Steam enters the double-flow high-pressure element at the left at 1000 lb/in^2 (gage), 546°F, and exhausts at about 200 lb/in^2 (abs) to the two large combined moisture-separator reheaters which straddle the three double-flow low-pressure elements. After the moisture is removed and the steam slightly reheated, it is passed to the six-flow

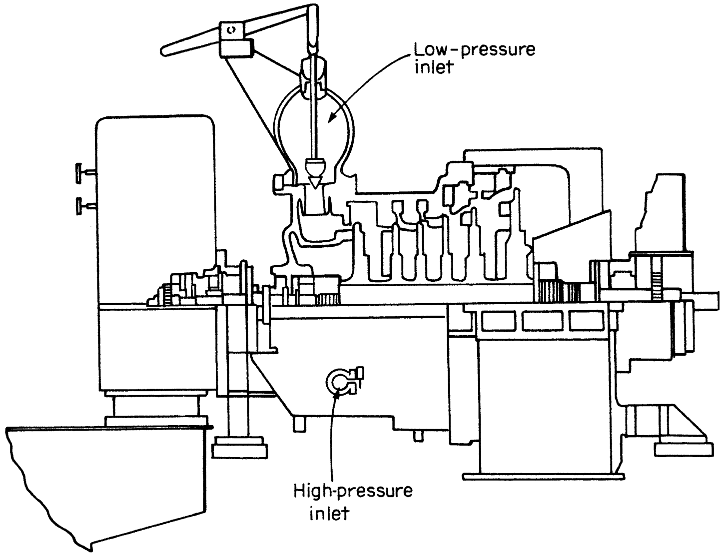

FIGURE 6-12 A 10,000 hp, 5500-r/min steam generator-steam feed-pump-drive turbine for nuclear application. (*General Electric.*)

low-pressure element where it is expanded to completion. The low superheat available with the light water reactors and the large ratings encountered require the use of 1800-r/min machinery to keep blade speeds low, reducing the erosion from moisture, and to provide the large flow areas which are more easily obtained using larger wheel diameters. The moisture-separator reheater is provided to decrease the erosion in the low-pressure elements and improve their performance. The *condensing boiler-feedwater-pump-drive turbine* was introduced in the 1960s, and became accepted rapidly because the increase in condensing annulus area served to improve both the heat rate and capacity of the station. Figure 6-12 illustrates a 10,000-hp straight condensing boiler-feed-pump-drive turbine for a nuclear application. Steam is extracted from the main unit cycle after it has gone through the moisture separator-reheater and is delivered to the inlet at approximately 150 lb/in^2 (abs) and from 0 to 100°F superheat. It is expanded to completion in the six stages. For operation at light load, steam is taken from the main steam header and sent to the high-pressure inlet in the lower half of the first stage.

6.2.2 Industrial Steam Turbines

In many industrial plants, particularly those in the pulp-and-paper, petrochemical, and related industries, the need exists for large amounts of electric power and process steam at various pressure levels. In this type of situation, industrial users can justify generating their own power and charging a large part of the cost to the process, because the steam is also needed. Plants have historically been built and expanded with various condensing and noncondensing extraction turbine types, as the process requires, and in sizes ranging from 1 to 200 MW.

6.2.3 Variable-Speed Turbines

The steam turbine is used extensively as the prime mover for ship propulsion at ratings above 10,000 shp. The cross-compound design is almost universal as it provides emergency capability for getting back to port as well as providing two pinions which divide the load on the low-speed gear, reducing gear weight. The major applications are in high-powered, high-utilization ships such as tankers and container ships. They are used almost exclusively in naval combat ships (aircraft carriers and nuclear submarines) as well as for large auxiliary supply ships.

Applications are predominantly nonreheat, but because of the steadily rising cost of fuel, reheat applications are gaining popularity.

Industry uses *mechanical-drive turbines* for a wide variety of purposes. These turbines drive paper machines; blast furnace blowers; and ethylene, ammonia, and liquefied natural-gas plant compressors because of their ability to follow the speed-output characteristics of this type of equipment without loss of efficiency from throttling, recirculation, or use of fluid couplings.

6.2.4 Special-Purpose Turbines

Turbines have been designed and built for many unusual applications. They have been built for use with working fluids other than steam in refineries and petrochemical plants. Mercury has been used as a working fluid in the *binary steam power plant.* Steam turbines have been tried in steam-locomotive applications.

Steam turbines utilizing *geothermal steam* have operated for many years in Italy, and more recently in New Zealand and the United States. The Geysers fields in California contain a high grade of geothermal energy as steam, available at the wellhead at about 100 lb/in^2 (gage). The high cost of liquid fuels has increased the attractiveness of the much more extensive geothermal brine sites as well. The geothermal-steam turbine is required to pass a much greater volume flow of steam per kilowatt generated than the central station plant. The presence of impurities in geothermal steam requires much more extensive use of alloys in the steam path and protection against moisture in the steam. The development of brine fields, which contain 300 to 500°F liquid in the wells, will require development of turbines with much larger volume-flow capacities to recover the low-level energy available. Alternative development may utilize heat exchangers which will transfer the energy to other fluids, such as isobutane, for expansion in the turbine.

6.3 STEAM-TURBINE PERFORMANCE

6.3.1 Rankine-Cycle Efficiency

The steam turbine constitutes the expansion portion of a vapor cycle, which requires separate devices, including a boiler, turbine, condenser, and feedwater pump, to complete the cycle. This vapor cycle for steam power plants is commonly called the Rankine cycle (Figs. 6-13, 6-14) and is less efficient than the Carnot cycle because the exhaust vapor is completely liquefied to facilitate pumping, and because superheat is added at increasing temperature. The work of the cycle is equal

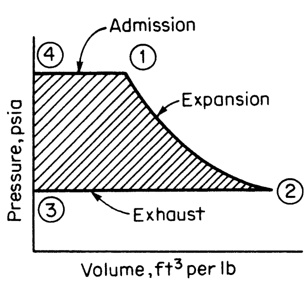

FIGURE 6-13 Pressure-volume diagram for the Rankine cycle; Phase a4-1, constant-pressure admission; phase 11-2, complete isentropic expansion; phase 2-3, constant-pressure exhaust. Crosshatched area represents the work of the cycle.

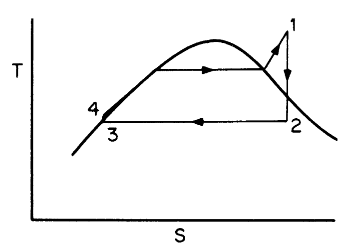

FIGURE 6-14 T-S diagram; nonreheat, nonextracting turbine cycle.

to $h_1 - h_2$ minus the small pump work $h_4 - h_3 = \nu_3(P_4 - P_3)/J$ required, and the heat added to the cycle is equal to $h_1 - h_4$. Therefore

$$\text{Rankine-cycle efficiency} = \frac{(h_1 - h_2) - \nu_3(P_4 - P_3)/J}{h_1 - h_4} \tag{6-4}$$

Cycle efficiency is not commonly used when comparing plant efficiencies because it is only indirectly determined, compared with heat rate, which can be quickly measured. In central-station practice, the station heat rate defines the heat required from fossil fuel, reactor energy, waste gases, etc., per kWh of station output (gross electric output minus all auxiliary power required within the plant). For example, a plant with a station heat rate of 10,000 Btu-fuel/kWh has a seal cycle efficiency of

$$\text{efficiency} = \frac{\text{output}}{\text{input}} = \frac{3412.1}{10{,}000} \times 100 = 34.1\% \tag{6-5}$$

Power plants for marine propulsion drive commonly use the "ships all-purpose fuel rate" (lb fuel/shp-h) as a measure of the plant's efficiency. Besides accounting for all losses required to generate the propeller-shaft output work, this fuel rate includes the requirements for the ship's "hotel" electric load, freshwater evaporators, and steam for heating and unloading cargo and cleaning tanks. A typical ship's fuel rate of 0.45 lb fuel/shp-h based on 18,500 Btu/lb fuel would indicate cycle efficiency for the ship as

$$\text{Cycle efficiency} = \frac{2544.1}{0.45 \times 18{,}500} \times 100 = 30.6\%$$

In the process industries, such as paper and petrochemical, large amounts of steam are used. Considerable by-product power can be generated by raising the boiler pressure above the process pressure and expanding the steam through a noncondensing turbine before exhausting it to the process. In this cycle, no heat is rejected because the exhaust steam is required for process and the thermodynamic cycle efficiency of this power is affected only by the boiler efficiency, the auxiliary losses chargeable to the power generation (mostly extra boiler-feed-pump work), and the mechanical and electrical losses of the turbine and generator.

The station heat rate of such by-product power generation ranges from 3900 to 4500 Btu/kWh, depending on the size of plant and the boiler efficiency, and cycle efficiencies of 80% to 85% are normal. This heat rate varies very little with turbine efficiency because energy not used to generate power is used for process. However, it is necessary to define the kilowatts generated per unit of heat to process in order to evaluate the influence of turbine efficiency or the initial steam conditions selected. Guaranteed steam rates are normally provided to evaluate the efficiency because they can be directly compared with the theoretical steam rate (TSR).

6.3.2 Engine Efficiency

The station heat rate is used to measure power plant performance, but it is of little use in evaluating the specific pieces of equipment in the cycle. The engine efficiency of the steam turbine defines its actual performance to the ideal performance. The Rankine-cycle work of the turbine is most conveniently obtained by use of the Mollier diagram (Fig. 6-15), where

$$\Delta W = h_1 - h_2 \tag{6-6}$$

and ΔW = Rankine-cycle work in Btu/lb, h_1 = steam enthalpy at throttle in Btu/lb, h_2 = steam enthalpy at exhaust in Btu/lb,

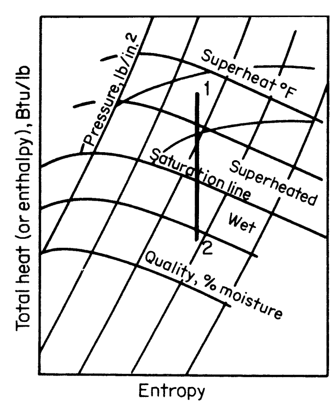

FIGURE 6-15 Steam chart (Mollier diagram.)

and h_1 and h_2 are at the same entropy (vertical line). The actual work of a real turbine is less than the ideal Rankine-cycle work, with engine efficiency defined as

$$\text{Engine efficiency} = \frac{\text{actual work, Btu/lb}}{\text{Rankine-cycle work, Btu/lb}} \tag{6-7}$$

6.3.3 Theoretical Steam Rates

The theoretical steam rate in lb/kWh for the Rankine-cycle work is expressed as

$$\text{TSR} = \frac{3412.14}{h_1 - h_2} \tag{6-8}$$

and the actual steam rate as

$$\text{ASR} = \frac{\text{TSR}}{\text{engine efficiency}} \tag{6-9}$$

The actual output of the turbine will be less than the isentropic work because of losses from nozzle and bucket friction, packing leakage, windage, carryover and exhaust losses, bearings, radiation, and throttling. The efficiency of the turbine, including its losses, is sometimes represented by the term η_{evpm}, to help identify the losses which are included in the efficiency. The subscript *e* denotes exhaust loss (significant on condensing units only), *v* denotes valve loss (control valves only), *p* denotes external packing loss (valve stems and shaft end packings), and *m* the mechanical losses. The efficiency of the generator or gear is represented by η_g.

This or similar terminology enables turbine designers to identify a particular efficiency for discussion. The stateline efficiency η represents the actual Mollier-chart expansion line of a particular turbine for given inlet steam conditions and exhaust pressure without any exhaust loss included.

The η_{evp} efficiency represents the internal efficiency corrected to include the exhaust loss, a "mean" of the control-valves pressure-drop loss, and the packing loss for the point in question. When an electric generator is the driven equipment, the overall engine efficiency η_{evpmg} is used to determine the throttle flow necessary to produce a given electric output (or vice versa).

6.3.4 Condensing-Turbine Efficiencies

Table 6-2 defines some approximate overall efficiencies of typical small straight condensing turbine-generators. The application of small turbines without regenerative feedwater heating is rare in central-station practice but is still found in waste-heat applications, process plants where feedwater heating is supplied by other sources, and increasingly in combined cycles where the stack gas is used to heat feedwater.

For turbines used in central stations, there are more satisfactory methods (see Bibliography at the end of this section) for predicting turbine efficiency, which take into account the many variables of the steam path and exhaust size and allow for inclusion of the regenerative cycle and reheat cycle in heat-balance calculations.

6.3.5 Regenerative Cycle

Steam can be extracted at several stages in the turbine to heat feedwater being returned to the boiler. In the Rankine cycle (Fig. 6-14), it was shown that the feedwater was heated from h_4 to h_1 in the boiler. By raising the temperature h_4 entering the boiler close to the saturation temperature in the drum, less fuel will be consumed in evaporating each pound of steam to h_1 conditions. The heat in the extracted steam is added to the feedwater without loss, and the heat rejected to the condenser decreases as extraction flow increases. The kilowatts do not decrease inversely with extraction flow, however, as partial expansion is made down to the extraction stages. The result is an improvement in heat rate.

The actual heat rate of a regenerative cycle must be determined from a heat balance prepared by using the extraction conditions available from the turbine and the heater characteristics as specified. Table 6-3 shows the influence of heater type, temperature difference, and piping pressure drop on the gross heat rate of a 50,000-kW unit.

6.3.6 Reheat Cycle

Practically all large (over 100,000 kW) central-station plants built since 1950 have been of the reheat type. In this type of fossil-fuel plant, the steam is expanded in the turbine down to about 25% of the initial pressure, then it is sent through a reheater where it is resuperheated back up to the original initial temperature (usually 1000°F) and returned to the turbine where it is expanded to completion. In general, reheating improves the heat rate by about 5% of which only 2% is due to a higher average cycle temperature and about 3% comes from improved turbine internal efficiency due to reduced moisture and increased reheat factor.

6.3.7 Gross and Net Heat Rates

The heat-balance cycle for the turbine, condenser, feedwater pump, and heaters usually defines the gross heat rate of the cycle when a motor-driven feed pump is used. The pump work on the feedwater is included, but the power consumed by the pump is not. When a turbine-driven boiler feed pump is used in the cycle (frequently in units above 300-MW rating), the steam for the feed-pump turbine is expanded in the main unit down to the crossover to the low-pressure elements (about 100 to 200 lb/in^2 [abs]), where it is sent to the pump turbine. In these cases, the pump power required is included in the heat balance, and the heat rate calculated is called the net heat rate. In this case, only the losses from the boiler and auxiliaries (excluding the feedwater pump) must be accounted for to obtain the station heat rate.

Table 6-4 shows typical values of gross and net heat rates at rated load for nonreheat and reheat units of typical ratings and inlet steam conditions. Exhaust pressure is 2.0 inHg (abs) in all cases, motor-driven feed-pump drive efficiency is 90%, pump efficiency is 78%, and the exhaust annulus area is normal for the rating.

The overall station heat rates of these applications are 15% to 25% greater than the net heat rate, depending on the steam-generator (boiler) efficiency and other auxiliary losses.

6.3.8 Nuclear Cycles

The turbines used in light-water nuclear cycles do not have the same freedom of steam conditions as fossil-fired cycles. The nuclear steam supply limits initial steam pressure to approximately 950 lb/in^2 (gage) at a saturated steam temperature of 540°F. The initial costs of these plants is so great that only the largest can be economically justified, and ratings are limited to about 800 MW minimum. Crossover pressures range from about 150 to 200 lb/in^2 (abs), and regenerative feedwater heating improvement is optimized by using about six heaters. These constraints and optimizations of the nuclear power-plant cycles have resulted in a rather narrow band of heat-rate fluctuations. At rated

load and 2.0 inHg exhaust pressure, the turbine net heat rate varies from about 9800 Btu/kWh at an exhaust loading of 1500 kW per square feet of annulus area up to about 10,000 Btu/kWh at 2000 kW/ft^2 of exhaust loading.

Turbines used in the high-temperature, gas-cooled reactor cycle operate at steam conditions, including reheat similar to those used in fossil-fired plants. Because of the low moisture content and lower volume flow required, 3600-r/min turbine design speed can be utilized as well. At 2400 lb/in^2 (gage), 1000/1000°F, 2.0 inHg (abs) design conditions, a heat rate of about 8300 Btu/kWh can be obtained, including the power required for gas recirculation. This represents a 15% to 17% improvement in cycle efficiency when the first plant becomes operational.

6.3.9 Combined Cycles

Improvement in the steam cycle has been rapid. The advancement of steam conditions, regenerative feed heating, reheating, and size of unit has brought the overall station heat rate down from 16,000 Btu/kWh to less than 8800 Btu/kWh on the best station.

The gas turbine developed very rapidly as a prime mover because of the improved steam cycle. During the 1950s, several exhaust-fired combined-cycle power plants were built, utilizing the exhaust gas from the gas turbine as the air supply for a fired main steam generator. After the Northeast Blackout of 1965, a large number of gas turbines were installed in the United States to serve as black start and peaking capacity units. As a result, they have become well established and accepted as a prime mover for peaking capacity.

Combined-cycle interest was renewed with the development of non-radiant-heat recovery steam generators, and the electric generation in combined-cycle plants changed from 80% to 90% steam-cycle power to 70% gas-cycle power. Since 1970, utilities have installed increasing numbers of this breed of combined-cycle plant, as they offer low initial cost, consume about one-third of the water used by straight steam plants, and provide a station heat rate 5% to 10% better than the most efficient steam plants. The major obstacle to universal acceptance of the steam-and-gas combined cycle is its fuel dependency on clean gaseous or liquid fuels.

In this combined cycle, the turbine condensate is mixed with sufficient LP economizer flow in the deaerator to raise the temperature sufficiently to avoid corrosion at the cold end of the heat-recovery steam generator. The use of regenerative feedwater heaters is avoided because of the availability of excess heat in the stack for that purpose. Part-load heat rate can be maintained at greatly reduced load in the multigas turbine plants because the units can be put in service sequentially. A so-called hockey-stick curve of part-load performance is shown in Fig. 6-16 for a combined-cycle plant utilizing four gas turbines. Below about 75% load, a gas turbine should be removed from service for best plant efficiency.

6.3.10 Noncondensing-Turbine Efficiencies

The straight noncondensing turbine generator is widely used in the process industries. The flow through a noncondensing turbine is dependent on the heat required in the process, and in order to determine the heat leaving the turbine, it is also necessary to know the enthalpy of the exhaust steam. Figure 6-17 is a plot of the mechanical and electrical efficiency of several turbine generators from 20% to 100% load. This curve permits the derivation of the internal wheel efficiency (η_{evp}) of the turbine, and ultimately the exhaust enthalpy.

6.3.11 Automatic-Extraction-Turbine Efficiencies

The automatic-extraction turbine provides the capability of delivering extraction steam at more than one process pressure simultaneously. When a condensing element is used, the kilowatt output of the unit can be maintained if the process flow varies, and will permit generation in excess of by-product power capability. The base efficiency for an automatic-extraction turbine is less than that of a straight condensing or straight noncondensing turbine because of (1) the introduction of a second control stage and accompanying parasitic losses, (2) the partial-load loss resulting when the high-pressure section of the automatic-extraction unit is passing only the nonextraction flow, and (3) the decreased pressure ratio of each section of the unit.

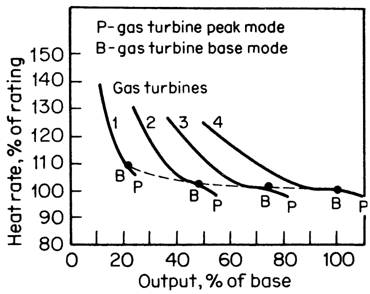

FIGURE 6-16 Output/heat rate chart for the combined-cycle power system.

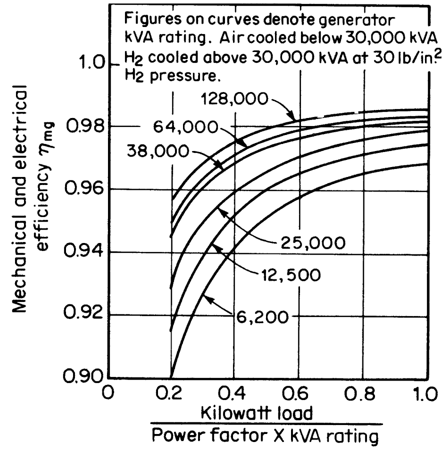

FIGURE 6-17 Typical mechanical and electrical efficiencies of turbine generators. (*General Electric.*)

The variation in throttle flow required for a change in extraction flow while maintaining constant kilowatt load can be derived from the available energy and efficiency of each section of the turbine. The extraction factor is a term which defines the relationship and represents the Δ throttle flow (ΔF_T) required for a Δ extraction flow (ΔF_x) of 1 lb/h at constant kilowatt load. The term represents a comparison of the used energy in the turbine below the automatic-extraction point to the total used energy of the turbine. The approximate extraction factor varies with the ratio of the theoretical steam rates for the turbine.

As extraction flow increases, the HP section of the unit generates more of the kilowatts and the LP section generates less until the steam flow to the LP stages is at the minimum necessary for cooling purposes. At this point, the maximum extraction for the load in question has been reached and further extraction flow must be accompanied at increasing output. The minimum cooling steam required varies with turbine size, extraction pressure, and the exhaust pressure. As an approximation, the minimum section flow in pounds per hour can be considered equal to the rating of the turbine in kilowatts.

6.4 GAS TURBINES

6.4.1 Cycles

Internal combustion engines, such as conventional automotive engines, operate on the Otto cycle; injection engines operate on the Diesel cycle; and the gas or combustion turbine operates on the Brayton cycle (Fig. 6-18), also called the *gas-turbine simple cycle*. Referring to Fig. 6-19*a*, an axial or centrifugal compressor delivers the compressed air to the combustion system, and fuel is burned

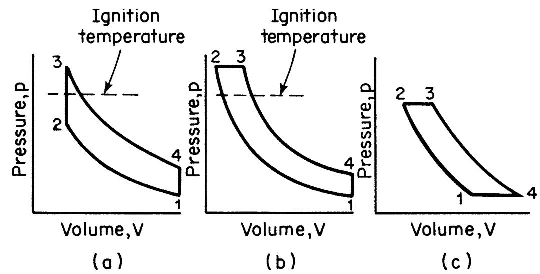

FIGURE 6-18 Ideal indicator cards (pressure-volume diagrams) for internal combustion cycles; (a) Otto cycle; (b) diesel cycle; (c) Brayton cycle. In general, phase 11-2 represents isentropic compression; phase 2-3, heat addition at constant pressure or volume; phase 3-4, isentropic expansion; and phase 4-1, heat rejection at constant pressure or volume.

to increase the fluid temperature. The products of combustion expand through the turbine, producing sufficient power to drive the compressor and the load. Some compressed air typically bypasses the combustor and is used to cool the turbine parts. The highest-pressure turbine airfoils contain internal cooling passages in order to maintain the metal temperature at acceptable levels for durability, while the gas path temperature is considerably higher than the metal temperature, to achieve high power and efficiency.

An improvement in power output and efficiency can be obtained through the use of an intercooler (Fig. 6-19*b*), in which air is cooled after part of the compression process. The intercooler reduces the work of compression of the high-pressure compressor and allows higher airflow and overall pressure ratio to be attained, while reducing the temperature of the cooling air for the turbine section.

Another efficiency improvement can be obtained from a regenerator or recuperator (Fig. 6-19*c*), which exchanges heat from the exhaust to the combustor inlet to reduce the fuel required to heat the gas. The highest efficiencies are available from combined cycles, where the gas turbine exhaust heat produces steam to drive a steam-turbine generator (Fig. 6-19*d*). The steam turbine output is obtained with no additional fuel input.

The most effective utilization of the fuel input is available through *cogeneration*, or combined heat and power. A typical cycle has the gas-turbine generating power and producing steam from its exhaust heat. The steam is sent to an industrial process, in some cases after generating some power in a noncondensing steam turbine. When credit is taken for the heat sent to process plus the power generated, efficiencies exceeding 80% are commonly achieved.

Simple cycles and combined cycles are by far the most commonly employed gas-turbine cycles. Some regenerative cycles were developed in the 1960s and early 1970s, but durability problems with the regenerators prevented further use. Newer regenerative cycle development started in the mid-1990s. Intercooled cycles are being studied principally as possible derivatives of commercial aircraft engines.

6.4.2 Design

Most gas turbines with outputs above 1 to 2 MW have multistage axial-flow compressors and turbines. Lower power units tend to have single-stage centrifugal compressors and radial-inflow turbines to minimize weight, size, and cost. Thermal efficiency improves with larger size, as friction and tip leakages become a smaller percentage of power produced, and multistage axial flow components become more efficient than radial stages. The same major components are included in a aeroderivative gas turbine, that is, one which was derived from an aircraft engine. This aeroderivative has two compressor sections, each driven by a separate turbine. This section of the gas turbine, called the *gas generator*, is derived from the aircraft engine. Hot gas exiting the gas generator drives the power turbine, which is connected to the load. Typical aeroderivatives differ from frame-type gas turbines in being lighter in weight and having a higher pressure ratio. Their outputs are limited to a maximum of about 50 MW because of the size of the aircraft engines from which they are derived. The largest frame-type gas turbines have outputs over 200 MW. Aeroderivatives tend to produce higher simple cycle efficiencies, whereas frame types produce the highest combined cycle efficiencies. For a given output, frame-type gas turbines tend to be somewhat less expensive than aeroderivatives.

For applications where the output shaft speed varies, as in a compressor drive, a separate power turbine is needed. This requires a multiple-shaft gas turbine (Fig. 6-20). A single-shaft gas turbine has a typical effective operating range of 85% to 105% of rated speed. With a separate power turbine to drive the load, the output shaft speed range is typically about 50% to 105% of rated speed.

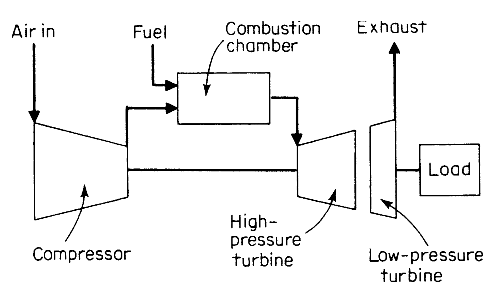

FIGURE 6-20 Multiple-shaft turbine.

6.4.3 Performance

Component efficiencies, airflow, pressure ratio, and turbine inlet (or firing) temperature are the major factors affecting gas-turbine output and efficiency. Typical multistage axial component efficiencies are in the 86% to 93% range. Material developments and turbine cooling techniques permit turbine rotor inlet temperatures to exceed 2500°F (1370°C) for the most advanced units.

6.4.4 Applications

The most familiar application of gas turbines has been for aircraft propulsion, where the turbine drives only the compressor and the remaining energy is used for thrust. The industrial gas-turbine industry started in the late 1950s, following the development of aircraft gas turbines. Generation of electric power, mechanical drive (principally gas or oil pipeline compression), and marine propulsion are the three applications of industrial gas turbines. Over 90% of the gas-turbine applications, as measured in megawatts of power produced, are in electric power generation. The majority of the navies of the world use gas turbines to propel most of their surface ships.

In electric power generation service, the combination of lower capital cost, shorter installation time, high efficiency, and environmental advantages compared to steam-turbine-based power plants has resulted in gas-turbine-based power plants having a major market for new power generation equipment.

Compliance with emissions regulations, particularly nitric oxide, or NO_x, is a major application consideration. In the late 1970s and the 1980s, water or steam was injected into the combustion reaction zone to decrease the flame temperature, which is the principal parameter affecting NO_x. Present technology is producing combustion system designs that feature premixed air and fuel in lean mixtures to reduce the flame temperature without any outside diluent.

Much work has been done to adapt gas turbines to coal fuel. Coal gasification, utilized to remove contaminants, is particularly attractive since the gas-turbine combined cycle can be integrated into the gasification process for improved efficiency. Air extracted from the gas turbine can be used as the source of oxidant for the gasification process, and the steam produced in the process can be expanded through the steam turbine. Figure 6-21 is a block diagram showing how various components relate in an integrated gasification combined cycle (IGCC).

7.1 INTRODUCTION

This section deals with ac electric machines that convert mechanical power into electrical power. Such generators can be either synchronous generators or induction generators. Rotational speed of a synchronous generator is exactly at a speed that is synchronized with the ac power frequency, and this rotational speed is kept constant with varying loading conditions. Rotational speed of an induction generator is slightly above synchronous speed, and this rotational speed varies slightly with varying loading conditions. Induction generators find their major power generation application in wind turbine power generation. Synchronous ac generators dominate present-day commercial power generation by fossil fuels, nuclear reactors, and hydraulic turbines. All discussions of ac generators in this section are focused upon synchronous generators.

AC synchronous generators range in size and capability from very modest machines that are rated at a few hundred watts to the largest machines that are rated at 2000 MW. This section is intended to provide a general understanding of the nature of ac synchronous generators of this size and capability. Most discussions are focused upon larger synchronous generators with ratings above 10 MW.

This section is not intended to serve as a guide to design or manufacture of these generators, and it is not intended to serve as a textbook that explains details of the theory of function of these machines. A few textbooks about generator design and theory that may be of interest to readers of this handbook are listed in the bibliography of this section.

7.2 BASICS OF MACHINE CONSTRUCTION AND OPERATION

7.2.1 Machine Morphology

All synchronous generators function as magnetic energy conversion devices to convert mechanical power into electrical power by means of magnetic fields. The input torque provided by the prime mover (the turbine) is balanced by the magnetic torque between the stationary and rotating structures in the generator.

Several different approaches are possible to accomplish this power conversion function. For the larger synchronous generators that are primarily discussed in this section, the magnetic fields are typically established by electrical currents circulated in stationary ac windings, and rotating dc windings, and these magnetic fields are circulated within the generator through highly permeable steel structures. In such a generator, the ac winding is electrically connected to an electrical power system and physically mounted on the stationary member of the generator (the stator), and the dc winding is electrically connected to a dc power source and physically mounted on the rotating member of the generator (the rotor). Because of the prevalence of polyphase power generation, distribution, and utilization, the ac winding in all but the smallest synchronous generators is generally a polyphase winding. The most common number of phases is three.

All larger synchronous generators include an ac armature winding and a dc field winding. The electromagnetic interaction of these two windings provides the basis for ac power generation. In some of the smallest synchronous generators, with ratings below a few hundred kilowatts, the magnetic function of the dc field winding is provided by permanent magnets. In all large synchronous generators, the dc field is provided by a dc field winding. This section is limited to discussions of generators, with an ac armature winding and a dc field winding.

In most large synchronous generators, the ac armature winding is located on the stator of the machine, and the dc field winding is located on the rotor, as illustrated schematically in Fig. 7-1. An important exception is a special synchronous generator that is generally known as a brushless exciter. A brushless exciter is a relatively small synchronous generator (50 to 500 kW) that is used to provide dc electric current to the rotating field winding of a large synchronous generator. In brushless exciter, the dc field winding is mounted on the stator and the armature winding is mounted on the rotor. That said, all further discussions of morphology in this section are based upon the most common arrangement for generators of 10 MW and above, where the ac armature winding is located on the stator of the machine and the dc field winding is located on the rotor, as illustrated in Fig. 7-1.

In a generator, like that illustrated in Fig. 7-1, the magnetic circuit consists of a steel stator core that is mounted upon the steel stator case and a steel rotor that is supported on bearings that are either set into the case or separately mounted to the foundation. The coils of the armature winding are mounted in the stator core, and the coils of the field winding are mounted on the rotor. Armature winding electrical coils for generators of the type shown in Fig. 7-1 are typically deployed in radial slots formed in the inner diameter of the stator, and field winding electrical coils are typically deployed in radial slots formed in the outer diameter of the rotor, as illustrated in Figs. 7-2 and 7-3 respectively.

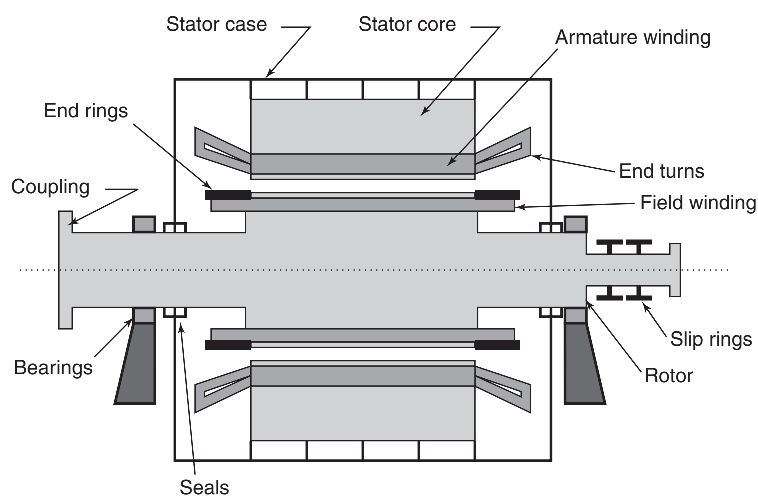

FIGURE 7-1 Elements of an ac generator.

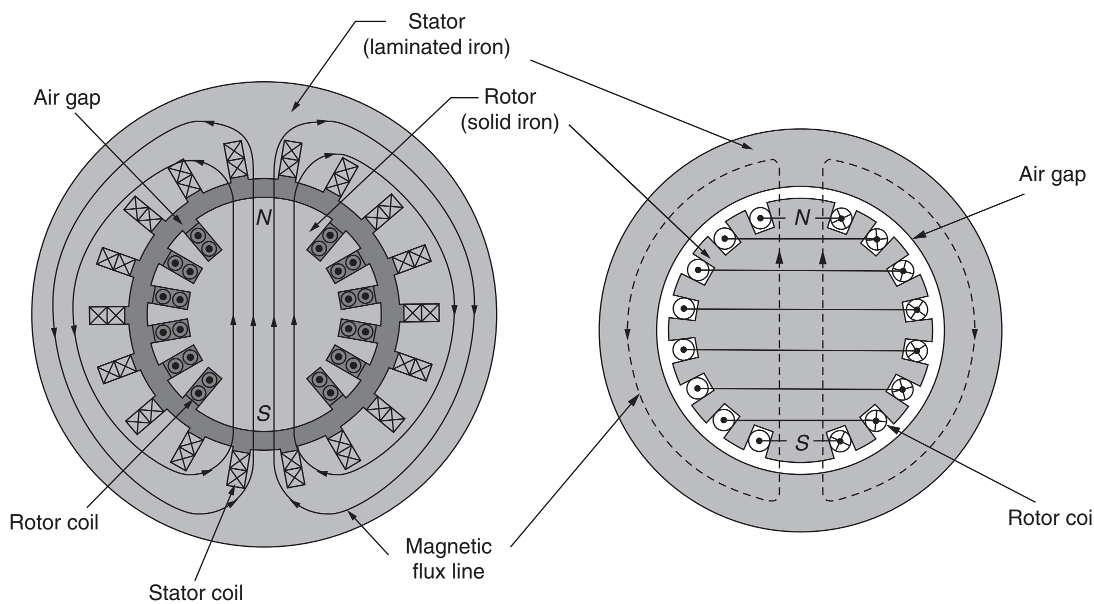

FIGURE 7-2 Round-rotor generator with two poles.

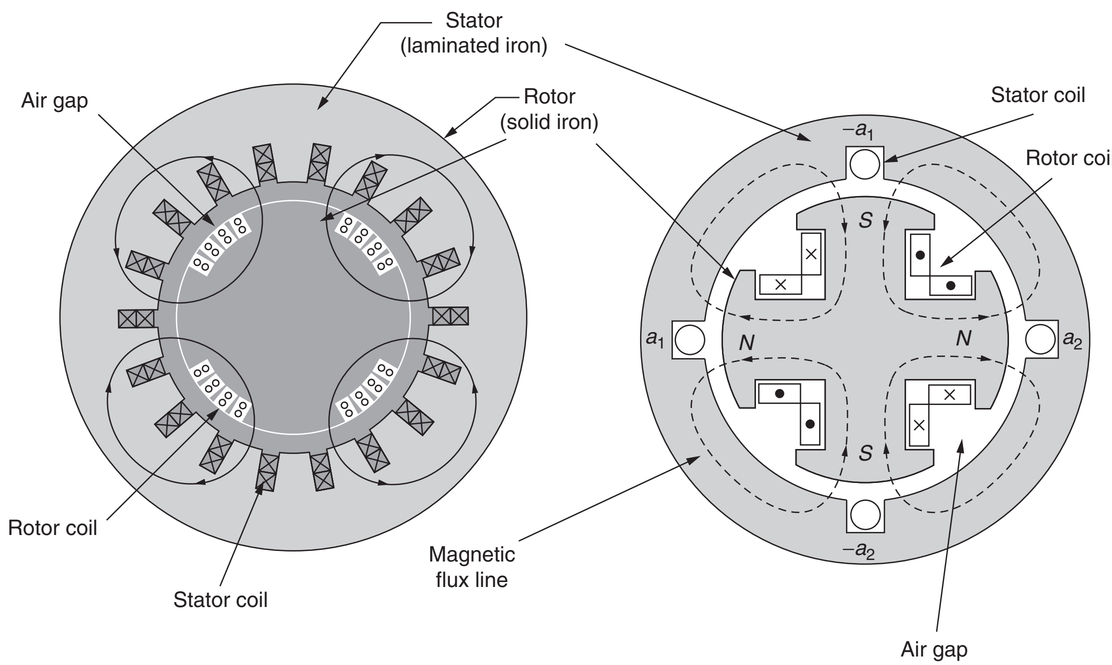

FIGURE 7-3 4-pole generator (left is round rotor, right is salient pole.

7.2.2 Poles and Frequency

The rotor and stator (field and armature) of a synchronous machine must have the same number of poles, as the magnetic interaction is between a succession of north-south magnetic-field pole pairs. The number of pole pairs for a machine will be noted as p. The relationship between electrical frequency f_e and mechanical speed N is

$$f_e = p\,\frac{N}{60} \tag{7-1}$$

where f_e is measured in hertz (Hz) and N is in revolutions per minute (r/min). A common expression for Eq. 7-1 is

$$N \cdot P = 120 \cdot f_e \tag{7-1a}$$

where P is number of poles (not number of pole pairs).

Synchronous generators are built in two elementary forms:

- *Round-rotor* machines are constructed with a rotor consisting of a cylinder of magnetic steel. In modern generators, the cylinder is formed from a single forging of vacuum degassed steel. The field winding is contained in radial slots in the surface of the rotor. Round-rotor machines usually have two or four poles as illustrated in Figs. 7-2 and 7-3 respectively. The diameter of the rotor of a typical 25-MW generator is about 700 mm. The diameter of a 2000-MW generator can approach 2 m.
- *Salient-pole* machines are constructed with a number of pole pieces mounted to a central rotor shaft. The rotor pole pieces can be solid steel or assemblies of steel plates that are bound together axially with bolts. The diameter of the rotor can range from less than 1 m in smaller salient pole generators to nearly 20 m in the largest hydroelectric generators.

In both round-rotor and salient-pole generators, the magnetic flux passing through the rotors does not vary in time, and the magnetic flux passing through the stator core does vary periodically in time at the electrical line frequency. Consequently, the rotors can be made of solid steel, but the stator cores must be made of thousands of thin layers of highly permeable electrical steel. Each layer of stator core steel is coated with a thin layer of electrical insulation.

For electric utility operation, in which generation takes place at 50 or 60 Hz, mechanical speed is inversely proportional to the number of poles. Thus, 2-pole machines, which turn at 3000 or 3600 r/min, are used for most fossil-(fuel)-fired steam turbine generators which require high shaft speeds. Most nuclear steam turbine generators, which have a lower shaft speed requirement, employ 4-pole designs and therefore turn at 1500 or 1800 r/min. Turbine generators for both fossil and nuclear power plants are typically round-rotor designs.

Hydroelectric generators, which typically have much lower shaft speeds than turbine generators and consequently require a large number of poles, are generally built as salient-pole machines. This is true also for generators intended for operation with large reciprocating engines, such as medium-speed diesels.

7.2.3 Basis of Operation

A synchronous generator works by causing an interaction of two multiple-pole magnetic-field distributions, those of the stator (armature) and, rotor (field). The interaction is said to be *synchronous* because, if the rotor is turning at the speed described by Eq. (7-1), the armature and, rotor magnetic fields are turning at the same physical speed. The synchronous operation may be described in two elementary ways, referred to as the magnetomotive force (mmf) *method* and the *flux method*. These are described here, assuming a simple, linear, round-rotor model for the machine. It should be noted that this model will, of necessity, be modified later to fully understand operation of the machine.

MMF Method. A principal feature of a synchronous generator is the mutual inductance between phases. Assuming a 3-phase machine, the mutual inductances between the field winding and the 3-phase windings are

$$M_{af} = M \cos p\phi \tag{7-2}$$

$$M_{bf} = M \cos\left(p\phi - \frac{2\pi}{3}\right) \tag{7-3}$$

$$M_{cf} = M \cos\left(p\phi + \frac{2\pi}{3}\right) \tag{7-4}$$

where M is the peak value of mutual inductance and ϕ is the angle between the axes of the field winding and the stator phase winding designated a. If it is further assumed that phase-phase inductances, both self- and mutual, are not a function of rotor position, the use of energy methods gives a simple expression for machine torque:

$$T = -pMi_a i_f \sin p\phi - pMi_b i_f \sin\left(p\phi - \frac{2\pi}{3}\right) - pMi_c i_f \sin\left(p\phi + \frac{2\pi}{3}\right) \tag{7-5}$$

If the rotor turns at a constant angular velocity $\omega/p = 2\pi f_e/p$, the field current is held constant at a value of I_f and the three stator currents are sinusoids in time, with the same amplitude and with phases that differ by 120°

$$p\phi = \omega t + \delta_i \tag{7-6}$$

$$i_a = I \cos \omega t \tag{7-7}$$

$$i_b = I \cos\left(\omega t - \frac{2\pi}{3}\right) \tag{7-8}$$

$$i_c = I \cos\left(\omega t + \frac{2\pi}{3}\right) \tag{7-9}$$

torque is

$$T = -\frac{3}{2} pMII_f \sin \delta_i \tag{7-10}$$

Note that torque is proportional to the product of the two current amplitudes and to the sine of the phase angle between the current distributions. Further, the torque is acting in a direction so as to align the two current distributions.

Flux Method. The flux method for estimating machine torque focuses on voltage (and hence flux) induced in the machine stator. If L_a is phase self-inductance and L_{ab} is phase-phase mutual inductance, flux linked by armature phase a is

$$\lambda_a = L_a i_a + L_{ab} I_b + L_{ab} I_c + MI_f \cos p\theta \tag{7-11}$$

Noting that the sum of phase currents is, under balanced conditions, zero and that the mutual phase-phase inductances are equal, this is

$$\lambda_a = (L_a - L_{ab}) i_a + MI_f \cos p\theta = L_d i_a + MI_f \cos p\theta \tag{7-12}$$

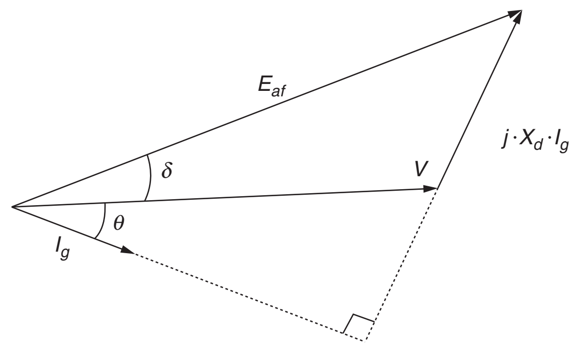
where L_d denotes synchronous inductance.

This flux is described by the equivalent circuit of Fig. 7-4, where

$$E_{af} = j\omega MI_f e^{j\delta} \tag{7-13}$$

and δ is the phase angle between *internal* voltage E_{af} and *terminal* voltage V, and $X_d = \omega L_d$.

Assume $R_a << X_d$, where R_a is the armature resistance.



(*a*) Overexcited (lagging power factor).

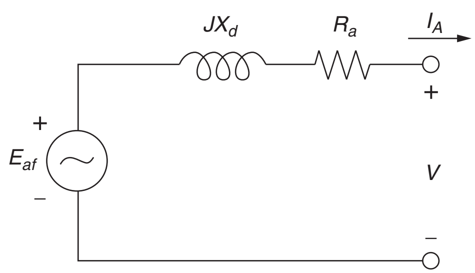


FIGURE 7-4 Steady-state equivalent circuit (R_a is neglected for analysis).

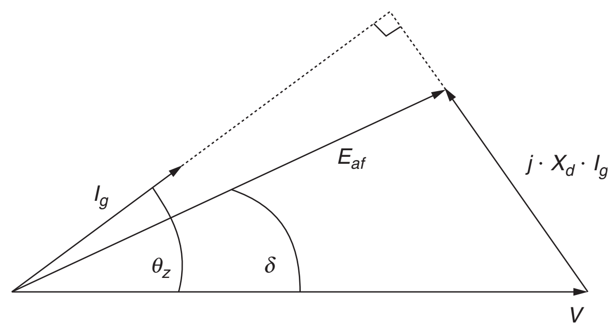

(*b*) Underexcited (leading power factor).

FIGURE 7-5 Round-rotor synchronous generator.

If the generator is connected to a voltage source (i.e., if V is fixed), terminal current is

$$I = \frac{V - E_{af}e^{j\delta}}{jX_d} \tag{7-14}$$

Real and reactive power into the terminals of phase a are

$$P_a = -\frac{1}{2}\frac{VE_{af}}{X_d}\sin\delta \tag{7-15}$$

$$Q_a = \frac{1}{2}\frac{V^2}{X_d} - \frac{1}{2}\frac{VE_{af}}{X_d}\cos\delta \tag{7-16}$$

Considering all three phases, total generated power is

$$P = -3P_a = \frac{3}{2}\frac{VE_{af}}{X_d}\sin\delta \tag{7-17}$$

Phasor diagrams illustrating the operation of a round-rotor synchronous generator are shown in Fig. 7-5. When the machine is *overexcited*, terminal current *lags* terminal voltage. When the generator is *underexcited*, terminal current *leads* terminal voltage.

7.2.4 Salient-Pole Machines: Two-Reaction Theory

Salient-pole generators, such as hydroelectric generators, have armature inductances that are a function of rotor position, making analysis one step more complicated. The key to analysis of such

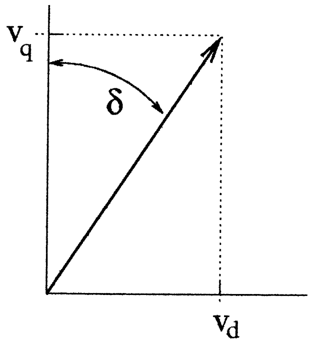

FIGURE 7-6 Direct- and quadrature-axis voltages.

machines is to separate mmf and flux into two orthogonal components. The two components are aligned with the direct axis and the quadrature axis of the machine (Fig. 7-6). The direct axis is aligned with the field winding, while the quadrature axis leads the direct by 90°. Then, if ϕ is the angle between the direct axis and the axis of phase *a*, flux linking phase *a* is

$$\lambda_a = \lambda_d \cos\phi - \lambda_q \sin\phi \tag{7-18}$$

Then, in steady-state operation, if $V_a = d\lambda_a/dt$ and $\phi = \omega t + \delta$, we obtain

$$V_a = -\omega\lambda_d \sin\phi - \omega\lambda_q \cos\phi \tag{7-19}$$

or

$$V_d = -\omega\lambda_q = V\sin\delta \tag{7-20}$$

$$V_q = \omega\lambda_d = V\cos\delta \tag{7-21}$$

One might think of the *voltage* vector as leading the *flux* vector by 90°. If the machine is linear, fluxes are given by

$$\lambda_d = L_d I_d + MI_f \tag{7-22}$$

$$\lambda_q = L_q I_q \tag{7-23}$$

Note that, in general, $L_d \neq L_q$, and for wound-field machines, $L_d > L_q$. Terminal voltage now has these components

$$V_d = -\omega\lambda_q = -\omega L_q I_q = V\sin\delta \tag{7-24}$$

$$V_q = \omega\lambda_d = \omega L_d I_d + \omega MI_f = V\cos\delta \tag{7-25}$$

which is easily inverted to produce

$$I_d = \frac{V\cos\delta - E_{af}}{X_d} \tag{7-26}$$

$$I_q = -\frac{V\sin\delta}{X_q} \tag{7-27}$$

where $X_d = \omega L_d$, $X_q = \omega L_q$, and $E_{af} = \omega MI_f$.

In the complex frame of reference

$$V = V_d + jV_q \tag{7-28}$$

$$I = I_d + jI_q \tag{7-29}$$

complex power is, in the sense of a generator

$$P + jQ = -\frac{3}{2}VI^* = -\frac{3}{2}\{(V_d I_d + V_q I_q) + j(V_q I_d - V_d I_q)\} \tag{7-30}$$

or

$$P = \frac{3}{2}\left[\frac{VE_{af}}{X_d}\sin\delta + \frac{V^2}{2}\left(\frac{1}{X_q} - \frac{1}{X_d}\right)\sin 2\delta\right] \tag{7-31}$$

$$Q = -\frac{3}{2}\left[\frac{V^2}{2}\left(\frac{1}{X_q} + \frac{1}{X_d}\right) - \frac{V^2}{2}\left(\frac{1}{X_q} - \frac{1}{X_d}\right)\cos 2\delta - \frac{VE_{af}}{X_d}\cos\delta\right] \tag{7-32}$$

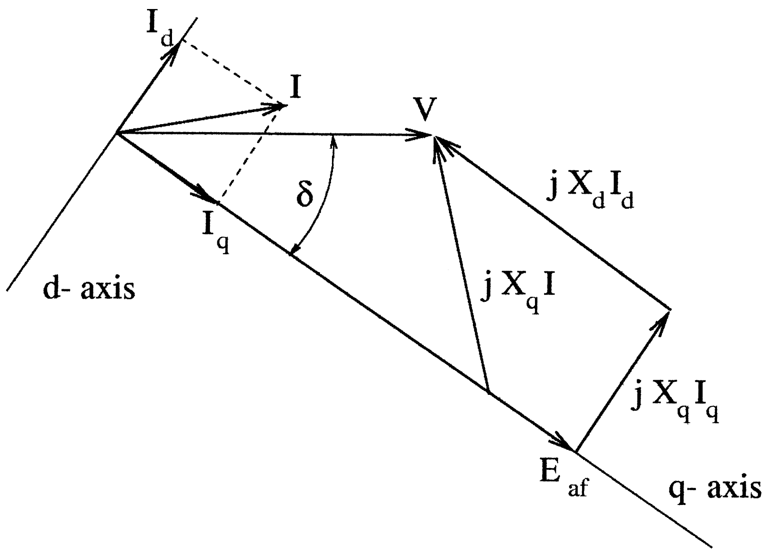

FIGURE 7-7 Vector diagram for salient-pole machine.

Figure 7-7 shows a phasor diagram for a machine with "positive" saliency (and ignoring stator resistance). It is helpful to note that in such a machine, a vector with complex amplitude $j\underline{I}X_q$ begins along the quadrature axis and ends at the ends of the terminal voltage vector.

7.2.5 Machine Size and Utilization

Generators produce torque through interaction between magnetic flux density and current over the surface of the stator, and reaction torque through the same type of interaction over the surface of the rotor. The stator and rotor face each other across the air gap. Power produced is

$$P = \omega_{\text{mech}} T = 2\pi \frac{f}{p} T = 2\pi \frac{N}{60} T \tag{7-33}$$

where torque produced is

$$T = 2\pi R^2 l \sigma \tag{7-34}$$

where f = electrical frequency, Hz
N = mechanical speed, r/min
R = stator inner radius
l = active length
σ = average value of air gap shear stress, given approximately by

$$\sigma \approx \frac{1}{\sqrt{2}} B_1 K_z \tag{7-35}$$

where B_1 is the peak value of fundamental magnetic flux density at the stator surface and K_z is the effective surface current density root mean square (rms) of the armature. The effective surface current density is ampere-turns per unit of periphery, modified by pitch and distribution factors, and by power factor.

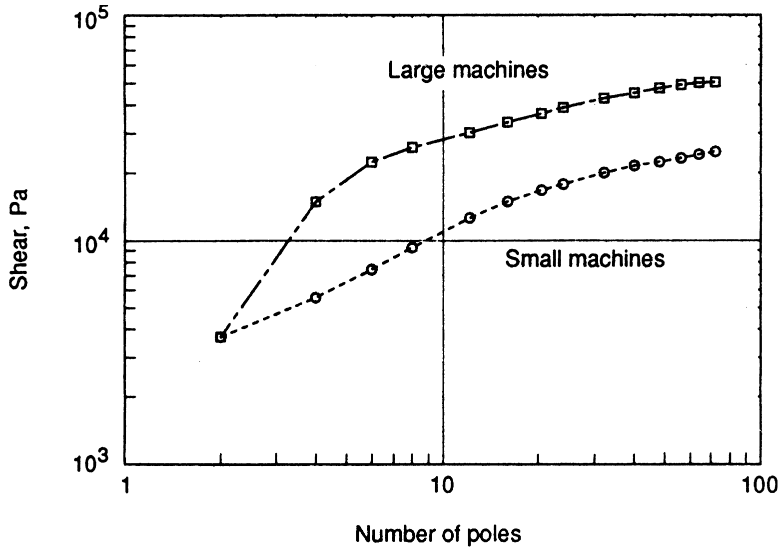

FIGURE 7-8 Typical shear stress, salient-pole, air-cooled generators.

Shear stress normally increases with pole pitch for a particular voltage and number of poles because the deeper armature slots and greater field coil space allow more ampere-conductors per unit of periphery. Typical shear stress levels for indirectly cooled, salient-pole generators are shown in Fig. 7-8. Shear is higher for directly cooled machines and a consequence of increased current density, as shown in Fig. 7-9.

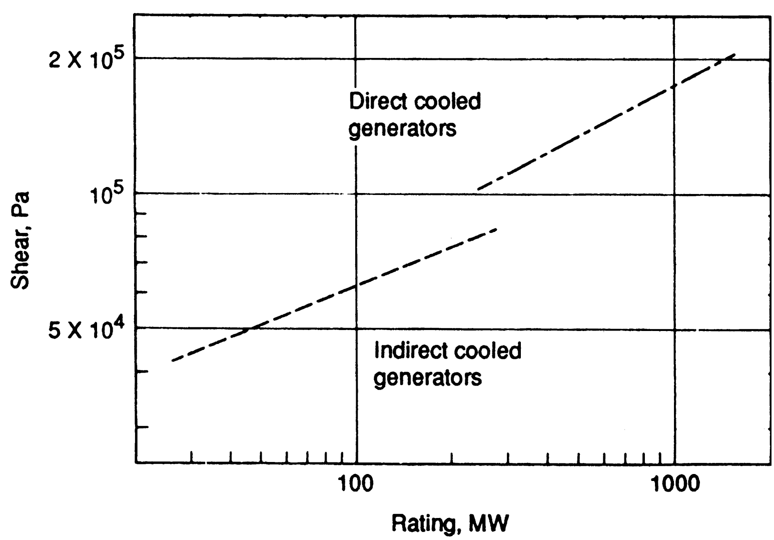

FIGURE 7-9 Typical shear stress, high-speed generators.

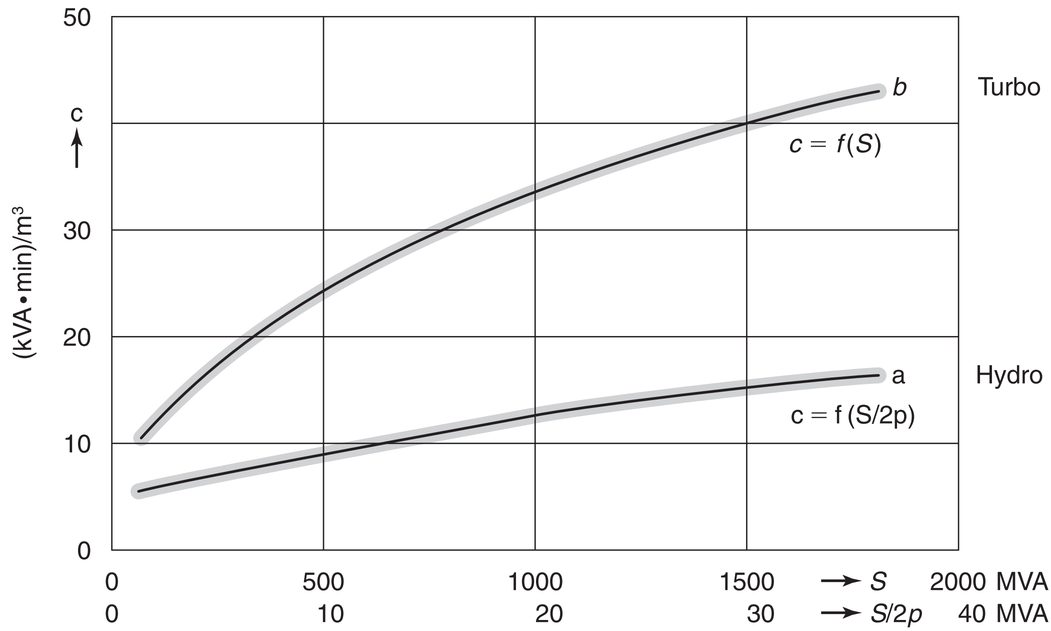

FIGURE 7-10 Utilization factors. (*ABB.*)

Another rough estimate of machine size employs the *utilization factor:*

$$c = \frac{S}{D^2 l N} \tag{7-36}$$

where S is machine rating, D and l are outside diameter and length, respectively, and N is rotational speed. Typical values for the utilization factor c are shown in Fig. 7-10. Here the utilization factor depends on unit rating (high-speed machines) or unit rating per pole (low-speed machines) and on cooling.

7.3 ELECTROMAGNETICS

Sketches of the major elements of synchronous generators, together with field "flux forms," are shown in Figs. 7-11 and 7-12. Here the generator is "unrolled" and shown as if the air gap were flat. Note that the main flux distribution air gap is not exactly sinusoidal. Thus the voltage produced will contain time harmonics. Assign C_n to be the amplitude of the nth-space harmonic of the flux density, relative to the peak amplitude B_0.

The fundamental flux per pole is

$$\Phi_1 = \frac{2RlB_0C_1}{p} \tag{7-37}$$

7.3.1 Generated Voltage

The rms amplitude of generated voltage is, for the time, fundamental

$$V_1 = \frac{1}{\sqrt{2}}\,\omega N_a k_w \Phi_1 \tag{7-38}$$

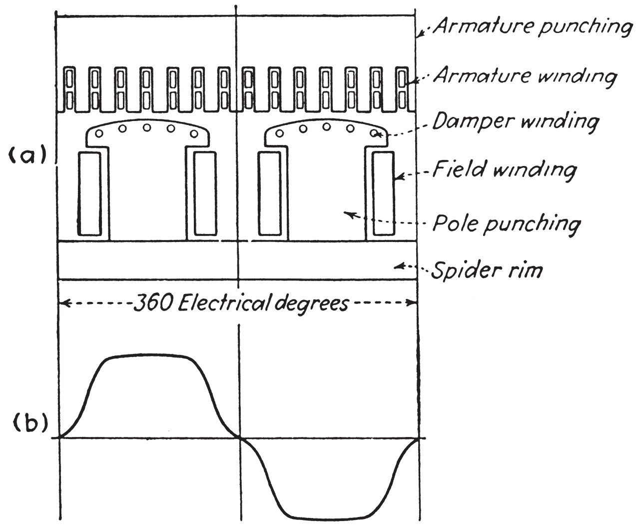

FIGURE 7-11 (*a*) Generalized sketch of one pair of poles for a salient-pole machine; (*b*) flux form for typical pair of poles (current in field winding only).

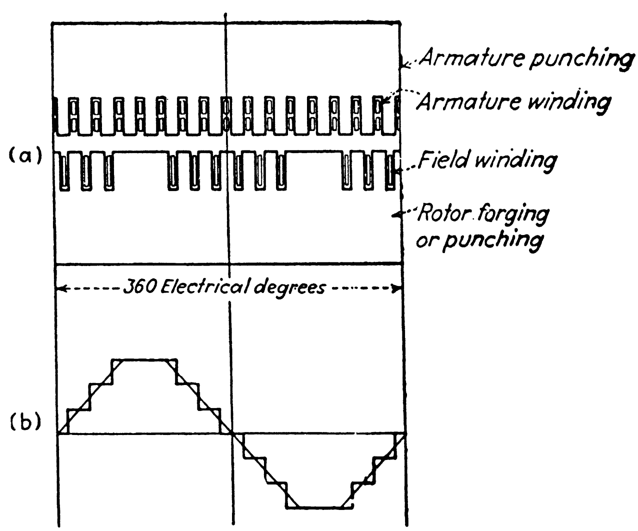

FIGURE 7-12 (*a*) Generalized sketch of one pair of poles for cylindrical rotor machine; (*b*) flux form for a typical pair of poles (current in the field winding only).

where V_1 is the time fundamental voltage induced in a phase and N_a is the number of turns in the phase. In a 3-phase machine connected in wye, line-line voltage is $\sqrt{3}$ times phase voltage. The winding factor k_{wn} is explained in Eqs. (7-40) through (7-42).

Harmonics. Time-harmonic voltages will be induced, and they are

$$V_n = V_1 \frac{C_n}{C_1} \frac{k_{wn}}{k_w} \tag{7-39}$$

It should be noted that certain time harmonics, those referred to as the *triplen* harmonics (odd factors of 3), are induced in all three phases of a 3-phase machine in phase. Thus, if line-line voltage is measured, these harmonics (orders 3, 9, 15, . . .) will turn out to have zero amplitude.

Tooth Ripple Effects. The voltage waveform predicted in Eq. (7-39) neglects the effect of armature teeth and slots on the air-gap flux. The resulting modulations of the air-gap fields dc not generate voltages in armature conductors directly, rather induce currents in the field winding, any damper windings that may exist, and in the rotor body itself and slot wedges. These currents produce flux components, which in turn produce voltages in the armature winding. The orders of these voltages are the integer multiple of the number of slots per pole pair, ±1. Thus, in a winding with 24 slots per pole pair, the harmonics will have orders of 23, 25, 47, 49, 71, 73, and so on.

Estimation of voltage waveform is actually quite complex. While Eq. (7-39) may be used for a first-order estimate, manufacturers of generators typically use numerical (finite element) methods for prediction of harmonic voltage production in actual practice.

Load Effects. Load on the machine affects the harmonic content in the following ways:

1. Increased field current tends to increase all internal voltages including harmonics.

2. Armature reaction generally reduces the fundamental voltage more than the harmonics and, through tooth and slot permeance variations, introduces additional harmonics.

3. Magnetic saturation changes harmonic magnitudes.

4. The fraction of harmonic *internal voltage* that appears at the machine terminals depends on the relationship between internal and load impedance.

Voltage Waveform Standards. There are two ways of specifying the nonideal (departure from a sine wave) nature of a voltage waveform. Both of these are defined in ANSI C42.10. Limiting values for these factors are specified in ANSI C50.12, C50.13, and C50.14.

Deviation Factor. This is, as the name implies, the maximum deviation from a sine wave. It is defined as the maximum difference between the actual waveform and the equivalent sine wave, normalized to the equivalent sine wave amplitude.

Telephone Influence Factor. This is a weighted sum of the magnitudes of all harmonics in the voltage waveform. The weighting of each harmonic is intended to reflect the relative objectional effect of inductive coupling at each harmonic frequency on telephone communications.

Pitch and Breadth Factors. The winding factor is $k_{wn} = k_{pn}k_{bn}k_{sn}$. Its component parts are called the *pitch factor*

$$k_{pn} = \cos \frac{n\alpha}{2} \tag{7-40}$$

the *breadth factor*

$$k_{bn} = \frac{\sin \dfrac{mn\gamma}{2}}{m \sin \dfrac{n\gamma}{2}} \tag{7-41}$$

and, when applicable, the *skew factor*

$$k_{bn} = \frac{\sin \frac{n\theta_s}{2}}{\frac{n\theta_s}{2}}$$

where α = *pitch angle*: the electrical angle between coil halves of the armature winding (this is generally a bit less than π to reduce the impact of higher harmonics and to make armature end windings shorter)

m = number of slots per pole per phase

γ = electrical angle between slots

θ_s = electrical angle of skew

Here, the relevant angles are stated in *electrical* terms. The electrical angle is p times the physical angle. Thus, in a 4-pole machine with 72 slots, the electrical angle between slots is $2 \times 360/72 = 10°$.

In many ac generators, the skew angle is zero for which the skew factor is unity. In some cases, the stator is skewed with respect to the rotor (or vice versa) to reduce the effects of slot openings in inducing currents in rotor parts with a consequent effect on rotor surface losses and noise.

7.3.2 Example of 4-Pole, Armature-Wound Machine

As an example, consider a 4-pole armature wound in 48 slots with a 5/6 relative pitch. The *coil pitch,* or the number of slot pitches between coil halves, is then 10 slots (5/6 × 48/4). The number of slots/pole/phase is 4 (48/[2 × 2 × 3]). Then the winding factors for the first few harmonics are

Harmonic	k_p	k_d	k_w
1	0.9659	0.9577	0.9250
5	0.2588	0.2053	0.0531
7	0.2588	–0.1576	–0.0408
11	0.9659	–0.1261	–0.1218
13	–0.9659	0.1261	–0.1218
17	–0.2588	0.1576	–0.0408
19	–0.2588	–0.2053	0.0531
23	–0.9659	–0.9577	0.9250
25	0.9659	–0.9577	–0.9250
29	0.2588	–0.2053	–0.0531
31	0.2588	0.1576	0.0408
35	0.9659	0.1261	0.1218
37	–0.9659	–0.1261	0.1218

Observe that the winding factors k_w for the harmonics 23 and 25 have the same value as the fundamental voltage. This is so for all harmonics whose numbers are equal to (integer multiple of number of slots per pair of poles) ±1. These harmonics are called slot harmonics, and the armature winding cannot attenuate the voltages induced by flux waves of these orders.

7.3.3 Armature Reaction

Current in the armature conductors produces an mmf which has the same number of poles as the field structure. The fundamental harmonic of this mmf rotates at synchronous speed, and adds to the field mmf in a vector sense as shown in Fig. 7-13. For generators supplying reactive current to an inductive load, the net effect of the armature reaction is to oppose the field mmf, requiring additional field current to sustain flux.

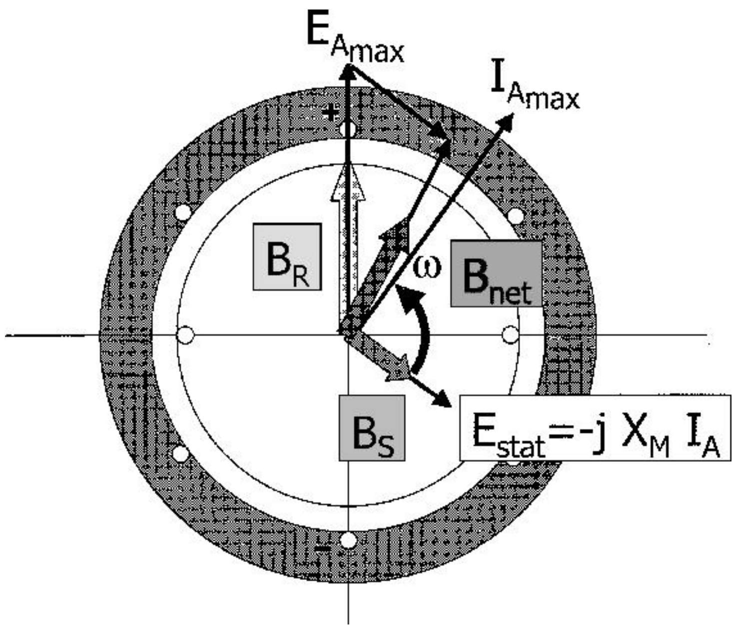

FIGURE 7-13 Armature reaction (vector analysis of magnetic fields).

The peak value of the space fundamental of armature reaction current for a 3-phase machine is

$$F_a = \frac{3}{2}\frac{4}{\pi}\sqrt{2}N_a I k_p k_b k_s \tag{7-43}$$

where I is rms terminal current, N_a is the number of series turns per phase, and the winding factors are as defined above.

