The number of conductors in one conduit or tubing is another important factor. The number of conductors of a certain size that may be installed in a given-sized conduit or EMT is limited to provide for ready installation and withdrawal without injury to conductor or insulating covering. Table 19-3 gives these values for commonly used conductors.

In considering the ampacity of conductors and conduit fill, it is important to note that derating of ampacity applies for increased ambient temperatures and for more than three conductors, excluding neutrals, in a conduit.

Flexible cords and fixture wire in some cases may be as small as No. 18 AWG; hence these are exceptions to the general rule that no conductor smaller than No. 14 should be used in light and power wiring. Owing to the heat generated in the lamp, heat-resistant wiring is required in fixtures.

19.4 TYPES OF CIRCUIT

Services and Feeders. No limit is placed on the electrical capacity of service conductors and service protection employed in bringing the electric supply into a building, since only one supply should be introduced whenever possible. Near the point of entrance of the supply, the heavy-service conductors are tapped by feeders, which conduct the electricity to panelboards at various load centers in the building, where the final branch circuits which supply individual lighting, heating, and power outlets originate (see Fig. 19-10). No limits are placed on the electrical capacity of feeders, but for practical purposes they are limited in size by the difficulty of handling large conductors and raceways in restricted building spaces, by voltage drop, and by economic considerations.

Each lighting fixture, motor, heating device, or other item of utilization equipment must be supplied by one of the types of branch circuit.

Branch Circuits for Grouped Loads. The uses and limitations of the common types of branch circuit are outlined in Table 19-7. It will be noted that lighting branch circuits may carry loads as high as 50 A, although fluorescent lighting is limited to use on circuits of 15- or 20-A rating. Such circuits are extensively employed in commercial and industrial occupancies. Branch circuits supplying convenience outlets for general use in other than manufacturing areas are usually limited to a maximum of 20 A, as the type of outlet required for heavier-capacity circuits usually will not accommodate the connection plug found on portable cords or lamps, motor-driven office machinery, etc.

Individual Branch Circuits. Any individual piece of equipment (except motors) may also be connected to a branch circuit meeting the following requirements: conductors must be large enough for the individual load supplied. Overcurrent protection must not exceed the capacity of the conductors or 150% of the rating of the individual load, if the single load device is a non-motor-operated appliance rated at 13.3 A or more. Only a single outlet or piece of equipment may be supplied.

Motor Branch Circuits. Owing to the peculiar conditions obtained during the starting period of a motor, and because it may be subjected to severe overloads at frequent intervals, motors, except for very small sizes, are connected to branch circuits of a somewhat different design from that previously discussed.

19.5 OVERCURRENT PROTECTION

Molded-Case Circuit Breakers. A circuit breaker is defined by the NEC as "a device designed to open and close a circuit by nonautomatic means and to open the circuit automatically on a predetermined overcurrent without damage to itself when properly applied within its ratings." In addition, the purpose of a circuit breaker (Fig. 19-11), as stated in the NEC, is to open the circuit if the current reaches a value that will cause an excessive or dangerous temperature in a conductor or its insulation.

FIGURE 19-11 Typical molded-case circuit breakers.

Underwriters' Laboratories (UL) Standard UL489, *Molded Case Circuit Breakers and Circuit Breaker Enclosures*, further specifies test and construction requirements for molded-case circuit breakers specifically intended to provide service entrance and feeder and branch circuit protection in accordance with the NEC. These UL requirements cover molded-case circuit breakers rated through 600 V. Underwriter's Laboratories specifies the applicable standards to which the circuit breaker is designed, whereas the NEC discusses proper applications of circuit breakers.

Ratings. The ratings which apply to circuit breakers and their actual assigned numerical values reflect mechanical, electrical, and thermal capabilities of those circuit breakers that comply with industry standards published by the National Electrical Manufacturers Association and UL. These ratings, which appear on the breaker, include the following:

1. *Voltage*. Circuit breakers are designed and marked with the maximum voltage at which they can be applied. They can be used on any system where the voltage is lower than this breaker rating. This includes both ac and dc voltage systems.
2. *Frequency*. Circuit breakers are normally suitable for use on 50- and 60-Hz electrical distribution systems. Rerating of the circuit breaker may be required at other frequencies.
3. *Continuous current*. Standard molded-case circuit breakers are calibrated to carry 100% of their rated current in free air at 40°C ambient. In accordance with the NEC, when installed in their enclosures, these breakers should not be continuously loaded over 80% of their current rating. However, there are certain molded-case circuit breakers specifically approved for 100% continuous rating available, and these are so marked.
4. *Current interrupting*. The current-interrupting rating is expressed in rms symmetrical amperes. It may vary with the applied voltage and is the maximum current the breaker can be expected to safely interrupt. These current-interrupting ratings may vary from 1500 through 200,000 A, depending upon applied voltage. Underwriter's Laboratory requires all circuit breakers to be so marked with their proper ratings.

Thermal-Magnetic Circuit Breakers. Thermal-magnetic circuit breakers provide two forms of overcurrent protection. The first is overload protection, which is achieved by a bimetal providing an inverse time-current response. The second is overcurrent protection, which is achieved magnetically.

WIRING DESIGN FOR COMMERCIAL AND INDUSTRIAL BUILDINGS **19-37**

Overload tripping is obtained through deflection of the bimetal, which is heated by the load current. During an overload condition, the bimetal deflects, causing the breaker to trip or open mechanically. The larger the overload, the faster the tripping of the circuit breaker; the smaller the overload, the longer it takes the circuit breaker to trip. This is commonly called an *inverse-time principle*.

Overcurrent (short circuit) protection is obtained through electromagnetic tripping action without any intentional time delay. An overcurrent condition must be interrupted rapidly (usually less than 20 ms) in order to protect downstream equipment. During overcurrent conditions, an armature is moved by electromagnetic force and initiates tripping action.

All circuit breakers are rated for continuous current. This continuous-current rating is dependent upon the maximum current the load is expected to draw for 3 h or more continuously. Ratings may be fixed or adjustable, depending on the circuit breaker. Some constructions may require replacing all or part of the trip unit to change the continuous current rating. Overcurrent trip characteristics are a function, multiple, or percentage of the continuous-current rating.

FIGURE 19-12 Current-limiting circuit breaker.

Current-Limiting Circuit Breakers. The NEC defines a current-limiting overcurrent protective device as "a device which, when interrupting current in its current limiting range, will reduce the current flow in the faulted circuit to a magnitude substantially less than that obtainable in the same circuit if the device were replaced with a solid conductor having comparable impedance."

Additionally, UL has the following current-limiting circuit-breaker definition: "a circuit breaker that does not employ a fusible element and that when operating within its current-limiting range, limits the let-through I^2 to a value less than the I^2 of a 1/2 cycle wave of the symmetrical prospective current."

Current-limiting circuit breakers (Fig. 19-12) not only provide high interrupting capability but also limit let-through current and energy to downstream devices. I^2t is an expression related to the energy resulting from current flow. Specific manufacturer's literature should be consulted for information on the current-limiting and energy-limiting characteristics of their particular circuit breakers.

Current-limiting circuit breakers provide the system designer with a means of reducing fault current and energy levels at downstream system components while still retaining the advantages, such as common trip and reusability, of circuit breaker protection. Current-limiting breakers can be reset and service restored in the same manner as conventional thermal-magnetic circuit breakers. There is nothing to replace even after clearing maximum fault currents. Figure 19-13 illustrates the current waveform resulting from current-limiting operation. At current levels below the threshold of current limitation, conventional non-current-limiting operation is the same as described for thermal-magnetic circuit breakers.

Solid-State Trip Circuit Breakers. Solid-state trip circuit breakers utilize solid-state electronic components to measure and time the output from current transformers. The solid-state circuitry then initiates tripping action based on predetermined settings. These components are housed in the trip unit section of the breaker.

The basic function of the trip unit is to provide long-time current-time delay and instantaneous current response characteristics necessary for proper circuit protection. Combinations of these characteristics provide time delay to override transient overload, delayed tripping for sustained overloads, and instantaneous tripping for high-level short circuits.

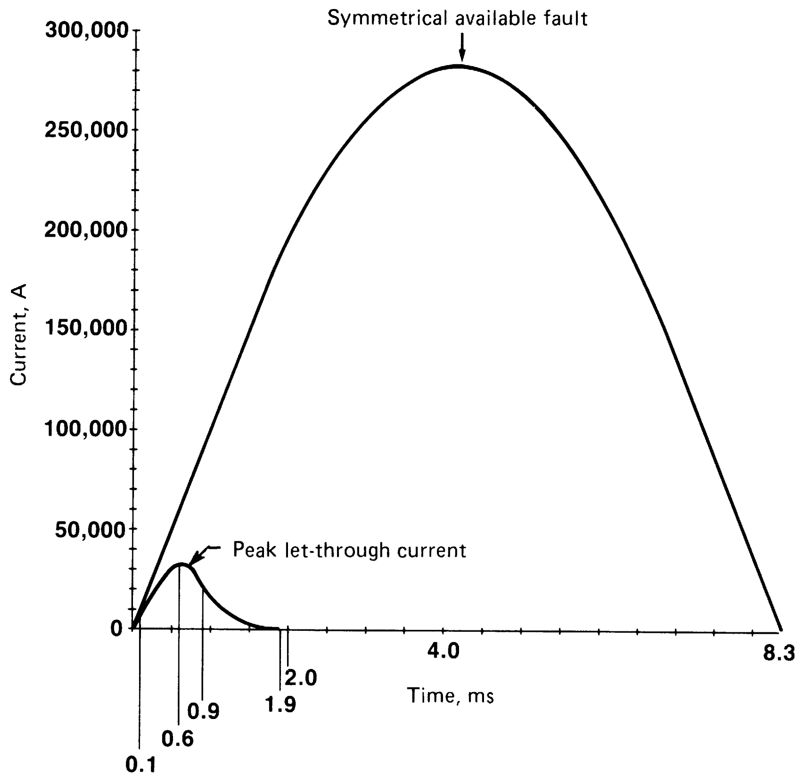

FIGURE 19-13 Time-current curve for a current-limiting breaker.

Solid-state trip units may also be equipped with short-time pickup and delay functions. These characteristics are useful for providing coordination with downstream or upstream circuit breakers and/or fuses. The resulting combination of long- and short-time delay characteristics provide delayed tripping for all levels of overcurrent below the instantaneous response. This provides time for downstream breakers to operate and clear the fault.

Solid-state trip units may also provide time-current characteristics for equipment ground fault protection in accordance with the NEC Sec. 230-95 requirements. The maximum current setting is 1200 A per NEC requirements, and time-delay settings are usually adjustable to permit coordination with other protective devices.

Time-Current Characteristic Curves. Circuit breaker time-current characteristic curves are a function of the type of trip function and its associated settings. A typical time-current characteristic curve is shown in Fig. 19-14 for a 400-A frame thermal-magnetic molded-case circuit breaker.

This particular curve applies for the continuous-current rating of 400 A and indicates total operational time from fault current initiation to clearing. This is a typical characteristic curve for a molded-case circuit breaker where overload sensing is achieved through a thermal element (a bimetal) and where instantaneous tripping is achieved magnetically.

In circuit-breaker frame sizes larger than 100 A, instantaneous operation is adjustable within approximately 5 to 10 times the continuous ampere rating.

Molded-case circuit breakers with more complex time-current characteristics are usually equipped with solid-state trip units. The continuous current rating may be adjustable using the long-time pickup function. In addition, long-time delay and short-time pickup and delay functions may be adjustable. The instantaneous response may also be adjustable.

Circuit breakers with solid-state trip units may also include integral equipment ground fault protection with current pickup and time-delay adjustments. Figure 19-15 illustrates a combined time-current characteristic curve for a solid-state electronic trip circuit breaker with all of these adjustments.

Further refinement of the solid-state trip unit short-time delay characteristics for overcurrent protection or the ground fault time-delay characteristics may be obtained by making part of the response curve a function of the product of time and the square of current (I^2t) illustrated by the sloping portions in Fig. 19-16. This sloping response curve often more readily coordinates with upstream or downstream thermal-magnetic circuit breakers and/or fuses.

It should be noted that solid-state trip units are available with varying degrees of complexity, and not all functions are provided for most applications. The specific manufacturer's literature should be consulted for guidance on individual units.

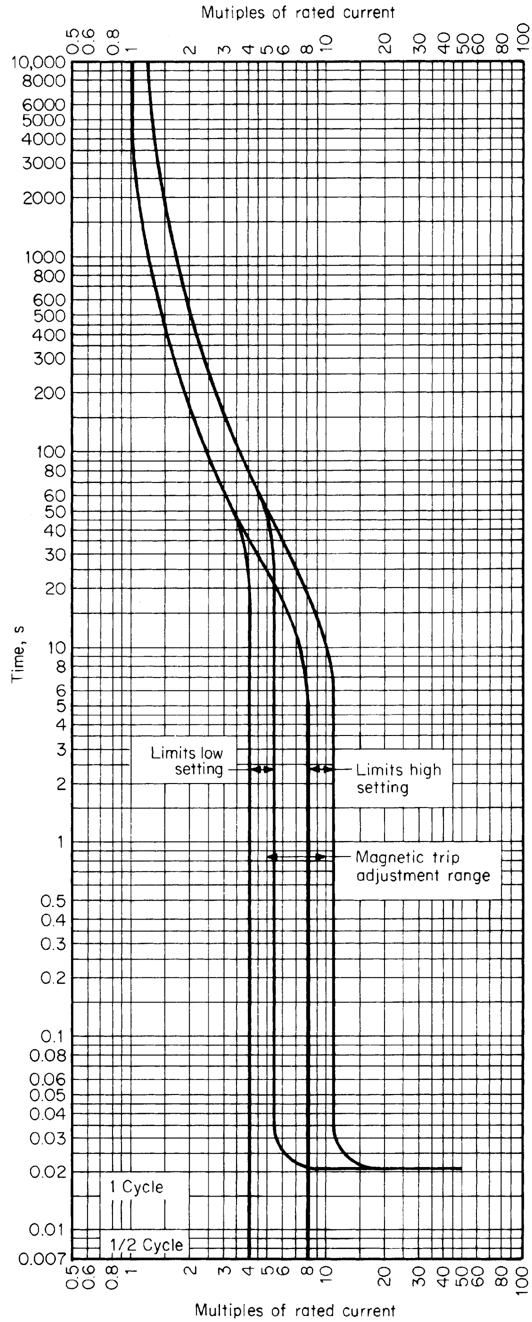

FIGURE 19-14 Characteristic tripping curve for molded-case breaker.

Series-Connected Ratings. *Series connection* of molded-case circuit breakers is a viable protection scheme, provided testing has verified performance. Underwriter's Laboratory presently recognizes series-connected short-circuit ratings and specifies test procedures to verify performance. Series-connected ratings must be based on tests and are only valid for specific circuit breaker types listed in the UL test reports. Individual manufacturer's series-connected ratings may be found in the *UL Recognized Component Directory*. Fuse-breaker coordinated combinations are also tested by UL and are applicable within their established guidelines.

Coordination. When protection is being considered, the performance of a circuit breaker with respect to the connected

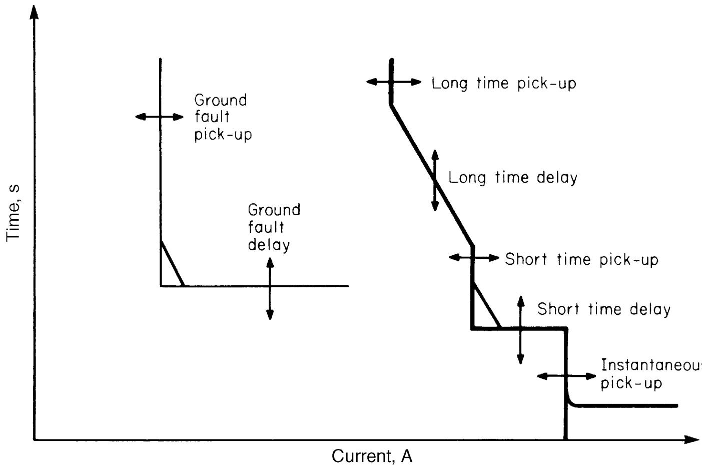

FIGURE 19-15 Time-current curve for solid-state electronic breaker.

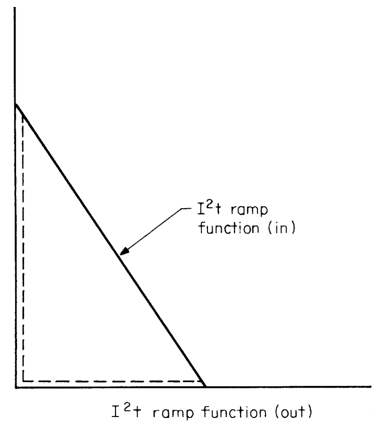

FIGURE 19-16 Sloping response curve for coordinating with thermal magnetic breakers or fuses.

conductors and load is a primary concern. Consideration is also given to the performance of circuit breakers with respect to other upstream and downstream circuit breakers and other protective devices. The object in coordinating protective devices is to make them selective in their operation with respect to each other. In doing so, the effects of short circuits on systems are reduced to a minimum by disconnecting only the affected parts of a system. Stated in another way, only the circuit breaker nearest the short circuit should open, leaving the rest of the system intact and able to supply power to the unaffected areas.

19.6 LOW-VOLTAGE BUSWAY

Low-Voltage Busways. Low-voltage busway (Fig. 19-17) provides a convenient, economical means of power distribution for a wide range of industrial and commercial buildings.

Description. Low-voltage (600 V and below) busways consist of a factory prefabricated housing which encloses current-carrying busbars. The housing protects the busbars from physical harm and provides mechanical support. Busbars, which are normally electroplated and insulated, may be either aluminum or copper.

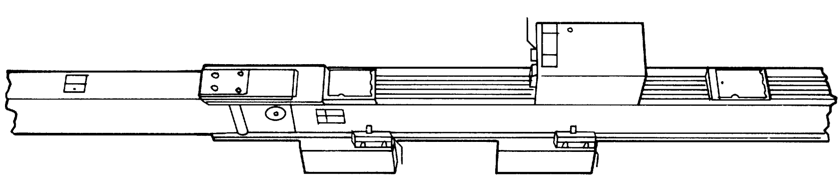

FIGURE 19-17 Low-voltage busway.

Types. Busway uses encompass a wide range of applications. For this reason, various types of busways have evolved. For medium- and high-current applications (100 to 5000 A), low-impedance *feeder* busway and *plug-in* busway are available. These types of busway are utilized to supply and/or distribute large blocks of power within a factory or office building. *Lighting* bus and *trolley* duct normally supply power to small lighting loads or moving loads such as hand tools on an assembly line. This type bus is rated 30 to 100 A.

Feeder busway is designed to provide maximum efficiency of power transfer from one point to another. If multiple-power tap-off points are required, then a plug-in busway is utilized. Plug-in busway is similar to a feeder busway except that plug-in openings are located at convenient intervals along the entire length. Various types of fusible or circuit breaker plug-in units may be easily attached at these openings to supply power to individual loads. Lighting contactors, motor starters, and other specialized devices are also available in plug-in unit form.

Applications. Busway uses are many and varied. However, they may be grouped into four major categories: (1) the main service busway, (2) the long feeder busway run, (3) the plug-in busway distribution, and (4) the electrical riser for tall buildings.

The *main service busway* is usually a fairly short run of high-ampere feeder busway which brings electricity from the power company supply point into the main switchboard in a building.

Long feeder busway runs are designed to carry large blocks of electrical power from one point to another with maximum efficiency. A typical example of this type of application would be a busway used to bring power from the main service switchboard to a remote distribution switchboard.

Plug-in busway distribution is the normal method for power distribution in most modern manufacturing areas today. The plug-in busway is positioned throughout the manufacturing area, and loads are connected to the busway using fusible or circuit breaker plug-in units. This wiring method is flexible and allows for the addition or movement of loads simply by relocating the plug-in units which attach to the busway.

Finally, *electrical busway risers* are used to form the backbone of the power distribution system in tall metropolitan buildings. The busway is positioned vertically within the building and tap-offs are used on each floor to provide the necessary power requirements. As load requirements increase in the future, the busway riser can be preplanned to allow for additional tap-offs, thus continuing to grow with the building.

Ratings. Low-voltage busway is available for applications up to 600 V ac and may be supplied for use on 3-phase, 3- or 4-wire systems. A wide range of feeder or plug-in busway ampere ratings may be selected (see Table 19-8). These ratings are based on actual heat rise within the busway. Current standards limit the maximum "hot-spot" temperature within the busway housing to 55°C above ambient.

Ground Bus. A busway with a separate, low-impedance ground conductor is also available to provide for (1) a low-level static ground path, and (2) a secure low-impedance ground return path for medium- and high-level ground faults. This ground conductor is generally bonded to the busway housing at intervals of 10 ft or less. It is designed to carry a continuous 50% ground fault current as well as high-level ground fault currents of a short duration.

Conductors. A busway can be supplied with either aluminum or copper conductors. Based on size considerations only, copper is a more efficient electrical conductor than aluminum. However, when actual cost is considered, aluminum conductors are favored even though they must be slightly larger than the copper conductor required for the same ampere rating. Both aluminum and copper

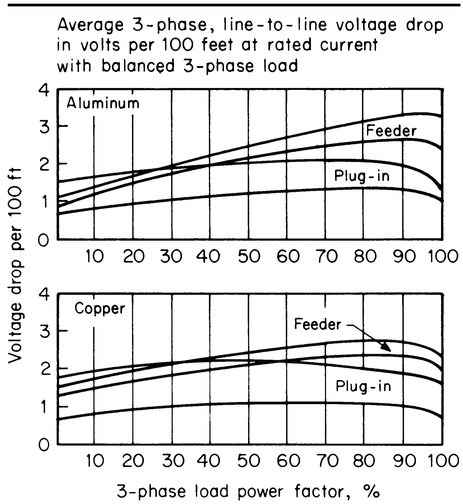
conductors are electroplated using tin or silver to ensure good surface conductivity at all electrical joints and plug-in unit connection points.

Available Fault Current Levels. In order to ensure that a busway can safely withstand the extreme physical forces, which can occur during a high-level fault, tests are conducted and maximum short-circuit levels are assigned to all busway components. The industry-recommended minimum short-circuit ratings for feeder and plug-in busway are shown in Table 19-9. In some instances optional higher short-circuit levels are available using alternate construction methods.

The actual available fault current throughout the entire electrical distribution system should be determined to ensure that all system components will function safely if a fault should occur.

Voltage Drop. Excessively low-voltage or wide-voltage variations on an electrical system can create many operating problems for the user. Modern low-impedance busway is designed to introduce an absolute minimum amount of voltage drop into the electrical system, thus helping to provide a stable source of electrical power. Typical feeder and plug-in busway voltage drop curves are shown in Table 19-10. Individual busway manufacturers can provide exact voltage drop curves for the specific busway ratings and types involved in each individual application.

TABLE 19-10 Typical Feeder and Plug-in Busway Voltage Drop Curves



Installation. A low-voltage busway system is made up of individual, factory-prefabricated components such as 10-ft straight lengths, elbows, tees, flanged ends, and cable tap boxes. These individual components are designed so they can be quickly joined together at the job site with a minimum of field labor. Typically, one grade-5 bolt and two large-diameter Belleville washers are utilized to connect all the bars in an entire bus stack (see Fig. 19-18). In some cases, special joint bolts are supplied with heads that pop off when torqued to the proper level, resulting in a tight connection. Larger ampere ratings may utilize two or three busbar stacks, which may require slight additional assembly time.

Prefabricated busway components reduce actual installation time to a minimum and result in a very low *installed cost* for the low-voltage busway. (The installed cost is the total material and labor cost necessary to provide a completed busway installation.)

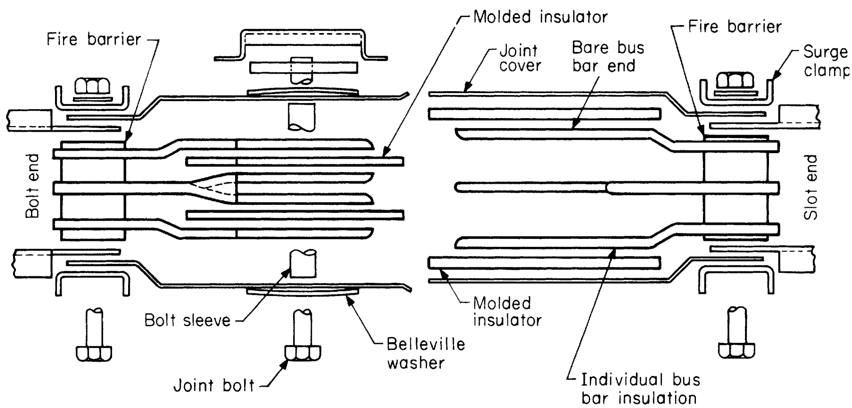


FIGURE 19-18 Busway one-bolt joint.

19.7 PROTECTIVE GROUNDING

Purpose of Grounding. Secondary ac distribution systems should be grounded at the neutral conductor if the maximum voltage to ground does not exceed 150 V and may be grounded if this voltage is above 150 but does not exceed 300 V (Fig. 19-19). This is to guard against imposition of a dangerous high voltage in case a breakdown in the transformer or crossing of primary- and secondary-circuit wires occurs.

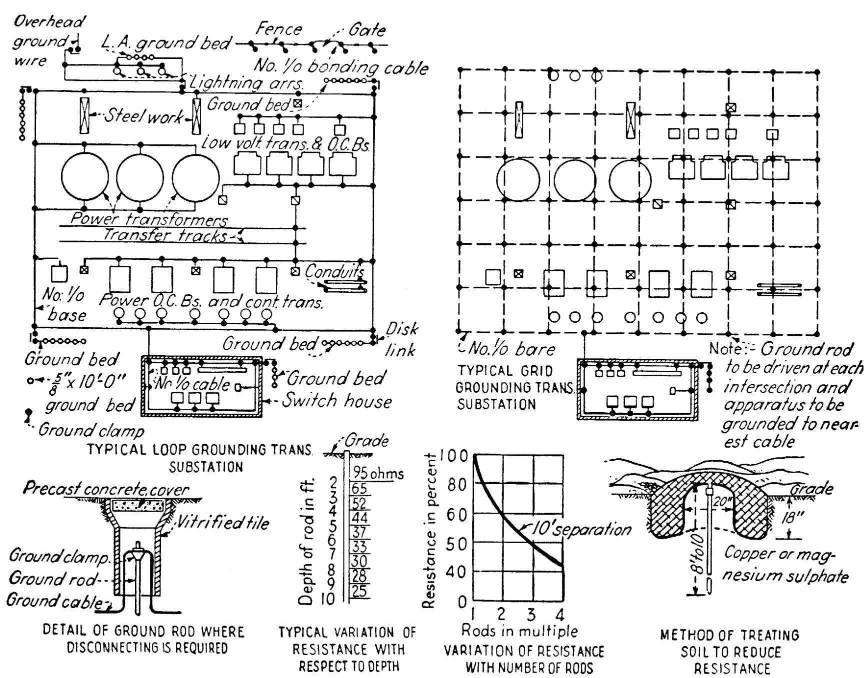

FIGURE 19-19 Complex equipment-grounding details showing connection, wire sizes, and grounds.

Conduits, metal raceways, cable armors, and metal cases or frames of equipment must be grounded (or isolated, as an alternative) and bonded so that, if this metal enclosure should come into contact with any of the circuit wires within it, no dangerous current would be passed to a person who touched the enclosure, since it is kept at ground potential.

The path to ground must be sufficiently low in resistance to allow enough current to flow to quickly open an overcurrent protective device and clear the fault. Otherwise, a voltage buildup will occur on metallic parts, with consequent hazards.

Size and Location of Ground Connection. The service neutral should be grounded at the point of entrance ahead of any disconnecting equipment with a copper wire or bus not smaller than indicated in Table 19-11. The neutral cannot be grounded at points beyond the load side of the disconnecting means (see NEC Article 250.24(A)(5)).

Metallic enclosures are commonly grounded through the grounding conductor used for the service neutral, although conduit or electrical metallic tubing may be used.

The grounding connection should be made to a grounding electrode such as (1) a metal underground water pipe, (2) a metal frame of a building, (3) concrete encased electrode, (4) a ground ring,

Notes:

1. Where multiple sets of service-entrance conductors are used as permitted in NEC 230.40, exception no. 2, the equivalent size of the largest service-entrance conductor shall be determined by the largest sum of the areas of the corresponding conductors of each set.

2. Where there are no service-entrance conductors, the grounding electrode conductor size shall be determined by the equivalent size of the largest service-entrance conductor required for the load to be served.

*This table also applies to the derived conductors of separately derived ac systems.

†See installation restrictions in NEC 250.64(A).

(5) rod or pipe electrode or, (6) a plate electrode. See NEC Article 250.52. Where each type of electrode is present, they must be bonded together. See NEC Article 250.50. Resistance of a continuous underground water-piping system will usually be less than 0.1 Ω, thereby ensuring effectiveness.

Polarization of Wiring. The conductor to be grounded must be continuously identified throughout the system to avoid errors in connections. For No. 6 AWG or smaller, this is accomplished by finishing the insulating covering with a white or natural-gray finish. Ends of conductors larger than No. 6 AWG are painted white or gray or wrapped with white tape, where exposed in outlets or panelboards.

19.8 SYSTEMS OF INTERIOR DISTRIBUTION

Standard Secondary-Voltage Types. Common interior distribution systems for buildings or plants having appreciable loads are

1. 3-Phase 4-wire 120/208-V serving power and lighting.
2. Single-phase 3-wire 115/230-V serving lighting with 3-phase 3-wire 240- or 480-V for power.
3. 3-Phase 4-wire 277/480-V serving power and fluorescent or mercury lighting with single-phase 115/230-V circuits for other utilization provided from the power system by means of local dry-type transformers.

For very large buildings and industrial plants, distribution is often provided at higher voltage, notably 13.2, 4.1, or 2.3 kV, stepped down to utilization voltage at strategically load-centered substations.

3-Wire Single-Phase Systems. The 3-wire 115/230-V single-phase system (Fig. 19-20) is very commonly used for interior wiring for lighting and miscellaneous purposes but not for motor loads much in excess of 5 hp. The neutral wire is grounded; hence it should not be fused at any point. The branch circuits may be 2-wire 115- or 230-V or 3-wire 115/230-V. The neutral conductor carries only the unbalance in load between the two ungrounded conductors. For circuits up to 200 A, it should have the same capacity as the ungrounded conductors. A factor of 0.7 may be applied to unbalanced loads above 200 A in determining its size.

3-Phase 3-Wire Systems. These are usually employed where motors form a substantial load and where lighting is supplied from a separate single-phase system or by transformer. The usual voltage is 240 or 480 V. Branch circuits may be either 2-wire single-phase or 3-wire 3-phase.

3-Phase 4-Wire Systems. The 3-phase 4-wire system (Fig. 19-21) is widely used. Branch lighting circuits are connected between any one of the phase wires and the neutral wire. Power is taken from the 3-phase wires. The neutral wire is grounded. The voltage between phase wires is usually 208 V, and between any phase wire and neutral it is 120 V.

Circuits that may be supplied include 2-wire 120- or 208-V; 3-wire 120/208- or 208-V; and 4-wire 120/208-V. In the case of a 3-wire circuit consisting of 2-phase wires and the neutral, the "neutral" differs from that of a 3-wire single-phase circuit in that with both sides of the circuit evenly loaded it will carry equal current in the phase wires.

2-Wire Systems. The 2-wire system is used where current is supplied at 115 V, as when obtained from a 115-V generator, and on installations connected to utility companies' lines when the installation is of small capacity. It is limited in capacity; requires excessively large copper for heavy loads; and, in general, is not considered a modern complete distribution method.

2- and 3-Wire DC Systems. These systems are similar in connections (except grounding on the premises) and use to the 2- and 3-wire single-phase ac systems.

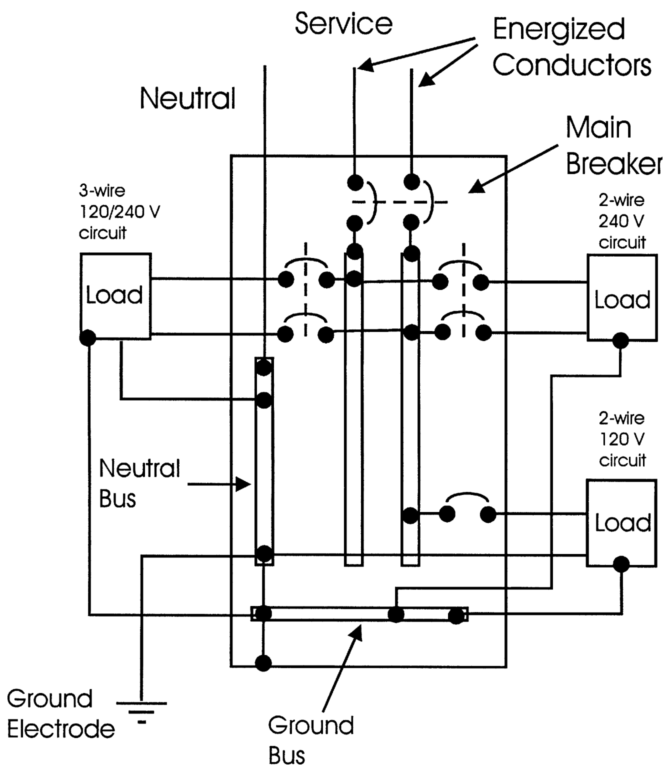

FIGURE 19-20 A 3-wire, 115/230-V, single-phase system.

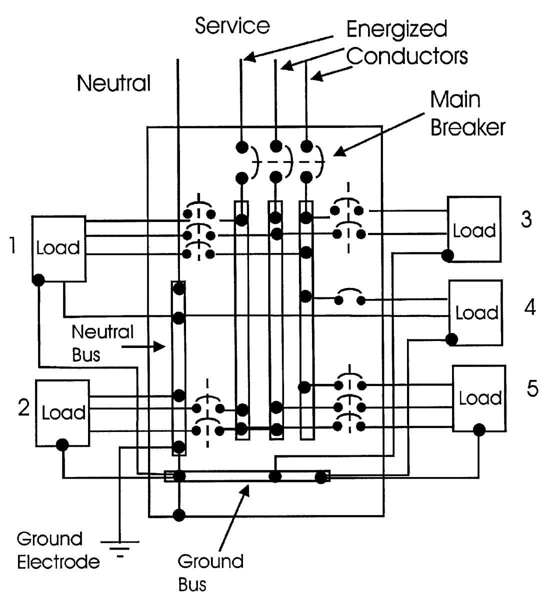

FIGURE 19-21 A 3-phase, 4-wire system: (1) 4-wire 120/208-V circuit; (2) 3-wire 120/208-V circuit; (3) 2-wire 208-V circuit; (4) 2-wire 120-V circuit; (5) 3-wire 208-V circuit.

2-Phase Distribution. This may be effected with 4 or 3 wires. In the former case, there is a pair of wires for each phase, while in the latter there is 1 wire for each phase and a common wire for both phases. The circuits must be balanced on either side, just as in the case of a 3-wire single-phase system. Where 3 wires are used, the common wire should be 1.4 times as large as either of the other two, since it must carry 1.4 times as much current. Motors are connected to both phases and employ all 3 or all 4 wires, as the case may be. With 4 wires, the lamps are connected to each phase as though the supply were single-phase, and care should be exercised to balance the phases as nearly as possible.

20.1 GENERAL

Types of Electric Motors. Electric motors provide motive power to a wide variety of domestic and industrial machinery. Their versatility, reliability, and economy cannot be equaled by any other form of drive. Successful motor application depends on selecting a type of motor which satisfies the kinetic starting, running, and stopping requirements of the driven machinery. There are several methods of classifying electric motors. First, based on the electric power supply, motors are classified as dc and ac motors. Figure 20-1 shows further classification of ac and dc motors based upon the stator and rotor construction.

Classifications based upon size and applications are micro, fractional-horsepower, integral-horsepower, gear, torque, servo, and stepper motors in both standard and premium efficiency designs. Various types of enclosures have been standardized by the National Electric Manufacturers Association, U.S.A. (NEMA). The following are the standard enclosure types and their characteristics:

Types	Characteristics
Open:	
Dripproof	Operate with dripping liquids up to 15°C from vertical
Splashproof	Operate with splashing liquids up to 100°C from vertical
Guarded	Guarded by limited size openings (less than ¾ in)
Semiguarded	Only top half of motor guarded
Dripproof fully guarded	Dripproof motor with limited-size openings
Externally ventilated	Ventilated with separate motor-driven blower; can have other types of protection
Pipe ventilated	Openings accept inlet ducts or pipe for air cooling
Weather-protected type 1	Ventilating passages minimize entrance of rain, snow, and airborne particles; passages are less than ¾ in. in diameter
Weather-protected type 2	Motors have, in addition to type 1, passages to discharge high-velocity particles blown into the motor
Totally enclosed:	
Nonventilated (TENV)	Not equipped for external cooling
Fan-cooled (TEFC)	Cooled by external integral fan
Explosionproof	Withstands internal gas explosion; prevents ignition of external gas
Dust-ignitionproof	Excludes ignitable amounts of dust and amounts of dust that would degrade performance
Waterproof	Excludes leakage except around shaft
Pipe-ventilated	Openings accept inlet ducts or pipe for air cooling
Water-cooled	Cooled by circulating water
Water-and-air-cooled	Cooled by water-cooled air
Air-to-air-cooled	Cooled by air-cooled air
Guarded TEFC	Fan-cooled and guarded by limited-size openings
Encapsulated	Has resin-filled windings for severe operating conditions

NEMA classification according to the variability of speed includes constant-speed motors such as ac synchronous motors; induction motors with low, medium, or high slip; dc short-wound motors; varying-speed motors such as dc series motors or repulsion motors; and variable-speed motors such as dc shunt-, series-, and compound-wound motors.

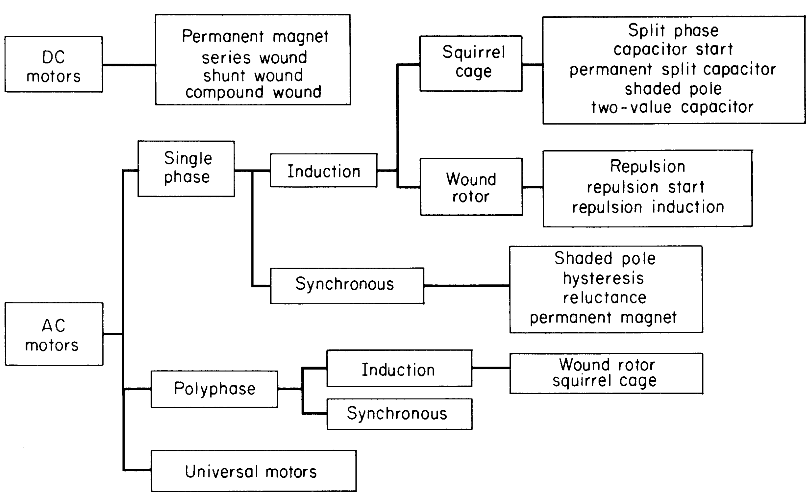

FIGURE 20-1 Classification of ac and dc motors.

Standards. Motors and generators are required to meet various industry and national standards and in some instances specific local codes and customer specifications. The more important of these standards may be briefly described as follows:

1. *NEMA Standards* are voluntary standards of the National Electrical Manufacturers Association and represent general practice in the industry. They define a product, process, or procedure with reference to nomenclature composition, construction, dimensions, tolerances, operating characteristics, performance, quality, rating, and testing. Specifically, they cover such matters as frame sizes, torque classifications, and basis of rating.
2. *IEEE Standards (AIEE)* concern fundamentals such as basic standards for temperature rise, rating methods, classification of insulating materials, and test codes.
3. *USA Standards* are national standards established by the United States of America Standards Institute, which represents manufacturers, distributors, consumers, and others concerned. USA Standards may be sponsored by any responsible body and may become national standards only if a consensus of those having substantial interest is reached. Standards may cover a wide variety of subjects such as dimensions, specifications of materials, methods of test, performance, and definition of terms. USA Standards frequently are those previously adopted by and sponsored by NEMA, IEEE, etc. The chief motor and generator standard of USASI is C50, "Rotating Machinery," which is substantially in agreement with current NEMA Standards.
4. *National Electrical Code* is a USA Standard sponsored by the National Fire Protection Association for the purpose of safeguarding persons and buildings from electrical hazards arising from the use of electricity for light, heat, power, and other purposes. It covers wiring methods and materials, protection of branch circuits, motors and control, grounding, and recommendations, regarding suitable equipment for each classification.
5. *Underwriters' Laboratories, Inc.* is an independent testing organization, which examines and tests devices, systems, and materials with particular reference to life, fire, and casualty hazards. It develops standards for motor and control for hazardous locations through cooperation with manufacturers. It has several different services by which a manufacturer can indicate compliance with Underwriters' Laboratories Standards. Such services are utilized on motors only in the case of explosionproof and dust-ignitionproof motors where label service is used to indicate to code-enforcing authorities that motors have been inspected to determine their adherence to Underwriters' Laboratories Standards for motors for hazardous locations.
6. *Federal Specification CC-M-641* for integral-horsepower ac motors has been issued by the federal government to cover standard motors for general government uses. Standard motors meet these specifications, but other Federal Specifications issued by various branches of the government for specific use may require special designs.
7. *World Standards*. Standards similar to our NEMA Standards have been established in other countries. The most significant are

   a. IEC (International Electrochemical Commission) Standard 72-1, Part 1

   b. German Standard DIN 42673

   c. British Standard BSI-2960, Part 2

   These standards specify dimensions, classes of insulation, and in some cases horsepower ratings.

20.2 DIRECT-CURRENT MOTORS

Classes of DC Motors. Direct-current motors are used in a wide variety of industrial applications because of the ease with which the speed can be controlled. The speed-torque characteristic may be varied to almost any useful form. Continuous operation over a speed range of 8:1 is possible. While ac motors tend to stall, dc motors can deliver over 5 times the rated torque (power supply permitting).

Reversal is possible without power switching. Permanent-magnet motors are available in fractional-horsepower ratings, while wound-field dc motors are classified as (1) shunt motor, in which the field winding is connected in parallel with the armature; (2) series motor, in which the field winding is connected in series with the armature; and (3) compound motor, which has a series-field and shunt-field winding. The shunt motor is used in constant-speed applications such as drives for dc generators in dc motor-generator sets. The series motor is used in applications where a high starting torque is required, such as in electric traction, cranes, and hoists. In compound motors, the droop of the speed-torque characteristic may be adjusted to suit the load.

The construction of dc motors with a wound field is practically identical to that of dc generators; with minor adjustment, the same dc machine may be operated either as a dc generator or as a motor. (See Sec. 8 of this handbook for construction, armature windings, commutator, etc.)

Permanent-magnet dc motors have fields supplied by permanent magnets that create two or more poles in the armature by passing magnetic flux through it. The magnetic flux causes the current-carrying armature conductors to create a torque. This flux remains basically constant at all motor speeds—the speed-torque and current-torque curves are linear.

Shunt Motors. DC shunt motors are suitable for application where constant speed is needed at any control setting or where appreciable speed range (by field control) is needed. The field circuit connection is shown in Fig. 20-2*a*.

Since a motor armature revolves in a magnetic field, an emf is generated in the conductors which is opposed to the direction of the current and is called the counter emf. The applied emf must be large enough to overcome the counter emf and also to send the armature current I_a through R_m, the resistance of the armature winding, the brushes; or

$$E_a = E_b + I_a R_m \qquad \text{volts} \tag{20-1}$$

where E_a = applied emf and E_b = counter emf. Since the counter emf at zero speed, that is, at starting, is identically zero and since normally the armature resistance is small, it is obvious in view of Eq. (20-1) that, unless measures are taken to reduce the applied voltage, excessive current will circulate in the motor during starting. Normally, starting devices consisting of variable series resistors are used to limit the starting current of motors.

The torque of a motor is proportional to the number of conductors on the armature, the current per conductor, and the total flux in the machine. The formula for torque is

$$\text{Torque} = 0.1175 Z\phi I_a \frac{\text{poles}}{\text{paths}} \times 10^{-8}\ \text{lb}\cdot\text{ft} \tag{20-2}$$

where Z = total number of armature conductors, ϕ = total flux per pole, and I_a = armature current taken from the line.

$$E_b = E_a - I_a R_m = Z\phi \frac{\text{r/min}}{60} \frac{\text{poles}}{\text{paths}} \times 10^{-8} \qquad \text{volts} \tag{20-3}$$

or

$$\text{r/min} = 60 \frac{E_a - I_a R_m}{Z\phi} \frac{\text{paths}}{\text{poles}} \times 10^{8} \tag{20-4}$$

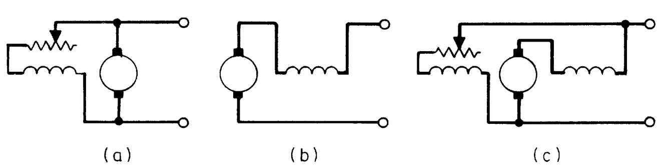

FIGURE 20-2 Field circuit connections of dc motor.

For a given motor, the number of armature conductors Z, the number of poles, and the number of armature paths are constant. The torque can therefore be expressed as

$$\text{Torque} = \text{constant} \times \phi I_a \qquad (20\text{-}5)$$

and the speed, likewise, is expressed as

$$\text{Speed} = \text{constant} \times (E_a - I_a R_m)/\phi \qquad (20\text{-}6)$$

In the case of the shunt motor, E_a, R_m, and ϕ are constant, and the speed and torque curves are shown as curves 1 (Fig. 20-3); the effective torque is less than that generated by the torque required for the windage and the bearing and brush friction. The drop in speed from no load to full load seldom exceeds 5%; indeed, since ϕ, the flux per pole, decreases with increase of load, owing to armature reaction, the speed may remain approximately constant up to full load.

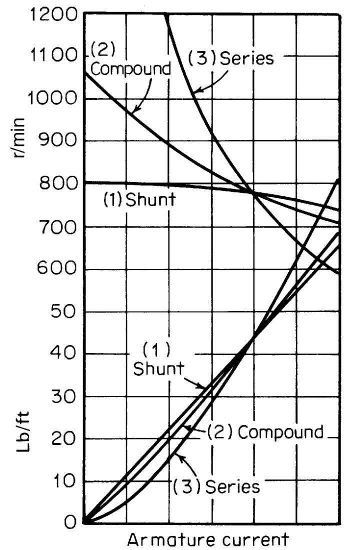

FIGURE 20-3 Motor characteristics.

Speed and Torque of Series Motors. Equations (20-6) and (20-5) apply to motors of all continuous-current types. In the case of series motors, the flux ϕ increases with the armature current I_a; the torque would be proportional to I_a^2 were it not that the magnetic circuit becomes saturated with increase of current. Since ϕ increases with load, the speed drops as the load increases. The speed and torque characteristics are shown in curves 3 (Fig. 20-3).

If the load on a series motor becomes small, the speed becomes very high, so that a series motor should always be geared or direct-connected to the load. If it were belted and the belt were to break, the motor would run away and would probably burst.

For a given load, and therefore for a given current, the speed of a series motor can be increased by shunting the series winding or by short-circuiting some of the series turns so as to reduce the flux. The speed can be decreased by inserting resistance in series with the armature.

Compound Motors. Compound-motor connections are shown in Fig. 20-2*c. The compound motor* is a compromise between the shunt and the series motors. Because of the series winding, which assists the shunt winding, the flux per pole increases with the load, so that the torque increases more rapidly and the speed decreases more rapidly than if the series winding were not connected; but the motor cannot run away under light loads, because of the shunt excitation. The speed and torque characteristics for such a machine are shown in curves 2 (Fig. 20-3).

The speed of a compound motor can be adjusted by armature and field rheostats, just as in the shunt machine.

Indirect compound is used on some dc motors. In this case, the heavy strap-wound series field is replaced by a wire-wound field similar to a small shunt field. This field is excited by an unsaturated dc exciter, usually separately driven at constant speed. This exciter is excited by the line current of the motor for which it supplies the series excitation (see Fig. 20-4). The output voltage and the current from the exciter are proportional to the main motor current; so a given proportionality exists between the load current of the motor and its wire-wound series-field strength. The use of a reversing switch and rheostat in the armature circuit of the series exciter permits variations in strength and even polarity

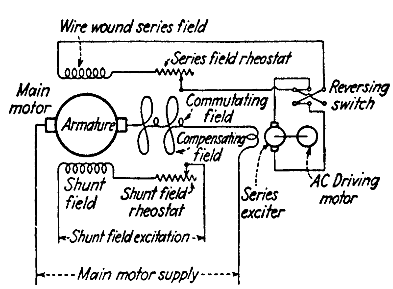

FIGURE 20-4 Direct-current motor with indirect compounding using a series exciter.

of the series field. This furnishes an easy method of changing the compounding of the motor if desired for various speeds, to maintain constant-speed regulation over a speed range. If desired, the series exciter rheostat can be mechanically connected to the shunt-field rheostat to accomplish this automatically.

Power Supplies. Power supplies to dc motors may be batteries, a dc generator, or rectifiers. The permanent-magnet and miniature motors use battery power supplies. Large integral-horsepower dc motors such as rolling-mill motors use dc generators as the power supply. Most fractional-horsepower and integral-horsepower dc motors operate with rectifier power supplies. Some of the types of rectifier power supplies are as follows:

1. Single-phase, half-wave
2. Single-phase, half-wave, back rectifier
3. Single-phase, half-wave, alternating-current voltage controlled
4. Single-phase, full-wave, firing angle controlled
5. Single-phase, full-wave, firing angle controlled, back rectifier
6. Three-phase, half-wave, voltage controlled
7. Three-phase, half-wave, firing angle controlled

The NEMA standard letter designations of dc motor test power supplies are as follows:

Power supply A—dc generator

Power supply C—3-phase 6-pulse controlled rectifier (230 V L-L, 60 Hz)

Power supply D—3-phase 6-pulse controlled rectifier (with three thyristors and three diodes) with free-wheeling diode (230/460 V L-L, 60 Hz)

Power supply E—3-phase 3-pulse controlled rectifier (460 V L-L, 60 Hz)

Power supply K—1-phase full-wave controlled rectifier with free-wheeling diode (230/115 V, 60 Hz)

When a direct-current integral-horsepower motor is operated from a rectified alternating-current supply, its performance may differ materially from that of the same motor when operated from a low-ripple direct-current source of supply, such as a generator or a battery. The pulsating voltage and current waveforms may increase temperature rise and noise and adversely affect commutation and efficiency. Because of these effects, direct-current motors must be designed or specially selected to operate on the particular type of rectified supply to be used. Armature-current form factor and ripple are two important parameters to be specified for motors which are required to operate with rectifier power supplies. The *form factor* is defined as the ratio of the rms value to the average value of the armature currents. Recommended rated form factors vary from 2.0 for 1-phase half-wave rectifier supplies to 1.1 for 3-phase full-wave rectifier supplies (see NEMA MG1-14.60). Because the letters used to identify the power supplies in common use have been chosen in alphabetical order of increasing magnitude of ripple current, a motor rated on the basis of one of these power supplies may be used on any power supply designed by a lower letter of the alphabet. For example, a motor rated on the basis of an E power supply may be used on a C or D power supply.

DC Motor Ratings. NEMA standard ratings of industrial dc motors for 240-V and 500/550-V dc supply voltages are given in Tables 10-4 and 10-5 of NEMA standard MG1. The rating is continuous unless otherwise specified. All short-term load tests shall commence only when the windings and other parts of the machine are within 5°C of the ambient temperature at the time of starting the test. Continuous and short-term ratings are based upon maximum ambient temperature and insulation class. Except in engine and boiler rooms, the maximum ambient temperature is 40°C and the insulation classes are A, B, and F, rated for temperature rises of 70°C, 100°C, and 130°C, respectively.

Losses and Efficiency. Power losses in dc motors are due to bearing friction, brush friction, windage, eddy currents and hysteresis in the armature core and pole faces, brush contact-drop, I^2R losses in the armature and field windings, and stray load losses. Typical values of total losses in industrial motors are 4% to 10% of the output. The bearing friction and brush friction losses are proportional to the speed of the motor, while the windage loss is proportional to the square of the speed. Eddy current loss in the armature teeth and in the armature core is proportional to the square of the speed and to the square of the air-gap flux density. Hysteresis loss in the armature teeth and core is proportional to the speed and the square of the flux density in the air gap. Brush contact drop is typically 1 V per brush arm for carbon-graphite brushes and 0.25 V for metal-graphite. Stray load losses are due to eddy currents in armature conductors, brush short-circuit losses in the commutator, and additional core loss arising from distortion of the magnetic field due to armature reaction. The efficiency of the dc motor is defined as

$$\eta = (\text{input electric power} - \text{losses})/\text{input power} \times 100\% \quad (20\text{-}7)$$

Typical efficiency variation with output is shown in Fig. 20-5.

Short-Time Ratings. The effect of time and enclosure on motor rating may be seen from the following: A given frame will have a rating of 12 hp at 500 r/min as an enclosed machine on continuous duty, or 19 hp at 500 r/min as an open machine on continuous duty, or 31 hp at 500 r/min with a 1-h rating, or 40 hp at 500 r/min with a $\frac{1}{2}$-h rating. The temperature rise on full load is 40°C as an open machine and 50°C as an enclosed machine. The horsepower is proportional to the speed over a range of 30% above or below the rated speed.

Methods of Speed Control. Speed of a dc motor is controlled either by varying the voltage across the armature, the field winding, or both. Series-parallel combinations are an effective means of reducing armature voltage and motor speed. This method is applied in cam-controlled traction motors. Two identical motors are connected in parallel or in series. When in parallel, full voltage is applied across each motor, causing it to run at base speed. When in series, the motor speeds are essentially one-half of base speed. Field-series resistance in shunt motors weakens the field, which causes the motors to run above the base speed. Speed range as high as 8:1 may be obtained in special motors. Armature-series resistance used with shunt or series motors produces motor speed below the base speed. In the series motor the field winding is also affected by the armature-series resistance, producing greater effect on the speed-torque characteristic than for the short motor where the field is constant. Speed control by this method is usually limited to approximately 50% of the base speed.

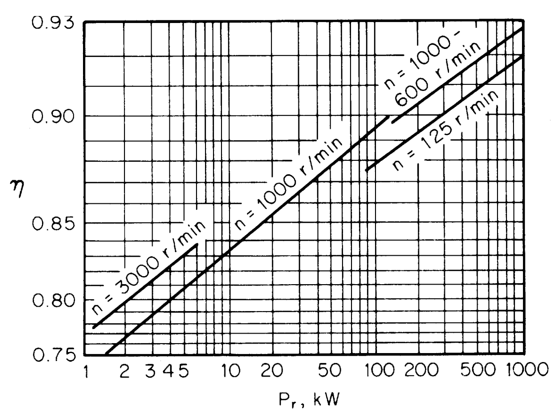

FIGURE 20-5 Typical efficiency curves of dc machines.

The above-speed control method results in power losses in the external resistors; solid-state dc motor control eliminates the power losses (see below).

Permanent-Magnet DC Motors. Permanent-magnet (PM) motors are available in fractional and low integral-horsepower sizes. They have several advantages over field-wound types. Excitation power supplies and associated wiring are not needed. Reliability is improved, since there are no exciting field coils to fail, and there is no likelihood of overspeed due to loss of field. Efficiency and cooling are improved by elimination of power loss in an exciting field. And the torque-versus-current characteristic is more nearly linear. Finally a PM motor may be used where a totally enclosed motor is required for a continuous-excitation duty cycle.

Temperature effects depend on the kind of magnet material used. Integral-horsepower motors with Alnico-type magnets are affected less by temperature than those with ceramic magnets because flux is constant. Ceramic magnets ordinarily used in fractional-horsepower motors have characteristics that vary about as much with temperature as do the shunt fields of excited machines.

Disadvantages are the absence of field control and special speed-torque characteristics. Overloads may cause partial demagnetization that changes motor speed and torque characteristics until magnetization is fully restored. Generally, an integral-horsepower PM motor is somewhat larger and more expensive than an equivalent shunt-wound motor, but total system cost may be less.

A PM motor is a compromise between compound-wound and series-wound motors. It has better starting torque, but approximately half the no-load speed of a series motor. In applications where compound motors are traditionally used, the PM motor could be considered where slightly higher efficiency and greater overload capacity are needed. In series-motor applications, cost consideration may influence the decision to switch. For example, in frame sizes under 5-in diameter the series motor is more economical. But in sizes larger than 5 in, the series motor costs more in high volumes. And the PM motor in these larger sizes challenges the series motor with its high torques and low no-load speed.

Brushless DC Motors. Brushless dc motors have a stationary armature and a rotating field structure, exactly opposite to how those elements are arranged in conventional dc motors. This construction speeds heat dissipation and reduces rotor inertia. Permanent magnets provide magnetic flux for the field. DC current to the armature is commutated with transistors rather than with the brushes and commutator bars of conventional dc motors.

Armatures of dc brushless motors typically contain 2 to 6 coils, whereas conventional dc motor armatures have from 10 to 50. Brushless motors have fewer coils because either two or four transistors are required to commutate each motor coil. This arrangement becomes increasingly costly and inefficient as the number of windings increases. A typical circuit of a brushless dc motor is shown in Fig. 20-6.

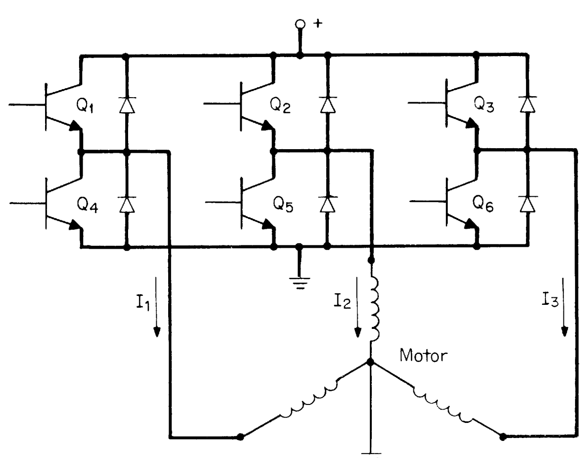

FIGURE 20-6 Typical circuit of a brushless dc motor.

The transistors controlling each winding of a dc brushless motor are turned on and off at specific rotor angles. The transistors provide current pulses to the armature windings that are similar to those provided by a commutator. The switching sequence is arranged to produce a rotating magnetic flux in the air gap that stays at a fixed angle to the flux produced by the permanent magnets on the rotor. Torque produced by a brushless dc motor is directly proportional to armature current.

DC Traction Motors. These are dc series motors typically rated 140 hp, 310 V, 2500 r/min. Four motors are used in each transit car, two on each axle. The power supply is 600 to 1000 V dc from the third rail, which is powered by 2500- to 5000-kW rectifier sets in rectifier substations located along the track. Starting and speed control are by either a cam controller or a chopper controller on board the transit car.

DC Servomotors. DC servomotors are high-performance motors normally used as prime movers in computers, numerically controlled machinery, or other applications where starts and stops must be made quickly and accurately. Servomotors have lightweight, low-inertia armatures that respond quickly to excitation-voltage changes. In addition, very low armature inductance in these motors results in a low electrical time constant (typically 0.05 to 1.5 ms) that further sharpens motor response to command signals. Servomotors include permanent-magnet, printed-circuit, and moving-coil (or shell) motors. The rotor of a shell motor consists of a cylindrical shell of copper or aluminum wire coils. The wire rotates in a magnetic field in the annular space between magnetic pole pieces and a stationary iron core. The field is provided by cast Alnico magnets whose magnetic axis is radial. The motor may have 2, 4, or 6 poles.

Each of these basic types has its own characteristics, such as inertia, physical shape, cost, shaft resonance, shaft configuration, speed, and weight. Although these motors have similar torque ratings, their physical and electrical constants vary considerably. The choice of a motor may be as simple as fitting one into the space available. However, this is generally not the case since most servosystems are very complex.

20.3 SYNCHRONOUS MOTORS

Definition. A synchronous motor is a machine that transforms electric power into mechanical power. That average speed of normal operation is exactly proportional to the frequency of the system to which it is connected. Unless otherwise stated, it is generally understood that a synchronous motor has field poles excited with direct current.

Types. The synchronous motor is built with one set of ac polyphase distributed windings, designated the *armature*, which is usually on the stator and is committed to the ac supply system. The configuration of the opposite member, usually the rotor, determines the type of synchronous motor. Motors with dc excited field windings on salient-pole or round rotors, rated 200 to 100,000 hp and larger, are the dominant industrial type. In the brushless synchronous motor, the excitation (field current) is supplied through shaft-mounted rectifiers from an ac exciter. In the slip-ring synchronous motor, the excitation is supplied from a shaft-mounted exciter or a separate dc power supply. Synchronous-induction motors rated below 5 hp, usually supplied from adjustable-speed drive inverters, are designed with a different reluctance across the air gap in the direct and quadrature axis to develop reluctance torque. The motors have no excitation source for synchronous operation. Synchronous motors below 1 hp usually employ a permanent-magnetic type of motor. These motors are usually driven by a transistor inverter from a dc source; they are termed *brushless dc motors*.

Standards. DC separately excited synchronous motors are covered by ANSI Standard C50.10-1965, Synchronous Machines, and C50.11-1965, Synchronous Motors. They are also covered by Part 21 of NEMA Standard MG-1 1972.

Theory of Operation. The operation of the dc separately excited synchronous motor can be explained in terms of the air-gap magnetic-field model, the circuit model, or the phasor diagram model of Fig. 20-7.

In the magnetic-field model of Fig. 20-7*a*, the stator windings are assumed to be connected to a polyphase source, so that the winding currents produce a rotating wave of current density J_a and radial armature reaction field B_a as explained below. The rotor carrying the main field poles is rotating in synchronism with these waves. The excited field poles produce a rotating wave of field B_d. The net magnetic field B_t is the spatial sum of B_a and B_d; it induces an air-gap voltage V_{ag} in the stator windings, nearly equal to the source voltage V_t. The current-density distribution J_a is shown for the current I_a in phase with the voltage V_t, and pf = 1. The electromagnetic torque acting between the rotor and the stator is produced by the interaction of the main field B_d and the stator

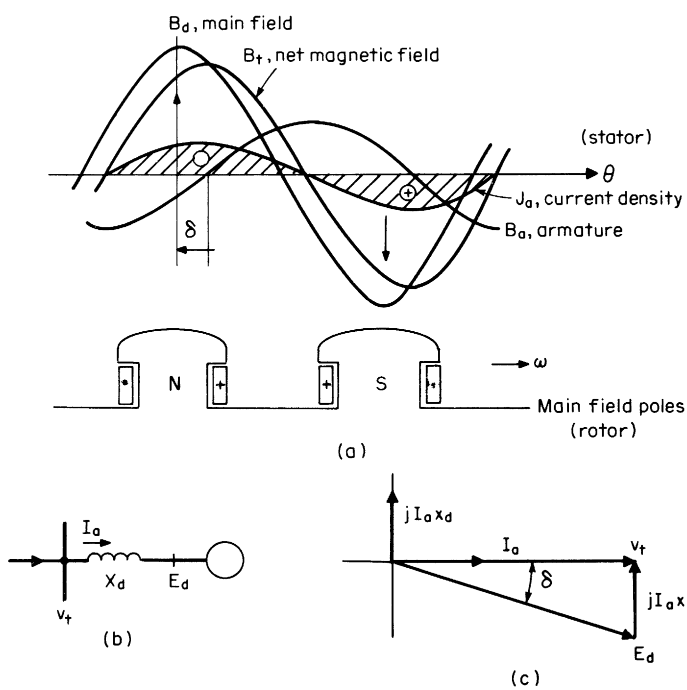

FIGURE 20-7 Operation of synchronous motor: (*a*) air-gap magnetic-field model; (*b*) circuit model; (*c*) phasor-diagram model.

current density J_a, as a $J \times B$ force on each unit volume of stator conductor. The force on the conductors is to the left $(-\phi)$; the reaction force on the rotor is to the right $(+\phi)$, and in the direction of rotation.

The operation of the synchronous motor can be represented by the circuit model of Fig. 20-7*b*. The motor is characterized by its synchronous reactance x_d and the excitation voltage E_d behind x_d. The model neglects saliency (poles), saturation, and armature resistance, and is suitable for first-order analysis, but not for calculation of specific operating points, losses, field current, and starting.

The phasor diagram of Fig. 20-7*c* is drawn for the field model and circuit model previously described. The phasor diagram neglects saliency and armature resistance. The phasors correspond to the waves in the field model. The terminal voltage V_t is generated by the field B_t; the excitation voltage E_d is generated by the main field B_d; the voltage drop $jI_a x_d$ is generated by the armature reaction field B_a; and the current I_a is the aggregate of the current-density wave J_a. The power angle δ is that between V_t and E_d, or between B_t and B_d. The excitation voltage E_d, in per-unit (pu),* is equal to the field current I_{fd}, in pu, on the air-gap line of the no-load (open-circuit) saturation curve of the machine.

Power-Factor Correction. Synchronous motors were first used because they were capable of raising the power factor of systems having large induction-motor loads. Now they are also used because they can maintain the terminal voltage on a weak system (high source impedance), they have lower cost, and they are more efficient than corresponding induction motors, particularly the low-speed motors. Synchronous motors are built for operation at pf = 1.0, or pf = 0.8 lead, the latter being higher in cost and slightly less efficient at full load.

The selection of a synchronous motor to correct an existing factor is merely a matter of bookkeeping of active and reactive power. The synchronous motor can be selected to correct the overall power factor to a given value, in which case it must also be large enough to accomplish its motoring functions; or it can be selected for its motoring function and required to provide the maximum correction that it can when operating at pf = 0.8 lead. In Fig. 20-8, a power diagram shows how the active and reactive power components P_s and Q_s of the synchronous motor are added to the components P_i and Q_i of an induction motor to obtain the total P_t and Q_t components, the kVA$_t$, and the power factor. The Q_s of the synchronous motor is based on the rated kVA and pf = 0.8 lead, rather than the actual operating kVA.

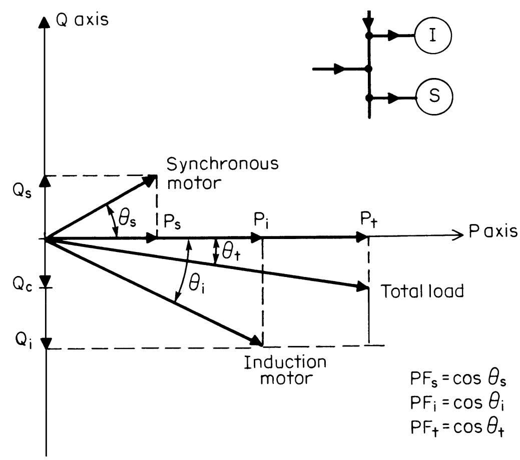

FIGURE 20-8 Power diagram of induction motor and synchronous motor operating in parallel, showing component and net values of *P* and *Q*.

The synchronous motor can support the voltage of a weak system, so that a larger-rating synchronous motor can be installed than an induction motor for the same source impedance. With an induction motor, both the *P* and *Q* components produce voltage drops in the source impedance. With a synchronous motor operating at leading power factor, the *P* component produces a voltage drop in the source resistance, but the *Q* component produces a voltage rise in the source reactance that can offset the drop and allow the terminal voltage to be normal. If necessary, the field current of the synchronous motor can be controlled by a voltage regulator connected to the motor bus. The leading current of a synchronous motor is able

*A reference unit for expressing all parameters on a common reference base. One pu is 100% of the chosen base.

to develop a sufficient voltage rise through the source reactance to overcome the voltage drop and maintain the motor voltage equal to the source voltage.

Starting. The interaction of the main field produced by the rotor and the armature current of the stator will produce a net average torque to drive the synchronous motor only when the rotor is revolving at speed n in synchronism with the line frequency f; $n = 120 f/p$, p = poles. The motor must be started by developing other than synchronous torques. Practically, the motor is equipped with an induction-motor-type squirrel-cage winding on the rotor, in the form of a damper winding, in order to start the motor.

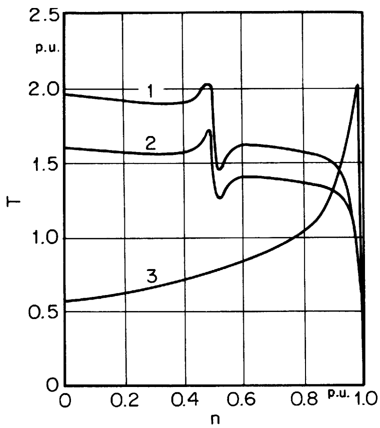

FIGURE 20-9 Characteristic torque curves for 5000-hp synchronous induction motor during runup at full voltage: (1) synchronous motor for pf = 1; (2) synchronous motor for pf = 0.8; (3) squirrel-cage induction motor.

The motor is started on the damper windings with the field winding short-circuited, or terminated in a resistor, to attenuate the high "transformer"-induced voltages. When the motor reaches the lowest slip speed, practically synchronous speed, the field current is applied to the field winding, and the rotor poles accelerate and pull into step with the synchronously rotating air-gap magnetic field. The damper windings see zero slip and carry no further current, unless the rotor oscillates with respect to the synchronous speed.

Starting curves for a synchronous motor are shown in Fig. 20-9. The damper winding is designed for high starting torque, as compared to an induction motor of the same rating. The closed field winding contributes to the starting torque in the manner of a 3-phase induction motor with a 1-phase rotor. The field winding produces positive torque to half speed, then negative torque to full speed, accounting for the anomaly at half speed. The maximum and minimum torque excursion at the anomaly is reduced by the resistance in the closed field winding circuit during starting. The effect is increased by the design of the damper winding.

The velocity of the rotor during the synchronizing phase, after field current is applied, is shown in Fig. 20-10. The rotor is assumed running at 0.05 pu slip on the damper winding. The undulation in speed, curve 1, is the effect of the poles attempting to synchronize the rotor just by reluctance torque. The added effect of the field current is shown by curve 2, and the resultant by curve 3. The effect of the reluctance torque of curve 1 is not dependent on pole polarity. The synchronizing torque of curve 2, with the field current applied, is pole polarity dependent; the poles want to match the air-gap

Torque Definitions. The torques described in the following paragraphs are listed in the Standards. The minimum values are given in Table 20-1.

Locked-rotor torque is the minimum torque, which the synchronous motor will develop at rest for all angular positions of the rotor, with rated voltage at rated frequency applied.

Pull-in torque is the maximum constant-load torque under which the motor will pull into synchronism, at rated voltage and frequency, when its rated field current is applied. Whether the motor can pull the load into step from the slip running on the damper windings depends on the speed-torque character of the load and the total inertia of the revolving parts. A typical relationship between maximum slip and percent of normal Wk^2 for pulling into step is shown in Fig. 20-11. Table 20-1 specifies minimum values of pull-in torque with the motor loaded with normal Wk^2; these values are given below. (See also Table 20-1.) *Nominal pull-in torque* is the value at 95% of synchronous speed, with rated voltage at rated frequency applied, when the motor is running on the damper windings.

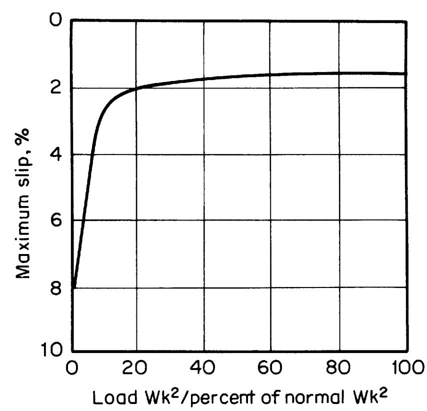

FIGURE 20-11 Typical relationship between load inertia and maximum slip for pulling synchronous motors into step.

Pull-out torque is the maximum sustained torque which the motor will develop at synchronous speed for 1 min, with rated voltage at rated frequency applied, and with rated field current.

In addition, the *pull-up torque* is defined as the minimum torque developed between standstill and the pull-in point. This torque must exceed the load torque by a sufficient margin to assure satisfactory acceleration of the load during starting.

The *reluctance torque* is a component of the total torque when the motor is operating synchronously. It results from the saliency of the poles and is a manifestation of the poles attempting to align themselves with the air-gap magnetic field. It can account for up to 30% of the pull-out torque.

The *synchronous torque* is the total steady-state torque available, with field excitation applied, to drive the motor and the load at synchronous speed. The maximum value as the motor is loaded is the pull-out torque, developed as a power angle $\delta = 90°$.

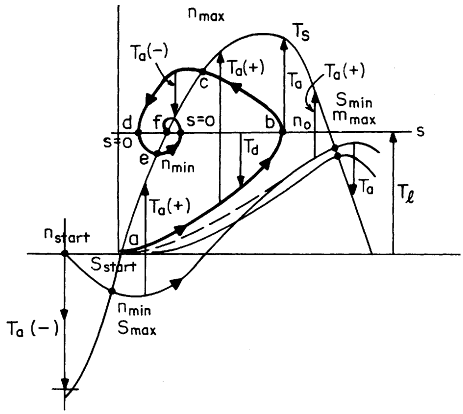

FIGURE 20-12 Locus of torque and speed versus power angle δ for a synchronous motor during a successful attempt and an unsuccessful attempt to synchronize.

Synchronization. Synchronization is the process by which the synchronous motor "pulls into step" during the starting process, when the field current is applied to the field winding. Initially, the rotor is revolving at a slip with respect to the synchronous speed of the air-gap magnetic-field waves. The rotor torque, produced by the damper windings, is in equilibrium with the load torque at that slip. The ability of the rotor to accelerate and synchronize depends upon the total inertia (Wk^2), the initial slip, and the closing angle of the poles with respect to the field wave at the instant field current is applied.

Figure 20-12 shows the torque versus angle δ locus for the rotor during a successful synchronization. The rotor is subjected to the synchronous torque T_s, which is a function of δ, and the damper torque T_d, which is a function of the slip velocity ($n_0 = n$). The torque T_a available to accelerate the rotor is the residual of $T_a = T_s + T_d - T_l$. In the figure, the closing angle is assumed zero at point *a*. Furthermore, $T_d = T_l$, so that the residual torque T_a is zero. The rotor has a finite slip, so that the power angle δ increases. As it does, the synchronous torque T_s increases, T_a increases and the rotor accelerates to point *b*, where $n = n_0$, $T_d = 0$. The slip goes negative, reverses the direction of the damper torque, but the rotor continues to accelerate to point *c*, where the speed is maximum and the accelerating torque is zero. The rotor falls back to points *d* and *e* at minimum speed, accelerates again, and finally synchronizes at point *f*.

If the initial slip is excessive, or if the inertia and/or load too great, the locus in Fig. 20-12 could follow the path *ab*′. The condition of $T_a = 0$ is reached below synchronous speed; the rotor never pulls into step, but oscillates around the initial slip velocity until the machine is tripped off.

Damper Windings. Damper windings are placed on the rotors of synchronous motors for two purposes: for starting and for reducing the amplitude of power-angle oscillation. The damper windings consist of copper or brass bars inserted through holes in the pole shoes and connected at the ends to rings to form the equivalent of a squirrel cage. The rings can extend between the poles to form a complete damper. Synchronous motors with solid pole shoes, or solid rotors, perform like motors with damper windings.

The design of the damper winding requires the selection of the bar and ring material to meet the torque and damping requirements. Figure 20-13 shows the effect on the starting curves for the damper winding of varying the material from a low-resistance copper in curve 1, to a higher-resistance brass or aluminum-bronze alloy in curve 2. Curve 1 gives a starting torque of about 0.25 pu, and a pull-in torque of 1.0 pu, of the nominal synchronous torque. Curve 2 gives a higher starting torque of about 0.5 to 1.0 pu, but a pull-in torque of about 0.4 pu of the nominal value. The additional starting torque of the field winding is superimposed on the torque of the damper alone. The damper winding must be designed to meet the characteristics of the load.

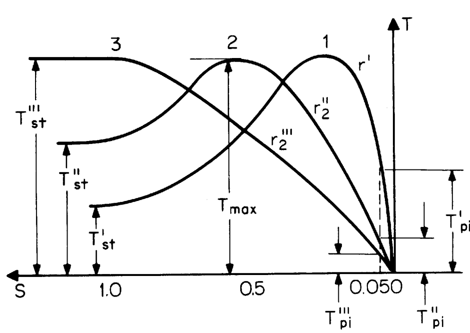

FIGURE 20-13 Effect of resistivity of damper material on the starting and pull-in torque of the synchronous motor. Damper winding 1, least resistance; damper winding 3, maximum resistance.

To design the damper winding so that the amplitude of the natural-frequency oscillation is reduced, the bar currents during the low-frequency sweeping of the air-gap flux across the pole faces must be maximized. Since the slip frequency is low, the currents and damper effectiveness are maximized by making the dampers low resistance, corresponding to curve 1 in Fig. 20-13. This design coincides with the requirement for low starting torque and high pull-in torque. In special cases, the equivalent of a deep-bar or double-bar damper can be used, if there is adequate space on the pole shoe.

Methods of Starting. The method used to start a synchronous motor depends on two factors: the required torque to start the load and the maximum starting current permitted from the line. Basically, the motor is started by using the damper windings to develop asynchronous torque or by using an auxiliary motor to bring the unloaded motor up to synchronous speed. Solid-state converters have also been used to bring up to speed large several-hundred-MVA synchronous motor/generators for pumped storage plants.

Techniques for asynchronous starting on the damper windings are the same as for squirrel-cage induction motors of equivalent rating. Across-the-line starting provides the maximum starting torque, but requires the maximum line current. The blocked-rotor kVA of synchronous motors as a function of pole number is shown in Fig. 20-14. If the ac line to the motor supplies other loads, the short-circuit kVA of the line must be at least 6 to 10 times the blocked rotor kVA of the motor to limit the line-voltage dip on starting. The starting and pull-in torques for three general classes of synchronous motors are shown in Fig. 20-15. The torques are shown for rated voltage; for across-the-line starting, the values will be reduced to V_t^2 (pu).

Reduced-voltage starting is used where the full starting torque of the motor is not required and/or the ac line cannot tolerate the full starting current. The starter includes a 3-phase open-delta or 3-winding autotransformer, which can be set to apply 50%, 65%, or 80% of line voltage to the motor on the first step. The corresponding torque is reduced to 25%, 42%, or 64%. The starter switches the motor to full voltage when it has reached nearly synchronous speed, and then applies the field excitation to synchronize the motor.

ANSI C50.11-1965 limits the number of starts for a synchronous motor, under its design conditions of Wk^2, load torque, nominal voltage, and starting method, to the following:

1. Two starts in succession, coasting to rest between starts, with the motor initially at ambient temperature, or
2. One start with the motor initially at a temperature not exceeding its rated load operating temperature.

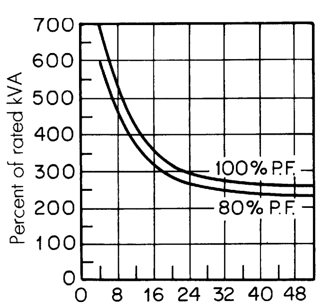

FIGURE 20-14 Approximate blocked-rotor kVA of synchronous motors.

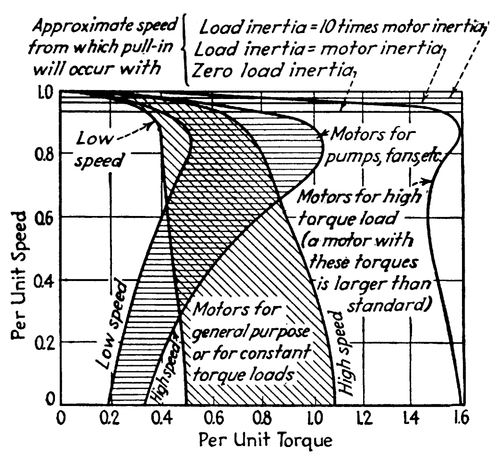

FIGURE 20-15 Approximate starting performance of synchronous motors.

If additional starts are required, it is recommended that none be made until all conditions affecting operation have been thoroughly investigated and the apparatus examined for evidence of excessive heating. It should be recognized that the number of starts should be kept to a minimum since the life of the motor is affected by the number of starts.

Exciters. DC separately excited synchronous motors are provided with a shaft-driven exciter to supply the field power. Exciters are classified into slip-ring types and brushless types. The slip-ring type consists of a dc generator, whose output is fed into the motor field winding through slip rings and stationary brushes. The brushless type consists of an ac generator, with rotating armature and stationary field; the output is rectified by solid-state rectifier elements mounted on the rotating structure and fed directly to the motor field winding. In each type, the motor field current is controlled by the exciter field current. Typical kilowatt ratings for exciters for 60-Hz synchronous motors are given in MG1-21.16 as a function of hp rating, speed, and power factor. For a given hp rating, the excitor kW increases as the speed is reduced, and as the power factor is shifted from pf = 1.0 to pf = 0.8 lead.

During starting, the motor field winding must be disconnected from the exciter and loaded with a resistor, to limit the high induced voltage, to prevent damage to the rectifier elements of the brushless type, and to prevent the circulation of ac current through a slip-ring-type dc exciter. The switching is done with a contactor for the slip-ring type, and with thyristors on the rotating rectifier assembly for the brushless type. Except for the disconnection for starting, the synchronous-motor excitation system is practically the same as for an ac generator of the same rating.