Space harmonic components of armature reaction current can produce losses in the rotor as they turn asynchronously. The magnitude of the harmonic mmf of order n is

$$F_{an} = \frac{3}{2}\frac{4}{n\pi}\sqrt{2}N_a I k_{pn} k_{bn} k_{sn} \tag{7-44}$$

The rotational speed of each of these harmonics is

$$\omega_n = \mu\frac{1}{n}\cdot\omega \tag{7-45}$$

where, for a 3-phase machine, the rotational direction is same as that of the fundamental (positive) for harmonics of orders 7, 13, 19,….., and is opposite from the rotation of the fundamental (negative) for harmonics of orders 5, 11, 17, … . The electrical frequency of the pairs of these waves in the rotor frame turns out to coincide, so that the armature harmonics of orders 5 and 7 and fundamental frequency both appear in the rotor frame at 6 times the fundamental frequency.

7.3.4 Magnetic Circuit and Material

The magnetic circuit of an ac generator, as with other electric machines, is made up of the air gap, the stator teeth and backiron, the rotor poles, and the shaft section. Each of these elements has an effect on machine rating and operation.

The function of the magnetic circuit is to carry flux that links the armature conductors to produce voltage.

Air gap. The air gap constitutes the division between the rotating part of the machine—the rotor, which carries the field winding—and the stationary part of the machine—the stator, which carries the armature winding. In ac generators, the air-gap dimension is determined by the electrical characteristics of the machine. There is a trade-off between excitation mmf (toward a small air-gap dimension) and armature reaction flux (toward a large air-gap dimension). This trade-off generally results in an air gap, which is substantially larger than mechanical considerations such as machining tolerances or windage loss would dictate.

Stator Teeth and Backiron. The armature magnetic circuit carries alternating flux and is always laminated, either with complete ring laminations (for small machines) or with overlapping segmented laminations. The material most commonly used is sheet steel, of an alloy containing about 3.5% silicon, in sheets of thickness between about 0.35 and 0.65 mm. Grain-oriented steel, with reduced losses and improved permeability in the direction of rolling, is often used in large turbogenerators. Orientation in the circumferential direction is advantageous in such machines because of the large proportion of steel and moderate flux densities in the backiron. At high flux densities characteristic of the armature teeth, the advantage of grain orientation becomes less pronounced.

The active region of the armature constitutes the alternation of stator teeth and slots carrying the armature winding. The division between teeth and slots is a compromise between flux-carrying capability and current-carrying capability. The trade-off generally results in a division that is about half slots and half teeth. Flux densities in the stator teeth are usually high enough to result in moderate saturation of the magnetic material.

Rotor Iron. The magnetic flux in the rotor is nearly constant, varying in the main only slightly with changes in load and terminal voltage and with small higher frequency components due to time and space harmonics of armature flux. This allows the rotor magnetic circuit to be made of solid steel.

In turbine generators, the rotor is typically made of a single-piece forging of steel with slots for the field winding cut by machining. The losses caused by harmonic driven eddy currents in the solid steel pole faces can be problematic, and are reduced by making the air gap larger, by increasing the number of stator slots and, by choosing a suitable (short-pitch) coil throw for the armature.

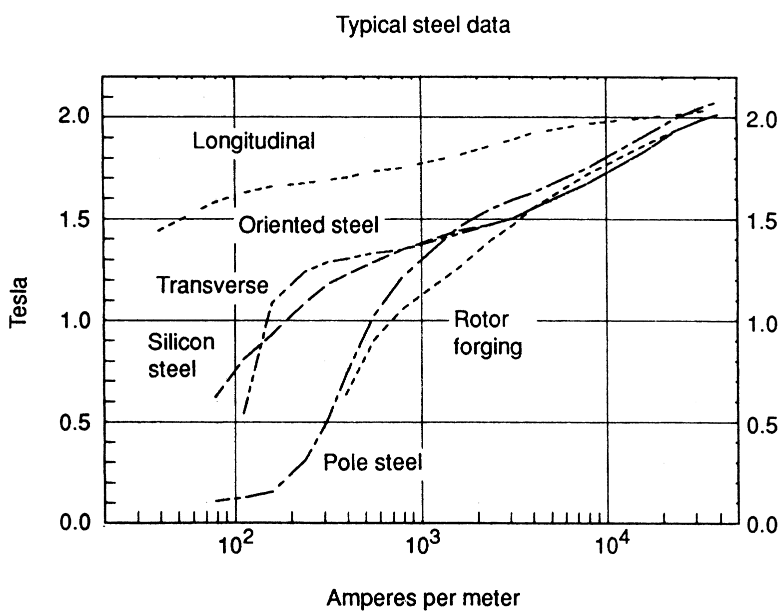

FIGURE 7-14 Magnetization curves of commonly used steels.

Salient-pole machines may have solid or laminated poles. In many cases, laminated poles are necessary to control eddy current losses. Pole laminations are commonly made of low carbon steel, 1.5 to 2 mm thick. Thinner steel, sometimes with silicon content, may be used where further control of eddy current losses is required. The shaft, or inner portion of the rotor of salient-pole machines, is often a solid forging, or in large machines such as hydroelectric generators may be fabricated from structural steel pieces.

Magnetic Materials. Typical magnetization characteristics of steel materials used in the magnetic circuit of ac generators are shown in Fig. 7-14.

7.4 MACHINE OPERATION

In normal operation, real power is dictated by the prime mover and reactive power is determined by the real power and by field current.

7.4.1 Capability Diagram

Equations (7-31) and (7-32) are approximate ways of estimating the real and reactive power output of a generator as a function of field current and torque angle. (Eq. 7-46 is provided for additional clarification.) If these are cross-plotted as shown in Fig. 7.14, a way of representing the capability of an ac generator emerges as shown in Fig. 7-15. This is called a *capability chart* for obvious reasons and four limits are shown.

$$
\begin{aligned}
P &= 3 \cdot V_\phi \cdot I_A \cdot \cos(\theta_z) = 3 \cdot V_\phi \left(\frac{E_A \cdot sin(\delta)}{X_s} \right) \\
Q &= \left(\frac{3 \cdot V_\phi}{X_s} \right) \cdot X_S \cdot I_A \sin(\theta_z) = 3 \cdot V_\phi \cdot I_A \sin(\theta_Z)
\end{aligned}
\tag{7-46}
$$

The final capability curve is shown in Fig. 7-16. Four limits are shown on this chart:

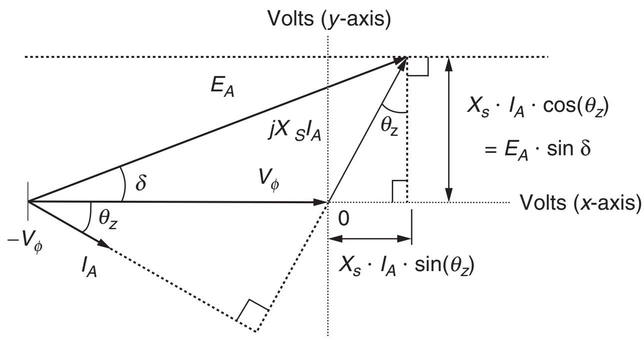
1. The field winding limit is generally related to the thermal capability of the field winding, and limits operation of the generator at high reactive power conditions.
2. The armature winding limit is generally related to the thermal capability of the armature winding, and is typically a limit on total kVA (kilovoltampere) output of the machine.
3. The stability limit is related to torque angles that are nearly at the peak of the torque-angle curve (90° for round-rotor machines).
4. Often, the configuration of magnetic flux is such that, at high reactive power absorption (negative Q), there is axial flux in the core ends, leading to excessive heating and limiting the reactive power that can be absorbed by the machine.

Very often the prime-mover power rating is plotted on the capability chart. It is, of course, a line of constant real power. The heating related limits (armature, field, and core end) may be functions of the state of the cooling system of the machine, such as hydrogen pressure. (See Sec. 7.10 on cooling.)

7.4.2 Saturation Curves and Excitation

Alternating-current generators are usually operated with at least part of the magnetic circuit partially saturated, so that the linear model of machine operation implied by some of the foregoing discussion does not give exactly the right answers. What follows is an approximate way of estimating excitation requirements for an ac generator.

It should be noted that numerical methods, employing finite elements, are now available and capable of making even more accurate estimates of machine performance including excitation



Note: $I_A \cos(\theta_z) = \dfrac{E_A \cdot \sin\delta}{X_S}$

requirements. When these more sophisticated methods are available, it is generally better to use them. The approximate method described here is included for two reasons: (1) because it may aid in a physical understanding of generator operations and (2) because it gives reasonably accurate answers without the need for a large number of computer "cycles."

Figure 7-17 shows open- and short-circuit characteristic curves for an ac generator. These curves are taken with the generator operating at rated speed. Important curves are

1. The air gap line is the extrapolation of open-circuit voltage versus field current at low levels of field current.
2. The no-load saturation curve is the actual open-circuit voltage versus field current characteristic.
3. The short-circuit saturation curve typically does not show saturation. It represents a measurement of current in the terminals of the generator, with the terminals short-circuited, versus field current.
4. The rated current, zero power factor saturation curve shows voltage at the terminals of the machine versus field current if the machine is operated with rated armature current at zero power factor.

Calculating Excitation Requirement. Field current required for machine operation consists of three parts

$$I_f = I_{FG} + I_{FSI} + I_{FS} \tag{7-47}$$

where, I_{FG} is the field current required to excite the air gap, I_{FSI} is the field current required to compensate for direct-axis armature current, and I_{FS} is the field current required to compensate for saturation. Note that this method does not account for saturation of the quadrature axis. Armature resistance is generally neglected.

Addition of the three components of current is shown in Fig. 7-18. In this figure, the field current that compensates for armature reaction is added at the power factor angle Θ. The current I_{FS} is the current required to compensate for direct axis saturation. I_{FS} is the distance from the air-gap line to the no-load saturation curve at the voltage corresponding to the flux level in the magnetic circuit. This voltage is referred to as the voltage behind Potier reactance. It is estimated as shown in Fig. 7-19.

To find the (fictitious) Potier reactance, refer back to Fig. 7-17. Note that for the zero power factor test, all the fluxes are on the direct axis, so they add directly. Two of the current components, I_{FG} and I_{FSI}, are easily determined. The difference between field current for the zero power factor test and the sum of these two currents is I_{FS}. Since this corresponds to the distance between the air-gap

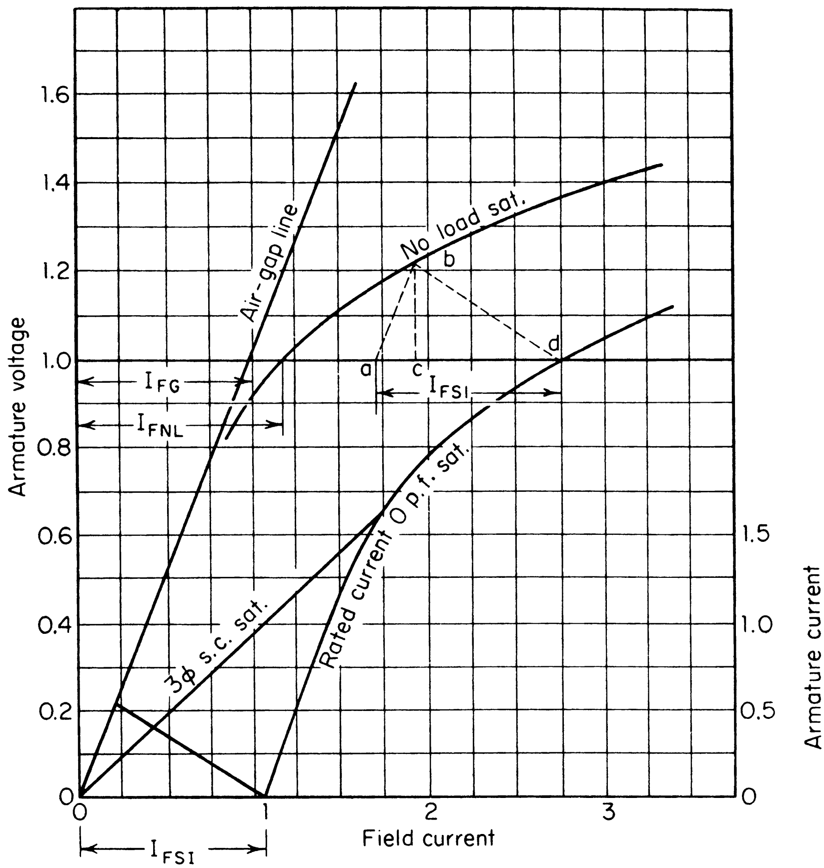

FIGURE 7-17 Typical saturation curves of an ac generator showing graphic determination of Potier reactance (quantities are in per unit values).

line and saturation curve at the voltage behind Potier reactance, it determines that voltage. For the zero power factor test, $I_a x_p$ is a vertical line of length x_p since $I_a = 1$. The distance between the saturation curve and air-gap line is the same as I_{FS} at a voltage found by casting a line parallel to the air-gap line from $I_F - I_{FSI}$. This is *ab* on Fig. 7-17. Then x_p corresponds to *bc* on the same figure.

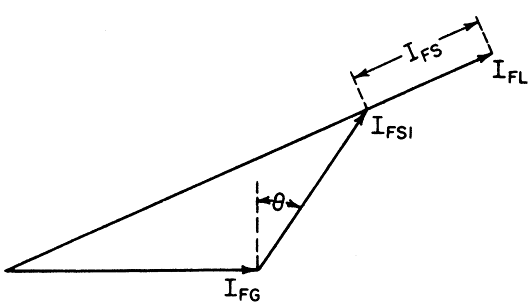

FIGURE 7-18 ANSI method of calculating load excitation.

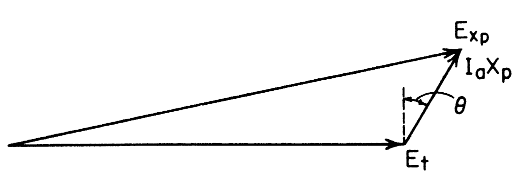

FIGURE 7-19 Calculation of voltage behind Potier reactance.

7.5 ARMATURE WINDINGS

A wide variety of winding types may be used to produce a desired voltage with the desired number of phases and a suitable waveshape. In small generators, "scramble wound" armature windings may be used. However, in most alternator applications, double-layer, form-wound coils in open slots with 60° phase belts are used. In such a winding, each slot has two conductor bars (often called *half-coils*), not necessarily from the same phase winding. These bars are insulated from ground and secured in the slot, usually by wedges. It is usually necessary for the bar to have the ability to slide axially in the slot to accommodate thermal expansion, but it must not be loose in either the radial or azimuthal directions. This has led to a number of proprietary techniques for armature construction.

7.5.1 Winding Forms

Figure 7-20 shows an example winding diagram. For the purposes of this figure, the machine is shown "rolled out flat," with the dotted lines on either side representing the same azimuthal location. In this case, the machine has 24 slots, each with two half-coils, as shown in the slot allocation section of the drawing, at the bottom of the figure. The upper part of the figure shows how one phase of the winding would be laid out. This drawing shows a lap type winding (the most commonly used) with a $^5/_6$ pitch. In a 24-slot, 2-pole winding a full-pitch coil would span 12 slots, while in the $^5/_6$ pitch winding the coils span 10 slots.

Fractional Slot Windings. Fractional slot windings, in which the number of slots per pole per phase is not an integer, have coil groups that differ from one another. These can be arranged to produce balanced voltages under circumstances that are beyond the scope of this discussion.

7.5.2 Stranding and Transposition

At power frequencies (50 or 60 Hz), the skin depth in copper is on the order of 1 cm so that it is usually necessary to subdivide armature conductors into a number of parallel strands. In form-wound

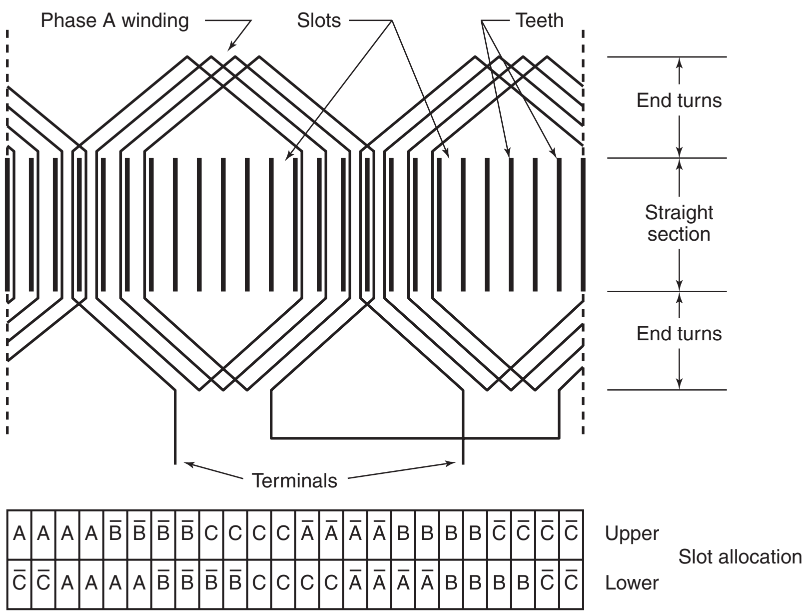

FIGURE 7-20 Armature in 24 slots, 5/16 pitch.

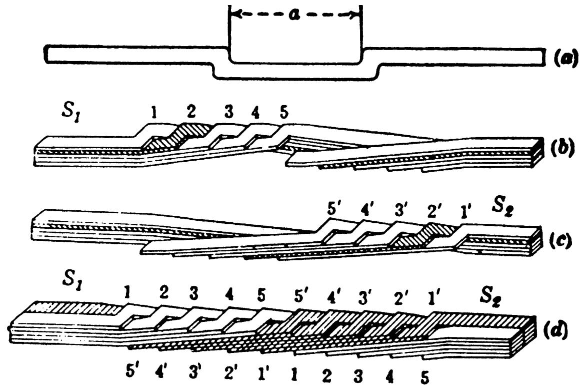

FIGURE 7-21 Illustration of Roebel transposition: (*a*) typical offset conductor strand; (*b*) group of conductor strands composing half the conductor; (*c*) complementary group; (*d*) assembly.

coils, these strands are usually rectangular to allow for good space factor. To prevent circulating currents between parallel strands, it is necessary to employ transposition to ensure that voltages induced in each strand are approximately the same.

The simplest form of transposition, often used in transformers and sometimes in generators, is to twist the armature conductors at 180° in the end turns. Or sometimes, groups of conductors are connected together in the end turns with a progressive transposition that constitutes a "twist" of the winding from half-coil to half-coil.

Transposition of strands in the end turns is generally not satisfactory in large ac generators. A transposition scheme attributed to Roebel is usually used (see Fig. 7-21). The Roebel transposition is equivalent to a twist of the conductors in the slot. It is usual to carry out the Roebel transposition only within the slot part of the winding. A variety of transpositions are used, including 180°, 360°, and 540°. The first two are effective only at eliminating circulating currents due to flux crossing the slot, but do not compensate for flux in the end windings. The 540° transposition, attributed to Ringland and Rosenberg (1959) is often applied because it filters out most of the circulating currents in a bar. Other more complex Roebel transposition arrangements that more extensively filter out circulating currents are possible but are rarely used because of manufacturing complexity. Bapat (1973) and Neidhoeffer (1990) outline general surveys about special transpositions.

7.6 INSULATION SYSTEMS

Electrical insulation is used to isolate field conductors from each other and ground, and in the armature winding to isolate strands and turns from each other and the whole winding from ground. Proper application of electrical insulation constitutes much of the art of ac machine design, particularly in the larger generator sizes.

7.6.1 Materials

International standards have established various classes of insulation systems based primarily on the maximum steady-state operating temperature and have established voltage proof tests to demonstrate the dielectric capability of insulation systems.

Of the several thermal classes of insulation systems, three are most applicable to ac generators. These are Classes 130, 155, and 180. Class 105 insulation materials are no longer used in modern ac generators. In the most recent revisions of IEEE C50-12 and C50-13, and IEC 60034-1 and 60034-3 standards for ac generators, the numerical classifications 130, 155, and 180 have been substituted for the previously used alphabetical classifications B, F, and H, respectively.

Class 130 systems comprise inorganic materials such as mica and glass fibers, organic materials such as synthetic films, and suitable binders. Until recently, Class 130 systems have been identified as Class B systems.

Class 155 systems comprise generally similar materials with binders capable of higher temperatures. Until recently, Class 155 systems have been identified as Class F systems.

Class 180 systems include silicone elastomers as well as mica, glass fibers, and higher-temperature binders. Until recently, Class 180 systems have been identified as Class H systems.

Synthetic chemistry has presented a continued flow of materials suitable for electrical insulation, and any of the above-mentioned insulation systems may be supplemented by new materials.

7.6.2 Temperature Measurements

Several methods of observing winding temperatures are used. Note that it is ordinarily not practical to actually measure the "hot spot" temperature directly, so that an allowance is normally given, based on the method of temperature measurement used.

Thermometer method. A thermometer (mercury filled, or other suitable temperature measuring device) may be applied to what is expected to be the hottest part accessible. Of the several methods described, this one gives readings furthest from the maximum winding temperature and therefore has the highest hotspot allowance.

Resistance method. The resistance of electrical conductors is a function of temperature. Thus, if the resistance of the winding can be measured and its resistance at a reference temperature is known, the average temperature of the winding may be calculated

$$T_2 = K + \frac{R_2}{R_1} \cdot (1 + T_1) \tag{7-48}$$

where R_1 is the resistance at temperature T_1 and R_2 is the resistance at temperature T_2. The constant K is 234.5°C for copper, 242°C for silver-alloyed copper used for hollow conductors, and 225°C for electrical conductivity aluminum.

Discharge coolant method. For directly cooled armature windings in the largest generators, the observable temperature is the coolant being discharged from the armature coils.

Embedded detector method. Thermocouples or resistive thermal detectors are built into the machine. In the most common application these are placed between the coil sides in a two-layer armature winding near the axial center or warmest region of the core.

Applied thermocouple method. Thermocouples are applied directly to the conductors, with little or no insulation. This method is used only for experimental testing to, for example, determine hot-spot allowances. It is not used for operational measurements.

7.6.3 Temperature Ratings

Temperature ratings of ac generator windings are based on measurements of winding temperatures and the thermal class of insulation used. These measurements are specified in IEEE C50-12 and C50-13, and IEC 60034-1. Generally, machines with smaller ratings employ the resistance method and larger machines employ embedded detectors or discharge coolant measurement methods.

7.6.4 Armature-Winding Insulation

Armature voltages range from about 220 V to about 27 kV. With such a wide range, different techniques are employed. In the armature, insulation is for strands, turns, and ground wall.

Strand insulation is required to prevent circulating currents within a conductor bar. The voltage levels are not high so mechanical integrity is the important feature of strand insulation. This is usually a layer of served fabric or film coating.

Turn insulation is used in multiturn coils, generally applicable only in small-size generators. This insulation is required to withstand turn-turn voltage, although in some cases large transient spikes of voltage may be incident on the winding.

Ground wall insulation must withstand full voltage to ground. Typically, the whole of an armature winding is insulated for full voltage, even though some of the coils, located near the neutral end of the winding, see lesser voltage.

In high-voltage armatures (above ~5 kV), some measures must be taken to control the effects of corona and partial discharge. In the slot portion of the coil, it is necessary to prevent discharges due to capacitive coupling through the insulation, from the surface of the insulation to the grounded stator core. These discharges are prevented by coating the outer surface of the insulated conductor with a conductive (sometimes called semiconducting) coating (paint or tape). To prevent discharges along the surface of the conductors in the end windings, those sections are sometimes coated with very weakly conducting coatings that are called grading coatings (paint of tape).

It is important to prevent electrical discharges in the vicinity of the winding because such discharges through air and in the presence of any water vapor will produce nitrous and nitric acid and ozone, substances corrosive to the materials of the winding.

7.6.5 Field-Winding Insulation

Field windings operate at much lower voltages (usually less than ~800 V). Some transient conditions, such as interruption of field current, can lead to much higher voltages.

Field windings are subject to the centrifugal forces due to rotation, and this presents special challenges. Dimensional stability is required of the field winding to prevent dynamic rotor imbalance. It is also necessary, in larger machines, to allow the field winding to expand thermally with respect to the rotor steel. The resulting "creepage" surfaces must allow slip in the axial direction but not movement in the other directions.

7.6.6 Insulation Maintenance

Failure of the insulation system of a generator produces a prompt outage of the generator. This produces ample reason to maintain the insulation system in good order. Insulation maintenance involves measures to reduce or eliminate sources of abnormal aging and damage to insulation, inspection to determine if deterioration has taken place, and testing to assess the state of the insulation system.

Service Conditions. Some operational conditions that produce accelerated insulation deterioration and ways of controlling them are described as follows:

Excessive temperature may be caused by blockage of ventilation paths or cooling tubes or by overload. Measurement of winding temperature is used to detect overtemperature conditions to allow the cause to be corrected.

Excessive voltage may be caused by control errors, but is usually the result of switching operations or lightning. This is usually a matter for correct system design to prevent such overvoltages.

Contamination can affect windings in one of the three ways. Some contaminants may attack insulation system, reducing its dielectric strength or affecting its mechanical properties. Some contaminants may thermally insulate parts, causing excessive temperatures. On the other hand, some contaminants such as conducting particles may lead to abnormal potential distribution and excessive voltage stresses. Control of contamination consists of preventing substances from entering the generator (if possible) and of inspecting periodically for signs of contamination or related damage.

Physical damage to insulation can occur for a variety of reasons, including vibration, overspeed, short-circuit forces or improper synchronization, and even damage by foreign objects. Generally, prevention and inspection are used to control such damage.

Corona, an electrical discharge around the surface of stator insulation, may be caused by contamination or by some inherent weakness in the insulation system itself.

Inspection. Visual inspection supplemented with simple physical tests may be carried out to diagnose incipient problems that might lead to eventual insulation failure. Some symptoms are described as follows:

Swelling or shrinking is evident from visual inspection, probing, and tapping on the insulation. Swelling is accompanied by reduction in physical integrity and sometimes by separation of insulation from the underlying conductor. Shrinkage leads to looseness in the slot.

Cracking results from abnormal mechanical stress or poor winding support. *Girth cracking* is displacement of insulation near the core ends of relatively large machines, caused by thermal cycling.

Substances noted on the winding can include contaminants such as oil, dust, and water and also deposits produced by corona, which may be white, gray, or red and may appear in regions of high electrical stress.

Slot wedges and fillers may become loose in service. This will lead to deterioration if not corrected, so any inspection of a generator should include checking of all the stator slot wedges.

Tests of Insulation Systems. Before commissioning a new generator and as part of generator maintenance programs, tests of insulation systems are carried out. There is a wealth of literature on this topic cited in the references. What appears here is only a first-order synopsis.

Testing of insulation systems in ac generators is used to uncover existing weaknesses or faults and to produce an indication of expected service reliability.

Some tests commonly employed are described as follows:

Insulation resistance is a straightforward test used to indicate the existence of contamination or moisture absorption. It seldom indicates the existence of an incipient fault. It is difficult to assign specific acceptable values for the results of insulation resistance tests, but it is possible to 'trend' the results of such tests.

Dielectric absorption tests are similar to a dc resistance test. A voltage in the range of 500 V to 5 kV is placed across the insulation and current is measured as a function of time. The *apparent* resistance is the ratio of voltage to current and is a function of time. The *polarization index* is the ratio of the value of this apparent resistance after 10 to the value after 1 min. The polarization index may be used for trending. Generally, for Class 130 and Class 155 insulation, a polarization index of about 2 or greater is an indication of a healthy winding, while a value of 1 or less is an indicator of potential trouble. Further description of resistance and dielectric absorption tests is contained in IEEE Standard 43.

Overvoltage tests are proof tests. Failure of an overvoltage test (called also *high potential* or *hi-pot*) is destructive. Such tests are carried out because failure of an insulation system under test conditions is much less damaging than failure in service. Overvoltage tests may be carried out with either ac or dc voltage, and employ voltage levels that are selected for the particular test. New windings (whether in a new generator or in a newly rewound generator) are typically tested to higher levels relative to their operating voltage, than are older windings that have been in service for a significant portion of their expected life. Typical values of high potential for testing new windings are twice operating line to line voltage plus 1000 V. Typical values of high potential for testing mature windings are between 125% and 150% of operating line to line voltage.

Direct current test voltage is related to the peak of the equivalent ac voltage. Details and test procedures are included in IEEE Standards 4 and 95.

Slot discharge may be detected in operation by using a *corona probe*, an antenna located inside the machine (Kurt et. al. 1984).

Rotor winding impedance tests can be used to detect failure of field-winding resistance. An alternating voltage is placed across the field winding, and individual coil voltages are measured. If the measured voltages are not the same, there is an indication of short-circuited turns.

Insulation power factor tests are generally used only on high-voltage machinery (above ~6 kV). Normally, the power factor, measured when applying voltage to a winding and measuring current, is quite low. Power factor measured as a function of applied voltage may be used for trending, and an increase in power factor with voltage is an indication of developing voids in the insulation.

Controlled overvoltage or dc leakage tests consist of measuring leakage current versus time. These tests are detailed in IEEE Standard 95.

7.6.7 Stator-Core Insulation

The stator core is made up of thin sheets of electrical steel that are coated by thin films of organic or inorganic insulation.

7.7 MECHANICAL CONSTRUCTION

Generators consist of a rotor, a stator and those mechanical parts required to hold the machine together and assure proper alignment, cooling, and other aspects of operation. Design criteria for the mechanical aspects of machine construction are based not only on anticipated steady state operation but also on abnormal aspects of operation such as overspeed and short circuits.

Essential variations in machine construction are salient pole versus round rotor and horizontal versus vertical shaft. In virtually all modern alternators the field is the rotating element and the armature is the stationary element. In salient-pole construction the field windings are wound around pole pieces. Such construction is used for machines with at least 6 poles, corresponding to shaft speeds of 1200 r/min or less in the 60-Hz world, or 1000 r/min in the 50-Hz world. Round-rotor construction, in which field windings are inserted in axial slots in a cylindrical rotor body, is used in essentially all 2-pole machines and most 4-pole machines because attaching salient poles to a rotor shaft becomes problematical at the higher shaft speeds associated with such machines.

The prime mover determines if the shaft is horizontal or vertical. Most generators driven by steam turbines, gas turbines, or reciprocating engines have horizontal shafts. Larger, low-speed hydraulic turbines have vertical shafts, while smaller, higher-speed turbines can have shafts that are vertical, horizontal, or even inclined. Magnetic circuits, stator, and armature windings of all machines are similar, only structural details differ.

7.7.1 Stator Construction

Armature cores are built up of thin laminations, produced as either segments or complete rings, depending on the size of the generator. Successive layers or groups of layers of the segmented laminations are staggered to minimize the effect of the joints in the magnetic circuit. The core is clamped between pressure plates and fingers to support it with sufficient pressure to prevent undue vibration of the laminations. Especially in long cores, the clamping arrangement may include some provision to compensate for compacting of the core after initial assembly.

The armature windings are fitted tightly in the slots and secured radially by wedges driven into suitable notches at the air gap end of the slots. It is necessary that the stator coil ends be able to resist the abnormal forces associated with short circuits. A supporting structure may be employed for this purpose. There are many variations of support design; most of them provide filler blocks between the coil sides, strategically located to transmit the circumferential forces from coil to coil, and additional structure to counteract the radial forces.

Coil supports ordinarily are designed to suit the need of a particular machine. Large 2-pole machines require a quite elaborate structure; the combination of large short-circuit currents and coil ends inherently flexible because of their long length makes these machines particularly susceptible to coil-end movement. Low-speed machines with stiffer coil ends require less support; in the smallest ratings the coils may be capable of withstanding the short-circuit sources without any additional support.

Stator frames, sometimes called casings, are commonly fabricated from structural steel, designed to support the core in alignment with the rotor and to suit the ventilating scheme used. In large machines with 2-pole or sometimes 4-pole construction, the stator core is mounted on springs to isolate core vibration from the machine frame.

7.7.2 Rotor Construction

The pole pieces of salient-pole alternators may be built up of steel laminations, both as manufacturing convenience and a means of limiting the loss in their air gap surfaces due to pulsations in air gap flux. The field coils, wound directly on the poles or preformed and then mounted on the poles, are suitably insulated from the poles for the voltages associated with normal and transient operation. The pole-and-coil assembly is bolted, dovetailed, or otherwise attached to the rotor body. It is the limitation of this attachment which usually dictates when round-rotor construction must be used rather than salient-pole construction.

The rotor body for a salient-pole machine may be a solid forging or assembly of heavy steel plates, for high-speed designs, or a spider-and-rim assembly for low-speed designs. The shaft may be integral with the body, as in the case of a forging, or may be bolted to or inserted into the body.

When the spider-and-rim construction is used, the entire assembly may be an integral weldment or casting, or the rim may be separate from the spider, as in the case of large waterwheel-driven generators. A common construction for this latter case is a rim built up of thin steel laminations, assembled around a cast or fabricated spider, bolted together between steel end plates and keyed to the spider.

The rotor of a round-rotor machine is cylindrical in shape with axial slots provided in its body for the field coils. The body is usually a steel forging with integral shaft ends. In special applications, other constructions may be used, with this same general configuration. The field coils are wound in axial slots in the rotor body, held in place by heavy slot wedges and by retaining rings over the coil ends.

Rotors are designed for operation at overspeeds, which depend on the characteristics of the prime mover. The overspeed limit (the speed above which the unit is no longer capable of safe operation) may be as low as 20% for a steam-turbine-driven unit or as high as 125% for some adjustable-blade, axial-flow hydraulic turbine-driven units.

7.7.3 Critical Speeds

The shaft system of the entire unit (generator plus prime mover) must be designed with regard to critical speeds. Both lateral and torsional critical speeds are considered. *Lateral critical speed* is the speed corresponding to the natural frequency of the shaft system in response to lateral or transverse forces such as residual unbalance forces. *Torsional critical speed* relates to the response of the shaft system to torsional forces. The lateral critical speed is associated with each mode of lateral vibration, the first critical speed corresponding to the lowest-frequency mode. Critical speeds are affected by shaft support, including foundation (particularly lateral critical speeds), and by internal and external damping.

It is preferable that the operating speed be at least 10% away from the nearest critical speed. Low-speed rotors ordinarily operate below the first critical speed. High-speed rotors, especially 2- and 4-pole turbogenerator rotors, usually operate above the first critical speed and sometimes above the second or even third critical speed. Multiplane balances are required for such rotors, and carefully planned speed profiles on start-up are required to avoid excessive stresses.

Torsional critical speeds are excited by external forces such as sudden load change, or a short circuit or other system disturbance, or cyclic variations in prime mover torque, such as from an internal combustion engine. Impulses from the buckets of a hydraulic turbine or from the gear teeth in a unit driven through the gear may also excite torsional vibrations.

It is possible that some components of a shaft system may have resonant frequencies, which are close to those that might be excited in operation. For example, long, last-stage turbine buckets might have a resonance at nearly twice the operating frequency, and that frequency is likely to be excited by negative-sequence currents. Care is required in selecting all components of the shaft system.

7.7.4 Bearings

Although, antifriction bearings are occasionally used on alternators of smaller ratings, the great majority are furnished with oil-lubricated babbitted bearings. For horizontal shafts at small ratings ring-oiled bearings are used, but at higher ratings recirculation of externally cooled oil is used.

Two principal types of thrust bearings are used on vertical alternators: the pivoted-shoe type and the spring type. The adjustable *pivoted-shoe* type, introduced in the United States by Albert Kingsbury, consists of a flat rotating collar or runner of steel or fine-grained cast iron resting on a stationary member consisting of several babbitted segmental shoes pivoted near their center on adjusting screws, which, by changing the elevation of the shoes, can provide equal loading on each. The screws also permit small adjustments in rotor elevation to correct generator and turbine clearances.

The bearings are immersed in oil. In operation, a thin, wedge-shaped film of oil is formed between the runner and the shoe. The oil is continuously circulated by the rotation of the runner and is cooled by either radiation or water cooling, usually within the oil bath but occasionally by an external system. Some of the larger bearings are cooled by means of water circulate through tubes embedded below the babbitt surface.

The *spring*-type bearing is inherently self-equalizing; that is, each shoe carries very nearly the same amount of load. A variation of the pivoted-shoe bearing, in which the shoes are supported on a system of interconnected levers, provides the same self-equalizing feature.

The *spherical bearing* is another variation of the pivoted-shoe thrust bearing, in which the runner is part of a sphere and the shoes of corresponding shape. This type of bearing restrains lateral movement of the shaft, serving the dual function of thrust and guide bearing.

Horizontal-shaft alternators occasionally require thrust bearing, as, for example, a single-impeller reaction turbine having unbalanced hydraulic thrust which must be restrained by the bearing. Thrust bearing designs for this application are generally of the pivoted-shoe type, either adjustable or equalizing.

Some thrust bearings, particularly of the adjustable pivoted-shoe type, may be provided with load cells for measuring and equalizing the thrust on the shoes. These may be of the hydraulic or strain-gage type, the latter is more common in modern applications. In addition to providing a check on the adjustment of the shoe loadings, these devices provide information about the hydraulic thrust characteristics of the turbine.

Guide bearings for vertical alternators are oil-lubricated babbitted rings. These are frequently segmented to facilitate assembly and may be composed of individual shoes which are radially adjustable. Guide bearings usually are partly immersed in an oil bath with oil circulated by the pumping action of sloping grooves in the babbitt surface. Occasionally, a separate lubrication system is provided which introduces oil at the top clearance of the bearing, collects it at the bottom, and recirculates it. It is common practice to place a guide bearing closely above the thrust bearing in the same oil pot. In some instances a guide bearing is on the outer periphery of the thrust runner.

Bearing Arrangements. Vertical alternators are classified by their bearing arrangement. In *suspended unit* the thrust bearing is located above the rotor and is provided with two guide bearings, one above the rotor and one below. The upper guide bearing is frequently placed just above and in the same oil pot as the thrust bearing. In "umbrella" unit, the thrust bearing is located below the rotor and one guide bearing also below the rotor, usually in the same oil pot and just above the thrust bearing. When umbrella arrangements are used, careful consideration must be given to the stability of the unit with respect to overturning moments. Large diameter, slow-speed units, in which the ratio of rotor diameter to the height of rotor center of gravity above the thrust surface is relatively large, lend themselves to umbrella construction. A principal advantage of umbrella construction is a substantial reduction in required powerhouse headroom, since the relatively high bearing support structure is below the rotor in the turbine pit. Furthermore, this structure itself usually spans a shorter distance when placed below the rotor and is not so high because of this, and shaft length may be reduced. A modified umbrella arrangement, having a guide bearing above the rotor, may be used when mechanical stability precludes classic umbrella construction. This retains some of the advantage of reduction in headroom requirement. The thrust bearing may be supported from the turbine head cover to achieve a more compact arrangement.

High-Pressure Lubrication. Horizontal journal bearings and thrust bearings are often provided with high-pressure oil ("jacking oil") to reduce starting torque and minimize bearing wear on start-up. Oil at pressures on the order of 10 MPa is introduced at the bottom of the journal bearing or at the center of each shoe or segment of a thrust bearing to lift the rotor and introduce an oil film in the bearing clearance before the shaft rotates.

Steam turbine generator units frequently are operated at very low speeds when they are disconnected from the system to prevent the shaft system from sagging while cooling or while at standstill for extended periods. This "turning gear" operation may be at 5 to about 50 r/min much below the speed at which the bearing would maintain an oil film. Jacking oil is usually used during this operation.

7.8 LOSSES AND EFFICIENCY

Efficiency of a generator is defined as

$$\eta = \frac{P_{\text{out}}}{P_{\text{in}}} \cong 1 - \frac{P_{\text{dissipation}}}{P_{\text{out}}} \tag{7-49}$$

Windage and friction includes loss from the bearings, shearing of the air or hydrogen at the rotor surface, mechanical work done on the air or hydrogen that flows through the rotor, and power expended by the cooling fans. This loss is generally not a function of operating point, but it does vary with the pressure of the cooling gas inside the generator. Provided that the cooling gas pressure is kept constant, this loss is usually considered to be independent of load.

Core loss is caused by hysteresis and eddy currents in the core laminations. It also includes losses induced in structural parts of the machine that are exposed to stray alternating magnetic flux at no-load conditions. Core loss is a function only of terminal voltage, and it is usually considered to be independent of load.

Field loss is ohmic loss caused by field current flowing in the field winding. This loss depends on both the field current and the temperature of the field winding. It thus varies with load.

Armature loss is ohmic loss caused by armature current flowing in the armature winding. This loss is defined by the square of the armature current multiplied by the dc resistance of the armature winding, corrected for temperature. This loss varies with load.

Stray load loss explains sources of loss not adequately covered by the other categories. It includes eddy current loss in the armature and losses in structural elements exposed to magnetic fields arising from armature current and to those parts of the rotor surface affected by armature leakage fields. Stray loss is generally proportional to the square of armature current and may, with only small error, be expressed as a fraction of armature transport loss.

7.9 TESTING OF AC GENERATORS

Tests are performed on generators to establish conformance with projected performance and dynamic performance parameters. Details of such tests are contained in IEEE Standard 115, IEC 60034-2 and IEC 60034-4 standards.

7.9.1 Resistance

Field and armature resistances are typically small, so measurements should be made using a 4-wire technique. It is important that resistance be measured at a known temperature so that correction can be made to actual operating temperature.

7.9.2 Open-Circuit Saturation Curve

The generator is driven by a motor to rated speed and excitation varied to produce terminal voltage over a range, typically from perhaps 30% to 120% that of rated. Some caution is required here, particularly for large machines in which excessive flux can damage the core. Open-circuit losses may be established by this test if the drive motor is well characterized and input power is measured.

7.9.3 Short-Circuit Saturation Curve

This test is similar to the open-circuit test, except the armature terminals are short-circuited and excitation varied to produce armature current over some convenient range. Windage and friction losses may be inferred from power input at zero excitation. Stray load loss may be estimated as the difference between input power at rated armature current and the sum of friction and windage and armature I^2R.

7.9.4 Zero Power Factor Saturation Curve

For a relatively small generator, the zero power factor saturation curve can be determined by running the machine with its shaft unloaded, driven by a second generator.

By adjusting the excitation on the ac generator under test and excitation on the second generator, it is possible to measure the zero power factor saturation curve.

Rather extensive discussion of this method is described in IEEE 115. For large generators for which this "back-to-back" method is not practical, the zero power factor curve is usually determined by numerical methods. Often those methods employ finite elements.

7.9.5 Deceleration

Deceleration may be used for determining losses if the inertia of the machine is known. Since, if the shaft of a machine is unloaded, power dissipated is

$$P_w = \omega_m J \frac{d\omega_m}{dt} = \frac{d}{dt}\left\{\frac{1}{2} J\omega_m^2\right\} \tag{7-50}$$

where ω_m is mechanical speed, deceleration through synchronous speed can give a good measure of dissipation. The test may be run with the machine operating either at open-circuit or short-circuit conditions, or at zero excitation. It is usually run from a slight overspeed. This test can be used to determine an unknown inertia from known losses and observed deceleration.

7.9.6 Heat Runs

These are tests performed by operating the generator at some condition until the temperature stabilizes. Heat runs at open-circuit, short-circuit, and zero power factor may be combined to estimate temperature rise in actual operation. In large machines, good estimates of dissipation may be made by measuring the temperature rise of coolant (e.g., water). This is an alternative or supplement to measuring input power to the drive motor or machine deceleration. ω_m

7.10 COOLING

Dissipation in generators appears as heat which must be removed. This heat appears in the armature conductors, field-winding conductors, stator core, rotor surface, and other structural elements of the machine. Cooling of armature and field conductors may be direct or indirect; the difference is direct contact of the cooling medium with the conductor or contact through electrical insulation.

7.10.1 Cooling Media

Alternating-current generators may be cooled by air, hydrogen, water, or (very infrequently) oil. In large machines, no matter what the cooling medium, heat is transferred to water in heat exchangers that are located within the machine case.

Smaller machines are cooled by air. Recently, there has been a trend toward air-cooling larger machines. The upper limit in size for air-cooled machines is, as of this writing, about 350 MVA, and may increase further. The advantage of air cooling is simplicity. The disadvantage is machine size.

Hydrogen has had wide application in cooling of larger generators. It has a high specific heat and thermal conductivity and low density, so it provides better heat transfer with lower windage losses than does air. Hydrogen also does not support oxidation, with some advantage to insulation systems. Cooling a generator with hydrogen requires additional systems to maintain hydrogen purity and to remove hydrogen from lubricating oil and shaft seals. Since the "explosive" range of hydrogen/oxygen mixtures is about 5% to 75% hydrogen, if the purity of hydrogen is kept above about 95%, the cooling medium will be nonexplosive.

Water is used in armature winding cooling in very large machines.

7.10.2 Ventilation Paths

Fans used in electric machines may be of either radial flow or axial flow, and a wide variety of cooling paths are used. Figures 7-22 and 7-23 show two possible schemes.

7.10.3 Stator-Core Ventilation

The stator core is usually gas (air or hydrogen)-cooled. Axial passages through the core may be formed by punching holes in the laminations. Radial passages are formed by spacers that hold the core packets apart. Radial passages might be about 1 cm in axial length with spacing of about 5 cm.

In some cases, as shown in Fig. 7-22, axial and radial cooling passages are mixed in one machine. In some cases, the ventilating gas passes first radially inward and then radially outward.

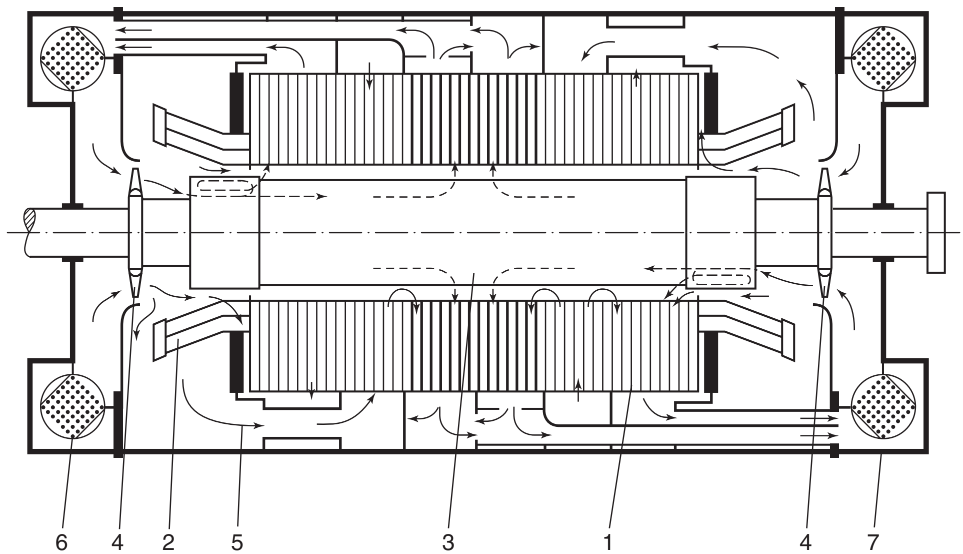

FIGURE 7-22 Cooling system, gas only. (1) stator core; (2) indirect-cooled stator winding; (3) rotor body; (4) axial-flow fans; (5) gas flow; (6) hydrogen cooler; (7) stator housing. (*ABB*.)

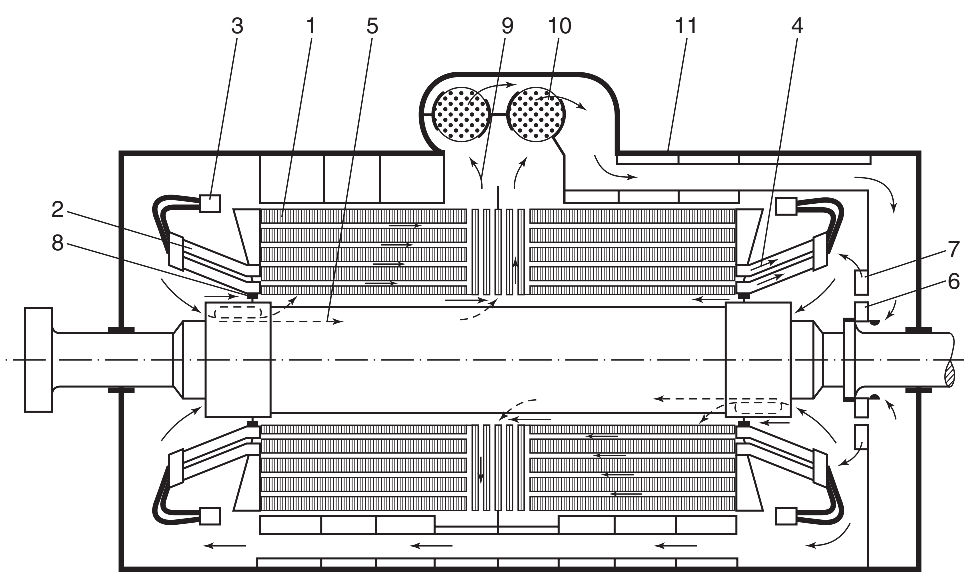

FIGURE 7-23 Cooling system, combination of gas and water. (1) stator core; (f2) water-cooled stator winding; (3) water manifold; (S45) water flow; (5) rotor body; (6) radial-flow fan; (7) diffuser; (8) air gap baffle; (9) gas flow; (10) hydrogen cooler; (11) stator housing. (*ABB*.)

7.10.4 Rotor Ventilation

As with the stator core, rotor cooling takes on a variety of forms. In some cases cooling gas passes axially from the ends of the rotor and then exits through holes in the rotor surface into the air gap, and then passes through the stator core. In other cases, gas passes radially inward from the air gap, diagonally through the rotor, and then radially outward to the air gap. This scheme can be coordinated with cooling of the stator core.

7.10.5 Direct and Indirect Cooling

Direct cooling, the norm for rotor windings and widely used in stator windings, exposes the cooling medium directly to the conductors. Figure 7-24 shows hydrogen and water directly cooled conductors for both stator and rotor.

In a directly gas-cooled stator, relatively large passages are built into the conductor bar. The conductor strands are transposed around the gas passages. There is strand insulation between the conductor strands and gas passage (which is often made of stainless steel), but the gas is within the ground wall. In a directly gas-cooled rotor the gas flow may be radial, axial, or diagonal, or some combination of all three.

In a directly water-cooled stator winding, the water flow may be in direct contact with the conductors. In some cases some or all of the conducting strands are made of hollow copper tubing. In others, stainless-steel tubes are used. Typically, water flows through the machine only one or two axial passes before being returned to the cooler. If water cooling is used, then

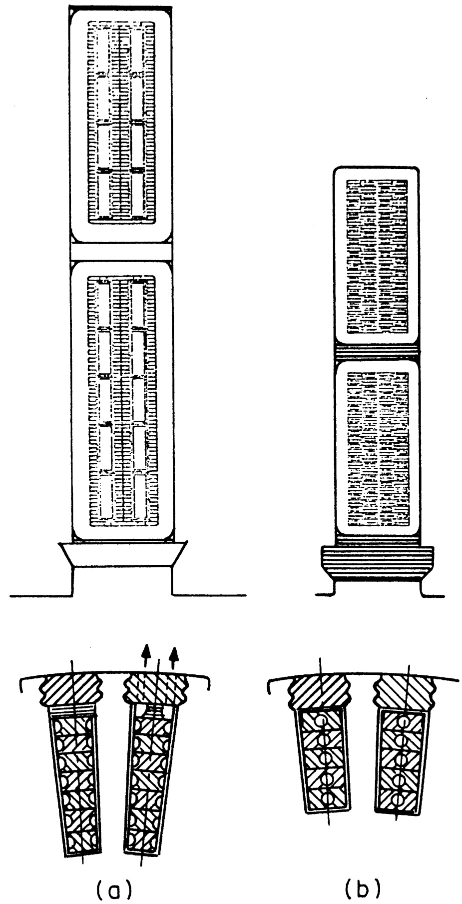

FIGURE 7-24 Directly cooled conductors; (*a*) hydrogen; (*b*) water.

1. The water is maintained at very high purity so that it has low conductivity.
2. Water is carried to the armature conductors through specially made hoses, since the conductor bars are at high potential and the water header is at ground.
3. Generally, hydrogen pressure in the machine is maintained above water pressure so that any leak will be of hydrogen into the water system, rather than water into the electrical insulation.

Water-cooled field windings are relatively rare, although many have been in highly reliable service for decades in some of the world's most powerful nuclear turbine generators.

7.11 DYNAMIC MODELS

In applying an ac generator to power systems, it is important to understand the dynamic performance of the machine. This section describes one way of estimating the dynamic performance of a generator. There is much literature on this topic, however, and what is done here will only skim the surface of a very deep topic.

Typical among the dynamic issues are levels of fault current, transient stability limits, responsiveness to excitation control, and damping of transient swings.

7.11.1 Per Unit System

Voltages, currents, and impedances are often expressed as *per unit* values, that is, a base for each quantity is assumed and every ordinary variable is compared with that base. Thus, when a machine is operating at its rated condition, both voltage and current magnitude could be said to be "one per unit." Multiplying voltage and current yields power, while dividing voltage by current yields impedance magnitude, so these can be expressed in per unit terms as well. The general form of the per unit (pu) is shown in Eq. 7-51.

$$pu = \frac{\text{actual}}{\text{base}} \tag{7-51}$$

Generally, the base apparent power or total power (S_{base}) and the base voltage (V_{base}) are specified; all other base values are determined from these two.

The use of per unit quantities has a number of advantages in analysis of electric machines. Not the least of these is that the use of the per unit index eliminates the need to refer to peak or rms, line neutral or line ground. In this development, all voltages, currents, fluxes, powers, and torques will be expressed in per unit. Time will not, however, be normalized, so rotational speed is measured in radians per second and time constants, in seconds.

7.11.2 Represented Circuits

Typical electrical models of electric machines represent the relationship between voltage and current in the various windings of the machine. Thus, the three phase windings and the field winding are represented. Important dynamics, however, arise from currents in elements of the rotor surface, the rotor body or amortisseur or damper bars, or some combination of all of these factors. These are typically represented by equivalent windings, too. For the purpose of this discussion, only one additional winding (referred to here as the "damper") will be included for each axis of the rotor.

The analysis begins with normalized variables referred to as the *direct* and *quadrature axes* of the machine. The per unit fluxes are

$$\begin{bmatrix} \psi_d \\ \psi_{kd} \\ \psi_f \end{bmatrix} = \begin{bmatrix} x_d & x_{ad} & x_{ad} \\ x_{ad} & x_{kd} & x_{fd} \\ x_{ad} & x_{fd} & x_f \end{bmatrix} \begin{bmatrix} i_d \\ i_{kd} \\ i_f \end{bmatrix} \tag{7-52}$$

$$\begin{bmatrix} \psi_d \\ \psi_{kd} \end{bmatrix} = \begin{bmatrix} x_q & x_{ad} \\ x_{aq} & x_{kd} \end{bmatrix} \begin{bmatrix} i_q \\ i_{kd} \end{bmatrix} \tag{7-53}$$

where the variables ψ represent per unit fluxes and i represents per unit currents. Subscripts d and q represent the direct and quadrature axes, respectively, while the subscripts a, k, and f represent the armature, damper, and field. There are only two armature variables here, where, strictly speaking, a third would be required. Ordinarily, the "zero" axis variable can be ignored as generators are usually connected so that no current can flow in that winding.

7.11.3 Equivalent Circuits

The equivalent circuits shown in Fig. 7-25 represent the same flux-current relationship as do Eqs. (7-52) and (7-53), with winding resistances added if

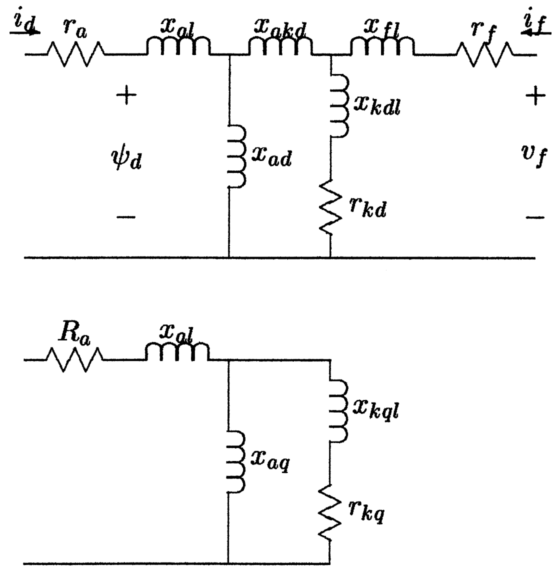

FIGURE 7-25 Direct and quadrature-axis equivalent circuits.

$$x_d = x_{al} + x_{ad} \tag{7-54}$$

$$x_{fd} = x_{ad} + x_{akd} \tag{7-55}$$

$$x_{kd} = x_{fd} + x_{kdl} \tag{7-56}$$

$$x_f = x_{fd} + x_{fl} \tag{7-57}$$

$$x_q = x_{al} + x_{aq} \tag{7-58}$$

$$x_{kq} = x_{kql} + x_{aq} \tag{7-59}$$

The interesting dynamics of the rotor can be now described by these two equivalent circuits.

7.11.4 Parameters

The various reactance and resistance parameters of the equivalent circuits of Fig. 7-25 may be calculated from first principles or may be measured by several different techniques. For example, IEEE Standard 115 describes a frequency response technique for measuring these parameters. Note that the parameter x_{al} appears in both direct- and quadrature axes. For this reason an apparently superfluous variable, x_{akd}, is used on the direct axis to allow an extra degree of freedom for an adequate "fit" between measurements and the equivalent circuit.

The equivalent circuits of Fig. 7-25 are only approximations to the actual performance of ac generators. In some cases it will be necessary to use higher-order models. Generally these are represented by multiples of the damper winding with different magnitudes and time constants. These are beyond the scope of this discussion.

7.11.5 Voltages

Voltages are produced by time variations of fluxes and by rotation of the machine. Translated into per unit measurement the voltages are

$$v_d = \frac{1}{\omega_0}\frac{d\psi_d}{dt} - \frac{\omega}{\omega_0}\psi_q + r_a i_d \tag{7-60}$$

$$v_q = \frac{\omega}{\omega_0}\psi_d + \frac{1}{\omega_0}\frac{d\psi_q}{dt} + r_a i_q \tag{7-61}$$

$$v_f = \frac{1}{\omega_0}\frac{d\omega_f}{dt} + r_f i_f \tag{7-62 }$$

$$v_{kd} = \frac{1}{\omega_0}\frac{d\psi_{kd}}{dt} + r_{kd} i_{kd} \tag{7-63}$$

$$v_{kq} = \frac{1}{\omega_0}\frac{d\psi_{kq}}{dt} + r_{kq} i_{kq} \tag{7-64}$$

$$v_0 = \frac{1}{\omega_0}\frac{d\psi_0}{dt} + r_a i_0 \tag{7-65}$$

7.11.6 Simulation Model

These expressions may be turned into a concise simulation model, suitable for use in modern computing apparatus for estimating performance of an ac generator. This is simply done by isolating the first-order time derivatives.

The state variables are the two stator fluxes ψ_d, ψ_q, two "damper" fluxes ψ_{kd}, ψ_{kq}, field ψ_f, and rotor speed ω and torque angle δ. The most straightforward way of stating the model employs currents as auxiliary variables

$$\begin{bmatrix} i_d \\ i_{kd} \\ i_f \end{bmatrix} = \begin{bmatrix} x_d & x_{ad} & x_{ad} \\ x_{ad} & x_{kd} & x_{fd} \\ x_{ad} & x_{fd} & x_f \end{bmatrix}^{-1} \begin{bmatrix} \psi_d \\ \psi_{kd} \\ \psi_f \end{bmatrix} \tag{7-66}$$

$$\begin{bmatrix} i_d \\ i_{kd} \end{bmatrix} = \begin{bmatrix} x_q & x_{ad} \\ x_{aq} & x_{kd} \end{bmatrix}^{-1} \begin{bmatrix} \psi_q \\ \psi_{kd} \end{bmatrix} \tag{7-67}$$

Then the state equations are

$$\frac{d\psi_d}{dt} = \omega_0 v_d + \omega\psi_q - \omega_0 r_a i_d \tag{7-68}$$

$$\frac{d\psi_q}{dt} = \omega_0 v_q - \omega\psi_d - \omega_0 r_a i_q \tag{7-69}$$

$$\frac{d\psi_{kd}}{dt} = -\omega_0 r_{kd} i_{kd} \tag{7-70}$$

$$\frac{d\psi_{kq}}{dt} = -\omega_0 r_{kq} i_{kq} \tag{7-71}$$

$$\frac{d\psi_f}{dt} = -\omega_0 r_f i_f \tag{7-72}$$

$$\frac{d\omega}{dt} = \frac{\omega_0}{2H}(T_e + T_m) \tag{7-73}$$

$$\frac{d\delta}{dt} = \omega - \omega_0 \tag{7-74}$$

and

$$T_e = \psi_d i_q - \psi_q i_d \tag{7-75}$$

For a practical simulation, v_d, v_q, and mechanical torque T_m must be specified.

7.11.7 Approximate Analysis

It should be clear from examining the equivalent circuits of Fig. 7-25 that the behavior of the machine, meaning its flux/current relationship, is a function of the speed of any given disturbance. This leads to approximate analyses of ac generators, which recognize the frequency dependence of the rotor elements.

Synchronous reactances x_d and x_q are applicable when the rotor is moving in synchronism with the magnetomotive force (mmf) produced by the armature currents, or when the deviation in speed is very small.

Transient reactance x'_d is applicable when armature mmf is changing with time, as in electromechanical transients or "swings." This effective reactance is reduced by the tendency of (nearly) short-circuited field winding to trap or hold flux nearly constant for periods comparable to or shorter than its time constant. This reactance is

$$x'_d \approx x_{al} + x_{ad} \,\|\, (x_{fd} + x_{fl}) \tag{7-76}$$

In some types of generators there may be an identifiable transient reactance on the quadrature axis, less than the quadrature-axis synchronous reactance, but in others the applicable reactance to use for the quadrature axis in transient events is just x_q.

For transient events that occur very rapidly, such as switching events and terminal short circuits, the effective reactances are the *subtransient* reactances. These result from the tendency of the amortisseurs (or even rotor iron) to support or trap flux. They are

$$x''_d = x_{al} + x_{ad} \,\|\, (x_{akd} + x_{kdl} \,\|\, x_{fl}) \qquad x''_d = x_{al} + x_{aq} \,|\, x_{kql} \tag{7-77}$$

The foregoing reactances are applicable when the armature mmf and rotor are rotating in synchronism or nearly so. The *negative-sequence* reactance x_2 is applicable with an armature mmf rotating backward at synchronous speed while the rotor is rotating forward. Negative-sequence currents arise from certain types of unbalanced operation. The negative-sequence reactance is approximately the average of subtransient reactances

$$x_2 = {}^1\!/_2(x''_d + x'_q) \tag{7-78}$$

Zero-sequence reactance is applicable to situations in which all 3 phases of the armature have identical currents such as would arise from a ground fault. Such currents do not produce substantial air-gap flux, and even some of the components of armature leakage are reduced, so the zero-sequence inductance is quite small.

7.11.8 Static and Transient Torque-Angle Curves

Torque-angle curves for operation of a synchronous generator may be written for both the synchronous and transient mode of operation. In per-unit these, torque-angle curves are for the steady state case

$$t_e = \frac{e_{af}}{x_d}\sin\delta + \left(\frac{1}{x_q} - \frac{1}{x_d}\right)\sin 2\delta \tag{7-79}$$

and for the transient case

$$t_e = \frac{e'_q}{x'_d}\sin\delta + \left(\frac{1}{x_q} - \frac{1}{x'_d}\right)\sin 2\delta \tag{7-80}$$

where δ is the torque angle, e_{af} is the internal voltage, and e'_q is the *voltage behind transient reactance*, and the terminal voltage is one per unit.

7.11.9 Stability by Equal Area

The relationship between power, which is directly proportional to torque, and displacement (power) angle is shown in Fig. 7-26. Note that the torque-angle curve for transient operation has a higher peak torque, although the two curves coincide at the steady-state operating point.

Disturbances from steady-state operation due to changes in prime mover torque, load changes, or faults cause load angle to change, usually with dynamic swings as described in this section. Generally, the most serious transient swing results from complete loss of load as from a nearby short-circuit. Under such a circumstance the generator, under the influence of prime mover torque, accelerates. The torque angle increases quadratically with time. Even after the power output is restored, the machine will swing forward until load torque stops its advance. A simple approximate way of estimating the maximum angle achieved is to use the *equal-area* criterion. The area of a disturbance is related to energy contributed to rotation, and for every (stable) situation the positive and negative areas must balance.

Pictured in Fig. 7-26 is a "critical" swing. The area underneath the prime mover torque curve from δ_0 to δ_c is the area that would be contributed if all load torque were zero during a period of acceleration between those two angles. If the area *above* the prime-mover torque between δ_c and δ_f is equal to or greater than this first area, the machine will regain synchronous operation. This establishes a *critical angle*. In turn, the *critical clearing time* t_c is established by

$$\delta_c - \delta_0 = \frac{1}{2}\frac{\omega_0}{2H}t_c^2 \tag{7-81}$$

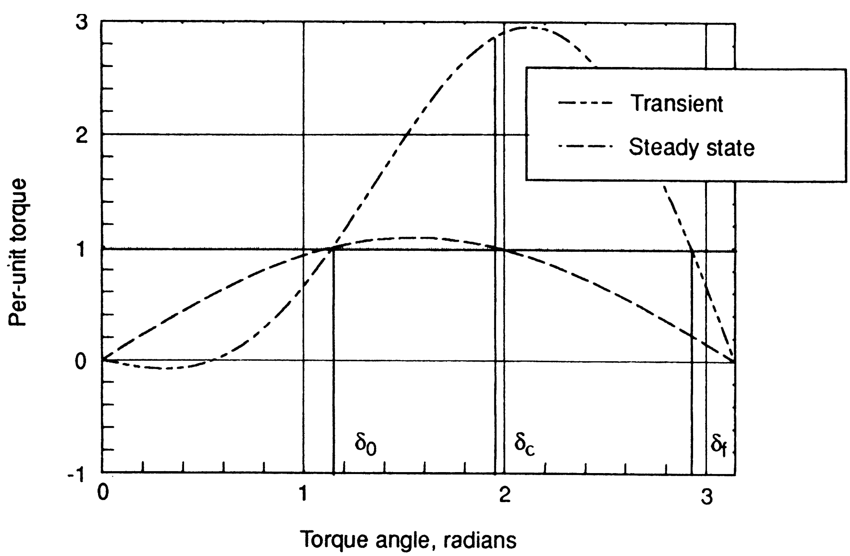

FIGURE 7-26 Torque-angle curves, steady state and transient.

7.11.10 Faults

If an ac generator is operated open-circuited at rated terminal voltage and then its terminals are suddenly short-circuited, the following currents flow in the terminal leads:

$$i_a = \left\{ \frac{e_{af}}{x_d} + \left(\frac{e_{af}}{x'_d} - \frac{e_{af}}{x_d}\right) e^{-(t/T'_d)} + \left(\frac{e_{af}}{x''_d} - \frac{e_{af}}{x''_d}\right) e^{-(t/T''_d)} \right\} \cos(\omega t - \theta_0) - \frac{e_{af}}{x''_d} \cos\theta_0 e^{-(t/Ta)}$$

$$i_b = \left\{ \frac{e_{af}}{x_d} + \left(\frac{e_{af}}{x'_d} - \frac{e_{af}}{x_d}\right) e^{-(t/T'_d)} + \left(\frac{e_{af}}{x''_d} - \frac{e_{af}}{x'_d}\right) e^{-(t/T''_d)} \right\} \cos\left(\omega t - \theta_0 - \frac{2\pi}{3}\right) - \frac{e_{af}}{x''_d} \cos\left(\theta_0 - \frac{2\pi}{3} e^{-(t/T_a)}\right)$$

$$i_c = \left\{ \frac{e_{af}}{x_d} + \left(\frac{e_{af}}{x'_d} - \frac{e_{af}}{x_d}\right) e^{-(t/T'_d)} + \left(\frac{e_{af}}{x''_d} - \frac{e_{af}}{x'_d}\right) e^{-(t/T''_d)} \right\} \cos\left(\omega t - \theta_0 + \frac{2\pi}{3}\right) - \frac{e_{af}}{x''_d} \cos\left(\theta_0 - \frac{2\pi}{3} e^{-(t/T_a)}\right)$$

These currents are shown in Fig. 7-27.