Brushless-type exciters are now used on all new high-speed synchronous motors (2 to 8 poles) that formerly were built with direct-drive dc exciters and slip rings. The brushless-type exciters require minimum maintenance and can be used in explosive-atmospheres. The circuit of a typical brushless-type excitation system is shown in Fig. 20-16. The semicontrolled bridge with three diodes and three thyristors rectifies the output of the ac exciter generator and supplies the motor field winding. The thyristors act as a switch to open the rectifier during starting and to close it during running, whereas the ac exciter generator is excited with its own field current. The resistor is permanently connected across the motor field winding during starting and running. It improves the torque characteristics during

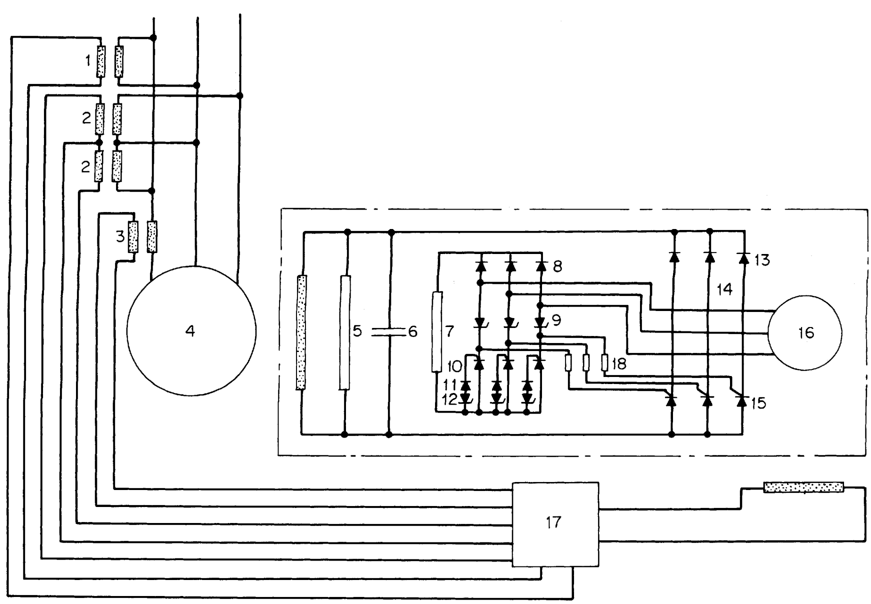

FIGURE 20-16 Brushless-type excitation system for a synchronous motor.

starting, and protects the bridge elements against transient overvoltages during running. The capacitor protects the diodes and thyristors against commutation overvoltages caused by hole-storage phenomena in conjunction with the inductances of the armature windings of the ac exciter generator.

The control system (Fig. 20-16) comprises a simple auxiliary rectifier arrangement connected in parallel with the main rectifier bridge and loaded with an auxiliary resistor 7. Each main thyristor has an auxiliary thyristor that provides the gate current and operates on the same phase of the ac excitor voltage. Consequently the trigger signal always occurs at the correct instant, that is, when the thyristors have a forward loading. No trigger signal is given during the blocking period. There is no excitation at the exciter during run-up, and therefore no trigger signal is applied to the gates of the thyristors and they remain blocking. The alternating current induced in the field winding flows in both directions through the protection resistor 5. When the machine has been run up to normal speed, the field voltage is applied to the ac exciter. It then supplies the control current and the thyristors are fired. Control losses are only 0.1% to 0.2% of the exciter power and are therefore negligible. The auxiliary thyristor 10 together with the diode 11 and Zener diode 12 prevents preignition of the thyristors during run-up due to high residual voltage in the ac exciter. On the other hand, the gates of the other thyristors are protected against overload by Zener diode 9 and resistor 18. If the voltage exceeds the Zener voltage, the Zener diode conducts the excess current.

Standard Ratings. Standard ratings for dc separately excited synchronous motors are given in NEMA MG1-1978, Part 21. Standard horsepowers range from 20 to 100,000 hp. Speed ratings extend from 3600 r/min (2-pole) to 80 r/min (90-pole) for 60-Hz machines, and five-sixths of the values for 50-Hz machines. The power factor shall be unity or 0.8 leading. The voltage ratings for 60-Hz motors are 200, 230, 460, 575, 2300, 4000, 4600, 6600, and 13,200 V. It is not practical to build motors of all horsepower ratings at these speeds and voltages.

Efficiency. Efficiency and losses shall be determined in accordance with IEEE test procedures for synchronous machines, Publication 115. The efficiency shall be determined at rated output, voltage, frequency, and power factor. The following losses shall be included in determining the efficiency: (1) I^2R loss of armature and field; (2) core loss; (3) stray-load loss; (4) friction and windage loss; and (5) exciter loss for shaft-driven exciter. The resistances should be corrected for temperature.

Typical synchronous motor efficiencies are shown in Fig. 20-17. The unity-power-factor synchronous motor—historically up to 3% more efficient than the NEMA design B induction motor, is now only 1% to 2% more efficient because of improvements in NEMA B designs and manufacturing techniques.

The 0.8 pf synchronous motor, because of the increased copper loss, is lower in efficiency; its efficiency is closer to that of the induction motor at high speed, but better at low speed.

Standard Tests. Tests on synchronous motors shall be made in accordance with *IEEE Test Procedure for Synchronous Machines*, Publ. No. 115, and ANSI C50.10-1965. The following tests shall be made on motors completely assembled in the factory and furnished with shaft and complete set of bearings: resistance test of armature and field windings; dielectric test of armature and field windings; mechanical balance; current balance at no load; and direction of rotation. The following tests may be specified on the same or duplicate motors: locked-rotor current; temperature rise; locked-rotor torque; overspeed; harmonic analysis and TIF; segregated losses; short-circuit tests at reduced voltage to determine reactances and time constants; field-winding impedance; and speed-torque curve.

The following tests shall be made on all motors not completely assembled in the factory: resistance and dielectric tests of armature and field windings. The following field tests are recommended after installation: resistance and dielectric tests of armature and field windings not completely assembled in the factory; mechanical balance; bearing insulation; current balance at no load; direction of rotation. The following field tests may be specified on the same or duplicate motors: temperature rise; short-circuit tests at reduced voltage to determine reactances and time constants; field-winding impedance.

The dielectric test for the armature winding shall be conducted for 1 min, with an ac rms voltage of 1000 V plus twice the rated voltage. For machines rated 6 kV and above, the test may be conducted with a dc voltage of 1.7 times the ac rms test value. The dielectric test for the field winding depends upon the connection for starting. For a short-circuited field winding, the ac rms test voltage is 10 times

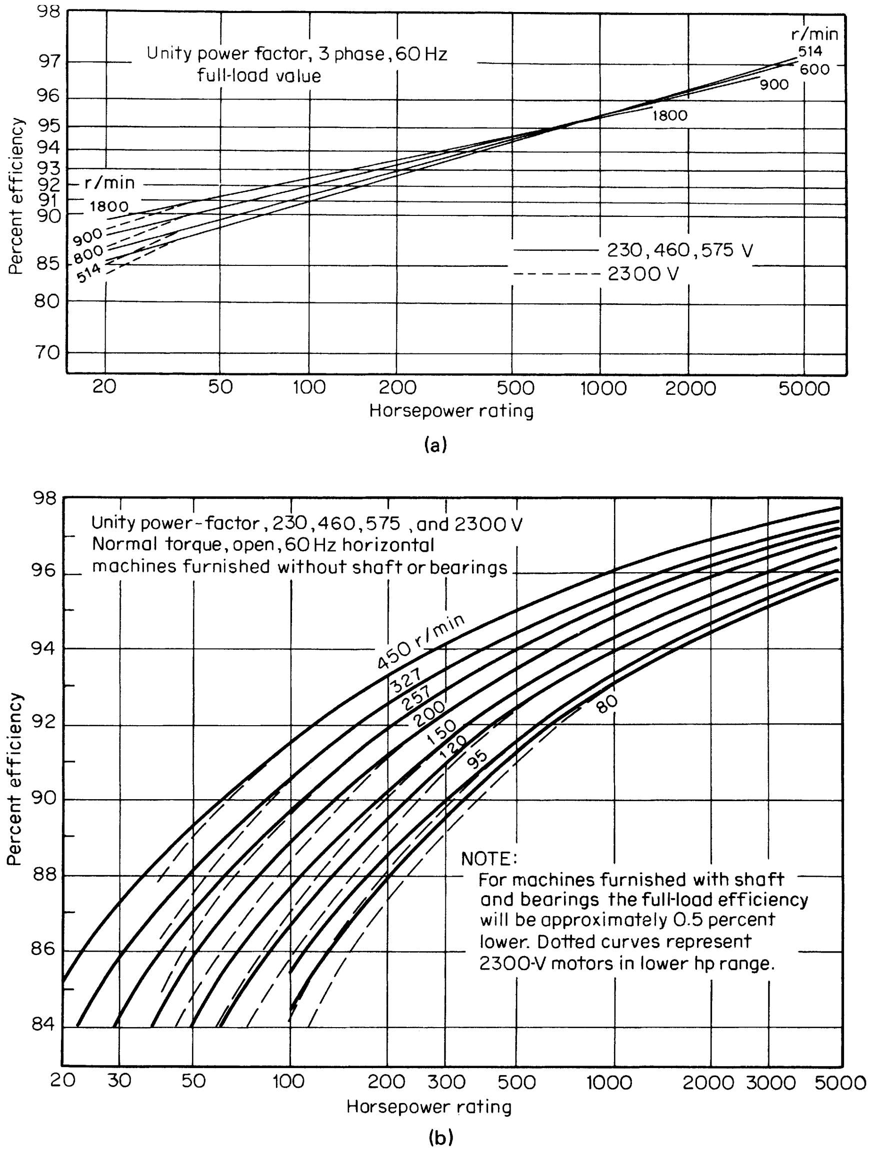

FIGURE 20-17 Full-load efficiencies of (*a*) high-speed general-purpose synchronous motors and (*b*) low-speed synchronous motors.

the rated excitation voltage, but no less than 2500 V, nor more than 5000 V. For a field winding closed through a resistor, the ac rms test voltage is twice the rms value of the *IR* drop, but not less than 2500 V, where the current is the value that would circulate with a short-circuited winding. When a test is made on an assembled group of several pieces of new apparatus, each of which has passed a high-potential test, the test voltage shall not exceed 85% of the lowest test voltage for any part of the group. When a test is made after installation of a new machine, which has passed its high-potential test at the factory and whose windings have not since been disturbed, the test voltages should be 75% of the original values.

Cycloconverter Drive. A unique application for large low-speed synchronous motors is for gearless ball-mill drives for the cement industry. For a recently installed drive, the motor is rated 8750 hp, 1.0 pf, 6850 kVA, 14.5 r/min 1900 V, 4.84 Hz, 40 poles, Class B. The power is provided by a cycloconverter over the range 0 to 4.84 Hz, as shown in Fig. 20-18. The cycloconverter consists of six thyristor rectifiers, each of which generates the polarity of the 3-phase ac voltage wave applied to the motor. The cycloconverter can be used effectively up to about one-third of the line frequency. The motor can be controlled in speed by the cycloconverter frequency, or in torque by the angle between the armature voltage and the field-pole position, approximately the power angle δ.

Inverter-Synchronous Motor Drive. Synchronous motors over about 1000 hp are being driven by machine-commutated inverters for adjustable-speed drives for large fans, pumps, and other loads. The machine-commutated inverter drive consists of two converters interconnected by a dc link as shown in Fig. 20-19*a*. The synchronous motor operates at constant volts per hertz, that is, voltage proportional to frequency and speed. The converter characteristics are shown in Fig. 20-19*b* and *c*. The $\pm V_d$ values are 1.35 times the line-line voltage on the ac side of each converter. For a given motor speed, frequency, and voltage, the firing angle of the rectifier is set at α_r to yield the required

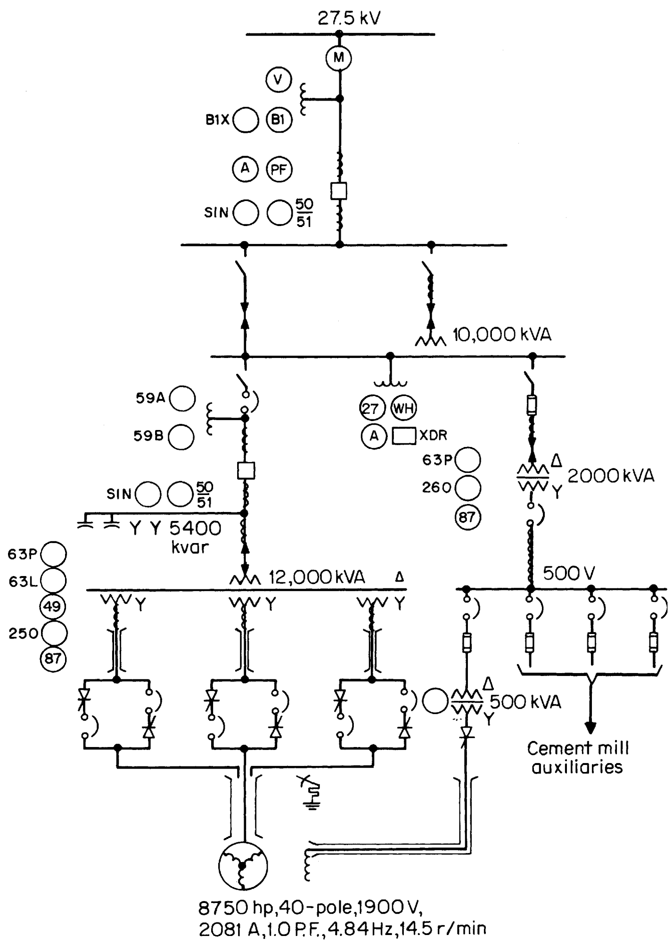

FIGURE 20-18 Cycloconverter-synchronous motor gearless drive system for ball mill.

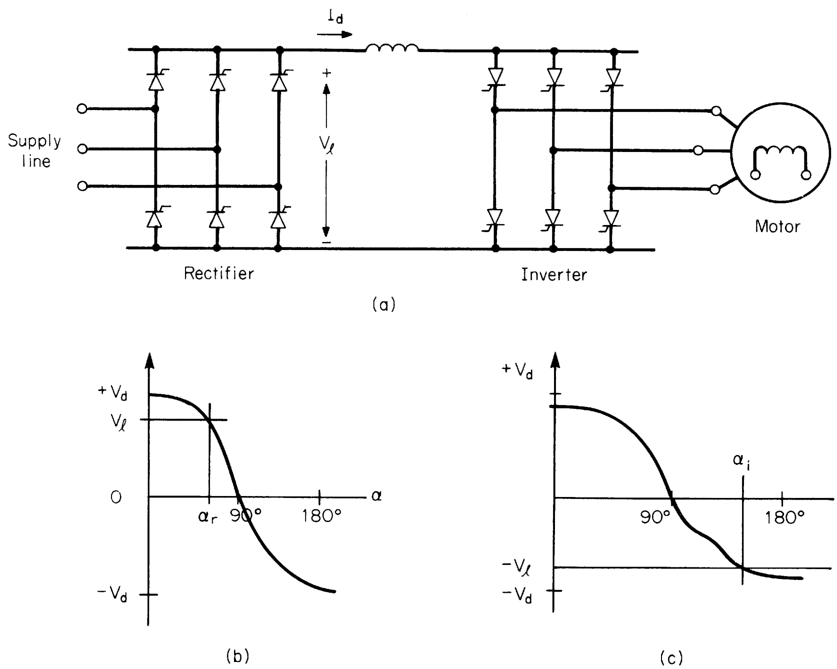

FIGURE 20-19 Diagram of (*a*) machine-commutated synchronous motor drive; (*b*) dc voltage vs. firing angle α_r, characteristic of rectifier; (*c*) dc voltage versus firing angle α_i characteristic of inverter.

dc voltage V_l for the link. The firing angle of the inverter is set at α_i in the inverting quadrant of the converter so that the link voltage V_l matches the internal ac voltage generated by the motor at the given speed. Power flows from the rectifier at $V_e I_d$ into the inverter and the motor. The inverter firing signals are synchronized to the motor voltage. For decelerating the motor, the rectifier and inverter functions are reversed by shifting the firing angles. Power flows from the motor into the dc link and to the supply line.

20.4 INDUCTION MACHINES

20.4.1 Theory of the Polyphase Induction Motor

Principle of Operation. An induction motor is simply an electric transformer whose magnetic circuit is separated by an air gap into two relatively movable portions, one carrying the primary and the other the secondary winding. Alternating current supplied to the primary winding from an electric power system induces an opposing current in the secondary winding, when the latter is short-circuited or closed through an external impedance. Relative motion between the primary and secondary structures is produced by the electromagnetic forces corresponding to the power thus transferred across the air gap by induction. The essential feature that distinguishes the induction machine from other types of electric motors is that the secondary currents are created solely by induction, as in a transformer, instead of being supplied by a dc exciter or other external power source, as in synchronous and dc machines.

Induction motors are classified as squirrel-cage motors and wound-rotor motors. The secondary windings on the rotors of squirrel-cage motors are assembled from conductor bars short-circuited by end rings or are cast in place from a conductive alloy. The secondary windings of wound-rotor motors are wound with discrete conductors with the same number of poles as the primary winding on the stator. The rotor windings are terminated on slip rings on the motor shaft. The windings can be short-circuited by brushes bearing on the slip rings, or they can be connected to resistors or solid-state converters for starting and speed control.

Construction Features. The normal structure of an induction motor consists of a cylindrical rotor carrying the secondary winding in slots on its outer periphery and an encircling annular core of laminated steel carrying the primary winding in slots on its inner periphery. The primary winding is commonly arranged for 3-phase power supply, with three sets of exactly similar multipolar coil groups spaced one-third of a pole pitch apart. The superposition of the three stationary, but alternating, magnetic fields produced by the 3-phase windings produces a sinusoidally distributed magnetic field revolving in synchronism with the power-supply frequency, the time of travel of the field crest from 1-phase winding to the next being fixed by the time interval between the reaching of their crest values by the corresponding phase currents. The direction of rotation is fixed by the time sequence of the currents in successive phase belts and so may be reversed by reversing the connections of one phase of a 2- or 3-phase motor.

Figure 20-20 shows the cross section of a typical polyphase induction motor, having in this case a 3-phase 4-pole primary winding with 36 stator and 28 rotor slots. The primary winding is composed

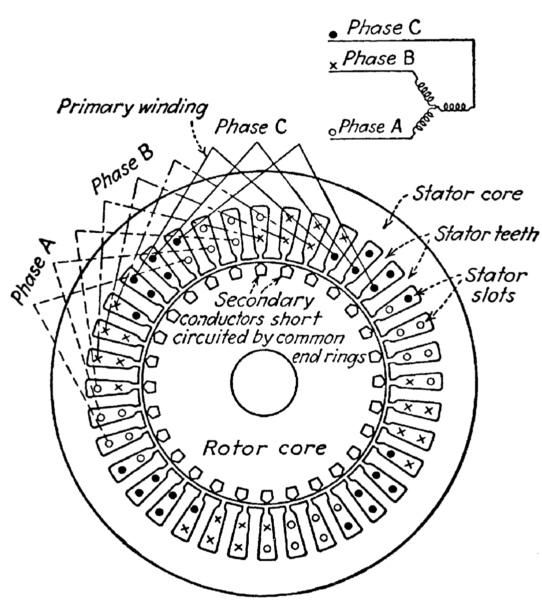

FIGURE 20-20 Section of squirrel-cage induction motor, 3-phase, 4-pole, 8/9-pitch stator winding.

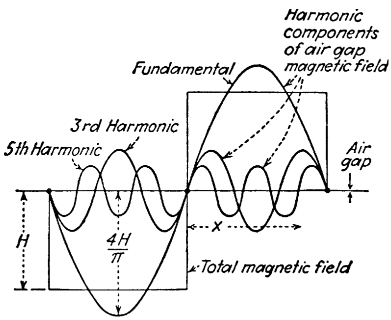
of 36 identical coils, each spanning 8 teeth, one less than the 9 teeth in one pole pitch. The winding is therefore said to have $^8/_9$ pitch. As there are three primary slots per pole per phase, phase A comprises four equally spaced "phase belts," each consisting of three consecutive coils connected in series. Owing to the short pitch, the top and bottom coil sides of each phase overlap the next phase on either side. The rotor, or secondary, winding consists merely of 28 identical copper or cast-aluminum bars solidly connected to conducting end rings on each end, thus forming a "squirrel-cage" structure. Both rotor and stator cores are usually built on silicon-steel laminations, with partly closed slots, to obtain the greatest possible peripheral area for carrying magnetic flux across the air gap.



FIGUE 20-21 Magnetic field produced by a single coil.

The Revolving Field. The key to understanding the induction motor is a thorough comprehension of the revolving magnetic field.

The rectangular wave in Fig. 20-21 represents the mmf, or field distribution, produced by a single full-pitch coil, carrying H At. The air gap between stator and rotor is assumed to be uniform, and the effects of slot openings are neglected. To calculate the resultant field produced by the entire winding, it is most convenient to analyze the field of each single coil into its space-harmonic components, as indicated in Fig. 20-21 or expressed by the following equation:

$$H(x) = \frac{4H}{\pi}\left(\sin x + \frac{1}{3}\sin 3x + \frac{1}{5}\sin 5x + \frac{1}{7}\sin 7x + \cdots\right) \tag{20-8}$$

When two such fields produced by coils in adjacent slots are superposed, the two fundamental sine-wave components will be displaced by the slot angle θ, the third-harmonic components by the angle 3θ, the fifth harmonics by the angle 5θ, etc. Thus, the higher space-harmonic components in the resultant field are relatively much reduced as compared with the fundamental. By this effect of distributing the winding in several slots for each phase belt, and because of the further reductions due to fractional pitch and to phase connections, the space-harmonic fields in a normal motor are reduced to negligible values, leaving only the fundamental sine wave components to be considered in determining the operating characteristics.

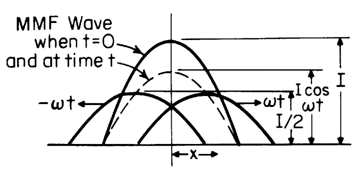


FIGURE 20-22 Resolution of alternating wave into two constant-magnitude waves revolving in opposite directions.

The alternating current flowing in the winding of each phase therefore produces a sine-wave distribution of magnetic flux around the periphery, stationary in space but varying sinusoidally in time in synchronism with the supply frequencies. Referring to Fig. 20-22, the field of phase A at an angular distance x from the phase axis may be represented as an alternating phasor $I \cos x \cos \omega t$ but may equally well be considered as the resultant of two phasors constant in magnitude but revolving in opposite directions at synchronous speed:

$$I \cos x \cos \omega t = \frac{I}{2}[\cos(x - \omega t) + \cos(x + \omega t)] \tag{20-9}$$

Each of the right-hand terms in this equation represents a sine-wave field revolving at the uniform rate of one pole pitch, or 180 elec deg, in the time of each half cycle of the supply frequency. The synchronous speed N_s of a motor is therefore given by

$$N_s = \frac{120f}{P} \quad \text{r/min} \tag{20-10}$$

where f = line frequency in hertz and P = number of poles of the winding.

Considering phase A alone (Fig. 20-23), two revolving fields will coincide along the phase center line at the instant its current is a maximum. One-third of a cycle later, each will have traveled 120 elec deg, one forward and the other backward, the former lining up with the axis of phase B and the latter with the axis of phase C. But at this moment, the current in phase B is a maximum, so that the forward-revolving B field coincides with the forward A field, and these two continue to revolve together. The backward B field is 240° behind the backward A field, and these two remain at this angle, as they continue to revolve. After another third of a cycle, the forward A and B fields will reach the phase C axis, at the same moment that phase C current becomes a maximum. Hence, the forward fields of all three phases are directly additive, and together they create a constant-magnitude sine-wave-shaped synchronously revolving field with a crest value two-thirds the maximum instantaneous value of the alternating field due to one phase alone. The backward-revolving fields of the three phases are separated by 120°, and their resultant is therefore zero so long as the 3-phase currents are balanced in both magnitude and phase.

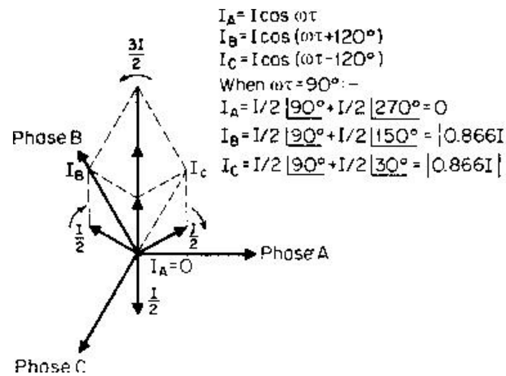

FIGURE 20-23 Resolution of alternating emf of each phase into oppositely revolving constant-magnitude components shown at instant when phase A current is zero ($\omega\tau = 90°$).

If a 2-phase motor is considered, it will have two 90° phase belts per pole instead of three 60° phase belts, and a similar analysis shows that it will have a forward-revolving constant-magnitude field with a crest value equal to the peak value of one phase alone and will have zero backward-revolving fundamental field. A single-phase motor will have equal forward and backward fields and so will have no tendency to start unless one of the fields is suppressed or modified in some way.

While the space-harmonic-field components are usually negligible in standard motors, it is important to the designer to recognize that there will always be residual harmonic-field values which may cause torque irregularities and extra losses if they are not minimized by an adequate number of slots and correct winding distribution. An analysis similar to that given for the fundamental field shows that in all cases the harmonic fields corresponding to the number of primary slots (seventh and nineteenth in a nine-slot-per-pole motor) are important and that the fifth and seventh harmonics on 3-phase, or third and fifth on 2-phase, may also be important.

The third-harmonic fields and all multiples of the third are zero in a 3-phase motor, since the mmf's of the three phases are 120° apart for both backward and forward components of all of them. Finally, therefore, a 3-phase motor has the following distinct fields:

1. The fundamental field with P poles revolving forward at speed N_s.
2. A fifth-harmonic field with $5P$ poles revolving backward at speed $N_s/5$.
3. A seventh-harmonic field with $7P$ poles revolving forward at speed $N_s/7$.
4. Similar thirteenth, nineteenth, twenty-fifth, etc., forward-revolving and eleventh, seventeenth, twenty-third, etc., backward-revolving harmonic fields.

Figure 20-24 shows a test speed-torque curve obtained on a 2-phase squirrel-cage induction motor with straight (unspiraled) slots. The torque dips due to three of the forward-revolving fields are clearly indicated.

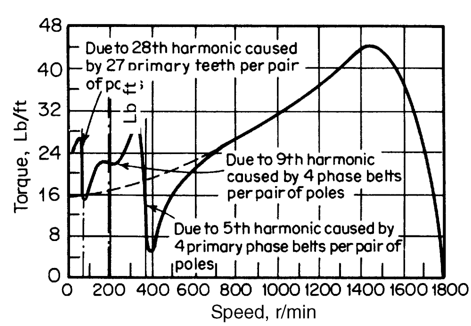

FIGURE 20-24 Speed-torque curve of 2-phase motor showing harmonic torque.

Torque, Slip, and Rotor Impedance. When the rotor is stationary, the revolving magnetic field cuts the short-circuited secondary conductors at synchronous speed and induces in them line-frequency currents. To supply the secondary *IR* voltage drop, there must be a component of voltage in time phase with the secondary current, and the secondary current, therefore, must lag in space position behind the revolving air-gap field. A torque is then produced corresponding to the product of the air-gap field by the secondary current times the sine of the angle of their space-phase displacement.

At standstill, the secondary current is equal to the air-gap voltage divided by the secondary impedance at line frequency, or

$$I_2 = \frac{E_2}{Z_2} = \frac{E_2}{R_2 + jX_2} \tag{20-11}$$

where R_2 = effective secondary resistance and X_2 = secondary leakage reactance at primary frequency.

The speed at which the magnetic field cuts the secondary conductors is equal to the difference between the synchronous speed and the actual rotor speed. The ratio of the speed of the field relative to the rotor to synchronous speed is called the slip *s*

$$s = \frac{N_s - N}{N_s}$$

or

$$N = (1 - s)N_s \tag{20-12}$$

where N = actual and N_s = synchronous rotor speed.

As the rotor speeds up, with a given air-gap field, the secondary induced voltage and frequency both decrease in proportion to *s*. Thus, the secondary voltage becomes sE_2, and the secondary impedance $R_2 + jsX_2$, or

$$I_2 = \frac{sE_2}{R_2 + jsX_2} = \frac{E_2}{(R_2/s) + jX_2} \tag{20-13}$$

The only way that the primary is affected by a change in the rotor speed, therefore, is that the secondary resistance as viewed from the primary varies inversely with the slip.

In practice, the effective secondary resistance and reactance, or R_2 and X_2, change with the secondary frequency, owing to the varying “skin effect,” or current shifting into the outer portion of the conductors, when the frequency is high. This effect is employed to make the resistance, and therefore the torque, higher at starting and low motor speeds, by providing a double cage, or deep-bar construction, as shown in Fig. 20-25. The leakage flux between the outer and inner bars makes the inner-bar reactance high, so that most of the current must flow in the outer bars or at the top of a deep bar at standstill, when frequency is high. At full speed, the secondary frequency is very low, and most of the current flows in the inner bars, or all over the cross section of a deep bar, owing to their lower resistance.

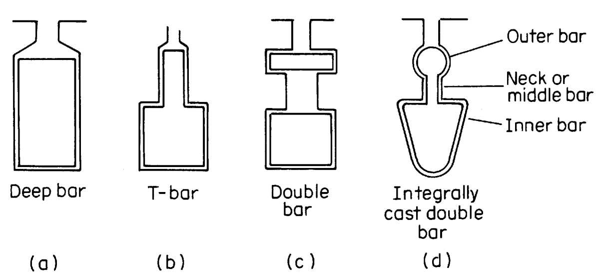

FIGURE 20-25 Alternative forms of squirrel cage rotor bars.

Analysis of Induction Motors. Induction motors are analyzed by two methods: (1) circle diagram and (2) equivalent circuit. The two methods are used for steady-state conditions. The circle diagram is convenient for visualizing overall performance but is too inaccurate for detailed calculations and design. The magnetizing current is not constant, but decreases with load because of the primary impedance drop. All of the circuit constants vary over the operating range due to magnetic saturation and skin effect. The equivalent circuit method predominates for analysis and design under steady-state conditions. The impedances can be adjusted to fit the conditions at each calculation point.

Circle Diagram. The voltage-current relations of the polyphase induction machine are roughly indicated by the circuit of Fig. 20-26. The magnetizing current I_M proportional to the voltage and lagging 90° in phase is nearly constant over the operating range, while the load current varies inversely with the sum of primary and secondary impedances. As the slip s increases, the load current and its angle of lag behind the voltage both increase, following a nearly circular locus. Thus, the circle diagram (Fig. 20-27) provides a picture of the motor behavior.

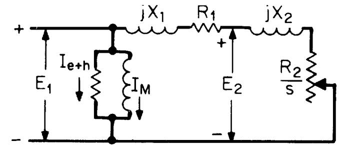

FIGURE 20-26 Equivalent circuit for circle diagram.

The data needed to construct the diagram are the magnitude of the no-load current *ON* and of the blocked-rotor current *OS* and their phase angles with reference to the line voltage *OE*. A circle with its center on the line *NU* at right angles to *OE* is drawn to pass through *N* and *S*. Each line on the diagram can be measured directly in amperes, but it also represents voltamperes or power, when multiplied by the phase voltage times number of phases. The line *VS* drawn parallel to *OE* represents the total motor power input with blocked rotor, and on the same scale *VT* represents the corresponding primary I^2R loss. Then *ST* represents the power input to the rotor at standstill, which, divided by the synchronous speed, gives the starting torque.

At any load point *A*, *OA* is the primary current, *NA* the secondary current, and *AF* the motor power input. The motor output power is *AB*, the torque X (synchronous speed) is *AC*, the secondary I^2R loss is *BC*, primary I^2R loss *CD*, and no-load copper loss plus core loss *DF*. The maximum power-factor point is *P*, located by drawing a tangent to the circle from *O*. The maximum output and maximum torque points are similarly located at *Q* and *R* by tangent lines parallel to *NS* and *NT*, respectively.

The diameter of the circle is equal to the voltage divided by the standstill reactance or to the blocked-rotor current value on the assumption of zero resistance in both windings. The maximum torque of the motor, measured in kilowatts at synchronous speed, is equal to a little less than the radius of the circle multiplied by the voltage *OE*.

Equivalent Circuit. Figure 20-28 shows the polyphase motor circuit usually employed for accurate work. The advantages of this circuit over the circle-diagram method are that it facilitates the derivation of simple formulas, charts, or computer programs for calculating torque, power factor, and

$$X = \frac{f}{f_t}\sqrt{\frac{V^2}{3I^2} - \left(\frac{W}{3I^2}\right)} \qquad \text{(see text)}$$

$X_1 = X_2 = 0.5X$ for single squirrel-cage or wound-rotor motors

$X_1 = 0.4X$ and $X_2 = 0.6X$ for low-starting-current motors

other motor characteristics and that it enables impedance changes due to saturation or multiple squirrel cages to be readily taken into account.

Formulas for calculating the constants from test data are given in Table 20-2, and their definitions are given in Table 20-3.

Inspection of the circuit reveals several simple relationships which are useful for estimating purposes. The maximum current occurs at standstill and is somewhat less than E/X. Maximum torque occurs when $s = R_2/X$, approximately, at which point the current is roughly 70% of the standstill current.

TABLE 20-3 Definitions of Equivalent-Circuit Constants

Unless otherwise noted, all quantities except watts, torque, and power output are per phase for 2-phase motors and per phase Y for 3-phase motors:

E_0 = impressed voltage (volts) = line voltage ÷ $\sqrt{3}$ for 3-phase motors
I_1 = primary current (amperes)
I_2 = secondary current in primary terms (amperes)
I_M = magnetizing current (amperes)
R_1 = primary resistance (ohms)
R_2 = secondary resistance in primary terms (ohms)
R_0 = resistance at primary terminals (ohms)
X_1 = primary leakage reactance (ohms)
X_2 = secondary leakage reactance (ohms)
$X = X_1 + X_2$
X_0 = reactance at primary terminals (ohms)
X_M = magnetizing reactance (ohms)
Z_1 = primary impedance (ohms)
Z_2 = secondary impedance in primary terms (ohms)
Z_0 = impedance at primary terminals (ohms)
Z = combined secondary and magnetizing impedance (ohms)
s = slip (expressed as a fraction of synchronous speed)
N = synchronous speed (revolutions per minute)
m = number of phases
f = rated frequency (hertz)
f_t = frequency used in locked-rotor test
T = torque (foot-pounds)
W_0 = watts input
W_H = core loss (watts)
W_F = friction and windage (watts)
W_{RL} = running light watts input
W_s = stray-load loss (watts)

Hence, the maximum torque is approximately equal to $E^2/2X$. This gives the basic rule that the percent maximum torque of a low-slip polyphase motor at a constant impressed voltage is about half the percent starting current.

By choosing the value of R_2, the slip at which maximum torque occurs can be fixed at any desired value. The maximum-torque value itself is affected, not by changes in R_2, but only by changes in X and to a slight degree by changes in X_M.

The magnetizing reactance X_M is usually 8 or more times as great as X, while R_1 and R_2 are usually much smaller than X, except in the case of special motors designed for frequent-starting service.

The equivalent circuit of Fig. 20-28 shows that the total power P_{g1} transferred across the air gap from the stator is

$$P_{g1} = mI_2^2 \frac{R_2}{s} \tag{20-14}$$

The total rotor copper loss is evidently

$$\text{Rotor copper loss} = mI_2^2 R_2 \tag{20-15}$$

The internal mechanical power P developed by the motor is therefore

$$\begin{aligned} P = P_{g1} - \text{rotor copper loss} &= mI_2^2 \frac{R_2}{s} - mI_2^2 R_2 \\ &= mI_2^2 R_2 \frac{1-s}{s} \qquad (20\text{-}16) \\ &= (1-s)P_{g1} \end{aligned}$$

We see, then, that of the total power delivered to the rotor, the fraction $1 - s$ is converted to mechanical power and the fraction s is dissipated as rotor-circuit copper loss. The internal mechanical power per stator phase is equal to the power absorbed by the resistance $R_2 (1 - s)/s$. The internal electromagnetic torque T corresponding to the internal power P can be obtained by recalling that mechanical power equals torque times angular velocity. Thus, when ω_s is the synchronous angular velocity of the rotor in mechanical radians per second

$$P = (1-s)\,\omega_s T \tag{20-17}$$

with T in newton-meters. By use of Eq. (20-16)

$$T = \frac{1}{\omega_s} mI_2^2 \frac{R_2}{s} \tag{20-18}$$

For T in foot-pounds and N_s in revolutions per minute

$$T = \frac{7.04}{N_s} mI_2^2 \frac{R_2}{s} \tag{20-19}$$

Torque and Power. Considerable simplification results from application of Thévenin's network theorem to the induction-motor equivalent circuit. Thévenin's theorem permits the replacement of any network of linear circuit elements and constant phasor voltage sources, as viewed from two terminals by a single phasor voltage source E in series with a single impedance Z. The voltage E is that appearing across terminals a and b of the original network when these terminals are open-circuited; the impedance Z is that viewed from the same terminals when all voltage sources within the network are short-circuited. For application to the induction-motor equivalent circuit, points a and b are taken as those so designated in Fig. 20-28. The equivalent circuit then assumes the forms given in Fig. 20-29. So far as phenomena to the right of points a and b are concerned, the circuits of Figs. 20-28 and 20-29 are identical when the voltage V_{1a} and the impedance $R_1 + jX_1$ have the proper values. According to

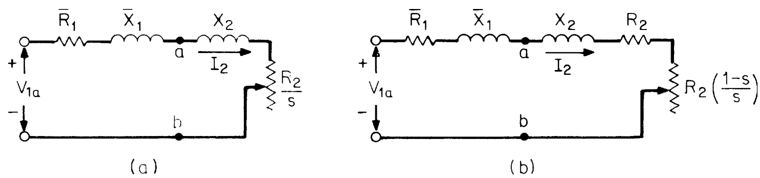

FIGURE 20-29 Induction-motor equivalent circuit simplified by Thévenin's theorem.

Thévenin's theorem, the equivalent source voltage V_{1a} is the voltage that would appear across terminals a and b of Fig. 20-28 with the rotor circuits open and is

$$V_{1a} = E_0 - I_0 (R_1 + jX_1) = E_0 \frac{jX_M}{R_1 + jX_{11}} \tag{20-20}$$

where I_M is the zero-load exciting current and

$$X_{11} = X_1 + X_M$$

is the self-reactance of the stator per phase and very nearly equals the reactive component of the zero-load motor impedance. For most induction motors, negligible error results from neglecting the stator resistance in Eq. (20-20). The Thévenin equivalent stator impedance $R_1 + jX_1$ is the impedance between terminals a and b of Fig. 20-28, viewed toward the source with the source voltage short-circuited, and therefore is

$$\overline{R}_1 + j\overline{X}_1 = R_1 + jX_1 \qquad \text{in parallel with} \quad jX_M$$

From the Thévenin equivalent circuit (Fig. 20-29) and the torque expression (Eq. 20-18), it can be seen that

$$T = \frac{1}{\omega_s} \frac{mV_{1a}^2(R_2/s)}{(\overline{R}1} + R_2/s)^2 + (\overline{X}_1 + X_2)^2 \tag{20-21}$$

The slip at maximum torque, $s_{\max T}$, is obtained by differentiating Eq. (20-21) with respect to s and equating to zero:

$$s_{\max T} = \frac{R_2}{\sqrt{\overline{R}_1^2 + (\overline{X}_1 + X_2)^2}}$$

The corresponding maximum torque is

$$T_{\max} = \frac{1}{\omega_s} \frac{0.5mV_{1a}^2}{\overline{R}_1 + \sqrt{\overline{R}_1^2 + (\overline{X}_1 + X_2)^2}}$$

20.4.2 Testing of Polyphase Induction Machines

Proof of guaranteed performance, the determination of torque or efficiency of driven machines, and the evaluation of design changes are some of the purposes that require accurate tests of induction machines. Normally, running-light, locked-rotor, resistance, and dielectric tests only are made on standard motors. Input-output tests or segregated-loss tests are made when accurate efficiency determination is required. The inconvenience of making input-output tests and the inaccuracies inherent in any method which determines the losses as a small difference between two large quantities make the segregated-loss methods of test preferable in many cases. Such tests are especially necessary when actual performance under the varying conditions of service is to be determined from a limited number of factory or laboratory test runs. Experience has shown that the equivalent-circuit method of calculation enables accurate predictions of efficiency and other performance data to be made, provided the circuit "constants" are determined in advance by careful tests.

The IEEE Test Code for Induction Machines[1] gives authoritative procedures for conducting all usual tests, and many of the data contained in the following sections are derived from this source.

Running-Light Test. The motor is run at no load with normal frequency and voltage applied, until the watts input becomes constant. On slip-ring motors, the brushes are short-circuited. Readings of amperes and watts are taken at one or more values of impressed voltage, with rated frequency maintained. Accurately balanced phase voltages and a sine-wave form of voltage are necessary for good results, requiring operation of the test alternator and transformers well below magnetic saturation. The watts input at rated voltage will be the sum of the friction and windage, core loss, and no-load primary I^2R loss. Subtracting the primary I^2R loss at the temperature of test from the input gives the sum of the friction and windage and core loss. Segregation of the core loss from the windage and friction is not necessary for normal efficiency or other rated-voltage performance calculations. However, the segregation can be made, if desired, by taking amperes and watts input readings, at rated frequency, at different voltages varying from 125% of normal down to about 15% voltage, or the point of minimum current. Plotting the input watts, less primary I^2R, against the square of the voltage and extrapolating the lower part of the curve in a straight line to intercept the zero-voltage axis determines the friction and windage. Typical data of such a test are shown in Fig. 20-30.

The value of the magnetizing reactance X_M in Fig. 20-28 is determined from the no-load current at rated voltage I_0 by using the value of primary leakage X_1 determined from locked-rotor test data.

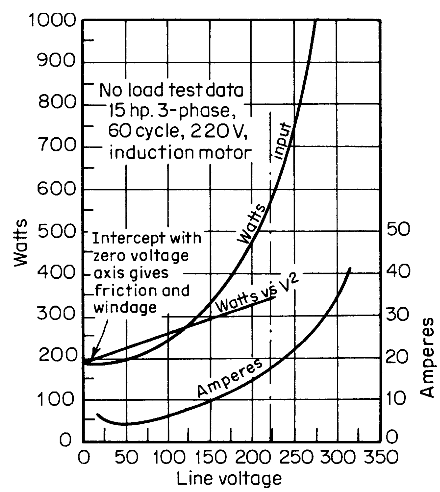

FIGURE 20-30 No-load excitation curves.

Locked-Rotor Test. The motor is blocked so it cannot rotate; a reduced voltage of rated frequency is applied to the terminals; and readings of volts, watts, and amperes are taken. Readings should be taken quickly, and the temperature of the windings should be observed before and after the test to minimize errors due to changing resistance values. In the case of machines with closed-slot rotors or very small air gaps, magnetic saturation of the leakage paths will occur, and it may be desirable to take readings at half or full voltage to establish the actual value of starting current. Equivalent-circuit performance calculations, however, should be based on data taken at approximately rated current.

When only low-voltage test data are available, the locked-rotor current at higher voltages can be estimated by the formula

$$I = \frac{V - V_0}{V_t - V_0} I_t \tag{20-22}$$

where V_t, I_t = test values of voltage and locked-rotor current; V, I = corresponding values at a different voltage; and V_0 = intercept of test current-voltage curve with zero-voltage axis, obtained by extrapolating the test curve as a straight line through points in the approximate range of 50% to 200% current. V_0 represents the voltage due to flux of saturation density crossing closed slot bridges and similar leakage flux paths.

The motor impedance per phase is determined from the volts, amperes, and watts readings. The total resistance component for a 3-phase motor is

$$R = \frac{W}{3I^2} \quad \Omega/\text{phase} \quad \text{Y} \tag{20-23}$$

and the reactance component is

$$X = \sqrt{\frac{V_2}{3I^2} - R^2} \quad \Omega/\text{phase} \quad \text{Y} \tag{20-24}$$

where W = watts input, I = line current, and V = voltage between lines.

Normally, the primary and secondary leakage-reactance values X_1 and X_2 are assumed equal, each having the value $X/2$.

The primary resistance is measured with direct current, a current about one-quarter of full-load value being preferably used, and readings being taken quickly to avoid errors due to temperature changes during the test. The primary resistance per phase Y is equal to one-half the resistance between any two terminals.

Subtracting the primary resistance at the temperature of test from the resistance component of the total impedance gives the effective secondary resistance at standstill. The starting torque may be calculated from this value by the equation

$$\text{Starting torque} = \frac{7.04KmI^2R_{2e}}{N_s} \quad \text{ft}\cdot\text{lb} \tag{20-25}$$

where I = amperes starting current per phase at specified voltage; m = number of phases; N_s = synchronous speed in r/min; R_{2e} = resistance component of motor impedance, less primary resistance at temperature of test, in ohms per phase; K = an empirical constant, usually approximately 0.9, which allows for nonfundamental secondary losses.

In practice, it is usual to measure the torque produced, by means of a lever arm and scale, in which case Eq. (20-25) provides a useful check on the accuracy of the measurements.

In the case of deep-bar or double squirrel-cage motors, the effective secondary reactance at speed is materially higher than at standstill, owing to the progressive shifting of the secondary current from the low-reactance, high-resistance paths into the low-resistance, high-reactance paths as the secondary, or slip, frequency decreases. Hence, for accurate performance calculations, it is necessary to determine the motor reactance at low secondary frequency. If a low-frequency supply is available, the locked-rotor test may be repeated at 15 Hz, or at most 25 Hz, for a 60-Hz motor. Calculation of the low-frequency reactance by Eq. (20-24) and multiplying this by the ratio of the rated to the test frequency will give the proper value to use in operating performance calculations.

Alternatively, the reactance value at speed may be obtained by adding an amount ΔX to the reactance determined by full-frequency locked-rotor test. The value of ΔX is approximately

$$\Delta X = R_{2e} - R_2 \tag{20-26}$$

where R_2 = secondary resistance of full-load slip, determined by the slip test.

Slip Test. Whenever feasible, a current-slip curve should be taken under actual load conditions, with rated voltage and frequency maintained at the motor terminals. Measurements at a few points in the neighborhood of full-load current are usually sufficient; but for slip-ring motors a wider range should be covered, owing to the variable resistance and should therefore be measured with a slip meter or stroboscopically. The slip-meter method makes use of a revolution counter differentially geared to the motor under test and to a small synchronous motor driven from the same power supply at the same synchronous speed. Care must be taken to correct the observed values of slip for the difference between the test temperature and the standard value of 75°C or the temperature attained in a full-load heat run with an ambient temperature of 25°C.

In practice, the value of current corresponding to an assumed value of $R_s 2/s$ is calculated exactly by the equivalent circuit; the corresponding value of s is read off the slip-current curve; and the true value of R_2 is obtained by multiplying R_2/s by this value of s. However, R_2 may be approximately determined as follows:

Very roughly, the secondary resistance is equal to

$$R_2 = 1.1\frac{E \cdot s}{I_1} \quad \text{approx} \cdot \Omega/\text{phase} \tag{20-27}$$

where E = terminal voltage per phase, s = ratio of revolutions per minute of slip to synchronous speed, and I_1 = observed phase current.

The coefficient 1.1 varies over a range of about 1 to 1.2, depending on the motor characteristics and the value of the test load.

In case direct slip measurements are not practicable, the value of R_2 determined by Eq. (20-23) in a low-frequency locked-rotor test may be used. Or, in the case of a wound rotor, the actual resistance between slip rings may be measured and multiplied by the square of the ratio of primary to secondary volts to obtain the resistance referred to primary. The voltage ratio is obtained by measurement of primary and secondary voltages at standstill with the slip rings open-circuited. Averages of several rotor positions are taken to avoid errors due to possible unbalance.

Stray-Load Loss Tests. Stray-load losses, W_s, are defined as the excess of the total measured losses above the sum of the friction and windage, core, and copper losses calculated for the conditions of load from the no-load tests described above. These extra losses are made up chiefly of high-frequency core losses and rotor I^2R losses caused by the pulsations of the leakage-reactance fluxes produced by load currents. While the stray-load losses may be determined by direct input-output tests with a dynamometer or calibrated driving motor, the result is a small difference between two large quantities and so accuracy is very difficult to obtain. Whenever such tests are made, it is desirable to repeat them with the direction of power flow reversed, so the measurement errors may be substantially canceled out.

There are several ways of determining the stray-load loss by separate loss measurements, but the procedure is fairly complex and must be carefully done if accurate results are to be obtained. These are described in the *IEEE Test Code for Polyphase Induction Machines*.

Performance Calculations. From the foregoing tests, all the circuit constants may be determined, enabling the equivalent-circuit calculations to be carried out. To facilitate this, the formulas for calculating the constants as defined in Table 20-3 are collected in Table 20-2.

The procedure in making performance calculations based on test data is first to divide E_0 by the appropriate expected value of normal current, an arbitrary value of R_2/s being thus obtained. With this value and the known circuit constants, calculations are carried through for one point, determining the actual value of I. By entering the test slip-current curve, the true value of s is found, and from this and R_2/s, R_2 is calculated. All the circuit constants are then known, whence the efficiency, power factor, torque, etc., are determined. Additional points are calculated with different values of s, covering the desired range of loads, and the exact characteristics are taken off curves plotted from the calculated results.

If values of torque, current, etc., are desired for considerable overloads or throughout the accelerating range, the value of R_2 and X should be modified to allow for magnetic saturation and eddy currents. Curves of reactance against current obtained by locked-rotor tests over the desired range of values and values of R_{2e} and corresponding values of ΔX obtained by locked-rotor tests at different frequencies are desirable for this purpose, especially in cases of closed-slot or double squirrel-cage rotors.

Temperature Tests. Temperature tests are made to determine the temperature rise of insulated windings under load conditions. ANSI Standards specify a limiting temperature for continuous-rated machines of 50°C by thermometer or 60°C by either the resistance- or the embedded-detector method for Class A insulating materials and corresponding values of 70°C by thermometer and 80°C by resistance or embedded detector for Class B insulation. Usually, the temperature is measured by mercury thermometers or thermocouples applied to the hottest accessible parts of the core and windings in several different locations. A small amount of putty is used to shield thermometer bulbs from the surrounding air, and care is taken to avoid external air currents, varying ambient temperatures, or other factors, which may introduce errors.

The preferred method of making a full-load temperature test is to maintain nameplate voltage, current, and frequency until the temperature becomes constant, readings being taken every half hour. When constant temperature is reached, the motor is stopped as quickly as possible and additional thermometers are applied to the rotating parts as soon as these have come to rest. The maximum permissible time of stopping is 1 min for machines of less than 50 kW rating, 2 min for 50 to 200 kW ratings, and 3 min for machines larger than 200 kW. The winding temperatures usually increase after shutdown; so readings must be recorded at frequent intervals until definitely falling temperatures are observed. The highest temperature reached at any time during the test is taken as the correct value. If the temperatures fall continuously after shutdown, a curve should be plotted of temperature versus time and extrapolated back to the moment of shutdown.

For protected-type or totally enclosed machines, it is often preferable to determine the temperature by the rise-of-resistance method. In this case, the "cold" resistance of the winding is measured at a known temperature, usually after the machine has been standing overnight at a uniform room temperature; and the "hot" resistance is measured immediately after shutdown. The hot resistance is taken as the highest value obtained after shutdown or is extrapolated back to the moment of shutdown if the resistance falls continuously.

The temperature is then calculated from the following formula:

$$T = \frac{R_T(234.5 + t)}{R_t} - 234.5 \qquad (20\text{-}28)$$

where T = winding temperature when R_T was measured, R_T = hot resistance, R_t = cold resistance, and t = winding temperature when R_t was measured.

20.4.3 Characteristics of Polyphase Induction Motors

Types. All polyphase induction motors may be classified as squirrel-cage or wound-rotor, and may be of the single-speed or multispeed type. Squirrel-cage motors are further classified by NEMA[1] for torque-speed and current-speed curves as Designs A, B, C, and D, and by Code designations from A to V for locked-rotor kVA/hp. For all induction motors, the allowable temperature rises and insulation systems are designated by classes A, B, F, and H. Finally, the mechanical dimensions are designated by frame sizes, and in enclosures from dripproof to totally enclosed with various types of ventilation. Both squirrel-cage and wound-rotor motors may be of the single-speed or multispeed type.

Based upon efficiency, motors are also classified as standard and energy-efficient motors. Several manufacturers have developed product lines of energy-efficient motors under various trade names. Some of these trade names are XE-Energy Efficient (Reliance Electric Co.), Energy Efficient Corro-Duty (US Electric Motors), and PE-21 Plus (Siemens).

Squirrel-Cage Motors. All integral-horsepower induction-motor design categories can mechanically withstand the magnetic stresses and locked-rotor torques of full-voltage line starting. The torque- and current-speed curves for Design A, B, C, and D squirrel-cage motors are shown in Figs. 20-31 to 20-33. Design B motors are most widely used; they have starting-torque and line-starting current characteristics suitable for most power systems. Design C and D motors have higher torque than Class B motors. For all design motors, the percentage torques tend to decline with

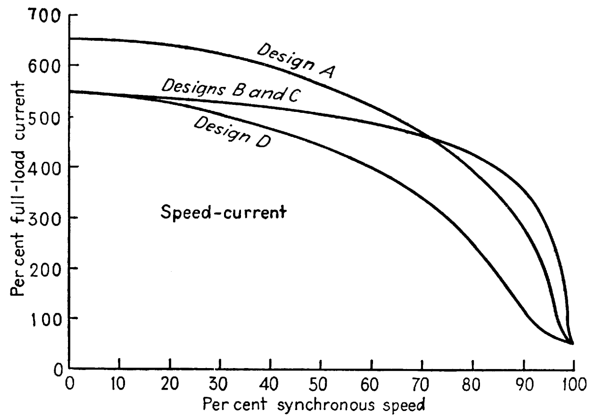

FIGURE 20-31 Typical speed-current curves for squirrel-cage induction motors.

increased hp rating cost. Typical load conditions and applications for Design A, B, C, and D motors are given in Table 20-4.

Wound-Rotor Motors. An insulated winding, usually 3 phase, is provided on the rotor; the terminal of each phase is connected to a slip ring on the shaft. The stationary brushes, which bear on the slip rings, are connected to external adjustable resistance or solid-state converters by which power can be removed from, or injected into, the rotor to adjust the speed. Speed-torque and speed-current curves for a typical wound-rotor motor for various amounts of external resistance are shown in Fig. 20-34. The numbers on the curves refer to the percent external resistance; 100% resistance gives rated torque at standstill. The use of solid-state converters in a modified Kraämer system is described later in reference to synchronous motor starting.

Wound-rotor motors are normally started with relatively high external resistance and this resistance is short-circuited in steps as the motor comes up to speed. Liquid rheostats are used in the higher ratings. This procedure allows the motor to deliver high-starting and accelerating torques, yet draw relatively light line current. Furthermore, most of the rotor-circuit losses during acceleration are dissipated in the external resistor rather than within the motor.

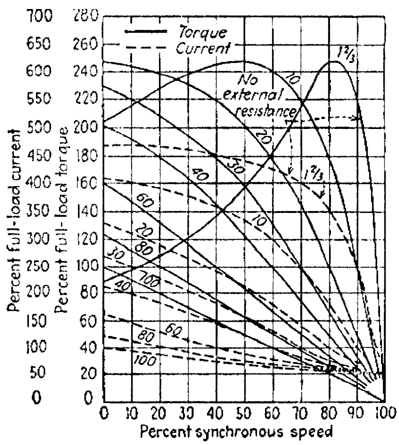

FIGURE 20-34 Speed-torque and speed-current curves of typical wound-rotor induction motor.

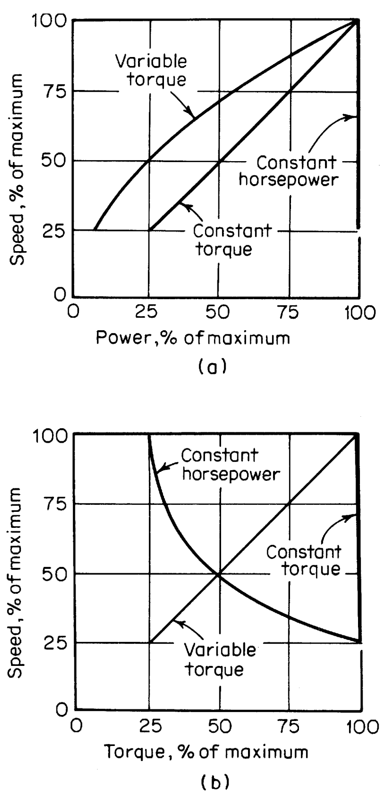

FIGURE 20-35 Basic load characteristics of multispeed motors having a 4:1 maximum speed ratio: (*a*) power; (*b*) torque.

The curves of Fig. 20-34 indicate that the external resistance reduces the speed at which the motor will operate with a given load torque. For any one value of external resistance, the motor has varying speed characteristics; any change in load results in a considerable change in speed. The lower the operating speed, the more pronounced the effect, so that it is usually not feasible to operate at less than 50% of full speed by this method. Furthermore, because the power loss in the rotor and external resistor is proportional to the slip, the efficiency is reduced in direct proportion to the speed reduction.

Breakdown torque is given by NEMA in MG1-12.40. Secondary data, including open-circuit slip-ring voltage and short-circuit slip-ring current, at standstill, are given in MG1-1034.

Slip-ring motors with external resistance are used as adjustable-speed motors from 50% to full speed for loads such as pumps and fans. They are used over the full speed range for hoists, elevators, and ski lifts. In addition, slip-ring motors are used to provide high starting and accelerating torque with low current for centrifuges, crushers, pulverizers, and other high-inertia loads. Solid-state ac and dc drives have replaced wound-rotor motors in many applications.

Multiple-Speed Squirrel-Cage Motors. Multispeed squirrel-cage motors may be of the single-winding or two-winding type. The former have a stator winding, which can be connected to give either one of two speeds having a ratio of 2:1. The method of connection is usually furnished by the controller manufacturer. The frame of the two-speed single-winding motor is about the same as that of the single-speed motor. The two-winding motor has two separate stator windings, which can be wound for any number of poles so that any two synchronous speeds can be obtained. In addition one or both of the stator windings may be arranged for reconnection as in a single-winding motor, giving a total of three or four speeds, but the two speeds obtained on a single winding must have a ratio of 2:1. Thus, a four-speed two-winding motor might have speeds of 1800, 900, 1200, and 600 r/min.

Multispeed motors are designed as (1) variable-torque motors, (2) constant-torque motors, and (3) constant-horsepower motors. The rated torque at four speed points for each type is shown in Fig. 20-35. Variable-torque motors have 1200/600 r/min, and are used on loads, such as in centrifugal pumps and fans whose horsepower requirement decreases more rapidly than the square of the reduction in speed. Constant-torque motors have horsepower ratings at each speed directly proportional to the speed, for example, 20/10 hp and 1200/600 r/min, and are used on conveyors, mixers, reciprocating compressors, printing presses, and other "constant-torque" loads. Constant-horsepower motors have the

same horsepower rating at all speeds. They are used principally on machine tools, such as lathes, boring mills, planers, and radial drills. Multispeed motors of the constant-torque or variable-torque type are usually given a standard horsepower rating at the top speed but may have odd horsepower ratings at the lower speeds, since the latter are fixed by the speed ratios.

Temperature Rise. Temperature rise is no longer used as a rating method. Instead the manufacturer specifies the ambient temperature and the insulation class. The temperature rise will not exceed the limit for the insulation system when the motor is loaded to its rating or to its service factor load. The temperature rise limits are given in Table 20-5.

The temperature attained by squirrel-cage windings, cores, and mechanical parts shall not injure the machine in any respect. Temperatures shall be determined in accordance with the *IEEE Test Procedures*, Publication Nos. 112A and 114. For Class F and H insulation systems, special consideration shall be given to the bearings and lubrication.

The temperature rise for motors operating at any other ambient temperature T_a than 40°C shall not exceed the values

For items a, b, e, f, i: temperature rise $= 0.9(T_h - T_a)$

For items c, d, g, h: temperature rise $= 0.965(T_h - T_a)$

where T_h, the hot-spot temperature, is given by the following table:

Class	Items *a* and *f*	All other items
A	115°C	105°C
B	140°C	130°C
F	165°C	155°C
H		180°C

Preferred values of ambient temperature above 40°C are 50°C, 65°C, 90°C, 115°C.

The time ratings for single-phase and polyphase induction motors shall be 5, 15, 30, 60 min, and continuous. All short-time ratings are based upon a load test which shall commence when the windings and parts of the motor are within 5°C of the ambient temperature.

Service Factor. General-purpose fractional- and integral-horsepower motors are given a "service factor," which allows the motor to deliver greater than rated horsepower, without damaging its insulation system. The motor is operated at rated voltage and frequency. The standard service factors are 1.4 for motors rated $^1/_{20}$ to $^1/_8$ hp; 1.35 for $^1/_6$ to $^1/_3$ hp; 1.25 for $^1/_2$ hp to the frame size for 1 hp at 3600 r/min. For all larger motors through 200 hp, the service factor is 1.15. For 250 to 500 hp, the service factor is 1.0.

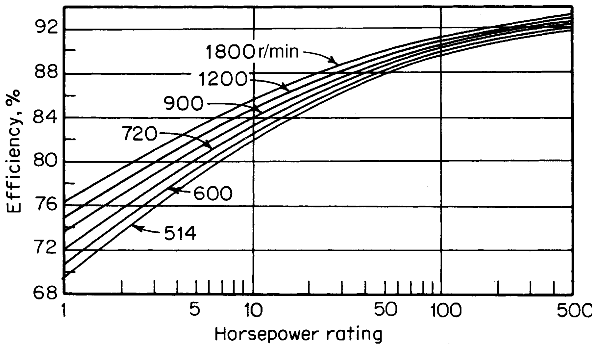

FIGURE 20-36 Typical full-load efficiencies of Design B squirrel-cage motors.

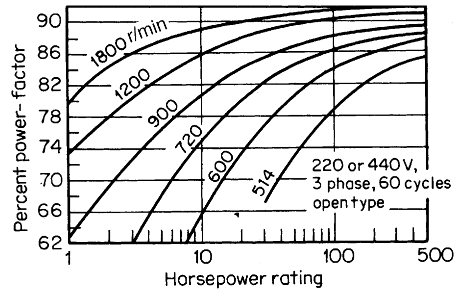

FIGURE 20-37 Typical full-load power factors of Design B squirrel-cage motors.

Efficiency and Power Factor. Typical full-load efficiencies and power factors of standard Design B squirrel cage induction motors are given in Figs. 20-36, and 20-37, respectively. The efficiencies of Design A motors are generally slightly lower, and those of Design D motors considerably lower. The power factors of Design A squirrel-cage induction motors are slightly higher, and those of Design C are slightly lower. Energy-efficient motors are those whose design is optimized to reduce losses. Comparative efficiencies of standard and energy-efficient motors of NEMA Design B are shown in Fig. 20-38.

Full-Load Current. With the efficiency and power factor of a 3-phase motor known, its full-load current may be calculated from the formula

$$\text{Full-load current} = \frac{746 \times \text{hp rating}}{1.73 \times \text{efficiency} \times \text{pf} \times \text{voltage}} \tag{20-29}$$

where the efficiency and power factor are expressed as decimals.

Torques and Starting Currents. Starting and breakdown torques of common Design A, B, and C squirrel-cage induction motors are given in Table 20-6. Relative values for other classes of squirrel-cage

motors are indicated by the curves of Fig. 20-33. The minimum breakdown torque for wound-rotor motors is 200% of full-load torque. As indicated by the curves of Fig. 20-34, the starting torque and starting current of wound-rotor motors vary with the amount of external resistance in the secondary circuit.

The starting kVA of a squirrel-cage motor is indicated by a code letter stamped on the nameplate. Table 20-7 gives the corresponding kVA for each code letter, and the locked-rotor current can be determined from

$$\text{Locked-rotor current} = \frac{\text{kVA/hp} \times \text{hp} \times 1000}{k \times \text{line volts}} \tag{20-30}$$

where $k = 1$ for single-phase, and $k = 1.73$ for 3-phase.

Maximum locked-rotor current for Design B, C, and D 3-phase motors has been standardized as shown in Table 20-8 for 230 V. The starting current for motors designed for other voltages is inversely proportional to the voltage.

Starting Methods. Wound-rotor motors are invariably started on full voltage but with external resistance in the secondary circuit. Ordinarily sufficient resistance is provided to give 100% torque at standstill, which means that 100% current will be drawn from the line. If a higher torque is required to start the load, less external resistance must be used, and the current drawn is proportionately higher. As the motor accelerates, the external secondary resistance is short-circuited in one or more steps.

The locked-rotor values in Table 20-8 are generally recognized as the minimum needed by motor designers to obtain the required torque characteristics for general-purpose motors. Squirrel-cage motors with these values are usually acceptable for full-voltage starting on power lines and also on combined light and power secondaries of 208 or 230 V, if manually controlled (infrequently started).

In the case of automatically controlled (frequently started) equipment, with 208- or 230-V motors supplied from combined light and power secondaries, current-reducing starters to reduce the current to about 65% of these values may be required, unless consultation with the power company indicates that the available system capacity will permit use of full-voltage starting. In any case, consultations with the power company for motor applications above 25 hp are advisable.

Autotransformer starters (compensators) are the most popular of any reduced-voltage type. They have the advantage that the ratio of torque developed by the motor to the current drawn from the line remains substantially the same as for full-voltage starting. The motor torque and the current drawn from the line (neglecting the magnetizing current of the autotransformer) are both reduced in proportion to the square of the voltage impressed on the motor. The magnetizing current of the autotransformer generally does not exceed 25% of motor full-load current. Normally, the motor accelerates nearly to full speed on the reduced-voltage connection and is then transferred to full voltage. Since the circuit to the motor is opened and then immediately reclosed, a transient inrush of current occurs which may be of much greater magnitude than the current normally drawn by the motor at the speed at which the transfer is made. This transient inrush, however, is of such extremely short duration that it does not produce an objectionable voltage disturbance on the average power system. Standard autotransformer starters are provided with 65% and 80% voltage taps in sizes up to 50 hp and with 50%, 65%, and 80% voltage taps in the larger sizes.

"Part-winding" starting is being more widely used for reducing starting current. This involves arranging the stator winding so that, by use of adequate control devices, one part of the stator winding is first energized and subsequently the remainder of the winding is energized in one or more steps. The purpose is to reduce the initial values of the starting current drawn and/or the starting torque developed by the motor. The usual arrangement involves energizing one-half the stator winding on the first step, resulting in approximately 50% of normal locked-rotor torque and approximately 60% of normal locked-rotor current. While this torque may be insufficient to start the motor in some applications, it permits drawing full-winding starting current from the system in two increments. Another method is to connect two-thirds of the winding on the first step, by using a 4-pole contactor, in which case the motor should accelerate promptly to full speed. The remaining third of the winding is then connected by closing a second contactor with only two poles.[2–4]

Resistor-type reduced-voltage starters are sometimes used. They have the disadvantage that the current drawn from the line is reduced in direct ratio to the impressed voltage, while the torque developed by the motor is reduced as the square of this voltage. The resistor is short-circuited, either all at once or in steps, when the motor comes up to speed. The circuit for the motor is not broken in transferring to full voltage, as is the case with the autotransformer starter. These features make the resistor-type starter adapted for use where "increment-type" starting-current restrictions exist. With the resistor-type starter, the contactors, which short-circuit the resistors as well as the line contactors, must carry the full current of the motor, whereas in part-winding starting, the contactors for the two parts of the winding each carry only half the total current.

Reactor-type reduced-voltage starters are sometimes used on larger motors, most frequently on high-voltage motors (2300 V or above), where oil circuit breakers are necessary to provide sufficient current-interrupting capacity. In such cases, the reactor and starting circuit breaker are placed in the neutral of the motor. The breaker can then be of low-interrupting capacity, since the fault current at this point is limited by the reactance of the motor windings.

Wye-delta starting, though quite common abroad, is used in the United States primarily for refrigeration compressors. This starter consists of a switching arrangement that transfers the motor winding from Y for starting to Δ for running. The current drawn and the torque developed by the motor are thus reduced to only one-third their full voltage values. This very low torque, the extra contactors required, and the current inrush when the circuit is reclosed on Δ make this scheme less attractive than others.

Motors are frequently supplied from power systems consisting of complex networks for which calculation of the voltage drop would be difficult. The voltage drop may be estimated, however, if the short-circuit kVA is known at the point of power delivery.

When motor-starting kVA is drawn from a system, the voltage drop in percent of the initial voltage is approximately equal to 100 times the motor-starting kVA divided by the sum of this kVA and the short-circuit kVA. The motor-starting kVA used should be that drawn by the motor if the initial system voltage is maintained. For example, if a 1000-hp motor has a starting kVA of 5000 at the initial system voltage and the system short-circuit kVA is 50,000, the voltage drop will be approximately

$$\frac{5000 \times 100}{(5000 + 50{,}000)} = 9\% \text{ of initial voltage}$$

In many systems, the short-circuit kVA varies over a wide range depending on the number of parallel lines in service, service interconnections, etc. While the highest short-circuit kVA is of interest for circuit interruption, the minimum short-circuit kVA should be used for voltage-drop calculations since it gives the highest value.

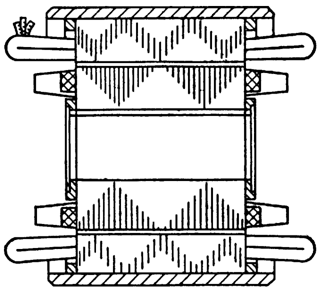

FIGURE 20-39 Cross section of shell-type motor.

Shell-Type Motors. These motors consist of stators and rotors only, without shafts, end shields, bearings, or conventional frame (Fig. 20-39). The rotors are mounted directly on a shaft of the driven machine, which must also include a suitable support for the stator and a ventilating arrangement. The motors are built with relatively small outside diameters but may be slightly longer than standard machines. Furthermore, horsepower ratings over a rather wide range are built in each frame diameter, the ratings for the different diameters overlapping slightly. Although a great many of the motors used are for operation at standard commercial frequencies giving speeds up to 3600 r/min (on 60 Hz), they are frequently supplied for operation at higher frequencies and correspondingly higher speeds. Frequencies up to 2000 Hz with a corresponding 2-pole motor speed of 120,000 r/min have been used, but the more common "high" frequencies range from 60 to 240 Hz, giving 2-pole motor speeds up to 14,400 r/min.

Shell-type motors are used principally on machine tools and woodworking machinery. Their relatively small physical size facilitates a compact design with maximum flexibility in arrangement of machine parts. The small diameter of the motors is of particular value, since it allows close spacing of spindle shafts.

The wide range of ratings available in each diameter reduces the cost of providing suitable mountings for the motors.

Motors of similar mechanical construction but with special insulation are used in hermetically sealed refrigeration and air-conditioning compressors, where the motor runs in an atmosphere of refrigerating gas. The insulation must neither harm nor be harmed by the refrigerant and, so that the refrigerant may be kept clean and dry, must not trap moisture or dirt.

Dimensions. NEMA has standardized mounting dimensions for various types of motors, those standardized for polyphase induction motors covering ratings from 1 to 125 hp (at 1800 r/min). For convenience each set of standardized dimensions has been assigned a frame number, and the various ratings of motors have been assigned frame numbers from the series. Any motor offered by a manufacturer having a frame number from this series will have the corresponding standardized mounting dimensions. These are listed in *NEMA Motor and Generator Standard*, Publ. MG1-1987.

20.4.4 Single-Phase Induction Motors

General Theory. If one supply line to a polyphase induction motor is opened, the motor will not develop any starting torque, although if it is already operating, it will continue to run at slightly reduced speed, with a somewhat lower breakdown torque. The crux of the single-phase motor problem, therefore, is in providing auxiliary means for starting.

The magnetic field of a single-phase winding carrying alternating current may be represented as a phasor stationary in space but alternating in time, or as the sum of two equal and oppositely revolving field phasors, which are constant in magnitude. In a polyphase motor, the backward-revolving field phasors of the several phases cancel each other, and the forward-revolving ones add directly, giving a uniform revolving field. In the single-phase motor, means are provided to reduce the backward field, but this field has always some remaining magnitude (except at one particular load in the case of certain capacitor-run motors), and consequently a single-phase induction motor always has extra losses and a double-frequency pulsating torque not possessed by a polyphase motor.

A simple way to visualize the effects of this backward field is to consider that the forward- and backward-revolving fields are separately produced by the same stator current; that is, they are connected in series. Each field may then be treated as a separate polyphase induction motor, the forward field having a slip s with respect to the rotor, and the other a slip $2 - s$. At standstill, both values of slip are unity, and the two circuits are identical. At all times, the net torque developed is equal to the difference of the separate torques produced by the two fields. On this basis, the single-phase induction motor equivalent circuit is given by Fig. 20-40.

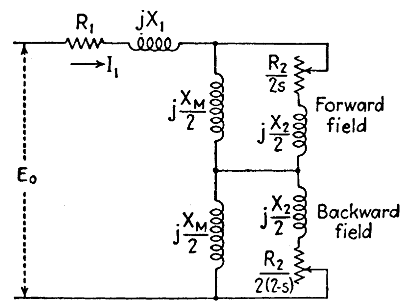

FIGURE 20-40 Equivalent circuit of single-phase induction motor.

The values of R_1, X_1, R_2, X_2, and X_M are the impedance constants derived by measurements across the single-phase terminals. Since half the total air-gap impedance at standstill is due to each field, the magnetizing and secondary impedance values are divided by 2 to obtain the values corresponding to the separate fields.

Inspection of this circuit reveals several interesting properties of the motor. At full speed, s is very small, and the backward field appears as an external series impedance of $R_2/4 + j(X_2/2)$. The corresponding loss $I^2R_2/4$ represents the power delivered to the rotor by the backward field. However, there is an equal loss due to the rotor's being driven forward at speed $1 - s$ against the backward-field torque; so the total loss caused by the backward field is $I^2R_2/2$, approximately. Since the backward-field rotor currents occur at double-line frequency, any double squirrel-cage or deep-bar rotor design which had an increased resistance at high frequency would greatly increase the power losses, and such designs, therefore, are seldom used for single-phase motors. The breakdown torque of a single-phase motor may be approximately calculated for a polyphase induction motor, if the impedance of the backward-revolving field is considered as a series impedance added in the primary circuit of the polyphase motor. Hence, any increase in the secondary resistance of a single-phase motor actually reduces the breakdown torque and lowers the speed at which breakdown occurs.

Another interesting characteristic is the double-frequency torque pulsation. The double-frequency current in the rotor reacting on the slip-frequency forward magnetic field evidently produces a torque pulsation, even at no load. Physically, the no-load part of the pulsating torque provides the means for supplying and removing the magnetic field twice each cycle in the axis at right angles to the stator winding, and the additional part under load corresponds to the double-frequency pulsation of the single-phase power input to the rotor. To prevent objectionable transmitted vibration and noise from this cause, it is usual to mount single-phase machines on supports with torsional elasticity of some type, often rubber rings encircling the bearing housings in the case of fractional-horsepower motors.

Shaded-Pole Motor. The simplest way of providing a single-phase induction motor with starting torque is to place a permanently short-circuited winding of relatively high resistance in the stator at an electrical angle of 30° to 60° from the main winding. Usually this auxiliary winding, called a "shading coil," consists of an uninsulated copper strip encircling approximately one-third of a pole pitch. The current induced in the shading coil, by the portion of the main field linking it, reduces the magnitude of this flux and also causes it to lag in time phase. In consequence, the air-gap field has two components, an undamped alternating flux and a damped flux displaced both in space and in time. Shaded-pole motors are used only in very small sizes normally below 50 W output. Principal applications are for desk fans and air circulators, where their simplicity, low torque, and low cost are well suited to the requirements.

The inherently high slip of a shaded-pole motor makes it convenient to obtain speed variation on a fan load by reducing the impressed voltage. It is common practice to provide multispeed fan operation by employing a small switched-series reactor or a phase-controlled solid-state device to control the motor voltage.

Resistance Split-Phase Motors. A considerably greater starting torque can be obtained by providing a separate starting winding, or auxiliary phase, 90° displaced in space from the main winding of a single-phase induction motor. This extra winding is normally wound with fewer turns of a much smaller size of wire, so that it has a considerably greater resistance to reactance ratio than the main winding, and it is connected directly across the power supply, in parallel with the main winding. Just as in the case of the shaded-pole motor, the field of the auxiliary winding is displaced in time and in space, so that its vectorial combination with the main field gives a much larger forward than backward field component. The motor can be reversed by reversing either the main or the auxiliary winding.

Since the auxiliary winding is normally located 90° from the main winding, the two are mutually noninductive at standstill and the standstill characteristics may be calculated from two independent circuits each like that of Fig. 20-40. By a similar analysis to that of the preceding section, the starting torque of a split-phase motor is

$$T = \frac{14.1aK}{N_s} I_M I_A R_2 \sin\theta \quad \text{ft} \cdot \text{lb} \tag{20-31}$$

where I_M = main winding starting current in amperes; I_A = auxiliary winding starting current in amperes; N_s = synchronous speed; R_2 = resistance component of standstill impedance of main winding, less the primary resistance; a = ratio of effective number of turns in auxiliary winding to main-winding effective turns; K = an empirical coefficient, which allows for nonfundamental rotor losses, usually equal to 0.9; and θ = angle of phase split between I_M and I_A.

Design limitations usually prevent θ from being greater than 30°, so that the starting torque per voltampere cannot exceed half that of a 2-phase motor built in the same parts. Since, in addition, both I_M and I_A are drawn from a single phase of the power supply, the starting current is excessive, limiting the use of the resistance split-phase motor to sizes below $^1/_3$ hp.

The auxiliary winding is opened automatically as the motor approaches full speed, as otherwise prohibitive losses would occur in it. Usually this is accomplished by means of a centrifugal switch or, in the case of hermetically sealed motors, by an electromagnetic relay. The high current density used to obtain an adequate resistance value makes the initial rate of temperature rise of the auxiliary winding very great, sometimes more than 50°C/s, so that these motors are not satisfactory for repeated starting or for inertia loads.

Earlier split-phase motor designs included motors with stationary external squirrel-cage members, with the primary windings on the rotor, receiving their power through slip rings. They are now normally built, however, with uniformly distributed partly closed stator slots, enameled-wire concentric stator windings, and a cast-aluminum or welded-copper squirrel cage on the rotor.

Typical characteristic curves for a $^1/_6$-hp 60-Hz 1725-r/min, resistance split-phase motor are shown in Table 20-11.

Repulsion-Start Induction-Run Motor. A common way of obtaining single-phase-motor starting torque is to provide a dc winding and commutator on the rotor, with a single pair of short-circuited brushes for starting and a centrifugal mechanism, which short-circuits the entire commutator as the motor approaches full speed. This gives a pure repulsion-motor starting characteristic with very high torque per ampere and pure single-phase induction-motor operating characteristics. These motors are widely used in sizes up to about 5 hp. Typical characteristics of a 1-hp 60-Hz 1800-r/min motor of this type are shown in Table 20-11.

Capacitor Motors. Low-cost low-voltage capacitors have proved extremely useful in improving the performance of split-phase motors. By inserting an external series capacitor in the auxiliary winding circuit and making this winding with many more turns of much lower resistance, the angle of phase split θ can be increased to 90°, or even more, and the coincident increase in the turn ratio a permits a further decrease in the auxiliary winding current. Thus, the capacitor-start motor gives an adequate starting torque for a reasonable starting current and at the same time has so much greater thermal capacity than a resistance split-phase motor, by virtue of the reduced winding-current density, that it is satisfactory for nearly all industrial single-phase motor applications.

Figure 20-41 illustrates a convenient method of determining the best size of capacitor to use with a given motor. I_M represents the locked-rotor current in the main winding and I_A the current in the auxiliary winding. With no external capacitor, $X_C = 0$, and the motor becomes a plain resistance split type. As X_C is increased, I_A moves ahead in time phase, following a circular locus, increasing the torque and reducing the total current drawn from the line. Points of maximum starting torque and maximum starting torque per ampere are indicated on the diagram.

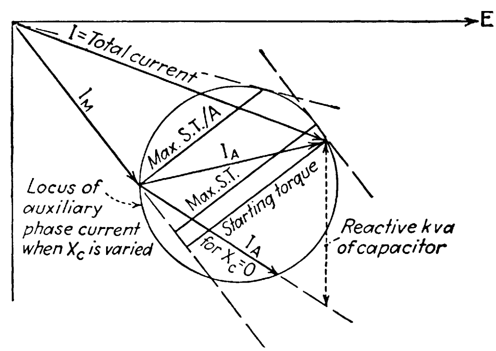

FIGURE 20-41 Capacitor-motor, starting-torque diagram.

Usually low-voltage electrolytic capacitors are used for starting purposes, since these are economical in 115-V intermittent ratings. However, in cases of severe starting duty, higher-voltage motors, or where capacitors are retained in the circuit during operation, paper or film-type, oil-filled ac capacitors are used.

For most applications, the auxiliary winding is opened by a centrifugal switch or relay, as the motor approaches full speed, just as in the case of the resistance split-phase motor. Such motors are called *capacitor-start motors*. In some cases of smaller-sized motors with low-starting-torque requirements, however, it is permissible to leave the capacitor permanently in circuit. These are called *permanent-split capacitor motors*. The limitations of starting torque and motor size on this type are the result of the inherent tendency of the auxiliary-winding current to increase in magnitude and shift backward in time phase as the motor accelerates, so that unless the capacitor impedance is very high, the motor will have objectionable losses and large torque pulsations at full speed. However, the power loss in the capacitor circuit at speed is very much less than in a shading coil for a given starting torque, and so the permanent-split capacitor motor is finding increasing use for fan drive in sizes up to $^1/_4$ hp.

For the larger capacitor motors, in sizes of $^1/_2$ hp and up, it is frequently economical to retain the auxiliary winding in circuits with a reduced capacitor size, to improve the operating characteristics. This is usually accomplished by providing a large electrolytic or highly stressed capacitor in parallel with a small oil capacitor at starting and cutting the former out of circuits with a centrifugal switch or relay when the motor approaches full speed. Such motors are called *capacitor-run motors* and have winding connections as shown in Fig. 20-42. The analysis of the capacitor motor

Horsepower, Speed, and Voltage Ratings. Standard horsepower and speed ratings of single-phase motors are given in Table 20-9. Motors built in frames having a continuous rating of less than 1 hp, open type, at 1700 to 1800 r/min are designated *fractional-horsepower* motors, and those built in larger frames are called *integral-horsepower* motors. Somewhat different standards of performance have been established for the two classes. ANSI C-50 and *NEMA Motor and Generator Standards*, Publ. MG1-1978, include basic standards for both fractional-and integral-horsepower motors which are normally followed in specifications and testing.

Both capacitor and split-phase motors are available in the multispeed as well as the single-speed type. They are used principally for belt and direct drive of centrifugal and propeller fans and are of the variable-torque class. The multispeed motors for fan drive allow a change in fan speed without changing pulleys, which is essential where remote or automatic control of the rate of air delivery is required.