DIRECT-CURRENT GENERATORS

8.1 THE DC MACHINE

Applications. The most important role played by the dc generator is the power supply for the important dc motor. It supplies essentially ripple-free power and precisely held voltage at any desired value from zero to rated. This is truly dc power, and it permits the best possible commutation on the motor because it is free of the severe waveshapes of dc power from rectifiers. It has excellent response and is particularly suitable for precise output control by feedback control regulators. It is also well suited for supplying accurately controlled and responsive excitation power for both ac and dc machines.

The dc motor plays an ever-increasing vital part in modern industry, because it can operate at and maintain accurately any speed from zero to its top rating. For example, high-speed multistand steel mills for thin steel would not be possible without dc motors. Each stand must be held precisely at an exact speed which is higher than that of the preceding stand to suit the reduction in thickness of the steel in that stand and to maintain the proper tension in the steel between stands.

General Construction. Figure 8-1 shows the parts of a medium or large dc generator. All sizes differ from ac machines in having a commutator and the armature on the rotor. They also have salient poles on the stator, and, except for a few small ones, they have commutating poles between the main poles.

Former contributors include Thomas W. Nehl and E. H. Myers.

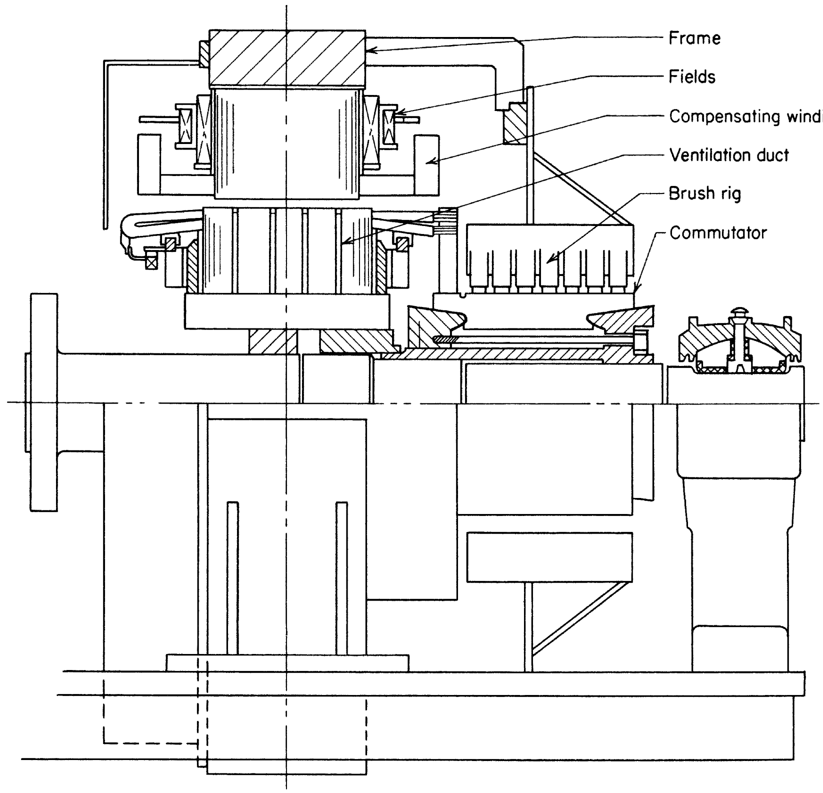

FIGURE 8-1 The dc machine.

Construction and Size. Small dc machines have large surface-to-volume ratios and short paths for heat to reach dissipating surfaces. Cooling requires little more than means to blow air over the rotor and between the poles. Rotor punchings are mounted solidly on the shaft, with no air passages through them.

Larger units, with longer, deeper cores, use the same construction, but with longitudinal holes through the core punchings for cooling air.

Medium and large machines must have large heat-dissipation surfaces and effectively placed cooling air, or "hot spots" will develop. Their core punchings are mounted on arms to permit large volumes of cool air to reach the many core ventilation ducts and also the ventilation spaces between the coil end extensions.

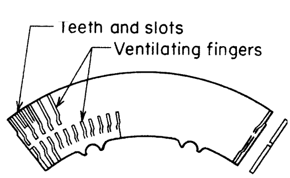

FIGURE 8-2 Armature segment for a dc generator showing vent fingers applied.

Design Components. Armature-core punchings are usually of high-permeability electrical sheet steel, 0.017 to 0.025 in thick, and have an insulating film between them. Small and medium units use "doughnut" circular punchings, but large units, above about 45 inches in diameter, use segmental punchings shaped as shown in Fig. 8-2, which also shows the fingers used to form the ventilating ducts.

Main- and commutating-pole punchings are usually thicker than rotor punchings because only the pole faces are subjected to high-frequency flux changes. These range from 0.062 to 0.125 in thick, and they are normally riveted.

The frame yoke is usually made from rolled mild steel plate, but, on high-demand large generators for rapidly changing loads, laminations may be used. The solid frame has a magnetic time constant of ½ s or more, depending on the frame thickness. The laminated frame ranges from 0.05 to 0.005 s.

The commutator is truly the heart of the dc machine. It must operate with temperature variations of at least 55°C and with peripheral speeds that may reach 7000 ft/min. Yet it must remain smooth concentrically within 0.002 to 0.003 in and true, bar to bar, within about 0.0001 in.

The commutator is made up of hard copper bars drawn accurately in a wedge shape. These are separated from each other by mica plate segments, whose thicknesses must be held accurately for nearly perfect indexing of the bars and for no skew. This thickness is 0.020 to 0.050 in, depending on the size of the generator and on the maximum voltage that can be expected between bars during operation. The mica segments and bars are clamped between two metal V-rings and insulated from them by cones of mica. On very high speed commutators of about 10,000 ft/min, shrink rings of steel are used to hold the bars. Mica is used under the rings.

Carbon brushes ride on the commutator bars and carry the load current from the rotor coils to the external circuit. The brush holders hold the brushes against the commutator surface by springs to maintain a fairly constant pressure and smooth riding.

8.2 GENERAL PRINCIPLES

Electromagnetic Induction. A magnetic field is represented by continuous lines of flux considered to emerge from a north pole and to enter a south pole. When the number of such lines linked by a coil is changed (Fig. 8-3), a voltage is induced in the coil equal to 1 V for a change of 10^8 linkages/s (Mx/s) for each turn of the coil, or $E = (\Delta\phi T \times 10^{-8})/t$ V.

If the flux lines are deformed by the motion of the coil conductor before they are broken, the direction of the induced voltage is considered to be into the conductor if the arrows for the distorted flux are shown to be pointing clockwise and outward if counterclockwise. This is generator action (Fig. 8-4).

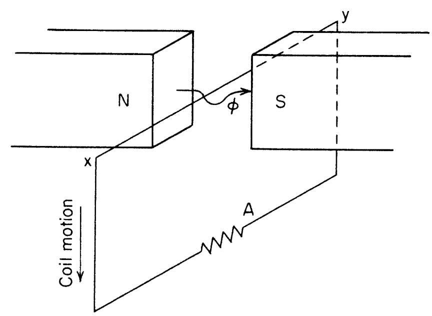

FIGURE 8-3 Generated emf by coil movement in a magnetic field.

Force on Current-Carrying Conductors in a Magnetic Field. If a conductor carries current, loops of flux are produced around it (Fig. 8-5). The direction of the flux is clockwise if the current flows away from the viewer into the conductor, and counterclockwise if the current in the conductor flows toward the viewer.

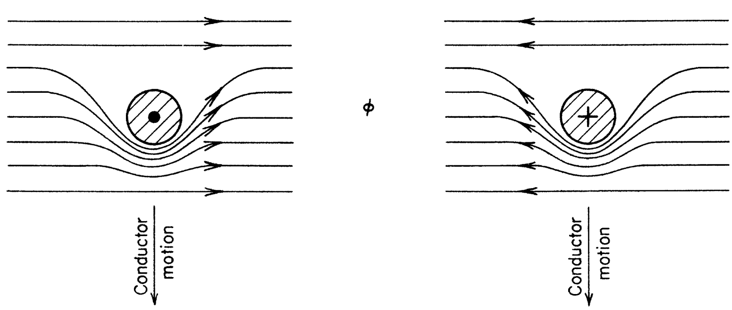

FIGURE 8-4 Direction of induced emf by conductor movement in a magnetic field.

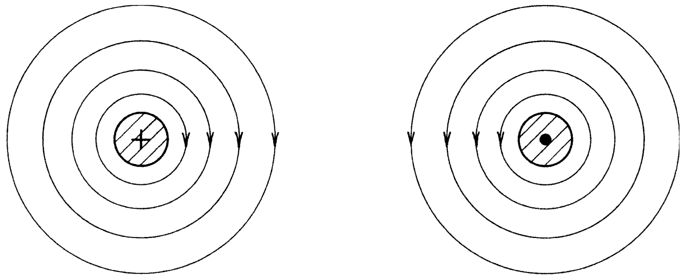

FIGURE 8-5 Magnetic fields caused by current-carrying conductors.

If this conductor is in a magnetic field, the combination of the flux of the field and the flux produced by the conductor may be considered to cause a flux concentration on the side of the conductor, where the two fluxes are additive and a diminution on the side where they oppose. A force on the conductor results that tends to move it toward the side with reduced flux (Fig. 8-6). This is motor action.

Generator and Motor Reactions. It is evident that a dc generator will have its useful voltage induced by the reactions described above, and an external driving means must be supplied to rotate the armature so that the conductor loops will move through the flux lines from the stationary poles. However, these conductors must carry current for the generator to be useful, and this will cause retarding forces on them. The prime mover must overcome these forces.

In the case of the dc motor, the conductor loops will move through the flux, and voltages will be induced in them. These induced voltages are called the "counter emf," and they oppose the flow of currents which produce the forces that rotate the armature. Therefore, this emf must be overcome by an excess voltage applied to the coils by the external voltage source.

Direct-Current Features. Direct-current machines require many conductors and two or more stationary flux-producing poles to provide the needed generated voltage or the necessary torque. The direction of current flow in the armature conductors under each particular pole must always be correct for the desired results (Fig. 8-7). Therefore, the current in the conductors must reverse at some time while the conductors pass through the space between adjacent north and south poles.

This is accomplished by carbon brushes connected to the external circuit. The brushes make contact with the conductors by means of the commutator.

To describe commutation, the Gramme-ring armature winding (which is not used in actual machines) is shown in Fig. 8-8. All the conductors are connected in series and are wound around a steel ring. The ring provides a path for the flux from the north to the south pole. Note that only the outer portions of the conductors cut the flux as the ring rotates. Voltages are induced as shown. With no external circuit, no currents flow, because the voltages induced in the two halves are in opposition.

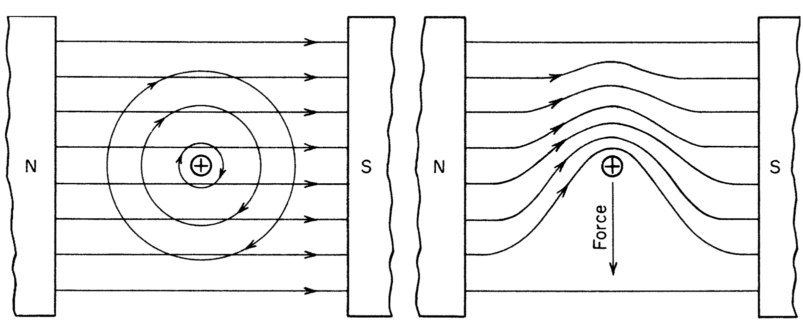

FIGURE 8-6 Force on a current-carrying conductor in a magnetic field.

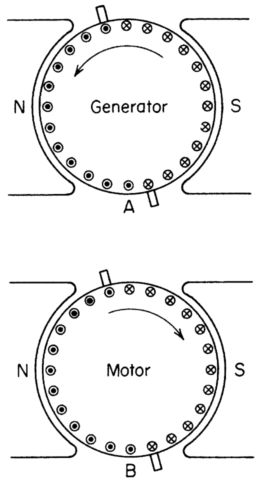

FIGURE 8-7 Direction of current in generator and motor.

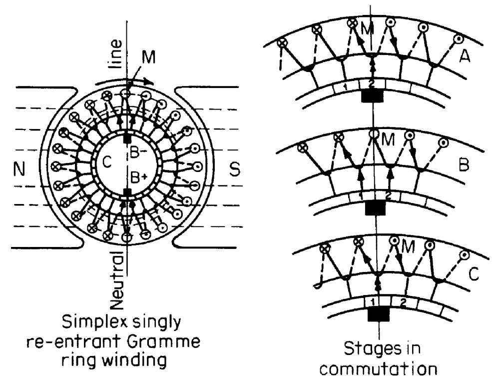

FIGURE 8-8 Principle of commutation.

However, if the coils are connected at a commutator C made up of copper blocks insulated from each other, brushes $B-$ and $B+$ may be used to connect the two halves in parallel with respect to an external circuit and currents will flow in the proper direction in the conductors beneath the poles.

As the armature rotates, the coil M passes from one side of the neutral line to the other and the direction of the current in it is shown at three successive instants at a, b, and c in Fig. 8-9. As the armature moves from a to c and the brush changes contact from segment 2 to segment 1, the current in M is automatically reversed. For a short period, the brush contacts both segments and short circuits the coil. It is important that no voltage be induced in M during that time, or the resulting circulating currents could be damaging. This accounts for the location of the brushes so that M will be at the neutral flux point between the poles.

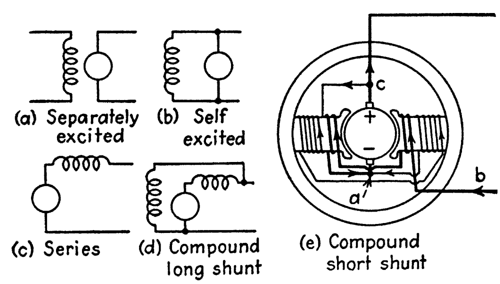

FIGURE 8-9 Methods of excitation.

Field Excitation. Because current-carrying conductors produce flux that links them as described above (in paragraphs on force on current-carrying conductors in a magnetic field), flux from the main poles is obtained by winding conductors around the pole bodies and passing current through them. This current may be supplied in different ways. When a generator supplies its own exciting current, it is "self-excited." When current is supplied from an external source, it is "separately excited." When excited by the load current of the machine, it is "series excited."

8.3 ARMATURE WINDINGS

Terms. The Gramme-ring winding is not used, because half the conductors (those on the inside of the ring) cut no flux and are wasted. Figures 8-8, 8-10, and 8-11 show such windings only because they illustrate types of connections so well.

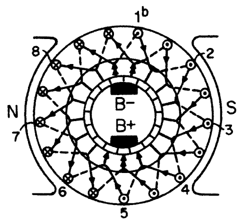

FIGURE 8-10 Singly reentrant duplex winding.

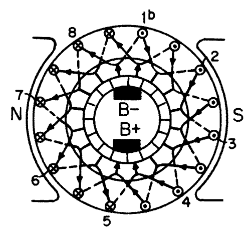

FIGURE 8-11 Doubly reentrant duplex winding.

A *singly reentrant winding* closes on itself only after including all the conductors, as shown in Figs. 8-8 and 8-10.

A *doubly reentrant winding* closes on itself after including half the conductors, as shown in Fig. 8-11.

As shown, a *simplex winding* has only two paths through the armature from each brush (Fig. 8-8). A *duplex winding* has twice as many paths from each brush and is shown in Figs. 8-10 and 8-11. Note that each brush should cover at least two commutator segments with a duplex winding, or one circuit will be disconnected at times from the external circuit. Although it is possible to use multiplex and multiple reentrant windings, they are uncommon in the United States. They are used in Europe in some large machines.

Modern dc machines have the armature coils in radial slots in the rotor. Nonmetallic wedges restrain the coils normally, but some wedgeless rotors use nonmetallic banding around the core, such as glass fibers in polyester resin. This permits shallower slots and helps to reduce commutation sparking. However, the top conductors are near the pole faces and may have high eddy losses. The coil ends outside the slots are held down on coil supports by glass polyester bands for both types.

Multiple, or Lap, Windings. Figure 8-12 shows a *lap-winding coil*. The conductors shown on the left side lie in the top side of the rotor slot. Those on the right side lie in the bottom half of another slot approximately one pole pitch away. At any instant the sides are under adjacent poles, and voltages induced in the two sides are additive. Other coil sides fill the remaining portions of the slots. The coil leads are connected to the commutator segments, and this also connects the coils to form the armature winding. This is shown in Fig. 8-13. The pole faces are slightly shorter than the rotor core.

Almost all medium and large dc machines use simplex lap windings in which the number of parallel paths in the armature winding equals the number of main poles. This permits the current per path to be low enough to allow reasonable-sized conductors in the coils.

Windings. Representations of dc windings are necessarily complicated. Figure 8-14 shows the lap winding corresponding to the Gramme-ring winding of Fig. 8-8. Unfortunately, the nonproductive end portions are emphasized in such diagrams, and the long, useful portions of the coils in the core slots are shown as radial lines. Conductors in the upper layers are shown as full lines, and those

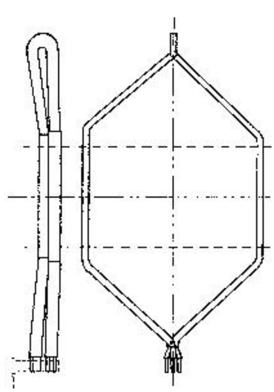

FIGURE 8-12 Coil for one-turn lap winding.

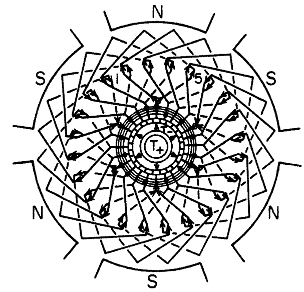

FIGURE 8-15 Simplex singly reentrant full-pitch multiple winding with equalizers.

in the lower layers as dotted lines. The inside end connections are those connected to the commutator bars. For convenience, the brushes are shown inside the commutator.

Note that both windings have the same number of useful conductors but that the Gramme-ring winding requires twice the number of actual conductors and twice the number of commutator bars.

Figure 8-15 shows a 6-pole simplex lap winding. Study of this reveals the six parallel paths between the positive and negative terminals. The three positive brushes are connected outside the machine by a copper ring $T+$ and the negative brushes by $T-$.

The two sides of a lap coil may be full pitch (exactly a pole pitch apart), but most machines use a short pitch (less than a pole pitch apart), with the coil throw one-half slot pitch less than a pole pitch. This is done to improve commutation.

Equalizers. As shown in Fig. 8-15, the parallel paths of the armature circuit lie under different poles, and any differences in flux from the poles cause different voltages to be generated in the various paths. Flux differences can be caused by unequal air gaps, by a different number of turns on the main-pole field coils, or by different reluctances in the iron circuits.

With different voltages in the paths paralleled by the brushes, currents will flow to equalize the voltages. These currents must pass through the brushes and may cause sparking, additional losses, and heating. The variation in pole flux is minimized by careful manufacture but cannot be entirely avoided.

To reduce such currents to a minimum, copper connections are used to short-circuit points on the paralleled paths that are supposed to be at the same voltage. Such points would be exactly two pole pitches apart in a lap winding. Thus in a 6-pole simplex lap winding, each point in the armature circuit will have two other points that should be at its exact potential. For these points to be accessible, the number of commutator bars and the number of slots must be a multiple of the number of poles divided by 2.

These short-circuited rings are called "equalizers." Alternating currents flow through them instead of the brushes. The direction of flow is such that the weak poles are magnetized and the strong poles are weakened. Usually, one coil in about 30% of the slots is equalized. The cross-sectional area of an equalizer is 20% to 40% that of the armature conductor.

Involute necks, or connections, to each commutator bar from conductors two pole pitches apart give 100% equalization but are troublesome because of inertia and creepage insulation problems.

Figure 8-15 shows the equalizing connections behind the commutator connections. Normally they are located at the rear coil extensions, and so they are more accessible and less subject to carbon-brush dust problems.

Two-Circuit, or Wave, Windings. Figure 8-16 shows a wave type of coil. Figure 8-17 gives a 6-pole wave winding. Study reveals that it has only two parallel paths between the positive and negative terminals. Thus, only two sets of brushes are needed. Each brush shorts $p/2$ coils in series. Because points a, b, and c are at the same potential (and, also, points d, e, and f), brushes can be placed at each of these points to allow a commutator one-third as long.

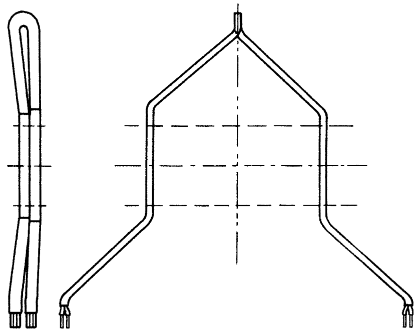

FIGURE 8-16 One-turn wave winding.

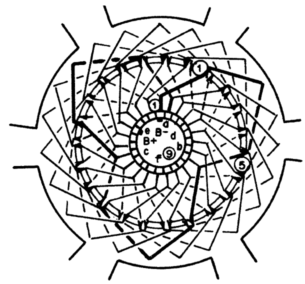

FIGURE 8-17 Two-circuit progressive winding.

The winding must progress or retrogress by one commutator bar each time it passes around the armature for it to be singly reentrant. Thus, the number of bars must equal $(kp/2) \pm 1$, where k is a whole number and p is the number of poles. The winding needs no equalizers because all conductors pass under all poles.

Although most wave windings are 2-circuit, they can be multicircuit, as 4 or 16 circuits on a 4-pole machine or 6, 12, or 24 circuits on a 12-pole machine. Multicircuit wave windings with the same number of circuits as poles can be made by using the same slot and bar combinations as on a lap winding. For example, with an 8-pole machine with 100 slots and 200 commutator bars, the bar throw for a simplex lap winding would be from bar 1 to bar 2 and then from bar 2 to bar 3, etc. For an 8-circuit wave winding, the winding must fail to close by circuits/2 bars, or 4. Thus, the throw would be bar 1 to 50, to bar 99, to bar 148, etc. The throw is (bars $\pm$ circuits/2)$(p/2)$, in this case, $(200 - 4)/4 = 49$. Theoretically such windings require no equalizers, but better results are obtained if they are used.

Since both lap and multiple wave windings can be wound in the same slot and bar combination simultaneously, this is done by making each winding of half-size conductors. This combination resembles a *frog's leg* and is called by that name. It needs no equalizers but requires more insulation space in the slots and is seldom used.

Some wave windings require *dead coils.* For instance, a large 10-pole machine may have a circle of rotor punchings made of five segments to avoid variation in reluctance as the rotor passes under the five pairs of poles. To avoid dissimilar slot arrangements in the segments, the total number of slots must be divisible by the number of segments, or 5 in this case. This requires the number of commutator bars to be also a multiple k of 5. However, the bar throw for a simplex wave winding must be an integer and equal to (bars $\pm$ 1)$(p/2)$. Obviously $(5k \pm 1)/5$ cannot meet this requirement. Consequently one coil, called a *dead coil*, will not be connected into the winding, and its ends will be taped up to insulate it completely. No bar will be provided for it, and thus the bar throw will be an integer. Dead coils should be avoided because they impair commutation.

8.4 ARMATURE REACTIONS

Cross-Magnetizing Effect. Figure 8-18*a* represents the magnetic field produced in the air gap of a 2-pole machine by the mmf of the main exciting coils, and part *b* represents the magnetic field produced by the mmf of the armature winding alone when it carries a load current. If each of the Z armature conductors carries I_c A, then the mmf between *a* and *b* is equal to ZI_c/p At. That between *c* and *d* (across the pole tips) is $\psi ZI_c/p$ At, where ψ = ratio of pole arc to pole pitch. On the assumption that all the reluctance is in the air gap, half the mmf acts at *ce* and half at *fd*, and so the cross-magnetizing effect at each pole tip is

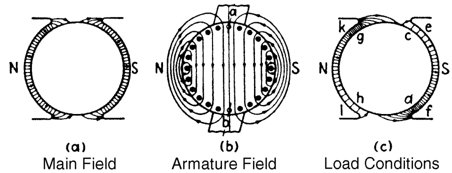

FIGURE 8-18 Flux distribution in (*a*) main field, (*b*) armature field, and (*c*) load conditions.

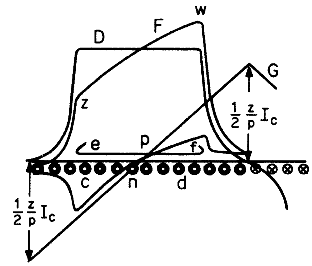

FIGURE 8-19 Flux distribution in a large machine with *p* poles.

$$\frac{\psi Z I_c}{2p} \quad \text{ampere-turns} \tag{8-1}$$

for any number of poles.

Field Distortion. Figure 8-18*c* shows the resultant magnetic field when both armature and main exciting mmfs exist together; the flux density is increased at pole tips *d* and *g* and is decreased at tips *c* and *h*.

Flux Reduction Due to Cross-Magnetization. Figure 8-19 shows part of a large machine with *p* poles. Curve *D* shows the flux distribution in the air gap due to the main exciting mmf acting alone, with flux density plotted vertically. Curve *G* shows the distribution of the armature mmf, and curve *F* shows the resultant flux distribution with both acting. Since the armature teeth are saturated at normal flux densities, the increase in density at *f* is less than the decrease at *e*, so that the total flux per pole is diminished by the cross-magnetizing effect of the armature.

Demagnetizing Effect of Brush Shift. Figure 8-20 shows the magnetic field produced by the armature mmf with the brushes shifted through an angle θ to improve commutation. The armature field is no longer at right angles to the main field but may be considered the resultant of two components, one in the direction *OY*, called the "cross-magnetizing component," and the other in the direction *OX*, which is called the "demagnetizing component" because it directly opposes the main field. Figure 8-21 gives the armature divided to show the two components, and it is seen that the demagnetizing ampere-turns per pair of poles are

$$\frac{Z I_c}{p} \times \frac{2\theta}{180} \quad \text{ampere-turns} \tag{8-2}$$

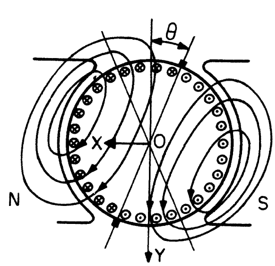

FIGURE 8-20 Demagnetizing effect.

where $2\theta/180$ is about 0.2 for small noncommutating pole machines where brush shift is used. The demagnetizing ampere-turns per pole would be

$$0.1ZI_c/p \quad \text{ampere-turns} \tag{8-3}$$

No-Load and Full-Load Saturation Curves. Curve 1 of Fig. 8-22 is the no-load saturation curve of a dc generator. When full-load current is applied, there is a decrease in useful flux, and therefore a drop in voltage *ab* due to the armature cross-magnetizing effect (see paragraph on flux reduction, above). A further voltage drop from brush shift is counterbalanced by an increase in excitation $bc = 0.1\ ZIc/p$; also a portion *cd* of the generated emf is required in overcoming the voltage drop from the current in the internal resistance of the machine. The no-load voltage of 240 V requires 8000 At. At full load at that excitation the terminal voltage drops to 220 V. To have both no-load and full-load voltages equal to 240 V, a series field of 10,700 − 8000 = 2700 At would be required.

8.5 COMMUTATION

Commutation Defined. The voltages generated in all conductors under a north pole of a dc generator are in the same direction, and those generated in the conductors under a south pole are all in the opposite direction (Fig. 8-23). Currents will flow in the same direction as induced voltages in generators and in the opposite direction in motors. Thus, as a conductor of the armature passes under a brush, its current must reverse from a given value in one direction to the same value in the opposite direction. This is called "commutation."

Conductor Current Reversal. If commutation is "perfect," the change of the current in a coil will be linear, as shown by the solid line in Fig. 8-24. Unfortunately, the conductors lie in steel slots, and self-and mutual inductances in Fig. 8-25 cause voltages in the coils short-circuited by the brushes. These result in circulating currents that tend to prevent the initial current change, delaying the reversal. In extreme cases, the delay may be as severe as indicated by the dotted line of Fig. 8-24. Because the current must be reversed by the time the coil leaves the brush (when there is no longer any path for circulating currents), the current remaining to be reversed at *F* must discharge its energy in an

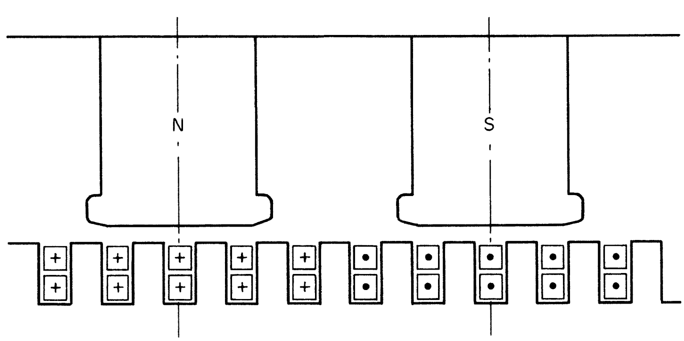

FIGURE 8-23 Conductor currents.

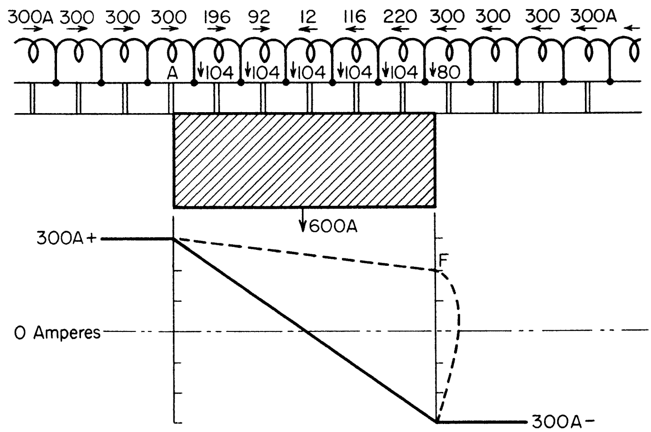

FIGURE 8-24 Commutation.

electric arc from the commutator bar to the heel of the brush. This is commutation sparking. It can burn the edges of the commutator bars and the brushes. However, most large and heavy-duty dc machines have some nondamaging sparking, and "sparkless" commutation is not required by accepted standards. However, commutation must not require undue maintenance.

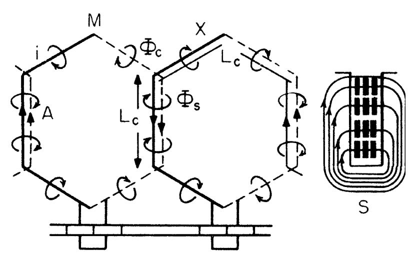

FIGURE 8-25 Magnetic field surrounding short-circuited coils.

The undesired voltages causing the circulating currents result from interpolar fluxes from armature reaction, leakage fluxes of the current-carrying armature conductors, and, in some cases, main-pole-tip spray flux. Beneficial factors reducing the circulating currents include the resistance of the short-circuited coil, the resistance of the commutator risers, and that of the brush body to transverse currents. However, the most important factor is the voltage drop at the sliding contact between the brush face and the copper commutator surface.

Commutator Brushes. Most dc machines use electrographitic brushes with about 60 A/in^2 current density at full load. These have an essentially constant contact voltage drop at the commutator surface of about 1 V for loads above one-third. This effective resistance to circulating currents is important to good operation of dc machines.

The cross-resistance of the brush body to circulating currents can be increased by splitting the brush into two wafers and making the crosscurrents cross the air gap between the two pieces. This has increased the good commutation range on some machines by 7%. The use of double brush holders, which have metal dividers between two brushes in the holder, is even more effective and has increased the good commutation range as much as 15% over single solid brushes.

Unless special brushes are used, machines should be operated for not more than a few hours at a time at brush densities below 30 A/in^2. If this is done, the commutator surface develops a hard glaze which makes the brushes chatter. This results in frayed shunts, chipped and broken brushes, and excessive brush-finger wear.

Reactance Voltage of Commutation. The sum of the voltages induced in the armature coil while it is short-circuited by the brushes while undergoing commutation is called the *reactance voltage of commutation*. One of the most important of the fluxes causing this voltage is the *slot-leakage flux* shown in

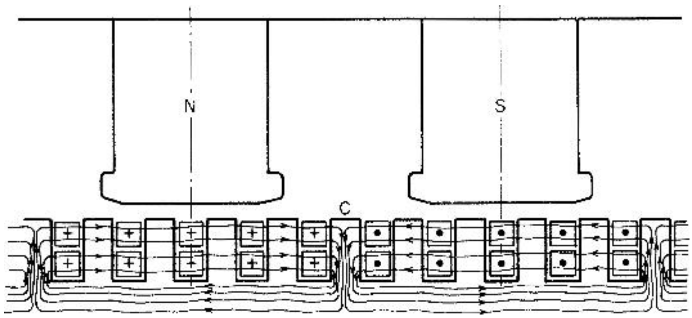

FIGURE 8-26 Slot-leakage flux.

Fig. 8-26. This is the resultant flux leakage from current in the individual slot conductors, as shown in Fig. 8-25. Because the radial fluxes in the rotor teeth from adjacent slot conductors essentially cancel except at point *C* (the point of current reversal), the resultant flux is as shown in Fig. 8-26. As the conductors commutate and pass through *C*, they cut the flux shown there and this generates the *reactance voltage of commutation.* Actually, part of this voltage is also due to leakage-flux changes at the coil ends, to armature reaction flux, etc., but, for simplicity, only the important slot leakage flux is shown.

Commutating Poles. The beneficial factors that limit the circulating currents in coils being commutated are not adequate to prevent serious delays in current reversal. Other means must be taken to prevent sparking.

If the flux at *C* (Fig. 8-26) could be nullified by an equal flux in the opposite direction, the circulating currents due to the slot leakage flux would be prevented.

The location of *C* is fixed by the location of the brushes. If the brushes were shifted toward the south main pole, a position could be found where the main flux upward into the south pole would cancel the downward flux due to slot leakage at *C*.

This method was used in the early history of dc machines. Unfortunately, the slot-leakage flux at *C* is proportional to conductor load current, whereas the flux into the south pole is not. Thus, a new brush position is needed for every change in load current.

A better solution is to provide stationary poles midway between the main poles, as shown in Fig. 8-27. Windings on these *commutating poles* carry the load current. Thus, the flux into the pole at *C* is proportional to the rotor conductor currents and, theoretically, can cancel the voltages induced in the coils being commutated by the slot leakage flux. In the case of the dc motor, the current

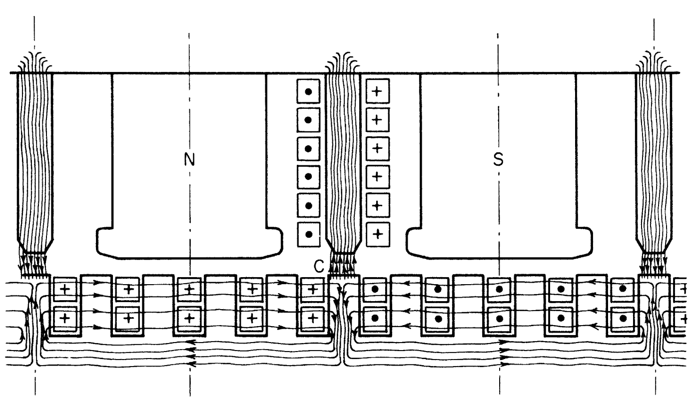

FIGURE 8-27 Slot-leakage flux and commutating-pole flux.

reverses in both the armature and the commutating field, and proper canceling is maintained.

Note that the strength of the commutating-pole winding must be greater than the armature-winding ampere-turns per pole by the amount required to carry the needed flux across the commutating-pole air gap.

Almost all modern dc machines use commutating poles, although some small machines have only half as many as main poles.

The commutating-pole tip is usually shaped with tapered sides to approximate the shape of the reactance voltage of commutation form (see Figs. 8-27 and 8-28).

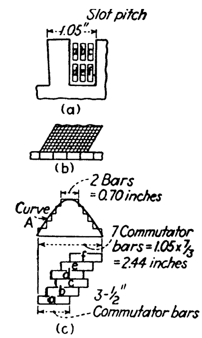

FIGURE 8-28 Commutating zone.

Reactance Voltage of Commutation Formula. To determine the useful flux needed across the commutating-pole air gap, it is useful to calculate the reactance voltage of commutation (the total of the voltages induced in the armature coil as it undergoes commutation). The approximate value of this voltage may be calculated by the use of the following formula:

$$E_c = \frac{\text{poles}}{\text{paths}}(l_c ZT)(\text{r/min})(10^{-10})\left[(K_i L_r) + K_2(PP)(4.5 + 0.2t_s) + \frac{L_r}{b_s}(3d_s + 2SP)\right] \text{ volts} \tag{8-4}$$

where
- I_c = current per armature conductor, A
- Z = total no. of armature conductors
- T = no. of turns/coil between commutator bars
- L_r = gross armature-core length, in
- K_1 = 18.5 for noncommutating-pole machines
  = 0 for machines with commutating-pole length = L_r
- K_2 = 1.0 for machines using nonmagnetic bands
  = 1.7 for machines using magnetic bands
- PP = pole pitch, in
- t_s = coil throw, slots
- b_s = width of slot, in
- d_s = depth of slot, in
- SP = slot pitch, in

This formula is based on the work by Lamme. (See Theory of Commutation by B. G. Lamme, *Trans. AIEE*, Oct. 1911, vol. 30.)

The Commutating Zone. This is defined as that space on the armature periphery through which a given slot moves while all the conductors lying in the slot commutate. In chorded windings, it is extended to include the coil edges in the chorded slots. The commutating zone thus depends on the number of commutating bars covered per brush.

The zone may be calculated by the following formula:

$$CZ = \frac{SP[(B/S) + (B/S \times Ch) + (B/Br) - Cir/p)]}{B/S} \tag{8-5}$$

where CZ is the commutating zone in inches, SP the rotor slot pitch in inches, B/S the number of commutator bars per slot, Ch the slot chording as a fraction of the slot pitch, B/Br the number of commutator bars spanned per brush, Cir the number of paralleled circuits in the armature, and p the number of main poles.

Consider an 8-pole simplex lap winding with three bars per slot, chording of ½ slot, 3½ bars per brush, and slot pitch of 1.05 in:

$$CZ = \frac{1.05 \times (3 + 1\tfrac{1}{2} + 3\tfrac{1}{2} - 8/8}{3} = 2.44 \text{ in}$$

In this machine, all the conductors in a slot are commutated while the armature periphery moves 2.44 in.

This can be seen graphically in Fig. 8-28, where (*a*) shows a slot with six conductors, (*b*) shows a brush covering 3½ bars, and (*c*) shows the graphical solution. In (*c*) the rectangle *a* represents as abscissa the space of 3½ commutator bars if they were at the armature surface. This is the length to commutate coil *a*. The ordinate represents to a convenient scale the commutation voltage induced in this conductor while it is being commutated. Rectangles *b* and *c* are the same for coils *b* and *c*. Since *b* commutates 1 bar later than *a*, it is shown one bar space to the right of *a*, etc. In a similar manner *d*, *e*, and *f* are shown. Normally *d* would be expected to start commutation at the same time as *a*, but, because of chording, it starts later, in this case 1½ bars later. Thus, the commutating zone starts with the beginning of rectangle *a* and is completed at the end of rectangle *f*. On adding the spaces of the parts, this is 3½ bars for *f*, 2 bars for the steps of *e* and *d*, and 1½ bars for chording, or a total of 7 bars at the rotor surface, which is 1.05 7⁄3, or 2.44 in.

The summation of the individual rectangles as smoothed off by curve *A* of (*c*) is a rough representation of the reactance voltages induced in the coils during commutation.

Single Clearance. The centerline of the commutating zone and curve *A* of Fig. 8-28 lie midway between the adjacent main-pole tips if the brushes are not shifted off neutral. The arc on the rotor surface between the tips of adjacent main poles is called the *neutral zone*. If the commutating zone is centered in this arc, the spaces left at each end are called the *single clearance*. Thus, the single clearance is

$$SC = (\text{neutral zone} - \text{commutating zone})/2 \tag{8-6}$$

The single clearance is an indication of the probability that spray flux from the main-pole tips might flow into the commutating zone. Such flux would not vary with load and would distort the form of the useful flux from the commutating pole. The commutating-pole useful flux form should closely resemble that of curve *A* in Fig. 8-28.

Noncompensated dc machines usually have main-pole tips with short radial dimensions and have limited spray flux into the neutral zone. The minimum single clearance for these should be not less than 0.6 in and not less than 0.9 in with commutation voltages above 3 or 4 V.

Compensated-machine main poles usually have tips 2 to 3 in deep to accommodate the compensating slots and are more likely to spray flux into the commutating zone. These require single-clearance minimums of 1.2 to 1.4 in.

If there is any question about tip flux reaching the commutating zone, flux plots should be made.

Commutating-Pole Excitation. Figures 8-18*b* and 8-19 show that flux should normally be expected in the commutation area. It is caused by the armature-winding ampere-turns per pole. It could be reduced to zero if the commutating pole had ampere-turns equal and opposite to those of the armature winding. This is $ZI_c/2p$ At/pole.

However, it is necessary that the commutating winding also produces useful flux across the commutating-pole gap to counteract the reactance voltage of commutation, as shown in Fig. 8-27. For this reason, the strength of the commutating field is usually 20% to 30% greater than the armature ampere-turns per pole. This difference is called the *excess ampere-turns*. These must be added to the circled dotted-line bar diagram of Fig. 8-29. The actual flux across the gap is set accurately during the factory test by adjusting the number of sheet-steel shims behind the commutating poles to set the reluctance of the gap for the exact flux needed.

Calculation of Commutating-Pole Air Gaps. With fixed excess ampere-turns on the commutating-pole winding and a certain commutation voltage at rated current and speed, only one particular commutating-pole air gap will result in the most favorable compensation of the commutation voltage. The shape of the pole tip will determine the form of the flux density under it, but the length of the air gap will determine the magnitude of the density.

To counteract the reactance voltage of commutation E_c, the approximate maximum flux density needed in the commutating-pole air gap is

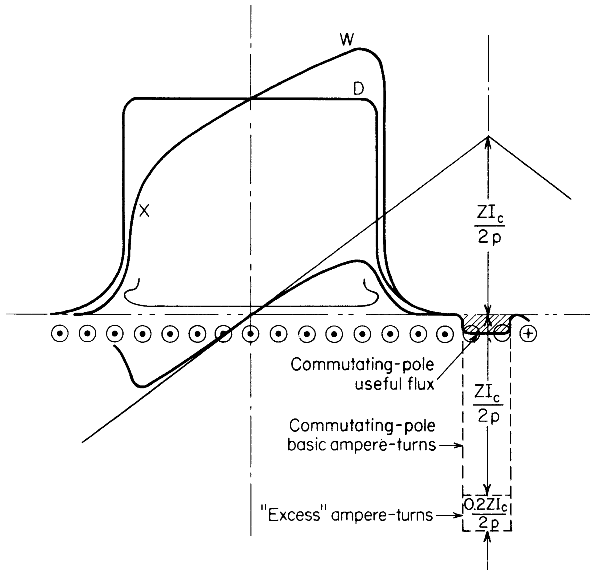

FIGURE 8-29 Commutating-pole ampere-turns.

$$B_m = \frac{E_c \times 23 \times 10^8}{Z/\text{bar} \times DL_c \times \text{r/min}} \tag{8-7}$$

where E_c is the full-load reactance voltage of commutation at speed r/min, Z is the total number of armature conductors, bars is the total number of commutator bars, D is the armature diameter in inches, L_c is the axial length of the commutating poles in inches, and r/min is the revolutions per minute for which E_c was calculated.

The approximate length of the needed commutating-pole single air gap may be calculated by the following formula:

$$\text{Gap} = \frac{3.19 \times \text{excess ampere-turns}}{B_m} \tag{8-8}$$

When the machine is on factory test, the excess ampere-turns can be adjusted to obtain the best commutation possible by placing another dc generator or a battery across the commutating winding to add to the load current flowing in it or to lower the excess by shunting out some of the load current. This is known as a "boost or buck" test. Afterward the commutating-pole air gap is changed to produce the "best" gap flux density with the actual excess ampere-turns. The new gap will be

$$\text{Gap}_2 = \frac{\text{excess At}_1}{\text{excess At}_2} \times \text{gap}_1 \tag{8-9}$$

Dimensions of Commutating Poles. If the useful flux across a commutating-pole air gap is not proportional to the machine load current, the compensation of the reactance voltage of commutation will not be correct for all loads and sparking may damage the brushes and commutator. Thus, the commutating pole must not saturate at the highest load currents to be accommodated. The base of the pole must carry not only the useful air-gap flux but also leakage fluxes from the commutating and main field coils which are near. These leakage fluxes are relatively large and must be determined with care by flux plotting if the danger of commutating-pole saturation exists.

The amount of leakage flux through the base of the pole depends on the length of the leakage paths, the number of coil ampere-turns, and the location of the commutating field. The leakage paths should be made as long as feasible, the coil ampere-turns as few as reasonable, and the commutating coil located as close to the pole tip as possible. Also, all sections of the commutating pole should be large enough to accommodate their flux.

For a normal compensated machine, the leakage flux will be about 75% of the commutating-pole useful flux, or about 140% of the useful flux in a noncompensated machine.

The approximate useful flux can be calculated by using the maximum commutating-pole air-gap flux density from Eq. (8-7). The average flux density of the commutating zone will be approximately

$$B_a = 0.83B_m \tag{8-10}$$

The flux density at overload in the base of the pole is

$$B_{cp} = \frac{K_3 \times K_4 \times B_a \times CZ}{L_c \times W_c} \tag{8-11}$$

where K_3 is 1.75 for compensated machines and 2.40 for noncompensated machines, K_4 is the ratio of overload current to rated current, B_a is the average flux density in the commutating zone, CZ is the width of the commutating zone, L_c is the axial length of the commutating pole, and W_c is the circumferential width of the pole at its base. B_{cp} should not exceed 80,000 to 90,000 lines/in^2 for good commutation.

Compensating Windings. Although the commutating pole is a good solution for commutation, it does not prevent distortion of the main-pole flux by armature reaction. The flux set up across the main-pole face by the armature mmf is shown in Fig. 8-30*a*. If the pole face is provided with another winding, as shown in Fig. 8-30*b*, and connected in series with the load, it can set up an mmf equal and opposite to that of the armature. This would tend to prevent distortion of the air-gap field by armature reaction. Such windings are called *compensating windings* and are usually provided on medium-sized and large dc machines to obtain the best possible characteristics. They are also often needed to make machines less susceptible to flashovers.

The use of compensating windings reduces the number of turns required on the commutating-pole fields, and this materially reduces the leakage fluxes of the field and, in turn, the pole saturations at high currents. The ampere-turns on the commutating field are reduced by about 50% with the use of a compensating field. This new winding may be considered to be some of the turns taken off the commutating-pole winding and relocated in slots in the main-pole faces.

The number and location of the compensating slots must be carefully chosen to match, as closely as possible, the rotor ampere-turns per inch. However, the slot spacing must not correspond closely to that of the rotor. This would cause a major change in reluctance to the main-pole useful flux every time the rotor moved from a position where the rotor and stator slots all coincided to where the rotor slots coincided with the stator teeth. This would occur once for every slot-pitch movement. The resulting rapid changes in useful flux would cause ripples in the output voltage and also serious magnetic noise. If too few slots are used, local flux distortions occur and the compensating winding loses some of its effectiveness (see Fig. 8-32).

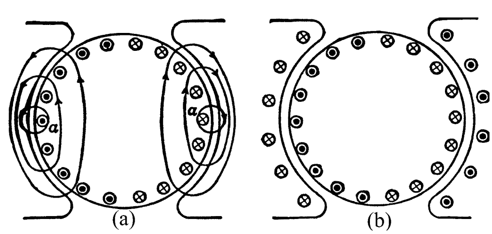

FIGURE 8-30 Armature field without (*a*) and with (*b*) compensating windings.

Compensation of armature reaction effectively reduces the armature circuit inductance. This makes the machine less susceptible to the bad effects of $L(di/dt)$ voltages caused by very fast load current changes.

During manufacture, it is possible to locate the compensating winding nonsymmetrically about the centerline of the main pole. This causes a direct-axis flux, which will give a series field effect (Fig. 8-31). For generator cumulative compounding, the slots must be shifted in the direction of the machine rotation. This shift gives a motor differential compounding. The effect cannot be adjusted after manufacture. It seldom exceeds ½ in, and this does not materially reduce the effectiveness of the compensation.

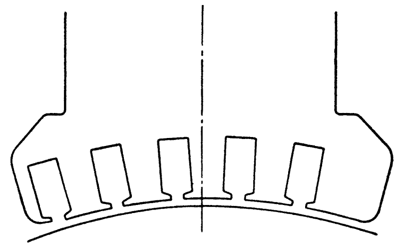

FIGURE 8-31 Offset compensating winding.

Volts per Bar. The mica thickness between the commutator segments depends on the machine design and varies from 0.020 in on small machines to 0.050 in on large units. Although several hundred volts would normally be required to jump these distances, the presence of ionized air from sparking and the presence of conducting carbon dust make it necessary that the voltage between segments be held to low values. If a low-resistance arc does jump between segments, it raises the voltages across the remaining bars. It also tends to ionize some air to form conducting paths across the rest of the bars. If this progresses until all the segments between brush arms of opposite polarity are bridged, then a *flashover* occurs and severe damage may result to the commutator, brushes, and brush holders.

Because the highest voltage between bars is the "trigger" that starts the flash, this is an important limit. The "average" volts per bar has little significance. Figure 8-29 shows that the maximum volts per bar depends on the field form. For the noncompensated machine shown, the maximum volts between segments exists at w. The segments connected to conductors at x have much less voltage between them, and those beyond the edge of the pole have almost none.

The relation between maximum volts per bar and the average depends on the armature ampere-turns per pole and the saturation curve of the gap and teeth at the pole tips. On neglecting the small voltage drop in the series and commutating windings, the voltage between brush arms is the machine voltage V, and the number of bars between arms is B/p. Thus

$$\text{Average volts/bar} = \frac{V \times p}{B} \tag{8-12}$$

where B is the total number of commutator bars and p the number of main poles.

Even if no distortion exists, only the conductors under the pole faces generate voltage, and so the corrected average volts per bar should be

$$\frac{V \times p}{B \times \psi} \quad \text{volts}$$

where ψ is the ratio of pole arc to pole pitch, about 0.65. This is represented by D in Fig. 8-29. However, the maximum volts per bar at w is greater than this, as the height w is greater than D, or

$$\text{Maximum volts per bar} = \frac{V \times p}{B} \times \frac{w}{D \times \psi} \tag{8-13}$$

In practice, the value of w/D for a noncompensated machine at full-strength main field varies from about 1.7 to 1.9. However, any reduction in saturation causes the effects of the armature ampereturns (which cause the distortion) to be magnified. The designer must check the actual value of w/D, since it may be as high as 4.5 for a dc motor at a weak main field strength (high speed). This is evident in Fig. 8-32. The distorting effect for the high-speed (low-average-flux) condition ϕ_{02} raises the maximum flux to ϕ_{w2}, which is over 3 times the change for the saturated

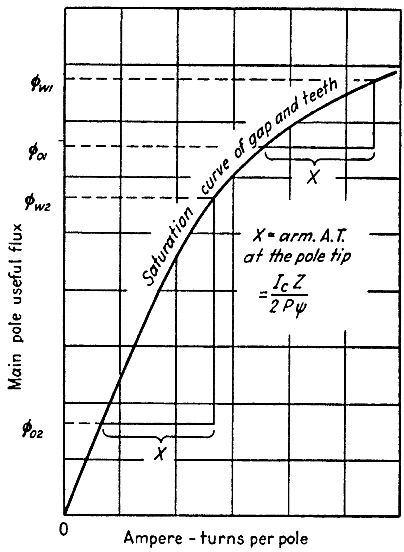

FIGURE 8-32 Effect of flux-distortion armature ampere-turns at normal and low saturation.

(low-speed) condition ϕ_{01} to ϕ_{w1} with the same distorting ampere-turns X.

The use of a compensating winding tends to eliminate the flux distortion, and for saturated conditions the flux curve coincides well with the no-load curve D of Fig. 8-29. However, under low saturation conditions the stationary compensating windings permit localized flux distortions. These are shown in Fig. 8-33. Similar distortions occur at low main flux densities on dc generators, but the output voltage V is reduced in the same proportion as the main flux, and the maximum voltage between bars is not affected seriously.

At full field on well-compensated motors or generators *w/D* is about 1.4 to 1.5. Direct-current motors at weak field may have ratios of 2.0 or more. On any questionable machine the designer should check this value carefully.

Approximate safe limits of maximum volts per bar are 40 V for motors and 30 V for generators on machines having 0.040-in-thick mica between segments.

Brush Potential Curves. When a dc machine develops some commutation sparking, the user may suspect that the commutating-pole air gap is not set correctly. "Brush potential curves" are often taken to prove or disprove such suspicions.

These are taken by measuring the voltage drops between the brush and commutator surface at four points while the machine is operating at constant speed and load current (see Fig. 8-34). The voltages at 1, 2, 3, and 4 are taken by touching the pointed lead of a wooden pencil to the commutator surface. The circuit is completed with leads and a low-reading voltmeter is shown.

The voltages are then plotted. A curve such as A of Fig. 8-34 may indicate undercompensation due to a too large commutating-pole gap. Curve C may indicate overcompensation with too much flux density in the commutating-pole air gap. Curve B is typical of good compensation.

Justification for such conclusions is based on the theory that best commutation (coil current reversal) will be linear while the coil passes under the brush. This is possible only if there are no circulating currents. Undercompensation should cause circulating currents that would crowd the current to the leaving edge of the brush and cause a high voltage at point 4. Overcompensation would reverse the current too soon and would actually reverse the voltage drop at point 4.

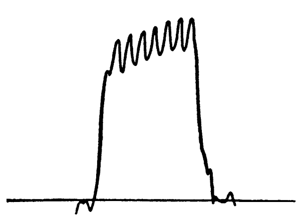

FIGURE 8-33 Main-pole flux distortion on a compensated motor at full load and $2\frac{1}{2}$ times base speed.

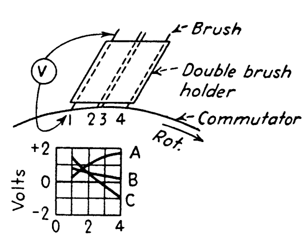

FIGURE 8-34 Brush potential curves.

Even to an expert, this test is only an indicator that more definitive tests, such as a buck-boost test, are needed [see Eq. (8-8)]. Many other factors, including brush riding, commutator surface conditions, and sparking, influence the readings. Where machine changes may be required, the manufacturer should be consulted.

8.6 ARMATURE DESIGN

EMF Equation. If 10^8 lines (Mx) of flux are cut by one conductor in 1 s, 1 V is induced in it. Therefore, the induced voltage of a dc machine is

$$E = \phi_t \times \frac{Z}{C} \times \frac{\text{r/min}}{60} \times 10^{-8} \tag{8-14}$$

where ϕ_t is the total flux in maxwells across the main air gaps and Z/C is the number of conductors in series per circuit (C).

Output Equation. Equation (8-14) is converted to watts output if both sides are multiplied by the load current I_L, $I_c \times C$. The formula can then be rearranged as

$$D^2L = \frac{\text{watts} \times 6.08 \times 10^8}{\text{r/min} \times B_g \times \psi \times q} \tag{8-15}$$

where D is the armature diameter and L is the armature gross core length, B_g is the main-pole air-gap density in maxwells (lines), ψ is the ratio of pole arc to pole pitch, q is $ZI_c/\pi D$ (a useful loading factor), and ϕ_t is the total air-gap flux equal to

$$B_g \psi \pi D L \tag{8-16}$$

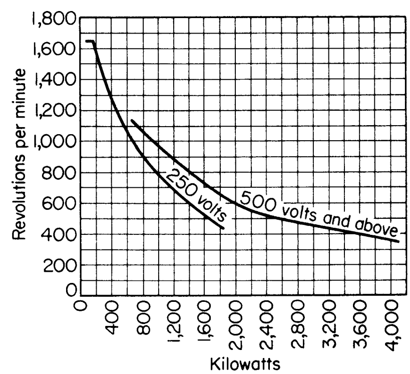

FIGURE 8-35 Standard speeds of dc generators.

Rotor Speeds. Standards list dc generator speeds as high as are reasonable to reduce their size and cost. This relation is seen from Eq. (8-15). The speeds may be limited by commutation, maximum volts per bar, or the peripheral speeds of the rotor or commutator. Generator commutators seldom exceed 5000 ft/min, although motor commutators may exceed 7500 ft/min at high speeds. Generator rotors seldom exceed 9500 ft/min. Figure 8-35 shows typical standard speeds. If the prime mover requires lower speeds than these, generators can be designed for them but larger machines result.

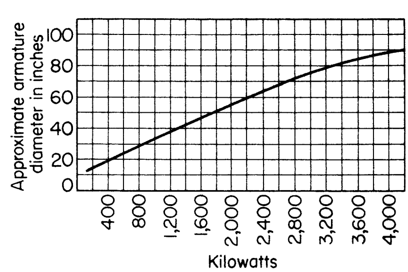

FIGURE 8-36 Approximate rotor diameters for standard speeds of dc generator.

Rotor Diameters. Difficult commutating generators benefit from the use of large rotor diameters, but diameters are limited by the same factors as rotor speeds listed above. The resultant armature length should be not less than 60% of the pole pitch, because such a small portion of the armature coil would be used to generate voltage. Typical generator diameters are shown in Fig. 8-36.

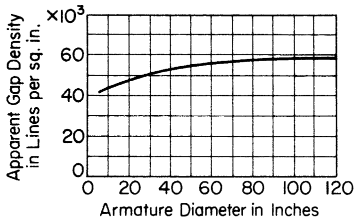

FIGURE 8-37 Curve of apparent gap density versus armature diameter.

Direct-current motor speeds must suit the application, and often the rotor diameter is selected to meet the inertia requirements of the application. Core lengths may be as long as the diameter. Such motors are usually force-ventilated.

Number of Poles and Other Rotor Design Factors. The rotor diameter usually fixes the number of main poles. Typical pole pitches range from 17.5 to 20.5 in on medium and large machines. When a choice is possible, high-voltage generators use fewer poles to allow more voltage space on the commutator between the brush arms. However, high-current generators need many poles to permit more current-carrying brush arms and shorter commutators. Commutators for 1000 to 1250 A/(brush arm)(polarity) are costly, and lower values should be used where existing dies will permit.

The main-pole air-gap flux density Bg is limited by the density at the bottom of the rotor teeth. The reduced taper in the teeth of large rotors permits the higher gap densities, as shown in Fig. 8-37.

Ampere conductors per inch of rotor circumference (q) is limited by rotor heating, commutation, and, at times, saturation of commutating poles. Approximate acceptable values of q are shown in Fig. 8-38.

The commutator diameter is usually about 55% to 85% of the rotor diameter, depending on the sizes available to the designer, the peripheral speed, and the resulting single clearances. Heating may also limit the choice.

Brushes and brush holders are chosen from designs available to limit the brush current density to 60 to 70 A/in^2 at full load, to obtain the needed single clearance, and to obtain acceptable commutator heating.

Selection of an Approximate Design. Consider a generator rated 2500 kW, 700 V, 3571 A, and 514 r/min. From Figs. 8-38 and 8-39

Armature Slots and Coils. The depth of an armature slot is limited by several factors, including the tooth density, eddy losses in the armature conductors, available core depths, and commutation. For reasonable frequencies (up to 50 Hz on medium and large dc machines), slots about 2 in deep can ordinarily be used.

Acceptable slot pitches range from 0.75 to 1.5 in. Small machines have shallower slots and a lower range of slot pitches. For medium and large machines, a reasonable tooth density usually results if the ratio of slot width to slot pitch is about 0.4.

Eddy losses in the conductors can be large compared with their load I^2R losses. Sometimes these must be reduced by making each armature conductor from several strands of insulated copper wire. The number of strands and their size depend on the frequency and the total depth of the conductor. An approximate formula for reasonable eddy losses is

$$\text{No. of strands} = (0.168)\,(f^{0.83})(d_c^{0.4}) \qquad (8\text{-}17)$$

where f is the frequency in hertz, (r/min × poles)/120, and d_c is the total depth of a conductor.

The insulation space required depends on the type used. Typical conductor strands have about 0.018 in of glass strands and varnish total. Mica wrappers, binding tapes, and varnish and slot finish allowance (0.010 in) total about 0.085 in on the coil width. If the space for the wedge and its retainer is included, the two coils depthwise total about 0.315 in (see Fig. 8-39).

8.7 COMPENSATING AND COMMUTATING FIELDS

Compensating Winding Data. The compensating winding should closely match the armature ampere-turns per inch, should avoid causing magnetic noise, and should result in an acceptable maximum volts per bar. Machines for 40°C temperature rise will have compensating bar densities of about 2500 to 3000 A/in^2. The pole tip section will limit the maximum depth of the compensating bar. Localized areas of high flux density must be avoided where flux must funnel between the pole "shoe" surface and the bottom of the compensating slot.

For single compensating bar-per-slot designs, the typical width required for insulation, varnish, and stacking factor is about 0.140 in. With the wedge space included, the insulation-depth requirement is about 0.400 in.

8.8 MAGNETIC CALCULATIONS

Flux Paths. Figure 8-40 shows the paths of the main-pole flux for a typical medium-sized machine. The commutating poles and the compensating slots are not shown. Saturation calculations involve only half the length of a complete flux loop, because that is all that one field coil accommodates. Except for the main-pole air gap and the rotor teeth ampere-turns, the calculations are simple. They require (1) the determination of flux densities by dividing the flux in a section by its cross-sectional area, $\beta = \Phi$ area; (2) reading a magnetization curve for the material involved to find the ampereturns per inch needed for the density; and (3) finding the total ampere-turns for the part by multiplying the length of the portion of the path by those ampere-turns per inch. Typical magnetization curves are shown in Fig. 8-41.

The rotor core is usually built up of sheet steel laminations 0.017 to 0.025 in thick. Because of burrs and surface coatings, a stacking factor of 93% is common. The main poles use thicker laminations, and a factor of 95% is common. If the frame is also made up of laminations, a similar factor is necessary. Of course, a solid frame uses its full area.

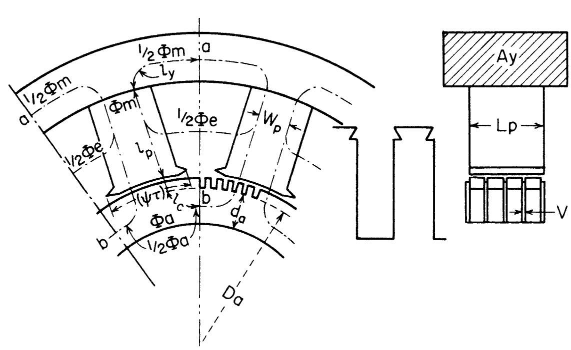

FIGURE 8-40 Paths of main and leakage fluxes.

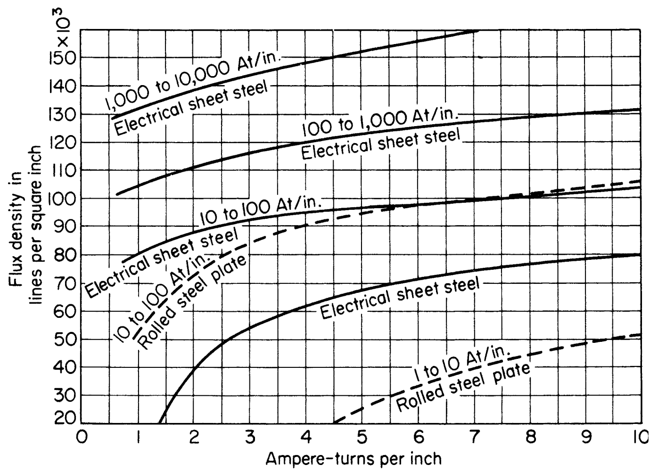

FIGURE 8-41 Magnetization curves.

The leakage flux ($^1\!/_2\ \phi_e$) in Fig. 8-40 from the main field coils must be included with the useful flux in the frame yoke and the pole body. Calculations depend on the actual machine dimensions and on the main field ampere-turns. However, the ampere-turns in these parts represent only a small part of the total required for the entire path, and it is usually accurate enough to estimate this leakage to be 12% of the useful flux normally and 20% at high saturations. For accurate calculations, the actual leakage can be plotted. No leakage fluxes are considered in computing the gap, teeth, or core densities.

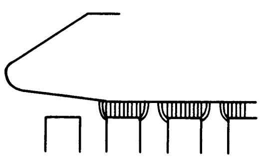

FIGURE 8-42 Distribution of flux in the air gap.

The Carter Coefficient and Gap Ampere-Turns. The presence of rotor slots, compensating slots, and vent ducts in the generator causes the actual densities in the main-pole air gap to be greater than for a smooth, solid core. Also, the average lengths of the flux paths are longer (see Fig. 8-42). The two effects may be lumped by assuming that the air gap is larger than measured mechanically. On considering the three factors (rotor slots, compensating slots, and vents) in succession, the formula

$$G_1 = G \times \frac{\text{G} + (\text{slot width}/5)}{G + (\text{slot width}/5)(1 - \text{slot width}/\text{slot pitch})} \tag{8-18}$$

gives the first corrected air gap G_1; this will closely approximate the effective air gap.

The ampere-turns across the gap will be

$$At_g = \beta_g \times 0.313 \times G_1 \tag{8-19}$$

The Rotor Teeth Ampere-Turns. For tooth densities below 100,000 lines/in^2, the ampere-turn drops in a tooth are so low that practically no flux will pass down the adjacent slot because the reluctance of air is so great. However, as tooth flux densities become larger, they produce very high ampere-turn drops from the top of the tooth to its bottom owing to saturation. Because these ampere-turns are also across the parallel flux path in the adjacent slot, when they are large enough, some useful flux will pass down the slot, relieve the tooth of some of its flux, and lower its actual density. If the tooth apparent density is calculated by assuming that all the flux across a slot pitch passes down the tooth, the actual density will be less than the apparent, depending on the amount of saturation.

The relation between the apparent tooth density β_{ta} and the actual tooth density β_t for different ratios of air area to iron area at any section of the tooth is shown in Fig 8-43. The *K* of these areas is

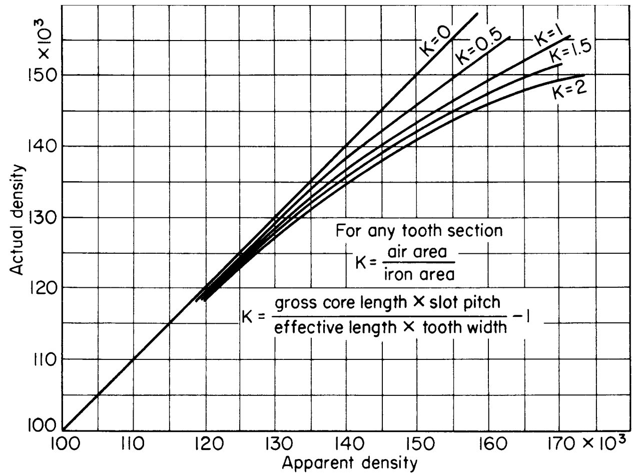

FIGURE 8-43 *K* curves.

$$K = \frac{\text{air area}}{\text{iron area}} = \frac{(\text{gross core length}) \times (\text{slot pitch})}{(\text{eff. core length}) \times (\text{tooth width})} - 1 \tag{8-20}$$

For accuracy in calculating tooth ampere-turns, it is desirable to divide the tooth into several parts, find the ampere-turns drop across each section, and total them. The flux density is found at the middle of each section, and the *K* ratio is calculated at the middle of each section.

Calculation of No-Load Saturation Data. Considering the 2500-kW, 700-V, 3571-A, 514-r/min generator, we have the values shown in Table 8-1. Using the magnetization curves of Fig. 8-41 and these data, the no-load saturation curve is calculated for several voltages. Note that 721 V is chosen in Table 8-2 on the assumption that the *IR* drop in the generator will not exceed 3%, or 21 V in this case. The generator (Fig. 8-44) must have this additional voltage induced in it for a 700-V terminal voltage. In the case of a motor, the induced voltage would be lower by the amount of the *IR* drop, or 679 V.