The standard voltage ratings for single-phase motors are 115 and 230 V for supply lines rated 120 and 240 V. Power companies place a limit on the size of motors that may be connected to single-phase lines. The limit usually falls between $^1/_2$ and 1 hp for 120-V circuits and between 3 and 10 hp for 240-V circuits.

Temperature Rise. The standard temperature rises and service factors for single-phase motors are the same as for polyphase motors.

Efficiencies and Power Factors. Typical efficiencies and power factors of the various types of induction motor that might be used to fill the requirements of the different ratings are shown in Fig. 20-43. Repulsion-start induction-run motors have about the same efficiencies and power factors except in the $1^1/_2$-to 3-hp range, where they are lower. Repulsion-induction motors have roughly the same efficiencies but higher power factors.

Single-Phase Motor Characteristics. The full-load current of a single-phase motor is equal to

$$\frac{746 \times \text{hp}}{\text{Efficiency} \times \text{voltage}} \qquad (20\text{-}32)$$

where the efficiency and power factor are expressed as decimals. Approximate values of full-load current are given in Table 20-10. These are used for selecting wire and fuse sizes if no more accurate data are available.

Characteristics of a 60-Hz, 4-pole, 1800-r/min, single-phase motor are shown in Fig. 20-43.

The horsepower rating of a single-phase motor is defined by its breakdown torque. Thus, any 1800-r/min motor with a breakdown torque between 31.5 and 40.5 oz · ft is, by definition, a $^1/_3$-hp motor. The value used for definition is the minimum of the range of manufacturing variation for that particular design.

Starting Current. Maximum values of locked-rotor current are established by NEMA for 60-Hz motors as shown in Table 20-10. In integral-horsepower sizes, NEMA has established two sets of locked-rotor values. The Design L motors include those types having inherently higher locked-rotor values. The Design L motors include those types having inherently higher locked-rotor current than Design M motors.

20.5 OTHER TYPES OF ELECTRIC MOTORS AND RELATED APPARATUS

Induction Generators. Any induction motor, if driven above its synchronous speed when connected to an ac power source, will deliver power to the external circuit. The generator operation is easily visualized from the equivalent circuit of Fig. 20-28, corresponding to negative slip. The induction generator must always take reactive power from the load or the line for excitation and for the I^2X losses. For this reason, the induction generator can only operate in parallel with an electric power system or independently with a load supplemented by capacitors. For independent operation, the speed must be increased with load to maintain constant frequency; the voltage is controlled with the capacitors.

An induction generator delivers an instantaneous 3-phase short-circuit current equal to the terminal voltage divided by its locked-rotor impedance. Its rate of decay is much faster than that of a synchronous generator of the same rating, corresponding to the subtransient time constant T'_{do}; sustained short-circuit current is zero.

The virtue of the induction generator is its ability to self-synchronize when the stator circuit is closed to a power system. At one time induction generators were used for small, unattended hydro stations. Since the late 1990s, induction generators have been used in a similar manner for wind turbines and cogeneration units. They have also been used for high-speed, high-frequency generators, because of their squirrel-cage rotor construction.

Synchronous Induction Motors. There are three types of motors that can start and run as induction motors yet can lock into the supply frequency and run as synchronous motors as well. They are (1) the wound-rotor motor with dc exciter, (2) the permanent-magnet (PM) synchronous motor, and (3) the reluctance-synchronous motor. The latter two types have been used primarily with adjustable-frequency inverter power supplies. In Europe, wound-rotor induction motors have often been provided with low-voltage dc exciters that supply direct current to the rotor, making them operate as synchronous machines. With secondary rheostats for starting, such a motor gives the low starting current and high torque of the wound-rotor induction motor and an improved power factor under load. Several different forms of these synchronous induction motors have been proposed, but they have not shown any net advantage over usual salient-pole synchronous or induction machines and are very seldom used in the United States. The PM synchronous motor is shown in Fig. 20-44*a*. The construction is the same as that of an ordinary squirrel-cage motor (either single or polyphase), except that the depth of rotor core below the squirrel-cage bars is very shallow, just enough to carry the rotor flux under locked-rotor conditions. Inside this shallow rotor core is placed a permanent magnet, fully magnetized. The rotor core serves as a keeper, so that the rotor is not demagnetized by removing it from the stator. In starting, the rotor flux is confined to the laminated core. As the speed rises, the rotor frequency decreases and the rotor flux builds up, creating a pulsating torque with the field of the magnet, as when a synchronous motor is being synchronized after the dc field has been applied. As the motor approaches full speed, therefore, the ac impressed field locks into step with the field of the magnet and the machine runs as a synchronous motor. The absence of rotor I^2R loss,

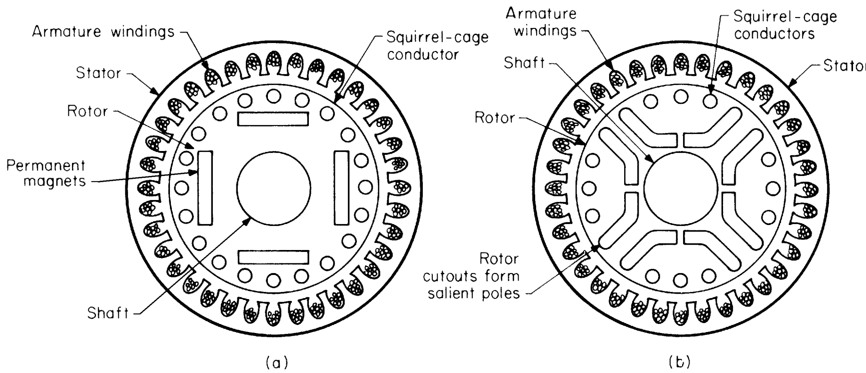

FIGURE 20-44 Cross section of (*a*) a conventional PM synchronous motor and (*b*) a reluctance-synchronous motor.

the synchronous speed operation, and the high efficiency and power factor make the motor very attractive for special applications, such as high-frequency spinning motors. When many such motors are supplied from a high-frequency source, the kVA requirements are reduced to perhaps 50% of those needed for usual induction motor types, with consequent large savings.

If the rotor surface of a *P*-pole squirrel-cage motor is cut away at symmetrically spaced points, forming *P* salient poles, the motor will accelerate to full speed as an induction motor and then lock into step and operate as a synchronous motor. The synchronizing torque is due to the change in reluctance and, therefore, in stored magnetic energy, when the air-gap flux moves from the low- into the high-reluctance region. Such motors are often used in small-horsepower sizes, when synchronous operation is required, but they have inherently low pull-out torque and low power factor, and also poor efficiency, and therefore require larger frames than the same horsepower induction motor. The PM synchronous motor has superior performance in every way, except possibly cost. A cross section of the reluctance-synchronous motor is shown in Fig. 20-44*b*. These motors are available up to about 5 hp.

If the number of rotor salients is nP, instead of P, and if the P-pole motor winding is arranged to also produce a field of $(n - 1)P$ or $(n - 1)P$ poles, the motor may lock into step at a subsynchronous speed and run as a subsynchronous motor. For the P-pole fundamental mmf, acting on the varying rotor permeance will create $(n + 1)P$ and $(n - 1)$ P-pole fields from this case, and these will lock into step with the independently produced $(n - 1)P$- or $(n + 1)P$-pole field, when the rotor speed is such as to make the two harmonic fields turn at the same speed in the same direction.

It is difficult to provide much torque in such subsynchronous motors, and their use is therefore limited to very small sizes, such as may be used in small timer or instrument motors.

Linear Motors. Linear induction motors (LIMs) have been built in fractional-horse-power ratings for such applications as moving drapes, and up to several thousand horsepower for driving tracked air-cushion transit vehicles on a guideway. Other applications include moving freight cars in yards, driving people-mover vehicles, and providing reciprocating motion for machine tools. LIMs are built like rotary induction motors with distributed multipole polyphase windings placed in the slots of a plane laminated status as shown in Fig. 20-45. When the windings are excited by a polyphase voltage of frequency f, an air-gap space flux wave is propagated along the length of the stator at a velocity of $v = 2fp$, where p is the pole pitch. The rotor consists of an aluminum or copper sheet, which is propelled by the field with a slip velocity to provide the required thrust. LIMs are either double-sided, with two facing stators operating on a single rotor, or single-sided, with the rotor sheet backed by a moving or stationary magnetic return path. The magnetic force density normal to the stator surface is considerable compared to the tangential force density that moves the rotor, which requires that the stator be well braced mechanically to maintain constant air-gap distances over the surface of the stator. The typical tangential force density is about 3 lb/in^2 for air-cooled windings, where the normal force density is about 30 lb/in^2.

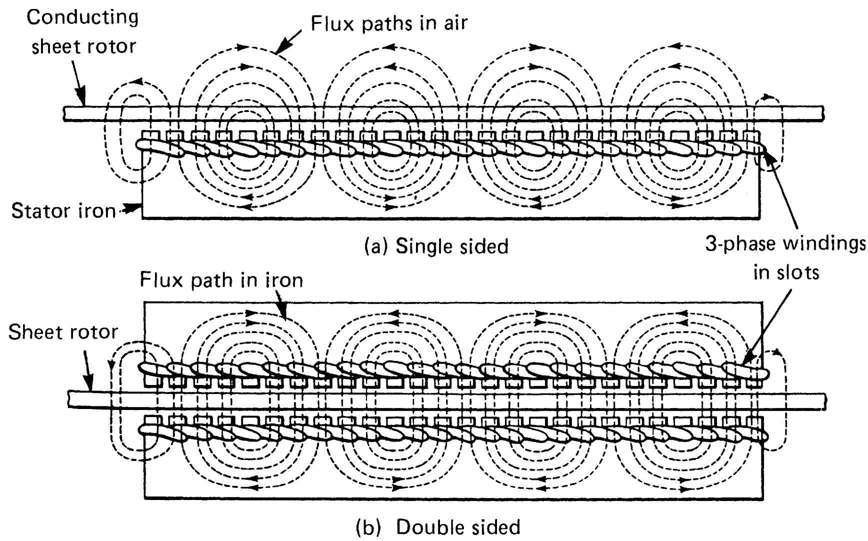

FIGURE 20-45 (*a*) Single-sided and (*b*) double-sided linear induction motors (LIMs) with sheet rotor.

The magnetic air gap of a double-sided LIM is the thickness of the sheet rotor plus the clearance between the rotor and the stators on either side. Whereas most rotary induction motors are built with an air gap of 0.025 to 0.1 mils, the air gap in the LIM is 0.25 to 1.5 in. For this reason, the magnetizing reactance of the LIM is lower than that of an equivalent rotary induction motor. Also the stator leakage reactance is higher. The equivalent circuit of the LIM is shown in Fig. 20-46*a*. Figure 20-46*b* shows the thrust-slip power factor and efficiency curves of a double-sided LIM. This LIM has an air gap of 1.47 in, a rotor sheet thickness of 0.25 in, and a stator length of 9.8 in. The two 3-phase windings of the stator are excited at 173 Hz from inverters to produce a linear synchronous velocity of 395 ft/s. Speed control and breaking of LIMs is done in the same way as in the rotary induction motors.

High-Frequency Motors. For high-speed tools and for spinning of rayon and other threads, a variety of interesting motor constructions have been developed. Normally these are 2-pole 3-phase motors, with special high-frequency power supply of 90, 120, or 180 Hz, giving operating speeds between 500 and 10,500 r/min and up to 25 hp. In textile applications, the motors usually drive individual spinning buckets, which are subject to considerable unbalance due to uneven building up of

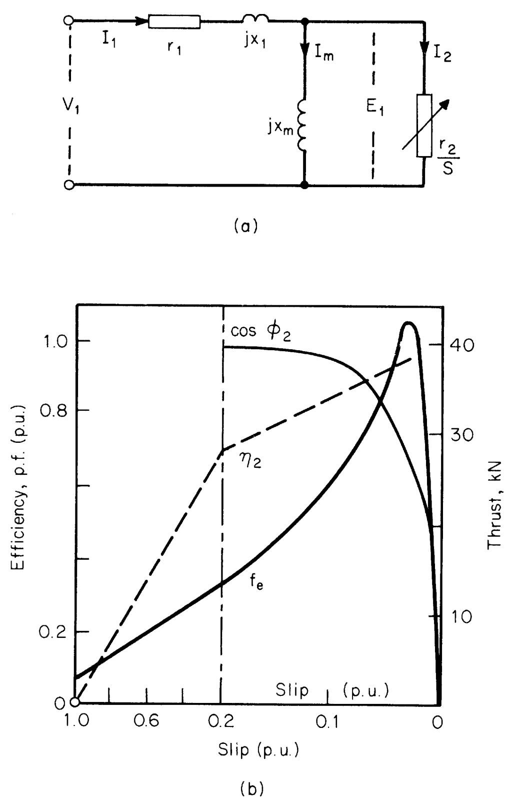

FIGURE 20-46 (*a*) Equivalent circuit of a double-sided LIM, (*b*) the characteristic curves of a typical LIM.

thread, etc. The continual starting and stopping for loading and unloading the buckets requires the motors to carry unbalance reliability through the entire speed range, necessitating careful design of mounting flexibility and shaft stiffness. Most usual applications, however, are in woodworking and similar industries, where separate motor stators and rotors are supplied to the tool manufacturers for building into their particular devices. These motors were powered from high-frequency alternators, but are now powered by adjustable-frequency solid-state inverters.

Three-phase 400-Hz power systems, used on large airplanes, have led to the development of 400-Hz motors with speeds of 12,000 and 24,000 r/min, having weights averaging 2 lb/hp for motors of 1 to 15 hp with 5-min ratings. These motors are open, with an external fan to force air over the windings.

Stepper Motors. The primary characteristic of a stepper motor is its ability to rotate a prescribed small angle (step) in response to each control pulse applied to its windings. Below about 200 pulses per second, the motor rotates in discrete steps in synchrony with the pulses; at higher frequencies up to 16,000 pulses per second, the motor skews without stopping between pulses. Although motors are available for step angles of 90° to 0.180°, the common step is 1.8°. Stepper motors are categorized as permanent-magnet rotor (PM), variable reluctance (VR), or hybrid (PM-VR). The rotor of the PM aligns itself with the energized stator poles as shown in Fig. 20-47*b*. The rotor turns until

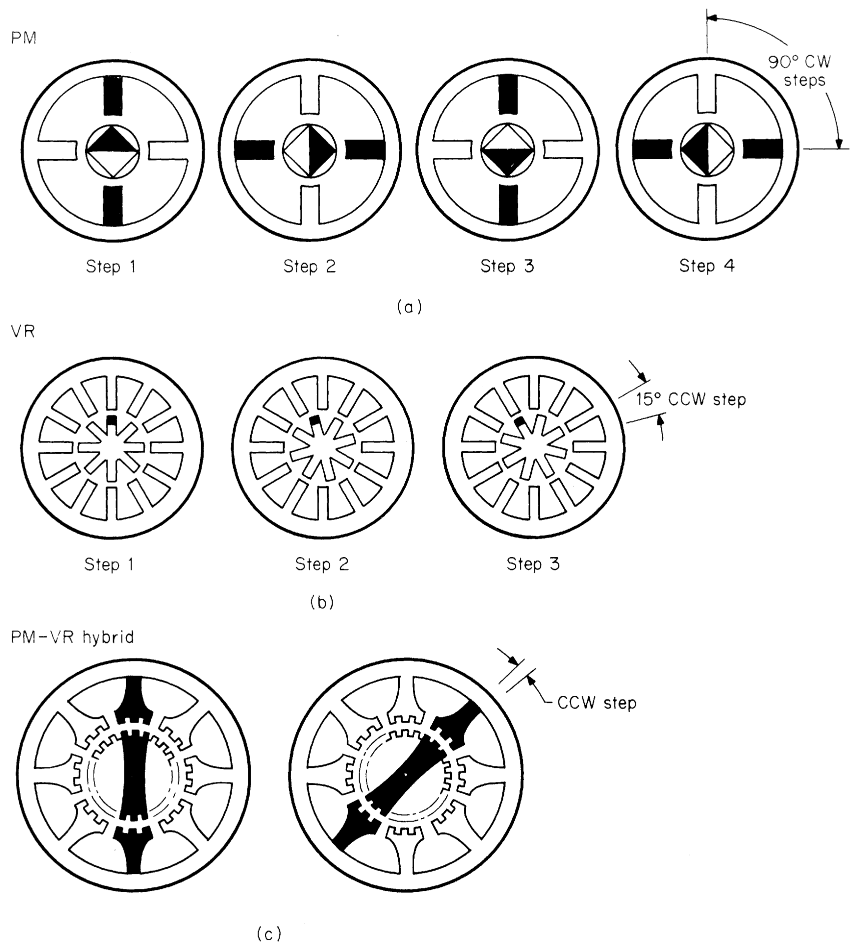

FIGURE 20-47 Three types of stepper motor.

the poles are aligned at each step. The PM-VR hybrid shown in Fig. 20-47*c* has a high skew rate yet retains holding torque when the power is turned off. Motors can be made to rotate in half-steps to increase accuracy. Performance of stepper motors is described by two types of curves: the pull-out torque versus speed curve, as shown in Fig. 20-48; and the holding torque angle curves, as shown in Fig. 20-49. Stepper motors are available with holding torques up to 4000 oz · in.

Hysteresis Motors. By constructing the secondary core of an induction motor of hardened magnet steel, in place of the usual annealed low-loss silicon-steel laminations, the secondary hysteresis loss can be greatly magnified, producing effective synchronous motor action. Such hysteresis motors, having smooth rotor surfaces without secondary teeth or windings, give extremely uniform torque, are practically noiseless, and give substantially the same torque from standstill all the way up to synchronous speed. A hysteresis motor is a true synchronous motor, with its load torque produced by an angular shift between the axis of rotating primary mmf and the axis of secondary magnetization. When the load torque exceeds the maximum hysteresis torque, the secondary magnetization axis slips on the rotor, giving the same effect as a friction brake set for a fixed torque.

Despite the interesting characteristics of this type of motor, it is limited to small sizes, because of the inherently small torque derivable from hysteresis losses. Only moderate flux densities are practicable, owing to the excessive excitation losses required to produce high densities in hard magnet steel, and, therefore, about 20 W/lb of rotor magnet steel represents the maximum useful synchronous power on 60 Hz. Hysteresis motors have found an important use for phonograph-motor drives, their synchronous speed enabling a governor to be dispensed with and freedom from tone waver to be secured.

The Telechron motor, which is so widely used for operating electric clocks, also operates on the hysteresis-motor principle. In the Telechron motor, a 2-pole rotating field is produced in a cylindrical air space, and into this space is introduced a sealed thin-metal cylinder containing a shaft carrying one or more hardened magnet-steel disks, driving a gear train. The 60-Hz magnetic field causes the steel disks to revolve at 3600 r/min, driving through the gears a low-speed shaft, usually 1 r/min, which merges from the sealed cylinder through a closely fitting bushing designed to minimize oil leakage. Although the magnetic field has to cross a very considerable air-gap length and pass through the tin walls of the metal cylinder, the power required to drive a well-designed clock is so small that sample output is obtained with only about 2-W input for ordinary household-clock sizes.

The hysteresis motor has been displaced for phonograph and tape-reel drives by the transistor-driven brushless dc motor. It has been displaced for electric clocks by solid-state circuits with digital readout.

20.6 ALTERNATING-CURRENT COMMUTATOR MOTORS

Classification. As compared with the induction motor, the ac commutator motor possesses two of the advantages of the dc motor: a wide speed range without sacrifice of efficiency and superior starting ability. In the induction motor, the starting torque is limited by the small space-phase displacement between the air-gap flux and the induced secondary current and by magnetic saturation of the flux paths. In the ac commutator motor, on the other hand, the air-gap flux and current are held at the optimum space-phase displacement by proper location of the brush axis, and the secondary current is not limited by magnetic saturation, giving high torque per ampere at starting. Furthermore, the series commutator motor may be operated far above the induction-motor synchronous speed, giving high power output per unit of weight.

Alternating-current commutator motors may be grouped into two classes:

1. Those motors in which the resultant mmf providing the flux increases with the load. When operated from a source of constant voltage, the speed of such motors decreases with increasing load. They are termed *series motors* from the similarity of their characteristics to those of series-wound dc motors. The speed at any given load may be varied by changing the applied voltage or, in some cases, by shifting the brushes.

2. Those motors in which the resultant mmf providing the flux is substantially constant irrespective of the load. For operation from a source of constant voltage, the speed of such motors is approximately constant. The speed may, however, be increased or decreased (independently of the load) by increasing or decreasing the voltage at the terminals of the motor, by brush shifting, or by the provision of suitably disposed and connected auxiliary coils. Such motors are termed *shunt motors*.

Alternating-current commutator motors are either single-phase or polyphase. A unique characteristic of all single-phase motors is a double line-frequency pulsation of the torque produced, corresponding to the sinusoidal variation twice each cycle of the single-phase power supplied. This torque pulsation is partly transmitted to the load, causing small speed pulsations and necessitating special coupling and mounting designs to minimize vibration and fatigue stresses.

Polyphase commutator motors have the advantage of better inherent commutating ability, due in part to the need for shifting the rotor current only 60° in time phase at each brush stud for a 6-phase motor or 30° for 12 phases, as compared with 180° shift for a single-phase or dc machine. Single-phase motors are generally limited to sizes below about 10 hp, except for railway applications.

With the advent of solid-state devices, the ac commutator motor is being displaced by the thyristor-rectifier-powered dc motors and inverter-fed induction motors, at less cost and superior performance. The dc motor does not have the difficulties of commutation, the requirement for extra windings, and shifting brush arrangements, and can be built on an unlaminated frame. The induction motor has no commutator and can run at the high speeds of the commutator motor.

Single-Phase Straight Series Motor. An ordinary dc series motor, if constructed with a well-laminated field circuit, will operate (although unsatisfactorily) if connected to a suitable source of single-phase alternating current. Since the armature is in series with the field, the periodic reversals of current in the armature will correspond with simultaneous reversals in the direction of the flux, and consequently the torque will always be in the same direction. But the inductance of the motor will be so great that the current will lag far behind the voltage, and the motor will have a very low power factor. The entire amount of armature flux produced along the brush axis generates a reactive voltage in the armature, which must be overcome by the applied voltage, without performing any useful function whatever.

When the motor is first thrown in the circuit, and before the armature has moved from rest, the field constitutes the primary of a transformer and sends flux through the armature core. Those armature turns, which at that instant are short-circuited under the brushes, act as short-circuited secondary coils and are traversed by heavy currents, which serve no useful purpose whatever and occasion serious heating. When the armature starts to revolve, these short-circuited turns are opened as they pass out from under the brushes and are replaced by other turns, which are momentarily short-circuited and then opened. These interruptions of heavy currents are accompanied by serious sparking, since the heating is concentrated at the few segments on which the brushes rest. As soon, however, as a certain speed is acquired, the heating is distributed over all the segments and the conditions are ameliorated. This source of sparking is, then, most serious at the moment of starting. This difficulty has been minimized by operating at a lower frequency than 60 Hz and by the employment of leads of high resistance connecting the winding to the commutator segments.

The simple single-phase series motor has therefore two major faults, low power factor and poor commutation at low speeds, confining its use to fractional horsepower and very high speed applications.

Single-Phase Compensated Series Motor. In all except the smallest sizes, it is usual to employ a compensating winding on the stator, in series with the armature and so arranged that its mmf as nearly as possible counteracts the armature mmf. A commutating winding is also frequently used, which somewhat overcompensates the armature reaction along the interpolar, or commutating-zone, axis and so provides a voltage to aid the current reversal, just as in a dc motor. By these means, the flux along the brush axis is reduced to a small fraction of its uncompensated value, and the power factor of the motor is greatly improved. Further improvement of the power factor is secured by using a smaller air gap and correspondingly fewer field ampere-turns than in an uncompensated motor, thus reducing the reactive voltage in the series field to a minimum.

Universal Motors. Small series motors up to about $^1/_2$-hp rating are commonly designed to operate on either direct current or alternating current and so are called *universal motors*. Universal motors may be either compensated or uncompensated; the latter type is used for the higher speeds and smaller ratings only. Owing to the reactance voltage drop, which is present on alternating current but absent on direct current, the motor speed is somewhat lower for the same load ac operation, especially at high loads. On alternating current, however, the increased saturation of the field magnetic circuit at the crest of the sine wave of current may materially reduce the flux below the dc value, and this tends to raise the ac speed. It is possible, therefore, to design small universal motors to have approximately the same speed-torque performance over the operating range, for all frequencies from 0 to 60 Hz. On a typical compensated-type $^1/_4$-hp motor, rated at 3400 r/min, the 60-Hz speed may be within 2% of the dc speed at full-load torque but 15% or more lower at twice normal torque, while on an uncompensated motor the speed drop will be materially greater.

The commutation on alternating current is much poorer than on direct current, owing to the current induced in the short-circuited armature coils, and this provides a definite limitation on their size and usefulness. If wide brushes are used, the short-circuit currents are excessive and the motor-starting torque is reduced, while if narrow brushes are used, there may be excessive brush chatter at high speeds, causing short brush life. Good design, therefore, requires careful proportioning of commutator and brush rigging to meet conflicting electrical, mechanical, and thermal requirements. Universal motors are generally used for vacuum cleaners, portable tools, food mixers, and similar small devices operating at maximum speeds of 3000 to 10,000 r/min.

The speed of the universal motor is controlled by means of a half-wave thyristor, or full-wave triac, as shown in Fig. 20-50. The control device governs the half-wave average voltage applied

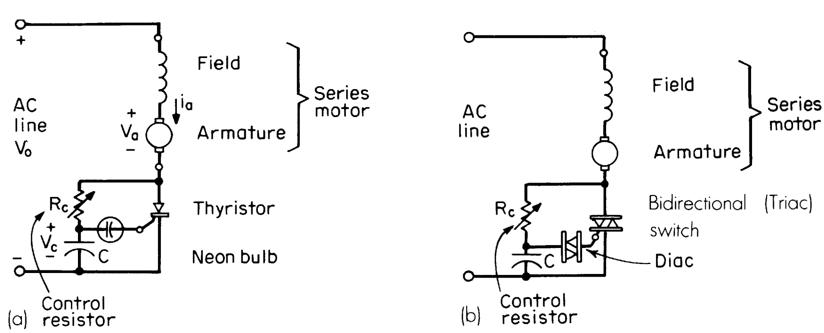

FIGURE 20-50 (*a*) Half-wave series universal motor circuit; (*b*) full-wave series universal motor circuit and the holding torque angle curves, as shown in Fig. 20-49. Stepper motors are available with holding torque up to 400 oz · in.

to the motor as a function of the firing angle. The firing circuits are usually relatively simple. The speed is controlled by changing a resistance value, such as R_c, in Fig. 20-50. The characteristics of a universal (series) motor with half-wave control are shown in Fig. 20-51.

20.7 FRACTIONAL-HORSEPOWER-MOTOR APPLICATIONS

Scope. A fractional-horsepower motor is defined by NEMA as either (1) a motor built in a frame with a NEMA two-digit frame number or (2) a motor built in a frame smaller than the NEMA frame for a 1-hp, open-construction, 1700- to 1800-r/min, induction motor. The two-digit frame number is defined as 16D, where D is the height of the shaft centerline above the bottom of the mounting base. Fractional-horsepower motors include 1-phase and 3-phase induction and synchronous motors, 1-phase universal motors, and dc motors. Ratings, with minor exceptions, are $^1/_{20}$ to 1 hp, inclusive. Motors of smaller ratings are classified as subfractional or miniature.

Purpose. General-purpose motors are of open construction, rated at 60°C temperature rise by resistance over a 40°C ambient temperature. They are designed according to standard ratings with standard operating characteristics and mechanical construction for rise under usual service conditions without restriction as to a particular application or type of application. A definite-purpose motor is any motor designed according to standard ratings with standard operating characteristics or mechanical construction for use under service conditions other than the usual or for on a particular type of application.

Selection of Type. The principal characteristics of fractional-horsepower motors are shown in Table 20-11. For any application, the motor selected should meet the application and power supply requirements at the least cost. Numerous trade-offs are possible, for example, speed changing infinite steps compared to continuously adjustable-speed solid-state drives.

Ratings. Standard voltage and frequency ratings are listed in Table 20-12*a* and 20-12*b*.

Service Conditions. General-purpose motors are designed to operate under the usual service conditions of 0 to 40°C ambient temperature, altitude to 3300 ft (1000 M), and installation on rigid mounting

General remarks: Standard motors are ordinarily designed to operate in ambient temperatures from 10 to 40°C. Variations in line voltage of plus or minus 10%, or variations in frequency of plus or minus 5% are allowable. Locked-rotor currents for single-phase motors, except split-phase high-torque and synchronous types, usually do not exceed the following limits established by NEMA:	For constant-speed operation, even under varying load conditions, where moderate torques are desirable or mandatory, this type is often used in preference to the more costly capacitor-start motor. Meets NEMA starting currents. Typical applications: blowers; centrifugal pumps; duplicating machines; refrigerators; oil burners; unit heaters.	High locked-rotor currents (in excess of NEMA) limit the use of this type on lighting circuits to applications where the motor starts only very infrequently, because of a tendency to cause flickering of the lights. Principal applications: washing and ironing machines; cellar-drainer pumps; tools for a home workshop.	Used where two definite speeds independent of load are required. Ratings above 1/4 hp usually made capacitor-start. Motor shown always starts on high-speed connection; transfer to low speed made by starting switch. Common applications: belted blowers for warm-air furnaces or for other purposes; attic ventilators; air conditioning apparatus.	A general-purpose motor suitable for most applications requiring constant speed under varying loads, high starting and running torques, high overload capacity. Also available as two-speed pole-changing motor above 1/4 hp. A few important applications are: refrigeration and air conditioning compressors; air compressors; stokers; gasoline pumps.	Primarily used for unit heaters, or for other shaft-mounted fans. Essentially a constant-speed motor, but by means of a two-speed switch, or by means of an auto-transformer, other speeds can be obtained, *with fan loads,* of horsepower rating selected closely matches the fan load. Can also be made in intermittent ratings for plug-reversing service.	A constant-speed motor suited to general-purpose applications requiring high starting torque, such as pumps and compressors. An associated type, the repulsion induction (buried cage) is used for door openers and other plug-reversing applications. Has been displaced for many applications by the capacitor-start motor.	For ratings below 1/20 hp, this is a general-purpose motor. For fan applications, speed control is affected by use of a series choke or resistor. Applications: fans, unit heaters, humidifiers, hair driers, damper controllers.	Cutouts in rotor result in synchronous-speed characteristics. Curve shown is for split-phase stator. Pull-in ability is affected by inertia of connected load. Used for teleprinters, facsimile-picture transmitters, graphic instruments, etc. Clocks and timing devices usually use shaded-pole hysteresis motors rated at a few millionths of a horsepower.	Companion motor to capacitor-start motor with comparable torques and generally suited to same applications if polyphase power is available. Inherently plug-reversible and suitable for door openers, hoists, etc. High-frequency motors used for high-speed applications, as for wood-working machinery, rayon spinning, and portable tools.	Light weight for a given output, high speeds, varying-speed and universal characteristics make this type very popular for hand tools of all kinds, vacuum cleaners, etc. Ratings above $^1/_4$ hp usually compensated. Some speed control can be effected by a resistor or by use of a tapped field. Used with reduction gear for slower speed applications.	By means of a centrifugal governor, a constant-speed motor having the advantages of the universal motor is obtained. Governor may be single-speed or adjustable even while running. Speed is independent of applied voltage. Used in typewriters, calculating machines, food mixers, motion-picture cameras and projectors, etc.	A constant-speed companion motor for the capacitor-start or split-phase motor for use where only dc power is available. For unit-heater service, armature resistance is used to obtain speed control. Not usually designed for field control.	Principally used as the dc companion motor to the shaded-pole motor for fan applications. Used in these small ratings in place of shunt motors to avoid using extremely small wire.

surfaces where there is no interference with the ventilation. Some general-purpose, definite-purpose, and special-purpose motors can operate under one or more unusual service conditions, which include exposure to dust, lint, fumes, radiation, steam, fungus, shock; operation where voltage, frequency, waveform, and form factor deviate from standards; and overspeed, overtemperature, and excess altitude operation. The manufacturer should be consulted for operation under unusual service conditions.

Thermal Protection. Many single-phase motors are now available with a built-in thermal protector, which affords complete protection from burnout due to any type of overload, even a stalled rotor. Most such devices are automatic-resetting, but some are manual-resetting. Motors that are protected usually are marked externally in some way to indicate the fact.

Reversibility. In general, standard motors of the types listed in the table can be arranged by the user to start from rest in either direction of rotation. There are exceptions, however. Shaded-pole motors, unless of a special design, can be operated in only one direction of rotation. Small dc and universal motors often have the brushes set off neutral, preventing satisfactory operation in the reverse direction. Single-phase motors, which use a starting switch ordinarily cannot be reversed while running at normal operating speeds, because the starting winding, which determines the direction of rotation, is then open-circuited. By use of special relays this limitation of split-phase and capacitor-start motors can be overcome when necessary. Such motors are built for small hoists. High-torque intermittent-duty permanent-split capacitor motors; repulsion-induction (buried-cage) motors; and split-series dc or universal motors are often built for plug-reversing service. Standard polyphase induction motors can be reversed while running, as can the smaller ratings of dc motors; such applications should preferably be taken up with the motor manufacturer.

Mechanical Features. Rigid and rubber-mounted motors are commonly available. Sleeve and ball bearings are both standard. Sleeve-bearing motors are designed for operation with the shaft horizontal, but ball-bearing motors can be operated with the shaft in any position. For operation with the shaft vertical, sleeve-bearing motors may require a special design. Rubber mounting is widely used for quiet operation, because all single-phase motors have an inherent double-frequency torque

pulsation. An effective and common arrangement uses rubber rings concentric with the shaft and so arranged as to provide appreciable freedom of torsional movement but little other freedom. Sometimes the driven member picks up the double-frequency torque pulsation and amplifies it to an objectable noise, for example, a fan with large blades mounted rigidly on the shaft. The cure for this difficulty is an elastic coupling between the shaft and the driven member; no amount of elastic suspension of the stator can help. Standard motors are generally open and of drip-proof construction. Splashproof and totally enclosed motors are easily available.

Inputs of Small Single-Phase Motors. See Table 20-13. Full-load torque, in terms of horsepower and rated speed, is

$$\text{Full-load torque, oz}\cdot\text{ft} = \frac{84{,}000 \times \text{hp}}{\text{r/min}} \tag{20-33}$$

Application Tests. The primary object of any application test is to determine the power requirements of the appliance or device under various significant operating conditions. A convenient way of doing this is to use a motor of approximately the right horsepower rating and of predetermined efficiency at various outputs. Watts input are carefully measured under each condition. From the watts input observed (never use current as a measure of load except for dc motors) and the known efficiency, the load is readily determined. Care should be taken in measuring the watts input to correct for the meter losses.

A second, and equally important, object of the test is to determine the actual locked-rotor and pull-up torques required by the appliance. The locked-rotor and pull-up torques of the test motor should be known or measured at rated voltage and frequency. (Locked-rotor torque often varies with slight changes in rotor position.) Using a transformer or induction regulator to obtain a variable voltage (do not use a resistance or choke for this purpose), measure the minimum voltage at which the motor will start the appliance and also the minimum voltage at which it will pull it up through switch-operating speed. Assuming that the pull-up and locked-rotor torques each vary as the square of the applied voltage, it is then a simple matter to determine the actual locked-rotor and pull-up torques required by the device. After a motor has been selected, it should be determined whether it can operate the device at 10% above and below normal rated voltage of the motor or over a wider range of voltage, if desired. If exceptional load conditions may occasionally be encountered, use of a motor equipped with inherent-overheating protection is often desirable.

Definite-Purpose Motors. For a number of important applications, involving large quantities of motors, NEMA has developed standards to meet these special requirements effectively and economically. Motors built to these standards are usually more readily obtainable and economical than special motors tailored to one application. Highlights and distinguishing features are given in Table 20-14. More details can be obtained in NEMA Standards.

TABLE 20-14 NEMA Standards for Definite-Purpose Motors

Application	Principal types	Distinguishing features
Universal motors	Universal: salient-pole and distributed field	Dimensional standards; common practices utilizing parts
Hermetic motors	Split-phase, capacitor-start, polyphase	Parts only for hermetic refrigeration condensing units
Belt-drive refrigeration compressors	Capacitor-start, repulsion-start, polyphase	Open; sleeve bearings, extended rear oiler; automatic-reset thermal overload protection
Jet-pump motors	Split-phase, capacitor-start, repulsion-start, polyphase	3450 r/min; ball bearings; open; machined back-end shield; automatic-reset overload protection
Motors for shaft-mounted fans and blowers	Split-phase, permanent-split capacitor, polyphase	Enclosed; horizontal; sleeve bearings; vertical, ball bearings; extended through bolts; capacitors on front end shield
Shaded-pole motors for shaft-mounted fans and blowers	Shaded-pole; two-speed, three speed	Open or totally enclosed; sleeve bearings; high slips
Belted fans and blowers	Split-phase, capacitor-start, repulsion-start; two-speed split-phase and capacitor-start	Open; sleeve bearings; resilient mounting; automatic-reset overload protection; extended rear oiler
Stoker motors	Capacitor-start; repulsion-start; polyphase	Totally enclosed recommended; automatic-reset overload protection
Motors for cellar drainers and sump pumps	Split-phase	Vertical, dripproof, 50°C; two ball bearings, or one ball, one sleeve; mounts on support pipe; built-in float-operated line switch; overload protection
Gasoline-dispensing pumps	Capacitor-start, repulsion-start, polyphase	Explosionproof; sleeve bearing; built-in line switch and capacitor; voltage-selector switch on single-phase
Oil-burner motors	Split-phase	Enclosed, face-mounted, round-frame; manual-reset overload protection; two line leads
Motors for home-laundry equipment	Split-phase	Low-cost, high starting current; open, 50°C; round-frame with ungrounded mounting rings; shaft extension with flat and hole for coupling
Motors for coolant pumps	Split-phase, capacitor-start, repulsion-start, polyphase	3450- and 1725-r/min; totally enclosed; ball bearings; machined back-end shield
Submersible motors for deep-well pumps	Split-phase, capacitor, polyphase	3450 r/min; designed for operation totally submerged in water not over 25°C (77°F); use external relay for starting

Small Synchronous Motors. Small synchronous motors in the 1.5- to 25-W range for timing, tape drives, small fans, and record players are available as brushless dc motors or as hysteresis motors. The brushless dc motor consists of a permanent-magnet field, 2-phase, synchronous motor driven by transistors from a dc source. The transistors are switched from a Hall-device signal that senses the rotor position. A regulator maintains constant speed.

Shaded-pole hysteresis motors, which operate at synchronous speed, are essentially the same as shaded-pole induction motors except that they use rotors of hardened-steel rings of a material having high hysteresis loss. Large quantities of such motors are built for clocks and timing devices. Clock motors have an input of 1.5 to 2 W and an output of a few millionths of a horsepower. Large motors with inputs up to 15 W are built for heavier duty applications. Rotor speeds are commonly 450, 600, and 3600 r/min. Most of these motors are furnished with built-in reduction gears to give output speeds of 60 r/min to 1 r/month.

Reluctance motors, both self-starting and manual-starting types, are available for similar applications. Another type used is the synchronous-inductor motor, which is essentially an inductor alternator used as a motor; field excitation is furnished by a permanent magnet.

20.8 MOTOR CONTROL

Industrial motor control includes (1) motor-starting devices, (2) speed-control devices, (3) stopping devices, and (4) motor-protecting devices.

Industrial motor control is designed and built in accordance with rules and standards established by several organizations. Detailed design-construction and test information is contained in such publications as the *National Electrical Code,* National Board of Fire Underwriters; *Standards for Industrial Control Apparatus,* Institute of Electrical and Electronics Engineers; *Industrial Control Standards,* National Electrical Manufacturers Association; *Standard for Industrial Control Equipment,* Underwriters' Laboratories; and *Standard Rotation, Connections and Terminal Markings for Electric Power Apparatus,* American National Standards Institute.

The essential functions of motor control are the starting, speed regulating, stopping, and protecting of electric motors.

20.9 MOTOR-STARTING DEVICES

A *contactor* is a device, generally magnetically actuated, for repeatedly establishing and interrupting an electric power circuit.

Figure 20-52 illustrates a single-pole dc contactor. Contactors of this type are rated on a continuous-current-carrying-capacity basis and on an intermittent-duty basis, at values depending on the duty cycle. The NEMA Standard 8-h open ratings range from 25 to 2500 A. The intermittent ratings are $133^1/_3\%$ of the open ratings. The shunt-operating coil is designed to withstand 110% of rated voltage continuously and to close the contactor successfully at 80% of rated voltage.

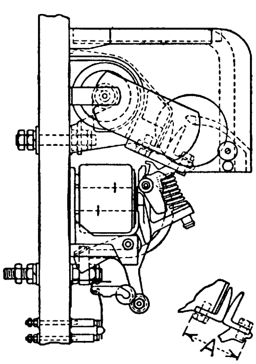

FIGURE 20-52 Direct-current contactor.

The *magnetic blowout* consists of a coil wound on a steel core and mounted between steel pole pieces. The pole pieces are lined with refractory material. The assembly is enclosed in an insulated box, which is swung down over the contacts. The blowout coil is generally connected in series with the contactor and carries motor current with the contactor closed. The current sets up a magnetic field through the core and pole pieces of the blowout structure and across the contact tips. When an arc is formed, the magnetic field of the arc and the magnetic field of the blowout repel each other and the arc is forced upward and away from the contacts. The extinguishing action, due to the lengthening of the arc and the cooling of the refractory material, is extremely rapid and thereby greatly reduces the wear and burning of the contacts.