Full-Load Saturation Curve for a Compensated Machine. Figure 8-45 shows the calculated no-load saturation curve. For a well-compensated machine, the brushes will have little or no shift, and essentially no useful flux will be lost because of armature reaction. Only the armature-circuit-resistance *IR* drop need be considered, and the full-load excitation ampere-turns required can be read directly from the no-load saturation curve at the induced voltage.

For the 2500-kW generator, the excitation required at 721 V is 7520 At at full load.

Full-Load Saturation Curve for a Noncompensated Machine. With commutating poles, there is no need for brush shift, but the uncompensated armature reaction will result in loss of useful flux as the load is increased. Figure 8-46 shows a method of calculating the additional ampere-turns excitation to replace this lost flux.

Maximum Volts per Bar Calculations. The distorting ampere-turns resulting from imperfect compensation of the armature ampere-turns by the compensating winding are found by plotting the two and noting the maximum difference. This is done at the maximum-overload-current point.

The distortion factor (Figs. 8-32 and 8-45) is determined from the gap and teeth saturation curve (Fig. 8-45). At double load, the induced voltage is considered to be 740 V.

8.9 MAIN FIELDS

Main Field and Main-Field Heating. Figures 8-47 and 8-48 show three types of dc main fields. Small machines commonly use those of Fig. 8-47. They are wound on molds and then slipped on the poles. Type A is wound on an insulating spool, and type B uses an insulated steel spool for better heat transfer and mechanical protection.

The arrangement of Fig. 8-48 is common on large and medium-sized dc machines. The turns of the inner section are wound tightly on the insulated pole body to avoid air spaces between the pole and the coil. This permits maximum heat transfer. The second section is spaced away from the inner coil to permit the cooling air to flow over the maximum surface area possible. The thickness of a coil section is limited to about $1^1/_4$ to $1^3/_4$ in for a small temperature gradient within the coil.

All three types may use wire insulated with varnish, double cotton covering, or glass slivers in varnish. Air pockets which act as barriers to transfer of heat must be avoided, and so rectangular wire is common. Also, varnish or resin is liberally applied during winding or applied by vacuum impregnation after the coil is wound.

Design criteria suitable for all dc machines cannot be established, because the field cooling depends on air pressures from the armature rotation, the air-passage areas through the fields, and the radiation of heat from adjacent parts. These factors vary with machine design. However, on medium and large self-ventilated dc generators (built as in Fig. 8-48) empirical data are useful.

The main fields receive heat, not only from their own I^2R losses, but from heat radiated from the hot armature and the commutation coils. Also, the air cooling the coils is already heated by the

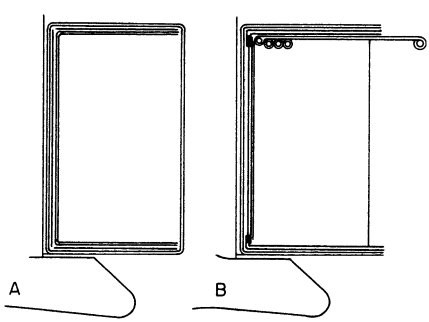

FIGURE 8-47 Two types of field-coil insulation, combined with fiber and metal spools, respectively.

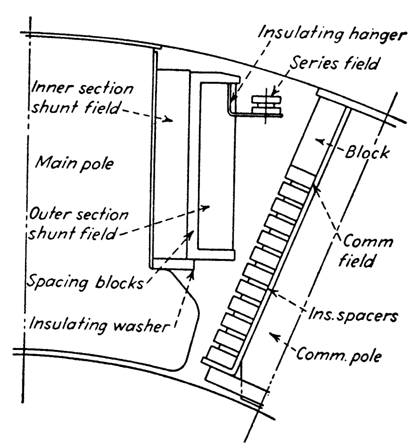

FIGURE 8-48 Ventilated field coils.

rotor. This lowers the temperature gradient for cooling the coils. The temperature rise of the fields must be calculated, not on the basis of the actual air temperature, but on the basis of the cool ambient-air temperature outside the machine. Figure 8-49 shows empirical data for such typical self-ventilated medium and large machines, built as shown in Fig. 8-48.

The "surface area" for these curves includes the entire periphery of the coil, because the heat transfer to the pole body is as effective as that to the air-cooled surfaces.

Little gain is made in cooling with increase in rotor velocities above 5000 ft/min because most of the armature air must pass through the limited field structure area. At high rotor speeds, the air is throttled owing to the high-velocity pressure drops.

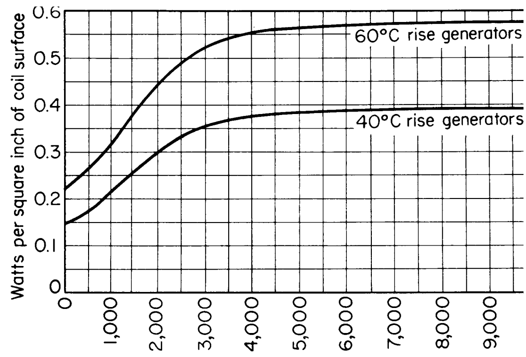

FIGURE 8-49 Main-field loss per surface area.

Main-Field Calculations. These are made by making a layout similar to that shown in Fig. 8-48. This permits the estimate of approximate mean length of turns ($\overline{L}_t$) for the sections.

The means of excitation and the particular application usually determine the *IR* drop of the main field. This is met in design by selection of the field wire cross-sectional area. This is calculated by Eq. (8-21).

$$\text{Conductor sectional area} = \frac{\text{At}/p \times \overline{L}_t \times p \times 8.25 \times 10^{-7}}{IR} \tag{8-21}$$

where At/p is the number of ampere-turns per pole needed, $\overline{L}_t$ is the mean length of turns, p is the number of coils in series, and IR is the required voltage drop.

Typical field calculations are

At/p	7520 At

These data indicate an acceptable field.

8.10 COOLING AND VENTILATION

Cause of Temperature Rise. The losses in a dc machine cause the temperature of the parts to rise until the difference in temperature between their surfaces and the cooling air is great enough to dissipate the heat generated.

Permissible measured temperature rises of the parts are limited by the maximum "hot-spot" temperature that the insulation can withstand and still have reasonable life. The maximum surface temperatures are fixed by the temperature gradient through the insulation from the hot spot to the surface.

The IEEE Insulation Standards have established the limiting hot-spot temperatures for systems of insulation. The *American National Standards Institute* Standard C50.4 for dc machines gives typical gradients for those systems, listing acceptable surface and average copper temperature rises above specified ambient-air temperatures for various machine enclosures and duty cycles. Typical values are 40°C for Class A systems, 60°C for Class B, and 80°C rise for Class F systems on armature coils. Class H systems usually contain silicones and are seldom used on medium and large dc machines. Silicone vapors can cause greatly accelerated brush wear at the commutator and severe sparking, particularly on enclosed machines.

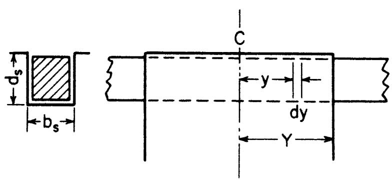

FIGURE 8-50 Heat paths in an armature conductor.

Temperature Gradients in Rotor Coils. Figure 8-50 represents a current-carrying conductor insulated from the core slot in which it is embedded. The hot spot is probably at the core centerline and near the center of the conductor. Heat will probably travel along the conductor to the end turn and also through the insulation to the iron. The amount of heat flowing in each direction is difficult to calculate. Also, variations in the coils, such as resin fill and tightness in the slots, make heat conductivity factors difficult to predict.

1. Assume that all the heat must travel down the conductor to the end turn. What will be the temperature difference in the conductor between the center of the core and its edge?

$$\text{Resistivity of copper at } 75°\text{C} = 8.25 \times 10^{-7}\Omega/\text{in}^3$$

$$\text{Thermal cond. copper} = 9.75 \text{ W/(in)(°C) for 1-in}^2 \text{ section}$$

Therefore, the energy crossing dy of Fig. 8-50 is

$$\text{Watts} = (I_c)^2 R_y = \frac{(I_c)^2(y)(8.25 \times 10^{-7})}{A} \tag{8-22}$$

where I_c is the conductor amperes, R_y the resistance of length y, and A the conductor cross-sectional area. The difference in temperature between two faces dy apart is

$$°\text{C} = \frac{(I_c^2)\,(y)(8.25 \times 10^{-7})}{A} \times \frac{dy}{A} \times \frac{1}{9.75} \tag{8-23}$$

and the difference in temperature between the center C and any point y is

$$°\text{C} = \frac{(I_c)^2(8.25 \times 10^{-7})}{A} \int_0^y \frac{y\,dy}{A} \times \frac{1}{9.75}$$

or

$$°\text{C} = 4.22\left(\frac{I_c}{A}\right)^2 (y)^2(10)^{-8} \tag{8-24}$$

Consider a current density of 2920 A/in^2 and a total core length of 16 in. Then the coil temperature gradient from the core center, with no ventilating ducts, to the edge is 28.8°C. This assumes that no heat passes through the insulation to the iron, and so medium and large machines normally use ventilating core ducts every few inches.

2. Assume that the end turns are so hot that no heat flows longitudinally down the coil. The I^2R loss of each inch of conductor length is

$$\text{Watts} = \frac{(I_c)^2(8.25 \times 10^7)}{A}$$

If the slot contains several conductors

$$\text{Watts} = (\text{ampere conductors})(\text{A/in}^2)(8.25 \times 10^{-7})$$

and the temperature difference between the bare conductor and the steel across the insulation is

$$°\text{C} = (\text{amp conductors})(\text{A/in}^2) \times \frac{\text{insulation thickness}}{2d_s + b_s} \times \frac{8.25 \times 10^{-7}}{0.003} \tag{8-25}$$

The factor 0.003 is the thermal conductivity of the insulation in watts per cubic inch per degree Celsius W/(in^3)(°C) difference. Thus, for 2142 ampere conductors per slot, 2920 A/in^2, a surface of two slot depths plus a slot width (times 1 in) = 5.07 in^2, and an insulation thickness of 0.051 in the temperature drop across the insulation is 17.65°C.

This figure cannot be considered precise because the thermal conductivity can vary widely with the insulation used and the presence of varying amounts of air in it. The conductivity figure for air is 0.0007, whereas that of mica is 0.007 W/(in^3)(°C). Also, heat moves along the coil. Because of these difficulties, empirical data from actual machines are more reliable and easier to use.

Heating of End Connections of Armature Windings. Small machines often have "solid" end windings banded down on insulated "shelf"-type coil supports. Larger machines are more heavily loaded per unit volume and usually have narrow coil supports, air spaces between the end turns, and ventilating air scouring both the top and bottom surfaces of the coil extensions.

With this construction, the approximate allowable product of ampere conductors per inch of outer circumference times the amperes per square inch for various rotor velocities is shown in Fig. 8-51 for a 40°C rise on the end turns.

Commutator Heating. A modern dc armature is shown in Fig. 8-52. The commutator diameter ranges from 55% to 85% of the rotor core, and the commutator necks joining the bars with the rotor

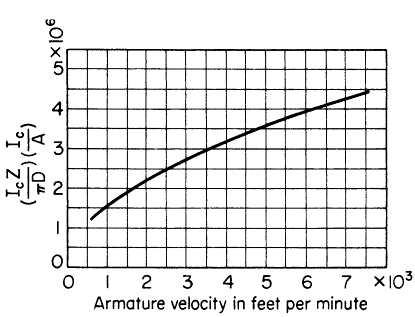

FIGURE 8-51 End-winding cooling.

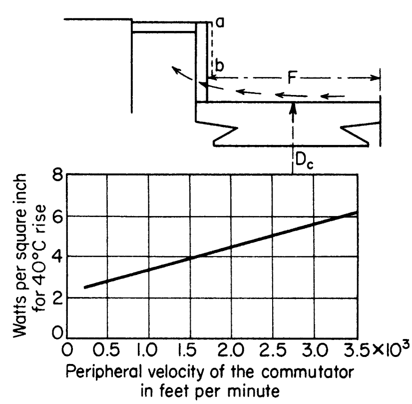

FIGURE 8-52 Temperature rise of a commutator.

winding extensions are usually separated from one another by air spaces, so that, when the armature revolves, air circulation is set up as shown by the arrows.

A typical relation between permissible watts per square inch of commutator surface and its peripheral velocity is shown in Fig. 8-52. The radiating surface is the commutator circumference times its face length. Neck area is not included.

The heat to be dissipated is that due to brush friction and the brush contact I^2R losses. There may be other losses due to poor commutation, brush chattering, and commutator surface, and, if so, the rise will be greater than indicated in Fig. 8-52. If commutation is very good and brush riding excellent, the temperature will be lower.

Application of Heating Constants. The paragraphs covering the design of the armature, main fields, compensating windings, and commutating windings included typical loading data such as ampere conductors per inch, amperes per square inch, flux densities, and watts per square inch of cooling surface. More accurate data depend on the exact arrangements used in a particular design. If possible, new design should be compared with similar machines which have already been tested. Any machine enclosure variation that restricts or increases the ventilation will affect the temperature rises.

8.11 LOSSES AND EFFICIENCY

Armature Copper I^2R Loss. At 75°C the resistivity of copper is $8.25 \times 10^{-7}\Omega/\text{in}^3$. Thus, for an armature winding of Z conductors, each with a length of $\overline{L}_t/2$ (half the mean length turn of the coil), each with a cross-sectional area of A and arranged in several parallel circuits, the resistance is

$$R_a = Z\frac{\overline{L}_t}{2A}\frac{8.25 \times 10^{-7}}{(\text{circuits})^2} \qquad \text{ohms} \tag{8-26}$$

The $\overline{L}_t$ is best found by layout, but an approximate value is

$$\overline{L}_t = 2[(1.35)(\text{pole pitch}) + (\text{rotor length}) \times 3] \tag{8-27}$$

There are also eddy current losses in the rotor coils, but these may be held to a minimum by conductor stranding in accordance with Eq. (8-17). Some allowance for these is included in the load loss.

Compensating, Commutating, and Series Field I^2R Losses. These fields also carry the line current, and the I^2R losses are easily found when the resistance of the coils is known. Their $\overline{L}_t$ is found from sketch layouts. At 75°C

$$R = T\frac{\overline{L}_t}{A}\frac{8.25 \times 10^{-7}}{(\text{circuits})^2}p \qquad \text{ohms} \tag{8-28}$$

where R is the field resistance in ohms, T the number of turns per coil, p the number of poles, $\overline{L}_t$ the mean length of turn, and A the area of the conductor. The total of these losses ranges from 60% to 100% of the armature I^2R for compensated machines and is less than 50% for noncompensated machines.

The brush I^2 loss is caused by the load current passing through the contact voltage drop between the brushes and the commutator. The contact drop is assumed to be 1 V.

$$\text{Brush } I^2R \text{ loss} = 2(\text{line amperes}) \qquad \text{watts} \tag{8-29}$$

Load Loss. The presence of load current in the armature conductors results in flux distortions around the slots, in the air gap, and at the pole faces. These cause losses in the conductors and iron that are difficult to calculate and measure. A standard value has been set at 1% of the machine output.

$$\text{Load loss} = 0.01(\text{machine output}) \tag{8-30}$$

Shunt Field Loss. Heating calculations are concerned only with the field copper I^2R loss. It is customary, however, to charge the machine with any rheostat losses in determining efficiency. Thus

$$\text{Shunt field and rheostat loss} = I_f V_{ex} \qquad \text{watts} \tag{8-31}$$

where I_f is the total field current and V_{ex} is the excitation voltage.

Core Loss. As seen from Fig. 8-53, the flux in any portion of the armature passes through $p/2$ c/r (cycles per revolution) or through $(p/2)[(\text{r/min})/60]$ Hz.

The *iron losses* consist of the *hysteresis loss*, which equals $K\beta^{1.6}fw$ watts, and the *eddy current loss,* which equals $K_e(\beta ft)^2w$ watts. K is the hysteresis constant of the iron used, K_e is a constant inversely proportional to the electrical resistance of the iron, β is the maximum flux density in lines per square inch, f is the frequency in hertz, w is the weight in pounds, and t is the thickness of the core laminations in inches.

The *eddy loss* is reduced by using iron with as high an electrical resistance as is feasible. Very high resistance iron has a tendency to have low flux permeability and to be mechanically brittle and expensive. It is seldom justified in dc machines. The loss is kept to an acceptable value by the use of thin core laminations, 0.017 to 0.025 in thickness.

Another significant loss is the *pole-face loss*. Figure 8-42 shows the distribution of flux in the air gap of a dc machine. As the armature rotates and the teeth move past the pole face, emfs are induced which tend to cause currents to flow across the pole face. These losses are included in the core loss.

Unfortunately, there are other losses in the core that may differ widely even on duplicate machines and that do not lend themselves to calculation. These include:

1. Loss due to filing of slots. When the laminations have been assembled, it will be found in some cases that the slots are rough and must be filed to avoid cutting the coil insulation. This burrs the laminations and tends to short circuit the interlaminar resistance.
2. Losses in the solid spider, core end plates, and coil supports from leakage fluxes may be appreciable.
3. Losses due to nonuniform distribution of flux in the rotor core are difficult to anticipate. In calculating core density, it is customary to assume uniform distribution over the core section. However, flux takes the path of least resistance and crowds behind the teeth until saturation forces it into the less used, longer paths below. As a result of the concentration, the core loss, which is about proportional to the square of the density, is greater than calculated.

Thus, it is not possible to predetermine the total core loss by the use of fundamental formulas. Consequently, core-loss calculations for new designs are usually based on the results from tests on similar machines built under the same conditions. Such test results are plotted in Fig. 8-54 for

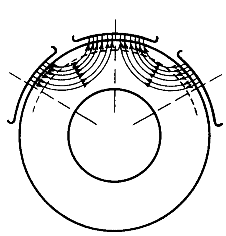

FIGURE 8-53 Distribution of flux in the armature.

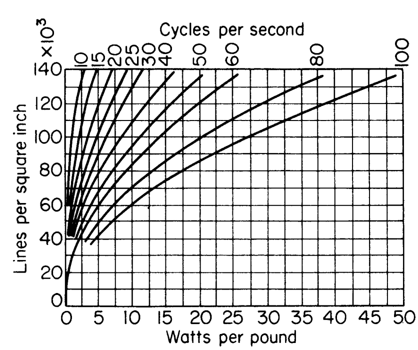

FIGURE 8-54 Iron-loss curves for a dc machine.

machines using ordinary laminations 0.017 in thick and a limited amount of filing. They do not include the pole-face losses, which would increase the values about 30%.

Brush Friction Loss. This loss varies with the condition of the commutator surface and the grade of carbon brush used. A typical machine has about 8-W loss/(in^2 of brush contact surface) (1000 ft/min) of peripheral speed when normal brush pressure of $2\frac{1}{2}$ lb/in^2 is used.

$$\text{Brush friction} = (8)\,(\text{contact area})\,\frac{\text{peripheral velocity}}{1000} \tag{8-32}$$

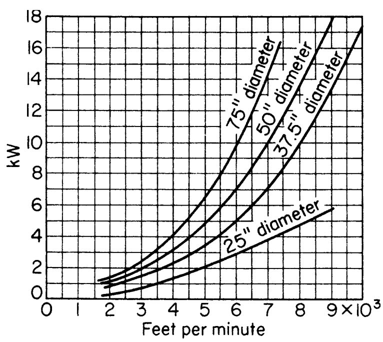

FIGURE 8-55 Friction and windage versus rotor velocity.

Friction and Windage. Most large dc machines use babbitt bearings and many small machines use ball or roller bearings, although both types of bearing may be used in machines of any size. The bearing friction losses depend on the speed, the bearing load, and the lubrication. The windage losses depend on the construction of the rotor, its peripheral velocity, and the machine restrictions to air movement. The two losses are lumped in most estimates because it is not practical to separate them during machine testing.

Figure 8-55 shows typical values of friction and windage losses for various rotor diameters referred to rotor velocities.

Efficiency. The efficiency of a generator is the ratio of the output to its input. The prime mover must supply the output and, in addition, the sum of all the losses. This is the input

$$\text{Efficiency} = \frac{\text{output}}{\text{input}} = \frac{\text{output}}{\text{output} + \text{losses}} \tag{8-33}$$

8.12 GENERATOR CHARACTERISTICS

The voltage regulation of a dc generator is the ratio of the difference between the voltage at no load and that at full load to the rated-load voltage. The characteristic is normally drooping as the load is increased, but it can rise because of series field effects or the action of circulating currents of communication at very low voltage operation.

For a dc generator, the terminal-voltage equation is

$$TV = E - IR = [K\phi_t)(\text{r/min}) - IR] \tag{8-34}$$

where E is the induced emf, IR is the armature circuit drop, K is a constant depending on the machine design, and ϕt is the total main-pole flux of the generator.

The regulation curves are easily calculated by using the no-load and full-load saturation curves shown in Fig. 8-56. The effect of the excitation method is found by the use of the field and rheostat IR line for self-excited machines and by the constant-ampere-turn line for separate excitation.

A separately excited compensated generator which is shunt-wound will have a voltage-load characteristic which will approach a straight line; it droops to full load an amount equal to the percent IR drop. There is little or no flux loss due to armature reaction or brush shift.

At voltages 10% or less of rated, the main-field strength is so weak that currents circulating in the coils short-circuited by the brushes at commutation may cause an increase in main-pole flux with load that causes a rising characteristic. These armature coils loop the main poles and their ampere-turns produce direct axis flux. A rising voltage characteristic can be undesirable, particularly if the generator supplies a dc motor whose speed is caused to rise with load, since this causes instability.

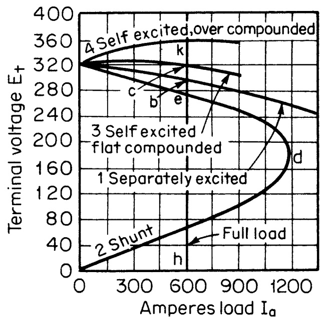

FIGURE 8-56 External characteristics versus excitation methods.

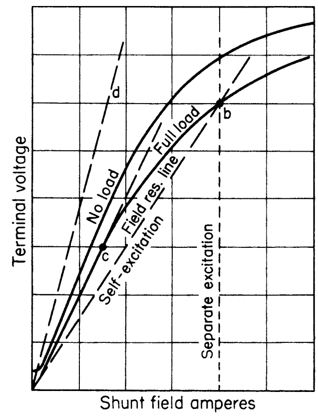

FIGURE 8-57 No-load and field-load saturation curves.

A separately excited noncompensated dc generator which is shunt-wound has a nonlinear loss of flux due to armature reaction as the load current is increased. It can be seen from Eq. (8-35) that this causes a characteristic which droops at an ever-increasing rate with load increase, giving a curve which is concave downward.

A self-excited noncompensated dc generator which is shunt-wound has its shunt-field excitation decreased as the terminal voltage drops. This results in a reduction of main-field ampere-turns and a loss of still more flux. This gives a severe droop which may be so great that, above a certain peak-load current, the terminal voltage will not be high enough to provide enough field current to maintain the voltage and load current and the voltage will collapse, as shown in *d* of Fig. 8-57.

Instability of Self-Excited Generators. A self-excited dc generator is unstable if the rheostat line does not make a definite intersection with the load-saturation curve (see Fig. 8-56). The shunt-field current is fixed by the terminal voltage, and the resistance is in the shunt-field circuit. Instability will exist if the slope of the rheostat line is nearly equal to or greater than the slope of a line tangent to the operating point on the saturation curve. In Fig. 8-57, point *b* is a stable operating condition, but point *c* is not, because a decrease in voltage decreases the shunt field ampereturns, and this produces a further decrease in voltage.

If the field circuit resistance were set at *d*, the self-excited generator would never build up beyond residual voltage. Another cause of failure to build up may be the connection of the shunt field. If the current flow due to residual voltage is such that it tends to kill the flux producing the residual voltage, no buildup occurs.

Compound-Wound DC Generators. The generators described above can be compounded by adding series fields excited by the load current. However, the resulting field strength of these fields is linear with load and the shape of the voltage-regulation curve is not changed thereby but is merely rotated upward or downward with the zero-load point as a pivot.

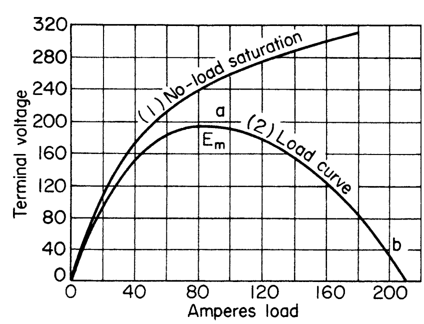

FIGURE 8-58 Characteristic curves of a series generator.

Series Generators. Curve 1 of Fig. 8-58 shows the relation between voltage and current if there is no armature resistance or armature reaction. This is actually the no-load curve of the machine obtained by separately exciting the series field. Curve 2 shows the actual relation between load current and terminal voltage. The total voltage drop is made up of a part caused by the decrease in flux by armature reaction and a part caused by the *IR* drop of the armature, brushes, and series fields.

Field Time Constants. The major delay in change of output voltage by an excitation change is caused by the inductance of the main fields. The time constant of the shunt field is the ratio of its inductance in henries to its resistance in ohms, and this ratio represents the time in seconds required for 63% of a field current change to occur when the excitation voltage is suddenly changed. In the case of the 2500-kW generator, a mean main-field inductance over the voltage range from zero to rated is 6.20 H. The main-field resistance is 2.21Ω. The field time constant is therefore 2.8 s.

The inductance L of a coil is the incremental change of flux linkages per incremental change in field current times 10^8. This is proportional to the slope of the saturation curve and is constant over the air-gap line. It is therefore a decreasing variable after the curve leaves the air-gap line (see Fig. 8-45). The overall inductance, as the voltage builds up from zero, is not so high as that of the air-gap portion or as low as at the rated-voltage point. A common compromise is the slope of a straight line drawn from zero voltage through the full-load point at rated voltage. For the 2500-kW generator the total flux at this point is 112.5×10^6 lines. With a leakage flux of 12%, each coil has a flux of 12.6×10^6 lines (see Table 8-2). As indicated earlier [see Eq. (8-21) and surrounding text], each coil has 192 turns and there are 10 coils in series. The field current is 39.1 A.

$$L = \frac{\phi T}{I_f} \times 10^{-8} = \frac{(12.6 \times 10^6)(192)(10)}{39.1} \times 10^{-8} = 6.2\ \mathrm{H} \qquad (8\text{-}35)$$

$$\text{Time constant} = \frac{L}{R} = 6.2/2.21 = 2.8\ \mathrm{s} \qquad (8\text{-}36)$$

This value is typical for large machines. Smaller generators have less copper in their fields and lower time constants. In cases where drive systems must have very rapid voltage adjustments, it is common to provide large forcing voltages on the field to overcome the inductive lag. These sudden excitation changes may be 4 to 10 times the *IR* drop of the field. This effectively reduces the time constant to one-fourth or one-tenth its normal value.

Armature-Circuit Time Constants. Compensating windings effectively lower the inductances of the armature circuit. The 2500-kW generator developed in this section has an armature-circuit inductance of 0.0001929 H and a circuit resistance of 0.00398Ω for a time constant of 0.048 s. This value is typical for large dc machines. Smaller noncompensated units have longer time constants.

8.13 TESTING

Factory Tests. These depend on the size, application, and design of the dc generator. The American National Standards Institute (ANSI) C50.4 for dc machines includes lists of recommended tests for dc generators and motors. The IEEE Test Code for dc machines covers recommended methods to be used for these tests.

8.14 GENERATOR OPERATION AND MAINTENANCE

General. Despite its rugged construction, a dc machine is a delicate device. Factory tests on large units may cost thousands of dollars and must be performed carefully to adjust the generator to obtain the best possible characteristics and commutation. Owing to shipping requirements, the generator may then have to be disassembled and shipped in several pieces. If the final assembly is not correctly accomplished, not only have the factory tests been wasted but the machine may be damaged.

The manufacturer's instruction book should be studied carefully.

Before Installation. Upon arrival, the generator should be inspected for damage and to be sure it is dry. If it is wet, consult the manufacturer. Drying out with heat should be done only by slowly raising the generator temperature to 100°C so that moisture can escape without forming gas pockets within the insulation.

If the generator is dry and clean, the windings should be checked with a megger for insulation resistance to ground measurements. If any readings less than 1 MΩ are found, check with the manufacturer.

Alignment. After the machines are installed and grouted to the foundations, all couplings should be opened and alignments of all shafts finally checked. Regardless of whether solid or flexible couplings are used, the alignment should be as accurate as possible. The difference between the bottom and the top openings should not exceed 0.002 in for 12 in of flange diameter, and the large opening should be at the top. Regardless of the size of coupling, the difference should not exceed 0.004 in. Differences at the side should not exceed 0.001 in. Shafts should be rotated 180° and rechecked.

The frame should be set on the *magnetic center* of the core. This position can be located by setting the armature in rotation and forcing it to oscillate longitudinally the full end play of the bearing by pushing on the end of the shaft. While the rotor is coasting and oscillating freely, excite the main field. The stator can then be shifted so that the rotor position with excitation coincides with the center of bearing end play.

Air gaps between the rotor and poles should be uniform. A typical limit of variation is 0.010 in. The brushes should ride properly on the commutator surface at both extremes of bearing end play.

Prerunning Checks. The circumferential position of the brushes on the commutator is important for commutation and also to provide the voltage characteristics set at the factory. Brushes should be on the factory test setting. The toes of the brushes should be aligned and should have no skew. The spacing between adjacent arms of brushes should be identical within 0.032 in. The brushes should move freely in their holders and should have a pressure against the commutator of 2 to 3 lb/in^2 on the basis of brush cross section. The faces of the brushes should accurately match the curvature of the commutator surface.

The polarity of the main fields may be checked by tracing the wiring around the frame or by lightly exciting the fields and using a compass around the frame behind the poles.

The oiling system for the bearings should be checked and the oil rings tested for freedom. The entire machine, particularly its air gaps, should be inspected for foreign material.

Running Checks. Note any unusual noise as the unit is brought up to speed. Bearing temperatures should level out at acceptable values within a few hours.

The voltage should be slowly raised at no load and commutation observed. If satisfactory, the voltage should be raised to 110% of rated and then reduced.

The generator may then be loaded gradually while commutation is observed, until rated current is reached. If commutation remains satisfactory until stable temperatures are achieved, the generator is ready for work.

Shunt-Wound Generators in Parallel. *A* and *B* of Fig. 8-59 are two similar generators feeding the same bus bars *C* and *D*. If *A* tends to take more than its share of the total load, its voltage falls and more load is automatically thrown on *B*. Also, if the driver of one of the generators slows down to stop, the emf of the machine falls until the other generator starts to drive it as a motor. This continues until its driver takes over again.

The external characteristics of the two machines are shown in Fig. 8-60. At voltage *E*, the currents in the generators are I_a and I_b, and the line current is $I_a + I_b$. To make machine *A* take more of the load, its excitation must be increased to raise its characteristic curve. If a 1000-kW generator and a 500-kW machine have the same regulation curves, the machines will divide the load according to their respective capacities, as shown in Fig. 8-61.

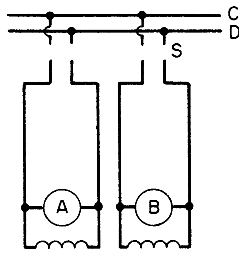

FIGURE 8-59 Shunt generators in parallel.

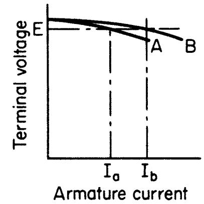

FIGURE 8-60 External characteristics of two shunt-wound generators in parallel.

Compound-Wound Generators in Parallel. *A* and *B* of Fig. 8-62 are two compound-wound machines. If *A* tends to take more than its share of the load, the series excitation of *A* increases, its voltage rises, and it takes still more of the load. Thus, the operation is unstable. If this continues until *A* takes all the load and the voltage of *B* drops to the point that *A* reverses the current in *B*, *B* will be driven as a motor. With the reversed current in the series field of *B* it becomes a differentially compounded motor, and the series weakens the flux to speed up the motor. This may progress to a point at which the unit may be damaged mechanically and electrically.

To prevent this, a bus bar of large section and of negligible resistance, called an *equalizer bus*, is connected from *e* to *f* (Fig. 8-62). Points *e* and *f* are then practically at the same potential. Therefore, the current in each series coil is independent of the current in its particular generator, is inversely proportional to the resistance of the coils, and is always in the same direction.

When a single compound generator has too much compounding, a shunt in parallel with the series field coils will reduce the current in these coils and so reduce the compounding. When compounded generators are operating in parallel using an equalizer bus, the current in the series field coils depends only on the resistance of the coils and a shunt connected across one of them is actually across all of them, reducing the compounding of all but not disturbing the relative compounding between the machines. To reduce the compounding of a single machine, it is necessary to place a resistance in series with the coils. This may require a large resistor to handle the large load current it must carry.

Maintenance. Except for the commutator and its brushes, maintenance of dc machines differs little from that of other rotating electrical machines. Proper lubrication must be provided for the bearings, and the machine must be kept clean and dry. In addition, the brushes should be checked periodically for commutation, riding ability, freedom of motion in the holders, pressure, and length.

Because the commutator necks are not insulated and receive full voltage, conducting dust from brush wear or from ventilating air can cause creepage currents between the risers and ground over insulated surfaces. To avoid this, the dc generator must be cleaned and blown out with clean, dry air at regular intervals. Air pressures above 25 lb/in^2 should not be used because of the danger of lifting the edges of insulating tape. The effectiveness of the cleaning program should be verified occasionally by megger readings.

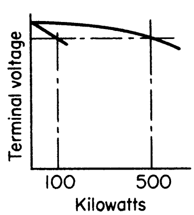

FIGURE 8-61 Division of load between two shunt generators in parallel.

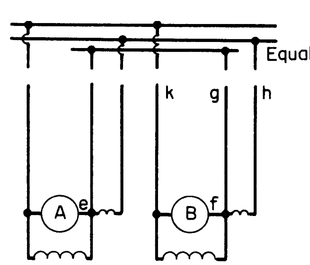

FIGURE 8-62 Compound generators in parallel.

Poor Commutation. Sparking and bar burning are usually due to one or more of the following causes:

1. *Brushes not in the proper position.*
2. *Incorrect spacing of brushes*. This may be checked by marking an adding-machine tape around the commutator.
3. *Projecting-bar-edge mica*. Mica between bars should be undercut about 0.063 in below the commutating surface, but occasionally slivers of mica are left inadvertently along the bar.
4. *Rough or burned commutator*. The commutator should be ground according to the manufacturer's instruction book.
5. *Grooved commutator*. This may be prevented by properly staggering the brush sets so that the spaces between the brushes of an arm are covered by brushes of the same polarity of other arms.
6. *Poor brush contact.* This is due to improper fitting of the brushes to the commutator surface. To seat the brushes, sandpaper should be moved between the commutator and the brush face. Emery cloth should not be used because its abrasive is conducting.
7. *Worn brushes replaced by others of wrong size or grade.*
8. *Sticking brushes.* These brushes do not move freely in their holders so that they can follow the irregularities of the commutator.
9. *Chattering of the brushes*. This is usually due to operation at current densities below 35 A/in^2 and must be corrected by lifting brushes to raise the density or by using a special grade of brush.
10. *Vibration*. This may be due to poor line up, inadequate foundations, or poor balance of the rotor.
11. *Short-circuited turns on the commutating or compensating fields*. These may be obvious on inspection but usually must be found by passing ac current through them for voltage-drop comparisons.
12. *Open or very high resistance joints between the commutator neck and the coil leads.* In this case, the bar at the bad joint will usually be burned.
13. *An open armature coil*. A broken coil conductor produces an effect similar to that produced by the poor joints described in the previous item. For emergency operation, the open coil may be opened at both ends, insulated from the circuit, and a jumper placed across the two affected necks. Since some sparking will probably result, operation should be limited.
14. *Short-circuited main-field coils*. With the resulting unbalanced air-gap fluxes under the poles, large circulating currents must be expected even with good armature cross connections. The offending coil may be found by comparing voltage drops across the individual coils.
15. *Reversed main-field coil*. This is an extreme case of the one described in the previous item.
16. *Overloading*.

8.15 SPECIAL GENERATORS

General. The adaptability of the dc generator for specific uses has led to the development of many special generators. These machines over the years made a significant contribution to industrial progress. However, most of these special applications have disappeared or are now being met with other devices such as silicon controlled rectifiers or programmed control of field currents to the main dc generator.

Synchronous Converters. Of all the special generators, this was one of the earlier and most widely used. It was the principal dc power source for streetcars and interurban lines. It was a most ingenious device, combining in a single armature and winding an ac motor taking its current from the lines through slip rings at the rear and a dc generator providing dc power from a commutator on the front

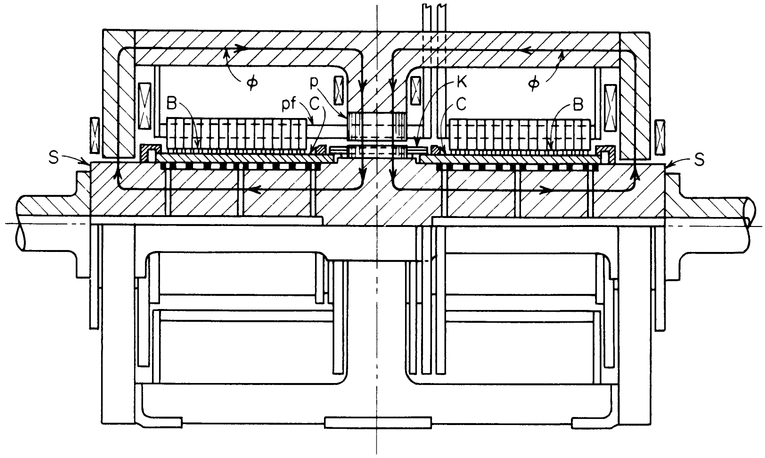

FIGURE 8-63 Brush-type homopolar generator.

end. Because the flow of the currents was in opposition, the resulting rotor winding could be small in cross section. A single stator provided flux for both functions. With the decline of street railway systems, the synchronous converter disappeared.

Rotating Regulators. These dc machines had trade names like Rototrol, Regulex, and Amplidyne. They, too, have been replaced by solid-state devices. In addition to having fields for feedback intelligence, response was enhanced using self-excited shunt fields tuned to the air-gap line or by means of cross-magnetization from armature reaction.

Three-Wire Devices. Because three-wire dc circuits are no longer in use, balancer sets and three-wire generators are relics in school labs or museums.

Homopolar or Acyclic DC Generators. The single-pole machine principle still fascinates electrical engineers and several research and development labs continue to study new arrangements of its basic parts. Fundamentally, it consists of a single conductor moving through a uniform single-direction flux with a collector at each end of the conductor. The output is a steady ripple-free pure dc current and no commutation. Currents reaching 270,000 A at 8 V were provided by one commercial unit shown in Fig. 8-63. Recent efforts have been mainly to use liquid metals to take the large currents from the rotating collectors and to obtain higher voltages by connecting units in series. Some success has been possible, but restricting the sodium potassium to the collector area has proved difficult.

SECTION 9
HYDROELECTRIC POWER GENERATION

U.S. Army Corps of Engineers
Hydroelectric Design Center

CONTENTS

9.1 GENERAL

9.1.1 Introduction

Hydropower is produced when kinetic energy in flowing water is converted into electricity. Hydropower has been a significant source of electrical energy in the United States since the early 1900s when manufacturers recognized and harnessed its tremendous potential to develop and build entire industries. Traditionally, hydropower has been a low-cost, reliable energy source. It utilizes a renewable fuel (water) that can be sustained indefinitely, and is free of fossil fuel emissions. And because hydroelectric generators are especially suited for providing peaking power, hydropower complements thermal generation and improves overall power production efficiency. Hydroelectricity presently constitutes approximately 10 percent of the United States' energy supply, which is enough to meet the needs of 28.3 million consumers.

9.1.2 Notations

a = celerity or speed of sound in water, feet/second

BOD = biological oxygen demand, parts per million/day

D = Winter-Kennedy piezometric pressure differential, feet

DO = dissolved oxygen, parts per million

E = specific energy, foot-pounds (force)/pound (force)

E_{rel} = relative efficiency, kilowatts/feet$^{1/2}$

E_t = turbine efficiency, percent or decimal

$E_{t\text{-}g}$ = combined turbine-generator efficiency, percent or decimal

G = local acceleration of gravity, feet/second^2

H = total net head or total dynamic head, feet

H_b = barometric pressure head, feet

H_d = design head (head of best efficiency), feet

HP = turbine output, horsepower

H_0 = initial piezometric head, feet

K = radius of gyration, feet

kW = generator output, kilowatts

L = length of water conduit, feet

MW = generator output, megawatts

MVA = generator or transformer capacity, megavolts-amperes

MVAR = generator output, reactive, megavars

N = rotational speed, revolutions/minute

N_s = specific speed, revolutions/minute-horsepower$^{1/2}$/head$^{5/4}$

Q = volumetric flow rate, feet^3/second

Q_{20} = 20 percent flow exceedence (time flow value is exceeded), percent

Q_{30} = 30 percent flow exceedence (time flow value is exceeded), percent

T or t = time, seconds

V = flow velocity, feet/second

V_0 = initial flow velocity, feet/second

W = weight, pounds (force)

WK^2 = angular inertia, pound-feet^2

γ = specific weight of water, pounds/foot^3

9.1.3 Nomenclature

The following terms are commonly used to describe hydroelectric equipment, facilities, and production:

Afterbay (tailrace). The body of water immediately downstream from a power plant or pumping plant.

Appurtenant structures. Intakes, outlet works, spillways, bridges, drain systems, tunnels, towers, etc.

Auxiliary power. The electric system supply to motors and other auxiliary electrical equipment required for operation of a generating station.

Base loading. Running water through a power plant at a roughly steady rate, thereby producing power at a steady rate.

Base load plant. Powerplant normally operated to take all or part of the minimum load of a system, and which consequently runs continuously and produces electricity at an essentially constant rate. Operated to maximize system mechanical and thermal efficiency and minimize operating costs.

Bulkhead. A one-piece fabricated steel unit that is lowered into guides and seals against a frame to close a water passage in a dam, conduit, spillway, etc.

Bulkhead gate. A gate used either for temporary closure of a channel or conduit before dewatering it for inspection or maintenance or for closure against flowing water. Bulkhead gates nearly always operate under balanced pressures.

Cavitation damage. Pitting and wear damage to solid surfaces (e.g., the blades of a hydraulic turbine) caused by the implosion of bubbles of water vapor in fast-flowing water.

Cofferdam. A temporary barrier, usually an earthen dike, constructed around a worksite in a reservoir or on a stream. The cofferdam allows the worksite to be dewatered so that construction can proceed under dry conditions.

Crest. The top surface of a dam or high point of a spillway control section.

Dam. A concrete and/or earthen barrier constructed across a river and designed to control water flow or create a reservoir.

Dewater (unwater). To drain the water passages and expose the turbine runner. Generally requires closing of an isolation valve or lowering of the headgates, and opening of the penstock drain valves.

Draft tube. Part of the powerhouse structure designed to carry the water away from the turbine runner.

Fish bypass system. A system for intercepting and moving fish around a dam as they travel downriver toward the ocean.

Fish ladders. A series of ascending pools constructed to enable salmon or other fish to swim upstream around or over a dam.

Fish screen. A screen across the turbine intake of a dam, designed to divert the fish into a bypass system.

Fish passage facilities. Features of a dam that enable fish to move around, through, or over without harm. Generally an upstream fish ladder or a downstream bypass system.

Forebay (headrace). The body of water immediately upstream from a dam or hydroelectric plant intake structure.

Generator. The machine that converts mechanical energy into electrical energy.

Head. The difference in elevation between two specified points, for example, the vertical height of water in a reservoir above the turbine.

High-head plant. A powerplant with a head over 800 ft.

Hydraulic losses. Energy loss in water passages primarily due to velocity losses at trash racks, intakes, transitions, and bends, and friction losses in pipes.

Intake. The entrance to a conduit through a dam or a water conveyance facility.

Intake structure. The concrete portion of an outlet works including trashracks and/or fish screens, upstream from the tunnel or conduit portions. The entrance to an outlet works.

Low-head plant. A powerplant with a head less than 100 ft.

Medium-head plant. A powerplant with a head between 100 and 800 ft.

Multipurpose project. A project designed for two or more water-use purposes. For example, any combination of power generation, irrigation, flood control, municipal and/or industrial water supply, navigation, recreation, and fish and wildlife enhancement.

Operating rule curve. A curve, or family of curves, indicating how a reservoir is to be operated under specific conditions and for specific purposes.

Outlet works. A combination of structures and equipment located in a dam through which controlled releases from the reservoir are made.

Peaking plant. A powerplant in which the electrical production capacity is used to meet peak energy demands. The site must be developed to provide storage of the water supply and such that the volume of water discharged through the units can be changed readily.

Penstock. A pipeline or conduit used to convey water under pressure from the supply source to the turbine(s) of a hydroelectric plant.

Pool. A reach of stream that is characterized by deep, low velocity water and a smooth surface.

Powerhouse. Primary structure of a hydroelectric dam containing turbines, generators, and auxiliary equipment.

Pumped storage plant. Powerplant designed to generate electric energy for peak load use by pumping water from a lower reservoir to a higher reservoir during periods of low energy demand using inexpensive power, and then releasing the stored water to produce power during peak demand periods.

Reservoir. A body of water impounded in an artificial lake behind a dam.

Runoff. Water that flows over the ground and reaches a stream as a result of rainfall or snowmelt.

Run-of-the-river plant. A hydroelectric powerplant that operates using the flow of a stream as it occurs and having little or no reservoir capacity for storage or regulation.

Single-purpose project. A project in which the water is used for only one purpose, such as irrigation, municipal water, or electricity production.

Spill. Water passed over a spillway without going through turbines to produce electricity. Spill can be forced, when there is no storage capability and stream flows exceed turbine capacity, or planned, for example, when water is spilled to enhance downstream fish passage.

Spillway. The channel or passageway around or over a dam that passes normal and/or flood flows in a manner that protects the structural integrity of the dam.

Standby power. Frequently provided as a backup for operating gates and valves in the event the principal power supply (usually electrical) fails. Includes engine-driven-generators or hydraulic oil pumps, each of which could be powered by gasoline, diesel, or propane, and power takeoffs on trucks or tractors. On small-sized gates or valves, the standby power is often hand-operated, such as a hand pump or crank.

Stoplogs. Large logs, planks, steel or concrete beams placed on top of each other with their ends held in guides between walls or piers to close an opening in a dam, conduit, spillway, etc., to the passage of water. Used to provide a cheaper or more easily handled means of temporary closure than a bulkhead gate.

Storage reservoir. A reservoir having the capacity to collect and hold water from spring time snowmelts. Retained water is released as necessary for multiple uses such as power production, fish passage, irrigation, and navigation.

Surge tank. A large tank, connected to the penstock, used to prevent excessive pressure rises and drops during sudden load changes in plants with long penstocks.

Switchyard. An outdoor facility comprised of transformers, circuit breakers, disconnect switches, and other equipment necessary to connect the generating station to the electric power system.

Tailrace. See Afterbay.

Tailwater. The water in the natural stream immediately downstream from a dam.

Transformer. An electromagnetic device used to change the magnitude of voltage or current of alternating current electricity or to electrically isolate a portion of a circuit.

Trashrack. A metal or reinforced concrete structure placed at the intake of a conduit, pipe, or tunnel that prevents large debris from entering the intake.

Trashrake (trash rake). A device that is used to remove debris, which is collected on a trashrack to prevent blocking the associated intake.

Turbine, hydraulic. An enclosed, rotary-type prime mover in which mechanical energy is produced by the force of water directed against blades or buckets fastened in an array around a vertical or horizontal shaft.

Turbine runner (water wheel). The rotor-blade assembly portion of the hydraulic turbine where moving water acts on the blades to spin them and impart energy to the rotor.

Unwater. See Dewater.

Wicket gates. Adjustable gates that pivot open around the periphery of a hydraulic turbine to control the amount of water admitted to the turbine.

9.2 HYDROELECTRIC POWERPLANTS

To determine the optimal location, size, and layout of a hydroelectric powerplant, numerous factors must be considered including the local topography and geologic conditions, the amount of water and head available, power demand, accessibility to the site, and environmental concerns. The overriding consideration in the design of a hydroelectric powerplant is that it adequately perform its function and is structurally safe.

9.2.1 Principal Features

The principal features of a hydroelectric facility are the dam, reservoir, spillway, outlet works, penstocks, powerhouse, fish passage facilities (if fish protection is required), surge tanks, and switchyard. Most hydroelectric powerplants are located at or immediately adjacent to a dam. Some plants, however, are located away from the dam, such as at the lower end of a pressure penstock, power tunnel, or power canal, or at a drop in an irrigation canal. In general, a powerplant is situated so that the penstocks will be as short as practicable in order to minimize the cost of the penstocks and the associated hydraulic losses, and to avoid the necessity for surge tanks.

Hydropower developments can be classified as either low-, medium-, or high-head projects. Figure 9-1 shows in outline the most common arrangements, and illustrates some of the features listed in the Sec. 9.13 for the various developments. Other sources of hydropower involve the use of ocean waves or tidal changes to generate electricity. These technologies are not as well developed as the more conventional hydropower sources and are not covered in this chapter.

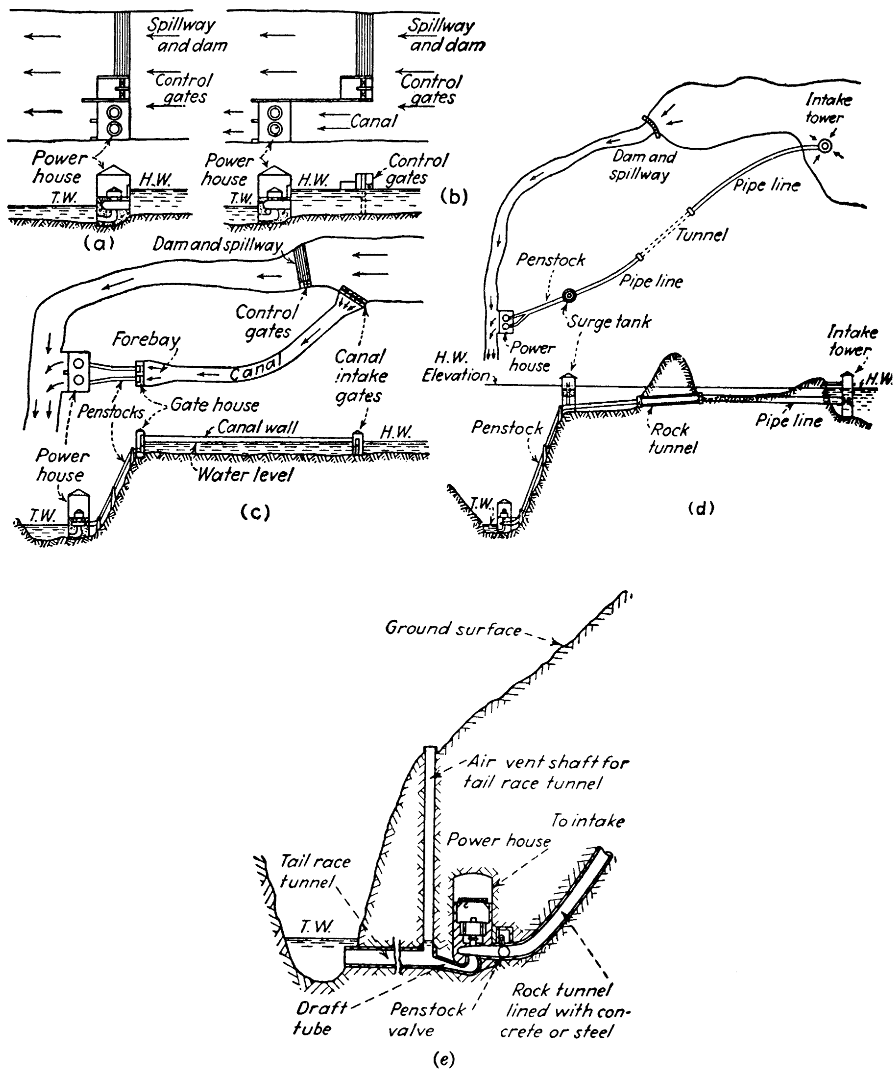

FIGURE 9-1 Outline sketches of several typical hydropower developments: (*a*) low-head development with dam, spillway, and powerhouse as an integral unit; (*b*) low-head development with a short intake canal and powerhouse separate from the dam; (*c*) medium-head development with a long intake canal, gatehouse, and penstocks connecting the forebay with the powerhouse; (*d*) high-head development with a large storage reservoir, pipeline, and tunnel leading to a surge tank at the upper end of the penstocks—powerhouse at the lower end of the penstocks is a considerable distance from the dam and spillway; (*e*) outline sketch of underground powerplant, showing penstock and tailrace tunnels.

9.2.2 Powerhouse Structure

The powerhouse foundation and superstructure contain the hydraulic turbine, water passages including draft tube, passageways for access to the turbine casing and draft tube, and sometimes the penstock valve. The superstructure also typically houses the generator, exciter, governor system, station service, communication and control apparatus, and protective devices for plant equipment and related auxiliaries as well as the service bay, repair shop, control room, and offices. The transformers and switchyard are usually located outdoors adjacent to the powerhouse and are not an integral part of it. Cranes are provided in the powerhouse to handle the heaviest pieces of turbine and generator and sometimes extend over the penstock valves. Alternative powerhouse designs have included separate cranes for the penstock valves. Another common powerhouse design is the outdoor type where the operating floor is placed adjacent to the turbine pits with the generator located outdoors on the roof of a one-story structure. In the outdoor type, each generator is protected by a light steel housing, which is removed by the outdoor gantry crane when access to the machine is necessary for other than routine maintenance. The erection and repair space is in the substructure and has a roof hatch for equipment access. The outdoor design reduces initial construction costs of the powerplant. However, the choice of indoor, semi-outdoor, or outdoor type is dictated not only by consideration of the initial cost of the structure with all equipment in place, but also by the cost of maintenance of the building and equipment, and protection from the elements.

9.2.3 Switchyard

To provide a reliable and flexible interface between the generating equipment and the power grid, a switchyard is usually associated with a hydroelectric powerplant. Switchyards include all equipment and conductors that carry current at transmission line voltages, including their insulators, supports, switching equipment, and protective devices. The system begins with the high-voltage terminals of the step-up transformer and extends to the point where transmission lines are attached to the switchyard structure. Switchyards are typically sited to be as close to the powerplant as space permits in order to minimize the length of control circuits and power feeders, and also to enable the use of service facilities in the powerhouse.

9.3 MAJOR MECHANICAL AND ELECTRICAL EQUIPMENT

Much of the major mechanical and electrical equipments installed in hydroelectric powerplants may be found in other generating, transmission, and distribution systems. Conventional types of power equipment are described in detail in other chapters of this handbook. In some cases, however, specialized equipment has been developed for hydropower applications. The following information is intended to emphasize equipment or configurations that are unique to hydropower facilities:

9.3.1 Turbines

The word “turbine” comes from Latin and means *spinning top*. Technically, hydraulic turbines that drive electric generators are called hydraulic prime movers. Whatever name is used, all hydraulic turbines convert fluid power into mechanical power by the same physical principle. They develop their mechanical power via the rate of change of angular momentum of the fluid. In most cases, the head is used to impart an angular momentum or prewhirl to the fluid. The action of the turbine runner is to remove this angular momentum or to straighten out the fluid streamlines. The effect of this change in angular momentum is to induce a torque on the shaft of the runner. The speed of rotation is the rate at which this angular momentum is changed, and torque multiplied by rotational speed is mechanical power.

The relative proportions of power transferred by a change of static pressure and by a change in velocity provide the most basic method of classifying turbines. The ratio of this transfer by means of a change in static pressure to the total change in the runner is called the degree of reaction, or more simply reaction. Therefore, if there is any significant pressure change in the runner of a turbine, it is a *reaction* hydraulic turbine. If there is no change in pressure, only in velocity, the degree of reaction is zero and these special cases are called *impulse* hydraulic turbines.

Aside from the most basic category as reaction or impulse, hydraulic turbines are classified in two separate ways—by the type of runner and by the configuration of the water passages. For reaction

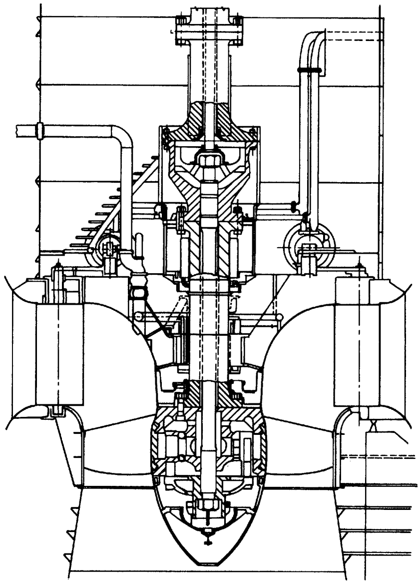

FIGURE 9-2 Sectional elevation of an adjustable-blade propeller (Kaplan) turbine.

turbines, there are different classifications of runners—axial, radial, and mixed. These terms denote whether the flow enters the runner parallel or perpendicular to the shaft, or at some angle in between. In modern reaction turbines, the flow leaves the runner axially.

For the lowest head applications, reaction turbines with propeller type runners are utilized. These may be *fixed blade* or if the pitch angle of the blades can be adjusted, they are called *Kaplans* (Fig. 9-2). In propeller turbines, the fluid enters and leaves the runner axially; therefore, these are axial flow machines. The ability to change the pitch angle maintains high efficiency over a wider power range. This is because as the flow rate is increased, or the head is increased, the velocity vector or the angle at which the fluid streamlines enter the runner gets steeper. Therefore, if the angle of leading edge of the blades is increased to remain aligned with the steepened fluid velocity vector, a higher efficiency is maintained. A cam in the governor that positions the blades based on the wicket gate opening controls the pitch angle of the blades. There are different cams for different increments of head. However, if instead of increments of head, the cam is also continuous in head; this is referred to as a *3-D cam*—the three dimensions being blade angle, wicket gate opening, and head.

A variation of the propeller design where the blades are not mounted perpendicular to the shaft, but at a downward or dihedral angle is the *diagonal* or *Deriaz* turbine. This arrangement transforms the runner into a mixed flow runner. The principle advantage in this arrangement is that it allows higher permissible operating heads.

Propeller, and especially Kaplan, turbines require a considerable amount of submergence under the tailwater elevation as they are prone to cavitation. In a Kaplan, maximum runaway speed occurs when the blades are full flat. (Full flat blade runaway speed can approach 300% of synchronous speed.) In order to minimize the runaway speed, the blades are normally hydraulically designed to drift to a full steep angle upon loss of governor oil pressure. However, maximum discharge at runaway speed is with the blades full steep (up to 150% of maximum discharge at synchronous speed).

A recent modification of the traditional Kaplan design is called a *minimum gap runner* (MGR). In this design, gaps between the blades and runner hub are hydraulically hidden and the discharge ring is a spherical cavity rather than a cylindrical cavity to minimize the gaps at the outer edge of the blades at steeper angles. The purpose of minimizing these gaps is to reduce injury to downstream migrating fish that will pass through the turbines.

For intermediate head applications, the most commonly used reaction turbine is the *Francis* turbine (Fig. 9-3). Depending on the exact shape of the inlet to the buckets, this may be a mixed or radial flow runner. A Francis runner looks somewhat like the impeller of a centrifugal pump. It has no adjustable or moveable parts. Unlike propeller or Kaplan turbines, where flow increases with runaway speed, Francis turbines tend to choke or reduce the flow with runaway speed. This characteristic can produce unwanted pressure rises in the penstock immediately following a load rejection (i.e., the loss of an electrical load).

For the highest head applications, the preferred choice is an impulse turbine. There are a number of different designs of impulse turbine runners. The most common is the *Pelton* (Fig. 9-4). In this design, jets discharge directly into buckets mounted around the periphery of a runner, which is housed in an atmospherically vented casing. Because the runner is at atmospheric pressure, impulse turbines are not subject to cavitation. The jet strikes a splitter in the middle of the bucket, which divides the jet in two. Each half of the jet turns almost a full 180° in the bucket and then falls free.

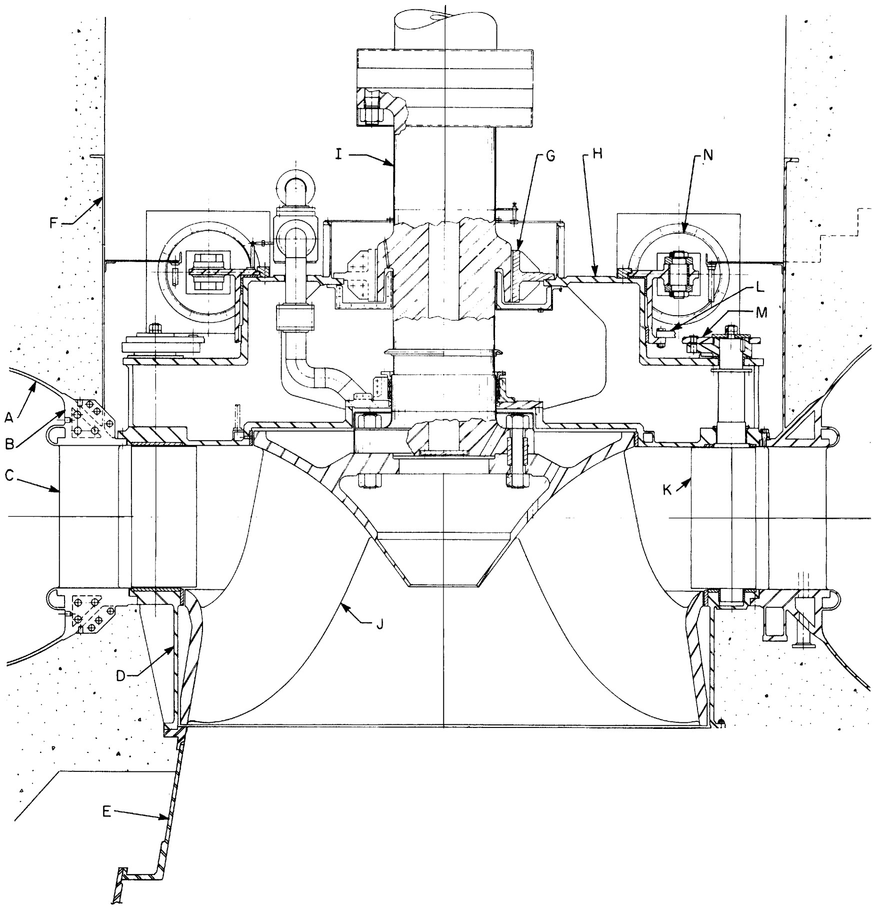

FIGURE 9-3 Sectional elevation of a Francis reaction turbine: A—spiral case; B—stay ring; C—stay vane; D—discharge ring; E—draft tube liner; G—main-shaft bearing; H—head cover; I—main shaft; J—runner; K—wicket gates; L—links; M—gate levers; N—servomotors.

The jet discharge is throttled or controlled by needle valves. Since this provides for a wide range of discharge from an individual nozzle and since multiple nozzles may be used on the same runner, Peltons can have a high efficiency over a very wide power range. If the shaft is mounted in the vertical, any practical number of nozzles can be used. However, if the shaft is horizontal, only two or three nozzles can be used. This is because of the need for gravity to clear the water from a bucket before the jet from the next nozzle strikes it.

A variation of the basic Pelton design is the *Turgo* impulse turbine. In this design, the jets strike the buckets at a side angle and discharge out the opposite side. The buckets do not have a splitter. The advantage is that this design allows larger nozzles with higher flow rates to be used for a given diameter of wheel.

Another design of impulse turbine is the *cross-flow* turbine. Today's cross-flow designs are developed from an earlier version called the *Banki* or *Michell* turbine. The name cross-flow comes from the action of the fluid to enter the vanes on one side of the horizontally mounted cylindrical runner and purported travel across the interior center and out the vanes on the other side. In point of fact, research has shown that the water actually rides around the periphery of the runner in the vanes until it can

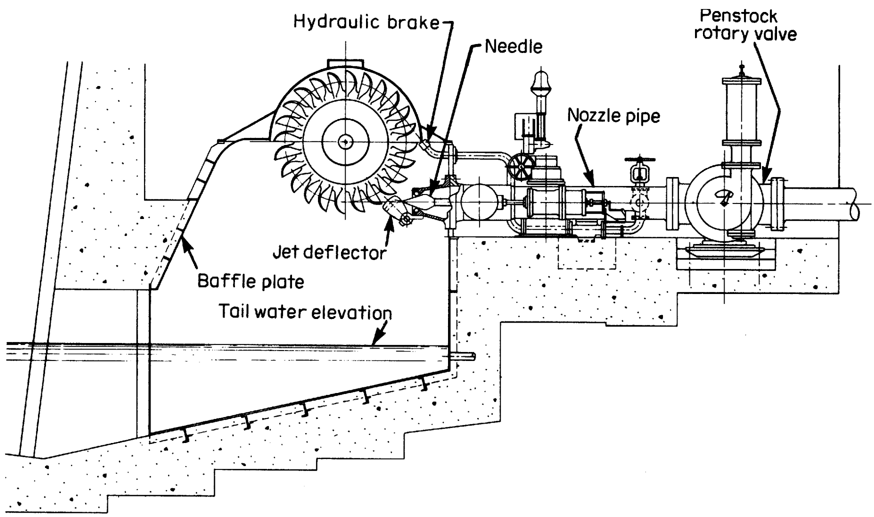

FIGURE 9-4 Section through a horizontal impulse turbine.

discharge out the other side. The principal advantages of this design are that it can operate at much lower heads than a Pelton and has a very wide range of flows. The wide flow range is achieved by dividing the runner into compartments. One commercial cross-flow turbine advertises a flow range of 16% to 100%. This is on the order of at least twice the flow range available from reaction turbines.

One significant difference between reaction and impulse turbines is that reaction turbines have draft tubes to convey the discharge from the runner to the tailrace. A draft tube is actually a conical diffuser, in which the cross-sectional area continually expands with distance along the centerline. The purpose of a draft tube is twofold. The first is to confine the high velocity discharge under the runner so that the static pressure may be below atmospheric. This increases the head across the runner. The second is to slow that high velocity prior to discharge into the tailrace. As a consequence of slowing the velocity, the pressure is recovered. For this latter reason, draft tubes are sometimes referred to as pressure recovery devices.

Aside from the different types of runners, turbines are classified by the different configurations of their water passages. Reaction turbines typically have vertical shafts. The runners of propeller type turbines with vertical shafts are surrounded by a circular water passage called a semispiral case. This is generally formed by concrete and fed with water directly from the forebay through intake bays. Francis turbine runners are surrounded by a full spiral case and, because of the higher head and increased water pressure, this is generally formed from rolled steel plate and then embedded in concrete. Water is generally conveyed to these spiral cases through penstocks. Typically, just upstream of the turbine there is a shut-off or isolation valve in the penstock. When this valve is closed, the turbine can be dewatered. Spiral cases supply water to circular sets of wicket gates and stay vanes in what is called the distributor section. The wicket gates control the rate of flow. The principal purpose of the stay vanes, however, is structural rather than hydraulic. They are used to transfer the vertical load of the weight of the upper powerhouse structure to the powerhouse foundation. Stay vane design may improve the efficiency of the turbine by providing smooth transition of flow to the turbine runner. With a vertical shaft, the beginning of the draft tube under the runner is pointed downward. In order to minimize the amount of required excavation, draft tubes are often constructed with an elbow to turn them horizontal about mid length and these are called elbow draft tubes.

To reduce excavation and cofferdam costs, low head units may have horizontal or inclined shafts. The water passages for horizontal or inclined shafts have less severe bends and turns and, therefore, tend to have lower hydraulic losses and higher efficiency. A common horizontal shaft configuration is to house the generator upstream of the runner in a submarine-like bulb. These are called *bulb* turbines, even though the runners are usually conventional fixed blade propeller or Kaplan types (Fig. 9-5). A variation on this design is to house the upstream generator in a concrete silo with the water passages on either side. This is called a *pit* turbine. Pit turbines typically use speed-increasing gearboxes to reduce the size of the generator. Rather than the generator being upstream, the shaft may extend downstream, either horizontally or inclined at an upward angle. In these configurations, the shaft can extend through the draft tube liner so that the generator is not housed inside the water passages. Whether the shaft is horizontal or inclined, these are referred to as *tubular* turbines (Fig. 9-6). There is even a design where the generator is housed around the periphery of the runner, called a *rim* turbine.

Due to the higher head, water is conveyed to impulse turbines through penstocks. The runners of most impulse turbines rotate in some type of splash containing housing. Since the runners of impulse turbines are vented and operate at atmospheric pressure, they must be set at an elevation higher than the maximum tailwater elevation to avoid being flooded out. The discharge is conveyed to the tail-race through some type of open surface canal or tunnel.

9.3.2 Generators

A hydraulic turbine converts the energy of flowing water into mechanical energy; a hydroelectric generator converts this mechanical energy into electricity. Almost all hydroelectric generators are synchronous alternating-current machines with stationary armatures and salient-pole rotating field structures. The stationary armature (stator) is comprised of a steel core encircled by a frame that is mounted to the powerplant foundation. A 3-phase armature winding, in which the alternating current is generated, is embedded in the stator core. The three phases of the armature winding are Y-connected at the neutral end. The rotating magnetic field is typically produced via a direct current–excited winding connected to an external excitation source through slip rings and brushes. An amortisseur winding is often mounted on the rotor poles to dampen out mechanical oscillations that may occur during abnormal conditions. The stators of hydroelectric generators usually have a large diameter armature compared to other types of generators, and can exceed 60 ft. The capacity of hydroelectric generators may range from a fraction of an MVA to more than 800 MVA. Hydroelectric generators are typically air-cooled, although the stator windings of the highest-capacity machines may be directly water-cooled.

The electrical and mechanical design of each hydroelectric generator must conform to the electrical requirements of the power transmission and distribution system to which it will be connected and also to the hydraulic requirements if its specific plant. Such constraints have made it impossible to standardize the size or capacity of hydroelectric generators. The rotational speeds of the generator and turbine are usually the same because their shafts are directly connected. In some cases, however, a speed increaser (gearbox) is used to enable the generator to operate at a higher speed than that of the turbine, thus permitting a smaller and less expensive generator to be used. Hydrogenerators are relatively low-speed machines, typically ranging from 50 to 600 revolutions per minute (rpm). Large diameter units with a lower hydraulic head operate at slower speeds, whereas physically smaller units with high hydraulic head operate at higher speeds. The best speed for each type of turbine is first established, and a generator is then designed that will produce 60 cycle alternating current at that speed. For a generator operating in a 60-Hz system, the rotational speed (in rpm) times the number of field poles on the rotor is always 7200. Hydroelectric generators are normally vertical shaft machines, although some smaller units are mounted horizontally.

9.3.3 Governors

Almost all hydraulic turbine generator units run at a constant speed. The governor keeps each unit operating at its proper speed through a high pressure hydraulic system that operates wicket gates which control water flow into the turbine. When there are load changes or disturbances in the power grid, the governors respond by increasing or decreasing power output of the generating units to meet power demands and keep the frequency of the power grid at 60 cycles. Governor-operating characteristics will be determined from the electrical, mechanical, and hydraulic characteristics of

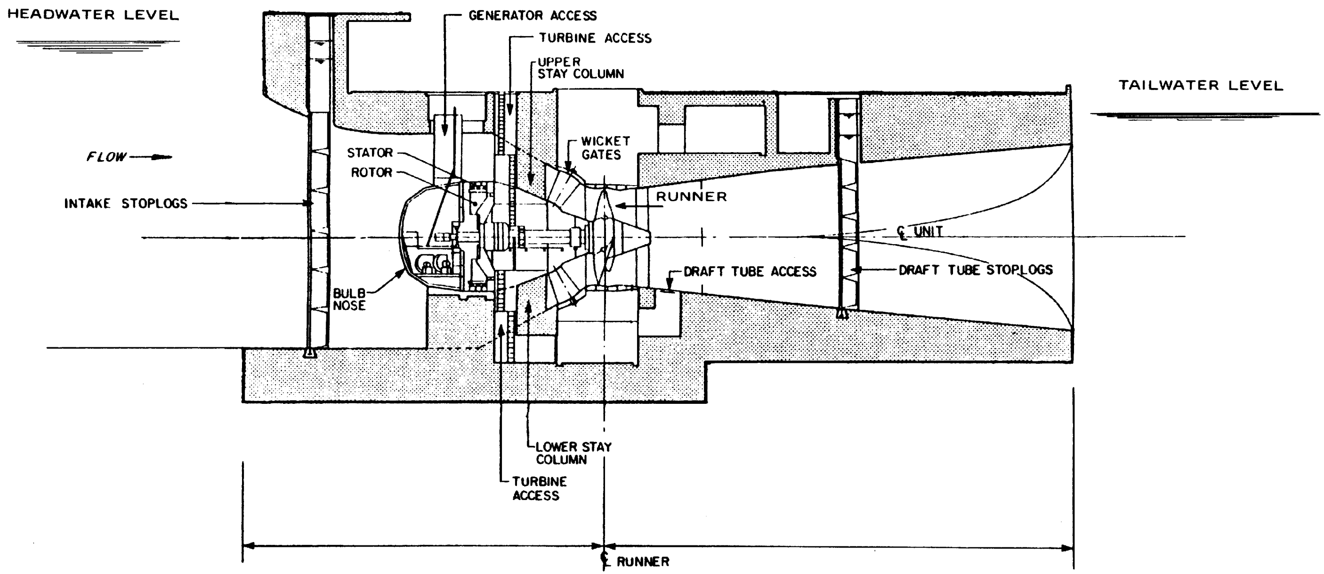

FIGURE 9-5 Sectional elevation of an axial-flow (bulb) turbine.

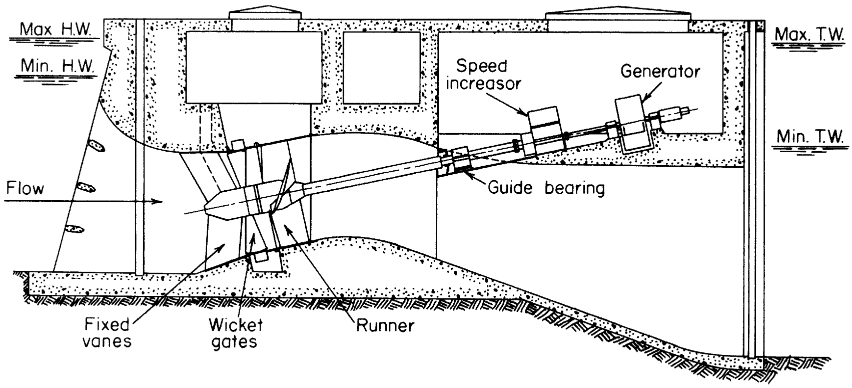

FIGURE 9-6 Sectional elevation of an axial-flow (tubulas) turbine.

the generator, turbine, and penstock. Older governors use mechanical speed sensing and control, interfaced to the hydraulic system to govern turbine speed. Newer systems incorporate electronic or digital speed sensing and controls with a hydraulic interface to the turbine governor.

9.3.4 Excitation Systems

The function of the excitation system is to supply direct current to the field winding of the main generator. This current is used to create the rotating magnetic field necessary for generator action. Control of the current in the field winding must be accurate, sensitive, and reliable to allow stable and economic operation of the generator. All excitation systems include an exciter, a voltage regulator, generator voltage and current transformers, and limiters and protective circuits. The exciter may be a rotating type that is directly connected to the generator shaft or a modern static system utilizing solid-state devices fed from a high-voltage bus.

9.3.5 Circuit Breakers

A circuit breaker is a mechanical switching device, capable of making, carrying, and interrupting current during normal operating conditions as well as under specified abnormal conditions, such as during a short circuit. Circuit breaker ratings and location are considered during the preliminary design of a powerplant to meet the switching flexibility and protection requirements of the generators, transformers, buses, transmission lines, etc. Generators at large multi-unit powerplants are commonly configured so that a dedicated unit breaker is situated between the phase terminals of each generator and the main step-up transformer. Smaller plants may only have provision for switching via a switchyard breaker on the high voltage side of the step-up transformer, the generator and transformer being connected and disconnected to the transmission network as a unit. In some cases, circuit breakers are used to perform switching between a main and transfer bus in the switchyard. A variety of switching schemes are possible and commonly used, depending on the local requirements and economic considerations. The ratings, design, construction, and operation of circuit breakers installed at hydroelectric powerplants are generally similar to those used in other power system applications.

9.3.6 Transformers

Most dams and associated hydroelectric powerplants are located a great distance from population centers; therefore, the economics of transmitting power over long transmission lines must be considered. Traditionally, hydro generation has been in the medium voltage range, or about 15 kV. Power transformers step the voltage up to the 100 to 500 kV range for a more economical transmission from the powerplant by minimizing transmission line losses.

Transformers associated with hydroelectric generation may differ somewhat from those used in transmission and distribution applications. For example, it is not uncommon for a single step-up transformer to accommodate multiple hydro generators. To maintain fault isolation between generators for such a transformer-sharing arrangement, each machine may be connected to an exclusive primary winding. Multiple primary windings are often used in hydropowerplants because of the relatively small power output ratings (MVA) of a typical generating unit. Thus, a single large transformer can be sized and manufactured to meet the requirements of multiple generators, providing a substantial savings in equipment cost.

Also unique to hydro plants is the use of the forced-oil-water (FOW) transformer cooling method. Although few, if any, new transformers are cooled this way because of environmental issues, the availability and efficiency of FOW made it the method of choice in the past. The availability and proximity to water made FOW an attractive and unique solution to step-up power transformer cooling.

9.4 BALANCE OF PLANT

9.4.1 Station Service

The station service supply and distribution system is provided to furnish power for the plant, dam auxiliaries, lighting, and other adjacent features of the project. Since hydroelectric plants are capable of starting with relatively low auxiliary power needs (compared to steam plants), they are often used to provide "black start" capability for the local transmission system. If the plant is to provide this capability, the station service system design must include an automatic start engine-driven generator to provide power to critical auxiliary powerhouse loads. This is in addition to the engine-generator the plant must have to operate spillway gates and other river regulating works when offsite power is unavailable.

The complexity and operational flexibility of the station service system are related to the number of main generator units and the importance of the plant to the overall power system. Large plants with numerous units may have two station service transformers and even dedicated station service hydro generators. Station service transformers are often fed from different main generator unit buses to allow the main units to carry station service loads upon disconnecting from the system. Smaller hydroelectric plants may have only one station service transformer and an engine-driven generator.

9.4.2 Switchgear

Station service systems at hydroelectric plants utilize standard metal-clad switchgear assemblies. In large plants, where the distance between the station service switchgear and the utilization equipment is large, the use of 4.16 or 13.8 kV distribution circuits is used where economically justified. Double-ended switchgear, consisting of two dry-type 13.8 or 4.16 kV transformers fed from separate sources, and connected to 600 V switchgear with a normally open tiebreaker between the two sections, is often used for important load centers.

9.4.3 Controls

Plant controls are comprised of computer-based controls, hard-wired or programmable logic, indicating and recording instruments, protective relays and similar equipments. Each generator or pair of generators often has local control panels or switchboards located near the units. For multiple unit plants, centralized controls are also used to coordinate the operation of all units within the powerhouse. The centralized control equipment is situated in a control room located at an elevation above the maximum high water levels. Centralized control is used to apportion MW and MVAR loading among multiple machines while respecting machine operating limits.

Small plants may not have a dedicated control room. They may have the local unit control panels integrated with the station service switchgear lineup, which usually requires additional compartments to accommodate the needed equipment.

9.4.4 Instrumentation

The instrumentation at hydroelectric projects has a number of unique features, most of which involve the measurement of hydraulic and mechanical parameters. There are two basic types of these parameters—performance and positional. Performance parameters include power, head, and flow. Positional parameters refer to such items as wicket gate opening, nozzle jet opening, and Kaplan blade angle position. Instrumentation to measure generator power output is covered in other chapters of this handbook.

Head is a performance parameter that can usually be measured to a high degree of accuracy. The traditional method is by the use of stilling wells. These are vertical tubes with restricted openings under the water surface of the elevation to be measured. This restricted opening serves to dampen the effect of wave action and provides a steady water surface inside the well. Floats with counterweights or electro tapes can be used inside the stilling well to measure the water surface elevation. More modern measuring devices use radar or acoustic waves rather than stilling wells. These waves are bounced off an open water surface to measure a vertical distance between the instrument and water surface.

The head measurement described above presents some challenges. Although head refers to distance or height, it is used to express the pressure resulting from the weight of a body of liquid since the weight is directly proportional to the height. Therefore, head actually represents a difference in hydraulic energy levels. However, when water is flowing, the elevation of the water surface is not the true energy level because it does not account for the kinetic energy contained in the velocity head, $V^2/2g$. Thus, measuring the elevation of a tailwater surface at a draft tube exit does not provide a correct downstream energy level. In addition, bends in the river or the operation of adjacent units may cause the head on any one individual unit to differ from the location where head is measured for the powerhouse. Thus, the location where head is measured is a unique feature of the accuracy of head measurement.

Volumetric flow rate is generally the most difficult performance parameter to measure to any degree of accuracy. For projects with penstocks or at least a water passage with a constant cross section of sufficient length, there are several methods to accurately measure absolute flow. However, with large, run-of-the-river projects where the cross section of the water passage is continually changing, accurately measuring flow becomes very difficult. In such situations, relative flow may be measured instead to determine a relative efficiency. Relative flow is uniquely measured by determining the effect that absolute flow has on another parameter that can be measured. The Winter-Kennedy piezometer system is commonly used for this purpose. This consists of two piezometer taps, one on the inside and the other on the outside of the spiral or semi-spiral case. The square root of the piezometric or pressure difference between these two taps is directly proportional to the flow rate. Therefore, a relative efficiency of the turbine-generator may be measured as $E_{rel} = \text{kW}/(H\sqrt{D})$, where kW is the generator output in kilowatts, H is head in feet, and D is the piezometric difference, usually in feet.

With reference to the positional parameters, the actual wicket gate opening is defined as the dimension of the largest sphere that can pass between the two gates. When a turbine is unwatered, the gate opening may be calibrated with a curved scale on the wicket gate operating ring or even an angle indicator on the top of the wicket gate stems. However, in order to use a straight-line motion sensor to measure the amount of wicket gate opening, the stroke of the wicket gate servomotor reach rod is used. This measurement is often called gate opening and used directly without converting to actual gate opening, even though the two do not have a linear relation. Because of the curved shape of wicket gates, the relation between actual gate opening and servomotor stroke is a shallow "S" curve. In addition, at each end of the servomotor stroke there is an area of squeeze. This is where the reach rod is moving to take up slack in the linkages, but the gates are in contact or at their stops and not moving. Therefore, a reading of a gate opening tends to be unique to each project.

The inner oil pipe in the oil head on a Kaplan turbine is generally used as the indicating surface to measure blade angle. This provides a linear motion for a position sensor and can be calibrated from the master blade position ring on the hub when the unit is unwatered. However, each turbine manufacturer has a different trigonometric convention to define the actual blade angle. There is no industry standard or convention for this measurement. Therefore, a reading of a blade angle tends to be unique to each family of turbines in a powerhouse.

9.4.5 Protection

Hydroelectric plants are protected using standard generator, transformer, and distribution system protection methods and schemes. A few features or practices that may not be common to other types of plants are discussed here. On large generators, whose stator windings consist of multiple-turn coils with multiple parallel circuits per phase, split-phase differential relaying is sometimes used to provide increased sensitivity to turn-to-turn shorts. Under-frequency and over-frequency relaying is often not used, or is set very liberally compared to steam units as the hydraulic turbine and generator are not susceptible to damage due to off-nominal frequency operation. Special schemes are used to provide selectivity on isolated-phase bus ground faults in installations where multiple high-resistance grounded units are tied together at the generator terminal voltage level.

9.4.6 Direct Current Systems

A direct current (dc) system is used to provide independent power for auxiliary equipment and systems including controls, relaying, data acquisition, communication equipment, fire protection, inverter, generator exciter field flashing, alarm functions, and emergency lights. The DC system consists of a storage battery with its associated charger, and provides the stored energy required to ensure adequate and uninterruptible power for critical powerplant equipment. In the event of a complete loss of station service power, the dc system supplies the power needed to conduct an orderly shut down of generating equipment which could be damaged if operated without auxiliary systems such as control power, cooling water, lubrication oil, etc. An inverter is fed from the battery for the critical alternating current loads. For plants equipped with black start capability (i.e., the ability to start up a plant when separated from the transmission system and the generators have been shut down), the dc system provides a dedicated power source for auxiliary equipment as well as field flashing of the generator exciter in order to restore a small amount of residual magnetism in the generator exciter field to allow the generator to build up voltage during start-up.

9.4.7 Annunciation

Annunciation systems are used to alert someone (typically the control room operator) when a critical plant or equipment parameter falls out of tolerance and requires attention and/or action. Annunciators generally provide visual and audible signals, such as lights and flashers along with a horn, bell, or buzzer. Acknowledge and reset functions may also be provided. Annunciation systems may consist of a separate annunciator hardwired into the plant, or a software feature programmed into the central control system. Typical alarm points include turbine bearing oil trouble, unit bearing overheating, generator excitation system trip or trouble, generator cooling water flow, generator stator high temperature, governor oil trouble, transformer differential, and transformer overheating.

9.4.8 Miscellaneous Equipment and Systems

A wide variety of mechanical and electrical auxiliary equipment and systems may be found at hydroelectric powerplants. Of the following items, not all will be incorporated into all plants. The size, service, and general requirements of the facility will usually determine which items are needed: water supply systems for raw, treated, and cooling water; sewage disposal equipment; heating, ventilating, and air-conditioning systems; fire detection and protection systems; telephone and code call systems; elevators; intake and discharge gates and valves; penstock drainage and unwatering systems; station drainage system; air receivers for draft tube water depressing system; insulating and lubricating oil transfer, storage, and purification systems; compressed air systems for service, generator brakes, and turbine governor; emergency engine-driven generators; metal-enclosed buses, surge protection equipment; and transformer oil pumps.

9.5 DESIGN ASPECTS

9.5.1 Criteria and Philosophy

The basic approach to designing a hydroelectric project is to first determine the rated discharge of the powerhouse. Hydrologic or other records are used to develop a historical graph of the frequency of volumetric flow rates. The flow values may be mean daily, weekly, or monthly. The period of record should be as long as possible. From this information, a flow exceedence graph is developed. This is a graph of flow versus the percent of time that a flow value exceeds. As a general rule of thumb, run-of-the-river projects (those having little reservoir storage capability) are sized to a Q_{20} and projects with storage are sized for a Q_{30}. The term Q_{20} means a flow value that exceeds 20% of the time. In other words, the project could utilize all of the flow for generation 80% of the time. Similarly, Q_{30} means a flow value that exceeds 30% of the time.

Next, a design head is determined. This is different from rated head and is the head at which best efficiency is to occur. Such a determination depends on the specifics of the project, but a weighted average head is often used. With the hydraulic head and estimated hydraulic losses in the penstock, a power duration curve may be developed. Annual energy production may then be calculated from the area under this curve multiplied by an appropriate conversion factor.

With the value of design head, a dimensionless parameter known as specific speed is determined from a historical experience curve of specific speed versus design head. Specific speed is defined as the speed at which a turbine would rotate if it were 1 ft in diameter and operating under 1 ft of head. It is calculated in U.S. units as $N_s = N(\mathrm{HP})^{1/2}/H_d^{5/4}$, where N_s is the specific speed, N is the rotational speed in rpm, HP is the turbine output (at full gate in this instance) in horsepower, and H_d is design head in feet. The specific speed is used as a classifying parameter of hydraulic turbines. With the value of specific speed, the type and configuration of turbine can be determined, which historically has been found to be the best selection for the same conditions.

Next, the size and number of generating units required to pass the rated discharge is determined. Generally, a fewer number of larger units is the more economical option. For some projects, the physical size of the unit has been limited to the maximum size runner that could be shipped in one piece. This is largely due to the extra manufacturing costs involved in furnishing split runners. However, other considerations, such as flexibility of operation and minimum loss of capacity during shutdown for repair or maintenance, may dictate the use of more, smaller units. Sometimes to achieve increased flexibility with few units, different size units are used in the same powerhouse.

9.5.2 Ratings

In the design of a hydroelectric plant, the generating equipment is first sized and then afterwards it is rated. Sizing refers to selecting the physical size of the equipment. Generally, hydrologic considerations of head and flow provide the basis for the determination of the type, number of units, runner diameter, setting, and synchronous speed of each hydraulic turbine selected for a particular project. Then the generator is sized to match the turbine speed and expected output at a selected head.

Once the equipment is sized, it can then be rated. However, the rating is done in the reverse order. First, the purchaser usually specifies the temperature rise criteria from which the manufacturer then rates the generator. The generator is rated in terms of kVA and power factor. It is a standard practice to set such thermal limits to that power output which causes no more than a 60 or 80°C temperature rise above ambient in the generator windings. It is a "soft" limit in that it can be physically exceeded. However, this can have a detrimental effect on the operational life of the insulation. Converting this generator output rating into a generator horsepower input gives the rating of the turbine. However, the actual turbine rating is not in units of horsepower, but in units of feet of head. This is because as head is increased a turbine can produce more power. This head is usually the net head, or the same head as used to develop the turbine performance characteristics. Therefore, the rating of a turbine is actually the lowest net head at which the turbine can drive the generator to produce its rated electrical output. This is a unique point, with the wicket gates full open. Therefore, it is also a "hard" limit since the turbine cannot physically produce more power unless the head is increased. As a consequence, if the turbine and generator are procured separately, it is not the turbine manufacturer but the purchaser who actually establishes the turbine rating. The discharge at this rated head is referred to as rated discharge.

There are a couple of notable alternatives to this rating procedure. Some owners equate the turbine rating to the generator nameplate rating at unity power factor, regardless of the nameplate power factor. This is referred to as the generator *capacity*.

Seeking to reduce the cost of procuring hydroelectric generators, a number of years ago some purchasers began rating their turbines at 115% of the generator nameplate rating at nameplate power factor. They then specified that the generators must be capable of "continuous operation" at 115% of rated generator output. In other words, they rated a turbine at the generator's overload rating and then specified the generator overload rating the way the regular nameplate rating is usually specified. (The turbines were also required to be able to produce an output of 115% of generator nameplate at unity power factor, at a higher head, without exceeding mechanical limits.) Today, the standard procedure is to use the full overload rating as the nameplate rating.

9.5.3 Speed Settings

Although some extremely small hydraulic turbines may power induction generators, most turbines are directly connected to synchronous ac generators. As a consequence, the speed of rotation must agree with one of the synchronous speeds required for the system frequency. The prevailing frequency for most systems in the United States is 60 Hz. In Europe and certain other parts of the world, 50 Hz is used. Synchronous speeds are determined by the formula, $N = 120 \times$ frequency (in cycles per second)/number of poles in the generator. The number of poles must be an even number since the poles are in pairs.

The need to rotate at a synchronous speed means that the turbine is constrained to rotate at a single speed as the hydraulic conditions of head and stream flow vary. This is a major constraint unique to the design of hydropower, negatively affecting the efficiency and smooth operation of the turbine. The speed should be as high as practicable since this decreases the cost of the turbine and generator. The proper selection of the synchronous speed is usually done with reference to the specific speed of the hydraulic turbine. As defined in Sec. 9.5.1, specific speed is calculated as $N_s = N(\mathrm{HP})^{1/2}/H_d^{5/4}$. However, in this calculation, the turbine output value is the horsepower at peak efficiency at design head rather that at full gate at design head. With the values of turbine output and design head, and the turbine specific speed at peak efficiency, a trial rotational speed is calculated. This is usually rounded up to the next higher synchronous speed, and the turbine output at peak efficiency recalculated. If the turbine output at either peak efficiency or full gate or rated discharge is not as desired, the size of the turbine is changed and the speed calculation repeated.

9.5.4 Water Hammer and Mass Oscillations

Water hammer is a transient pressure phenomenon that can occur in moving water in a closed conduit. If there is a change of velocity, for example, due to the closing of a valve, pressure waves are created that travel up and down the conduit. Upstream of the closing valve, the fluid is progressively decelerated and compressed, causing a positive pressure transient to travel upstream. Once this wave reaches an open surface, it is reflected back toward the valve as a negative pressure wave. When it reaches the valve, it will be reflected again. This process is repeated time and again until the wave is attenuated by friction. On the downstream side of the valve, the transients are reversed with a negative wave initially traveling downstream. The greater the distance between the valve and an open surface, the higher the peak magnitude of the pressure rise. The pressure waves travel at the speed of sound or the acoustic velocity called the celerity, which is given the symbol "a." The celerity varies depending on the conduit boundaries, the static pressure, and the water temperature (and salinity), but is typically on the order of 2000 to 3000 ft/s.

The water passages of a hydroelectric project must be designed to withstand both the maximum positive and negative pressure transients to prevent potentially catastrophic damage to the valves or rupture of the penstock. The magnitude of the maximum transients can be controlled by the design of the dynamic elements. For example, the maximum rate of valve movement, such as the rate at which the wicket gates of a turbine can move, can be controlled by limiting the size of the oil ports in the servomotors. Slower gate closure, however, results in higher generator overspeed when an electrical load is lost.

The magnitude of pressure transients can also be mitigated by surge tanks, accumulators, or quick acting pressure relief valves. A surge tank has an open surface. Consequently, it provides a partial negative return wave and acts to shorten the effective length *L* of the conduit. There are a number of different types of surge tanks, such as the simple riser, restricted riser, differential, etc. The more the flow is restricted in either or both entering and leaving the surge tank, the less the pressure transients are mitigated, but the more hydraulically stable the surge tank. An accumulator does not have an open surface, but has an enclosed dome of air or gas. The quick acting valves operate in a manner analogous to safety valves.

A separate but related phenomenon to water hammer is mass oscillation. Rather than a wave within the fluid, this term denotes the actual movement or velocity of the fluid. Consequently, it is much slower and, therefore, separated from pressure transients on a time basis. Using a surge tank as an example, if the turbine wicket gates start to close, a positive pressure wave is transmitted upstream. Part of that wave continues upstream to the reservoir water surface, but a part also reaches the free surface of the surge tank and is reflected back as a negative wave. As the initial positive wave reaches the riser of the surge tank, it causes part of the flow still coming downstream to be diverted up into the surge tank and the elevation of the water surface in the tank starts to rise. Consequently, the deceleration, $-dV/dt$, of the flow upstream of the tank is not as rapid, which serves to mitigate the magnitude of the pressure transient upstream from that point. Another example of mass oscillation is the separation of the water column. If a valve is closed very rapidly in a high velocity flow, the momentum of the fluid downstream of the valve can cause the fluid column to separate at that point. As can be imagined, this can have dire consequences.

9.6 OPERATIONAL CONSIDERATIONS

9.6.1 Runaway Speed

Runaway speed is the maximum rotational speed to which a generating unit can be driven with an open circuit breaker and the available hydraulic and mechanical conditions. The term usually refers to a fixed wicket gate opening, and in the case of Kaplan turbines, a fixed blade angle. During a load rejection, the water column continues to provide energy to the turbine runner. Since this energy can no longer be converted into electrical energy, a portion is mechanically stored and the rest is dissipated in turbulence before being discharged from the turbine. The energy is stored via increased angular momentum of the turbine runner, shaft, and generator rotor. The total amount of energy that can be stored is a function of the rotating inertia, or WK^2, and the increase in rotational speed.

If the wicket gates do not move to a closed position, the speed will increase until limited by hydraulic conditions, windage, and friction. The hydraulic conditions include the available head, the turbine's performance characteristics such as off design efficiency, and cavitation, which can reduce the efficiency of the energy transfer. Windage refers to air resistance, mostly in the generator, and friction refers to mechanical "sliding" friction. Ultimately, the decreased amount of fluid energy that can be transferred from the water column is balanced by the increased windage and friction, at which point runaway speed is achieved. The higher the head, the larger the wicket gate opening, or the flatter the blades on a Kaplan turbine, the higher the runaway speed. For this latter reason, the blades on Kaplan turbines are often designed to tilt to their steepest position on loss of governor control.

Francis and Kaplan turbines have different runaway speed characteristics. Francis turbines typically have less WK^2 than Kaplans and, therefore, achieve runaway speed faster. At runaway speed, Francis turbines tend to "choke" the flow, reducing the discharge. Kaplans, on the other hand, tend to increase the flow with increasing speed at a given gate and blade angle. On Kaplan turbines, on-cam runaway speed is achieved if load is rejected, the gates do not move, and the blades are at the proper cam position for the gate opening and head and do not move. If the blades move to any other position without moving the gates, it is referred to as off-cam runaway speed. Also with Kaplans, maximum runaway discharge is when the blades are full steep.

If the wicket gates are free to move and the unit is under governor control, a shutdown sequence is initiated upon load rejection. However, since the wicket gates take a finite time to close, a transient increase in synchronous speed, known as overspeed, is achieved. In order to limit this overspeed, the wicket gates should close as quickly as possible. However, the faster they close, the higher the pressure transient of water hammer that is sent back upstream. For this reason the rate of closure, called the gate-timing element, is a compromise between overspeed and water hammer. The peak overspeed can be reduced by increasing the inertia of the rotating parts. Normally, the maximum design overspeed is 150% of synchronous speed.

9.6.2 Cavitation

Cavitation is a phenomenon involving the creation of bubbles containing water vapor. It occurs when the local pressure is reduced to or below the vapor pressure of water. Literally, the water boils, but at low temperature. The formation of vapor-filled bubbles is more likely to occur under conditions of high flow velocity (such as high rpm operation or high flow rates) and low pressure (such as low tailwater). Cavitation occurs in reaction hydraulic turbines, but not in impulse turbines whose runners are vented to atmospheric pressure. Minimum pressures in reaction turbines tend to occur at the trailing edge on the underside or suction side of blades or buckets. As these bubbles are carried downstream, back to higher-pressure areas, they collapse or implode. These implosions generate extremely high pressure pulses, sufficient to pit and erode the surfaces of the hardest steels. There are many types of cavitation including leading edge, areal, traveling, leakage, etc. Cavitation damage reduces turbine-operating efficiency and, if left unchecked, can lead to severe damage and extensive repairs. Most types of cavitation, but not all, can be lessened or eliminated by increasing the submergence of the turbine runner.

Model tests are primarily used to check turbine runner, wicket gate, draft tube, casing, and sometimes inlet work designs for optimum performance. They are also used to predict the conditions under which cavitation will occur. However, their predications have a degree of uncertainty because cavitation is actually 2-phase flow and the same hydraulic model cannot have similitude with both a liquid and a gas phase. The result is that a model prediction of cavitation is usually biased. That is, if the model shows cavitation at a certain condition, the prototype will definitely cavitate at that same condition. However, if the model does not cavitate, the prototype may still experience cavitation. For this reason, turbine designers try to maximize the amount of safety margin.

Aside from submergence, controlling cavitation is best achieved through design of the runner so that velocities at critical areas do not lower the static pressure to the vapor pressure. Other control methods include welding an overlay of a cavitation-resistant material on the base metal. Sometimes, special anticavitation fins are added to turbine blades on propeller type turbines to minimize blade tip cavitation. The injection or aspiration of air bubbles has been used to cushion the action of the pressure pulses.

9.6.3 Turbine Efficiency

The formula for turbine efficiency is developed from the definition of fluid power. If the volumetric flow rate Q, in cubic feet per second (ft^3/s), is multiplied by the specific weight of water γ, in pounds (force) per cubic foot (lbs_f/ft^3), the weight flow rate γQ, in lbs_f/s, passing through the turbine is obtained. This term may then be multiplied by the head H, in feet. (Technically, head is called the specific energy E and has units of ft-lbs_f/lbs_f.) The resulting expression, γQH, has units of ft-lbs_f/s and represents the power available in the fluid column. Dividing this expression by 550 ft-lbs_f/s per horsepower gives the power in the fluid column in units of horsepower. Since this expression represents power "in," dividing it into the horsepower "out" of the turbine yields the turbine efficiency

$$E = HP/(\gamma QH/550)$$

If the combined turbine-generator efficiency is to be calculated, the formula may be changed to

$$E_{t-g} = 1.3411(\text{kW})/(\gamma QH/550)$$

where kW is the generator output in kilowatts.

In selecting the type of turbine for a given hydroelectric powerplant, it is important to consider the efficiency performance of the various types of turbines available for the head contemplated. Not only is this true for the value of the maximum efficiency obtainable, but also for both the percentage of full load where this maximum efficiency occurs and the efficiencies at part loads and at full load (Fig. 9-7).

Impulse turbines are usually a couple of percent less efficient than comparable reaction turbines. However, because of their ability to use multiple jets, they can have a flat efficiency profile over a very wide power range. Francis turbines can have among the highest peak efficiencies. However, their runners have no mechanical adjustment and, therefore, their profiles are sharply peaked with efficiencies degrading significantly at part loads. Fixed blade propeller turbines also can have high peak efficiencies, but like Francis turbines, their profiles are sharply peaked. This latter feature is modified by Kaplan turbines, which are propeller turbines with adjustable blades. As head and flow conditions change, the pitch angle of the blades can be adjusted to maintain a relatively flat efficiency profile over a wide range of power and head. However, Kaplan turbines do have slightly reduced peak efficiencies due to increased leakage around the ends of the blades.

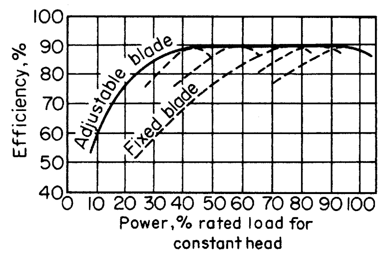

FIGURE 9-7 Efficiency-load relations for fixed- and adjustable-blade propeller turbines.

9.6.4 Operating Limits

Hydroelectric projects often operate under a number of different limits or constraints. These limits may affect either generating capacity or generating efficiency, and usually originate from one of three sources—physical, contractual, or regulatory.

Physical limits are those imposed by the physical characteristics of the generating equipment or the hydraulics. For example, the maximum output of the generator may be limited such that the temperature rise above ambient within the generator insulation does not exceed a specified value. The output of the turbine may be limited to avoid operating in zones where draft tube surging occurs. Such surging causes a fluctuation in power output. The head may be limited to a minimum value to prevent the forebay from being low enough to allow air to be drawn into the penstock through a vortex at the intake.

Contractual limits are imposed by the procurement specifications of the equipment. They usually apply while the equipment is under the manufacturer's warranty. For example, the specifications may limit the turbine output as a function of head to avoid cavitation damage while the turbine is under warranty.

The majority of operating limits are regulatory in nature. The hydropower licensing procedure described in the following section provides ample opportunities for the imposition of operating limits. These limits are of two types—static or time varying. An example of a static limit is a project that is in the path of ocean bound juvenile anadromous fish which may be restricted to operating within 1-percent of peak turbine efficiency during migratory seasons. (Water turbulence is at a minimum at peak turbine efficiency and, therefore, fish survival is thought to be increased.) An example of a time varying limitation is a limit on the ramp rate or the rate at which the generated power level may be changed. Such a limit may be imposed to prevent varying the elevation of the tailwater too rapidly.

9.6.5 Regulatory Requirements

Hydropower is regulated through three legal venues—water rights, state regulatory permits, and federal licensing. Water rights are required on all hydropower developments in the United States. These are administered through state statutes, which vary greatly from state to state. In addition, individual states have various other legal requirements, involving consultations with state agencies and permits.

Federal regulation of hydroelectric power began in 1920 when Congress enacted the Federal Water Power Act and established the Federal Power Commission (FPC) to administer the Act. In 1977, as part of the Department of Energy Organization Act, Congress created the Federal Energy Regulatory commission (FERC), which assumed most of the FPC's hydro regulatory responsibilities. This commission has jurisdiction over nonfederal development of hydropower projects, constructed after 1920, which meet one or more of the following criteria:

- Occupy in whole or in part lands of the United States.
- Are located on navigable waters in the United States.
- Utilize surplus water or water power from government dams.
- Affect the interests of interstate commerce.

A project's connection to the electrical grid, with transmission lines that cross state boundaries, is considered to be engaged in interstate commerce. Consequently, the vast majority of hydroelectric projects in the United States are subject to FERC jurisdiction.

Often, the first step in the licensing process is to obtain a preliminary permit from FERC. A permit simply reserves the site to the permit holder during the investigation and application phase. Permits are usually issued for a 2-year period, with extension to a third year available. Although a permit provides for a priority advantage in obtaining a fully approved license, under the FPC, municipalities are given preference to hydropower sites.

There is a provision in the licensing process called an exemption. This term may be a misnomer for it does not mean exempt from the licensing process. To achieve an exempt status, an application must still be made. Exemptions are granted to projects meeting certain criteria. One such criterion is that of a project on a man-made conduit, such as at a drop in an irrigation canal. An exemption is granted in perpetuity with no need to apply for an exemption at some future time.

If a site is jurisdictional and ineligible for an exemption, it is necessary to proceed with a formal application. There are two types of licenses. A minor license is for projects under 5 MW, and a major license is for those over 5 MW. Obtaining a license requires a number of different types of studies, consultations with a number of different agencies, preparation of a license application, and can be expensive and time consuming. An FERC license conveys to the license holder the right of eminent domain. Licenses are issued for a specified period of time, usually ranging from 30 to 50 years. Typically, new projects are issued 50-year licenses to offset major capital investments into the project. Any significant change to a project, particularly one affecting the aquatic environment, requires a reopening of the existing license. A change in generating capacity that uses more or less water can have an effect on the aquatic environment.

9.7 UNIQUE FEATURES AND BENEFITS OF HYDRO

9.7.1 Water Resources

Hydroelectric power generation is only one of several potential benefits of river resources development. Multipurpose hydropower projects also provide flood control, flow augmentation, irrigation, municipal water supply, navigation, and recreation opportunities. Hydropower plants convert about 90% of the energy in falling water into electric energy. This is much more efficient than fossil-fueled powerplants, which lose more than half of the energy content of their fuel as waste heat and gases. Hydropower is free of fossil fuel emissions and does not contribute to air pollution, acid rain, or global warming. Furthermore, no trucks, trains, barges, or pipelines are needed to bring fuel to the powerplant site. The earth's hydrologic cycle provides a continual supply of water from rainfall and snowmelt, making hydropower one of the most economic energy resources. And because hydropower is especially suited for providing peaking power, hydroelectricity complements thermal generation and improves overall power production efficiency. Hydro resources often allow utilities to delay or forego construction of additional peaking capacity.

9.7.2 Ancillary Services

Ancillary services comprise the resources and functions (excluding basic generation and transmission capacity) required to support the transfer of electrical energy from generating sources to loads while maintaining reliable operation of the interconnected transmission system. There are several critical ancillary services, which hydro generators are especially effective in providing. These services include the following:

Reactive Supply and Voltage Control. The provision of reactive power from generation sources to support transmission system operations, including the ability to continually adjust transmission system voltage in response to system changes. This service is required to maintain voltage control and stability. Hydroelectric generators, operating in synchronous condense mode, are capable of producing reactive power up to the nameplate capacity of the unit.

Regulation. The provision of adequate generation response capability. Under automatic generation control, supply resources are continuously balanced with minute-to-minute load variations. This service is required to maintain frequency at scheduled values and to help ensure that instantaneous tie line deviations do not cause degradation of transmission system reliability.

Spinning Reserve. Generation capacity is synchronized to the system but is unloaded and able to respond immediately to serve load in case of a system contingency. Capacity is fully available within 10 minutes.

Black Start. The ability of a generating unit or station, during a system restoration, to go from a complete shutdown condition to an operating condition and start delivering power without assistance from the electric system. Requires a dedicated power source for auxiliary equipment and the ability to create own field in exciter. Only required in areas that may become isolated.

9.7.3 Pumped Storage

Pumped-storage plants differ from conventional hydroelectric projects. In a pumped storage scheme, the power station is located between an upper and a lower dam. During periods of high electrical demand, the plant is operated in generating mode. Water is released from the upper dam through the station's turbines and into the lower dam where it is stored. During periods when demand for electricity is low, the machines are put into pump mode to pump water from the lower dam back into the upper dam where it is stored until the station needs to generate again. Pumped storage schemes are net consumers of electricity.

Early pumped storage projects involved separate pumps and turbines. Since the economics of pumped storage favor the highest possible head, configurations included both single and multiple stage pumps and turbines. Sometimes separate motors and generators and even separate penstocks were used. Eventually, reversible pump turbines, in which the pump and turbine are the same machine, were developed. These are not turbines, but are actually pumps with centrifugal impellors, that when operated in the reverse rotational direction are capable of generating as turbines.

The design process of selecting a pump turbine is similar to that of a conventional turbine. One factor of note is that specific speed for a pump is calculated from a different formula, $N_s = N(Q)^{1/2}/H^{3/4}$, where in U.S. units N_s is specific speed, N is rotational speed in rpm, Q is pump discharge in gallons per minute, and H is total dynamic head in feet.

It is an inherent characteristic of reversible pump turbines that the peak efficiency in the generating mode occurs at a slower rotational speed than in the pumping mode. Therefore, unless a more costly 2-speed motor-generator can be used, the selected single, synchronous speed is a compromise speed. Thus, neither the turbine nor pump can operate at their individual peak efficiency. Another factor in this compromise selection of synchronous speed is that the turbine peak efficiency is usually higher than the pump peak efficiency. This is because a pump has additional internal losses including "recirculation" losses. Additionally, the shape of the efficiency profile for the pump mode is more sharply peaked than for the turbine mode.

Generally, a pump turbine needs to spend more time out of a 24-h period in the pumping mode than in the generating mode for the same water exchange. This ratio is referred to as the *duty cycle.* For example, if a pumped storage project pumps for 16 h in order to generate at rated capacity for the remaining 8 h, it is said to have a 16-h duty cycle.

9.8 ENVIRONMENTAL CONCERNS

9.8.1 Fish Passage

Addressing the environmental impact on rivers and maintaining a balance with the plants, fish and wildlife that also depend on the river has never been more difficult. Depending on the particular site of a hydroelectric project, providing for the passage of upstream and downstream migrants can be an important factor. While it may not be a factor for such sites as drops in man-made irrigation canals, it is a critical factor at sites on rivers with anadromous and catadromous fish. Anadromous denotes fish, such as salmon, that mature at sea, but return to fresh water to reproduce. Catadromous are the opposite in that they mature in fresh water, but reproduce at sea, such as certain types of eels. Hydroelectric projects at such migration sites are usually required to be designed with specific upstream and downstream passage facilities.

There are several different types of passage facilities for upstream migrants. The most common is a fish ladder. This is an open surface, shallow gradient, conduit with a series of small plunge pools to dissipate the hydraulic energy from the forebay to the tailwater. However, there are different designs of fish ladders for different migrant species. Salmon will climb the ladder by jumping the weirs connecting each plunge pool. However, shad will not jump, but will climb ladders that have small holes cut in the each weir at the bottom of the each plunge pool. Often extra water is released directly from the forebay as a submerged jet at the entrance to the fish ladder. This is referred to as "fish attraction water." At some powerhouses, overflow weirs are constructed along the entire downstream length for fish to migrate into and be channeled into the fish ladders. Another design of an upstream migrant facility is a fish elevator. In this design, a "crowder" is used to gather the fish into an elevator bucket that is hoisted up to the forebay elevation.

For downstream migrants, there are also a number of design options. One of the oldest is to simply open the gates on controlled spillways during the migratory season as a "fish flush." Another is to collect the downstream migrants, such as at fish hatcheries, and transport them by barges around the hydroelectric projects. Still another option is to install fish screens in the intakes to divert fish from going through the turbines, but into channels that carry them around the powerhouse. There are several different types of fish screens, including submerged bar, extended submerged bar, traveling, etc. Fish screens do disrupt the hydraulics within a turbine and decrease its overall efficiency. A unique type of fish screen called the Eicher fish screen is a wedge wire screen installed downstream of the intake in a penstock. Named after the inventor, George Eicher, it is a self-cleaning screen. This self-cleaning is achieved by simply tilting the screen on horizontal pinions so that the downstream side faces upstream.

Downstream migrants most commonly encounter lower head projects with propeller turbines. For the downstream migrants that do pass through the turbine water passages, five mechanisms of injury have been categorized and studied: strike, grinding and abrasion, decompression, shear and turbulence, and cavitation. For properly submerged lower head projects with propeller turbines, the latter three causes of injury are not as important as the first two. Consequently, to minimize strike, and grinding and abrasion, a unique design of Kaplan runner called a minimum gap runner has been developed. In this design of runner, overhangs and recesses in the runner hub hydraulically hide gaps between the inner edge of the blades and hub, and spherical rather than cylindrical cavities form the discharge ring.

9.8.2 Water Temperature

The presence of a hydroelectric project can improve or degrade the temperature of the aquatic environment. The increased cross section of a forebay or upstream reservoir of a project acts to slow the velocity of a natural river. This tends to decrease the mixing of the vertical water column and leads to stratification. Limnologists, who scientifically study bodies of fresh water, classify this stratification into three distinct layers. Upper most is the epilimnion, where the water is warmed by sunlight. Then at a depth, where sunlight no longer penetrates, there is a thermocline, where the temperature drops rapidly. Below that is the layer of cooler water called the hypolimnion. During the summer months these layers tend to be well defined. However, in winter this distinction tends to fade and may even reverse with the upper layer becoming the coolest and sinking to the bottom.

Hydroelectric projects can be designed to mitigate this temperature stratification or even improve the downstream effect of natural impoundments by two basic approaches. The first is to cause the mixing of the vertical water column. Bubbler hoses can be placed along the bottom of the reservoir to develop air curtains that set up vertical circulation patterns. Large, unhoused, mixing propellers can be used in a similar manner. Fountain-like aerators can be used to spray water from near the bottom of the reservoir into the air.

The second basic approach is to selectively withdraw water from different elevations in the reservoir into the powerhouse intakes. One way this is done is by designing thermal withdrawal towers with foundations that rest on the bottom of the reservoir. These towers have gated ports at different elevations. The water from different reservoir elevations tends to mix inside the tower before entering the penstock. A similar design is to retrofit thermal withdrawal enclosures around conventional powerhouse intakes. These also have gated ports at different elevations and the water from the different elevations tends to mix in the intake. Such structures allow hydroelectric projects to even improve the natural environment, particularly, by discharging cooler water from the bottom of the reservoir in summer.

Aside from the biological factors, water temperature has a minor effect on generation. Temperature, along with elevation and latitude, determines the specific weight of water. The heavier the water, the more electricity that can be generated by a given quantity. Typically, fresh water has a specific weight in U.S. units of about 62.4 lb/ft^3. If this value is divided by the local acceleration of gravity g, in feet per second squared, the value of the density of water is obtained in slugs per cubic foot.

9.8.3 Dissolved Oxygen

Hydroelectric projects can affect the dissolved oxygen (DO) content of their aquatic environment in both beneficial and detrimental ways. Among other things, DO is one of the best indicators of the health of a water ecosystem. In a natural body of water, decrease in the dissolved oxygen levels is often an indication of an influx of some type of organic pollutant. The rate at which oxygen is depleted, usually measured over a 5-day period, is the biological oxygen demand (BOD). Oxygen is consumed by plants and animals during respiration and by aerobic bacteria during the process of decomposition. As a consequence, oxygen consumption is greatest near the bottom of a reservoir, in the hypolimnion, where sunken organic matter accumulates and decomposes. Conversely, oxygen is produced by direct absorption from the atmosphere, by plant photosynthesis or is obtained from inflowing streams. Since photosynthesis requires sunlight, and the air/water interface is at the surface, the higher concentrations of DO are found in the higher elevations of a reservoir, in the epilimnion. Physically, DO can range from 0 to 18 parts per million (ppm), but 5 to 6 ppm are needed to maintain a diverse biota population. DO concentration is most affected by water temperature. Cold water can hold more of any gas than warmer water. The DO concentrations may vary significantly at any time and place due to a number of factors besides temperature, such as barometric pressure, elevation, salinity, season, time of day, wind, and reservoir depth.

Another atmospheric gas that can be of concern is nitrogen. Unlike oxygen, nitrogen is biologically inert. However, it is capable of existing in a supersaturated state for a long period of time. If the gas is in sufficient excess, it can cause a potentially lethal condition, known as “fish bubble disease.” This condition, similar to the bends in divers, is caused when nitrogen comes out of solution in the tissues of fish. Rivers can become supersaturated with nitrogen where the hydraulic jump at the base of spillways entraps large amounts of air in deep pools. If these deep strata are not exposed again to the atmosphere, such that the nitrogen can be "cleansed," it will go into solution. This tends to happen when the tailwater is not free flowing, but is the reservoir of the next downstream hydroelectric project.

Although a powerhouse can do little relative to preventing oxygen depletion in the reservoir or nitrogen supersaturation in the tailrace, it can improve the environment by significantly increasing the DO level of the discharge. The most common method is by aspiration of atmospheric air immediately downstream of the runner of a reaction turbine. The area under the runner at the start of the draft tube is at a low pressure, usually subatmospheric. This is by design to maximize the pressure differential across the runner in order to maximize efficiency. However, by installing air pipes or using existing piping, such as vacuum breakers, atmospheric air can be drawn in or aspirated into that area. Some of the atmospheric oxygen will go into solution and increase the DO of the discharge. The amount of DO increase depends on the water temperature, the ratio of flow rates of air to water, the size of the air bubbles, the distribution of the air in the cross section of hydraulic flow, and the contact time before the bubbles are vented to the surface of the tailwater. This aspiration process does increase the pressure under the runner and this decreases generating efficiency.

Another method to increase DO is to inject commercial oxygen into the powerhouse intake. This is done only rarely because of the expense. Still another method is to use air bubbler hoses laid along the bottom of the reservoir.

10.1 TRANSFORMERS

10.1.1 Transformer Theory

Elementary theory is developed from the viewpoint of a 3-phase three-leg concentric-cylindrical two-winding transformer, with the primary low-voltage winding next to the core and the secondary high-voltage winding outside the primary winding. This corresponds to a generator-step-up transformer of moderate kVA. Most of the information is also applicable to single-phase transformers with windings on two legs, 3-phase transformers with five-leg cores, transformers with the primary winding outside the secondary winding, three-winding transformers, substation transformers, etc.

Sinusoidal voltage is induced in windings by sinusoidal variation of flux

$$E = 4.44 \times 10^{-8} a_c BfN \tag{10-1}$$

where a_c = square inches cross section of core, B = lines per square inch peak flux density, E = rms volts, f = frequency in hertz, and N = number of turns in winding.

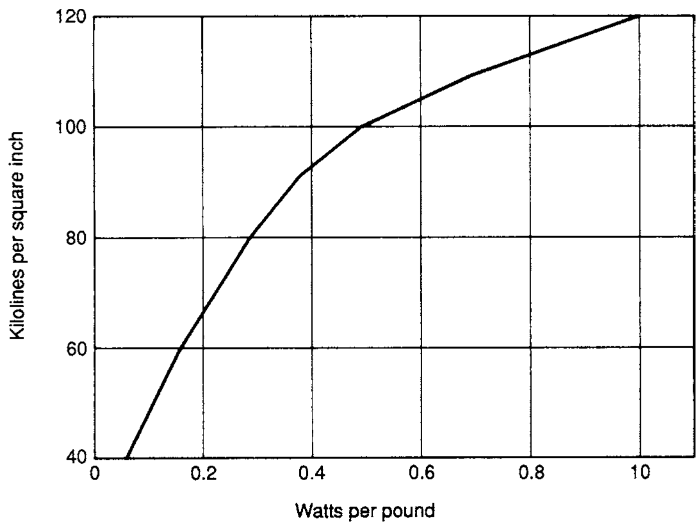

FIGURE 10-1 Typical core-loss curve for transformer core steel at 60 Hz.

The induced voltage in the primary (excited) winding approximately balances the applied voltage. The induced voltage in the secondary (loaded) winding approximately supplies the terminal voltage for the load.

Voltage ratio is the ratio of number of turns ("turn ratio") in the respective windings. The rated open-circuit (no-load) terminal voltages are proportional to the turns in the windings, but under load the primary voltage usually must be somewhat higher than the rated value if rated secondary voltage is to be maintained, because of regulation effects.

Characteristics on Open Circuit. The core loss (no-load loss) of a power transformer may be obtained from an empirical design curve of watts per pound of core steel (Fig. 10-1). Such curves are established by plotting data obtained from transformers of similar construction. The basic loss level is determined by the grade of core steel used and is further influenced by the number and type of joints employed in construction of the core. Figure 10-1 applies for 9-mil-thick M-3-grade steel in a single-phase core with 45° mitered joints. Loss for the same grade of steel in a 3-phase core would usually be 5% to 10% higher.

Exciting current for a power transformer may be established from a similar empirical curve of exciting volt-amperes per pound of core steel as given in Fig. 10-2. The steel grade and core construction are the same as for Fig. 10-1. The exciting current characteristic is influenced primarily by the number, type, and quality of the core joints, and only secondarily by the grade of steel. Because of the more complex joints in the 3-phase core, the exciting volt-amperes will be approximately 50% higher than for the single-phase core.

The exciting current of a transformer contains many harmonic components because of the greatly varying permeability of the steel. For most purposes, it is satisfactory to neglect the harmonics and assume a sinusoidal exciting current of the same effective value. This current may be regarded as composed of a core-loss component in phase with the induced voltage (90° ahead of the flux) and a magnetizing component in phase with the flux, as shown in Fig. 10-3.

Sometimes it is necessary to consider the harmonics of exciting current to avoid inductive interference with communication circuits. The harmonic content of the exciting current increases as the peak flux density is increased. Performance can be predicted by comparison with test data from previous designs using similar core steel and similar construction.

The largest harmonic component of the exciting current is the third. Higher-order harmonics are progressively smaller. For balanced 3-phase transformer banks, the third harmonic components

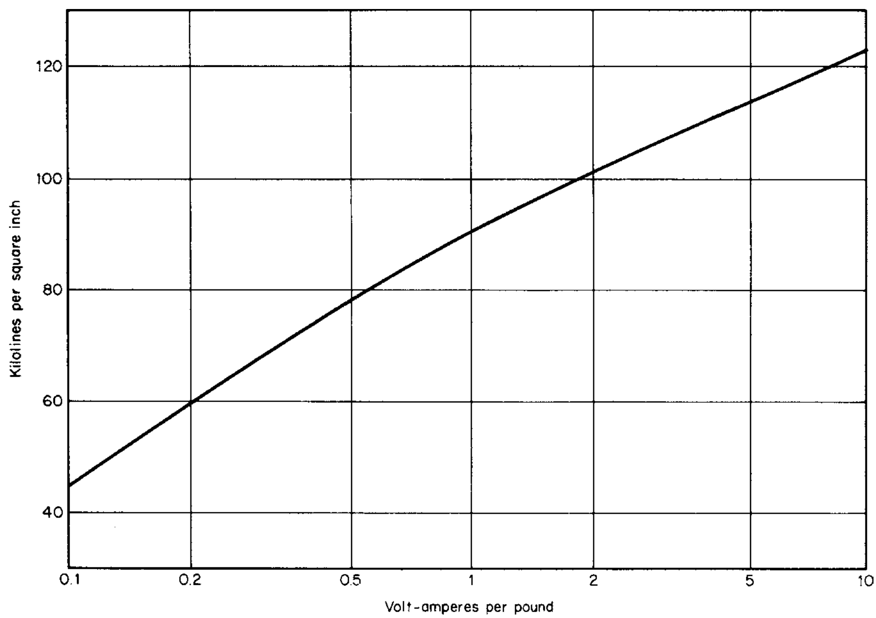

FIGURE 10-2 Typical exciting voltampere curve for transformer core steel at 60 Hz.

(or multiples of the third) are displaced by 120 fundamental degrees (deg) (or multiples of 120 fundamental deg) or 360 harmonic deg and therefore constitute a zero-phase-sequence system. Triple-harmonic currents may flow internally in delta-connected windings and externally in zero phase sequence paths in the connected system. The division of third-harmonic exciting current among available paths is not readily calculable.

Magnetizing Inrush Current. If an idle transformer is energized at a time in the voltage cycle when the flux in the core would normally be other than the actual residual flux in the core, the sinusoidal flux curve will be initially offset, and the offset decreases gradually with time [see Specht (1969) in References list at end of Sec. 10.1.3]. In extreme cases, the peak flux may be more than doubled, exceeding saturation of the core, and causing peak magnetizing current several times rated load current. Magnetizing inrush current is important, principally because of the possibility of false operation of transformer protective relays.

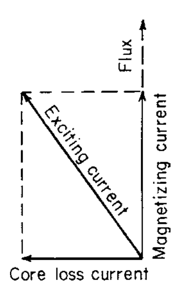

FIGURE 10-3 Phasor diagram of equivalent sinusoidal exciting current.

Characteristics on Short Circuit. If the primary winding of a transformer with 1:1 turn ratio is excited with the secondary winding short-circuited, a small exciting current flows in the primary winding, producing mutual flux mostly in the core. In addition, a short-circuit current flows forward in the primary and reverses in the secondary, causing leakage flux that passes between the two windings and completes its path through the core. The mutual and leakage flux together make net flux linkages with the secondary to induce voltage to supply the resistance drop in the secondary and make net flux linkages with the primary to induce a counter voltage equal to the applied voltage less the resistance drop in the primary. Figure 10-4 shows the space and phase relationships neglecting the exciting current. It is apparent that

$$E_P = I_P(R_P + R_S + jX) = I_P Z \tag{10-2}$$

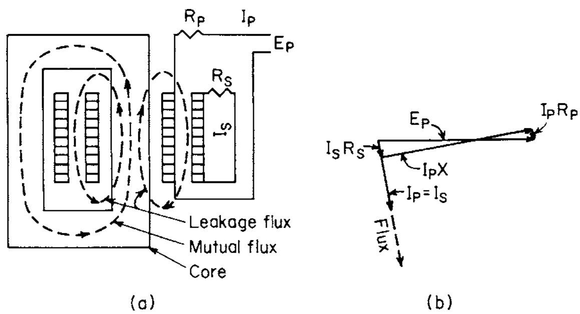

FIGURE 10-4 Short-circuited transformer: (*a*) flux distribution, single-phase; (*b*) phasor diagram, 1:1 ratio.

where E_P = rms volts applied to primary (phasor), I_P = rms amperes in primary (phasor), R_P = ohms resistance of primary winding, R_S = ohms resistance of secondary winding, X = ohms reactance (corresponding to the voltage induced in the primary by the leakage flux), and Z = ohms impedance $(R_P + R_S + jX)$.

Resistance, Reactance, and Impedance. R_P and R_S are effective ac resistances. They are greater than the dc resistances as measured with direct current, because they include eddy loss in the conductor and stray loss in the core clamps, tank, etc. The reactance of the transformer is X, and the impedance is $Z = R_P + R_S + jX$.

Load Loss. The loss on short-circuit test at rated current is the load loss at rated kVA

$$L_L = I_R^2 R = I_R^2 Z_M \cos\theta \tag{10-3}$$

where I_R = rms amperes rated current, L_L = watts load loss at rated current, R = ohms ac resistance $(R_P + R_S)$, Z_M = ohms impedance magnitude $[(R^2 + X^2)^{1/2}]$, and θ = impedance angle of transformer.

The load loss at another current is

$$L = \frac{L_L I^2}{I_R^2} \tag{10-4}$$

where I = rms amperes and L = watts load loss.

Characteristics under Load. Exciting current in the primary winding produces mutual flux mostly in the core. Opposing currents in the primary and secondary windings cause leakage flux, which passes between the two windings and completes its path through the core. The magnitude and phase of the mutual flux depend on the voltage. The magnitude and phase of the leakage flux depend on the current. The mutual and leakage flux together generate in the primary a counter voltage equal to the applied voltage less the resistance drop in the primary, and generate in the secondary a voltage equal to the terminal voltage plus the resistance drop in the secondary.

For most purposes the effect of the leakage flux can be represented by the effect of series reactance in the secondary-winding circuit. Figure 10-5 shows the space relationships and the phase relationships in a transformer of 1:1 ratio. It is apparent that

$$E_P = E_S + I_S(R_S + jX) + I_P R_P \tag{10-5}$$

where E_P = rms volts at primary terminal (phasor), E_S = rms volts at secondary terminal (phasor), I_P = rms amperes in secondary (phasor), I_S = rms amperes in secondary (phasor), R_P = ohms

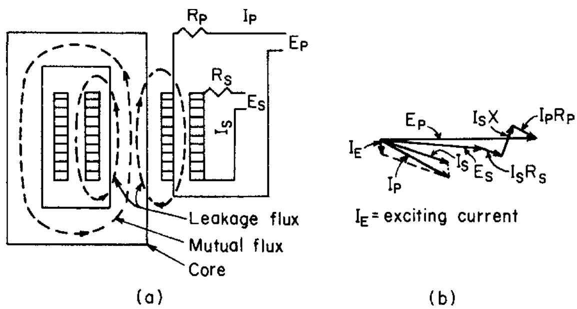

FIGURE 10-5 Loaded transformer: (*a*) flux distribution, single-phase; (*b*) phasor diagram, 1:1 ratio.

resistance of primary winding, R_S = ohms resistance of secondary winding, and X = ohms reactance of transformer.

Equivalent Circuits. Figure 10-6 shows a circuit which for most practical purposes is equivalent to the transformer of Fig. 10-5. The exciting current, I_E, is made up of two components, a magnetizing component flowing through X_M (the major component), and a loss component flowing through R_M. The values of R_M and X_M can be related to Figs. 10-1 and 10-2 if the core flux density at rated voltage is known. It will be found that these quantities vary with the voltage applied to the primary winding and they are usually determined for the rated voltage condition. For many purposes, the exciting current can be neglected and this leads to the simpler circuit of Fig. 10-7.

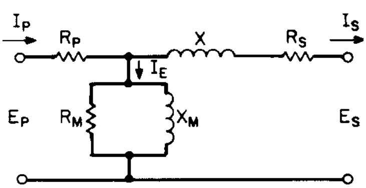

FIGURE 10-6 Equivalent circuit of a two-winding transformer considering exciting current.

Effect of Turn Ratio. Equation (10-5) and Fig. 10-7 represent a transformer of 1:1 turn ratio. A transformer of turn ratio T secondary to primary can be transformed into an

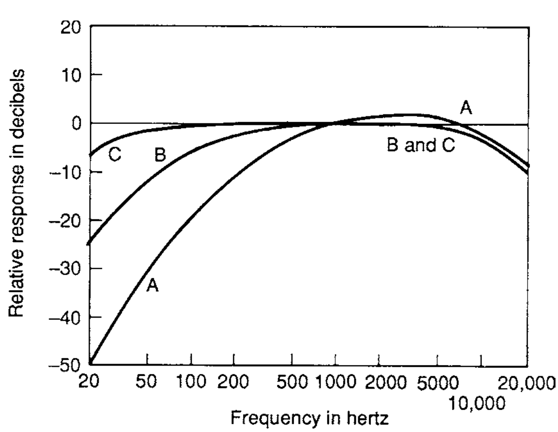

FIGURE 10-7 Equivalent circuit of a two-winding transformer neglecting exciting current.

equivalent 1:1 transformer by imagining the secondary winding replaced by a winding with the same number of turns as the primary winding, but using the same weight of conductor and occupying the same space as the secondary winding. I_S, E_S, and R_S in the real secondary winding become I_S/T, E_S/T, and R_S/T^2. The impedance of the load, Z_L, becomes Z_L/T^2. Thus, although Eqs. (10-2) to (10-5) and Figs. 10-4 to 10-7 were given for 1:1 turn ratio, they can be applied to any turn ratio. The fact that the simple series impedance of Fig. 10-7 may be used as equivalent to a transformer of any turn ratio is very helpful in the analysis of electric power systems. Secondary-winding characteristics corresponding to a fictitious secondary winding of 1:1 turn ratio are called secondary characteristics referred to the primary side. If more convenient, all characteristics can be referred to the secondary side by a reverse process.

Percent and Per Unit. Current, voltage, and kVA are frequently expressed as per unit or percent of rated value (25% = 0.25 per unit). The procedure is extended to resistance, reactance, and impedance by defining per unit impedance as (ohms impedance) × (rated current in amperes) ÷ (rated voltage in volts). Quantities expressed in percent or per unit are the same regardless of whether they are referred to the primary side or the secondary side.

Regulation. It is apparent from Eq. (10-5) that if the load current and the secondary voltage are at rated value, the primary voltage must exceed rated value. The excess is called regulation. Regulation in per unit is defined as the difference between primary and secondary voltage divided by secondary voltage. For rated load at lagging power factor and rated secondary voltage, regulation is given exactly by Eq. (10-6) or approximately by Eq. (10-7).

$$G_r = [(R_r + P_r)^2 + (X_r + Q_r)^2]^{1/2} - 1 \tag{10-6}$$

$$G_0 = 100\left[P_rR_r + Q_rX_r + \frac{(P_rX_r - Q_rR_r)^2}{2}\right] \tag{10-7}$$

where G_0 = percent regulation, G_r = per unit regulation, P_r = per unit load power factor, $Q_r = (1 - P_r^2)^{1/2}$, R_r = per unit resistance of transformer, and X_r = per unit reactance of transformer.

The calculation of regulation of a three-winding transformer is considerably more complex, depending on the load sharing between the two secondary windings. It will not be treated here.

Impedance Data. Resistance and reactance of transformers tend to follow normal patterns according to the ratings. Figure 10-8 shows resistance in percent (as determined by measurement of load loss on impedance test). Specific units may vary as much as ± 30% depending largely on the evaluation of losses as compared with capital cost. Figure 10-9 shows ranges of reactance in percent. Special designs (transformers with all windings high-voltage, autotransformers, designs with

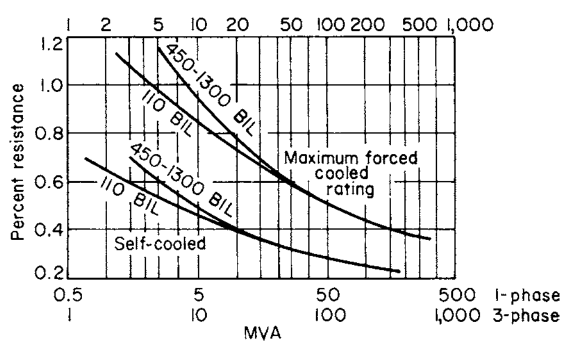

FIGURE 10-8 Resistance of typical power transformer.

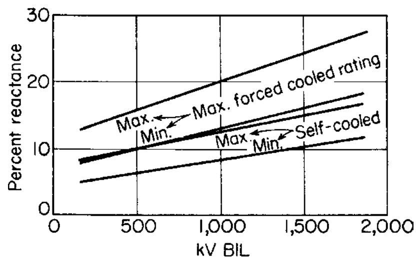

FIGURE 10-9 Reactance of typical power transformer.

overload ratings, etc.) may have reactances outside the limits shown.

Efficiency. This is given by

$$F_r = \frac{E_S I_S \cos\theta}{E_S I_S \cos\theta + L_{NS} + L_{LS}} \tag{10-8}$$

where E_S = rms volts at secondary terminals, F_r = per unit efficiency, I_S = rms amperes in secondary, L_{LS} = watts load loss at I_S, L_{NS} = watts no-load loss at $E_S(I_S = 0)$, and θ = impedance angle of load.

Three-Winding-Transformer Load Losses. The load losses of three-winding transformers, with all three windings carrying loads simultaneously, may be calculated from characteristics obtained by considering each pair of windings as a two-winding transformer.

$$L_T = \left(\frac{I_P}{I_A}\right)^2 \frac{L_{PS} + L_{PT} - L_{ST}}{2} + \left(\frac{I_{SP}}{I_A}\right)^2 \frac{L_{ST} + L_{PS} - L_{PT}}{2} + \left(\frac{I_{TP}}{I_A}\right)^2 \frac{L_{PT} + L_{ST} - L_{PS}}{2} \tag{10-9}$$

where I_A = rms amperes reference current referred to winding P; I_P = rms amperes in winding P; I_{SP} = rms amperes in winding S referred to winding P; I_{TP} = rms amperes in winding T referred to winding P; L_{PS} = watts load loss in windings P and S as a two-winding transformer at I_A; L_{PT}, L_{ST} = similar; and L_T = watts total load loss.

The loss is usually computed at, or corrected to, a temperature of 75°C for 55°C average rise units and 85°C for 65°C average rise units.