Several factors are important in the performance of contactors. To obtain trouble-free service and maximum contact life, the following items should be in accordance with the manufacturer's specifications: initial and final contact pressures, magnetic gap, arc gap, and wear allowance. The contact pressures can be measured by means of a spring balance, initial pressure with the contactor open,

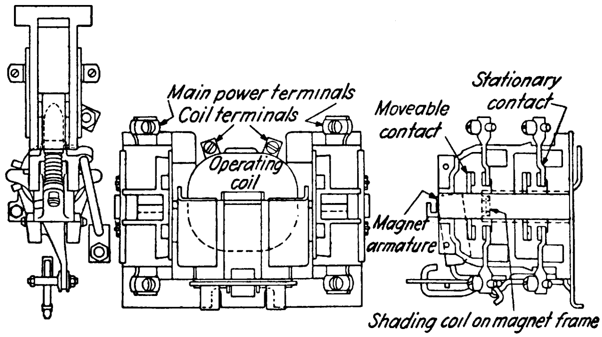

FIGURE 20-53 Alternating-current contactor.

and final pressure with the contactor closed. The magnetic gap is the distance from the centerline of the core to a corresponding point on the armature lever, and the arc gap is the distance between the arcing tips. Contacts can be kept smooth by filing with a fine file. Contact-wear allowance is the total thickness of material that may be worn away before the contact between the two surfaces becomes ineffective. The contacts should be renewed when worn so that the distance A (Fig. 20-52) between the back edges of the contacts, with the contactor closed, becomes less than the specified amount. This usually corresponds to the condition where the contacts are worn to approximately half their original thickness.

Current-carrying contacts are usually made from copper, either left plain or plated with silver or cadmium. The contacts should not be lubricated. Hinge pins and bearings should be lubricated with a light machine oil. The surface of the core and the armature, which seal when the contactor is closed, should be kept clean.

An ac contactor is similar in construction to a dc contactor, except that laminated iron structures are used. A shading coil is used at the core face to ensure continuous force of the armature and thus obtain quiet operation. AC contactors are available with 2, 3, or 4 main poles for interrupting all line circuits to single-phase, 3-phase, or 2-phase 4-wire motors (see Fig. 20-53 and Table 20-15). Standard ac contactors are designed to interrupt 10 times rated motor current, based on the contactor horsepower rating. The contactors are also designed to thermally withstand 15 times rated motor

current for 1 s, to permit protective devices such as circuit breakers and fuses to clear fault current carried by the contactor.

A *drum switch* consists of stationary contact fingers held by spring pressure against contact segments on the periphery of a rotating cylinder or sector. Drum controllers have many advantages over the faceplate and multiple-switch types. The mechanical construction is better, heavy contact pressures can be maintained, parts can be well insulated, blowout magnets and arc shields can be used, and the structure can easily be completely enclosed. Less space is required by the drum control, and it is easier to operate. Drum controllers are built in 8-h ratings for dc motors up to 40 hp, 115 V, and 75 hp, 230 V.

The design of starting-duty resistors requires the determination of the total ohms, the distribution of this resistance between the steps available, and the calculation of the current-carrying capacity, and the selection of the resistance material. Standard resistors to meet various classes of service are designated by class numbers in accordance with the NEMA *Table of Classification of Resistors*. NEMA also publishes a resistor application table intended as a guide in specifying and designing resistors (see *NEMA Industrial Control Standards*). This table lists typical machines with the corresponding NEMA resistor-classification number. For example, a lathe should have a dc starter with resistor classification No. 115. This resistor has sufficient total ohms to limit the current inrush on starting to 150% of full-load current. It will be designed to have current-carrying capacity for an average accelerating current (rms value) of 125% full-load current, on the basis of starting once during each 80-s period and with an accelerating time of 5 s.

Resistors must be available in a wide range of ohmic values and current capacity. Resistor units are stacked in parallel and series combinations to achieve the required values. For low ohms and high capacity, cast-iron or punched-steel grids are used. These steel grids range from 0.01-Ω, 160-A to 0.40-Ω, 20-A continuous rating per grid. For high ohms and low capacity, wire-wound resistors are used with a unit resistance range from 4.0 to 6400 Ω and dissipation up to 900 W. Intermediate resistance requirements are fulfilled with edge-wound ribbon resistors with a unit resistance range of 0.05 to 8.6 Ω and dissipation up to 1320 W.

Resistors must be sized and arranged in assemblies so that the temperature rise for bare resistive elements does not exceed 375°C above 40°C ambient. The maximum current should not exceed the 10-s rating. Care must be taken to limit excess voltage on wire-wound resistors to avoid surface flashover. Resistors are generally insulated for 600 V rms to ground. Manufacturers will provide assembled resistor units for specific functions or provide the derating curves for the arrangement of the resistor units into assemblies, as a function of duty cycle, ambient temperature, and grouping.

20.9.1 AC Motor Starting

Selection of an ac starter is a compromise between requirements and cost. The primary requirements of the starter, obviously, are that the motor starting torque shall be adequate to start the load under worst-case line voltage and load conditions; also, that the line current shall not exceed limits set by the utility or plant voltage dip. A useful table is shown in Table 20-16. The available starters are listed in descending value of starting torque, based on a 60-hp, 440-V, 60-Hz, 900-r/min motor. Compared to the starters with series-connected elements, the autotransformer starter provides a means for reducing the line current below the motor current. The current and torque in Table 20-16 are shown for 100% line voltage. For reduced line voltage, the current is reduced in proportion; the torque is reduced as the square of the voltage. Limit on voltage dip is 15% to 20%.

The secondary requirements in starter selection include smoothness of acceleration, maintenance, power factor, reliability, and efficiency. The selection of a closed-transition starter depends upon whether the motor and the supply line can withstand the peak current as the time the starter transfers the motor to full voltage.

Alternating-current across-the-line starters are simple in construction, easy to install and maintain, and inexpensive. A typical starter consists of a 3-pole contactor with a thermal overload relay for protecting the motor. The starter connects the motor directly to the line, impressing full voltage to the motor terminals. It is particularly suitable for squirrel-cage motors. Since these starters connect the motor directly to the supply lines, the motor will draw an inrush current of 6 to 10 times running current. In the

Autotransformer 50% tap	140	43
Resistor starter to give 50% applied voltage	233	43

majority of installations this is not objectionable and will not damage the motor or the driven machinery. When the starting inrush must be lower, some form of reduced-voltage starting must be used. The common types of starters are autotransformer, primary-resistance, part winding, Y-Δ, and solid-state.

Autotransformer starters have two autotransformers connected in open Δ to provide reduced-voltage starting. Three taps are supplied, as shown in Fig. 20-54, giving 50%, 65%, and 80% of full line voltage. The motor current varies directly as the voltage impressed on the motor terminals. The line current varies as the square of the impressed voltage and is therefore lower than with resistor-type starters. The torque also varies as the square of the impressed voltage. The 50% voltage tap will therefore provide 25% starting torque. Connections should be made to the lowest tap that will give the required starting torque.

Characteristics of this type of starter are low line current, low power from the line, and a low power factor. Acceleration is not continuous, because the torque developed by the motor remains practically constant during the starting period, on the first step; then changes to another value on the second step. The starter shown in Fig. 20-54 is an open-transition type. The motor is disconnected from the line during the transfer period. A closed-transition starter which uses the Korndorfer connection is shown in Fig. 20-55. When the *S* contactor opens, the autotransformers act as series reactors until the *R* contactor closes.

Autotransformer starters are available in manual and automatic types. In the manual type the contacts are operated by means of a lever extending to one side of the enclosing case. The lever is equipped with a low-voltage release magnet. The automatic open-transition starter (Fig. 20-54) consists of a 5-pole starting contactor *S* and a 3-pole running contactor *R*. The closed-transition starter (Fig. 20-55) consists of a 3-pole main contactor (*M*) and 2-pole start and run contactors (*S* and *R*).

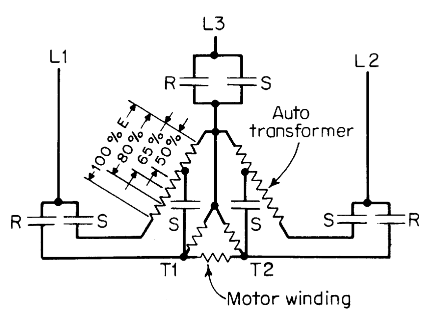

FIGURE 20-54 Connections for autotransformer starter.

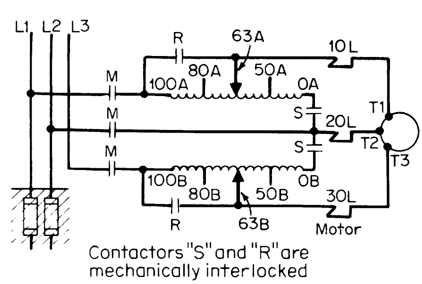

FIGURE 20-55 Connections for a closed-transition autotransformer motor starter.

When the "run" button is pressed, the starting contactor closes, connecting the transformer to the line and the motor to the reduced-voltage taps. A timing relay is operated by the starting contactor. The motor accelerates, and, after a specified number of seconds, the timer contacts close, deenergizing the starting contactor and energizing the running contactor. The transformer is disconnected and the motor connected to line voltage.

Primary-resistor-type starters connect the motor to the line through a series resistor. Reduced voltage at the motor is obtained because of the voltage drop across the resistor. As the motor accelerates, the current drawn from the line declines, and consequently the voltage drop across the resistor is lowered, and the motor voltage at the motor terminals is increased. The torque delivered by the motor is therefore constantly increased as the motor speed increases. After a definite interval, a timing device operated by the main contactor energizes the accelerating contactor, which short-circuits the resistor. There is no transfer period during which the motor may lose speed, and therefore smooth acceleration is obtained. In comparison with the autotransformer-type starter, the primary-resistor type takes more power from the line on starting but provides smoother acceleration, faster acceleration with a given initial torque, and higher power factor. In the smaller sizes, the primary-resistor starter costs less than the autotransformer starter.

In *part-winding ac starters,* the motor winding must be in two parts, and at least six terminal leads must be provided on the motor. The method is therefore applicable to those motors which are designed for use on either of two voltages, the windings being in parallel on the lower voltage and in series on the higher voltage. For example, a 230/460-V motor could be used on 230 V with a part-winding controller. The controller would then be arranged to connect one section of the winding to the supply lines as soon as the starting button is pressed. Then, after a time delay provided by a timing relay, a second contactor would connect the other section of the motor winding to the supply lines, in parallel with the first section. In this way, the starting current is reduced to approximately one-half of what would be required if both winding sections were connected at the same time, as they would be with a standard 3-lead motor. The starting torque when the first winding section is connected will be less than half of the torque that would be obtained if both sections were connected at the same time. Contactors used for part-winding starters need capacity to handle only the circuit which they control, and so may be rated at one-half of the rating that would be required to handle the whole motor. Overload relays are provided for each section of the winding.

Y-Δ *ac starters* are a form of reduced voltage starter used with 6-lead motors in which 57% voltage is applied to the windings on the first step, full voltage on the second step. The starting current and starting torque are 33% of the full-voltage values. The Y-Δ starter is used for compressors and other loads that can be unloaded for starting, or can tolerate the 33% starting torque.

Y-Δ starters are built for open-transition, as shown in Fig. 20-56, or closed-transition operation, as shown in Fig. 20-57. The open-transition starter operates as follows: Relay contactor *S* is energized, connecting the motor windings in Y. A normally open auxiliary contact on contactor *S* closes,

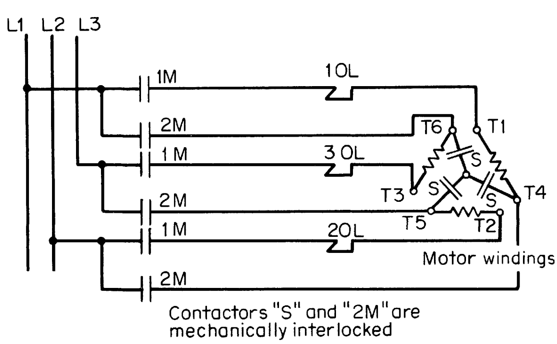

FIGURE 20-56 Open-transition Y-Δ starter.

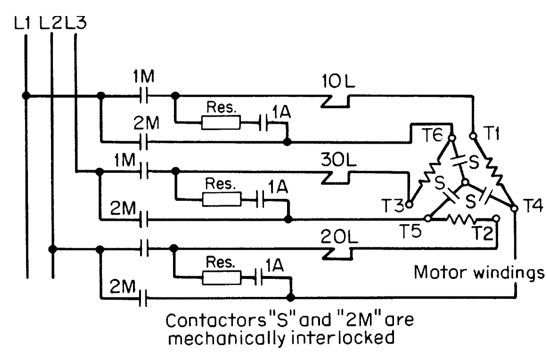

FIGURE 20-57 Closed-transition Y-Δ starter.

energizing contactor 1*M*. Its contacts close, energizing the motor windings in Y. After a predetermined interval, the contactor is deenergized, contacts on timer *TR* open deenergizing contactor *S*, opening its contacts and thereby opening the Y-connected winding. The motor is now temporarily deenergized. A normally closed auxiliary contact on contactor *S* closes, energizing contactor 2*M* in addition to 1*M*. The motor is reenergized in Δ.

The closed-transition starter of Fig. 20-57 operates as follows: Contactor *S* is energized, connecting the motor windings in Y. A normally open auxiliary contact on contactor *S* closes, energizing contact 1*M*, closing its contacts, energizing the motor windings in Y. After a predetermined interval, contactor 1*A* is energized, connecting resistors *Res* in Y and paralleling them across the Y-connected motor winding. A normally closed auxiliary contact on contactor 1*A* opens, deenergizing contactor *S*, opening its contacts and placing resistors *Res* in series with the motor winding. The motor is now connected in Δ. A normally closed auxiliary contact on contactor *S* closes, energizing contactor 2*M*, closing its contacts and thereby shorting out the resistors *Res*. The Δ-connected compressor motor is now energized at full voltage.

Solid-state ac starters employ back-to-back phase-controlled thyristors in two or three of the lines to the motor as shown in Fig. 20-58. The thyristors are controlled during the starting period to maintain about 300% line and motor current by gradually increasing the motor voltage from the initial value. Starting is smooth; the current and starting torque can be adjusted easily. The solid-state starter is applied where the line current is critical and where repetitive motor starting limits the life of electromagnetic contactors.

Slip-ring ac motor starters consist of a contactor to connect the motor primary to the supply lines and a resistor and resistor switching means for the secondary circuit. The starting torque depends on the ohmic value of resistance used; maximum torque is obtained when the resistance is selected for an inrush of approximately 3 times full-load current. Sufficient resistance is generally used to limit the inrush current to 150% or 200%. The resistor is cut out step by step as the motor accelerates, until the slip rings are short-circuited. The commutating means may be a faceplate controller, a drum, or a series of magnetic contactors controlled by current or time relays. High starting torque and low running slip can be obtained with a slip-ring motor.

20.9.2 DC Motor Starting

Direct-current motors of small capacity may be started by connecting the motor directly to line voltage. Motors rated 2 hp or more generally require a reduced-voltage starter. The reduced voltage for starting is obtained by using resistance in series with the motor armature or by varying the armature supply voltage. Manual or magnetic control may be used.

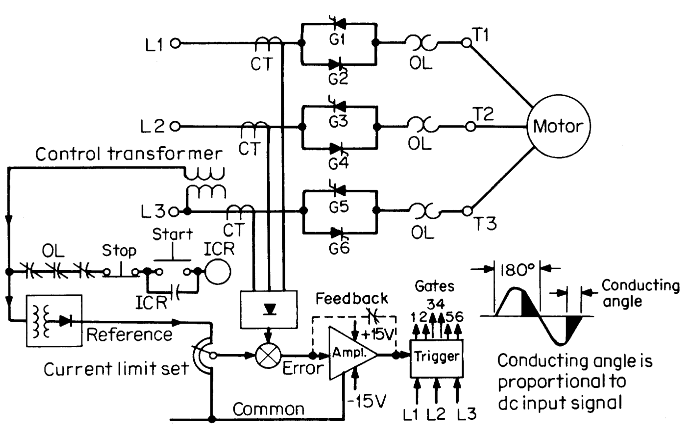

FIGURE 20-58 Diagram of solid-state ac motor starter.

DC motors in adjustable-voltage, adjustable-speed drives are started by turning the speed control up from zero to the desired speed, or by internal circuits that ramp the armature voltage to the desired value. Starting equipment, other than the armature-voltage rectifier or generator, is not required.

Direct-current manual starters are satisfactory for applications that do not require frequent starting and stopping and where the starter can be mounted near the operator without requiring long motor leads. Across-the-line starters provide the simplest means of starting small dc motors. Manually operated switches for this service are available in sizes up to 1.5 hp at 115 V and 2 hp at 230 V. For larger motors resistance is connected in series with the motor armature to limit the current inrush on starting. A manually operated means is then provided for removing the resistor from the circuit in a series of steps. Starters are available in the faceplate type, the multiple-switch type, and the drum type. The faceplate type is built for motors up to 35 hp, 115 V, and 50 hp, 230 V. It consists of a movable lever and a series of stationary contact segments to which sections of resistor are connected. The resistor sections are short-circuited one at a time by moving the lever across the segments.

Manual starters have generally been replaced by push-button-operated magnetic control that incorporates overload protection and other safety features.

Direct-current magnetic starters are used for applications where case and convenience of operation are important; where the starter is operated frequently; where the motor is located at a distance from the operator; where automatic control by means of a pressure switch, limit switch, or similar device is desired; and for large motors which require the switching of heavy currents. Resistance is connected in series with the motor armature to limit the initial current and is then short-circuited in one or more steps.

For larger motors a series of magnetic contactors is used, each of which cuts out a step of armature resistance. The magnetic contactors are operated as the motor starts by one of two methods called *current-line acceleration* and *time-limit acceleration;* the starting time is always matched to the burden of the load. Time-limit acceleration is advantageous where the starting time of the motor must be integrated into a timing sequence for an overall machine or process. Examples of each will be given.

Figure 20-59 shows a type of *time-limit acceleration* where the operation of contactors, and therefore the rate of acceleration, is governed by a *magnetically operated definite time relay*. This time relay operates on the principle of discharging a capacitor, thus obtaining a definite time period, which is unaffected by changes in temperature and load or by dust and dirt. With the motor at rest, a circuit is obtained through a normally closed contact on *M* to energize the *CT* timing-delay coil and to charge capacitor *C*1. Contacts *CT*1 and *CT*2 on relay *CT* are open with the relay energized. Capacitor *C*2 is charged through the normally closed contact on the 2*A* contactor. Pressing the "start" button energizes the main contactor *M*, which maintains itself through a normally open interlock finger. Relay *FA* is energized, and its contact *FA*1 short-circuits the field rheostat. The motor accelerates from rest to a speed determined by the value of the *R*1-*R*3 resistor. The circuit to timing relay *CT* is opened by the interlock on *M*, and capacitor *C*1 discharges through the *CT* coil and the *AB* resistor. Contacts *CT*1 and *CT*2 can be individually adjusted to close at any time during the capacitor discharge period. Closing *CT*1 energizes the 1*A* contactor, which short-circuits the *R*1-*R*3 resistor. The motor then accelerates to a speed determined by the value of the *R*2-*R*3 resistor step. Closing *CT*2 energizes 2*A* and connects the motor across the line, permitting it to accelerate to normal speed.

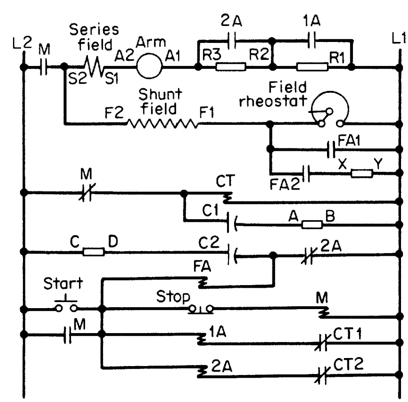

FIGURE 20-59 Time-limit acceleration with definite-time relay.

Relay *FA* is deenergized when 2*A* closes. Contacts *FA*1 and *FA*2 remain closed for a definite time because of the discharge of capacitor *C*2 through the *FA* relay coil. When contact *FA*1 opens, a resistance is inserted in the motor shunt field, equivalent to the field-rheostat resistance and *XY* resistance in parallel. Opening *FA*2 disconnects *XY*, and the motor runs at a speed determined by the setting of the field rheostat.

Direct-current starters with current-limit acceleration are designed to half the starting operation whenever the required starting current exceeds an adjustable predetermined value, the starting operation being resumed when the current falls below this limit. With current-limit acceleration, the time required to accelerate will depend entirely upon the load. When the load is light, the motor will accelerate rapidly, and when it is heavy, the motor will require a longer time to accelerate. For this reason a current-limit starter is not so satisfactory as a time-limit starter for drives having varying loads. Time-limit starters are simpler in construction, accelerate a motor with lower current peaks, use less power during acceleration, and always accelerate the motor in the same time regardless of variations in load. Current-limit starters are desirable for motors driving high-inertia loads. A typical current-limit starter is shown in Fig. 20-60. The relays *SR*1-*SR*2 have normally closed contacts connected in series with the coils of the accelerating contactors. The coils of these relays are connected in the main motor circuit. The relays are provided with an adjustment so they can be set to close on a selected value of current.

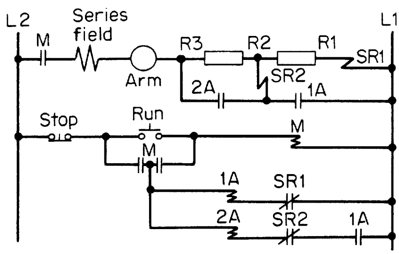

FIGURE 20-60 Direct-current series-relay accelerations.

Pressing the "run" button energizes the main contactor *M*, which closes and connects the motor to the line in series with the *R*1-*R*3 resistor. Motor current will flow through the *SR*1 coil, and its contacts will open rapidly and prevent 1*A* from closing. When the motor has accelerated enough to bring the line current down to the value for which *SR*1 is set, the relay contacts will close; a circuit is then provided for 1*A*, which closes, cutting out the first step of resistance and short-circuiting the *SR*1 coil. Current now flows through the *SR*2 coil and the 1*A* contacts. *SR*2 relay contacts open and prevent 2*A* from being energized. The motor accelerates again, and when the current falls to the value for which *SR*2 is set, its contacts close, energizing 2*A* and connecting the motor across the line.

Magnetic controllers for large dc motors are manufactured in forms to suit the application. The controllers are available in the following forms: (1) nonreversing, without and with dynamic braking; (2) nonreversing with speed regulation by field control, without and with dynamic braking; and (3) reversing with dynamic braking, without and with speed regulation by field control.

20.9.3 Synchronous Motor Starting

Methods of Starting Synchronous Motors. The method used to start a synchronous motor depends upon two factors: the required torque to start the load and the maximum starting current permitted from the line. Basically, the motor is started by using the damper windings to develop asynchronous torque, or by using an auxiliary motor to bring the unloaded motor up to synchronous speed. Recently, solid-state frequency converters have been designed to bring up to speed large several-hundred-MVA synchronous motor/generators for pumped-storage plants.

Synchronous-motor starters of the full-voltage type connect the motor directly to the supply lines. The field winding is short-circuited through a discharge resistor during the starting period. The field is connected to the dc lines when the motor is at a speed near synchronism. Reduced-voltage starters connect the motor to a reduced voltage for starting and transfer to full voltage at a speed just below synchronism. This transfer may be controlled by a time relay or a frequency relay. The field is energized either immediately before or immediately after the full-voltage switch closes. Most modern synchronous motors obtain their field voltage from a brushless exciter on the shaft.

Figure 20-61 is a simplified diagram of a synchronous motor controller arranged for starting the motor directly across the line and synchronizing by a relay operating at a selected frequency. Pressing the start button energizes relay 1*CR* and contactor *M* to connect the motor stator windings to the ac lines. Current at line frequency is induced in the rotor field winding that flows through the discharge resistor *FD* and the coil of relay *FR*. A small portion of this current flows through the reactor *X*, but the amount is limited, as the frequency is high. Relay *FR* closes rapidly, and the contacts on *FR* open the circuit to the *FS* field contactor. As the motor accelerates, the frequency of the induced current in the field winding decreases and an increasing portion of the current flows through the reactor *X*. At a speed close to synchronism most of the current flows through *X*, and there will no longer be enough current flowing through the coil *FR* to keep the relay armature closed. Relay *FR* then opens, and the contacts on *FR* close to energize field contactor *FS*. Contactor *FS* connects the field to the dc lines and opens the field discharge circuit through resistor *FD*, and the motor pulls into synchronism.

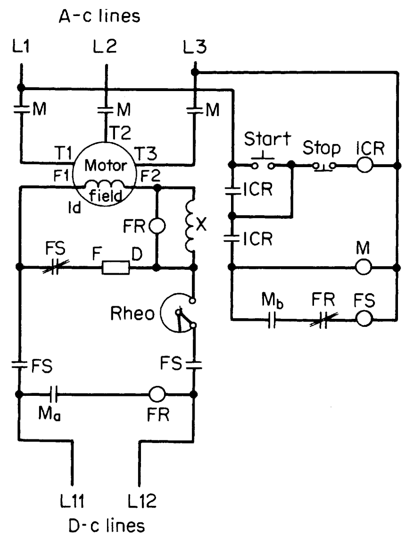

FIGURE 20-61 Full-voltage synchronous motor controller with synchronization based on frequency.

Relay *FR* is polarized by a coil connected across the dc lines through interlock contacts M_a. Polarizing the synchronizing relay provides a means for energizing the field contactor at a point in the ac wave most favorable to synchronism. Brushless synchronous motors use electronic circuits on the rotating portion to control the switching time for the field.

Speed-Control Devices. Speed control of electric motors may be obtained by various means. The design of a speed-regulating controller is determined by the type of motor with which it will be used. Table 20-17 lists the various types of motor in general use and the corresponding type of speed control for each.

Multispeed squirrel-cage motors are suitable for applications that require up to four operating speeds but that do not require speed control between these fixed speeds. However, a solid-state inverter plus a single-speed motor might be less costly than a multispeed motor, and provide much more cost-efficient operation.

Controllers for multispeed ac squirrel-cage motors may be either the drum type or the magnetic type. Drum controllers are widely used, because the many changes in connections required to obtain different speeds can be readily accomplished. Drum controllers can be used with reconnected winding or separate-winding-type motors and with constant-torque, variable-torque, or constant-horsepower motors. Low-voltage and overload protection can be obtained by using a magnetic contactor and overload relay. When complete control by push buttons or other pilot devices is required, magnetic contactors are used to change the motor connections. Controllers of this type can be arranged to permit starting at any speed or to permit starting only at the slowest speed and changing to each higher speed in sequence.

Primary Voltage Control. AC squirrel-cage motors are inherently constant-speed motors when supplied directly from utility lines. Narrow-speed-range control is obtained by adjusting the primary voltage on Design D motors using saturable reactors or solid-state phase-controlled thyristors in the stator circuits. Wide-speed-range control is obtained by adjusting the primary frequency and voltage on Design B motors using motor-alternator sets or solid-state frequency converters. The frequency of 60-Hz motors is typically adjusted from 3 to 120 Hz. From 3 to 60 Hz, the voltage is raised proportional to frequency so that the motor can deliver its full rated and breakdown torque. From 60 to 120 Hz, the voltage is kept constant so that the motor can deliver its rated horsepower.

Speed is controlled with thyristors in each of the lines to the stator of the induction motor as shown in Fig. 20-62*a*. Retarding the firing angles of the thyristors reduces the stator voltage of the

motor. The torque at each speed is reduced as V_2, as shown in Fig. 20-62*b*. NEMA Design D motors ensure a sufficient range of descending torque in which the motor can stably drive its load. The power loss in the rotor is proportional to the torque × slip. With pump and fan loads, as shown in Fig. 20-62*b*, the torque is reduced as speed, so that the rotor power loss is acceptable at reduced speed. Typical ranges of pump and fan operation are 50% to 100% speed, 10% to 100% power.

Other Speed-, Frequency-, or Voltage-Controlling Devices. Adjustable-frequency ac induction motor drives consist of a solid-state rectifier, a solid-state inverter, the motor, and necessary controls. As shown in Fig. 20-62*a*, the rectifier converts power at 60-Hz line frequency to dc power; the inverter converts dc power to power for the motor which is adjustable in frequency and voltage. Inverters are classified by their output; they include six-step voltage, current source, and pulse-width-modulated voltage. The six-step inverter in Fig. 20-63*a* causes the motor current to approximate a sine wave.

These ac drives operate in two modes with respect to base speed, as shown in Fig. 20-63*b*. From near zero to base speed, the inverter frequency and voltage are raised in proportion so that they both reach rated value for the motor at base speed. This is termed the *constant-torque mode* because the motor can deliver its rated torque anywhere in the speed ranges below base speed. From base speed to 200% or more of base speed, the inverter frequency is raised, but the voltage is maintained constant at the rated motor voltage. The consequence is that the magnetic field in the air gap of the motor decreases and the motor is able to deliver only $^1/_7$ times its rated torque. However, the product of torque and speed is constant; the operation is termed the *constant horsepower mode*. The maximum speed depends on the mechanical capability of the motor to run above base speed and the maximum design frequency for the inverter.

AC synchronous motors are speed-controlled in special applications where their self-excitation simplifies the frequency conversion equipment and where two or more motors must operate in synchronism with the supply. Adjustable-frequency, adjustable-voltage power is supplied from a motor-alternator set, or from a solid-state frequency converter. The solid-state converter is of the cycloconverter type for speeds up to 30% of the rated speed. For wide speed range, the frequency converter is a forced-commutated inverter or a load-commutated inverter, which relies on the self-excitation of the motor to commutate the thyristors.

Synchronous motors with permanent-magnet fields rated up to about 30 hp are used in textile applications, where multiple motors are operated in synchrony from a common power supply. Synchronous motors in the range of 750 to 5000 hp and larger are used for driving large blowers, boiler fans in power plants, large pumps, and other applications requiring large motors. The block diagram for a load-commutated inverter drive is shown in Fig. 20-64. The two converters are phase-controlled thyristor bridges which can rectify or invert power, as necessary. The thyristors in the inverter operate in the firing-angle range from 90° to less than 180°, and they are commutated by the voltage generated in the stator windings of the motor by the rotating field.

AC slip-ring motor control requires that power be extracted from the rotor windings via the slip rings to reduce the motor speed, that is, increase the slip. Three methods are used: (1) secondary resistors, (2) rotor-power recovery by auxiliary rotating machines, and (3) rotor-power recovery by auxiliary solid-state rectifier and converter. The auxiliary systems recover the electric energy that would be dissipated in the secondary resistors.

AC slip-ring motor secondary-resistor speed regulators consist of a contactor to connect the primary of the motor to the supply lines and some form of resistance-switching device for the secondary circuit. The switching device may be a three-arm faceplate controller, a drum, or magnetic contactors. Regulating devices differ from starting devices in that the switching means can remain continuously on any one of the resistor steps. The motor will therefore operate continuously at a reduced speed, as determined by the amount of resistance remaining in the motor circuit. The use of secondary resistance for speed control is not an efficient method because of the power loss in the resistor. The amount of speed reduction obtained will vary directly with the load on the motor. Speed controllers of this type are usually designed for 50% speed reduction. Under favorable conditions, however, motors can be operated at 75% speed reduction.

The resistors are of the same type as the resistors used for armature regulation of dc motors.

Rotor-power recovery drives are often classified as either constant horsepower or constant torque; the designation refers to the inherent limitation in power based on full current and flux in the main

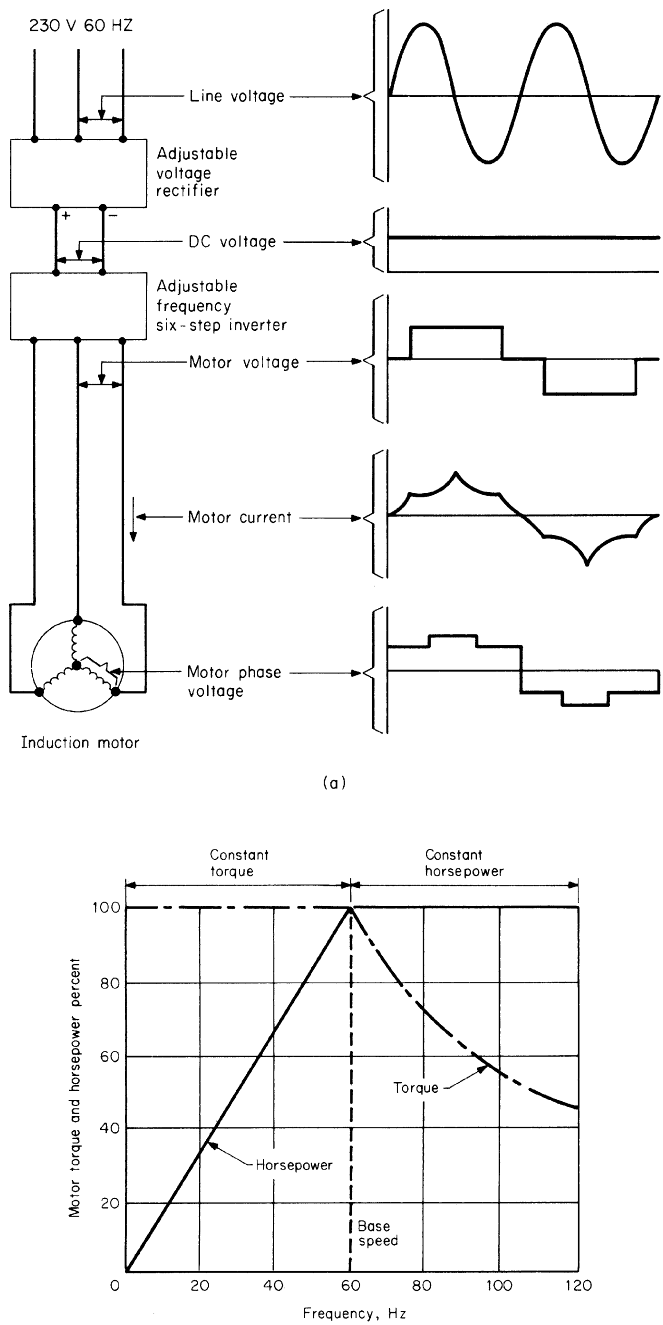

FIGURE 20-63 (*a*) Adjustable-frequency induction-motor drive using six-step inverter; (*b*) torque and horsepower capabilities of adjustable-speed drive below and above base speed.

machine. In the first scheme (constant-horsepower drive), the slip energy is converted into mechanical power and then returned to the main motor shaft. Since horsepower is a function of the product of torque and speed, such motors have high torque at low speeds and lower torque at higher speeds. In drives using this arrangement, the auxiliary machine is mounted on or mechanically geared to the main motor shaft (Fig. 20-65*a*).

In the second scheme (constant-torque drive), the slip energy is converted into electric power of the frequency and voltage of the supply circuit and is returned or fed back into the line. Since this power is not delivered to the main motor shaft, the auxiliary machine is not mechanically attached to the shaft but is separately driven. As the limiting torque of the main motor is constant, the maximum horsepower output is proportional to the operating speed (Fig. 20-65*b*).

The classical recovery systems using auxiliary machines are termed the *Scherbius drive* and the *Krämer drive.* The former employs ac commutator machines; the latter relies on a dc link and rotary converters. A variation of the Krämer drive uses a synchronous motor and a dc generator in place of the rotary converter and a constant-speed set feeding the slip power back into the line. This drive has been used for a number of large wind-tunnel drives. It is particularly adapted to a wide range of speed control and to minimum disturbance on starting.

In a solid-state version of the modified Krämer drive, the slip-ring power is rectified in a diode bridge, then passed over a dc link to a line-commutated inverter that returns the power to the supply line. The drive operates with characteristics similar to the adjustable-armature-voltage dc system. The speed is controlled by the firing angle of the inverter. The recovery systems are economical for narrow speed ranges, such as for fans and pumps, or where the horsepower rating is so large that the costs of the controls are minimized.

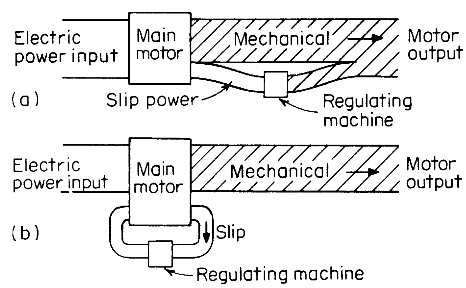

FIGURE 20-65 (*a*) Constant-horsepower drive; regulating machine, coupled to main motor, returns power mechanically; (*b*) constant-torque drive; regulating machine, mechanically separate from main motor, returns slip power electrically.

DC solid-state adjustable-voltage control utilizes phase-controlled 1-phase or 3-phase thyristor bridge rectifiers to provide armature and field voltage to independent-field dc motors. A typical armature-voltage supply is shown in Fig. 20-66*a*. As the firing angles of the thyristors are adjusted from 90° to 0°, the dc armature voltage rises from zero to rated value, and the speed follows in proportion.

The speed-torque characteristics of the dc drive are shown in Fig. 20-66*b*. In the range from zero to base speed, the field current is at maximum, but the armature voltage is raised until it reaches rated value at base speed. At any one setting of armature voltage, the speed is relatively constant over the load torque range. The firing angles of the thyristor are adjusted by a regulator to maintain the speed constant at the set point. At any speed, the rated torque is available in this range. Above base speed, the armature voltage is held at rated, but the field current is reduced to obtain the higher value of speed. The maximum output of the motor is its rated horsepower in this range.

DC series-wound motors are used for hoisting and electric traction applications where the speed is controlled either by series switched resistors or by a solid-state chopper. Where full voltage is applied, the motor operates on a varying speed-torque characteristic. For example, the speed will vary over a 10 to 1 range, as the motor load is reduced from rated to minimum torque. The series-motor controller shown in Fig. 20-67 shifts the series-motor characteristic in four resistance steps, *R*1 through *R*4. Adding resistance forces the motor to run at a lower speed for the same torque. For each resistance step, the motor has a varying speed-torque characteristic. In electric traction applications, higher motor speed is obtained by shunting the series field with additional resistors. The series motor will regenerate energy to the dc line when the series field current is supplied from another source to force the generated armature voltage higher than the line voltage.

Solid-state chopper control is replacing resistor speed control of dc series motors in rapid-transit cars operating from wayside dc lines and in battery-powered electrical industrial trucks. The chopper is more energy efficient than resistor controllers and permits stepless control of motor speed or torque. Choppers for rapid-transit cars are rated up to 1000 kW at 1000 V dc, for four-series traction motors.

A simplified circuit for a chopper is shown in Fig. 20-68*a*. The chopper applies voltage to the motor in a series of pulses, as shown in Fig. 20-68*b*. The pulse frequency is typically in the 200 to 400 pulses per second range. The width of the pulse can be varied over about a 10:1 range in a system called time-ratio control. The widest pulse provides full voltage and maximum motor speed, as shown in Fig. 20-68*c*; the narrowest pulse provides minimum voltage and speed. Each pulse is ended by turning off the thyristor with the commutating switch, which is actually another thyristor circuit. When the thyristor is turned off, the motor current continues through the diode, until the thyristor is turned on to start the next pulse. The energy loss in the thyristor is small compared to the resistors of the controller shown in Fig. 20-67. The thyristor, diode, and motor can be reconfigured for the motor to regenerate to the dc line or the battery.

Armature-regulating and field-regulating resistors are used for the speed control of dc motors fed from fixed-voltage dc supplies as shown in Fig. 20-69. Armature-regulating resistors provide starting and speed-control duty in multiple steps, usually for fan loads. The resistors are usually designated for continuous duty, in accordance

with a NEMA classification number between 91 and 96, inclusive. The specific classification within this group is determined by the motor-starting current allowed, with all resistance in the circuit. The total ohms in the resistor are usually determined by the speed reduction required and the torque of the load. The *IR* drop across the resistor is the difference between the dc line voltage and the armature voltage, which is proportional to the speed. The current *I* is proportional to the torque. For example, at 50% speed a fan load requires 25% to 40% of its current at full speed. The total ohms are divided into steps to give equal speed changes per step.

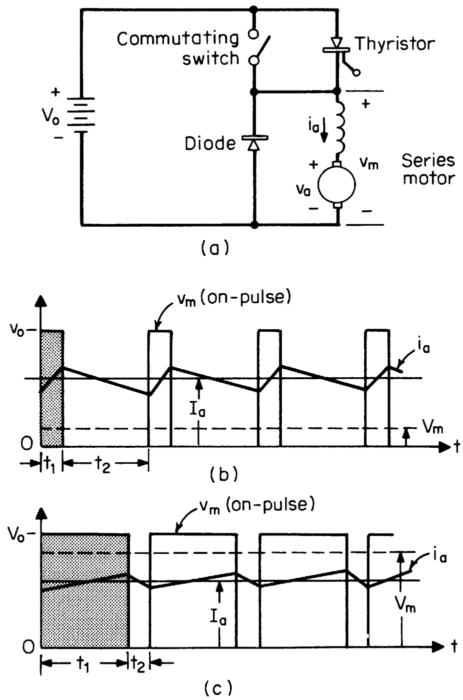

FIGURE 20-68 Chopper speed control for series motor: (*a*) circuit; (*b*) waveforms at low speed; (*c*) waveforms at high speed.