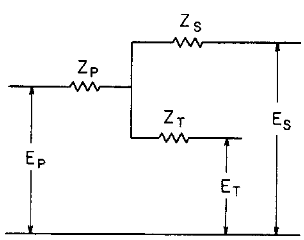

FIGURE 10-10 Equivalent circuit of a three-winding transformer.

Three-Winding-Transformer Equivalent Circuit. The equivalent circuit of a three-winding transformer may be determined from the three impedances obtained by considering each pair of windings separately. One form is shown in Fig. 10-10, in which

$$Z_P = \frac{Z_{PS} + Z_{PT} - Z_{ST}}{2} \tag{10-10}$$

$$Z_S = \frac{Z_{PS} + Z_{ST} - Z_{PT}}{2} \tag{10-11}$$

$$Z_T = \frac{Z_{PT} + Z_{ST} - Z_{PS}}{2} \tag{10-12}$$

where Z_P, Z_S, Z_T = ohms branch impedances in Fig. 10-10; Z_{PS} = ohms impedance from winding P to winding S in two-winding equivalent circuit of Fig. 10-7; and Z_{PT}, Z_{ST} = similar. All ohmic values of impedance must be referred to one common winding (i.e., the primary winding).

Four-Winding-Transformer Equivalent Circuit. The equivalent circuit of a four-winding transformer may be determined from the six impedances obtained by considering each pair of windings separately. One form is shown in Fig. 10-11, in which

$$Z_P = \frac{Z_{PQ} + Z_{PS} - Z_{SQ}}{2} - \frac{Z_A Z_B}{2(Z_A + Z_B)} \tag{10-13}$$

$$Z_S = \frac{Z_{PS} + Z_{ST} - Z_{PT}}{2} - \frac{Z_A Z_B}{2(Z_A + Z_B)} \tag{10-14}$$

$$Z_T = \frac{Z_{ST} + Z_{TQ} - Z_{SQ}}{2} - \frac{Z_A Z_B}{2(Z_A + Z_B)} \tag{10-15}$$

$$Z_Q = \frac{Z_{TQ} + Z_{PQ} - Z_{PT}}{2} - \frac{Z_A Z_B}{2(Z_A + Z_B)} \tag{10-16}$$

$$Z_A = (K_1 K_2)^{1/2} + K_1 \qquad Z_B = (K_1 K_2)^{1/2} + K_2 \tag{10-17}$$

$$K_1 = Z_{PT} + Z_{SQ} - Z_{PS} - Z_{TQ} \qquad K_2 = Z_{PT} + Z_{SQ} - Z_{PQ} - Z_{ST} \tag{10-18}$$

where Z_A = ohms branch impedance in Fig. 10-11 (complex); Z_B, Z_P, Z_S, Z_T, Z_Q = similar; Z_{PS} = ohms impedance (complex) from winding P to winding S in two-winding equivalent circuit of Fig. 10-7; and Z_{PT}, Z_{PQ}, Z_{ST}, Z_{SQ}, Z_{TQ} = similar.

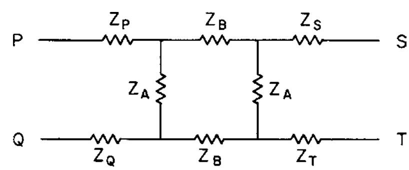

FIGURE 10-11 Equivalent circuit of a four-winding transformer.

Phase-Interconnected Transformers. These transformers that is with windings from more than one phase on a single core leg can be represented by an equivalent circuit only if each winding on a leg is considered as if it were brought out to separate terminals [see Cogbill (1955) in list at end of Sec. 10.1.3].

10.1.2 Transformer Connections

Parallel Operation. Two single-phase transformers will operate in parallel if they are connected with the same polarity. Two 3-phase transformers will operate in parallel if they have the same winding arrangement (e.g. Y-delta), are connected with the same polarity, and have the same phase rotation. If two transformers (or two banks of transformers) have the same voltage ratings, the same turn ratios, the same impedances (in percent), and the same ratios of reactance to resistance, they will divide the load current in proportion to their kVa ratings, with no phase difference between the currents in the two transformers. If any of the above conditions are not met, the load current may not divide between the two transformers in proportion to their kVA ratings and there may be a phase difference between currents in the two transformers.

Two unlike transformers connected in parallel will supply current to a load as follows:

$$I_L = \frac{E_P}{\dfrac{1}{(T_1/Z_1) + (T_2/Z_2)} + Z_L \dfrac{(1/Z_1) + (1/Z_2)}{(T_1/Z_1) + (T_2/Z_2)}} \tag{10-19}$$

where E_P = rms volts on primary side (phasor), I_L = rms amperes total load current (phasor), T_1 = turn ratio secondary to primary of unit 1, T_2 = turn ratio secondary to primary of unit 2, Z_1 = ohms impedance of unit 1 referred to secondary side (complex), Z_2 = ohms impedance of unit 2 referred to secondary side (complex), and Z_L = ohms impedance of load (complex).

The magnitude of the current in unit 1 is

$$I_{r1} = \frac{\{[T_1 R_{r2} I_{rL} + (T_1 - T_2) E_{r1} \cos\theta]^2 + [T_1 X_{R2} I_{rL} + (T_1 - T_2) E_{r1} \sin\theta]^2\}^{1/2}}{[(T_1 R_{r2} + T_2 R_{r1})^2 + (T_1 X_{r2} + T_2 X_{r1})^2]^{1/2}} \tag{10-20}$$

where E_{r1} = rms voltage of secondary terminals in per unit of unit 1, I_{rL} = rms total load current in per unit of unit 1, I_{r1} = rms current in secondary of unit 1 in per unit of unit 1, T_1 = ratio secondary turns to primary turns in unit 1, T_2 = ratio secondary turns to primary turns in unit 2, R_{r1} = equivalent resistance of unit 1 in per unit of unit 1, R_{r2} = equivalent resistance of unit 2 in per unit of unit 1, X_{r1} = equivalent reactance of unit 1 in per unit of unit 1, X_{r2} = equivalent reactance of unit 2 in per unit of unit 1, and θ = impedance angle of load (lagging current positive).

NOTE: Per unit means percent divided by 100, that is, 10% = 0.1 per unit.

The current in the second unit may be determined by using Eq. (10-20) with designation of first and second transformers reversed.

Phase-interconnected transformers (i.e., with windings from more than one phase on a single core leg) offer special complication when unlike units are connected in parallel. [See Cogbill (1955) in list at end of Sec. 10.1.3.]

3-Phase to 3-Phase Transformations. The delta-delta, the delta-Y, and the Y-Y connections are the most generally used; they are illustrated in Fig. 10-12. The Y-delta and delta-delta connections may be used as step-up transformers for moderate voltages. The Y-delta has the advantage of providing a good grounding point on the Y-connected side which does not shift with unbalanced load and has the further advantage of being free from third-harmonic voltages and currents; the delta-delta has the advantage of permitting operation in V in case of damage to one of the units. Delta connections are not the best for transmission at very high voltage; they may, however, be associated at some point with other connections that provide means for properly grounding the high-voltage system; but it is better, on the whole, to avoid mixed systems of connections. The delta-Y step-up and Y-delta step-down connections are without question the best for high-voltage transmission systems. They are economical in cost, and provide a stable neutral whereby the high-voltage system may be directly grounded or grounded through resistance of such value as to damp the system critically and prevent the possibility of oscillation.

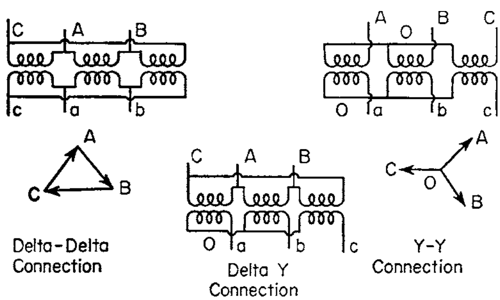

FIGURE 10-12 Standard 3-phase/3-phase transformer systems.

The Y-Y connection (or Y-connected autotransformer) may be used to interconnect two delta systems and provide suitable neutrals for grounding both of them. A Y-connected autotransformer may be used to interconnect two Y systems which already have neutral grounds, for reasons of economy. In either case, a delta-connected tertiary winding is frequently provided for one or more of the following purposes.

In *stabilization of the neutral,* if a Y-connected transformer (or autotransformer) with a delta-connected tertiary is connected to an ungrounded delta system (or poorly grounded Y system), stability of the system neutral is increased. That is, a single-phase short-circuit to ground on the transmission line will cause less drop in voltage on the short-circuited phase and less rise in voltage on the other two phases. A 3-phase three-leg Y-connected transformer without delta tertiary furnishes very little stabilization of the neutral, and the delta tertiary is generally needed. Other Y connections offer no stabilization of the neutral without a delta tertiary. With increased neutral stabilization, the fault current in the neutral on single-phase short circuit is increased, and this may be needed for improved relay protection of the system.

Third-harmonic components of exciting current find a relatively low impedance path in a delta tertiary on a Y-connected transformer, and less of the third-harmonic exciting current appears in the connected transmission lines, where it might cause interference with communication circuits. Failure to provide a path for third-harmonic current in Y-connected 3-phase shell-type transformers or banks of single-phase transformers will result in excessive third-harmonic voltage from line to neutral. The bank of a 3-phase, three-legged core-type Y-connected transformer acts as a delta winding with high impedance to the other windings. As a consequence, there is very little third-harmonic line-to-neutral voltage and a separate delta tertiary is not needed to reduce it.

An external load can be supplied from a delta tertiary. This may include synchronous or static capacitors to improve system operating conditions.

Loading Y-Connected Transformers Line to Neutral. Load can be connected line to neutral only if (1) the source side of the transformer is delta-connected, or (2) the source side is Y-connected with the neutral connected back to the source neutral.

If one of these two conditions is not maintained, the neutral will shift, reducing the voltage of the loaded phase and increasing the voltage of the other phases.

The Open-Delta Connection, or V Connection. This is an unsymmetric connection which is used if one transformer of a bank of three single-phase delta-connected units must be cut out because of failure. It is a connection that is sometimes resorted to as an emergency expedient or used as a temporary measure with the intention of completing the delta when conditions of load warrant the addition of a third unit. If one phase of a 3-phase delta-connected transformer of the shell type should fail, operation may be continued at reduced capacity by short-circuiting the damaged phase; if of the core type, operation may be continued by leaving the damaged phase open-circuited, provided that the windings are still capable of withstanding the voltage stresses. Since full-line currents flow in the windings out of phase with the transformer voltages, the normal capacity of the open-delta bank is reduced to 57.7% of its delta rating.

The T Connection. This uses two transformers, the first called the "main" transformer, connected from line to line; and the second, called the "teaser" transformer, connected from the midpoint of the first to the third line. It requires that the midpoint of both primary and secondary windings be available for connections. It has an advantage over the V connection in being more nearly symmetrical if the proper taps have been provided. As in the case of the V connection, two transformers of a bank of delta-connected transformers, one of which has failed, may be connected in T, and if 10% taps can be used for the teaser transformer, the transformation will be more nearly symmetrical than if the V connection were used. Where T-connected transformers are installed, they may later be changed to delta with the addition of one more transformer and an increase in rating of the bank of 73%. In the T connection (Fig. 10-13) the transformer *AD*, known as the teaser transformer, may be a duplicate of the main transformer so as to be interchangeable with it, and it may or may not be provided with an 86.6% tap. Its rated capacity will then be 15.5% more than actually necessary. The main transformer operates at a power factor of 0.866, and therefore, if the two transformers are duplicates, their total rated capacity will be 15.5% greater than the capacity of the load in kVA, or each transformer must have a rating of 0.577 of the kVA delivered. If the transformers are not interchangeable, the teaser may be reduced to a rating of one-half the kVA delivered.

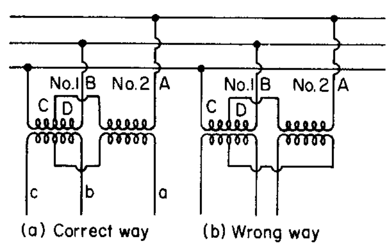

FIGURE 10-13 T-connected transformers.

In connecting transformers in T, *care should be taken to keep the relative phase sequence of the windings the same;* otherwise the impedance of the main transformer may be excessively high and cause undue unbalance. Figure 10-13 illustrates the right and the wrong way.

3-Phase to 6-Phase Transformation. 6 Phases are commonly used for supply of rectifiers. Six phases can be obtained as shown in Fig. 10-14 (double delta) or as in Fig. 10-15 (double Y) respectively. It is not necessary in this transformation, when the neutral connection is required, to have two secondary windings; instead a middle tap may be brought out, all the middle taps being connected together to form the neutral.

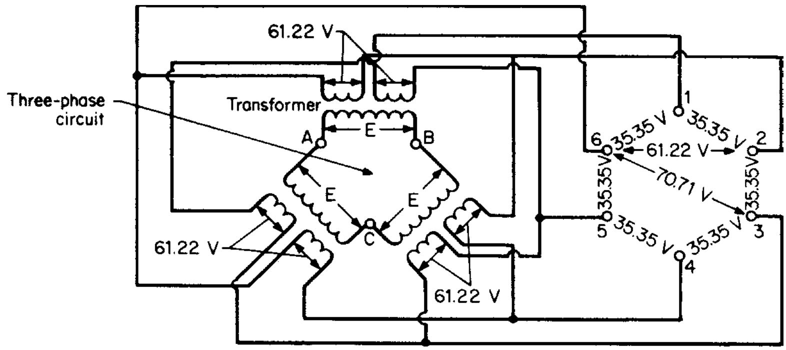

FIGURE 10-14 Three-phase/six-phase transformation, double delta.

The Interconnected Y Connection. This connection (see Fig. 10-16) is commonly referred to as the *zigzag* connection. It may be used with either a delta-connected winding as shown or a Y-connected winding for step-up or step-down operation. In either case, the zigzag winding produces the same angular displacement as a delta winding and, in addition, provides a neutral for grounding purposes. Owing to the angular relation of voltages of the zig and zag windings, the amount of conductor material required for such a connection is 15% greater than a corresponding Y or delta connection. If a transformer consists of zigzag and Y connections, a third winding, delta-connected, is usually necessary for reasons given under the Y-Y connection. If the delta-connected winding is included for purposes other than that of providing a third source of power, in some cases it is practical to design it for the same voltage as the zigzag winding and connect it in parallel with the zigzag winding to form the delta-grounded transformer connection [see Gross and Rao (1953) in list at end of Sec. 10.1.3].

The zigzag connection is used extensively for grounding transformers, the sole purpose of which is to establish a neutral point for grounding purposes; therefore no other windings are required.

10.1.3 Power Transformers

Power transformers may be defined as transformers used to transmit or distribute power in ratings larger than distribution transformers (usually over 500 kVA or over 67 kV). Some of the following information on power transformers is also applicable to other types of transformer.

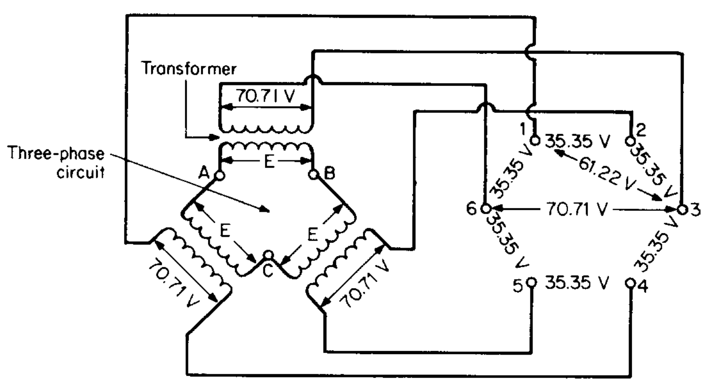

FIGURE 10-15 Three-phase/six-phase transformation, double Y.

The Rated Constants of a Power Transformer. The kVA, terminal voltages and currents are defined in ANSI C57.12.80. They are all based on the rated winding voltages at no load, although it is recognized that the actual primary voltage in service must be higher than the rated value by the amount of the regulation, if the transformer is to deliver rated voltage to the load on the secondary.

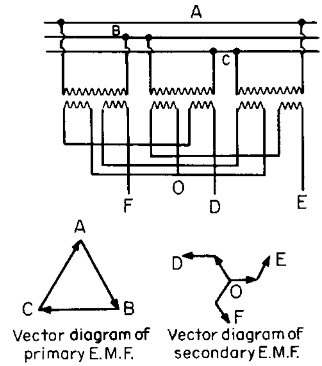

FIGURE 10-16 Interconnected Y connection.

10.1.4 Design

The design of commercial transformers requires the selection of a simple yet suitable form of construction so that the coils are easy to wind and the core is easy to build. At the same time, the mean length of the windings and magnetic circuit must be as short as possible for a given cross-sectional area, so that the amount of material required and resulting losses are minimized. The core must provide a continuous path for magnetic flux while its lamination pattern must be easy to cut and stack. The windings should be insulated in a simple and economical manner, should permit the dissipation of heat (due to losses) by means of cooling ducts, and should be mechanically strong to withstand short-circuit forces.

Two Types of Transformer in Common Use. When the magnetic circuit takes the form of a single ring encircled by two or more groups of primary and secondary windings distributed around the periphery of the ring, the transformer is termed a *core-type transformer*. When the primary and secondary windings take the form of a common ring which is encircled by two or more rings of magnetic material distributed around its periphery, the transformer is termed a *shell-type transformer* (Fig. 10-17). Actually, core-type (or "core-form") in U.S. power-transformer engineering usage means that the coils are cylindrical and concentric (the outer winding over the inner) whereas shell-type (or "form") denotes large pancake coils that are stacked or interleaved to make primary-secondary (P-S) groups. Except for certain extremes of current rating, the choice between the core- and shell-type construction is largely a matter of manufacturing facilities and of individual preference.

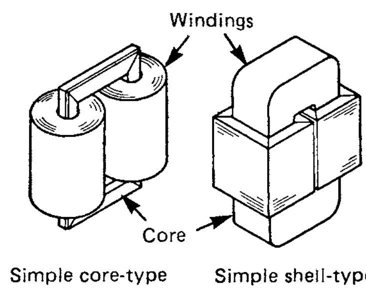

FIGURE 10-17 Forms of magnetic circuits for transformers.

Core-form transformer characteristic features are a long mean length of magnetic circuit and a short mean length of windings. Commonly used core constructions for single-phase and 3-phase units are shown in Figs. 10-18 and 10-19, respectively. The three-leg (one active leg) and four-leg (two active) construction of single-phase cores and the five-leg (three active) construction of 3-phase cores are used to reduce overall height. In these cases, the core encloses the cylindrical windings in

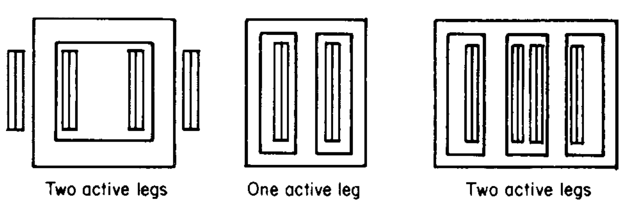

FIGURE 10-18 Single-phase core-form core construction.

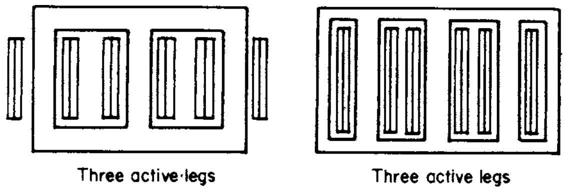

FIGURE 10-19 Three-phase core-form core construction.

a similar fashion to the shell-form construction. The simple concentric primary (inside) and secondary (outside) winding arrangement is common for all small- and medium-power transformers. However, large MVA transformers frequently have some degree of interleaving of windings, such as secondary-primary-secondary (S-P-S). The core-form construction can be used throughout the full size range of power transformers.

Shell-form transformer characteristic features are short mean length of magnetic circuit and long mean length of windings. This results in the shell-form transformer having a larger area of core and smaller number of winding turns than the core form of same output and performance. Also, the shell form would typically have a greater ratio by weight of steel to copper. Figure 10-20 shows the conventional 3-phase shell-form core with the coils in cross section. Primary-secondary-primary (P-S-P) coil grouping is most common, but P-S-P-S-P is often used.

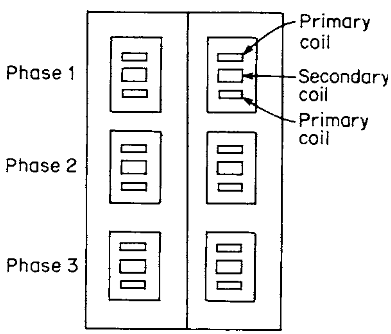

FIGURE 10-20 Conventional 3-phase core for the rectangular-pancake-interleaved-coil structure (shell type). The groups of pancake coils may be round or rectangular.

Design Process. The design process begins with a customer specification. This contains the desired characteristics which allow the design engineer to make economical choices between different materials and construction geometrics. Some of these characteristics are voltage (kV), power rating (MVA), impedance (%), loss evaluation ($/kW), temperature rating (°C), and cooling class (OA, FA, FOA). Some additional factors which influence the transformer design are requirements for tertiary windings and no-load or load taps.

After the customer specification is understood, the design optimization can begin. Most power transformers are designed starting with a certain winding arrangement and dimensions of the core and coils. Initial characteristics of the transformer are calculated and then compared to the desired characteristics. The initial dimensions are then modified to better meet the desired characteristics. Repeating the process leads to close agreement of calculated characteristics with desired characteristics. The repeated calculations, converging on the optimum design, are usually performed by computer. Closeness of agreement of calculated characteristics with tested characteristics depends upon the degree of refinement of the design process, the closeness of agreement of the physical properties of the materials used (particularly the dielectric properties of the insulating materials and the magnetic properties of the core steel) with the properties assumed in the design calculation, and the accuracy of the manufacturing procedures and processes.

Refinement of the design process results from comparison with test data obtained on similar transformers. This applies particularly to core loss, stray loss, noise level, reactance, and dielectric strength. The following calculation methods are mostly approximate.

With an assumed core cross section and flux density, the *number of turns* in each winding is established from Eq. (10-1). The flux density is adjusted to give an integral number of turns in the low-voltage winding, and then an acceptable ratio of open-circuit terminal voltage results from an integral number of turns in the high-voltage winding.

Leakage flux density in the main gap (insulation space between windings) for a transformer with one core leg per phase, as shown in Fig. 10-21, is as follows:

$$B_L = \frac{4.52 I_R N}{h_E} \qquad (10\text{-}21)$$

where B_L = lines per square inch peak leakage flux density, h_E = inches effective length of leakage flux path, I_R = rms amperes rated current of winding, and N = number of turns in winding.

If there is more than one leg per phase, Eq. (10-21) applies to the portion of winding on one leg. The effective length of leakage path is difficult to evaluate accurately. For concentric cylindrical windings, it is approximately

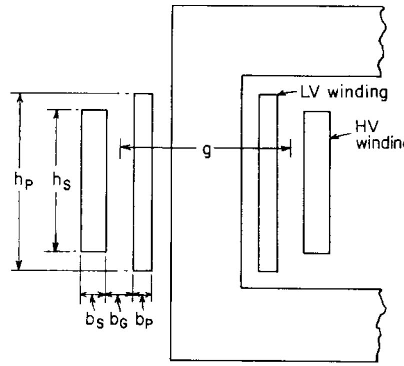

FIGURE 10-21 Dimensions of core-type concentric windings for reactance calculations.

$$h_E = \frac{h_P + h_S}{2} + 0.8\left(\frac{b_P + b_S}{3} + b_G\right) \qquad (10\text{-}22)$$

where b_G = inches radial distance between windings, b_P = inches radial width of winding P, b_S = inches radial width of winding, S, h_P = inches length of winding P, and h_S = inches length of winding S.

Leakage reactance may be calculated for a transformer with one set of coils per phase as follows:

$$X_r = \frac{2.01 \times 10^{-7}\, a_L f I_R N^2}{E_R h_E} \qquad (10\text{-}23)$$

where a_L = square inches effective cross section of leakage flux path, E_R = rms volts rated voltage of winding, f = frequency in hertz, h_F = effective length of leakage flux path in inches, I_R = rms amperes rated current of winding, N = number of turns in winding, and X_r = per unit reactance.

The effective cross section of the leakage flux path is difficult to evaluate accurately. For concentric cylindrical windings, it is approximately

$$a_L = \left(b_G + \frac{b_P + b_S}{3}\right)\pi g \qquad (10\text{-}24)$$

where g = mean diameter of main gap, in.

Resistance loss in winding is

$$W_R = 2.57\, M^2 \frac{234.5 + C}{309.5} \qquad (10\text{-}25)$$

$$L_R = H_C W_R \qquad (10\text{-}26)$$

where L_R = watts resistance loss in winding, M = rms kiloamperes per square inch current density, H_C = pounds weight of copper in winding, C = temperature in degrees Celsius, and W_R = watts per pound resistance loss in winding.

Eddy loss in the winding may be regarded as caused by circulating current induced in the strand by the magnetic flux passing through the strand. For a two-winding transformer,

$$W_E = 2.06 \times 10^{-10} d^2 f^2 B_L^2 \frac{309.5}{234.5 + C} \qquad (10\text{-}27)$$

$$L_E = H_C W_E \qquad (10\text{-}28)$$

where B_L = lines per square inch peak leakage flux density, from Eq. (10-21), C = Celsius temperature, d = inches thickness of strand perpendicular to flux, f = hertz frequency, L_E = watts eddy loss in winding, H_C = pounds weight of copper in winding, and W_E = watts per pound average eddy loss in winding.

Load loss is the sum of resistance and eddy losses in all windings plus stray loss. The stray loss is in itself an eddy loss produced by the leakage flux penetrating the surface of other conducting components, such as the core, core clamps, and tank. Historically, the stray loss has been predicted from test results on similar transformers, but finite element computer solutions have recently been developed to define the leakage flux paths accurately and permit more exact calculation of both stray and eddy losses.

No-load loss equals watts per pound determined from Fig. 10-1, multiplied by weight of the core multiplied by a correction factor depending on core configuration and processing and determined by experience.

General Design Characteristics. The relationship of power-transformer characteristics to scale factor can be illuminated by considering the effect of increasing all dimensions in the ratio S, while retaining the same thickness of core lamination and thickness of conductor strand, but imagining the conductor turns to be reconnected for a terminal voltage proportionate to the insulation thickness. Similarly the effect of increasing the flux density in the ratio B and the current density in the ratio M can be examined. The results are shown in Table 10-1.

Core dimensions are generally standardized in steps, with only a small number of dimensions varying to meet the requirement of the particular rating. Cold-rolled grain-oriented silicon steel strip in gages of 0.009 to 0.014 in is used with mitered corner joints to take advantage of the good characteristics of this material when carrying flux in the rolling direction.

10.1.5 Insulation

Insulation systems in power transformers consist of a fluid—either liquid or gas—together with solid materials. Petroleum-based oils have been used to insulate power transformers since 1886 and are still used in virtually all medium and large transformers (Sheppard 1986). Askeral was used from

1932 through the mid-1970s when the flammability of mineral oil was a concern, but it has since been completely phased out of transformer production because of environmental concerns. It has been replaced by any of a wide variety of high-flash-point fluids (silicones, high-flash-point hydrocarbons, clorinated benzenes, or chlorofluorocarbons). Gas systems include nitrogen, air, and fluorogases. The fluorogases are used to avoid combustability and limit secondary effects of internal failure. Some transformers have been constructed using low boiling-point liquids such as Freon which allows improved heat transfer using a 2-phase cooling system.

Within the core and coil assembly, insulation can be divided into two fundamental groups: major insulation and minor insulation. Major insulation separates the high- and low-voltage windings, and the windings to core. Minor insulation may be used between the parts of individual coils or windings depending on construction. Finally, turn insulation is applied to each strand of conductor and/or groups of strands forming a single turn.

Oil-Insulated Transformers. Low cost, high dielectric strength, excellent heat transfer characteristics, and ability to recover after dielectric overstress make mineral oil the most widely used transformer insulating material. The oil is reinforced with solid insulation in various ways. The major insulation usually includes barriers of wood-based paperboard (pressboard), the barriers usually alternating with oil spaces. Because the dielectric constant of the oil is 2.2 and that of the solid is approximately 4.0, the dielectric stress in the oil ends up being higher than that of the pressboard, and the design of the structure is usually limited by the stress in the oil.

The insulation on the conductors of the winding may be enamel or wrapped paper which is either wood- or nylon-based. The use of insulation directly on the conductor actually inhibits the formation of potentially harmful streamers in the oil, thereby increasing the strength of the structure (Nelson 1989). Again, the limit of dielectric strength is usually that of the oil.

Heavy paper wrapping is also usually used on the leads coming from the winding. In this case, the insulation serves to reduce the stress in the oil by moving the interface from the surface of the conductor (where the stress is high) to a distance away from the conductor (where the stress is considerably lower). Again, the stress in the oil determines the amount of paper required, and the thermal considerations establish the minimum size of the conductor for the necessary insulation.

Askeral-Insulated Transformers. These transformers have constructions similar to the oil-insulated transformers. The relatively high dielectric constant of the askeral aids in transferring the dielectric stress to the solid elements. Askeral has limited ability to recover after dielectric overstress, and thus the strength is limited in nonuniform dielectric fields. Askerals are seldom used over 34.5-kV operating voltage. They are powerful solvents; their products of decomposition are so harmful that they have been completely abandoned in transformers manufactured after the mid-1970s.

Fluorogas-Insulated Transformers. Fluorogases have better dielectric strength than nitrogen or air. Although their heat transfer characteristics are poorer than oil, they are better than nitrogen or air because of their higher density. Both dielectric strength and heat transfer capability increase with pressure; in fact, the dielectric strength at 3 atm gage pressure—where some fluorocarbon-insulated transformers operate—can approach that of oil. The gas insulation is reinforced with solid insulation used in the form of barriers, layer or disk insulation, turn insulation, and lead insulation similar to oil-immersed transformers.

It is usually economical to operate fluorogas-insulated transformers at higher temperatures than oil-insulated transformers. Suitable solid insulating materials include glass, asbestos, mica, high-temperature resins, and ceramics.

Dielectric stress on the gas is several times higher than in the adjacent solid insulation; care must be taken to avoid overstressing the gas.

Nitrogen and Air-Insulated Transformers. These are generally limited to 34.5 kV and lower operating voltages. Air-insulated transformers in clean locations are frequently ventilated to the atmosphere. In contaminated atmospheres a sealed construction is required, and nitrogen is generally used at approximately 1 atm and some elevated operating temperatures.

Design of Insulation Structures. Three factors must be considered in the evaluation of the dielectric capability of an insulation structure—the voltage distribution must be calculated between different parts of the winding, the dielectric stresses are then calculated knowing the voltages and the geometry, and finally the actual stresses can be compared with breakdown or design stresses to determine the design margin.

Voltage distributions are linear when the flux in the core is established. This occurs during all power frequency test and operating conditions and to a great extent under switching impulse conditions. (Switching impulse waves have front times in the order of tens to hundreds of microseconds and tails in excess of 1000 μs.) These conditions tend to stress the major insulation and not inside of the winding. For shorter-duration impulses, such as full-wave, chopped-wave, or front-wave, the voltage does not divide linearly within the winding and must be determined by calculation or low-voltage measurement. The initial distribution is determined by the capacitative network of the winding. For disk and helical windings, the capacitance to ground is usually much greater than the series capacitance through the winding. Under impulse conditions, most of the capacitive current flows through the capacitance to ground near the end of the winding, creating a large voltage drop across the line end portion of the coil.

The capacitance network for shell form and layer-wound core form results in a more uniform initial distribution because they use electrostatic shields on both terminals of the coil to increase the ratio between the series and to ground capacitances. Static shields are commonly used in disk windings to prevent excessive concentrations of voltages on the line-end turns by increasing the effective series capacitance within the coil, especially in the line end sections. Interleaving turns and introducing floating metal shields are two other techniques that are commonly used to increase the series capacitance of the coil.

Following the initial period, electrical oscillations occur within the windings. These oscillations impose greater stresses from the middle parts of the windings to ground for long-duration waves than for short-duration waves. Very fast impulses, such as steep chopped waves, impose the greatest stresses between turns and coil portions. Note that switching impulse transient voltages are two types—asperiodic and oscillatory. Unlike the asperiodic waves discussed earlier, the oscillatory waves can excite winding natural frequencies and produce stresses of concern in the internal winding insulation. Transformer windings that have low natural frequencies are the most vulnerable because internal damping is more effective at high frequencies.

Dielectric stresses existing within the insulation structure are determined using direct calculation (for basic geometries), analog modeling, or most recently, sophisticated finite-element computer programs.

Allowable stresses are determined from experience, model tests, or published data. For liquid-insulated transformers, insulation strength is greatly affected by contamination and moisture. The relatively porous and hygroscopic paper-based insulation must be carefully dried and vacuum impregnated with oil to remove moisture and gas to obtain the required high dielectric strength and to resist deterioration at operating temperatures. Gas pockets or bubbles in the insulation are particularly destructive to the insulation because the gas (usually air) not only has a low dielectric constant (about 1.0), which means that it will be stressed more highly than the other insulation, but also air has a low dielectric strength.

High-voltage dc stresses may be imposed on certain transformers used in terminal equipment for dc transmission lines. Direct-current voltage applied to a composite insulation structure divides between individual components in proportion to the resistivities of the material. In general the resistivity of an insulating material is not a constant but varies over a range of 100:1 or more, depending on temperature, dryness, contamination, and stress. Insulation design of high-voltage dc transformers in particular require extreme care.

10.1.6 Cooling

Removal of heat caused by losses is necessary to prevent excessive internal temperature that would shorten the life of the insulation. The following paragraphs cover the procedure for calculating the internal temperature of oil-insulated self-cooled power transformers of conventional core-type construction using radiators. Almost all modern power transformers have insulation systems designed for operation at 65°C average winding rise over ambient temperature and 80°C hottest-spot winding rise over ambient in an average ambient of 30°C. Older power transformers were designed for 55°C average winding rise/65°C hottest-spot winding rise over ambient.

The average temperature of a winding is the temperature determined by measuring the dc resistance of the winding and comparing it with the measurement previously obtained at a known temperature. The rise of the average temperature of a winding above ambient temperature is

$$U = B + E + N + T \tag{10-29}$$

where B = degrees Celsius rise of effective oil over ambient, E = degrees Celsius rise of average oil over effective oil, N = degrees Celsius rise of average coil surface over average oil, T = degrees Celsius rise of conductor over coil surface, and U = degrees Celsius rise of average conductor over ambient.

The effective oil temperature is the equivalent uniform temperature with equal ability to dissipate heat to the air. The effective oil temperature is approximately the average of the oil entering the top of the radiator and the oil leaving the bottom of the radiator. The oil temperature is approximately the same as the temperature of the adjacent radiator surface exposed to air. A smooth, vertical transformer-tank surface will dissipate heat to the air as follows:

$$D_B = 1.40 \times 10^{-3} B^{1.25} + 1.75 \times 10^{-3}\,(1 + 0.011A)B^{1.19} \tag{10-30}$$

where A = degrees Celsius ambient temperature, B = degrees Celsius effective oil rise over ambient, and D_B = watts per square inch dissipated to the air.

The first term of Eq. (10-30) covers heat transferred by convection. Usually, the radiator consists of parallel flattened tubes with limited accessibility to cooling air, and it is therefore necessary to multiply the first term by an experimentally determined friction factor (less than 1). The second term of Eq. (10-30) covers heat transferred by radiation, on the assumption of low temperature emissivity of 0.95, which applies to most painted surfaces commonly encountered. For any other value of low temperature emissivity this term should be multiplied by emissivity/0.95 (see Table 10-2). Usually, the radiator consists of parallel flattened tubes which radiate heat to each other. The net radiation of heat can be determined by considering the transformer and radiators replaced by a nonreentrant enveloping surface. If the second term of Eq. (10-30) is multiplied by the ratio of the area of the enveloping surface to actual surface (less than 1), the effect of reabsorption of radiation is eliminated. When radiation is small compared with convection, it can be assumed that A = 25°C and the $B^{1.19}$ can be replaced by $0.79B^{1.25}$, and Eq. (10-30) becomes

where V = ratio of envelope surface area to actual surface area and F = friction factor determined by experiment.

The temperature rise of average oil over effective oil, E, is usually negligible for normal transformer designs. It may become important if (1) the center of gravity of the radiators is not elevated sufficiently above the center of gravity of the core and coils, (2) there is unusual loss in the oil space over the core such as might result from high-current leads, (3) a winding has usually restricted oil ducts, or (4) pumps are used to circulate oil through the radiator without channeling the pumped oil through the oil ducts of the coil. For such cases, E is best evaluated by comparison with performance of previous designs.

The temperature rise of average coil surface over average oil, N, carries the loss in the coil through a film of stationary oil into moving oil. For a horizontal pancake coil (vertical axis), most of the heat escapes through the thin oil film on the upper surface and very little heat escapes from the lower surface. On the assumption that all the heat escapes from the upper surface, the temperature rise is

$$N = 13.2D_N^{0.8} \qquad °\text{C} \tag{10-32}$$

where D_N = watts per square inch dissipated from the coil to the oil.

For a vertical pancake coil (axis horizontal), the heat leaves both sides equally, and

$$N = 14D_N \qquad °\text{C} \tag{10-33}$$

The temperature rise of conductor over coil surface, T, carries the heat from the copper through the solid insulation applied to the conductor and the coil,

$$T = R_T t D_N \qquad °\text{C} \tag{10-34}$$

where D_N = watts per square inch dissipated from the coil to the oil, R_T = degrees Celsius per watt per inch thermal resistivity, and t = inch length of path.

The components of the winding rise over ambient are determined from Eqs. (10-31), (10-32), or (10-33), and (10-34) by using values of watts per square inch determined from the calculated losses and the design geometry. Then the total rise is determined from Eq. (10-29).

Oil circulation is as follows. The oil moves generally upward through ducts in the core and coils, rising in temperature as it goes. It moves generally downward through the radiators, falling in temperature as it goes (see Fig. 10-22). The space above the core and coils is filled with hot oil so that the height-temperature curve of the circulating oil forms a triangle *def*. The difference in weight of the two columns of oil which furnishes the circulating force is proportional to the area of the triangle

$$w = 2.50 \times 10^{-5}\, ml \tag{10-35}$$

where m = inches headroom, I = degrees Celsius top oil rise over average oil, and w = pound force per square inch circulating force.

I is established by the following relations:

$$L = 222IG_C \tag{10-36}$$

$$w = G_C R_H \tag{10-37}$$

$$I = 13.5\left(\frac{LR_H}{m}\right)^{1/2} \tag{10-38}$$

where G_C = gallons per minute rate of circulation of oil, L = watts loss, and R_H = friction opposing oil flow in pound-force per square inch per gallon per minute.

R_H is not easily evaluated except by test, but Eq. (10-38) is useful in evaluating the effect of changing L or m.

The limiting temperature rises are

$$H = B + E + I \tag{10-39}$$

$$S = B + E + N + T + I = U + I \tag{10-40}$$

where H = degrees Celsius top oil rise over ambient temperature and S = degrees Celsius hot-spot rise over ambient temperature.

Equation (10-40) gives the temperature of the top pancake coil. Values of N and T may need to be separately computed for this coil or for other coils if they have different loss density or different insulation than the main winding coils. If a coil other than the top coil is found to have higher conductor rise over adjacent oil, then appropriately reduced values of I should be used to calculate S for that coil.

Variation of temperature with load is as follows. If temperature rise conditions for rated load (or for any load) are known, temperature rises for any other load can be determined

$$B_2 = B_1\left(\frac{L_2}{L_1}\right)^{0.8} \tag{10-41}$$

$$N_2 = N_1\left(\frac{L_2}{L_1}\right)^{0.8} \tag{10-42}$$

$$T_2 = T_1\frac{L_2}{L_1} \tag{10-43}$$

$$I_2 = I_1\left(\frac{L_2}{L_1}\right)^{1/2} \tag{10-44}$$

where B_1, N_1, T_1, I_1, and L_1 correspond to the known condition and B_2, N_2, T_2, I_2, and L_2 correspond to the new condition.

The total loss should be used for L_1 and L_2 in Eqs. (10-41) and (10-44). The resistance and eddy loss only should be used for L_1 and L_2 in Eqs. (10-42) and (10-43). The exponent in Eq. (10-42) should be 1.0 for vertical pancake coils. At constant voltage the resistance loss varies with the square of the load kVA and with the resistivity as affected by average temperature of copper according to Eq. (10-25). The eddy loss varies with the square of the load and inversely with the resistivity of the copper according to Eq. (10-27). The stray loss varies with the square of the load and may be assumed to vary inversely with the resistivity of the copper, like the eddy loss. The core loss may be assumed unaffected by load or temperature. For many purposes, it is reasonable to assume that the entire load loss varies with the square of the load and with the resistivity.

Consider the following example. What is the temperature rise in a 30°C ambient at 80% load of a transformer with the following characteristics?

Load loss is 2 times no-load loss at 85°C

Load loss is assumed all resistance loss 85°C

Full-load temperature rises with 85°C losses are

$$B_1 = 45$$

$$N_1 = 15 \qquad U_1 = 65$$

$$T_1 = 5 \qquad S_1 = 80$$

$$I_1 = 15 \qquad H_1 = 60$$

On assuming (for a trial) that the average copper temperature will be 80°C, the relative load loss is

$$(0.8)^2 \times \frac{234.5 + 80}{234.5 + 85} = 0.630$$

and the relative total loss is

$$\frac{0.630 \times 2 + 1}{3} = 0.753$$

Then

$$B_2 = 45(0.753)^{0.8} = 35.9°\text{C}$$

$$N_2 = 15(0.630)^{0.8} = 10.4°\text{C}$$

$$T_2 = 5 \times 0.630 = 3.2°\text{C}$$

$$I_2 = 15(0.753)^{0.5} = 12.0°\text{C}$$

$$U_2 = 35.9 + 10.4 + 3.2 = 49.5°\text{C}$$

$$S_2 = 35.9 + 10.4 + 3.2 + 12.0 = 61.5°\text{C}$$

$$H_2 = 35.9 + 12.0 = 47.9°\text{C}$$

The average copper temperature is 49.5 + 30 = 79.5°C, which is close enough to the assumed 80°C.

Consider another example. What is the temperature rise in a 30°C ambient at 140% load for the same transformer? Upon assuming (for a trial) that the average copper temperature will be 140°C, the relative load loss is

$$(1.4)^2 \frac{234.5 + 140}{234.5 + 85} = 2.30$$

and the relative total loss is

$$\frac{2.30 \times 2 + 1}{3} = 1.87$$

Then

$$B_2 = 45(1.87)^{0.8} = 74.2°\text{C}$$

$$N_2 = 15(2.30)^{0.8} = 29.2°\text{C}$$

$$T_2 = 3 \times 2.30 = 6.9°\text{C}$$

$$I_2 = 15(1.87)^{0.5} = 20.5°\text{C}$$

$$U_2 = 74.2 + 29.2 + 6.9 = 110.3°\text{C}$$

$$S_2 = 74.2 + 29.2 + 6.9 + 20.5 = 130.8°\text{C}$$

$$H_2 = 74.2 + 20.5 = 94.7°\text{C}$$

The average copper temperature is 110.3 + 30 = 140.3, which is close enough to the assumed 140°C. These temperatures would be considered excessive for continuous loading and should not be continued for any extended time period.

Industry loading guides (ANSI/IEEE C57.92) provide tables that give winding hottest-spot temperature and top oil temperature for representative transformers over a wide range of ambient temperature and per unit loading conditions. These guides also contain a cautionary note that operation at hottest-spot temperatures above 140°C may cause gassing in the solid insulation and oil which could reduce the dielectric integrity of the transformer (Heinrichs 1979, McNutt, et al. 1980).

Transient thermal conditions must also be considered. Since transformer temperature takes many hours to stabilize after a change in loading, it is sometimes desirable to calculate the temperature during the transient period.

$$B_H = B_U - (B_U - B_0)\epsilon^{-h/hB} \tag{10-45}$$

$$h_B = \frac{K_B(B_U - B_0)}{L_D - L_0} \tag{10-46}$$

$$\begin{aligned} K_B &= 0.06H_{CC} + 0.04H_T + 1.33G_T \quad \text{for nondirected flow cooling} \\ K_B &= 0.06H_{CC} + 0.06H_T + 1.93G_T \quad \text{for directed flow cooling} \end{aligned} \tag{10-47}$$

where B_H = degrees Celsius effective oil rise after h hours, B_0 = degrees Celsius initial oil rise, B_U = degrees Celsius ultimate effective oil rise for the new load, G_T = gallons of oil, $\epsilon = 2.718$, h = hours after the change in load, h_B = hours time constant of the transformer, H_{CC} = pounds weight of core and coils, H_T = pounds weight of tank and fittings, K_B = watthours per degree Celsius thermal capacity of the transformer, L_D = watts dissipated at the new load, L_0 = watts loss at the initial condition ($h = 0$).

Equation (10-45) applies whether B_U is greater or less than B_0. However, if B_0 and L_0 are zero, then

$$B_H = B_U(1 - \epsilon^{-h/h_B}) \tag{10-48}$$

$$h_B = \frac{K_B B_U}{L_D} \tag{10-49}$$

The rise of average conductor over average oil ($N + T = Q$) is a single variable for transient calculations. The ultimate value is reached in 15 to 30 min

$$Q_H = Q_U - (Q_U - Q_0)\epsilon^{-h/h_Q} \tag{10-50}$$

$$h_Q = \frac{K_Q(Q_U - Q_0)}{L_0 - L_D} \tag{10-51}$$

$$K_Q = 0.05H_C\frac{a/2 + b}{b} \tag{10-52}$$

where a = square inches cross section of strand insulation, b = square inches cross section of copper strand, H_C = pounds weight of copper in winding, K_Q = watthours per degree Celsius thermal capacity of winding, L_D = watts dissipated at $h = 0$, L_0 = watts loss at $h = 0$, h = hours, h_Q = hours time constant of winding, Q_H = degrees Celsius average conductor rise over average oil after h hours, Q_0 = degrees Celsius initial average conductor rise over average oil, and Q_U = degrees Celsius ultimate average conductor rise over average oil.

Equation (10-50) applies whether Q_U is greater or less than Q_0. However, if Q_U and L_0 are zero, then

$$Q_H = Q_0\epsilon^{-h/h_B} \tag{10-53}$$

$$h_Q = \frac{K_Q Q_0}{L_D} \tag{10-54}$$

Now consider another example. If the transformer in the previous example operates in a 30°C ambient at 80% load until ultimate temperature conditions are established and then operates at 140% load, what will be the conditions after 4 h at 140% load? Assume nondirected flow cooling. It is now necessary to specify additional characteristics of the transformer as follows:

$$H_C = 20{,}000 \qquad a = 0.018$$

$$H_{CC} = 100{,}000 \qquad b = 0.090$$

$$H_T = 30{,}000$$

$$G_T = 10{,}000$$

$$\text{Total loss} = 150.000 \text{ W at } 85°\text{C}$$

Then $$K_B = 0.06 \times 100{,}000 + 0.04 \times 30{,}000 + 1.33 \times 10{,}000 = 20{,}500 \qquad (10\text{-}55)$$

Assume that the average winding temperature after 4 h is 125°C.

$$L_D = \frac{2 \times (1.4)^2(234.5 + 125)/319.5 + 1}{3} 150{,}000 = 270{,}540 \text{ W}$$

$$L_0 = 0.753 \times 150{,}000 = 112{,}950 \text{ W}$$

$$h_B = \frac{20{,}500\,(74.2 - 35.9)}{270{,}540 - 112{,}950} = 4.98 \text{ h}$$

$$B_H = 74.2 - (74.2 - 35.9)\epsilon^{-4/4.98} = 57.0°\text{C}$$

$$\left.\begin{aligned} N_H &= 29.2 \\ T_H &= 6.9 \\ I_H &= 20.5 \end{aligned}\right\} \text{(these reach ultimate value before 4 h)}$$

$$U_H = 57.0 + 29.2 + 6.9 = 93.1°\text{C}$$

$$S_H = 57.0 + 29.2 + 6.9 + 20.5 = 113.6°\text{C}$$

$$H_H = 57.0 + 20.5 = 76.5°\text{C}$$

Consider the following example of a load cycle. If the transformer examined in the preceding example operates in a 30°C ambient on a daily cycle of 20 h at 80% load and 4 h at 140% load, what are the temperature rises at the end of the 140% load period? Since the transformer time constant was approximately 5 h, it would be reasonable to assume that the oil temperature will have essentially stabilized after 20 h at 80% load. (The time constant for the transient from 140% load to 80% load will be essentially the same as the time constant for the transient from 80% load to 140% load.) As a result, the temperature rises at the end of the 140% load period during this cycle will be the same as those found in the previous example. Figure 10-23 shows the complete set of time-temperature curves for the 24-h cycle.

The short-circuit temperature rise is calculated on the assumption that all heat generated in the copper is stored in the copper until the short circuit is over

$$C_2 = 309.5 \times \left\{\left[\left(\frac{C_1 + 234.5}{309.5}\right)^2 + g\right]\epsilon^{M^2 s/10{,}800} - g\right\}^{1/2} - 234.5 \qquad (10\text{-}56)$$

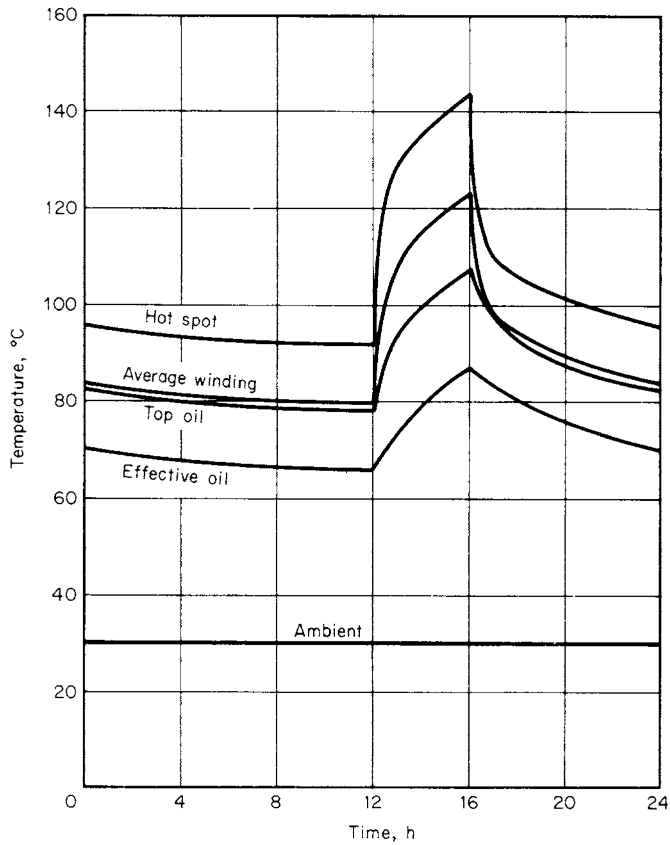

FIGURE 10-23 Transformer temperatures during the daily load cycle.

where, C_1 = degrees Celsius average temperature of winding at start of short circuit, C_2 = degrees Celsius average temperature of winding at end of short circuit, M = rms kiloamperes per square inch current density, s = seconds duration of short circuit, and g = ratio of eddy loss to resistance loss in winding at 75°C.

The temperature resulting from any short circuit may be read directly from Fig. 10-24, which is plotted from Eq. (10-56).

For example, if a short circuit resulting in 50 kA/in^2 current density is held for 3.5 s in a winding with 10% eddy loss ($g = 0.1$) at 75°C, and with a starting temperature of 75°C, what is the average temperature of the winding at the end of the short circuit?

On the curve for $g = 0.1$, at 75°C, the value of M^2s is 5300.

$$5300 + 50^2 \times 3.5 = 14{,}050$$

On the curve for $g = 0.1$, at $M^2s = 14{,}050$, the temperature is 246°C.

Fan-cooled transformers use external fans to improve heat dissipation from the radiators, and sometimes internal pumps to circulate the oil through the radiators (and sometimes also through cooling ducts in the core and coils). With fan cooling the effective oil-temperature rise B is determined from test data on the particular arrangement, instead of Eq. (10-31). With oil pumps I is determined from Eq. (10-38). It is usually possible to obtain 67% more capacity with fans and pumps running.

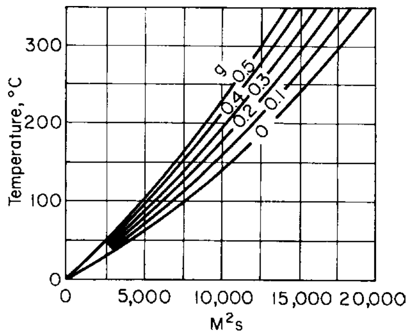

FIGURE 10-24 Temperature of windings after short circuit, with all heat stored, where g = ratio of eddy current loss to resistance loss at 75°C, M = rms kiloamperes per square inch current density, and s = seconds duration of short circuit. *Example*: For initial temperature of 75°C from the curve of $g = 0.1$, read $M^2s = 5300$. For $M = 50$ and $s = 3.5$; $(50)^2 \times 3.5 = 8750$. Total $M^2s = 14{,}050$. Then, from curve of $g = 0.1$, read final temperature: 246°C.

Forced-oil-cooled transformers use external oil-to-air heat exchangers requiring both air fans and oil pumps for all operating conditions. The effective oil rise B is calculated from the characteristics of the oil-to-air heat exchanger, and I is determined from Eq. (10-36). Forced-cooled transformers have no continuous load capacity without pump and fans.

Water-cooled transformers usually have the oil withdrawn from the transformers at the top of the tank, pumped through an external cooler, and returned to the bottom of the tank. The temperature drop of the oil in passing through the cooler is

$$Y = \frac{L}{G_c \times 111} \tag{10-57}$$

where Y = degrees Celsius drop of oil in cooler, L = watts loss, and G_c = gallons-per-minute rate of circulation of oil.

The effective oil-temperature rise B may be calculated from the characteristics of the oil-to-water heat exchanger. The top oil rise over average oil, I, is $Y/2$. The other components of temperature rise are calculated as for a self-cooled transformer.

Operation at high altitude increases the effective oil rise of air-cooled transformers. ANSI C57 provides for a compensating correction of 0.4% of rated kVA for self-cooled transformers or 0.5% of rated kVA for forced-air-cooled or forced-oil-cooled transformers for each 330 ft of additional altitude above 3300 ft altitude.

Effect of Tank Color. Most paint used on transformers has a low temperature emissivity of about 0.95. Metallic surfaces, particularly polished surfaces, have less low temperature emissivity and will cause correspondingly higher oil-temperature rise. The same is true of aluminum or bronze paint. For these cases, Eq. (10-31) can be used with V' substituted for V, where V' is $V/0.95$ multiplied by the low temperature emissivity from Table 10-2. On large power-transformers with many radiators or heat exchangers the effect is small.

For transformers exposed to intense sunlight, the additional temperature rise resulting from the use of aluminum paint is largely offset by the fact that aluminum paint absorbs only about 55% of the impinging solar radiation, whereas most commonly used paints absorb about 95%.

10.1.7 Load-Tap Changing

Ratio Changes with Shifted Taps. In transformers designed for maintaining a constant voltage on a power system, the ratio of transformation is usually changed by increasing or decreasing the number of active turns in one winding with respect to another winding. Since the turn ratio of the transformer must be changed without interfering with the load, means are provided for shunting the load current from one winding tap to the next. For this purpose, an auxiliary *preventive autotransformer* is generally used, designed to limit the resulting circulating current to a safe value during the interval when two adjacent taps are bridged. Because of the circulating and the load current which passes through the current-limiting impedance, arcing always takes place as the power circuit is transferred from tap to tap.

Although a variety of switching equipment and transformer connections have been used for the purpose of changing taps under load, the underlying principle remains unchanged and is shown by the transformer connection in Fig. 10-25.

Example. To move from transformer tap A to B, it is first necessary to close the circuit to B, as shown in Fig. 10-25, before opening the circuit at A. During the interval when A and B are both closed on adjacent taps, a circulating current flows through and is limited by the impedance on the loop composed of the tap winding *AB* and autotransformer *C*. With both ends of the autotransformer connected to *A*, the load current divides equally between the two halves of the autotransformer. Since the current flows in opposite directions, a negligible amount of reactance is introduced into the circuit and the only loss is the I^2R due to the 50% load current in each half of the autotransformer winding. With *A* closed and *B* open, all the load current flows through one-half of the autotransformer, magnetizing the autotransformer and thereby introducing into the circuit the induced voltage. It is important, therefore, that the magnetizing reactance be kept as low as possible to avoid excessive arcing duty on the circuit-interrupting device.

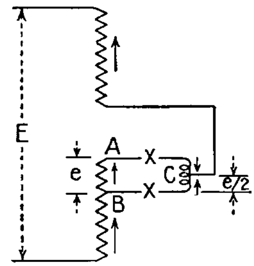

FIGURE 10-25 Bridging position for ratio change under load.

With *A* and *B* closed on adjacent taps, the tap voltage *e* is impressed on the autotransformer *C* and causes a circulating current to flow through the impedance loop. Because of the autotransformer action, a voltage midway between *A* and *B* is impressed in the circuit. The load current again divides equally through the autotransformer windings.

To avoid an excessive voltage drop through the autotransformer when one side is open and at the same time to keep the circulating current at a low level when in the bridging position, the autotransformer is usually designed with an air gap in the magnetic circuit to get a magnetizing current of approximately 60% of the normal full-load current.

Voltage across Autotransformers. Figure 10-26 shows the voltage relations across an autotransformer and switching contacts during a tap-changing cycle using an autotransformer designed for 60% circulating current and with 100% load current at 80% power factor flowing through it. Perfect interlacing between the autotransformer halves is assumed, and the voltage drop due to resistance of the autotransformer winding is neglected.

A study of Fig. 10-26 will disclose the fact that increasing the magnetizing reactance of the autotransformer to reduce the circulating current will

1. Increase the voltage across the full autotransformer winding
2. Increase the voltage to be ruptured
3. Introduce undue voltage fluctuations in the line

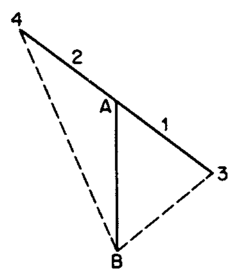

FIGURE 10-26 Vector relations for bridging position *AB*—voltage across adjacent taps; *A*-1 and *A*-2— reactance volts due to load current in only half the autotransformer winding; *A*-3 and *A*-4—induced voltage across full auto transformer winding; *B*-4—voltage ruptured when bridging position is ruptured at *A* (Fig. 10-25); *B*-3—voltage ruptured when bridging position is ruptured at *B* (Fig.10-24).

Since *B*-4 and *B*-3 represent the voltages appearing across the arcing contacts when the bridging position is opened at *A* and *B*, the voltage-rupturing duty will increase with

1. Increase in voltage between adjacent taps
2. Increase in load
3. Decrease in power factor of the load
4. Decrease in the magnetizing current for which the autotransformer is designed

Load-Tap-Changer Motor Mechanisms. The mechanism which drives the tap changer, and the control of this mechanism, must be designed so that a tap change, once initiated, is certain to be completed.

The mechanical coupling between the operating motor and the tap-changing switches may be through fixed-ratio gears, Geneva gears, cams, springs, or combinations of these. All mechanisms require means for keeping the motor energized until the change of tap is accomplished and for bringing the tap changer to rest on each operating position. The degree of permissible coasting of the motor is determined by the motor mechanism and the switch design.

The need for extremely accurate stopping of the motor is avoided by arranging the parts so that the motor may coast somewhat after the operating position is reached without moving the tap changer around the operating position. This may be accomplished by the inactive sectors of Geneva gears or cams or by the motor travel inherently involved in recharging a spring. Motor mechanisms are provided with limit switches and mechanical stops to prevent operation beyond the limit positions. Operation counters and position indicators are standard auxiliaries on most tap chargers. On large station-type units where the control devices are generally mounted on a remote-control panel, remote position indicators, either of the self-synchronizing type or of the digital type are generally used.

Automatic Control for Tap Changers. It is usual practice to use some sort of voltage measuring device to control the operation of the motor which drives the tap changer. Such devices may be mechanical, balancing the force of a solenoid actuated by the voltage against weights or springs, or they may be an electrical network, usually a bridge circuit which balances against the voltage of a Zener dioide. With either type of device, a voltage higher than a desired upper limit will start the tap-changer driving motor to change to the next lower tap voltage; similarly, a voltage lower than the desired lower limit will cause a change to the next higher tap.

The circuit usually includes a time delay to prevent tap changes, which would occur unnecessarily during very short time variations in voltage. It also may include a line drop compensator to facilitate maintaining the voltage within a given band at a point (load center) some distance from the transformer. The line-drop compensator introduces a signal into the voltage regulating relay circuitry. This represents the voltage drop due to line impedance between the transformer and the load center.

The voltage-regulating relay (or contact-making voltmeter) should be adjusted so that the voltage bandwidth, or spread between voltages at which the raising and lowering contacts close, will be not less than the percentage transformer tap plus an allowance for irregular voltage variations. For example, a tap-changing transformer with $1\frac{1}{4}\%$ taps should have a minumum voltage bandwidth of approximately $1\frac{1}{4}\% + \frac{1}{2}\% = 1\frac{3}{4}\%$.

In addition, the voltage-regulating relay may contain a component for use when load tap-changing transformers are operated in parallel. In this case, the tap changers must be controlled so that they are approximately on the same tap position. The component, a paralleling reactor, is used with external circuitry to detect, and generate a signal to minimize, circulating current that results when the tap changers are not on like positions.

Voltage Control, a Part of the Power Transformer. The simplest and generally the least expensive connection for voltage control is to provide the necessary taps in the power transformer. For single- or 3-phase delta connection the taps are preferably located on the interior of the winding (Fig. 10-27) so as to avoid the abnormal voltage stresses to which end coils are usually subjected. In the Y connection the taps may be placed at the neutral end of the winding, and if the neutral is to be solidly grounded, it becomes possible, by locating the taps next to ground, to use load changers designed with greatly reduced insulation; thus, for example, 15-kV apparatus may be placed in the grounded neutral end of a much higher-voltage circuit.

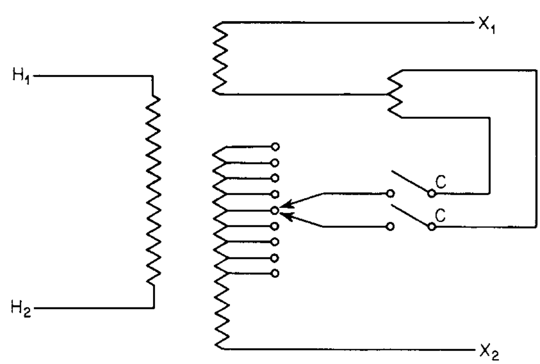

FIGURE 10-27 Tap-changing equipment in the middle of the winding.

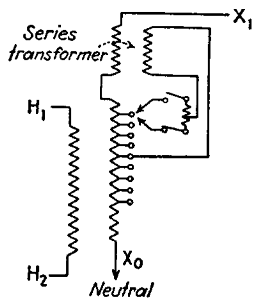

FIGURE 10-28 Tap-changing circuit with taps located in the interior of the transformer winding and an auxiliary series transformer to bring the current and voltage duty on equipment within rating limits.

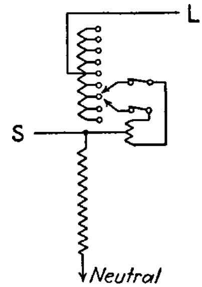

FIGURE 10-29 Regulating single-core autotransformer with taps located in the series winding and circuit connected for boost and buck.

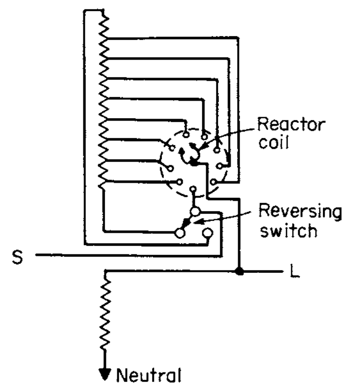

FIGURE 10-30 Regulating single-core autotransformer with a reversing switch to obtain buck and boost.

If the rated current of the transformer exceeds that of the switching equipment, a series transformer may be used (Fig. 10-28). Excitation is derived from taps inserted in the secondary of the power transformers, and by means of the series transformer, the desired voltage is inserted into the circuit. Thus, if a ratio of 3:1 exists in the series transformer, the current handled by the switching equipment becomes one-third of the current in the line.

Regulating Transformers (Single-Core). When a power transformer is not available or it is not desirable to equip the power unit with voltage control, regulating autotransformers are used. In the simplest of these, the necessary taps and switches are placed in the series winding of an autotransformer (Fig. 10-29). For 3-phase circuits, in order that the derived voltage may be in phase with circuit voltage, a Y connection is commonly used, and hence all the precautions necessary to safeguard the operation of Y-connected autotransformers should be observed. A tertiary winding may or may not be provided, depending on circuit conditions. As the series winding is inserted in the line, adequate insulation must be provided for the tap-changing equipment and taps against the abnormal voltages to which the circuit is subjected.

Economy in transformer size may be obtained by means of a reversing switch which functions to reverse the connections to the series winding when the regulator is passing through the neutral position. The circuit is so designed and the mechanical sequence is such that the reversing switch operates without rupturing current. The connection diagram (Fig. 10-30) shows the load tap changer provided with nine taps, which gives 17 full-cycle or 33 half-cycle positions. The ratio adjuster is designed with contacts uniformly spaced on the circumference of the circle so as to permit motion through two revolutions.

The Series Transformer. In many instances the voltage of the circuit is greater than that for which the switching equipment is designed, and in others the current to be handled exceeds the safe limits of operation. In either case, voltage control can be obtained without the design of special switching equipment by using an insulating series transformer (Fig. 10-31) in addition to the exciting transformer, the combination functioning, as far as the circuit is concerned, like an autotransformer. The primary of the exciting transformer is generally connected in Y in order that the derived voltages may be in phase with circuit voltages. The secondary of the exciting transformer provided with the regulating taps is usually connected in delta. The local circuit, consisting of the secondary of the exciting transformer with its taps and the primary of the series transformer being insulated from the main circuit, may be designed for the voltage and current best suited for the available switching equipment. Because of the additional cost and losses of the series transformer, it is used only when the voltage

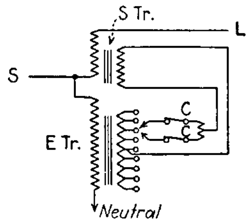

FIGURE 10-31 Exciting transformer with taps in the secondary and a series transformer forming complete isolation for tap-changing equipment.

or current limitations of the switching equipment demand it and when the control cannot be inserted in the grounded neutral of the transformer bank.

Tap-Changer Designs for Moderate kVA and Current. In the smaller ratings, where both the voltage and the current are moderate, the energy to be ruptured in switching from tap to tap becomes relatively so small that light and simple equipments are feasible. A variety of mechanical designs, together with special circuits, has been evolved with the purpose of providing simpler, smaller, and inherently less expensive equipments. The following may be noted:

1. Designing the tap changer so that it is capable of rupturing the current directly on the same switches which select the taps
2. Designing the circuit so that the tapped winding is reversed in going from maximum to minimum range, thereby securing a substantial reduction in the rating of core and coils for a given output
3. Using higher switching speed, by means of which the life of the arcing contacts is increased

Tap Changers Designed to Interrupt Current. The contactors *C* (Fig. 10-27) operate to open the switching circuits so that there is no interrupting duty on the selector contacts which connect to the transformer taps. When the rated current is moderate, it becomes possible to rupture the current directly on the tap-selector switches and thus obtain a major economy in the cost of the mechanical equipment. This method is shown in Fig. 10-30.

High-Speed Switching. Large units include contactors with high-speed contacts which serve as extinction devices that are specially designed to repeatedly interrupt the high currents and voltages encountered. They may be single- or multiple-break contactors operating in oil or in air with magnetic-arc chutes, or oil-blast contactors. Vacuum switches with their longer life (reduced maintenance) have become widely used. In small units, however, the arcing duty is mild. It is nevertheless necessary to keep in mind that mild arcing duty in the smaller equipment is partly offset by the likelihood of greater frequency of operation. Such units are usually equipped with full automatic control; they are likely to be located on distribution circuits where the voltage is more erratic. Many of them are located on the lines at considerable distances from substations, and some of them are placed on poles. It is desirable, therefore, to reduce maintenance to a minimum. For these reasons, it is necessary to provide means for high-speed switching on the smaller units where the tap-selector switches are used to rupture current. High-speed action of the tap-changer switches is obtained through Geneva gears or cams which bring the contact fingers to the required high speed at the moment of parting or through a spring drive in which the motor is used to store energy with the release of a spring snapping the contact fingers from one shelf to the next. By these means, the duration of the switching arc may be reduced to one or two contactors correspondingly reducing the amount of contact burning and increasing the life of the contacts.