Field-regulating resistors should be designed on the basis of actual test data on the motor with which the control is to be used. The motor manufacturer will supply such data as the resistance of the shunt field or the maximum field amperes, the required rheostat resistance or the minimum field amperes. The total ohms in the rheostat will therefore be determined by the motor data. The number of steps in the rheostat must be large enough to limit the speed increase per step to an acceptable value. The character of the resistor material used may require a large number of steps, in order to keep the wattage per step on the rheostat within limits. The number of steps must be sufficiently large to keep the voltage drop at any step within specified limits to prevent arcing on the contacts. The arcing limits for sliding contacts vary from 200 V at 0.4 A to 50 V at 1 A and 25 V at 4 A. This voltage is the product of the step ohms and the amperes flowing before the step is inserted. The amount of resistor material required in the field rheostat is determined by the wattage which must be dissipated. Each step must be designed on the basis of the maximum current which it will have to carry. The total wattage capacity of the rheostat will be the summation of the step wattage. The distribution of the resistor between the various steps can be determined on the basis of obtaining either equal speed changes per step or equal percentage speed changes per step. Common practice at present is to provide equal speed changes per step, and a speed reduction to 20% of what is rated can be obtained with armature-regulating resistors. A speed increase up to 200% can be obtained by field resistors with a properly designed motor.

20.10 STOPPING DEVICES

Electric braking is used when the dc or ac motor is allowed to make several revolutions before coming to rest. In electric dynamic braking, the kinetic energy of the motor and the load is absorbed in the resistance of the motor windings, or in a resistor switched into the circuit. In electric regenerative braking, the energy is returned to the supply line. Magnetic brakes are used to obtain quick, accurate stopping

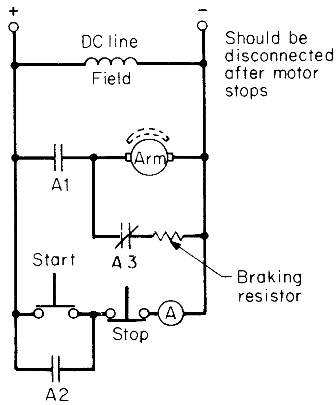

FIGURE 20-70 Dynamic braking circuit for shunt-wound dc motor.

and to hold the load after stopping. Most brakes are spring-set and electrically released, so that braking will be obtained even though an electrical failure occurs.

Dynamic braking of a dc shunt-wound motor can be obtained by disconnecting the motor from the line and shunting the armature with a resistor. As shown in Fig. 20-70, when the motor is running, contacts *A*1 and *A*2 are closed, and *A*3 is open. When the stop button is pressed, contact *A*1 opens to disconnect the armature from the line; holding contact *A*2 opens; and contact *A*3 closes to put the braking resistor across the armature terminals. The field must remain connected to the line during braking. For constant-speed motors, the ohmic value of the braking resistor is $R = (E - I_a R_a)/I$. The value of *I* determines the amount of braking obtained and may vary from 150% to 300% of normal current. With shunt motors, having speed regulation by shunt-field control, the general practice is to strengthen the field during braking by short-circuiting the field rheostat. When this is done, the ohms in the braking resistor should be $R = (E - I_a R_a)/I \times$ speed range by field. The braking obtained decreases as the motor speed is reduced. The final stopping of the motor is due to friction, since at standstill no braking torque is obtained. For very quick stopping the braking resistance can be reduced in several steps as the speed decreases, thereby keeping the current at a high value. This type of braking is effective where it is necessary to stop a motor quickly. Mechanical brakes must be used to hold a load at a standstill.

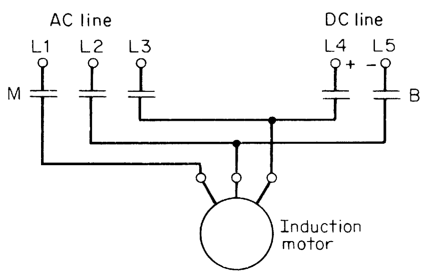

FIGURE 20-71 Dynamic braking circuit for 3-phase induction motor. Contacts *M* are for line-starting the motor. Contacts *B* are for applying direct current for braking.

Dynamic braking with an ac induction motor can be obtained by disconnecting the motor from the power supply and applying direct current to one of the stator phases. As shown in Fig. 20-71, the kinetic energy of the rotor and the load is dissipated in the rotor circuit resistance.

Plugging is used with *dc motors* to obtain very rapid reversing and is accomplished by connecting the motor to the line in the reverse direction while it is still rotating in the forward direction. The countervoltage of the armature is added to line voltage to force current through the armature and series resistor. The total resistance in circuit for plugging should be $R_t = 2(E - I_a R_a)$/inrush current. With the armature drop assumed as 10%, the formula may be written $R_t = 1.8E/1.5I = 1.2E/I$, where E = line voltage and I = normal current. The plugging resistance is determined by subtracting the armature resistance from R_t.

Plugging is used with *ac motors* to obtain a very quick stop. Three-phase squirrel-cage and wound-rotor motors may be plugged by reversing the line connections to any two of the stator terminals while the motor is running in the forward direction. In order to use plugging as a stopping means, a zero-speed switch is necessary to open the reverse contactor and prevent reversing the motor. A common form of zero-speed switch is the friction type, in which a contact is held closely by the friction of a small belt over a pulley driven by the motor. Any slight reversal of the motor will cause the contacts to open. Another type of zero-speed switch uses a disk which rotates in the magnetic field produced by Alnico magnets. Eddy currents are induced in the driven disk, and the magnetic reaction turns the magnet assembly to close the contacts. The contacts can be adjusted to open when the motor is near zero speed.

An electrical plugging relay is also used which remains closed until the line current decreases to the normal inrush current corresponding to the starting condition, or zero speed on the motor. This device has the advantage of not requiring a mechanical connection to the motor or machine.

Regenerative braking is used with dc adjustable-armature-voltage controllers to obtain rapid stopping. For a solid-state armature converter, either the dc motor field current is reversed to reverse the armature voltage, or a second reverse polarity converter is switched in. In the first case, the direction of the armature current remains the same, but the armature voltage reverses. In the second case, the direction of the armature current reverses, but the armature voltage remains the same. The regulator controls the firing angles of the converters to maintain prescribed armature current during the braking period. For an ac-motor-driven dc generator supplying the dc motor in a Ward Leonard system, the generator voltage exceeds the countervoltage of the driven motor, and power is taken from the ac lines to keep the driven machine rotating. If the field strength of the generator is decreased, the generator voltage becomes less than the countervoltage of the motor and the motor feeds power back to the generator and to the ac lines. When the countervoltage exceeds the generator voltage, a heavy reverse current is obtained, as the value of this current is limited only by the low resistance of the loop circuit. A very rapid stop is obtained, since the voltage across the generator field can be reduced to zero in about 3 s.

Direct-current brakes are set by a spring and are released by means of a solenoid or a direct-operating magnet. The coil in the operating device may be for either series or shunt connection and for continuous or intermittent duty. Series-wound brakes are operated by motor current and require 80% full motor current to release with a continuous-duty coil and about 40% full-load current with an intermittent-duty coil. The brake will be held released on about 10% full-load motor current. Intermittent-duty series brakes are rated as either $^1/_2$-h duty or 1-h duty, to correspond to the rating of intermittent-duty series motors. A series-brake coil will carry full motor current continuously, for a period corresponding to its rating, without exceeding a temperature rise of 75°C. Shunt brakes may be for either continuous or intermittent duty. Intermittent duty is defined as 1 min on and 1 min off or the equivalent, the longest time on not to exceed 1 h. Shunt brakes will release at 80% of normal voltage, when adjusted for rated torque. The larger-sized brakes use partial-voltage coils and protecting resistors. Series brakes have a heavy wire coil, which is less likely to give trouble, are faster in operation, and will set whenever the armature circuit is open. Data on a line of dc magnet-operated shoe brakes are given in Table 20-18.

Alternating-current brakes have three forms of operating mechanism: solenoid type, torque-motor type, and thrustor type. The smaller sizes of brakes are usually made in the solenoid type. On the larger sizes, a vertically mounted torque motor and antifriction ball jack provide a quiet, low-inrush-current operating means. On application of power to the motor, the rotary motion of the armature is transformed into straight-line motion through the antifriction jack. With the brake fully released, the torque motor is stalled across the line. When the motor is disconnected from the line, the spring in the brake overhauls the motor mechanism and applies the brake. Data on a line of brakes of this type are given in Table 20-19.

The thrustor-type operating mechanism consists of a self-contained motor-driven centrifugal pump, oil chamber, and a piston which produces a straight-line movement to release the brake.

The *brake size* for most applications can be determined by using the formula $T = 5252 \times \text{hp/r/min}$, where T = full-load motor torque in pound-feet, hp = motor horsepower, r/min = speed of shaft on which brake wheel is mounted. A brake should be selected with a torque rating equal to or greater than the full-load motor torque T. In some cases, the braking torque is determined by extreme operating conditions against which the brake must hold, for example, heavy ice loads on bascule bridges or conditions

of unbalance on skip hoists. In these cases, the maximum load must be calculated and translated into pound-feet torque at the shaft on which the brake is mounted. Sufficient lining area is provided on all sizes of brake for the average application. However, a careful check as to lining area must be made when brakes are used for frequent stopping or for stopping high-inertia loads.

20.11 MOTOR-PROTECTING DEVICES

Fuses should be provided for motor circuits, in accordance with the NEC. The current rating of the fuse must be considerably higher than the current rating of the motor, or the fuse will blow when the motor is started. For that reason fuses do not provide adequate overload protection. They furnish protection for the motor only in case of a short circuit or a very heavy overload. Their primary purpose is to protect the circuit rather than the motor.

Magnetic-type overload relays are operated by direct magnetic action of the motor current on a plunger. The relay consists of a series coil connected in the motor circuit and a plunger which is pulled up into the center of the coil when a certain value of current has been reached. When the plunger is lifted, a contact is tripped, opening the motor contactor-coil circuit and disconnecting the motor from the line. The tripping current can be varied by adjusting the initial position of the plunger with respect to the coil. Time delay in tripping is obtained by attaching a small oil dashpot to the plunger. The time delay can be adjusted so that the overload will not trip on the starting-current inrush but will trip on small sustained overloads.

Thermal overload relays are available in the bimetallic type and the fusible-alloy type. The bimetallic type has two heaters in series with the circuit to be protected, and above these heaters are two strips of bimetallic material, which act as latches for the contact members. Bending of the bimetallic strips under heating of overload current will release the latches and allow the contacts to open. The fusible-alloy type has two heaters, each surrounding a thermal element consisting of a small tube, inside which is a loose-fitting shaft. The tube and shaft are rigidly joined by a special low-melting eutectic alloy. On overload, the increased current drawn melts the alloy, allowing the shaft to turn and the contacts to open.

Characteristics of a typical thermal overload are shown in Fig. 20-72. An inspection of these curves shows that the thermal overload adequately protects the wiring, that the fuse blows first on short-circuit current, and that the thermal relay allows the motor ample time to accelerate. A thermal overload has a

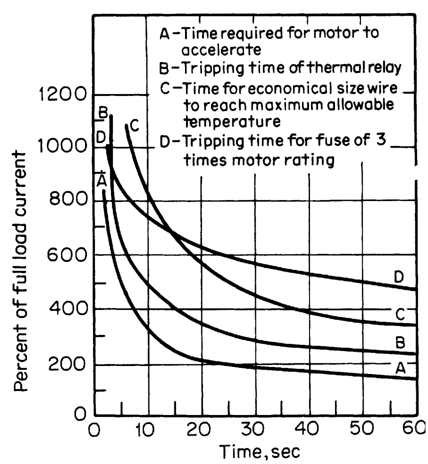

FIGURE 20-72 Characteristics of thermal overload relays.

tripping characteristic which corresponds closely to the heating characteristics of a motor and, therefore, provides an ideal protecting means. An overload coil should be selected so that the maximum permissible output can be obtained from the motor. A motor rated 40°C rise on the basis of 40°C ambient temperature will have a final safe temperature of approximately 95°C and will operate at 15% overload continuously without overheating. An overload coil should therefore be selected having an ultimate tripping current equivalent to 15% overload on the motor. A continuous overload of 15% would therefore ultimately trip the thermal relay. For overloads in excess of 15%, the tripping time would be shorter than the time required for the motor to reach a dangerous temperature.

Low-voltage protection is the effect of a device, operative on the reduction or failure of voltage, to cause and maintain the interruption of power to the main circuit.

With magnetic controllers, this protection is obtained by using some form of 3-wire master switch. Should the line voltage drop to a low value or fail altogether, the main-line contactor will open and remain open, stopping the motor. To restart, it is necessary to push the "start" button. This type of control should always be used where the unexpected restarting of a motor after voltage failure may be dangerous to workers or equipment.

Low-voltage release is the effect of a device, operative on the reduction or failure of voltage, to cause the interruption of power to the main circuit but not to prevent the reestablishment of the main circuit on return of voltage. Such protection is obtained when a 2-wire pilot device, for example, a snap switch, float switch, or pressure switch, is used.

Phase-failure protection is the effect of a device, operative upon the failure of power in one wire of a polyphase circuit, to cause and maintain the interruption of power in all the wires of the circuit.

Phase-reversal protection is the effect of a device, operative on the reversal of the phase rotation in a polyphase circuit, to cause and maintain the interruption of power in all wires of the circuit. Protection of this type is necessary on elevators, where reversing of the phases would cause the car to start in a direction opposite to that in which the operator expects it to move.

Field-failure protection is usually provided in controllers for dc shunt- and compound-wound motors. The coil of a relay is connected in series with the motor shunt field, and a normally open contact of the relay is connected in the stop circuit. If the field circuit is opened, the relay will be deenergized and the motor will be disconnected from the line. This prevents overspeeding the motor owing to an open circuit in the field. A *field protective relay* is used to insert resistance in series with the shunt field whenever the motor is not running. The coil of the relay is connected in parallel with the main switch coil, and a normally open relay contact is used to short-circuit a step of resistor in the field circuit. The resistor should be designed to reduce the voltage across the field to one-half line voltage. This reduces the field wattage to one-fourth the normal value and prevents overheating the field with the motor at standstill.

A *field-discharge resistor* should be provided for 230-V motors rated $7^1/_2$ hp or more and for 550-V motors rated 5 hp or more whenever the shunt-field circuit must be opened. The ohmic value of a discharge resistor should be 1 to 3 times the ohms in the field. If a resistance of three times the field ohms is used, the induced voltage, when the circuit is opened, will be 4 times normal line voltage. This voltage, caused by the inductance of the field, must be limited to prevent damage to the insulation of the field windings. On nonreversing controllers without dynamic braking, the shunt field can be connected behind the main contactor and the field allowed to discharge through the motor armature.

20.12 AC DRIVES

General Theory of AC Drives. There are three basic types of ac machine—synchronous machines, wound-rotor induction machines, and squirrel-cage induction machines (see Table 20-20). Each of these machines is normally applied to a fixed-speed application. The speed of each is determined by the internal mechanical and electrical configuration. It can be displayed as

$$\text{Speed (r/min)} = \frac{120 \times \text{frequency (Hz)}}{\text{No. of poles}}$$

Except for special cases, the number of poles in a machine is fixed and the incoming line frequency is normally fixed. Therefore, except for slip in induction machines, a given ac motor operated on a given electrical network will operate at a single fixed speed.

If the line frequency supplying the motor can be adjusted, then the speed of the motor can also be adjusted. That is the basis for adjustable-speed drives for ac motors.

Application and Economics of Speed Control. As previously noted, ac motors provide the motive power for a wide array of industrial applications. Most of these involve a centrifugal type of load, for example, fans, blowers, compressors, or pumps. The configuration of these devices is such that the *torque* required to turn them is proportional to the square of the speed. And the *power* required to turn them is proportional to the *cube* of the speed. The relationships

$$\text{Torque} \propto (\text{r/min})^2$$

$$\text{Power} \propto (\text{r/min})^3$$

is what makes adjustable-speed drives (ASDs) economically attractive.

Most of these devices are part of a process that requires some degree of flow or pressure control. This is normally performed via mechanical throttling of the flow, for example, inlet or outlet dampers, guide vanes, valves, or bypass systems. The net result of any of these methods is the consumption of excess energy required to overcome the pressure drop or bypass flow each creates.

However, efficient and precise control of the flow or pressure in a system can be obtained by directly controlling the speed of the device. This direct-speed control, coupled with the speed/power and speed/torque relationships shown above, results in an exceptionally efficient method of controlling the process. Several programs are commercially available to calculate energy savings and paybacks based on energy rates, operating profiles, internal rates of return, etc.

Power Semiconductor Devices. In order to supply an adjustable frequency to an ac motor, the incoming constant-frequency voltage or current must first be *rectified* to a dc current or voltage. This dc voltage or current is then *inverted* to an adjustable frequency output. This is accomplished by power semiconductor devices.

These devices allow current to flow in only one direction. They act as electronic switches. Various types can be fired on and off at certain times in the cycle. This selected firing allows control of the resultant voltage or current.

Power electronic devices come in three basic types (Fig. 20-73):

Diodes. This is an uncontrolled device, that is, current can flow only in one direction. However, there is no gate to control the firing angle.

Thyristors. These devices also allow current to flow in only one direction. However, they include a gate circuit to delay firing until a given angle in the sine wave. This allows control of the resultant output dc current. However, it normally is turned off or *commutated* only when the voltage across it drops to zero.

Gate turnoff (GTO) *thyristors*. These are similar to basic thyristors. They also include a turn*off* gate that allows the current to be blocked at any point in the cycle.

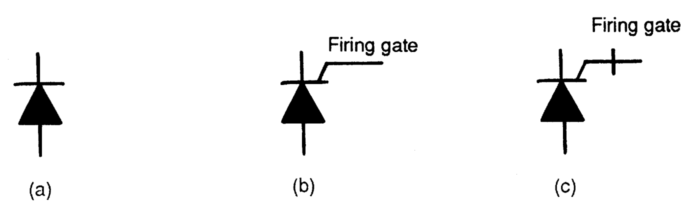

FIGURE 20-73 Main power electronic device used in modern frequency converters: (*a*) diode; (*b*) thyristor; (c) gate turnoff (GTO) thyristor.

AC Drive Systems. Electronic speed control offers much more than just energy savings. Reduced maintenance and reduced mechanical and thermal stresses are just a few of the advantages that can be realized.

The key to maximizing the many advantages of adjustable speed drives is applying the proper type of drive system. Following is an overview of the most important types of drive systems available today.

Most drive systems are composed of three major components—the input transformer, the frequency converter, and the ac machine. Additional components may include dc link reactors, harmonic filters, output filters, switchgear, etc. The requirements for these components will depend on the type of drive, user specifications, and vendor recommendation.

Connection to the Electrical Network. Most types of drive systems are connected to the electrical network through an input transformer (Fig. 20-74). This transformer serves many purposes. It transforms the network voltage to the optimal voltage for the frequency converter. It effectively lowers the short-circuit capacity seen by the drive to reduce "line notching" that can occur when thyristors commutate from one phase to another. It also provides impedance in the line to reduce distortion. A line reactor can be used if the line voltage and converter voltage match. However, a three-winding transformer can be used to dramatically reduce harmonic distortion. The two secondary windings are phase-shifted 30 electrical degrees by connecting one in a delta configuration and one in a wye configuration. This effectively eliminates fifth and seventh harmonics and their multiples.

LCI/Synchronous Motor Drives. In this system, the line-commutated rectifier acts with the dc link smoothing reactor as a dc current source. The load-commutated inverter operates with the synchronous machine's voltage and frequency to switch the dc current to the windings. The synchronous machine behaves like a dc machine with the inverter operating as a static commutator.

The load-commutated inverter (LCI) (Fig. 20-75) is the simplest type of frequency converter. Because the rectifier thyristors are commutated by the line voltage and frequency, and the inverter thyristors are commutated by the synchronous machine voltage and frequency, no special circuits are needed to accomplish commutation.

This type of drive has the added inherent advantage of 4-quadrant operation. Therefore, it is suitable for drives which may require regenerative braking or operation in both the motoring and generating modes.

LCI/Induction Motor Drives. An induction motor can also be driven with an LCI-type drive (Fig. 20-76). However, because of the inherent characteristics of an induction machine, the thyristors in the inverter section cannot be self-commutated by the motor voltage until it reaches approximately 50% speed. Therefore, additional circuitry must be added across the inverter or across the individual thyristors to force the voltage to zero and turn off the thyristors. Additionally, a filter on the output of the inverter is normally required to produce a sinusoidal current form to the motor.

This type of drive is commonly used as a retrofit to existing squirrel-cage induction motors. However, care should be exercised on such applications. All frequency converters impose additional losses and, therefore, additional heating on motors. Higher stresses are also placed on the insulation

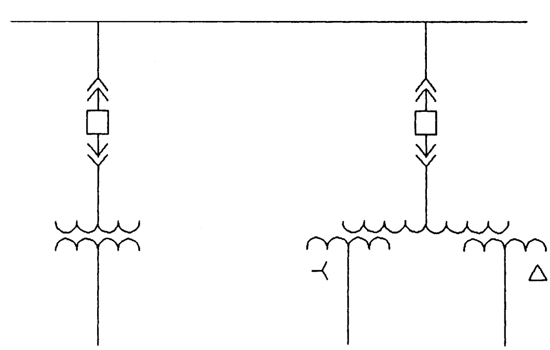

FIGURE 20-74 Two- and three-winding transformers.

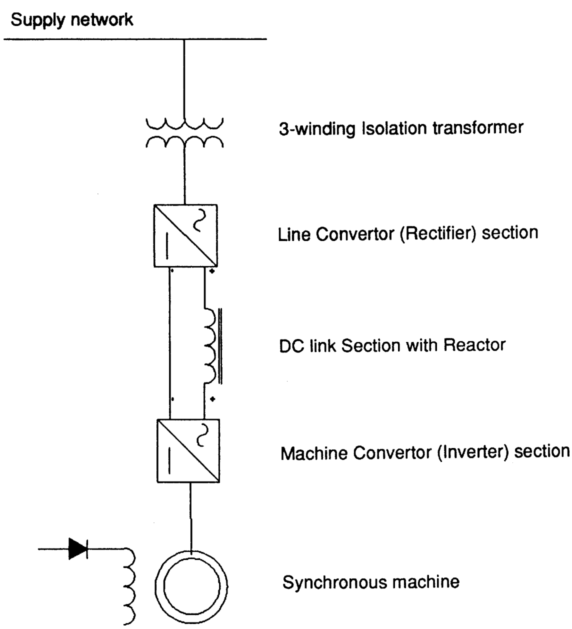

FIGURE 20-75 Basic LCI system design.

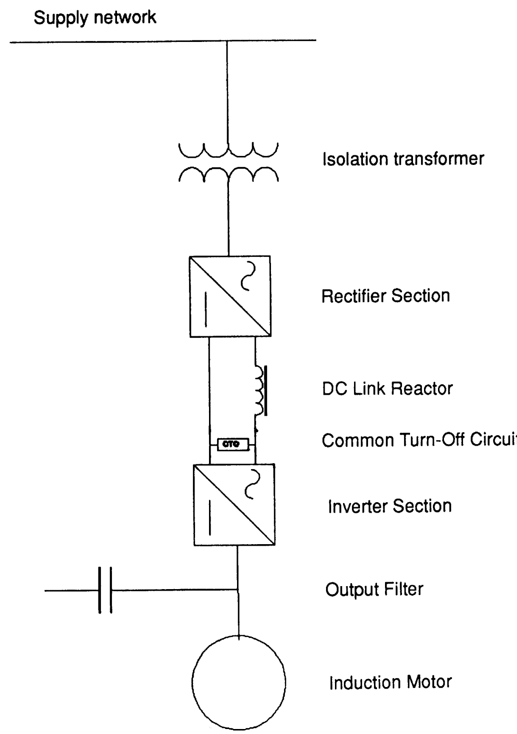

FIGURE 20-76 LCI drive with induction motor.

of the motor windings due to the distortion of the inverter's output waveform.

PWM/Induction Motor Drives. With the advent of high-power GTO thyristors, pulse-width modulated (PWM) frequency converters for powers up to 10,000 hp are now available. These can be supplied as either voltage-source (Fig. 20-77) or current-source configurations. For either configuration, the ability to *turn off* the device via a gate pulse eliminates a number of components in the power circuit.

The voltage source drive in particular has a number of benefits. The uncontrolled diode rectifier section results in a high line-side power factor (near unity) throughout the speed range. The distortion seen by the electrical network is also reduced since diodes always have an effective firing angle of zero. The PWM voltage-source output of the inverter produces a near-sinusoidal current in the motor. High dynamic performance can also be realized. Full torque can be maintained and controlled throughout the speed range—even at zero speed.

A unique application of voltage-source PWM drives is their use on coordinated sectional drive systems. Because the voltage in the dc link is maintained at a constant value, several inverter sections can be connected to the same rectifier/dc link section. This can result in significant savings in money and in space.

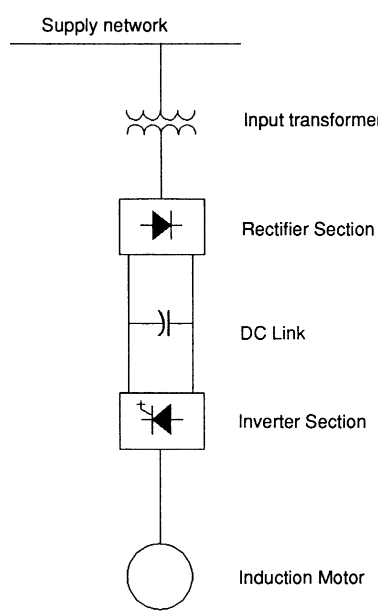

FIGURE 20-77 Voltage-source PWM inverter drive.

Slip Recovery (Cascade) Drives. A much different solution is a slip recovery, or cascade, drive system (Fig. 20-78). While the previously described systems vary the voltage and the frequency applied to the stator of the ac machine, a cascade drive is connected in the rotor circuit of a wound-rotor motor. Wound-rotor or slip-ring motors can be speed-controlled by connecting an external resistor to the rotor circuit via the slip rings. Since the slip (and hence the speed) of an induction motor is directly proportional to the losses in the rotor, increasing or decreasing the external resistance could vary the speed over a limited range. Historically, the resistance was adjusted via a liquid rheostat for stepless control, or a grid resistor for several steps in resistance. This method was also commonly used for starting of high inertia loads. The motor's starting torque and current characteristics could be adjusted during starting. Once it reaches rated speed, the slip rings are short-circuited and the motor functions as a squirrel-cage induction motor.

The cascade drive controls the speed in a similar fashion. However, as its name implies, rather than dissipating the energy across external resistors, it *recovers the slip energy* and returns it to the electrical network. This is realized by converting the low-frequency rotor current into line-frequency current. It is then transformed to the supply voltage via a feedback transformer. Starting is normally accomplished via conventional means with a liquid or grid resistor.

The cascade drive is an excellent solution when the speed range is relatively narrow—normally 50% to 70% to 100%. Because the converter handles only the *slip* power, it is much smaller than other types of frequency converters. As an example, if the desired speed range is 70% to 100%, the converter must be sized to handle only 30% of the rated power. This results in a very economical solution.

An additional advantage of this type of drive is that a bypass arrangement is inherent in the design. The normal starting sequence is to bypass the drive and connect it once the motor reaches a minimum control speed. Therefore, if the drive malfunctions for any reason, it can be bypassed and isolated. In this way repair can be accomplished without shutting down the process.

Other Drive Types. There are other types of ac drive systems used for specialized applications. One of these is the *cycloconverter* drive. This drive is normally applied to low-speed, high-torque, high-performance applications. These include metal rolling mills, large grinding mills for ore or in

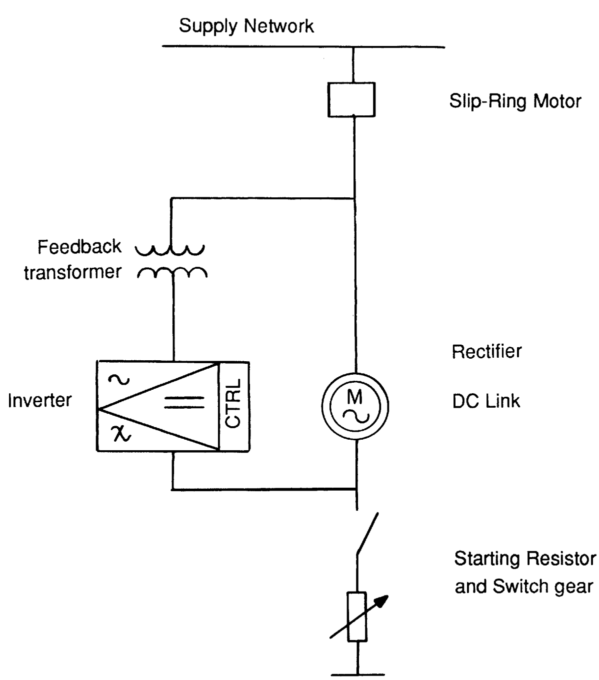

FIGURE 20-78 Slip recovery (cascade) drive.

cement applications, and ship propulsion. All these applications require precise speed and torque control to optimize the process.

The cycloconverter is effectively a separate frequency converter on each phase of a synchronous or induction motor. This allows for a more precise fabrication of the voltage waveform to the motor. This, in turn, results in a current wave shape that very closely approximates a sine wave. Consequently, the torque produced by the motor is very smooth throughout the speed range.

The design of the cycloconverter is such that its output frequency cannot exceed one-third of the line supply frequency. So, for a 60-Hz system, the maximum output frequency is 20 Hz. A 12-pole motor, which would normally have a synchronous speed of 600 r/min on a 60-Hz system, cannot be run up to only 200 r/min with a cycloconverter drive.

Another type of relatively exotic drive is the supersynchronous converter cascade. This is used for matching frequencies from a variable-frequency generator, for example, a hydropower station with varying head and speed.

Harmonic Impact of Drives on Electrical Networks. *All* drives result in some harmonic distortion in the electrical network to which it is connected. This is due to the fact that the power semiconductor devices "chop up" the incoming sine wave and reconstruct it at another frequency. By definition, this chopping up of the waveform results in distortion from a pure sine wave.

Harmonic distortion can have effects in several areas. Electronic equipment, such as computers, can malfunction due to changes in zero-crossing points in the supply waveshape. Motors may run hotter due to harmonic currents.

Many factors affect the magnitude of the distortion. The type of rectifier section on the drive has a major effect. Uncontrolled diode bridges will typically produce less distortion. Thyristor rectifier bridges will be somewhat higher since the firing angle is greater than zero.

The short-circuit capacity of the system at the point of connection is the major factor in determining distortion. The distortion can be estimated from Fig. 20-79. These curves clearly indicate that if the drive is connected to a relatively strong system, that is, one whose short-circuit capacity (SCC) is substantially higher than the converter rating, the total harmonic distortion seen by the network may not exceed the limits established by IEEE 519.

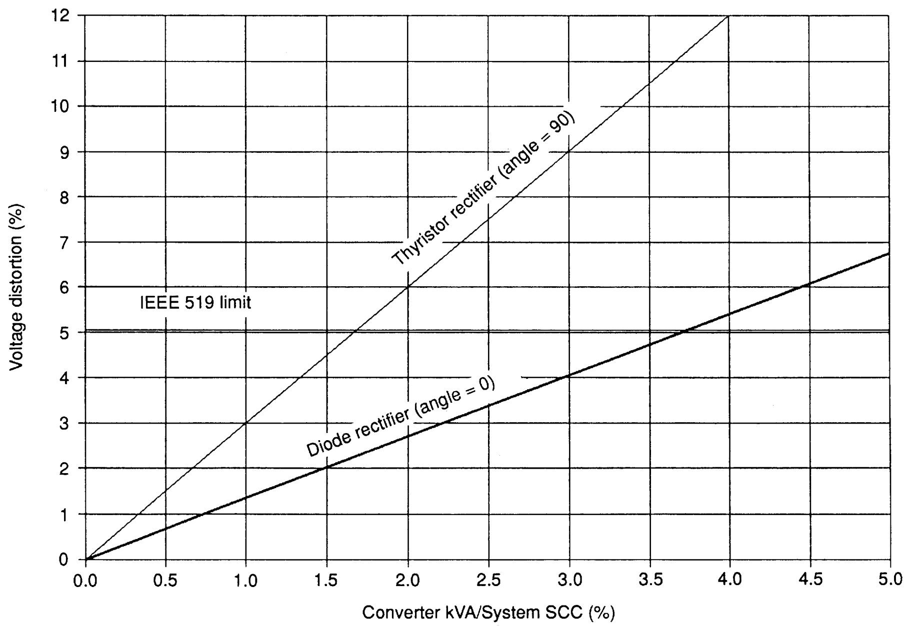
Connecting to the network with a 12-pulse configuration (through a 3-winding transformer) has a great impact on the distortion. The connection effectively eliminates the fifth and seventh harmonics and all multiples of them. Since the magnitude of the harmonic is inversely proportional to the order number, these are the greatest contributors to distortion.

If multiple drives are connected to the same bus, distortion can be further minimized by phase shifting the primaries of the drives to effectively create a 24-pulse connection. This is only feasible with drives utilizing a diode rectifier. This is due to problems with timing of the device firing on thyristor-type rectifiers.

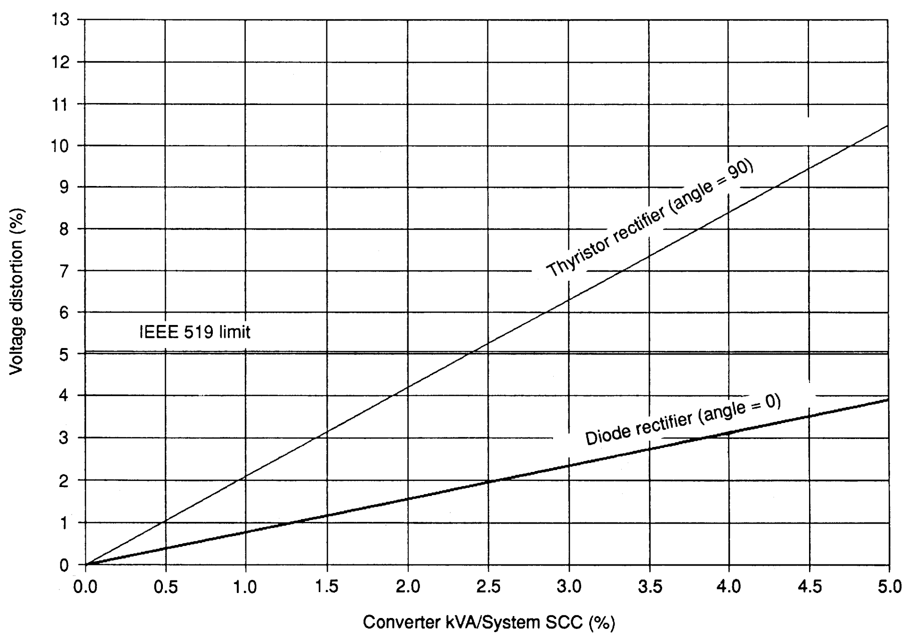
If the type and configuration of the drive do not limit the harmonic distortion to an acceptable level, filters can be installed on the bus to further reduce their effect. These filters are configured with reactors, capacitors, and resistors to "trap" the unwanted harmonics. Typically they are "tuned" to a specific order number, that is, normally there are fifth, seventh, and eleventh harmonic filters. These filters need to be properly coordinated with the drive supplier and the electrical network to ensure that resonances are not created that could interact with other equipment.

Impact of Drives on Mechanical Systems. Careful consideration should be given to the *mechanical* system when applying a drive. One key point may be the natural critical speed or resonance point of the motor. When applied as a constant-speed machine, the motor may operate above or below its natural frequency with little problem. However, if the critical speed is within the desired speed control range, problems can occur. These can be addressed in several ways. Critical speeds can be changed somewhat via bearing or base configurations. Or, the drive can be programmed to avoid certain frequency or speed bands. In this case, the drive will quickly accelerate or decelerate the motor through the resonance points to minimize potential problems.

Just as the electrical network sees distortion from a drive, the connected load (normally a motor) also sees an imperfect sine wave as the output of the drive. This distortion of the incoming current



(a)



(b)

FIGURE 20-79 Harmonic distortion: (*a*) 6-pulse rectifier; (*b*) 12-pulse rectifier.

or voltage is translated into a distortion of the motor torque. This can be realized as torque pulsations at the motor shaft output. For many applications, this does not present a problem. However, for all applications, a detailed torsional analysis of the complete mechanical system should be performed to ensure that the drive will not excite any torsional resonance points. If such problems are uncovered early, they can usually be easily addressed through modifications to the drive or through a flexible type of coupling to dampen the torsional vibrations. The system torsional analysis may be performed by the drive vendor, the driven equipment vendor, or both.

Summary. Properly applied, ac drive systems can have tremendous positive impact on a wide range of processes and applications. Carefully engineered drive systems can provide many years of trouble-free operation.

21.1 INTRODUCTION

21.1.1 Links between Competitive Advantage, Efficiency Improvement, and Environmental Compliance

Since the last edition of this handbook, a newly competitive environment is emerging in the industrial and commercial applications of electric power. While the areas of improving energy efficiency and meeting stricter environmental regulations is still a concern to business and industry, the need to maintain a competitive edge in an increasingly global economy is having a definite impact on energy-related decisions. Technology investments are still being made in process and business enhancements, but the driving force is business economics. Producing goods and delivering services in a way that is "cheaper, better, and faster" is the goal of most competitive organizations. Technologies at the forefront of improving business operations include sophisticated information and communications systems, new sensors and control systems, and constantly improving electrotechnologies. The success of electrical engineering today will depend to a great degree on the extent to which the engineer understands this technological changes, and participates in the business decision making of the company. Nevertheless, the ultimate objective of any successful business is still to improve performance while cutting costs.

Sensors. From an electrical engineering perspective, sensors are an essential element in the operation and control of a manufacturing or other electricity-driven process. Sensors include all devices that respond to a physical, chemical, or biological stimulus and transmit a resulting impulse for measurement or control. Simple devices include electrochemical sensors that determine ionic or molecular concentration, potentiometric sensors that measure the potential difference between two electrodes, and amperometric sensors such as the Clark cell for measuring oxygen in some fluids (see Sec. 24 for more details). In all cases, the sensor typically responds to a change in condition, and converts the measured variable into an electric signal.

New advances in sensor technology encompass on-line machine diagnostics, remote and noninvasive detection, and improved durability in hostile environments. Sensors are used in industrial plants and mills to control process flows, assembly-line speeds, chemical concentration levels, and many other variables. A typical application of sensors is in industrial flexible manufacturing systems, assemblies of one or more machine tools and workpiece-handling devices, inspection sensors, and part-washing equipment and/or material storage equipment, all operating in a coordinated manner under the control of a central or distributed computer. A flexible manufacturing system is employed to process a variety of finished parts (see Fig. 21-1). Commercial building facility management systems include sensors for input data, remote-terminal units, the central processor, and human-machine interface devices. Functions typically go far beyond energy management, including not only heating, ventilation, and air conditioning (HVAC), but also fire management, security, and access control.

Information and Communications Systems. The information and communications systems in a plant or facility consist of collecting hardware, software, and input/output devices and connecting wire or cable that transmits voice and data, and then processing these data into information and knowledge for decision-making purposes. Improved communications systems are being developed based on high-speed data transfer and expanded application of voice recognition interface. This is the basis for emerging smart information systems that will take full advantage of language translation, natural-language processing, artificial intelligence, storage and processing of only useful data, and interactive computer-based training.

Electrotechnologies. For the electrical engineer, the technologies that use electricity to manufacture or transform a product are of special interest—collectively, these technologies are known as *electrotechnologies*. The industrial-commercial market continues to represent significant opportunities for electrotechnologies, ranging from process heating to metal heating, cutting, and welding. In most electrotechnologies, electromagnetic, electrochemical, and/or electrothermal effects are central parts of the process. Examples of these technologies include induction heating and melting; plasma processing; infrared, microwave, and radio-frequency processing; freeze concentration; and electroseparation. Some of these technologies, such as infrared heating, also have natural-gas-fired alternatives.

A broad set of electrotechnologies includes electric motors, used in the commercial and industrial sectors to drive pumps, fans, and compressors for a wide range of applications. These applications include HVAC applications, fluid processing, compressors to drive freeze concentration, and membrane separation. In the area of materials processing, motors furnish the power for cutting, grinding, and crushing. Finally, the raw materials and manufactured products are moved around the factory floor by motors driving conveyors, cranes, elevators, and robots.

21.1.2 Environmental Compliance

The environmental impact of the industrial and commercial applications of electric power has also rapidly become a primary concern in many industry sectors. Environmental concerns, many heightened by more stringent laws and regulations, are widespread, including such problems as the release of volatile organic compounds (VOCs) during solvent use for example, in industrial painting and curing and disposal of oil-water emulsions, toxic wastes, and other industrial effluents. Mitigation of these problems is typically addressed with the "TR3 approach"—treat, reduce, reuse, or recycle. For example, the generation of VOC emissions can be reduced (or eliminated) with the use of water-based paints or powder coatings combined with infrared drying. A parallel treatment option would include the use of solvent recovery heat pumps, or perhaps freeze concentration to separate VOCs from wastewater.