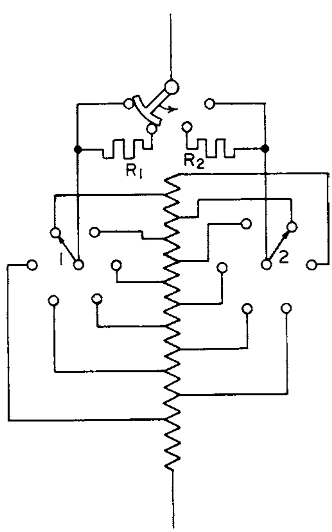

FIGURE 10-32 Tap-changing circuit employing tap selectors and contact, or diverter switch, and resistors to bridge the taps during switchover.

Use of Resistors. Another method, used more frequently in load tap changers of European design, makes use of resistors to bridge the tap instead of a preventive autotransformer. Figure 10-32 shows the tap selectors 1 and 2 connected to alternate taps in the winding. The contactor, or diverter switch, shown connected to 1 and R_1, progressively connects only to R_1, then to R_1, and R_2, then to R_2, and finally to R_2 and tap selector 2. For the next tap change, tap selector 1 moves to an adjacent tap and is then followed by the diverter switch operating in a reverse manner from R_2 and 2 back to R_1 and 1. Since the resistors are designed to carry current for only a very short time, the diverter switch is usually spring-actuated and moves through its sequence in a few cycles of 60-Hz current. This method has the advantage of relatively small-size resistors but requires a transformer tap for each operating voltage, while the autotransformer circuit uses the tap bridging position for an operating voltage and thus requires half the number of transformer taps.

Applications for Voltage Control and Equipment. The control of transformer ratio under load is a desirable means of regulating the voltage of high-voltage feeders and of primary networks. It may be used for the control of the bus voltage in large distributing substations. It finds a wide field of application in controlling the ratio on step-up transformers operating from power stations whose bus voltage must be varied to suit local distribution.

In industrial work, it is used for the control of current in a variety of furnace operations and electrolytic processes. It also furnishes a convenient means for voltage regulation of concentrated industrial loads.

A lot of load tap-changer equipment is installed at points of interconnection between systems or between power stations, in order to control the interchange of reactive current, or, in other words, to control the power factor in the tie line. This reactive current may be highly undesirable, especially as it may add to the burden on a fully loaded generating system. It can be increased, eliminated, or reversed by inserting a suitable small ratio of transformation between the systems. It can be varied in amount and in direction of flow to suit varying system conditions, if this ratio is variable and under the control of a station operator. Inserting such a ratio of transformation in a tie line by means of tap-changing equipment is equivalent in its effect on the flow of reactive current to raising or lowering the voltage on one of the systems. Current can be exchanged at any power factor from zero lag to zero lead, without interfering with the voltage maintained on either system.

Transformers for Phase-Angle Control. Tap-changing equipment is sometimes used in a loop system, for phase-angle control, for the purpose of obtaining minimum losses in the loop due to unequal impedances in the various portions of the circuit.

Transformers used to derive phase-angle control do not differ materially, either mechanically or electrically, from those used for inphase control. In general, phase-angle control is obtained by interconnecting the phases, that is, by deriving a voltage from one phase and inserting it in another.

The simple arrangement given in Fig. 10-33*a* illustrates a single-core delta-connected autotransformer in which the series windings are so interconnected as to introduce into the line a quadrature voltage. One phase only is printed in solid lines so as to show more clearly how the quadrature voltage is obtained. The terminals of the common winding are connected to the midpoints of the series winding in order that the inphase voltage ratio between the primary lines *ABC* and secondary lines *XYZ* is unity for all values of phase angle introduced between them.

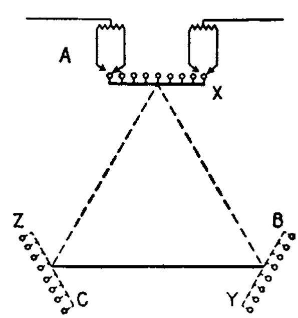

FIGURE 10-33*a* Phase-shifting regulating transformers; single-core delta-connected common winding for low-voltage systems.

As large high-voltage systems have become extensively interconnected, a need has developed to control the transfer of real power between systems by means of phase-angle-regulating transformers. The most commonly used circuit for this purpose is the two-core, four-winding arrangement shown in Fig. 10-33*b*. The high-voltage common winding is Y-connected, with reduced insulation at the neutral for economy of design, and a series transformer is employed so that low-voltage-switching equipment may be used.

10.1.8 Audible Sound

Source of Sound. Transformers, although they are classed as static apparatus, vibrate and radiate audible sound energy. In general, there are three different sources of transformer noise:

1. *Core vibration due to magnetostriction*. Core steel laminations undergo elongations and contractions (magnetostriction) as flux through them varies. This magnetostriction is nonlinear and independent of flux direction. Hence, noise is emitted in even multiples of the excitation frequency, that is, 120, 240, 360 Hz, etc., for a 60-Hz power system. The harmonic components decrease in magnitude as the mode of vibration goes up. However, an overexcited transformer or core-resonance may produce abnormally high third or higher harmonic frequencies.
2. *Noises from cooling equipment*. All rotary machinery on a transformer, including fans and pumps, produces noise with a broadband frequency spectrum. This "white noise" can have various magnitude and directionality depending on the design of the fans and pumps and on their arrangement.
3. *Coil vibration from energization*. Coils in a transformer are under cyclical stresses due to stray fluxes. The resultant motion resembles a vibrating spring and can also emit noise with harmonics of 120 Hz. However, this component is generally much lower than the previous two sources unless the transformer has a low induction level and high power ratings.

Sound Measurement. Sound waves produce small fluctuations in the atmospheric pressure which are sensed by the human ear.

Sound-level-measuring equipment as specified by ANSI Standard S1.4 consists of a microphone, amplifier, frequency weighting network, and indicating meter.

The most common type is A-weighing (Fig. 10-33*c*). It represents the sensitivity of the young adult ears to moderate sound levels over most of the audible spectrum. A linear response gives the actual sound intensity level. One-third octave and narrowband sound-level measurements are used to identify the source of an unexpectedly noisy transformer.

Standard Transformer Sound Level. ANSI/IEEE C57.12.90 specifies the method for measuring the average sound level of a transformer. The measured sound level is the arithmetic average of a number of readings taken around the periphery of the unit. For transformers with a tank height of less than 8 ft, measurements are taken at one-half tank height. For taller transformers, measurements are taken at one-third and two-thirds tank height. Readings are taken at 3-ft intervals around the string periphery of the transformer, with the microphone located 1 ft from the string periphery and

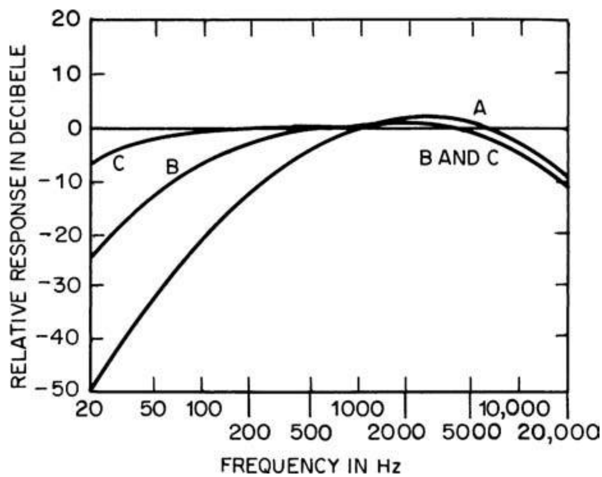

FIGURE 10-33*c* Weighting curves; A-weighting reduces the intensity of noise toward the lower end of the audible spectrum.

6 ft from fan-cooled surfaces. The ambient must be at least 5 and preferably 10 dB below that of the unit being measured. There should be no acoustically reflecting surface, other than ground, within 10 ft of the transformer. The A weighting network is used for all standard transformer measurements regardless of sound level.

NEMA Publication TR 1 contains tables of standard sound levels. For oil-filled transformers, from, 1000 to 100,000 kVA, self-cooled (400,000 kVA, forced-oil-cooled) standard levels are given approximately by Eq. (10-58)

$$L = 10 \log E + K \tag{10-58}$$

where E = equivalent two-winding, self-cooled kVA (for forced-oil-forced-air-cooled units, use 0.6 × kVA), K = constant, from Table 10-3, and L = decibel sound level.

Example. A transformer rated 50,000 kVA self-cooled, 66,667 kVA forced-air-cooled, 83,333 kVA forced-oil-forced-air-cooled, at 825 kV BIL, would have standard sound levels of 78, 80, and 81 dB on its respective ratings.

Public Response to Transformer Sound. The basic objective of a transformer noise specification is to avoid annoyance. In a particular application, the NEMA Standard level may or may not be suitable, but in order to determine whether it is, some criteria must be available. One such criterion

is that of audibility in the presence of background noise. A sound which is just barely audible should cause no complaint.

Studies of the human ear indicate that it behaves like a narrowband analyzer, comparing the energy of a single frequency tone with the total energy of the ambient sound in a critical band of frequencies centered on that of the pure tone. If the energy in the single-frequency tone does not exceed the energy in the critical band of the ambient sound, it will not be significantly audible. This requirement should be considered separately for each of the frequencies generated by the transformer core.

The width of the ear-critical band is about 40 Hz for the principal transformer harmonics. The ambient sound energy in this band is 40 times the energy in a 1-Hz-wide band. The sound level for a 1-Hz bandwidth is known as the "spectrum level" and is used as a reference. The sound level of the 40-Hz band is 16 dB (10 log 40) greater than the sound level of the 1-Hz band. Thus, a pure tone must be raised 16 dB above the ambient spectrum level to be barely audible.

The transformer sound should be measured at the standard NEMA positions with a narrow-band analyzer. If only the 120- and 240-Hz components are significant, an octave-band analyzer can be used, since the 75- to 150-Hz and 150- to 300-Hz octave bands each contain only one transformer frequency. The attenuation to the position of the observer can be determined.

The ambient sound should be measured at the observer's position. For each transformer frequency component, the ambient spectrum level should be determined. An octave-band reading of ambient sound can be converted to spectrum level by the equation

$$S = B - 10 \log C \tag{10-59}$$

where B = decibels octave-band reading, C = hertz octave bandwidth, and S = decibels spectrum level.

Example. Consider the following case:

Transformer sound at 120 Hz by NEMA method = 72 dB

Transformer-sound attenuation to observer = 35 dB

Ambient sound at the 75- to 150-Hz octave band = 36 dB

72 − 35 = 37 dB at the observer's position

36 − 10 log (150 − 75) = 17.3-dB ambient spectrum level

The 120-Hz transformer sound at the observer's position exceeds the ambient spectrum level by 19.7 dB. This is 3.7 dB greater than the 16-dB differential which would result in bare audibility; thus the transformer sound will be audible to the observer.

When transformer sound exceeds the limits of bare audibility, public response is not necessarily strongly negative. Some attempts have been made to categorize public response on a quantitative basis when the sound is clearly audible (Schultz and Ringlee 1960). For a case where specific knowledge of transformer- and ambient-sound-level frequency composition is not available, some more general guidelines are useful. Typical average nighttime ambient-sound levels for certain types of communities have been established. These are 30 dB for a "quiet suburban," 35 dB for a "residential suburban," and 40 dB for a "residential urban" community. All sound levels are based on the A scale of weighing. Calculations for typical transformer frequency distributions have been made to determine the nighttime transformer noise which will be audible 50% of the time in these communities. The results are 24 dB for quiet suburban, 29 dB for residential suburban, and 34 dB for residential urban. The NEMA standard sound level can be corrected for attenuation with distance to the nearest observer and checked against the above guides for audibility.

The broadband sound from fans, pumps, and coolers has the same character as ambient sound and tends to blend in with the ambient. While the noise from cooling equipment may be audible to a neighboring observer, it will seldom, if ever, cause a complaint.

Sound Attenuation with Distance. A point source in a free field radiates sound in spherical waves. The resultant sound pressure varies inversely with the square of the distance from the source; thus the sound level is reduced by 6 dB for each doubling of distance. The sound of auxiliary cooling equipment follows this relation for decrement with distance, since it is the sum of point-source sound contributions.

The transformer tank, which radiates vibrational energy from the core, is a more complex sound source and does not appear as a point source except at substantial distance from the tank. The modes of tank vibration are complicated, and various parts of the tank may act as independent sources, with different amplitudes, phase relations, and frequencies. Studies of scale models (Johnson et al. 1956) and full-size units have uncovered certain useful relationships as follows:

$$A = 20 \log \frac{2.83\,D}{Q} \tag{10-60}$$

$$Q = 1.7(WH)^{1/2} \tag{10-61}$$

where A = decibels attenuation for distance exceeding Q, D = distance from transformer to observer, H = height of transformer tank, Q = critical distance from transformer beyond which it appears as a point source, and W = width of transformer tank perpendicular to a line from transformer to observer.

Equations (10-60) and (10-61) apply in the absence of wind, temperature gradients, and reflecting surfaces other than ground. Each of these factors may significantly influence the observed sound level at a distance from the source, but not always in predictable fashion.

Site Selection. There are a number of methods available for avoiding transformer-noise complaints. Some of the discussion in the previous paragraphs suggests that potential noise problems should be considered when the substation site is selected. It may be possible to take advantage of attenuation with distance to reduce the transformer sound at the nearest observer position to an inaudible level. It may also be possible to choose the site in a location where the normal ambient noise will mask the transformer sound. If these possibilities are kept in mind during the planning stages, more expensive solutions to noise problems may be avoided later.

Design Measures. Manufacturers have at their disposal a variety of means of obtaining sound reduction. Most measures aim at reducing noise generation.

1. *Reducing core vibration*. Since magnetostriction is a function of flux intensity, a manufacturer's first option is to reduce induction levels of transformers. This has an additional advantage of reducing no-load losses. Alternatively, grades of steel having a different magnetostrictive characteristics can be substituted for the same induction-level design. A step-lap design can also reduce noise emission from joints. Finally, the designer has to anticipate the natural frequencies of the core mechanical structure and avoid their coincidence with harmonics of 120 Hz.
2. *Reducing cooling equipment noises*. The most significant noise reduction measure for cooling equipment is to reduce fan rotational speed or adjust the fan blade incidence angle. There is ample supply of low-noise designs, ranging from low speed to encased fans, from which manufacturers can choose.

When all possibilities of noise emission are exhausted and still further noise reduction is required, some sort of a mass-damper or absorption system has to be incorporated on or outside the tank structure. Moderate reductions can be realized by the use of barriers within the tank. Some of these are "soft" barriers, which operate on the principle of absorbing vibrational energy from the core and reducing its transmission to the tank. Others are "mass" barriers, which operate on the principle of loading the tank to decrease its magnitude of vibration for given energy transmission from the core. To achieve large sound reductions (as much as 25 to 30 dB), some manufacturers employ complete external enclosures of steel. For smaller substation units, these enclosures can be preassembled and shipped in place over the transformer tank.

Improving Existing Installation. To reduce the sound level of an existing transformer, the most satisfactory method has been found to be the erection of barrier walls on one or more sides of the transformer. The attenuation which can be achieved depends on the transmission loss through the barrier, the diffraction over and around the barrier, and the pressure buildup between the tank and the barrier.

Transmission loss through a barrier wall is a function of the mass of the wall. Structural requirements of most practical masonry barriers ensure sufficient mass to produce 25 to 40 dB attenuation through the wall. The effectiveness is usually limited by diffraction around the edges of the barrier. A theoretical method for calculation of attenuation as limited by diffraction has been formulated as follows:

$$N = \frac{2}{\lambda}[(M^2 - U^2)^{1/2} - M + (G^2 - U^2)^{1/2} - G] \tag{10-62}$$

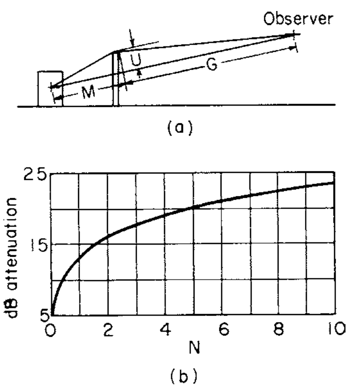

FIGURE 10-34 Effectiveness of a barrier in reducing noise level: (*a*) identification of dimension for calculation of the dimensionless parameter *N* from Eq. (10-62); (*b*) determinations of attenuation in decibels.

where *M*, *U*, and *G* are as defined in Fig. 10-34, in any convenient unit (feet or inches), λ = wavelength of harmonic under investigation, in units consistent with *M*, *U*, and *G*, and *N* = dimensionless parameter given in Fig. 10-34.

The calculation procedure is to determine *N* from the equation and then find the corresponding attenuation from Fig. 10-34*b*.

Test results on models and full-size transformers with two- and three-wall barriers correlate reasonably with Eq. (10-62). Data on four-wall enclosures generally do not correlate. It has been found that approximately 10-dB attenuation can be achieved with a four-wall enclosure having walls 5 ft higher than the transformer.

Enclosures with fewer than four walls should extend at least a distance *M* beyond the tank, so that attenuation will be limited by diffraction over the top rather than around the ends of the barrier. It should be noted that the sound level on the open side of this type of enclosure will be increased above what it was without the enclosure. Energy is redirected from the critical side of the transformer to the less critical side.

The effective attenuation of an enclosure can be reduced by pressure buildup between the tank and the barrier. The buildup is the result of reflection from hard wall surfaces and reinforcement of direct and reflected waves. Buildup will be most pronounced for spacings between tank and barrier walls which are multiples of the half wavelength of any of the principal sound frequencies. Such spacings should be avoided. Sound-absorbent lining on the interior surface of the barrier walls is helpful in reducing or eliminating buildup.

Masonry enclosures can also be used to hide substation transformers and associated equipment and in that way alleviate complaints which are based on appearance in addition to noise. Some utilities use a three-sided enclosure which resembles the houses in the neighborhood (Buck 1959). A casual observer on the street may not detect the presence of the substation.

10.1.9 Partial Discharges

Partial discharges may take place in liquid or gaseous dielectrics when the dielectric stress at the point of maximum stress concentration reaches the breakdown level but when complete breakdown of the dielectric is prevented because the dielectric stress decreases very rapidly away from the point of maximum stress concentration or because a solid dielectric intervenes. One form of such partial discharge, in air around a small conductor at high voltage, has been called “corona” because of its appearance as a visible glow around the conductor surface.

The local breakdown in the region of stress concentration ionizes a path (forms a streamer) in a very short time (microseconds), effectively short-circuiting a small region of the dielectric, and a pulse of current appears in the main dielectric circuit, reflecting the instantaneous short-circuiting of part of the circuit capacitance.

Partial discharges usually are accompanied by chemical decomposition of the liquid or gas, and sometimes they cause erosion of the adjacent solid insulation. A partial discharge in oil usually causes chemical breakdown, with the formation of carbon and gas, and unless the gas is immediately able to escape, more severe discharges in the gas itself may lead to complete breakdown of the insulation structure.

The presence of gas bubbles in the insulation of an oil-insulated transformer may result in partial discharges; this is the reason for particular attention to filling transformers with oil under vacuum.

Partial discharges may also be caused by wet fibers or any small conducting particles which distort the electric field and cause local points of stress concentration.

Partial discharges can be detected when they occur within the insulation of a transformer by any of a number of schemes which detect or measure either the pulse of current or the momentary loss of voltage at the transformer terminal. The charge transfer at a terminal can be measured in picofarads, but this generally does not give the actual transfer of charge which occurs somewhere within the transformer. Two techniques are commonly used to measure partial discharge activity. NEMA Publication 107 describes a method for measuring the equivalent high-frequency voltage, usually at 1 MHz, which appears at the terminals of the transformer, while ANSI/IEEE CS7.113 presents a trial-use guide to measure picocoulombs (apparant charge). The apparent charge technique is more sensitive to partial discharges occurring within the winding but also can be more susceptible to external signals. For both techniques, for power transformers the coupling capacitor can be replaced by the capacitance of the high-voltage busing, using the potential tap, as the means for coupling to the high-voltage circuit, with the effect of the capacitive impedance of the bushing being reduced by an adjustable reactor connected to the bushing tap. The voltage-measuring instrument is described in ANSI C63.2.

Basic-Impulse Insulation Level (BIL) Reduction. The need to demonstrate absence of significant partial discharges in operation is increased for higher circuit voltages where improved surge-arrester characteristics have encouraged a continuing trend toward BIL reduction. Because of progressively decreasing margins between the conventional induced test voltage and operating voltage, new standards for transformers rated 115 kV and above require a 1-h induced voltage test with continuous monitoring of partial-discharge levels to demonstrate the soundness of the insulation. During this test all parts of the insulation system must be overstressed to a degree corresponding to 150% of maximum system voltage at the high-voltage terminals (see ANSI/IEEE C57.12.00).

Partial Discharges in Transformers. This may also be detected by acoustic transducers in the oil or on the tank wall. If a sensitive transducer shows no partial discharges, any partial discharges picked up on the bushing tap originate outside the transformer. If the transducer shows corona, it can be used to locate the source of partial discharges within the transformer tank by measuring the time interval after the partial discharges voltage appears at the bushing tap until the effect appears at the transducer. Then the distance from the transducer to the source of partial discharges is 1 in for each 15 μs of delay.

10.1.10 Radio-Influence Voltage

Excessive partial discharges may cause high-frequency voltages to appear at the terminals which can interfere with radio communication. Suitable maximum limits of voltage in compliance with Federal Communication Commission requirements have been established and are shown in NEMA Publication TR 1. For power transformers, this limits the high-frequency voltage at 1 MHz, measured at about 110% of operating voltage, to 250 μV up to 14.4 kV operating, 650 μV up to 34.5 kV operating, 1250 μV up to 69 kV operating, and 5000 μV up to 345 kV operating.

10.1.11 Testing

Standard Tests. ANSI/IEEE C57.12.00 defines routine, design, and other tests for liquid-immersed transformers. The following are listed as routine tests for transformers 501 kVA and larger:

1. Measurement of resistances of the windings
2. Measurement of turns ratio

3. Phase-relation tests: polarity, angular displacement, and phase sequence
4. No-load loss and exciting current
5. Load loss and impedance voltage
6. Low-frequency dielectric tests (applied voltage and induced voltage)
7. Leak test on the transformer tank
8. Lightning-impulse tests (full wave and chopped wave; for transformers with high-voltage windings from 115 through 765 kV)

The following are listed as design tests for transformers 501 kVA and larger (required on only one unit of a given design):

1. Temperature rise tests (could be omitted if a unit which is essentially a thermal duplicate had been previously tested)
2. Lightning-impulse tests (full wave and chopped wave; for transformers with high-voltage windings of 69 kV and below)
3. Audible sound level
4. Mechanical tests of lifting and moving devices
5. Pressure test on the transformer tank

Other tests listed in ANSI/IEEE C57.12.00 (including short-circuit tests and specialized dielectric tests) shall be made only when specified. Test procedures for all routine and design tests (and many other tests) are defined in the test code document ANSI/IEEE C57.12.90.

The regulation of a transformer may be determined by loading it according to the required conditions at rated secondary voltage and measuring the rise in secondary voltage when the load is disconnected. The rise in voltage when expressed as a percentage of the rated voltage is the percentage regulation of the transformer. This test is seldom made, because the regulation is easily calculated from the measured impedance characteristics.

Efficiency of a transformer is seldom measured directly, because the procedure is inconvenient and the efficiency can be readily calculated.

10.1.12 Oil-Preservation Systems and Detection of Faults

Oil-Preservation Systems. Although transformer oil is a highly refined product, it is not chemically pure. It is a mixture principally of hydrocarbons with other natural compounds which are not detrimental. There is some evidence that a few of these compounds are beneficial in retarding oxidation of the oil.

Although oil is not a “pure” substance, a few particular impurities are most destructive to its dielectric strength and properties. The most troublesome factors are water, oxygen, and the many combinations of compounds which are formed by the combined action of these at elevated temperatures. A great deal of study has been given to the formation of these compounds and their effects on the dielectric properties of oil, but there apparently is no clear relation between these compounds and the actual dielectric strength of the transformer insulation structure.

Oil will dissolve in true solution a very small quantity of water, about 70 ppm at 25°C and 360 ppm at 70°C. This water in true solution has relatively little effect on the dielectric strength of oil. If, however, acids are present in similar amounts, the capacity of oil to dissolve water is increased, and its dielectric strength is reduced by the dissolved water. Small amounts of water in suspension cause severe decreases in dielectric strength. The primary reason for concern over moisture in transformer oil, however, may not be for the oil itself but for the paper and pressboard which will quickly absorb it, increasing the dielectric loss and decreasing the dielectric strength as well as accelerating the aging of the paper.

It is generally recognized today that the best answer to the problem of air and water is to eliminate them and keep them out.

For this purpose, in American practice, transformer tanks are completely sealed. About three basic schemes are used in sealed transformers to permit normal expansion and contraction of oil (0.00075 per unit volume expansion per degree Celsius) as follows:

1. A gas space above the oil large enough to absorb the expansion and contraction without excessive variation in pressure. Some air may unavoidably be present in the gas space at the time of installation but soon the oxygen mostly combines with the oil without causing significant deterioration, leaving an atmosphere which is mostly nitrogen.
2. A nitrogen atmosphere above the oil maintained in a range of moderate positive pressure by a storage tank of compressed nitrogen and automatic valving. This scheme has the advantage that the entrance of air or moisture is prevented by the continuous positive internal pressure, and the disadvantage of somewhat higher cost.
3. A constant-pressure oil-preservation system consisting of an expansion tank with a flexible synthetic-rubber diaphragm floating on top of the oil. This scheme has the advantages that the oil is never in contact with the air and there is always atmospheric pressure and not a variable pressure on the oil. The disadvantage is the higher cost. A number of mechanical variations and elaborations of this general idea have been devised.

It is now generally recommended that the constant-pressure oil-preservation system of item 3 be employed on all high-voltage power transformers (345 kV and above) and on all large generator step-up transformers. This is a consequence of unfavorable experience with transformers having gas-cushion systems, which inherently operate with large quantities of the cushion gas in solution in the hot oil under load. If the oil is suddenly cooled (reduction of ambient temperature or load), the oil volume contracts and the static pressure of gas over the oil drops rapidly, allowing free gas bubbles to come out of solution throughout the insulation system. The dielectric strength of the oil and cellulose insulation system is drastically weakened when it has free gas inclusions, and this has occasionally led to electrical failure of operating transformers.

Fault Detection. Detection of internal faults in transformers at an early stage of their development is most desirable to limit the extent of damage. Two levels of seriousness of faults are recognized. Incipient (or developing) faults have not yet progressed to the point where they affect the functional capability of the transformer, but it is likely that their seriousness will increase with time if not corrected. Examples would include partial discharge sites within the insulation, intermittent low-energy sparking, overheated conductor insulation, or hot metal parts in contact with oil only. More serious or permanent internal faults affect functionality immediately and must be removed quickly before their consequences can jeopardize the safety of personnel or other equipment.

Most commonly employed means of sensing incipient faults relate to detection of gases generated at the fault site. Automatically operating gas-detection devices which can be supplied on the transformer employ any of the following principles:

1. Free gas accumulation at the cover
2. Sensing of combustible gases within a gas cushion over the oil
3. Separation of certain gases dissolved in the oil

These devices are indicators of possible internal problems. Verification of the problem should be done by gas-in-oil analysis using a gas chromatograph. In addition, periodic manual sampling of the oil for laboratory analysis should be practiced. The composition of the gas dissolved in the oil is very useful for diagnosis of the nature of an incipient fault.

Permanent internal faults can be detected by fault-pressure relays or differential relays, either of which give a signal that can be used to trip circuit breakers and remove the transformer from the system. The fault-pressure relay senses the sudden buildup of pressure produced by arc-generated gases after a fault has occurred. Unfortunately, such relays can also be operated by any other event which causes a rapid pressure change, so they cannot be set to be too sensitive. Differential relays sense that more current is flowing into the transformer than is flowing out, but relays which are insensitive to the initial inrush of exciting current should be used. After a transformer has been disconnected as a result of relay operation, it is always desirable to get it back into service as quickly as possible. Following differential-relay operation, circuit breakers may be reclosed to check whether the fault is self-healing. The penalty for reconnection of a damaged transformer is that if the fault recurs, the damage to the transformer and possibly associated equipment will be greater. Under no circumstances should a transformer be reconnected to the system following operation of a fault-pressure relay without thorough investigation of the cause of the relay operation.

When a transformer has been taken out of service because of fault indications, the following procedure should be used:

1. If there is a gas space, take samples of the gas from the gas space for analysis to determine whether products of decomposition are present.
2. Take oil samples for extraction of dissolved gases for similar analysis.
3. Make insulation power factor, insulation resistance, and turns ratio tests to check whether their results conform to normal values.
4. Perform any other tests which seem to be indicated by the results of the first tests.
5. Check the operation and calibration of the protective relay.

10.1.13 Overcurrent Protection

Effects of Overcurrent. A transformer may be subjected to overcurrents ranging from just in excess of nameplate rating to as much as 10 or 20 times rating. Currents up to about twice rating normally result from overload conditions on the system, while higher currents are a consequence of system faults. When such overcurrents are of extended duration, they may produce either mechanical or thermal damage in a transformer, or possibly both. At current levels near the maximum design capability (worst-case through-fault), mechanical effects from electromagnetically generated forces are of primary concern. The pulsating forces tend to loosen the coils, conductors may be deformed or displaced, and insulation may be damaged. Lower levels of current principally produce thermal heating, with consequences as described later on loading practices. For all current levels, the extent of the damage is increased with time duration.

Protective Devices. Whatever the cause, magnitude, or duration of the overcurrent, it is desirable that some component of the system recognize the abnormal condition and initiate action to protect the transformer. Fuses and protective relays are two forms of protective devices in common use. A fuse consists of a fusible conducting link which will be destroyed after it is subjected to an overcurrent for some period of time, thus opening the circuit. Typically, fuses are employed to protect distribution transformers and small power transformers up to 5000 to 10,000 kVA. Traditional relays are electromagnetic devices which operate on a reduced current derived from a current transformer in the main transformer line to close or open control contacts, which can initiate the operation of a circuit breaker in the transformer line circuit. Relays are used to protect all medium and large power transformers.

Coordination. All protective devices, such as fuses and relays, have a defined operating characteristic in the current-time domain. This characteristic should be properly coordinated with the current-carrying capability of the transformer to avoid damage from prolonged overloads or through faults. Transformer capability is defined in general terms in a guide document, ANSI/IEEE C57.109, *Transformer Through Fault Current Duration Guide.* The format of the transformer capability curves is shown in Fig. 10-35. The solid curve, *A*, defines the thermal capability for all ratings, while the dashed curves, *B* (appropriate to the specific transformer impedance), define mechanical capability. For proper coordination on any power transformer, the protective-device characteristic should fall below both the mechanical and thermal portions of the transformer capability curve. (See ANSI/ IEEE C57.10-38 for details of application.)

10.1.14 Protection Against Lightning

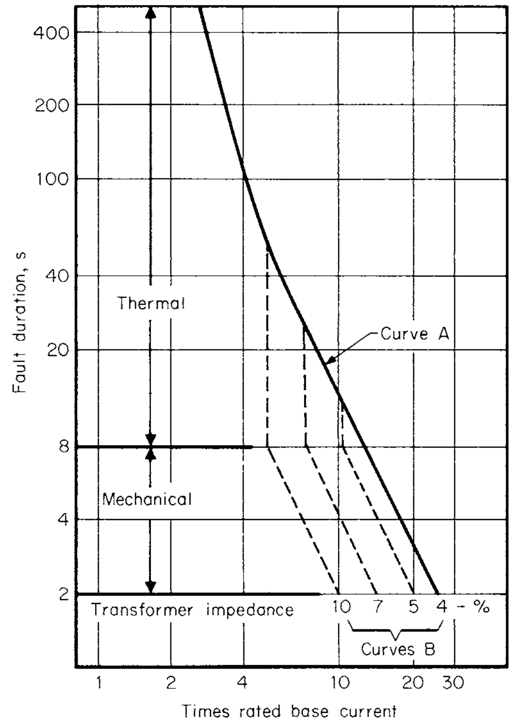

FIGURE 10-35 Transformer through-fault protection curves.

Impulse insulation level may be demonstrated by factory impulse-voltage tests using 1.5 × 50-μs full waves and chopped waves. The full wave demonstrates the BIL for traveling waves coming into the station over the transmission line. The chopped wave demonstrates strength against a wave traveling along the transmission line after flashing over an insulator some distance away from the transformer. These waves do not simulate direct lightning strokes on or near the transformer terminals, which would result in the application of a steep-front wave to the transformer winding. Such strokes are usually avoided by ground wires or protecting grounded structures.

A transformer may be subjected to severe lightning voltages as a result of a direct stroke to the transformer terminal, adjacent bus, or transmission line. Less severe voltages may result from strokes on a distant part of the system or from strokes to ground near the system. Since lightning voltage may exceed the insulation strength of the transformer, protection is necessary.

Voltage-time curves are used in evaluating protection, because for short times the insulation strength changes significantly with duration of voltage. Protection is effective if the voltage-time curve of the transformer is above the voltage-time curve of the protective equipment, so that for any time duration the kilovolts insulation strength of the transformer exceeds the protective level at the same duration. The voltage-time curves of transformer insulation have considerable "turn-up," that is, for durations under 10 μs the kilovolts insulation strength is much greater. Rod gaps in air are unsuitable for protecting transformers, because they have even more turn-up than do transformers.

Surge Arresters. The modern surge arrester has very little turn-up and is an essential adjunct to the transformer whenever there is lightning exposure.

The required surge arrester rating depends on the effectiveness of the neutral grounding. The rating is expressed in percent of rated line-to-line power-frequency voltage that the arrester will withstand. Effectiveness of system grounding is described by the ratios of the zero-sequence resistance and impedance to the positive-sequence resistance and impedance. An 80% arrester is commonly used when the ratio of zero sequence to positive sequence is between 0.5 and 1.5 for resistance and between 1 and 3 for impedance. Lower ratios may permit 75% or 70% arresters. Higher ratios may require 85% or 90% arresters. Use of the 100% protective level is not economical at high voltages (Honey 1987).

Figure 10-36 shows the voltage-time curve of a 345-kV transformer, with 1050-kV BIL (reduced by two steps) compared with the voltage-time curve of a 90% metal-oxide surge arrester. Since this new type of arrester has no series gaps to spark over, the characteristic is described as a protective

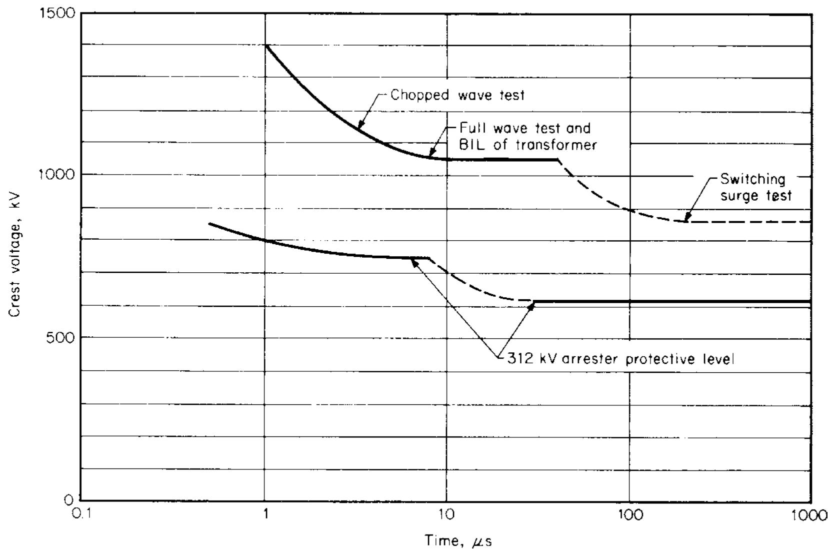

FIGURE 10-36 Surge-arrester protection margin for impulse and switching-surge conditions for a 345-kV transformer with BIL reduced two steps. The arrester curve shown is for an 8 × 20 μs current wave of 15-kA crest.

level rather than a sparkover level. The voltage-time curve of an arrester depends on the amount of impulse current. The voltage-time curve shown in Fig. 10-36 corresponds to 15,000-A crest, which is not likely to be exceeded except by direct strokes. For best protection, the arrester should be located as close as possible to the terminals of the transformer, and the arrester ground should be connected by a short, direct conductor to the transformer tank and substation grounding system.

The steep rate of rise of lightning current as such may result from a nearby direct stroke will produce discharge voltages higher than shown in Fig. 10-36 and may damage the lightning arrester. Therefore, the substation and the first half mile of connected transmission lines should be protected against direct strokes by a suitable combination of grounded masts and ground wires (Linck 1975).

10.1.15 Installation and Maintenance

Proper installation and maintenance of power transformers is needed to assure long life in service. General requirements from ANSI C57.93 and from manufacturer's instructions are summarized below. Most power transformers have additional manufacturer's installation and maintenance instructions which should be carefully observed. These instructions, including safety practices, should be followed for the protection of workers and the transformer.

Transformers are processed tested, and inspected before shipment. Smaller transformers are shipped filled with oil and fully assembled when shipping clearances and weights permit. For most large-power transformers, the external components, such as coolers and bushings, must be removed to meet shipping dimensions. Also, the oil is removed to reduce weight, and the unit is secured in dry gas.

Inspection on Arrival. Before removal from the car, inspect for shipping damage. If damage is found, a claim should be filed with the carrier and the manufacturer should be notified.

Transformers shipped oil-filled should be inspected for evidence or leakage or entrance of moisture during shipment. If the transformer is received in damaged condition, tests should be made to check the transformer for dryness. Oil samples taken from the bottom valve should be tested for moisture limits. Where bushings are shipped in place, insulation power-factor measurements can be used. Power factors of new transformers range from 0.2% to 0.5% at 25°C. In any case, a power-factor measurement may be helpful for comparison with test values recorded by the manufacturer prior to shipment.

Transformers shipped gas-filled are fitted with a connection to which a compound pressure/vacuum gage can be connected. The gage should have a range of +10 lb/in^2. A positive or negative pressure indicates that the tank is tight; a continuous zero reading indicates a probable leak. If there is a reason to question dryness, the moisture can be estimated by a dew-point measurement of the gas in the transformer. Add dry gas immediately to about 3-lb/in^2 (gage) pressure and check for leaks.

Dew point is sensitive to temperature changes; therefore it is essential that the insulation temperature be accurately determined. Some instruments will not provide accurate dew-point readings below 32°F. The final degree of insulation dryness should be determined by measuring the insulation power factor or insulation resistance. If the measured dew point exceeds an acceptable value, contact the manufacturer for recommended course of action.

A preliminary internal inspection is not normally required unless shipping damage is apparent. (*Caution:* Do not enter any transformer until the gas in the tank is replaced by dry air with at least 19.5% oxygen content. Exercise caution when entering a transformer and avoid introducing contamination. The time the transformer is open for inspection should not exceed 2 h, and dry air should be circulated.)

Oil sampling. Samples of oil should be taken from the bottom. An oil-sampling valve is provided at the bottom of the transformer tank for this purpose. A metal or glass thief tube can be conveniently used to obtain a bottom sample from an oil barrel. Test samples should be taken only after the oil has settled for some time, varying from 8 h for a barrel to several days for a large transformer. Cold oil is much slower in settling. In drawing samples of oil from a sampling valve, some oil should first be discarded so that the sample will come from the bottom of the container and not from the sampling pipe. Examine a sample in a clear glass container for free water, which in any quantity is readily observable. The sample container should be a large-mouthed glass bottle, 1 qt or larger, with cork or glass stopper. The bottle should be carefully cleaned and dried before being used. Bottles should be of amber color if samples are to be stored to be tested later for color or sludge-forming characteristics. Refer to ASTM 923-81 for important details of oil-sampling technique.

Testing for Oil Dielectric Strength. The testing fixture should be cleaned thoroughly to remove any particles or fibers and rinsed out with a portion of the oil to be tested. The testing fixture should be filled with oil, and both oil and fixture should be at room temperature. Allow 3 min for air bubbles to escape before applying voltage. Tests are made by two methods. ASTM D877 uses 1-in-diameter square-edge electrodes spaced 0.10 in apart and a rate of voltage rise of 3000 V/s. ASTM D 1816 uses special radiused-surface electrodes spaced 0.04 in apart, with continuous oil circulation, and a rate of voltage rise of 500 V/s. The latter test is more sensitive to slight moisture or particulate contamination. In either case, the average voltage for five breakdowns is taken as the dielectric strength of the oil. Strength of new oil should exceed the minimum value for good oil as shown in Table 10-4. (See also ANSI/IEEE C57.106.)

Filtering to Increase Dielectric Strength. If the oil tests below "good," it should be filtered to remove impurities and moisture. It is best to discharge filtered oil into a clean, dry tank and avoid mixing with unfiltered oil. If the filtered oil must be discharged back into the transformer tank, the oil should be withdrawn from the bottom filter-press valve and, after filtering, returned through the top filter-press valve. Oil should not be filtered while the transformer is energized, because the dielectric strength may be temporarily reduced by aeration. If no facilities are available for making dielectric tests, send a sample to the manufacturer marked with the serial number of the transformer.

Drying the Core and Coils. This should be necessary only if an accident occurs during shipping, storage, or service. (Refer also to ANSI/IEEE C57.12.11 and C57.12.12.)

If possible, determine the extent of the moisture and manner in which it entered the tank. The manufacturer should be contacted for recommendations concerning additional checks and strips for drying out the transformer. If drying is necessary, one or more of the following methods may be used, depending on the facilities available:

1. Heat and vacuum
2. Vacuum only
3. Heat in oil
4. Heat in air

A low value of residual moisture can be attained most rapidly by method 1. Method 2 is effective but requires longer time and better vacuum equipment. Method 3 is very slow and not as effective as the vacuum method. Method 4 is recommended only for smaller, low-voltage transformers.

Method 1: Heat and Vacuum. The following procedures may be used to elevate the temperature of the core and windings prior to the vacuum process:

1. Using external heaters and pump equipment, spray hot oil through the cover of the transformer. Maintain a vacuum of 10 torr or less on the transformer during the oil spraying operation in order to prevent oxidation of the oil and to aid in the removal of gas from the insulation. Pump the oil from the bottom of the transformer through filters, through the heat exchanger, and back to the cover of the transformer. Use the minimum amount of oil necessary to establish circulation. Degassing-dehumidifying equipment may be used if the equipment is available. The oil temperature entering the top of the transformer should be between 50°C (122°F) and 75°C (167°F). The temperature of the core and coils will be elevated to equilibrium conditions when the output oil temperature becomes constant, and the temperature of the core and coils will be near the temperature of the output oil.
2. Heat may also be generated by circulating current through the windings. This requires a controlled source of power connected to either winding, with the other winding short-circuited. For this method, the transformer should be filled to normal level. Connect the vacuum pump to a suitable valve above the oil level. The temperature of the windings should not exceed 95°C and the oil 85°C. Initial currents up to full-rated current may be used, then reduced as the temperature approaches the desired value. The voltage required to circulate this current will depend on the impedance of the transformer, which can be obtained from the instruction plate. After the desired winding and oil temperatures have been reached, disconnect the power supply and drain the oil from the transformer tank. When the oil has been drained from the tank, close the valves and start the vacuum pump. Continue pulling vacuum on the transformer until the water extraction stops.

Method 2: High Vacuum. This method requires the use of a suitable vacuum pump, capable of pumping down to an absolute pressure of 0.05 mmHg (6.67 Pa) or lower, and a refrigerated vapor trap to collect the water. No additional heat is required if an adequate vacuum pump is used.

Drain the oil from the transformer, filling the tank with dry nitrogen as the oil is drained. Remove heat exchangers and other external pipe connections and seal these openings, preferably with blanking plates. Connect the vapor trap and vacuum pump to a suitable pipe connection on the tank. Seal the tank and pressure test for leaks. After ensuring that all leaks have been eliminated, start the vacuum pump. Water extraction from the insulation will begin when the residual vapor pressure in the tank is reduced below the vapor pressure of water in the insulation. Drying may be continued as long as moisture is being extracted or may be terminated when the residual moisture content of the insulation has been reduced to the desired level as determined from a moisture equilibrium chart.

Method 3: Heat in Oil. This method is slow and limited to smaller, low-voltage transformers. Also, method 3 may be used for transformer tanks not designed for full vacuum. This method requires the use of a suitable oil filter with either a vacuum-drier-type or blotter press, plus a heater which will enable hot oil at a temperature of approximately 85°C to be circulated in the transformer tank until positive indication of drying out of the windings has been obtained. The transformer should be filled with oil to cover the core and windings and the oil circulated through either the filter-press valve and drain valve or through top and bottom radiator valves. Wherever possible, to reduce heat losses due to radiation, prevent the oil from circulating through the coolers. Blanket the outside of the transformer tank to reduce to a minimum the time of drying out and the amount of heating required to keep the oil temperature constant.

With this method the moisture is removed through the oil filter. If a blotter-press filter is used, the rate of water extraction will depend on the degree of saturation of the filter papers. Filter papers must be extremely dry and papers must be changed frequently if this method is to be effective. The rate of transfer of moisture increases with temperature; hence it is desirable to operate at the highest temperature which will not cause deterioration of the oil.

Method 4: Hot-Air Drying. This is limited to small low-voltage transformers and where clean dry air is available. With the transformer assembled in its tank, the tank should be blanketed in order to reduce to a minimum the amount of heating required, and also to keep the interior of the tank at a uniform temperature to prevent condensation in the tank.

Dry air should be forced by a fan over the heating elements, then through an opening at the base of the tank to pass over and through the coils before exhausting through an opening in the cover. Baffles should be placed between the hot-air inlet and the windings to prevent the flow of hot air from being concentrated on one small portion of the windings.

Time Required for Drying. This can range from 72 h to 3 weeks depending on the size and condition of the transformer and the method of drying. In general, the use of a high vacuum and a cold trap is faster and more efficient than heat alone.

Insulation Resistance. This will indicate the degree of dryness only when the transformer is dried without oil. If the initial insulation resistance is measured at room temperature, it may be high, although the insulation is not dry, but as the transformer is heated up, it will drop rapidly.

As the drying proceeds at a constant temperature, the insulation resistance will generally increase gradually until toward the end of the drying period, when it increases quite rapidly and then levels off at a high value. The drying should continue until the resistance is constant for a period of 12 h.

Insulation Power-Factor Reading. These readings (at 60 Hz) will indicate the degree of dryness. The power factor will first increase as the temperature increases and then will gradually decrease as drying progresses. Drying should continue until the power factor is constant for a period of 12 h. If power factor is measured on transformers dried in oil by the short-circuit method, the power factor should be used to supplement oil tests as a measure of dryness.

Filling without Vacuum. (*Note:* This method should be practiced only on low-voltage transformers. Check manufacturer's recommendations.) Use extreme care to keep moisture out of the core and coils. The tank should not be opened to the atmosphere until the core and coils are under oil, unless vacuum filling is available. The oil shipping tank or oil drums should not be opened until their temperature is the same as or higher than that of the surrounding air and the transformer is in place and ready to receive the oil. Metal or synthetic rubber hose should be used for filling, because transformer oil is contaminated by natural rubber. Oil should never be added to a transformer without passing through a filter press.

Static charges can be developed when transformer oil flows in pipes, hoses, or tanks. Oil leaving a filter press may be charged to over 50,000 V. To accelerate dissipation of the charge in the oil, ground the filter press, the tank, and all bushings or winding leads during oil flow into any tank. Conduction through oil is slow; therefore it is desirable to maintain these grounds for at least 1 h after the oil flow has ended.

Avoid explosive gas mixtures in any container into which oil is flowing. Arcs can occur along the surface of the charged oil even though all metal is grounded.

Filling with Vacuum. The vacuum line should be connected to a tapped opening on a cover-mounted shipping plate or to a valve near the top of the tank. An opening of 2 in minimum is recommended. The oil line can be connected to a suitable opening on a cover-mounted shipping plate or the top filter-press valve. The oil line should always be connected at the top of the tank so that the oil can be deaerated as it enters.

Transformers with operating voltage less than 161 kV and with core and coils not exposed to the atmosphere should be filled under vacuum better than 25 mmHg absolute pressure. The vacuum should be held 4 h before filling and continued during filling until the core and coils are covered. The vacuum can then be removed for installation of bushings and the remaining oil added without vacuum. Transformers with an operating voltage of 161 kV and above or transformers with core and coils exposed to the atmosphere should be completely filled under a vacuum better than 2 mmHg absolute pressure. A 2-mm vacuum should be held until the tank is filled to the 25°C level.

The filling rate should be under 1500 gal/h to facilitate evacuation and complete oil filling of all air pockets and voids. It is also recommended that the core and coil temperature be above 10°C to prevent “frost” formation.

Energization. When the voltage is first applied, it should, if possible, be brought up slowly to its full value so that any wrong connection or other trouble will be discovered before damage results. After full voltage has been applied successfully, the transformer should preferably be operated for a short period without load.

When the transformer is first energized it should be kept under close observation for the first 8 h. Check and record the oil temperature, the winding temperature, the tank pressure, and the ambient temperature. Watch particularly for any sudden changes. After 7 days of operation, check for oil leaks and for abnormally high usage of nitrogen if the transformer is equipped with Inertaire. Stop all oil and gas leaks. The observation should continue on a daily schedule for 7 days and then weekly for the first month of operation. An oil sample should be taken during the first month of operation for gas-in oil analysis. This analysis should be repeated annually. Heat exchangers, tap changer, pumps, fans, etc., should be serviced per manufacturer’s instructions.

Internal Inspection of In-service Transformers. This is not necessary unless there is a specific indication of a problem. Oil analysis is a good method to discover potential problems. Sludging of the oil, low dielectric strength, moisture in the oil, or the presence of combustible gases are conditions that may merit an internal inspection of the transformer.

Generation of combustible gas usually indicates internal trouble (not necessarily serious). Analysis of the gas sometimes helps to identify the source. If collection of combustible gas continues without discoverable cause, partial discharge voltage measurement may establish whether or not there is an internal fault.

Severe system disturbances, incidence of through-fault, or a circuit-breaker operation would also be reason for an internal inspection of a transformer.

Operating without Cooling. A liquid-cooled transformer should not be run continuously, even at no load, without the cooling liquid. In an emergency, forced-oil air-cooled transformers may be operated without fans and pumps (1) at rated load for approximately 1 h, starting at full-load temperature rise,

(2) at rated load for approximately 2 h, starting cold (at ambient temperature), (3) at rated voltage and no load for approximately 6 h, starting at full-load temperature rise, and (4) at rated voltage and no load for approximately 12 h, starting cold.

When only a portion of the cooling equipment is operating, the transformer may be operated at reduced load approximately as indicated in Table 10-5.

10.1.16 Loading Practice

The *temperature limitation of loading* must be considered. Ordinarily, the kVA that a transformer should carry is limited by the effect of reactance on regulation or by the effect of load loss on system economy. At times, it is desirable to ignore these factors and increase the kVA load until the effect of temperature on insulation life is the limiting factor. High temperature decreases the mechanical strength and increases the brittleness of fibrous insulation, making transformer failure increasingly likely, even though the dielectric strength of the insulation material may not be seriously decreased. Overloading of transformers should be limited by reasonable consideration of the effect on insulation life and the probable effect on transformer life.

The *insulation life of a transformer* is defined as the time required for the mechanical strength of the insulation material to lose a specified fraction of its initial value. Loss of 50% of the tensile strength is the usual basis for evaluating conductor insulation for power transformers. (*Note:* A transformer may continue to perform beyond the predicted life if it is not disturbed by short-circuit forces, etc. This is because at the mechanical end point, the disintegration of the fibers is not total as shown by degree of polymerization measurements, the true indicator of paper insulation integrity.)

The *aging of insulation* is a chemical process that occurs more rapidly at higher temperatures according to the Arrhenius reaction-rate theory, as expressed in

$$\log h = \frac{K_1}{C + 273} + K_2 \tag{10-63}$$

where C = temperature in degrees Celsius of insulation, K_1, K_2 = constants determined by test, and h = hours of life. Use of this equation permits results of relatively short duration tests at relatively high temperature to be extrapolated to indicate probable insulation life at moderate temperatures. ANSI/IEEE C57.92-1981 contains loading recommendations for power transformers up to 100 MVA with 55°C and 65°C average winding-rise insulation systems based on extrapolated life tests. Figure 10-37 shows the corresponding curves of rate of loss of life as a function of temperature as defined in this document. The constants in Eq. (10-63) are

$$55°\text{C rise} \qquad K_1 = 6972.15 \qquad K_2 = -14.133$$

$$65°\text{C rise} \qquad K_1 = 6972.15 \qquad K_2 = -13.391$$

ANSI/IEEE C57.91 provides similar loading recommendations for distribution transformers, including the following values for the constants in Eq. (10-63):

$$55°\text{C rise} \qquad K_1 = 6328.8 \qquad K_2 = -11.968$$

$$65°\text{C rise} \qquad K_1 = 6328.8 \qquad K_2 = -11.269$$

Accepted methods for functional life evaluation have been established for both distribution transformers and for power transformers.

To determine the aging of the insulation resulting from a specific daily load cycle (1) establish an approximately equivalent stepped load cycle, (2) calculate the resulting curve of hot-spot

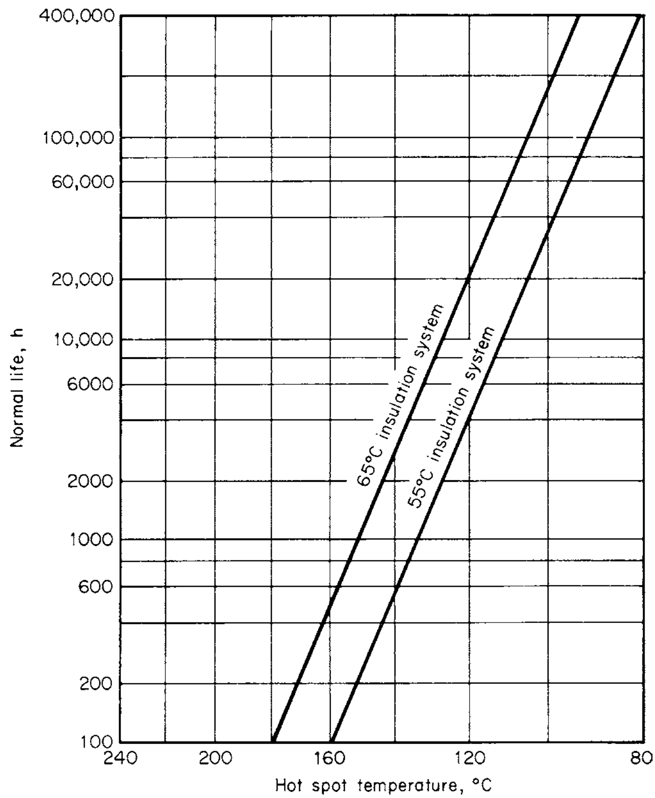

FIGURE 10-37 Loss of life as a function of temperature for power transformers up to 100 MVA under loading conditions of ANSI/IEEE C57.92.

temperature, (3) replace the hot-spot temperature curve by an approximately equivalent stepped curve, (4) calculate the percent aging for each step from the applicable curve of Fig. 10-37, and (5) add the aging for all the steps in the daily cycle. The result is the fraction of insulation life used up each day. The reciprocal is the number of days of total insulation life if the same load cycle repeats every day.

For example, consider a transformer with a daily load cycle of 4 h at 140% load and 20 h at 80% load in 30°C ambient. The hot-spot temperature curve shown in Fig. 10-23 is reproduced in Fig. 10-38, together with an equivalent stepped curve. The calculation of loss of life per day is shown in Table 10-6.

The normal life at every temperature can be determined from Fig. 10-37 or from Eq. (10-63) for the 65°C rise insulation system. The fraction of the life consumed during each time step can then be calculated and summed for all of the time steps in the 24-h period. In this case, 0.09% of the life is consumed in one day, so the total life would be 1111 days or about 3 years if this load cycle were continued. For comparison, a transformer with a 65°C average winding-rise insulation system (80°C hot-spot rise) operating in a 30°C ambient would have a hot-spot temperature of 110°C and a normal life of 65,000 hours or 7.4 years. The shortening of the insulation life from 7.4 years to 3 years is a measure of the severity of the load cycle. The actual transformer life may, of course, be shorter or longer, depending on exposure to overvoltage, overcurrent, shock, contamination, fault conditions, etc.

Loading-capability tables for normal consumption of life and for moderate sacrifice of life are documented in ANSI/IEEE C57.92 for power transformers. Information is provided for situations

involving different ambient temperatures, different peak-load durations, and different loads prior to the peak for an assumed set of representative transformer characteristics.

Ambient temperature affects load capacity by an amount dependent on the type of cooling, as shown in Table 10-7.

For ambient temperature of air-cooled transformers, use the average value over a 24-h period or 10°C under the maximum temperature during the 24-h period, whichever is higher. For ingoing water temperature, use the average value over a 24-h period or 5°C under the maximum temperature during the 24-h period, whichever is higher.

Limitations. The temperature of the top oil should never exceed 110°C for power transformers with a 55°C average winding-rise insulation system or 110°C for those with a 65°C average winding-rise insulation system. The consequence of exceeding these limits could be oil overflow or excessive pressure. The winding hot spot should not exceed 150°C for the 55°C average winding-rise insulation system or 180°C for the 65°C average winding-rise insulation system. These limitations are based principally on a concern for rates of insulation aging, but it should be noted that free bubbles may be evolved at hot-spot temperatures above 140°C, with consequent weakening of dielectric strength. The peak short-duration loading should never exceed 200% of rating, except for transformers rated over 100 MVA a limit of 150% of rating is recommended (IEEE Standard 756). This reflects a concern for stray flux heating in large units.

10.1.17 Loss Evaluation

Loss evaluation is a procedure by which the buyer and seller achieve an economic balance in adding material to the transformer design to get lower losses. It is achieved by establishing a value in dollars per kilowatt for load loss and a similar value for no-load loss.

An incremental investment in capacity is required to generate power to supply loss and bring it to the transformer. In addition, there is a continuing expense for fuel to supply the lost power. The continuing expense is converted to present worth and added to the incremental investment to give the total present worth of the loss. This present worth of a kilowatt of loss is naturally higher for the no-load loss, which is continuous, than it is for the load loss, and the value is higher the farther the transformer is from the generator; the values will of course depend on the accounting rules and procedures in force at the particular location.

The following equations are commonly used to establish loss evaluations:

$$V_L = S + \frac{8760EF_L}{R} \tag{10-64}$$

$$V_N = S + \frac{8760EF_N}{R} \tag{10-65}$$

where E = dollars per kilowatthour cost of energy (this can conceivably be very low for a hydro station but can range up to 0.02 or more for fuel-fired stations, depending on fuel cost, and, of course, the figure will be even higher at locations remote from the generating station), F_L = ratio of average load loss to rated load loss, F_N = ratio of average no-load loss to rated no-load loss (1.00 for continuous operation), R = per unit (%/100) annual carrying charge on system investment (covers insurance, taxes, depreciation, and return on investment), S = dollars per kilowatt system investment

(200 and up, depending on the system investment out to the transformer location), V_L = dollars per kilowatt evaluation of rated load loss, and V_N = dollars per kilowatt evaluation of rated no-load loss.

Since the load losses of a transformer vary as the square of the load, it is important to state the MVA rating at which the load losses will be evaluated. Since it is common practice of most transformer manufacturers to optimize the design of the transformer at its self-cooled rating, the dollar value of losses for the load loss should be specified at the self-cooled rating. If the dollar value of losses for the load loss is specified at some load other than the self-cooled rating, it can be adjusted to the self-cooled rating by multiplying the dollar value by the square of the ratio of the load at which the losses will be evaluated and the self-cooled rating.

It is also important that the transformer manufacturer knows if the buyer is using the present-worth, the levelized annual cost, or the capitalized cost method of evaluation. If the present worth method is being used, the present-worth multiplier should be stated; if the levelized annual cost method is being used, the carrying charge should be stated so the manufacturer, in either case, knows how the dollar values of losses equate to the first cost of the transformer.

Loss evaluation is an important factor in purchasing new transformers, as in many cases the evaluation of the total loss equals or exceeds the price of the transformer.

10.1.18 Autotransformers

Part of an autotransformer winding is common to both primary and secondary circuits. The common portion is called the common winding, and the remainder is called the series winding. The high-voltage terminal is called the series terminal, and the low-voltage terminal is called the common terminal. Part of the power passes from one winding to the other by transformation, and the rest passes directly through without transformation. Figure 10-39 shows an autotransformer compared with an equivalent two-winding transformer. Both have the same ratio of secondary voltage to primary voltage, T, and both have the power output. The fraction $1 - T$ of the power is transformed, and the fraction T passes through without transformation. The fraction $1 - T$, called the "co-ratio," is a measure of the required size of the core and coils as compared with a two-winding transformer. In addition, the losses and reactance are reduced in approximately the same ratio. For a low value of $1 - T$ the economy of an autotransformer compared with a transformer is attractive.

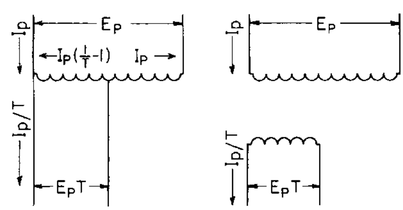

FIGURE 10-39 Comparison of an autotransformer with a two-winding transformer.

The following special characteristics of autotransformers may need consideration: A metallic connection exists between the primary and secondary circuits; this is generally of little consequence with low-voltage circuits, but with high-voltage systems the neutral point must be grounded for safe operation.

The impedance of an autotransformer is normally lower than that of the equivalent two-winding transformer, and the short-circuit current is higher.

Taps near the neutral are relatively ineffective, because turns tapped out at the neutral come out of both circuits and increase core flux density without greatly changing the voltage ratio. The high-voltage rating is more effectively adjusted by taps in the series winding. The low-voltage rating is more effectively adjusted by tapping turns out of the common winding while turns are added to the series winding or by placing the tapping winding in the low-voltage line.

Inversion of the neutral may occur under abnormal conditions in Y-connected autotransformers with ungrounded neutrals. If the voltage on a series terminal is lower than the voltage on the corresponding common terminal, high voltage tends to appear on the neutral. Inversion of the neutral can occur on power-frequency voltage or on transient voltage. Grounding the autotransformer neutral, use of a delta tertiary, and use of three-leg 3-phase cores all help to prevent inversion of the neutral.

Autotransformers are most commonly used to connect two transmission systems at different voltages, frequently with a delta tertiary winding. It is also possible to apply an autotransformer as a generator step-up transformer when it is desired to feed two different transmission systems. In this case the delta tertiary winding is a full-capacity winding connected to the generator, and the two transmission systems are connected to the autotransformer windings. Advantages of the autotransformer when compared to a normal transformer include lower impedance, lower losses, better regulation, smaller size, and lighter weight.

10.1.19 Distribution Transformers

Distribution transformers are generally considered as transformers of 500 kVA, and smaller 67,000 V and below, both single-phase and 3-phase. Older installations are primarily pole-/platform-mounted units. Newer installations are frequently pad-mounted units. Typical applications are for supplying power to farms, residences, public buildings or stores, workshops, and shopping centers.

Distribution transformers have been standardized as to high- and low-voltage ratings, taps, type of bushings, size and type of terminals, mounting arrangements, nameplates, accessories, and a number of mechanical features, so that a good degree of interchangeability results for transformers in a certain kVA range of a given voltage rating. They are now normally designed for 65°C rise.

The most popular primary voltages are 12,470Y/7200, 13,200Y/7620, and 12,000 V delta.

Many of the 2400- and 4800-V primary systems have been converted to 7200 and 7620 V. There is also increasing use of higher-voltage distribution systems such as 24,900Y/14,400 and 34,500Y/19,900 V. Secondary voltage for pole-type units is usually 120/240 or 240/480, 240/120 on single-phase pad-mount units and 208Y/120 on 3-phase units.

Magnetic cores, in general, are composed of cold-rolled silicon steel strip. They take various forms, all designed so that the magnetic flux will pass through the sheet in the direction of the rolling in order to secure the maximum benefit of the superior magnetic quality of this material. For an appreciable portion of the 24-h day, the typical distribution transformer (particularly the pole-mounted 5- to 167-kVA range) is lightly loaded. Because of this, the loss in the core is a significant portion of the total daily loss. Cores for these units are therefore designed for low exciting current and for relatively low core loss to minimize the operating cost. Low-loss cold-rolled silicon strip has contributed materially to reduced losses, weights, and dimensions. New amorphous steel alloys are providing additional opportunities to reduce the units operating costs.

Coils are usually wound in a concentric layer arrangement, with cooling ducts distributed periodically between the layers to maintain reasonable differentials between oil temperature and the average coil and hot-spot temperatures. As a matter of practical operating procedure, distribution transformers are subjected to considerable numbers of overloads for short time periods. Hot-spot temperatures must be limited on these overload excursions if the transformer is to have a long insulation life. It is now general practice to employ thermally upgraded materials in the insulation system to improve aging characteristics. Increased mechanical strength is achieved by using a special intermittent coating of a heat-reactive adhesive on the layer insulation to bond the coil into a rigid mass during the drying process. Heat and vacuum drying plus vacuum oil filling imparts good dielectric strength to the windings.

Aluminum and copper conductors are both used in the coils of distribution transformers. The decision to use one material over another is based on the required loss performance levels for individual utilities. Aluminum conductor is widely used in the secondary windings, where full-width aluminum strip is employed. Such coils are also mechanically stronger.

To cool the unit, the radiating surface of the tank itself suffices in the smaller ratings. In the larger ratings, auxiliary cooling is provided by the addition of fins or tubes. By these means, the height, size, and weight are held to desirable minimums. Special attention is given to sealing the transformers from the atmosphere. Likewise, careful attention is given to the external finish and fittings to assure reliable service for many years of exposure to the elements. External connectors are good for either aluminum or copper conductors.

The conventional pole type (Fig. 10-40) consists of core and coils securely mounted in an oil-filled tank, with the necessary terminals brought out through their appropriate bushings. The high-voltage bushings may be two in number, but one bushing plus a ground terminal on the tank wall connected to the ground end of the high-voltage winding for use on multiple-grounded circuits is the most common usage. The conventional type includes just the basic transformer structure without any protective equipment. The desired overvoltage, overload, and short-circuit protection is obtained by using lightning arresters and primary fuse cutouts separately mounted on the pole or crossarm closely adjacent to the transformer. The primary fuse cutout provides a means of visually detecting blown fuses on the system primary and also serves to remove the transformer from the high-voltage line, either manually when desired or automatically in the event of an internal coil failure.

The self-protected transformer (Fig. 10-41*a*) has an internally mounted, thermally controlled secondary circuit breaker for overload and short-circuit protection; an internally mounted protective link in series with the high-voltage winding to disconnect the transformer from the line in the event of an internal coil failure; and a lightning arrester or arresters integrally mounted on the outside of the tank for overvoltage protection. On most of these transformers, except some 5-kVA ratings, the circuit breaker operates a signal light when a predetermined winding temperature has been reached, as a warning before tripping. If the signal is unheeded and the breaker trips, the breaker may be reset and the load restored by an external handle. Usually, this can be accomplished with the normal breaker setting. If, however, the load has been a long-sustained one which has allowed the oil to reach a high temperature, the breaker may soon

trip again, or it may be impossible to reset so that it will remain closed. In such cases, the trip temperature may be set up by an auxiliary external control handle to allow reclosing of the breaker for the emergency until a larger transformer can be installed.

Figure 10-41*b* shows the rural cooperative style. Figure 10-42 show a cutway view of the self-protected design.

3-Phase self-protected transformers are similar to the single-phase units except that a 3-pole circuit breaker is used. The breaker is arranged to open all 3 poles in case of a serious overload or fault on one of the phases (Fig. 10-43).

The self-protected transformer for secondary banking is another variation. Such transformers are provided with the two secondary breakers to sectionalize the low-voltage circuits, confining the outage to just the faulted or overloaded section, leaving the entire transformer capacity available for supplying the remaining sections. These are also made for single- and 3-phase units.

"Station-type" distribution transformers are normally rated 250, 333, or 500 kVA. A "pole/station type" distribution transformer is used. For distribution to low-voltage ac networks in areas of high-load density, network transformers are available in even higher ratings.

Losses and Characteristics. For the pole-type ratings 100 kVA and smaller, full-load efficiencies range from 97% to 99%, and impedance is generally less than 2%.

Recent trends have been toward further reduction of no-load loss, exciting current, and sound level. Replacement of much of the round and rectangular conductors in the secondary winding with full-width strip has resulted in more compact windings with greatly increased mechanical strength.

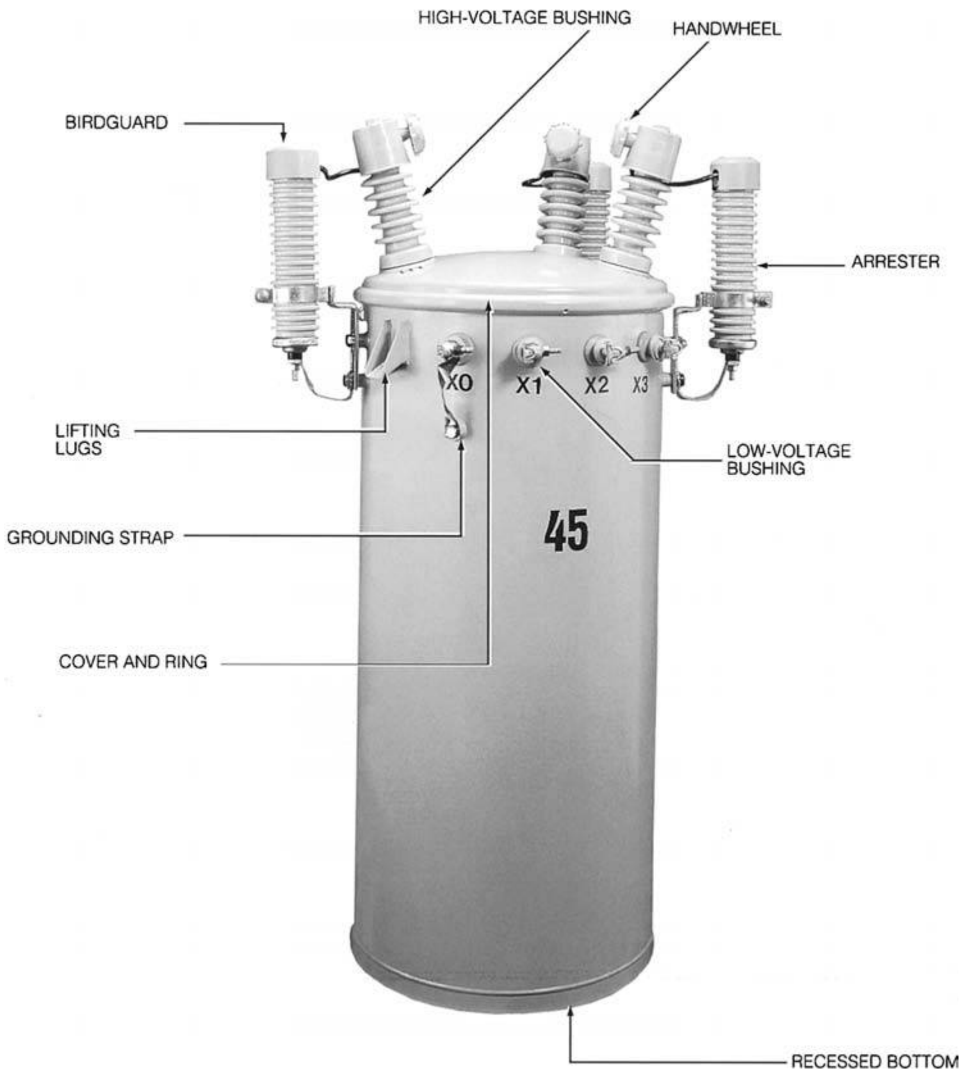

FIGURE 10-43 Three-phase, pole-type distribution transformer.

More effective utilization of distribution transformer investment is being made possible through transformer-load-management programs.

Transformers for Underground Distribution Systems. Since more distribution circuits are being put underground, transformers have been especially developed to be used with such systems. The most widely used type is the pad-mounted transformer, so called because it is designed to mount on a concrete-surface slab or pad. A typical transformer is shown in Fig. 10-44. The essential differences from the pole-type transformers are only in the mechanical arrangement:

1. A rectangular case in two compartments.
2. One compartment containing the conventional core-coil assembly.

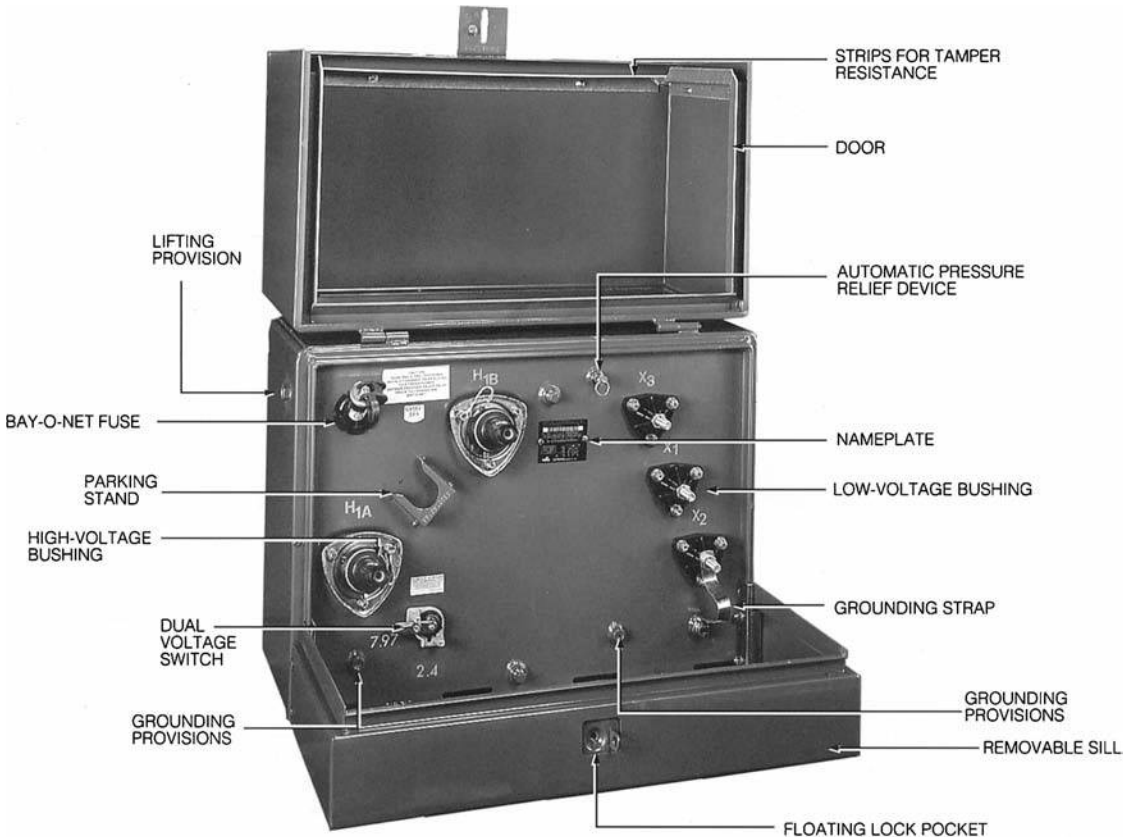

FIGURE 10-44 Single-phase, pad-mounted transformer.

3. A second compartment for cable termination and connection. The primary cable conductors are connected by plug-in connectors suitable for load make or break. The secondary conductors usually bolt to bushing terminals.
4. Fuses of various sorts provided for by a fuse holder placed in a well in the side of the tank so that the fuse holder can be drawn out.

Another transformer arrangement is designed to operate in a subterranean vault. This looks more like a pole-type transformer but is usually made with a corrosion-resistant steel tank, plug-in primary connectors, and a temperature rise in free air of only 55°C to allow for the higher ambient temperature which may actually exist in a vault.

Ferroresonance in Distribution Transformers. *Ferroresonance* is the name given to the phenomenon where the exciting reactance of the transformer can become nearly equal to the capacitive reactance of the line to ground, forming a resonant circuit. Such a resonant circuit can distort the normal line impedance to ground so that one line of a 3-phase circuit can rise to a destructive voltage.

Such a phenomenon practically never occurs in a normal circuit configuration with the transformers loaded, but it can exist under a combination of the following circumstances which usually occur only during switching of a 3-phase bank or blowing of a fuse in one line:

1. System neutral grounded, ungrounded transformer neutral
2. No load on the transformer
3. Relatively large capacitance line-to-ground such as may exist in cable circuits (underground distribution) or very long overhead lines (although ferroresonance can be and has been corrected by adding still more capacitance which presumably throws the combination out of resonance again)

Although ferroresonance has been studied at some length, it still does not seem possible to reliably predict its occurrence. Experience indicates that it is possible to prevent ferroresonance during switching on a transformer bank if all three transformers are resistance-loaded to 15% or more of their rating, or if special switches are used to assure that the three lines close simultaneously.

10.1.20 Furnace Transformers

Furnace transformers supply power to electric furnaces of the induction, resistance, open-arc, and submerged-arc types. The secondary voltage are low, occasionally less than 100 V, but generally several hundred volts. Sizes range from a few kVA to over 150 MVA, with secondary currents over 100,000 A. High currents are obtained by parallel connection of many winding sections. Current is collected by internal bus bars and brought through the transformer cover by the bus bars or by high-current bushings.

The power input to the furnace is controlled by adjusting the output voltage of the furnace transformer. Optimum performance of the furnace may require adjustment of the secondary voltage over a range of 3:1 or more. This may by accomplished by a regulating transformer between the high-voltage power source and a fixed-ratio furnace transformer. More frequently, regulation is obtained by taps in the high-voltage winding. In addition to taps in the high-voltage winding, a delta-Y switch in the high-voltage winding is often used to extend the range of voltage by an additional ratio of 1.73.

Motor-operated off-load tap changers are usual, but occasionally on-load tap-changing equipment is justified by the saving in melt time and reduced breaker maintenance. The load-tap-changing duty is more severe than on the usual power transformer, not only with respect to frequency of operation but also because of the extreme range, which results in large kVA increments per tap.

Circuit reactance furnishes current stability for ac arc furnaces. In the larger sizes, the inherent impedance of the transformer and its associated secondary conductors is sufficient for adequate stability. This is not generally true for smaller arc furnaces. Consequently, it is customary in furnace transformers rated 7500 kVA and below to include a reactor in the tank with the transformer. This reactor is connected in the high-voltage circuit and is furnished with taps to permit adjusting the total reactance to that required to maintain arc stability under the existing service conditions.

10.1.21 Grounding Transformers

A grounding transformer is intended primarily to provide a neutral point for grounding purposes. It may be a two-winding unit with a delta-connected secondary winding and a Y-connected primary winding which provides the neutral for grounding purposes, or it may be a single-winding 3-phase autotransformer with windings in interconnected Y or zigzag. With the latter, the windings consist of six equal parts, each designed for one-third the line-to-line voltage; two of these parts are placed on each leg and connected as in Fig. 10-45. In the case of a ground fault on any line, the ground current flows equally in the three legs of the autotransformer, and the interconnection offers the minimum impedance to the flow of the single-phase fault current.

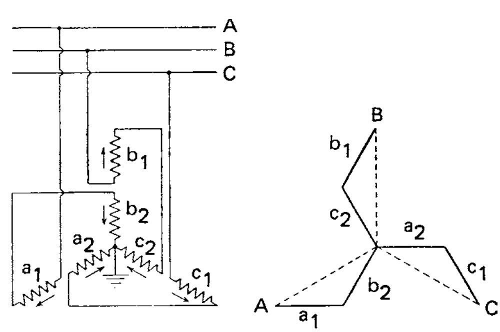

FIGURE 10-45 Grounding autotransformer with interconnected Y or zigzag windings.

10.1.22 Instrument Transformers

Functions. Instrument transformers are used to step transmission or distribution line voltages and currents down to levels that can be safely handled by metering and control devices. They are used to transform the primary voltage or current to values suitable for ratings of instruments, meters, relays, and other metering or control equipment. In a sense, they isolate the equipment from the lines. The normal secondary ratings are 5 A for current transformers and 115 or 120 V for voltage transformers. However, other current and voltage ratings are used depending on the application.

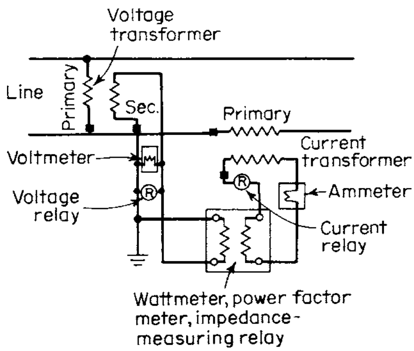

FIGURE 10-46 Voltage and current transformers as commonly connected to isolate meters, relays, and other equipment, and to transform current and voltage to convenient values.

To provide better protection, the secondary circuit should be grounded at one point. Metal cases should also be grounded.

The primary winding of a current transformer is connected in series with the load for which the current is to be measured or controlled. The primary winding of a voltage transformer is connected in parallel with the load for which the voltage is to be measured or controlled (Fig. 10-46). The secondary windings provide a current or voltage that is substantially proportional to the primary values for the operation of measuring instruments and control devices.

Polarity. When instrument transformers are used with measuring or control devices that respond only to the magnitude of the current or voltage, the direction of the current flow does not affect the response and the connections to the secondary terminals can be reversed without affecting the operation of the devices. When they are used with measuring or control devices that respond to the interaction of two or more currents, the correct operation of the devices depends on the relative phase positions of the currents, in addition to the magnitudes. To show the relative instantaneous directions of current flow, one primary and one secondary terminal are identified with a distinctive polarity marker, these indicate that at the instant when the primary current is flowing into the marked primary terminal the secondary current is flowing out of the marked secondary terminal (see Fig. 10-47).

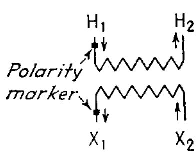

FIGURE 10-47 Polarity definition. Arrows indicate the instantaneous relative direction of currents in the windings.

Errors in Current Transformers. There are two types of errors that affect the accuracy of the measurements made with current transformers. The ratio-correction factor is the true ratio of the primary to the secondary current, divided by the nameplate ratio

$$F_{CR} = \frac{R_{CT}}{R_{CN}} \tag{10-66}$$

where F_{CR} = ratio correction factor of current transformer, R_{CT} = true ratio [(primary current)/(secondary current)], and R_{CN} = nameplate ratio [(primary current)/(secondary current)] of current transformer.

The phase-angle error is the angle of lead of the current leaving the marked secondary terminal over the current entering the marked primary terminal.

Relative Importance of Ratio and Phase Angle Errors. The ratio correction factor of current transformers affects the magnitude of the outputs. Therefore, they are important for meters that measure power for revenue purposes or other applications where the magnitude of the current is important. For example, a ratio correction factor of 1.010 indicates that the secondary current is lower than the correct value by 1% and that all measuring or control devices connected in the secondary circuit will have 1% less current than the primary current divided by the marked ratio.

The phase-angle error does not affect current-actuated devices such as ammeters or overcurrent relays, but the accuracy or operation of devices that respond to the products, the sums, or the differences of currents are affected by the phase-angle error. A wattmeter is a device that responds to the product of the voltage applied to the potential terminals, the current through the current coils, and the power factor which is the cosine of the angle between the voltage and current. The phase-angle error becomes very important if the power factor of the load being measured, such as measurement of the load losses in large power transformers, is small because the magnitude of the phase-angle error is significant compared to the angle between the voltage and the current in the devices being measured. If the current is supplied from the secondary of a current transformer with unity nameplate ratio, unity ratio correction factor, a phase-angle error of β, and primary current lagging the voltage, the wattmeter will not indicate the true watts, $EI \cos\theta$, but will indicate $EI \cos(\theta - \beta)$. If the sign of β is plus, the $\cos(\theta - \beta)$ will be larger than the $\cos\theta$ and the wattmeter will read high (see Fig. 10-48). If the sign of β is minus, the wattmeter will read low. To obtain the true watts, the apparent watts should be multiplied by the phase-angle correction factor K_β, which is dependent on both the phase-angle error of the transformer and the power factor of the load, as follows:

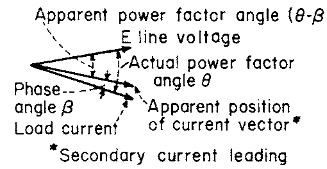

FIGURE 10-48 Effect of positive phase angle in increasing the apparent power factor.

$$K_\beta = \frac{\cos\theta}{\cos(\theta - \beta)} = \frac{1}{\cos\beta + \sin\beta\tan\theta} \tag{10-67}$$

where K_β = phase-angle correction factor of current transformer, β = angle of lead of secondary current over primary current, and θ = angle of lag of load current behind load voltage.

Summarizing the Effect of Current-Transformer Errors. Ratio correction factors: Above 1.000 the secondary current is low, and below 1.000 the secondary current is high. Phase-angle errors with lagging load current: Positive phase-angle errors cause wattmeter readings to be high if the load-current power-factor angle is greater than the phase-angle error, and negative phase-angle errors cause the wattmeter readings to be low.

In practical metering problems β will be less than 30 min and K_β can be written

$$K_\beta = 1 - \sin\beta\tan\theta = 1 - \tan\theta \qquad \text{where } \beta \text{ is in radians}$$
$$K_\beta = 1 - \beta\tan\theta/3438 \qquad \text{where } \beta \text{ is in minutes} \tag{10-68}$$

The uncertainty in knowledge of the exact values of β and θ represents a greater error than will result from this simplification of Eq. (10-67).

Transformer Correction Factor. The transformer correction factor to be applied to the reading of the wattmeter for both the ratio and phase-angle errors is given by Eq. (10-69)

$$F_T = F_{CR}K_\beta \tag{10-69}$$

where F_T = transformer correction factor.

If F_{CR} and K_β are both between 0.985 and 1.015, Eq. (10-70) may be used with an error under ± 0.0003:

$$F_T = F_{CR} + K_\beta - 1.000 \tag{10-70}$$

Classification of Errors. ANSI C57.13 classifies current transformers as to accuracy by a method which limits the total error in a wattmeter or watthour-meter reading resulting from the combination of ratio and phase-angle errors, over a range of power factors of the metered load of 0.6 to 1.0. The most accurate classification (usually specified for use with watthour meters for billing metering) is 0.3, which means that the total error at the meter caused by the current transformer will not exceed 0.3% at rated current (or at maximum continuous current), 0.6% at 10% rated current. ANSI C57.13 also recognizes 0.6 and 1.2 accuracy classes. The accuracy class is specified in connection with one or more of the standard burdens (see the next paragaph). For example, "0.3 B-0.2" describes a transformer of 0.3 accuracy class when loaded with a B-0.2 burden on the secondary terminals.

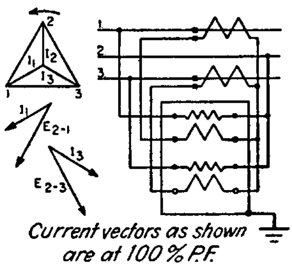

FIGURE 10-49 Metering connections for 3-phase, 3-wire lines with two watthour-meter elements.

Standard Burdens. ANSI C 57.13 also recognizes a number of standard values of secondary impedance loading (called "burden" in instrument-transformer parlance) for use in describing current transformer performance. The burdens are designated as B0.1, B0.2, B0.5, B0.9, B1.8 to mean impedances of 0.1, 0.2, etc., ohms at 0.9 power factor, and also B1.0, B2.0, B4.0, and B8.0 for corresponding impedances at 0.5 power factor. (These standard burden impedances are only applicable if rated secondary current is 5 A.)

Effect of Phase-Angle Errors on Metering 3-Phase 3-Wire Power with a Two-Stator Watt-hour Meter. With the meter connected as indicated in Fig. 10-49 with balanced load, if the marked ratio and ratio correction factor are both 1.000 and the phase-angle error β is the same for both current transformers

$$K_\beta = \frac{E_1 \cos(\theta + 30) + E_1 \cos(\theta - 30)}{[E_1 \cos(\theta + 30 - \beta) + E_1 \cos(\theta - 30 - \beta)]} = \frac{1}{\cos\beta + \sin\beta \tan\theta} \qquad (10\text{-}71)$$

This is identical with Eq. (10-67) for a single-phase measurement.

Causes of Errors. The errors in a current transformer are due to the energy required to produce the core flux, which induces the secondary winding voltage that supplies the current through the secondary circuit. The total ampere-turns available to provide secondary current are vectorially equal to the primary ampere-turns minus the ampere-turns required to produce the core flux.

A change in secondary burden alters the flux required in the core and changes the core-exciting ampere-turns; leakage flux entering the core changes the magnetic characteristics of the core and affects the core-exciting ampere-turns.

Calculation of Ratio and Phase-Angle Errors. Caculation of ratio and phase angle in current transformers can, in theory, be done simply by first calculating the exciting ampere-turns required to magnetize the core and subtracting them from the primary ampere-turns to get the secondary ampere-turns (vectorial subtraction). The difficulty in calculation is that in many transformers the leakage flux which flows in only part of the core is as large as the working flux and its effect on exciting ampere-turns is most difficult to calculate (Wentz 1941). For exact determination of ratio and phase angle, therefore, actual measurement of ratio and phase angle as described in ANSI C57.13 is necessary.

Approximate calculation of ratio for relaying service is more practical and in fact often necessary because transformers supplying relays must often operate at currents up to 20 times normal or even higher, and exact measurements are extremely difficult and expensive. Accordingly, ANSI C57.13 recognizes an adequate ratio-error calculation method for current transformers in which the leakage flux which enters the core has only a negligible effect on performance. This calculation method is described in the Test Methods Section of C57.13. The ratio error calculated by this method may in fact be greater than the actual ratio error, but it is certain that it will not be less, a conservative result.

Generally, the leakage flux in a current transformer can be said to be negligible only in a current transformer consisting of a toroidal core with the secondary winding fairly well distributed around the core, for example, an assembly intended to be placed over a bushing in a circuit breaker or transformer and then only if the return conductor is at a distance at least as great as in typical circuit breakers. If this type of transformer is used with a primary coil or even a single primary turn placed around one side of the core, it is doubtful that the leakage flux will be negligible.

Transformers with negligible leakage flux (principally bushing type) are designated in C57.13 as Class C transformers, meaning that it is safe to calculate the ratio error.

Classification of Current Transformers for Relaying Service. Transformers for which calculation of ratio will give conservative results are designated as Class C; all other transformers are designated as Class T, meaning that their performance must be determined by test. The performance of both types of transformers is then classified according to the voltage the secondary can deliver to the burden at 20 times rated secondary current without exceeding 10% ratio error. The established standard secondary terminal voltages are 10, 20, 50, 100, 200, 400, and 800, corresponding to the voltage required by ANSI standard burdens at 20 times normal current (100 A). A current transformer is classified by the letter C or T plus the standard voltage, such as C200 or T400.

Short-Time Current Limits. Current transformers may have to carry very large currents in the event of a short circuit of the system, especially when a low-rated branch circuit is supplied from a large system with a high fault-current capability. The large currents in the winding have two principal effects:

1. The primary winding is repelled from the secondary by the electromagnetic forces, which are proportional to the square of the current.

2. The windings heat very rapidly at a rate nearly proportional to the square of the current.

In order to apply current transformers properly, it is necessary to give them ratings:

1. Mechanical short-time rating, the current, usually stated in terms of times normal, which the transformer can withstand mechanically even if the current is initially fully offset.

2. Thermal short-time rating, the current which will not heat the winding to more than 250°C for copper conductors or 200°C for EC aluminum conductors. This limit is not to be demonstrated by test but is calculated on the conservative assumption that all the heat generated by the current is stored in the conductor.

C57.13 may be consulted for additional detail and for the test method to be used to demonstrate the mechanical limit.

Types of Construction. The types of current transformers are the wound type which consists of primary and secondary windings completely installed and permanently assembled on the magnetic circuit; the bar type, which is similar to the wound type except that the primary is a single straight and fixed turn; the window type, which has a secondary winding completely insulated and permanently assembled on the magnetic circuit and a window through which a conductor can be passed to provide a primary winding; and the bushing type, which is a special window type designed to fit over apparatus bushings, with the conductor through the bushing as the primary winding.

Current transformers are classified in accordance with the major insulation used as dry-type, compound-filled, molded, or liquid-immersed.

Safety Precautions. The secondary winding should always be short-circuited before disconnecting the burden. If the secondary circuit is open, with primary current flowing, all the primary ampere-turns are magnetizing ampere-turns and usually will produce an excessively high secondary voltage across the open circuit. All instrument-transformer secondary circuits should be connected to ground; when instrument-transformer secondaries are interconnected, only one point should be grounded. If the secondary circuit is not grounded, the secondary becomes, in effect, the middle plate of a capacitor, with the high-voltage winding and ground acting as the other two plates.

Errors in Voltage Transformers. There are two types of errors that affect the accuracy of the measurements made with voltage transformers. The ratio error is the difference between the true ratio of the primary to secondary voltage and the ratio that is marked on the nameplate. The phase-angle error is the difference in the phase position of the voltage applied to the secondary burden and the voltage applied to the primary winding.

The ratio error is expressed as a ratio correction factor by which the secondary-voltage value should be multiplied to obtain a secondary voltage that is directly proportional to the primary voltage

$$F_{PR} = \frac{R_{PT}}{R_{PH}} \tag{10-72}$$

where F_{PR} = ratio correction factor of the voltage transformer, R_{PT} = true ratio (primary/secondary) of the voltage transformer, and R_{PN} = nameplate ratio (primary/secondary) of the voltage transformer.

The phase-angle error is designated by the symbol γ, is expressed in minutes, and is defined as positive when the voltage applied to the burden from the marked to the unmarked secondary terminal leads the voltage applied to the primary from the marked to the unmarked terminal.

Relative Importance of Ratio and Phase-Angle Errors. The effect of the ratio and phase-angle errors of voltage transformers is the same for current transformers, except that with a lagging power-factor load a positive voltage transformer phase-angle error will cause the wattmeter to read low. To obtain the true watts, the apparent watts should be multiplied by the phase-angle correction factor K_γ:

$$K_\gamma = \frac{\cos\theta}{\cos(\theta + \gamma)} = \frac{1}{\cos\gamma - \sin\gamma\tan\theta} \tag{10-73}$$

where K_γ = phase-angle correction factor of the voltage transformer, θ = angle of lag of load current behind load voltage, and γ = angle of lead of secondary voltage over primary voltage.

Classification of Errors. The errors in a voltage transformer change with the current required by the burden connected across the secondary terminals, the frequency, and the magnitude of the secondary voltage. ANSI C57.13 classifies voltage transformers as to accuracy by a method essentially the same as that for current transformers, the principal difference being that the limits of error apply over the range of rated voltage from 90% to 110% and from zero burden up to the burden at which the rating is given. The standard burdens for rating purposes are given in Table 10-8. The complete ANSI accuracy classification of a voltage transformer must include the secondary burden, such as 0.3X or 0.6Z.

Voltage transformers are made for all the standard rated circuit voltages. They are usually dry-type or molded for voltages below 23 kV and liquid-filled for the higher voltages.

Other Error Calculations and Corrections. The measurement of power by using a wattmeter and both current and voltage transformers requires a correction for the ratio and phase-angle errors of both of the instrument transformers and a correction for the phase angle α in minutes of the potential circuit of the wattmeter. Figure 10-50 shows the relative phase positions of the primary and secondary

voltages and currents of the instrument transformers if both β and γ are positive. If the potential circuit of the wattmeter is inductive by a small amount, the current in this circuit will lag the voltage and the phase angle will have the same effect as a negative voltage-transformer phase angle. The total phase-angle correction factor is

$$K_S = \frac{\cos(\theta + \beta - \gamma + \alpha)}{\cos\theta} \tag{10-74}$$

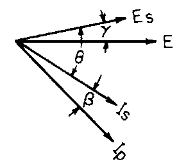

FIGURE 10-50 Vector relations in current and voltage transformers, where p = 5 primary and s = 5 secondary.

where K_S = total phase-angle correction factor, α = angle of lag of potential circuit of wattmeter, β = angle of lead of secondary current over primary current, γ = angle of lead of secondary voltage over primary voltage, and θ = angle of lag of secondary current behind secondary voltage.

The true watts, with all corrections included, is

$$P = WR_{CN}R_{PN}F_{CR}F_{PR}K_S \tag{10-75}$$

where F_{CR} = ratio-correction factor of current transformer, F_{PR} = ratio-correction factor of voltage transformer, P = watts drawn by load, R_{CN} = nameplate ratio of current transformer, R_{PN} = nameplate ratio of voltage transformer, and W = watts reading of wattmeter.

In watt-hour meters, the phase angle corresponding to α is corrected for in the meter by the lag adjustment or by making an overall calibration and adjustment for all errors, including the ratio and phase-angle errors of the instrument transformers.

Figures 10-51 and 10-52 show typical ratio-correction-factor and phase-angle curves for a current and a voltage transformer.

Consider the following example in which a load is measured with 50/5-A current transformer, with a 12.5-VA 90% power-factor burden characteristic curve according to Fig. 10-51 with 2300:115 V voltage transformer rated 200 VA with a 75-VA 85% power-factor burden characteristic curve according to Fig. 10-52 and with a lag angle of 6 min in the wattmeter potential circuit. What is the load true watts when the instruments read 500 W, 115 V, and 5 A, calibration errors of instruments being neglected? From Fig. 10-51

$$F_{CR} = 0.9997 \qquad \beta = -2'$$

From Fig. 10-52

$$F_{PR} = 0.9984 \qquad \gamma = +1$$

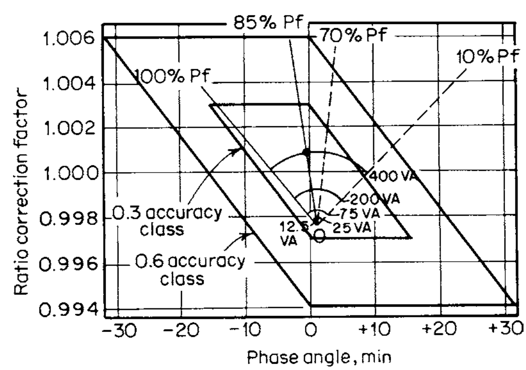

FIGURE 10-52 Typical curves of ratio-correction factors and of phase angle for a voltage transformer.

Stated above

$$\alpha = +6'$$

$$\theta = \cos^{-1}\frac{500}{5 \times 115} = \cos^{-1} 0.86957 = 29°35.47'$$

From Eq. (10-74)

$$K_S = \frac{\cos(29°35.47' - 2' - 1' + 6')}{\cos(29°35.47')} = \frac{0.86914}{0.86957} = 0.9995$$

From Eq. (10-75)

$$P = 500 \times 10 \times 20 \times 0.9997 \times 0.9984 \times 0.9995 = 99760$$

Ferroresonance in voltage transformers can occur when a voltage transformer is connected line to ground on an ungrounded system if the capacitive reactance, line to ground, can equal the exciting reactance of the voltage transformer, a condition which typically occurs at considerable overvoltage. A parallel resonant circuit of very high impedance is formed, raising the line-to-ground voltage considerably above normal; if the voltage is high enough, the voltage transformer will fail due to excessive exciting current or high-voltage stresses.

Measures taken to reduce the incidence of ferroresonance include operation at low flux densities, resistance loading of the secondaries, and insertion of resistance in the connection of the voltage transformer primary neutral to ground.

Transient performance of current transformers with initially offset primary current has been given a great deal of study in recent years. It has been realized for many years that a transformer has difficulty in transforming the dc component of an offset current. No one method of calculation has been generally acceptable but study of the references will help one to arrive at a solution of most practical problems.

10.2 CIRCUIT BREAKERS

By DAVID S. JOHNSON, JEFFREY H. NELSON and TED W. OLSEN

Definitions of terms used in this section can be found in the IEEE standards and application guides referenced in this section and/or in the *IEEE Authoritative Dictionary of Terms*.

10.2.1 Fundamentals

Definitions. *Circuit breakers* are mechanical switching devices capable of making and breaking currents under either normal or specified abnormal (short circuit) conditions on the power system. Though circuit breakers are primarily defined by their protective capabilities and ratings under abnormal short circuit conditions, they also perform switching duties under a myriad of other system conditions, each of which has its own set of switching stresses.

Circuit breakers are rated primarily by power frequency voltage, insulation levels (BIL, switching impulse, hi-pot voltage), continuous current, short-circuit current, and interrupting time. Reference is made to IEEE C37.100[1] for definitions of ratings subjects, and to IEEE C37.04[2] and IEEE C37.06[3] for values of ratings typically applied to circuit breakers.

Circuit breakers employ a variety of media for high voltage insulation and/or current interruption. The type of media employed in a specific design is often designated as a prefix in the naming of the circuit breaker, for example, vacuum circuit breaker, or sulfur hexafluoride (SF_6) gas circuit breaker.

Circuit breakers are often categorized as being of either "dead tank" or "live tank" design. In the dead tank case, the interrupting contact system is enclosed in a grounded tank, typically surrounded by an insulating fluid (oil) or gas (SF_6) (see Figs. 10-53 and 10-54 for examples of dead tank circuit breakers).

The electrical current enters the tank through high voltage entrance bushings (Fig. 10-55), passes through the contact system, and then exits through another high voltage entrance bushing. In the live tank case, the interrupting contact system is supported by insulators at some height above ground potential, but is not contained within a grounded tank system (see Figs. 10-56 and 10-57 for examples of live tank circuit breakers). There is no grounded tank or enclosure surrounding the live parts. Dead tank design allows the placement of current transformers, which are necessary for protective relaying input signals, around the high voltage entrance bushing. Live tank design offers no location to place current transformers, and therefore must be independently placed adjacent to the circuit breaker.

History of Development. In the early days of electrification (1890), switches were of the hand-operated, knife-blade type.

Air Switches. With increasing current and voltages, spring-action driving mechanisms were developed to reduce contact burning by faster-opening operation. Later, main contacts were fitted with arcing contacts of special material and shape, which opened after and closed before the main contacts. Further improvements of the air

switch were the brush-type contact with a wiping and cleaning function, the insulating barriers leading to arc chutes, and blowout coils with excellent arc-extinguishing properties. These features, as well as the horn gap contact, are still in use in low-voltage ac and dc breakers.

Oil Circuit Breaker. Around 1900, in order to cope with the new requirement for "interrupting capacity," ac switches were immersed in a tank of oil. Oil is very effective in quenching the arc and establishing the dielectric strength of an open break after current zero. Deion grids, oil-blast features, pressure-tight joints and vents, new operating mechanisms, and multiple interrupters were introduced over several decades to make the oil circuit breaker a reliable apparatus for system voltages up to 362 kV.

Minimum-Oil Circuit Breaker. These breakers were developed after 1930, used mainly in Europe, and make the special low-oil-volume interrupting chambers of extra-light weight. By means of current-dependent oil streams in different directions and supported by oil injection, the arc is cooled and extinguished effectively. The interrupters are mounted on porcelain or molded-resin supports, thus avoiding oil as an insulating medium to ground.

Standard transformer oil can be used for both oil and minimum-oil circuit breakers.

Air-Blast Circuit Breaker. Further increase of system voltages and generating capacities triggered the search for faster and stronger circuit breakers utilizing oiless arc interruption. After 1940, the air-blast circuit breaker was developed, making use of the good insulating and arc-quenching properties of dry and cleaned compressed air.

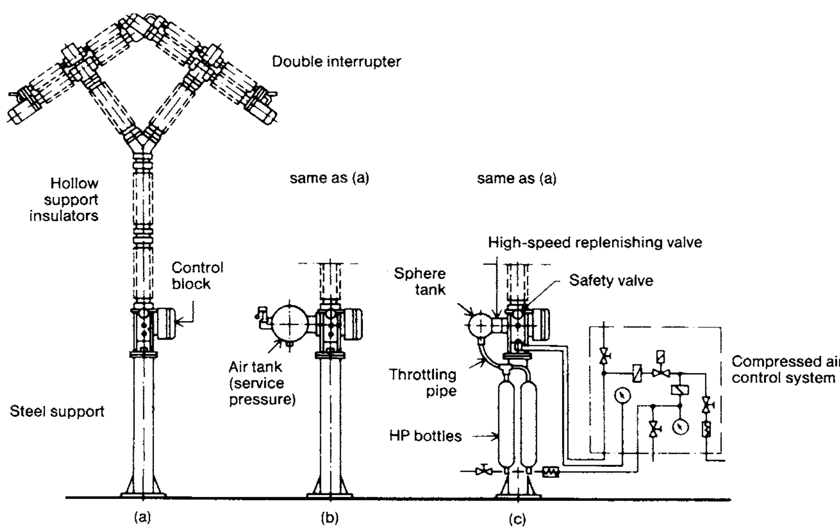

FIGURE 10-56 Modular setup of a 362-kV outdoor air-blast circuit breaker with two uprating steps: (*a*) without air tank, low braking capability; (*b*) with air tank, standard breaking capability; (*c*) with constant-pressure air supply and high breaking capability.

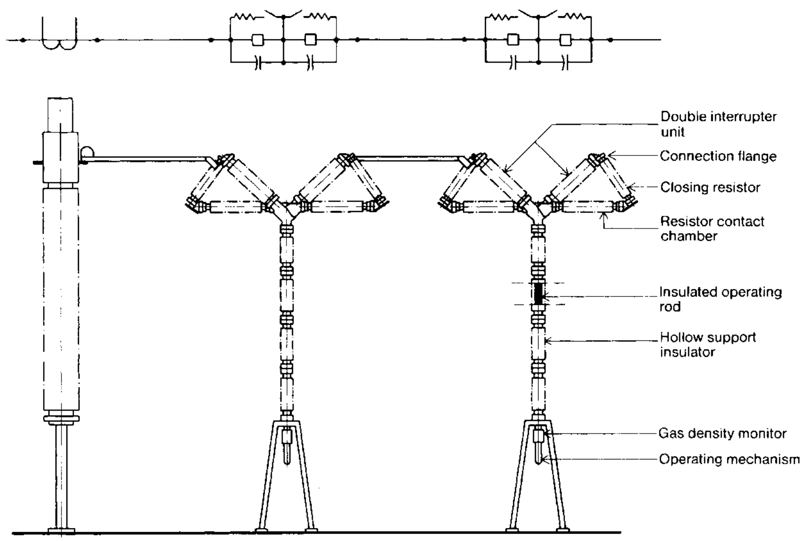

FIGURE 10-57 Live-tank SF_6 outdoor circuit breaker and current transformer arrangement, 800 kV, 3000 A, 40 kA.

Figure 10-58 shows a typical air-blast circuit breaker of modular design, installed in 1950.

Further development of the air-blast circuit breaker led to two-cycle interrupting time, extra-heavy interrupters, and the constant-pressure control system.

The magnetic air circuit breaker uses a combination of a strong magnetic field (coil or soft iron plates) with a special arc chute to lengthen and cool the arc until the system voltage cannot maintain the arc any longer. This interrupting principle was applied mainly in the distribution voltage range in metal-clad switchgear from the 1940s to the 1980s.

SF_6 Gas Circuit Breakers. SF_6 gas circuit breakers were first developed in the early 1950s by Westinghouse Corporation, following the discovery of the excellent arc quenching and insulating properties of SF_6 gas (see Fig. 10-59). Both live tank and dead tank designs were introduced from the late 1950s into the 1960s. SF_6 remains the dominant insulating and arc-quenching medium at higher voltages (72.5 kV and above) even today.

Dead tank SF_6 gas circuit breakers were incorporated into gas-insulated substations (GIS) up to 800 kV from the mid-1960s through the present. Gas insulated substations offer space savings and

environmental advantages over conventional outdoor substations, using the reduced insulation gap requirements of SF_6 gas.

SF_6 gas circuit breakers were initially of the two-pressure type, in which high pressure gas for interruption is compressed and stored for later interrupting duty. Later designs employed the puffer principle, in which interrupting pressure is developed during the contact motion itself, and no high pressure gas is stored. The latest designs of SF_6 gas circuit breakers utilize the arc thermal energy itself to develop the interrupting pressure; these designs are referred to as *self-blast* or *thermal-assist* circuit breakers.

Vacuum Circuit Breakers. Vacuum interrupter technology is a relatively recent development, from the 1960s to 1970s. Vacuum circuit breakers employ a vacuum bottle, which includes the contact system. The contacts within the vacuum bottle are driven, through a bellows, by a low energy mechanism. The contact stroke of vacuum circuit breakers is short, which leads to very reliable, low mechanical-energy designs. Vacuum interrupters have now improved in their range of voltages, short-circuit currents, and continuous current capabilities, such that most medium voltage application requirements can be met. Vacuum circuit breaker designs have become the dominant technology for outdoor breakers and metal-clad switchgear applications at 38 kV and below.

Design Fundamentals. Circuit breaker designs typically consist of the following construction elements: (1) contact system or interrupter, at high voltage; (2) insulation between the contact system and ground potential (SF_6 gas, porcelain, molded resin); (3) operating mechanism and related control systems; and (4) an insulated link between the operating mechanism and the high voltage contact system. In addition, dead tank circuit breakers incorporate high voltage entrance bushings that carry current at high voltage through the circuit breaker tank shell. Dead tank designs may also include bushing type current transformers (BTCT), which are conveniently placed around the conductor of the high voltage entrance bushings.

Tripping facilities. Tripping facilities, including circuit breaker controls, and the mechanical tripping mechanism of the circuit breaker operating mechanism, are vital to ensure proper operation during all conditions.

Short Circuit Duty. The *short-circuit duty* is determined by the maximum short-circuit that the rotating machinery connected to the system at the time of short circuit can pass through the breaker to a point just beyond the breaker, at the instant the breaker contacts open. The short-circuit current is determined by the characteristics of synchronous and induction machines connected to the system at the time of the short circuit, the impedance between them and the point of short circuit, and the elapsed time between the starting of the short circuit and the parting of the breaker contacts.

In *calculating* short-circuit currents of high-voltage ac circuit, it is ordinarily sufficiently accurate to take into account only the reactance of the machines and circuits, whereas in low-voltage circuit resistance as well as reactance may enter into the calculation. In dc circuit, resistance only is ordinarily sufficient.

For first *approximations*, the reactance and typical time-decrement curves of the synchronous machines may be used. For close calculations, the actual reactances and time characteristics of the equipment should be used, and calculation made for single- as well as 3-phase faults. The “per unit” impedance system and the “internal voltage” method, using “symmetrical components,” are often used in more exact calculations. Programs are available for digital computer studies of system short-circuit currents, both balanced 3-phase and phase-to-ground.

The *interrupting capacity*, in kilovolt amperes, is the product of the phase-to-ground voltage, in kilovolts, of the circuit and the interrupting ability, in amperes, at stated intervals and for a specific number of operations. The current taken is the rms value existing during the first half-cycle of arc between contacts during the opening stroke.

Symmetrical Current Basis. It has become a widely adopted practice to determine the interrupting capability of circuit breakers in kiloamperes symmetrical. The rated short-circuit current in rms kiloamperes is referred to the rated maximum voltage in kilovolts.

The ratings structure and tables of ratings for ac high-voltage circuit breakers are found in IEEE C37.04[2] and IEEE C37.06[3].

The short-circuit current interrupting process is characterized first by an arc appearing between the breaker contacts. The arc contains a high conductivity plasma column originating from the high temperature and related gas ionization (in the case of gas-blast interrupters). Interruption will occur at current zero and in this case is first determined by successful cooling of the arc (through gas flow) to eliminate the ionized gas conductive path, and then the race to build up dielectric strength of the open contact gap faster than the rise of the power system recovery voltage.

Several specific problems are encountered during the interrupting process of gas-blast interrupters:

1. Arc plasma temperatures exceeding 20,000 K.
2. The turbulent supersonic flow of the quenching gas in a changing flow geometry with speeds ranging from a few hundred meters per second to several thousand meters per second.
3. The interrupter-moving system and its drive accelerates the moving masses in the few thousandths of a second to speeds as high as 10 m/s while simultaneously compressing the quenching gas.
4. The stress places on the network system by the current interruption and the recovery voltage.

The *interrupting principle* of an SF_6 puffer-type interrupter is sketched in Fig. 10-60. On opening, the fixed and moving contacts are pulled apart by the operating mechanism. Thus, the fault current is forced to flow along the arc plasma. The contact movement combined with the compression cylinder movement in the opposite direction compresses the quenching gas inside the cylinder. The quenching gas is consequently forced to flow through the contact system, and the insulated nozzle toward the exhaust. This intensive flow of quenching medium along the arc rapidly removes the energy converted within the arc plasma and transforms the path between the open contacts into an insulating gap.

DC Interruption. DC interruption (see Fig. 10-61) is basically different from ac interruption. After contact parting, the arc is lengthened and cooled and consequently the arc voltage is rising. The current will extinguish after the change in current *di*/*dt* becomes negative and the arc voltage rises above service voltage. DC circuit breakers must therefore operate fast, in order to allow the voltage to build up in a few milliseconds. The energy originating from the generator and inductance will have to be absorbed by the arc. Magnitude and duration of short-circuit current depend on the height of network inductance. With rising inductance, the short-circuit current will decrease, whereas the duration of the arc will increase.

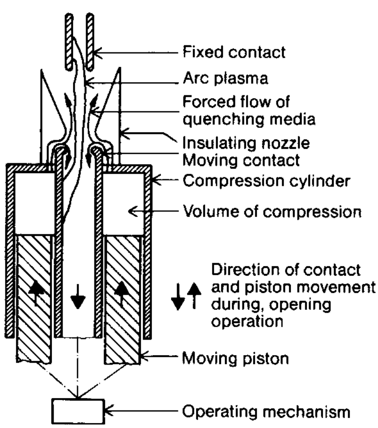

FIGURE 10-60 Principle of puffer-type arc interrupter.

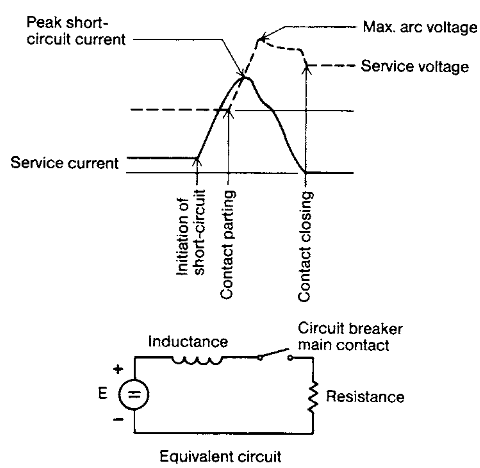

FIGURE 10-61 Direct-current interruption; typical shape of short-circuit current and recovery voltage.

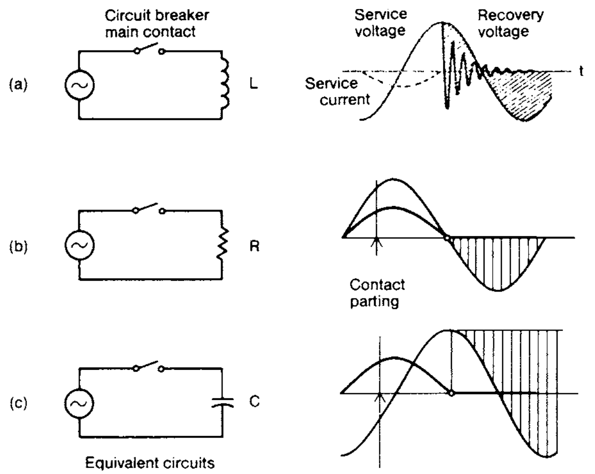

FIGURE 10-62 Typical shape of recovery voltage on interruption: (*a*) induction current; (*b*) resistive current; (*c*) capacitive current.

AC Interruption. AC interruption occurs at current zero. During the following half-cycle, the *recovery voltage* will build up across the circuit breaker main contacts. The typical appearance of recovery voltage will differ in inductive, resistive, and capacitive circuits (see Fig. 10-62). When opening an inductive circuit, the recovery voltage will rise suddenly at a high rate because current interruption occurs at the moment of system voltage peak. This case requires fast building of dielectric strength of the open contact gap.

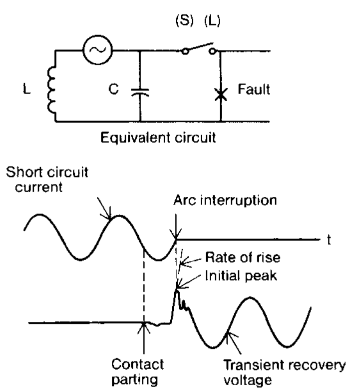

FIGURE 10-63 Alternating-current interruption; typical shape of short-circuit current and transient recovery voltage.

When interrupting resistive load, current and voltage pass through zero at about the same moment. The recovery voltage will therefore rise at a moderate rate and no particular problems are imposed on the circuit breaker.

At the moment of interruption of capacitive current, the capacitance is fully charged. The recovery voltage rises slowly during the first half cycle but continues to rise to a value twice the system voltage. This may lead to restrikes, undesired network oscillations, and overvoltages.

The waveforms of short-circuit current and transient recovery voltage in a simplified network system are shown in Fig. 10-63. At the moment of fault-current interruption the two sections—source side (*S*) and line side (*L*)—of the network are decoupled and oscillate independently about their driving voltage. The difference of these two transients appears across the open contacts of the breaker pole. The behavior of this transient recovery voltage is determined by the circuit parameters. The still-moving or already fully-open breaker contacts must be able to withstand the recovery voltage. The most severe stress for the open contact gap is the *initial peak* and the *rate of rise* (kV/μs) of the recovery voltage.

If the recovery voltage exceeds the gap insulation, the arc will restrike and current will continue until the next current zero, when interruption will again be attempted. The rate of rise of recovery voltage is a function of the constants of the circuits which supply power through the breaker. The larger the adjacent capacitance to ground before the major inductance limiting the fault current, the slower will be the rise of the recovery voltage. Some breakers modify the recovery voltage characteristics by limiting the current, modifying its power factor, and so on.

10.2.2 Severe Interrupting Conditions

The following severe cases of circuit-breaker switching conditions have to be considered carefully: terminal fault, short-line fault, out-of-phase switching, switching of small inductive currents, switching of capacitive currents, closing on a fault. The chosen examples are typical only; they are uniformly based on similar and simplified network configurations and are restricted to single-phase fault conditions. Other switching conditions may also be important.

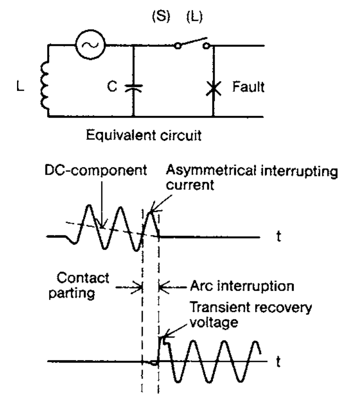

FIGURE 10-64 Principle of terminal-fault interruption, equivalent circuit; typical shape of short-circuit current and transient recovery voltage.

Terminal Fault. After interruption of short-circuit current, the recovery voltage oscillates toward the service frequency driving voltage via an initial peak. The natural frequency is determined by the inductance and capacitance of the driving system (Fig. 10-64).

The dc component of the short-circuit current depends on the time constants of the network components like generators, transformers, cables, and high-voltage lines and their reactances of the zero-sequence and the positive sequence networks. The recovery voltage will accordingly vary depending on the location of the circuit breaker within the network.

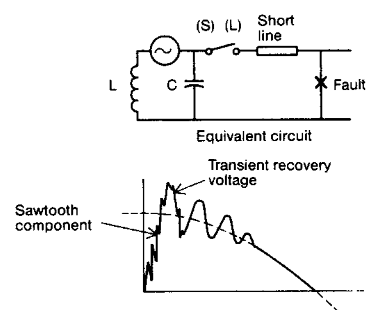

FIGURE 10-65 Principle of short-line fault interruption, equivalent circuit; typical shape of recovery voltage.

Short-Line Fault. In the case of a short-line fault, a section of line lies between the breaker and the fault location (Fig. 10-65). After the short-circuit current has been interrupted, the oscillation at the line side (*L*) of the breaker assumes a superimposed "saw-tooth" shape. The rate of rise of this line oscillation is directly proportional to the effective surge impedance and the time rate of change of current (di/dt) at current zero. The component on the supply side (*S*) basically exhibits the same waveform as a terminal fault. The circuit breaker is stressed by the difference between these two voltages. Because of the high frequency of the line oscillation, the transient recovery voltage has a very steep initial rate of rise. Since the initial rate of rise increases with increasing rate of current change, the limiting interrupting capability of many breaker designs is determined by the short-line fault.

Out-of-Phase Switching. Two network systems with driving voltages $E1$ and $E2$ are connected via a high-voltage transmission line (Fig. 10-66). Since the circuit is closed via the closed circuit breaker, the resulting driving voltage is equal to the sum of the two system voltages. Driving voltage $E2$ may, for example, exceed voltage $E1$ by the voltage drop across the transmission line. After opening the breaker, the transient recovery voltages of the disconnected networks oscillate independently.

The circuit breaker is stressed by the difference of these two voltages. In the case of disconnection of long lines, the recovery voltage across the breaker could be increased because of the Ferranti effect, where the voltage of the receiving end can be up to 15% higher than the sending end if the line is lightly loaded.

Interruption of Small Inductive Currents. This occurs (see Fig. 10-67) when disconnecting unloaded transformers, reactors, or compensating coils. An arc is produced between the contacts when the circuit breaker is opened. The arc voltage is approximately constant at higher currents, since the arc energy is removed only be convection. With small currents, the arc voltage increases as a result of arc looping and a change in the cooling mechanism.

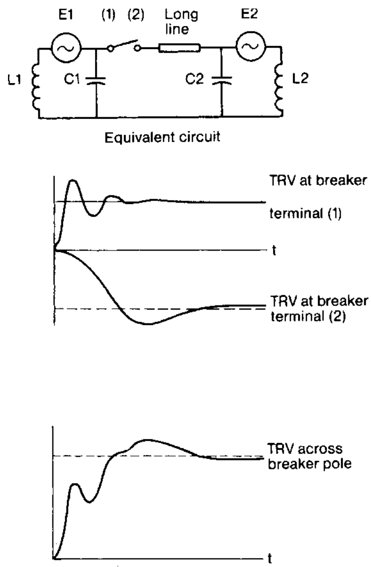

FIGURE 10-66 Principle of out-of-phase switching, equivalent circuit; typical shape of recovery voltage.

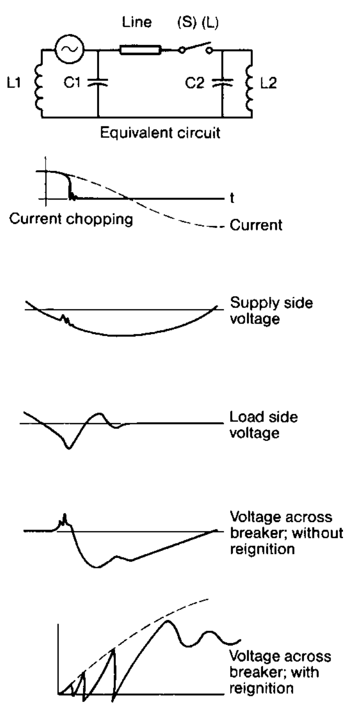

FIGURE 10-67 Principle of small-inductive-current interruption; equivalent circuit; typical shape of current and voltage.

When approaching current zero, the arc current begins to oscillate as a result of interaction with the system; that is it becomes unstable.

As a result of the high oscillation frequency, the current interruption may occur prior to the natural zero passage, can be regarded as instantaneous, and is called *current chopping*. The chopping current is affected not only by the properties of the circuit breaker but also to a great extent by the system parameters.

Energy at the disconnected load side (*L*) oscillates with the natural frequency of the capacitances local to the circuit breaker. The maximum voltage is attained at the moment when all the energy is converted into capacitive energy.

As a result of the resistive losses, the voltage on the disconnected load side decays to zero. During current chopping, the breaker is stressed by the supply-side voltage on one side and by the load voltage on the other side. The supply side voltage is at a maximum, since the load is highly inductive. The load side voltage is the oscillating voltage as the energy exchanges from inductive energy to capacitive energy. This load side voltage will have a high frequency of up to several thousand cycles per second. During this increasing stress, reignition across the breaker may occur.

However, the arc is immediately extinguished again because of the low current and the process begins anew. Hence, the reignition also helps reduce the energy stored in the disconnected circuit.

Interruption of Capacitive Currents. Capacitive currents occur during line drooping as well as during disconnecting unloaded cables or capacitor banks (Fig. 10-68). Although, switching of capacitor banks is regarded as a special application, disconnecting of charged lines is a frequent switching operation.

Current chopping may occur at a low instantaneous current value during interruption of capacitive currents, but this does not lead to overvoltages. After interruption of current, the voltage at the line capacitance (*L*) remains at the peak value of the power frequency voltage, whereas the voltage on the source side (*S*) oscillates about the driving voltage. The difference between the two voltages appears across the circuit breaker with an amplitude of more than double the rated voltage. If the circuit breaker cannot withstand this higher voltage *restriking* may occur. Restriking is similar to closing transmission lines with trapped charge. After restiking, a transient current flows through the circuit breaker, which is of higher frequency than that of the system and which can again be interrupted during the reignition process. After *reextinction*, the line is charged to the potential of the peak value of the equalizing process, whereas the circuit-breaker terminal on the source side (*S*) recovers to the system voltage. A very high differential voltage appears across the breaker, which may lead to renewed restriking and even switching failures. Restrike-free interruption of capacitive currents is thus of the utmost importance. Basically, the same phenomenon occurs during disconnection of capacitor banks. To determine the voltage stresses of the circuit breaker, however, the grounding condition of the supply system and capacitor bank and the arrangement of the bank have to be taken into account.

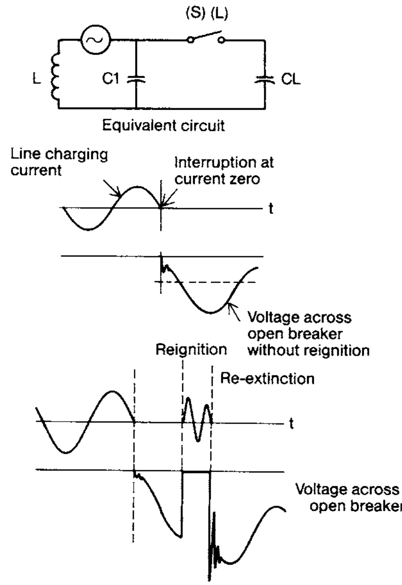

FIGURE 10-68 Principle of capacitive current interruption, equivalent circuit; typical shape of current and voltage.

Closing on a Fault. This (see Fig. 10-69) directs the stress onto the circuit breaker contact system, particularly as regards the electrodynamic and thermal forces. The current and voltage stress is different during closing on (a) symmetrical or (b) asymmetric short-circuit current.

The deciding factor is the moment of contact touch relative to the phase angle of system voltage. In case contact touch and consequently ignition of the arc occurs at the voltage maximum, the short-circuit current will appear symmetrical. The other extreme case takes place with the moment of closing at voltage zero. Here the asymmetrical short-circuit current contains the maximum dc component. A contact system designed for fast closing operation will be subjected to a shorter arcing time and consequently to reduced contact burning when closing on symmetrical currents. Fast operation is therefore not only important for opening but also for circuit-breaker closing.

10.2.3 Ratings and Selection

Voltage Rating and Insulation. Circuit breakers are built for voltage ratings as defined in IEEE C37.04[2] and IEEE C37.06[3]. They have to be dimensioned to withstand the maximum voltages as specified. The rated maximum voltage is the upper limit for operation.

For circuit breakers rated in accordance with ANSI C37.06-1987[4] (or earlier), the range between upper and lower limit is defined by voltage range factor *K*. Current-interrupting capabilities vary within this range in inverse proportion to the operating voltage.

For circuit breakers rated in accordance with ANSI C37.06-1997[4] (or later), the current-interrupting capability is a constant kA value at any voltage equal to or lower than the rated maximum voltage.

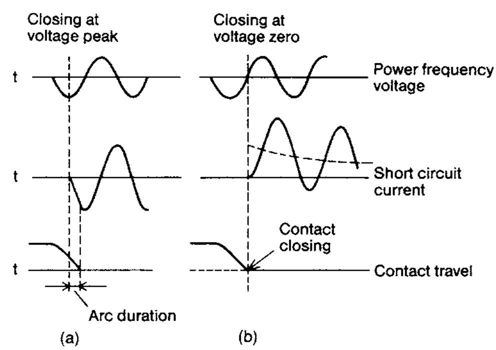

FIGURE 10-69 Stress on contact when closing on a fault, contact travel related to (*a*) symmetric, and (*b*) asymmetrical short-circuit currents.

The insulation level is determined by the rated withstand test voltages specifying the low-frequency voltage (kV, rms) and the impulse voltage (kV, crest). High-voltage breakers must essentially withstand switching surges and both full and chopped-wave lightning impulses. For multiple-break circuit breakers, equal voltage distribution over the series breaks is achieved by grading capacitors paralleled to the interrupting chambers. Coordination between inner and outside insulation, as well as insulation coordination between interrupters and ground insulation, has to be properly designed to prevent flashover inside the breaker or over the open break.

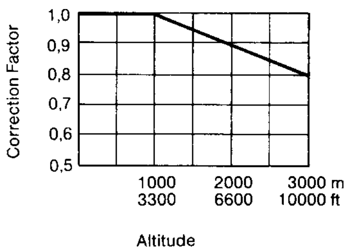

FIGURE 10-70 Altitude-correction factor for voltage ratings.

Outdoor breakers are generally available with special bushings that provide increased creepage distance for installation sites with highly contaminated air. For heavily polluted atmospheres, spray washing of live or deenergized breakers may be an additional measure. Because of the method of design with enclosed ground insulation, the GIS circuit breaker is not influenced by atmospheric pollution.

For installation at altitudes above 3300 ft (1000 m), altitude correction factors have to be applied (Fig. 10-70). The values of rated maximum voltages and insulation levels are multiplied by these factors to obtain the values for the application. The altitude correction factors are as listed in ANSI/IEEE C37.04-1979. Correction factors are under discussion in an IEEE Switchgear committee working group and are expected to change. These factors will be published in IEEE C37.100.1[5].

Particular reference is made to the rating structures and preferred ratings for ac high-voltage circuit breakers per the latest standard revisions of IEEE C37.04[2] and IEEE C37.06[3].

Continuous Current Rating. The *rated continuous current* is the current a circuit breaker has to be able to carry continuously without exceeding a specified temperature rise limit in a specified ambient temperature. Attention must be paid to reduction factors arising from the kind and site of installation, class of insulation material, and electrical endurance requirements.

High-voltage ac breakers must be able to interrupt the rated short-circuit current (kA, symmetrical). They shall be capable of performing the required closing-latching-carrying-interrupting duties in immediate succession. The closing and latching capability (peak kA) is 2.6 times rated short-circuit current (kA, symmetrical) for circuit breakers rated in accordance with ANSI C37.06-1997 (or later). For circuit breakers rated in accordance with ANSI C37.06-1987 (or earlier), the closing and latching capability (rms asymmetrical kA) is 1.6 K times rated short-circuit (kA, symmetrical). The current-carrying capability is determined by the 3-s short time current (kA, rms).

Selection and Application. The proper selection and application of circuit breakers is an extremely important element in the design of an electrical system. Breakers are relied on to separate a defective portion of the system from the remainder to prevent the spread of damage and to permit the good potion to continue in service.

Application conditions and considerations for ac high-voltage circuit breakers are outlined in the latest revision of IEEE C37.010[6], C37.011[7], C37.012[8], and C37.015[9].

Among others, the following criteria have to be considered when selecting a circuit breaker:

System data, such as maximum system voltage, insulation level, short-circuit requirements, and line or cable parameters.

Switching conditions, such as service currents; switching of unloaded transformers, unloaded lines and cables, choke coils, capacitors, generators, and motors; interrupting short-circuit currents and performing special duties like phase opposition, evolving fault, closing on a fault, closing on long lines; duty cycle, reclosing, and operating times.

Service requirements, such as special application for industrial plants, hazardous plants, furnace duty, railway duty, marine duty, maintenance, and operation.

Site of Installation, altitude above 3300 ft, climactic conditions, humidity, wind load, ice, air contamination, space requirements, environmental requirements, earthquake, connection to and function with other switchyard and network components, open installation, or metal-clad switchgear.

10.2.4 Operating Functions

Opening Operation and Duty Cycle. Reaction time and speed of modern breakers has increased to reach standard interrupting times of 2 to 5 cycles, with 2 to 3 cycles being common at high voltage. Interrupting time is measured from energizing of the trip coil until the extinguishing of the arc. The interrupting time during close-open operations may exceed the rated imterrupting time by either $^1/_2$ cycle (for 2 and 3 cycle breakers) or by 1 cycle (for 5 cycle breakers).

The current standard operating duty cycle consists of the following:

$$\text{Open} - T - \text{Close-Open} - 3\ \text{min} - \text{Close-Open}$$

T is defined as either 15 s or 0.3 s depending on whether the circuit breaker is rated for high speed reclosing; this distinction is important in application. Even circuit breakers rated for high speed reclosing must still be allowed a 0.3-s delay to allow for proper recovery of insulation following the initial fault interruption.

For existing oil and air-magnetic circuit breakers, the standard operating duty cycle was: Open − 15s − Close − Open. For additional operations, and/or any close operation in the duty cycle with a time delay of less than 15 s after an opening operation, the interrupting rating and related required capabilities of the oil or air-magnetic breaker have to be derated. All operations within a 15-min period are considered part of the same duty cycle and a duty cycle shall have no more than five opening operations. For guidance on interrupting capability for reclosing service for oil and air-magnetic breakers manufactured after 1960 refer to IEEE C37.010[6]. Circuit breakers manufactured prior to IEEE C37.7-1960[10] have different basis of rating.

Closing Operation. Circuit breakers are designed to perform the closing and reclosing operations as per standard requirements.

When operated to close on long lines, extra-high-voltage circuit breakers require special measures to keep switching overvoltages within specified limits. Such measures may be single or multiple step *closing resistors*, synchronously closing at the moment of voltage zero, or *polarity-controlled-closing*, which means closing during the period of equal polarity at the line and source side of the breaker.

When operated to close on capacitor banks special measures may be taken to limit transient currents and voltages. Such measures may be closing resistors; controlled closing at the moment of voltage zero for grounded wye capacitor banks; or controlled closing on ungrounded wye capacitor banks where the first phase is closed at the moment of voltage zero and the other two phases are closed at a point where the voltage difference between the two phases is zero.

When operated to close on power transformers or shunt reactors special measures may be taken to limit inrush transient currents and transient voltages. Such measures may be single or multiple step closing resistors, or controlled closing at the moment of voltage peak.

The magnitude of overvoltages on energizing and reenergizing is influenced by the nature and variables of the power system. Parameters of supply side and line must be taken into account in order to compute the overvoltages or to determine them using transient network analyzers or transient analysis software, such as electromagnetic transients programs (EMTP), power systems computer aided designs (PSCAD), or alternative transient program. (ATP).

For a summary of the magnitude of overvoltages occurring when energizing high-voltage lines, based on numerous studies and measurements in high-voltage networks, see Table 10-9. Surge arresters may also be used to limit switching overvoltages.

TABLE 10-9 Overvoltages Occurring When Energizing High-Voltage Lines

Prevailing condition	Overvoltage factor (per unit)
1. Line with trapped charge, no compensation, no means of reduction employed	>3
2. Line without trapped charge, no compensation, no closing resistors, or with trapped charge, no closing resistor, but polarity-dependent closing	2.0−2.8
3. Same as no. 2, but with compensation	2.0−2.5
4. Single-stage closing resistors, compensated line	≤ 2.0
5. Two-stage closing resistors, optimum compensation	≤ 1.7
6. Two-stage closing resistors, combined with polarity-dependent closing, or compensation with optimized multistage closing resistors	1.5