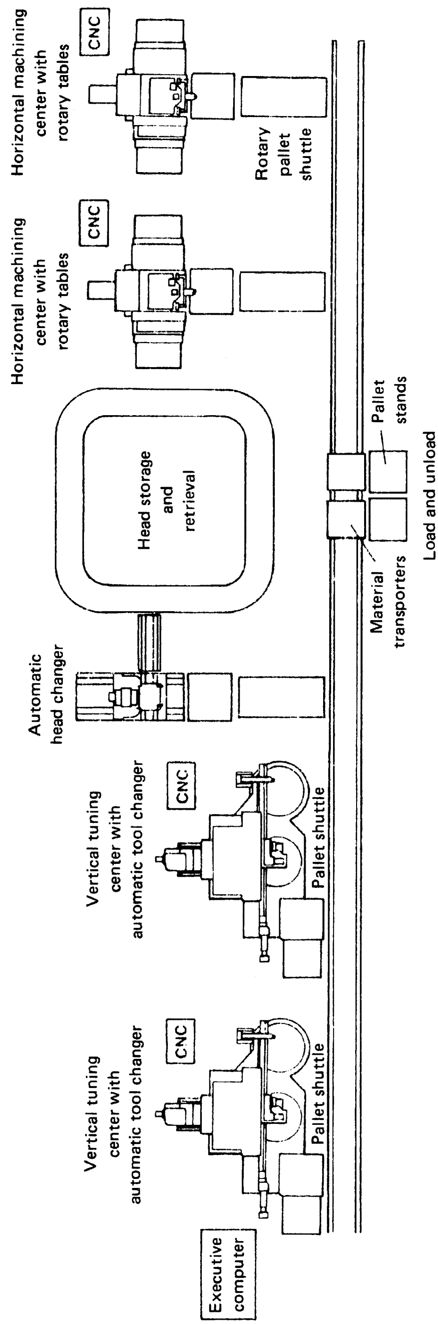

FIGURE 21-1 Schematic illustration of a flexible manufacturing system.

21.2 TRENDS IN BUSINESS AND INDUSTRY ENERGY USE

21.2.1 Impact of Deregulation

By 1900, electric utilities produced approximately two-fifths of the electricity in the United States. The balance of power was supplied by business and industry which generated their own electricity. As larger and more efficient generators and more transmission lines were installed by the electricity industry, costs came down and the associated increase in convenience prompted most customers to concentrate on their core business operations and purchase electricity from the utilities. As originally configured, the electric power industry was based on a central source of power supplied by efficient, low-cost utility generation, transmission, and distribution. Utilities were granted exclusive franchise areas in which to operate, and along with this exclusivity came the obligation to serve all consumers within that territory, and, in most cases, state regulation of privately owned electric utilities in the early 1900s. States typically regulated utility rates, financing, and service, and established utility accounting systems.

The U.S. electric power industry today is in the process of restructuring, which began with the introduction of federal deregulation policies starting with the passage of the Public Utility Regulatory Policies Act (PURPA) of 1978. PURPA was initially positioned as a way to encourage the development and use of alternative fuel resources in the industry. The important long-term effect was the introduction of some level of competition by providing new participants with a gateway to electric utility markets. The key elements of PURPA were the requirements for public utilities to purchase available power from qualified cogenerators and small power producers at rates that were less than or equal to the utility's avoided costs, and provide backup service to cogenerators and small power producers at nondiscriminatory and reasonable rates. In addition, the nonutility generators were exempted from various state and federal regulations. The entrance of a new group of suppliers demonstrated that cogenerators and small power producers represented a viable source for new supply of energy and power services.

The Energy Policy Act expanded markets further in 1992, and in 1996, the Federal Energy Regulatory Commission (FERC) issued rules for implementing open access to the transmission network and for utilities to recover the costs associated with transmission lines and other plant and equipment investments that may be "stranded" as markets become more competitive. Today, the state public utility commissions are actively studying retail competition, and some have already introduced pilot programs or have drawn up plans for restructuring. Newly formed entities, such as power marketers, brokers, and independent system operators, are emerging on the scene. The electric utility companies are being merged and acquired, promising a much different power supply picture in the future.

21.2.2 Role of the Energy Service Company

As the electric utility market has slowly begun to entertain competition, a new kind of business has emerged: the energy service company. The energy service company (ESCO) may be independent, or may be a subsidiary of an electric or gas utility company, and it typically develops, installs, and finances projects designed to improve the energy efficiency and lower operating and maintenance costs for commercial and industrial facilities. ESCOs generally assume the technical and performance risk associated with a specific project, and often act as the project developer and manager. These companies not only install and maintain the energy equipment but also measure, monitor, and verify the project's energy savings. All services provided by the ESCO are usually bundled into the project's cost and are repaid through the savings generated. Projects undertaken include high-efficiency lighting, high-efficiency heating and air conditioning, efficient motors and variable-speed drives, and centralized energy management systems. ESCOs frequently work on a performance-based contracting basis, and often the company's payments are directly linked to the amount of energy that is actually saved.

21.2.3 Retail Power-Supply Options

The ongoing transformation and ever-increasing competitive nature of the electric industry has greatly enlarged the scope and complexity of how electricity will be delivered to the customer. A broad range of power technology options are available and emerging, including fuel cells, turbines, microturbines, reciprocating engines, and a range of renewable technologies (e.g., photovoltaic and wind). Both economics and reliability are also factors being considered in the development and implementation of these technologies. Many of these technologies are "distributed," meaning that they are typically sited close to the customer load and are generally smaller in size than the megawatt-sized utility units. Technologies such as solid oxide fuel cells offer a combination of performance and flexibility which makes them an ideal supply resource that helps address regulatory, environmental, and competitive challenges in delivering essential power and energy services. By converting fuel energy directly into electricity, fuel cells provide a clean and strategically economical resource. Microturbines are also getting a lot of attention, and consist of a compressor, combustor, turbine, and generator. This technology is derived from aircraft auxiliary power systems and diesel engine turbochargers. A number of companies are currently field-testing demonstration units, and commercial deliveries started in 1999.

Some deregulation measures did not succeed as originally planned. For example, California's 1996 law deregulating the electricity market, once hailed as a model for others:

- Forced utilities to sell off much of their generating capacity
- Prohibited them from signing long-term contracts to buy supplies
- Barred increases in consumer rates until 2002

People inside and outside of the state of California wonder how such problems could happen in their state, the home of Hollywood and Silicon Valley. Even though it's a complicated issue, it mostly results from geography—the state's population and businesses (especially power-draining high-tech industries) have grown by leaps and bounds over the past decade, while no new power generation plants have been built in the state over the past decade.

Additionally, power can't be stored up and used at a later time. Supply must equal or exceed demand at the very instant that the demand is there. Due to California's lack of power generation facilities, California is obtaining power from across the Western United States and less-than-adequate a rainfall in the Pacific Northwest has resulted in less power being available from the hydroelectric plants of the Northwest.

21.3 ELECTRICITY IN AGRICULTURE

There were 1.9 million U.S. farms in 1997, compared to 5.4 million farms in 1950. Farm output has increased steadily since the mid-1980s, reflecting almost universal use of automation and improved chemical fertilizers. Food products and fiber are the primary outputs of the agricultural sector.

Increased global economic growth had driven increased demand for food and fiber worldwide. The U.S. comparative advantage in agricultural production and transportation has allowed it to capture an increasing share of the growing global demand. In 1996, U.S. agricultural exports reached $60 billion, and in 1997 exports were $57 billion and farm prices were firm. Exports slipped to $55 billion in 1998 as recession hit Asia and expanded production around the world has lowered crop prices.

21.3.1 Energy Use in Agriculture

Electricity consumption in the agricultural sector has been decreasing, reflecting farm consolidation and efficiency improvement.

21.3.2 Technology Innovation

Increased automation (discussed below) controlled by increasingly sophisticated and lower-cost computer systems has helped improve farming operations across the board. Introduction of advanced technology, such as the written-pole motor, promises improved electric operations to farmers. This motor helps farmers meet the challenge of serving irrigation loads in remote areas. Typically, any irrigation load greater than 15 hp can be served only by a 3-phase motor. Most irrigation sites, however, are several miles from the nearest 3-phase service, and it is seldom economically feasible to extend service to this distance. Solutions to the problem include the use of a phase converter (discussed in Sec. 21.3.8) to create 3-phase power, or installation of gasoline or diesel engines. These solutions can result in poor power quality and can be expensive and time consuming.

A new type of motor has been developed that is slow-starting and can provide up to 60 hp with a single-phase power supply. In addition, this motor can ride through brief power outages. This new type of motor is designed with high-starting torque, and contains magnetic poles which are continuously and instantaneously written on a magnetic layer in the rotor by an exciter pole in the stator. The magnetic poles can be written to a different spot on the rotor during each revolution whenever the rotor speed changes, keeping the pole pattern constant. They are held in the same pattern when the motor reaches full speed. This variation of the poles during start-up gives the motor its slow-starting, high-torque characteristics. A squirrel-cage winding in the motor also adds induction torque in starting.

This slow-starting capability of the motor, combined with the high-starting torque, offers some benefits to the user. The power quality impact on other customers on the line is limited, and the motor pulls only about 2 times the full load current on start-up, compared to a usual draw of 6 times full load current with most motors.

21.3.3 Automation

Larger-scale farming has adopted automation as standard practice. Solid-state electronic devices are used to control livestock feeding by triggering food-release mechanisms at established intervals; phototransistors are used to thin crops by scanning planted rows with precision and at high speed; electronic sensors are also used on farming machinery to monitor shaft speeds, materials flow, and other parameters.

Planting and harvesting machines are equipped with electronic monitoring devices indicating information such as shaft speeds, material flow rates, temperatures, and seeding malfunctions. Reed switches or hinged-plate switches are used to flash light signals or actuate buzzers and horns, and miniature electrical generators, the output of which is proportional to the speed, indicate shaft revolutions per minute relative to a desired value. This information is displayed on a console within the combine cab, or on the tractor.

Electronic crop thinners, using a phototransistor scanning system for each crop row, have resulted in higher vegetable crop yields than is possible with hand thinning, since earlier thinning and a more uniform plant population are possible. Other uses of electronics include automatic temperature and humidity controls for crop drying and storage, and automated surface sprinkler systems such as the solid-set, permanent-overhead, and center-pivot type (utilizing control consoles, operating through buried cables, microwave channels, VHF radio, and pressure and temperature control switches) to provide round-the-clock irrigation control. Overriding time controls provide cooling when predetermined temperatures are reached.

Livestock-feeding systems use electronic controls for time-interval feeding of individual animals based on current production level, weight, age, etc. A transmitter at the feed station sends a signal to a transponder unit on the animal, which upon activation switches on a relay controlling the feed unit. Automatic data recording can be accomplished for individual animals by means of a special neck band, thus enabling rapid and detailed collection of data which, aided by a computer, facilitates efficient management of larger enterprises. Electric motor drives for farm tractors are possible in the near future.

21.3.4 Farm Structures

Water Systems. Water requirements for the farm household and farm enterprises, excluding irrigation, are frequently supplied by a single well. The water-supply equipment is usually an automatic hydropneumatic or air system having pumping capacity of 300 to 600 gal/h and using a $1/4$- to 1-hp motor, depending on the total head in feet and the rate of pumping. Home water requirements average 50 gal/(person)(day). In addition, livestock requirements must be added: each horse, steer, or dry cow, 12 gal; each milk cow, 35 gal for drinking and washing equipment; each hog, 3 gal; each sheep, 2 gal; each 100 chickens, 8 gal. For yard fixtures, each $3/4$-in hose outlet requires 300 gal/h.

Where the source of supply is not more than 22 ft below the pump, a shallow-well system can be used. A jet-centrifugal pump has a practical lift limit of 80 to 100 ft, and piston-type pumps can go as deep as 800 ft with a suction lift below cylinder of 22 ft. This type is placed directly over the well and is generally recommended where pumping depths exceed 80 ft. Automatic pressure switches are usually set to start the pump when the pressure falls to 20 lb and stop it when 40 lb has been obtained. The energy requirement per 1000 gal of water pumped rarely exceeds 2 kWh.

Heating Systems. Electrical heating of farmstead structures is generally confined to milk houses, individual pen-type areas for young livestock, and poultry brooders. Electric heating in the milk house is ideal, as it is odorless, is conveniently controlled, and meets the high sanitary standards required. The milk-house temperature should not exceed 40°F. Several types of heaters have been successfully used: (1) the forced-air circulating type requiring 1500 to 3000 W; (2) batteries of 250-W infrared heat lamps directed toward working areas and water pipes; and (3) heat-pump systems, which utilize the heat removed in cooling the milk. In this type the ice-bank refrigeration system (either bulk or immersion coolers) extracts heat from the water in building up the ice, the heat thus being available for the milk house. Electricity used in this indirect manner produces about three times as much heat as it would if directly used in a resistance heater. Only coolers with 1/2-hp or larger motors are recommended for this application.

In the colder regions, the milk house must be insulated for the most economical cost of installation and operation. In these areas an electrically heated milk house needs at least a 1500-W heater serviced by a 230-V line. Thermostats are usually attached to the heater unit, and operating consumption ranges from 1000 to 3000 kWh a season.

The need for infrared heat lamps during the first week of hog farrowing and sheep lambing has been proved. A 250-W lamp will heat an area 24 in in diameter when 3 ft above the floor. The lamps should be positioned at least 6 in above animals and at least 30 in above the floor when bedding is used.

Ventilation Systems. Electrically powered mechanical ventilation of livestock structures provides low-cost positive control for the removal of excess animal body heat, objectionable odors, and condensation, and for temperature and humidity control. A full-grown cow will give off 3000 Btu/h of body heat; 1000 chickens, about 800 Btu/h. Accurately controlled tests with dairy cows at the University of Missouri showed that temperatures above 75°F and relative humidities over 75% resulted in sharp declines in milk production and body weight.

In general, summer ventilation should maintain inside temperatures equal to or below the outside temperature, while in winter the reverse is true. Thermostatically controlled motor-driven fans are installed as required, with adequate fresh-air intakes to prevent excessive energy costs. Two-speed fans, chosen to move the maximum air volumes required for various livestock, will permit airflow to be reduced in cold weather. Fan motors range from 1/20 to 1/2 hp and will consume 250 kWh/year and up, depending on usage. One kilowatthour of electricity will move about 1 million ft^3 of air.

21.3.5 Plant Production

Irrigation Pumping. More electrical energy is used for irrigation pumping than for any other field operation. Proper design of an irrigating system will depend on the following factors: (1) the acreage and kind of crop to be irrigated; (2) the amount of water that must be supplied; (3) the amount of underground water available; and (4) the depth at which it is found.

Except where the water requirements are small and the depth to water great, plunger pumps are rarely used. The more common type is the centrifugal turbine pump, but where the lift is not more than 15 ft, the horizontal centrifugal pump is also used. The bowl of the turbine pump should be set below any expected drawdown in the well, and this will depend on the porosity of the surrounding strata as well as the rate of pumping.

Vertical turbine pumps require vertical motors with either solid or hollow shafts and thrust bearings capable of carrying the pump load. Horizontal pumps should be connected to their motors through flexible couplings to avoid the use of belts. With average allowance for evaporation, irrigating an acre 1 ft deep requires 340,000 gal. The soil can be wet to a depth of 4 ft by using 4 to 6 in of water. From 10 to 20 in is required to produce the ordinary crops. With an overall efficiency of 50% for pump and motor, each acre-foot of water will require about 2 kWh of electricity for each foot of lift. New motor designs promise to reduce the costs of irrigation for fields remote from the main electrical service.

Methods of Irrigation. These include overhead pipes, stationary spray plants, and portable sprinkler systems. In the overhead type the discharge pipes are supported on posts and are located about 50 ft apart in lengths up to 600 ft. The pipes are usually supported on rollers so that they can be oscillated by a type of water motor, and nozzles are spaced 2 ft or more apart. Sixty gal/min of water per acre at 30 lb pressure is satisfactory. Stationary spray plants can reduce spraying time in orchards by 50% or more compared with portable units. A central pumping station, mixing tanks, and symmetrically located discharge pipes complete the layout. The pumps are usually three- or four-cylinder, single-action, with capacities of 10 to 60 gal/min at pressures up to 600 lb or more, requiring motors of 5 to 30 hp. Outlets are located at regular intervals for attaching the spray hose. Spray nozzles discharge up to 8 gal/min depending on pressure and orifice size. Power required is usually under 10 kWh/(acre)(application). Portable systems utilize lightweight, quick-coupled pipes, with sprinklers attached. Laid on the ground, they require considerable labor to move, but the initial investment is less than with other types. Sprinklers operate at pressures of 20 to 50 lb/in^2 and cover circles 40 to 90 ft in diameter, delivering 3 to 30 gal/min. A motor as small as 2 hp will apply 1 in water to 3 acres of land per week, although larger outfits are commonly used.

Grain Conditioning. Field harvesting and on-the-farm storage losses of small grains and ear corn can be materially reduced where mechanical crop-drying or conditioning equipment is utilized. Early harvest reduces field losses due to shattering or lodging of grain and shelling, which may occur during mechanical harvesting. Crops can be harvested when weather conditions are most favorable as soon as possible after they mature, thus reducing the chance of storm damage while the crop dries in the field.

Heated-Air Crop Dryers. Equipment needed includes an oil burner, a power-driven fan, and a drying bin for the ear corn or small grain.

Most of the dryers are portable. Each unit consists of a power-driven fan, a heater, and safety controls. Such dryers have two characteristics that determine their performance in drying grain: (1) the rate at which heat is supplied (rate of fuel consumption per hour) and (2) the rate of air supply in cubic feet per minute. These dryers are normally equipped with oil burners that consume fuel at the rate of 3 to 14 gal/h and fans powered by 3- to 5-hp electric motors that deliver 9000 to 15,000 ft^3/min of air. Usually 9000 ft^3/min of 30°F air, with a relative humidity of 70%, can be heated to 70°F with an oil consumption of 3 gal/h used in a direct-heat dryer and 4.2 gal/h for the dryer if a heat exchanger is used. The U.S. Department of Agriculture reports that 1000 bu of car corn was dried from 30% to 13% moisture in 167 h.

Shelled corn, wheat, and oats can also be dried with heated air. Depth of grain in drying bins is 4 to 5 ft. Airflow must be uniform through grain, and temperatures of heated air should not exceed 110°F for seed corn and 140°F for wet milling. Temperatures up to 200°F have been used without affecting feed value.

Unheated-Air Crop Dryers. Wheat, oats, and barley are harvested in the summer, when atmospheric conditions are relatively favorable for grain drying with unheated air. Wheat combined at a moisture content as high as 20% can be successfully dried with unheated air. Minimum airflow is 3 ft^3/min · bu with grain up to depths of 4 ft. With 16% moisture content, airflow may be as low as 1 ft^3/min · bu with wheat up to depths of 8 to 10 ft.

21.3.6 Materials Handling

Conveyers and Elevators. Livestock and crop production requires much time and labor for loading, transporting, and unloading materials. Portable chain and flight conveyers, commonly called elevators, are available in lengths of 8 to 50 ft or more and in widths of 6 in to more than 20 in. They may be operated at angles up to 70°, depending on the material being handled, but care must be taken to prevent overturning or collapsing, particularly at the greater angles. The smaller sizes are generally used for moving loose, bulky materials such as small grains, chopped forage, and bedding and will require up to $^3/_4$-hp motors. Larger sizes are mounted on wheels and are used for baled, bagged, and packaged products, as well as other materials. Power requirements range from $^1/_4$ up to 5 hp, depending on the speed, angle of elevation, and weight of the material being handled. Vertical elevators for baled hay are mounted directly to the outside of barn walls. A 42-ft model will require a 2-hp motor.

Auger conveyers requiring fractional-horsepower motors are used for the horizontal and vertical moving of grains. Automatic feeding arrangements may employ 10-in-diameter forage augers in multiples of 5- or 10-ft sections up to 100 ft in length. Three-horsepower motors are required for lengths up to 90 ft, and 5 hp is needed for longer units. *Pneumatic conveyance* of grains and feed is increasingly popular on farms where the distance between storage or processing areas and feeding areas is considerable. This method is safe, has few moving parts, and is dust-free. The pipe can be placed in almost any path, above- or belowground. An air velocity of 4000 ft/min is required for proper operation with a 5-in pipe conveying about 4500 lb of grain/h. This will require $2^3/_4$ hp for each 100 ft of length.

Silo Unloaders. Mechanically operated silo unloaders remove the silage from the silo and deposit it at the foot. The operating mechanism of the top-unloading type is essentially a radial beam with scrapers or augers which collect the silage and bring it to the center of the silo, where it is picked up by a motor-driven air or mechanical device and delivered to the silo chute. Silage then falls down the silo chute, where it is collected for feeding.

There is also a bottom type of silage unloader. The operating mechanism consists of an endless chain mounted on a movable beam. The chain is equipped with scrapers which move the silage out of the silo as the chain revolves.

Unloaders eliminate the need for climbing the silo daily, reduce spoilage by removing silage at a uniform depth, and save up to 200 h/year of time. Results of Ohio State University tests indicate that top removal of grass silage at a rate of 1 ton/h requires 4.3 kWh and that 1.6 tons/h of corn silage requires 2.5 kWh. Three- to ten-hp motors operate the unloaders, and approximately 300 kWh is used annually.

Barn Cleaners. Electrically operated mechanical devices remove manure from poultry, dairy, and livestock barns. In poultry houses the cleaners may be placed under a slatted floor or in a wire-covered pit under tiers of mechanical feeders and waterers. In dairy barns they are installed in the gutters behind the cows. The dragline type uses a motor-driven drum to pull a belt or chain conveyer, equipped with cross flights, to an inclined elevator at the end of the barn, depositing the manure in a field spreader or pit.

The endless-chain type is well adapted to the larger stable where two rows of cows are housed. A single chain with wood or steel paddles travels around the gutters and up a short elevator, discharging the manure outside the stable. In this type of installation connecting or cross gutters must be installed at each end of the two rows of existing gutters so that an endless chain can be installed. The oscillating type uses a reciprocating bar with hinged paddle or auger conveyer. Portable types generally use a scoop steered by the operator and drawn along the gutter by a cable attached to a motor-driven drum. Cleaners are operated by electric motors of 2- to 5-hp capacity. They can be set to operate automatically for a predetermined cleaning period or can be switched on as need arises. Electric-energy use ranges from $^1/_2$ to 1 kWh a month for each cow housed in the stable.

21.3.7 Maintenance

Emergency Power. With increased dependence on electric power for time-controlled mechanical feeding, pipeline milking systems, manure removal, etc., the added investment in emergency power units may be justified compared with the possible economic loss if regular power fails. Generators ranging from 3 to 15 kW and rated at 120/240 V are available in tractor power-takeoff (PTO) and engine-driven types. The latter may be manually or automatically started. Automatic generators must be of higher capacity, because peak-connected loads will be carried if power fails. Nonautomatic types should have a "power off" alarm and must be PTO-equipped with an overload circuit breaker. The tractor PTO-driven generators are least expensive to purchase, as the tractor engine serves as the generator drive. Output is controlled by an engine tachometer and/or voltmeter in the generator unit. Manufacturers claim a voltage rating within 2% of the normal supply voltage. Required generator capacity is obtained by totaling the power needs of essential loads, plus allowances for future loads and high starting currents of the motors. Double-throw switches must be used at the point of connection into the wiring, to prevent generator damage and power feedback into the supply line.

Arc Welders. A highly mechanized agriculture requires that many machinery and structural repairs be made by the farmers themselves. A survey by the Kansas Farm Electrification Council indicates that the number of dollars invested in electric welders was greater than for any other item of electric farm equipment. The electric arc welder is inexpensive, efficient, and an almost indispensable tool on modern farms. The 180-A transformer-type ac welder is satisfactory for most farm shops. This machine can cut, hard-surface, and weld metals up to 1/2 in thick. It requires a line voltage of 220 to 240 V single-phase, 60 Hz. Current outputs from 30 to 180 A are possible. Duty cycle at maximum output is 20% with an open-circuit voltage of 25 V. A carbon-arc-torch attachment is used for brazing, soldering, and heating purposes. Larger generator-type units, either engine or tractor PTO-driven (hence portable), may be used as emergency power generators, supplying 5000 W of 230- or 115-V single-phase 60-Hz power.

Phase Converters. Most farms have 100- or 200-A single-phase service, which limits them to the use of 7 1/2- or 10-hp motors. Two types of phase converters are available which will convert single-phase to 3-phase current. By connecting the converters between the electric meter and the motor, they will permit the use of 3-phase motors up to 20 hp or more. In addition, the *National Electric Code* states that service entrances need be heavy enough to handle only the largest-power-demand equipment, plus a portion of all other equipment, rather than the total connected load as before. This is advantageous where irrigation pumps, grain dryers, large feed mills, etc., are in use.

Other Shop Equipment. This includes electrically powered air compressors, drill presses, grinders, hoists, lathes, saws, and paint sprayers. These generally require 1/4- to 1/2-hp motors. Battery chargers drawing approximately 2 kWh/charge are popular.

21.4 THE FOOD INDUSTRY

The food industry is diverse, essentially composed of eight sectors: dairy, processed fruits and vegetables, breakfast cereals, wet corn milling, bakery products, sugar and confectionery, fats and oils, and alcoholic beverages. The industry relies on a variety of energy sources.

Food manufacturing processes are as diverse as the industry itself. They can be as simple as boiling a potato or as complex, intricate, and technical as converting corn into starches, sweeteners, and corn oil. In between these two extremes are numerous processes with varying degrees of technological complexity, requiring a mixture of physical, thermal, and biochemical transformations.

One of the simpler food production processes is liquid heating, essentially applying heat through water or some other medium. For example, water temperatures of 125°F and above are required for the scalding of poultry, while pressure cooking involves the application of steam in rotation cookers. In the beverage industry, boiling converts insoluble starch into liquefied starch to obtain brewer's malt. Baking involves the application of heat to cook or brown foods. Baking and roasting apply heat directly to the foods. Frying uses a transfer medium—typically oil. Baking is used extensively in the bread-and-cookie industry. The more complex processes also involve the application of thermal energy to effect chemical or biochemical changes in the composition of foods. Temperatures above 140°F are required to pasteurize milk.

Food preservation techniques include thermal processing, moisture removal, chemical processing, and irradiation. Cooking, boiling, baking, and other procedures use heat to inactivate microorganisms, enzymes, or harmful chemicals in food. Removal of some of the moisture in foods often extends the length of time during which the product can be stored without spoilage, such as in dehydration. Current dehydration techniques include warm, hot air, or steam; freeze drying for coffee and herbs, and the concentration of milk and fruit juices; and microwave and vacuum technologies. The chemical additives most commonly used with food are salt and smoke (used in curing and smoking operations). The last type of food preservation technique is a recent introduction: ionizing radiation—or irradiation—which uses gamma rays, electron beams, and x–rays to sterilize a variety of products. This sterilization is brought about by a chemically induced destruction of insects and microorganisms which would otherwise accelerate the spoilage process. The industry is critically dependent on energy for food preservation.

The most electricity-intensive food-processing sectors are wet corn milling, meat-packing plants, fluid-milk producers, soybean-oil mills, malt beverages, frozen fruits and vegetables, poultry dressing plants, bakeries, flour-milling plants, and soft-drink plants. Most of these consume large amounts of electricity because of their size.

21.5 THE TEXTILE INDUSTRY

The textile industry consumes raw materials from the agricultural and chemical industries and supplies raw materials to producers in the home furnishings (accounting for 45% of industry output), apparel (30%), and industrial fabrics industries (25%). Overall energy consumption in the textile industry has increased in response to industry growth and productivity improvements. Electric machine drives account for 57% of electricity use, lighting and other facility services consume 23%, and HVAC systems account for about 14%.

In response to increased foreign competition, the textile industry has had to invest in productivity and efficiency improvements. Productivity improvements are reflected in increase in the amount of energy consumed per employee. This increase is largely attributable to increased process automation. Improvements in energy efficiency are evident in the decreased amount of energy consumed per value of shipment. The textile industry uses large amounts of energy in process heating. Although large electric and thermal loads provide attractive opportunities for cogeneration, cost pressures have constrained cogeneration investments.

In response to highly competitive market conditions, textile manufacturers have adopted “quick response” (QR) systems that improve communication between suppliers, manufacturers, and end users. Although QR systems are fundamentally information technology systems that are not themselves energy intensive, they provide opportunities to increase the level of automation in a facility.

The most electricity-intensive textile plants are greige mills, which produce unfinished woven and knitted goods. Electricity supplies about 80% of the total energy requirement in a greige mill. The application of mechanical moisture-removal equipment such as vacuum extractors and roller squeezers is expected to impact electrical plant design and consumption, primarily as a result of the potential energy savings and process simplification in textile drying and finishing.

21.6 THE PETROLEUM INDUSTRY

The petroleum refining industry encompasses a broad range of operations that provide raw materials to almost every manufacturing industry. Petroleum refiners produce fuels and solvents—lubricants that are essential to the operation of most industrial facilities. Additionally, petroleum refiners produce feedstocks for the plastics and petrochemical industries.

Electricity accounts for about 3.5% of the industry’s total energy use. About 80% of the total electricity consumption is used to operate pumps, compressors, fans, and other machine-driven applications.

21.6.1 Oil Refineries

Introduction. Oil refineries are seeking to maintain or increase their profit levels by upgrading existing processes and replacing aging equipment with more efficient and lower-operating-cost options. In the petroleum refining process, the primary raw material, crude oil, is heated, separated, and converted into up to 10 major product categories: motor gasoline, fuel gas, liquefied petroleum gases (LPGs), jet fuel, diesel fuel, lubricants, kerosene, fuel oils, asphalts, and coke.

In the United States, motor gasoline and jet fuel provide the highest revenue and are produced in the highest quantities. Diesel and home heating oils and residual fuels used by power plants, ships, and industrial boilers are also important products that contribute to the industry's bottom line. Each refinery has a varied product slate, the mix of products produced in response to market demands.

Generally speaking, a refinery can be classified as one of three types: gasoline (cracking), fuel oil (hydroskimming or topping), and coking. A gasoline refinery produces a greater percentage of gasoline and less heating and other heavy oils. The refinery increases its gasoline yield by upgrading the heavy oils. A fuel oil refinery primarily produces ship, industrial, and home heating oils, some gasoline, and kerosene. A maximum amount of gasoline and a much reduced percentage of heavy oils are produced in a coking refinery.

General. Oil refineries vary greatly in the variety and quantity of products and crude-oil throughput. A basic refinery producing gasoline and other fuel products would include operations such as those described below. These are merely typical of the many processes in current use.

Crude-Oil Desalting. Water is added to the crude oil to dissolve the unwanted salt. The mixture is passed through a vessel containing electrodes between which a potential of several kilovolts is maintained. The potential gradient causes the salt and water to coalesce and settle to the bottom of the vessel, where the mixture is drawn off. The desalted crude oil is discharged near the top of the vessel.

Crude-Oil Distillation. The crude oil, which is a mixture of a large variety of hydrocarbons having different boiling points, is heated in a furnace to about 750°F and then enters a fractionating tower. The components are separated according to boiling range, since the lighter ones rise in the tower as gases and the heavier ones fall in the tower as liquids. Trays with specially designed openings in them are installed at intervals in the tower to ensure intimate mixing of the rising gases and the falling liquids and to provide places where liquids having certain boiling ranges may be drawn off the tower. The operation is first performed in a distillation tower in which the pressure is maintained somewhat above atmospheric pressure and again in another tower which is kept under vacuum in order to reduce the boiling temperatures of the hydrocarbons and thereby prevent thermal cracking, which is decomposition due to excessive heat. The combined unit is called an atmospheric and vacuum, or A&V, unit. It is also sometimes called a "two-stage pipe still." The main fractions produced are condensable gas, gasoline components, diesel fuel, heating oils, gas oils, and residuals. All of these are processed further.

Fluid Catalytic Cracking. To increase gasoline yield from a crude oil, heavy gas oil from the distillation unit is processed in a cracking unit. The heavy molecules are brought in contact with a catalyst under proper conditions of temperature and pressure and are converted into lighter molecules. Thus lighter products are formed which are suitable for use as gasoline and distillate fuel components. The use of a catalyst promotes the cracking reaction at a lower temperature and pressure and produces larger quantities of products having more valuable qualities than is possible with straight thermal cracking.

The clay catalyst is in powder form, and it is handled as a fluid. The cracking reaction causes the formation of carbon deposits on the catalyst particles. These are removed by controlled burning in a regenerator vessel. The catalyst is continually being circulated through the reactor and the regenerator by means of gas flow and airflow, respectively.

Combustion Air Blower. Combustion air for the regenerator is provided by a large centrifugal air blower driven by an induction motor and gear increaser or by a steam or gas turbine.

Gas Compressor. Some of the products of the catalytic cracker are drawn off as gas. This gas is compressed, condensed, and fractionated to provide other fuel products and feedstocks for petrochemical processes. A centrifugal compressor is used, and it is driven by an induction motor through a gear increaser or by a directly coupled steam turbine or gas turbine.

Catalytic Re-forming. In this process hydrocarbon molecules are rearranged and recombined to form molecules of higher octane rating which can be used as gasoline components. Hydrogen is produced in this process. Large reciprocating and centrifugal compressors are used to move the large volumes of gas involved in the process. Hydrogen is a by-product of this process.

Hydrofining. This process uses hydrogen in the treatment of other products, such as jet fuels, distillates, and lubricating oils, to improve quality and to remove sulfur.

Cooling-Water Pumps. Large volumes of water are used for cooling-process streams and for condensers. Water may be conserved by the use of induced-draft cooling towers.

Cooling-water circulating pumps are driven by vertical motors. Standby pumps are driven by steam turbines.

Power Supply. Refining operations are continuous processes, and uninterrupted runs of 1 or more years are expected between planned shutdowns for maintenance or turnarounds. Therefore, it is essential that the power supply be extremely reliable.

Often duplicate full-capacity feeders are installed to the refinery, and sometimes these are run from different substations, for increased security. Many refineries practice cogeneration to take advantage of their high steam loads.

Distribution Systems. Because refinery loads are often concentrated to a large extent in fairly well-defined process areas, it is common to install unit substations in the major process areas. These substations contain power transformers to provide 4160- or 2400-V power, 480-V power and lighting transformers, or provision for feeding lighting transformers. They also contain all associated switchgear, motor-control, and emergency generators.

A typical refinery *process-unit distribution* system is shown in Fig. 21-2.

Area Classification. Flammable gases and vapors are processed in oil refineries. Therefore, it is necessary to classify the various locations according to the material that is present and also according to the degree of hazard expected.

Reference should be made to the applicable electrical code for requirements governing installations in classified areas.

The actual classification of areas is usually made by the electrical design engineer in consultation with persons who are familiar with the operation of the process.

The most common classification for refinery process units is Class I, Group D; the class consists of hazardous gases and vapors, and the group comprises gasoline and many of the petroleum products.

Current practice is to classify outdoor, freely ventilated process areas as Division 2. Indoor process areas that are not freely ventilated and places below grade level are classified as Division 1. Areas in which a permanent ignition source is located, such as around a furnace, are not classified. Pressure-ventilated unit substations and control buildings are not classified. However, some companies follow the practice of classifying control rooms as Division 2.

21.6.2 Electric Motors

Type of Motor. Two-pole induction motors having NEMA Design B characteristics are used to drive the majority of refinery-process pumps. Motors operating at slower speeds are used for some applications, such as for driving reciprocating compressors or for driving centrifugal compressors through gear-speed increasers.

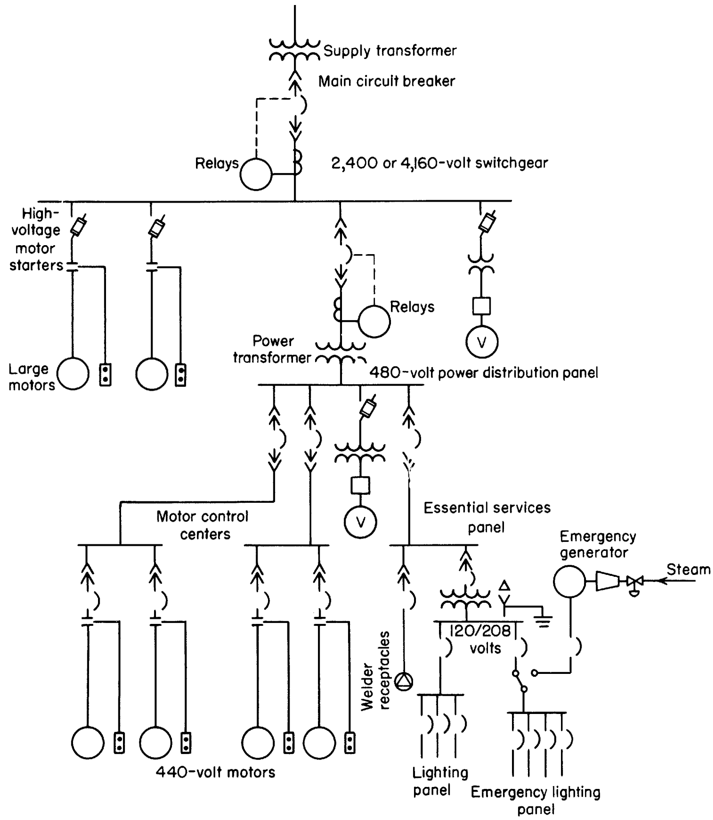

FIGURE 21-2 Typical refinery process-unit distribution system.

21.6.3 Emergency Power Supply

Emergency Generator. Generators provide emergency power for critical motor loads, emergency lighting, and instruments. Generators are driven by steam turbines or diesel engines, which start automatically when the normal refinery power supply fails. Capacities range from 15 to 300 kW. Output voltage is 120/208 V 3-phase or 480 V 3-phase. Load is automatically transferred to the generator after it has reached normal operating speed.

Batteries. Batteries are used when a continuous supply of power must be available for process instruments, emergency controls, and shutdown devices. They are also used for remote-control systems. Voltages of 24, 48, and 120 V are used. Inverters provide power for critical ac instruments and are sometimes used for computer power supply. Battery chargers are transferred to the emergency generator on loss of normal power.

Batteries should have enough capacity to carry full load for half an hour with the charger off. Charger capacity must be sufficient to carry the full dc load and to recharge the battery in 8 h.

21.6.4 Oil-Well Pumping

Methods of Forced Production. When there is insufficient natural pressure to force the crude oil to the surface, some method of forced production is used. The most common methods are described as follows.

High-Pressure Gas Lift. Gas is forced to the bottom of the well or to an intermediate point in the well. The gas mixes with the oil in the well and induces flow by decreasing the density of the fluid.

Water Flooding. Treated water is forced into the formation through nearby wells in order to increase the pressure in the formation and induce flow.

Bottom-Hole Hydraulic Pump. High-pressure crude oil is carried down the well in tubing, and it is used to drive a reciprocating pump located at the bottom of the well.

Bottom-Hole Centrifugal Pump. A special motor-driven multistage centrifugal pump is lowered to the bottom of the well. This method is used where large volumes of fluid must be pumped.

Sucker-Rod Pump. A reciprocating single-acting pump is installed at the bottom of the well on the end of a tube inside the well casing. In sucker-rod pump drives, the plunger is operated by a sucker rod from the surface. Various methods are available to drive the sucker-rod string, but generally a walking beam is used to provide the desired vertical motion.

Central Power Units. Central power units driven by electric motors are sometimes used to serve as many as 15 or 20 wells. Operating rods lead out to each pump to provide reciprocating motion to the walking beams.

Individual Engine or Motor Drives. These are more commonly used than multiple drives because they can be started and stopped individually and the pumps can be operated at different speeds. Electric motor drives are preferred because they can be started and stopped by a timer, they provide consistent, trouble-free performance regardless of weather conditions, and maintenance and investment costs are low. Also, it is easy to measure power demand and energy consumption of an electric motor. The well may be counterbalanced readily by an ammeter.

Motor Types. Torque requirements vary widely during the pumping cycle, and peaks occur when the sucker-rod string and fluid load are lifted and when the counterweight is lifted. NEMA Design D motors, although relatively expensive, are well suited to this service, since they minimize current peaks and provide adequate torque under all service conditions, including automatic operation by time control. NEMA Design C motors may be used where operating conditions are less severe. NEMA Design B motors must be used with care in this service to avoid high cyclic current peaks, which may be objectionable on a small system, particularly if several wells should "get in step." The use of Design B motors can also lead to oversizing of motors in an attempt to obtain sufficient starting torque. This results in the operation of the motor at a relatively low load factor, with consequent low power factor.

Double- or Triple-Rated Motors. These are special motors developed for oil-well pumping. They are totally enclosed, fan-cooled NEMA Design D motors that can be reconnected for 2- or 3-hp ratings at a common speed of 1200 r/min. Typical horsepower ratings are 20/15/10 and 50/40/30. They provide flexibility in the field since they permit the selection of the horsepower rating at which the motor may be operated most efficiently. They also permit changing the pumping speed by changing the motor pulley and reconnecting the motor.

Single-Phase Operation. If single-phase power only is available, it is advisable to consider the use of single-phase/3-phase converters and 3-phase motors. This avoids the use of large single-phase capacitor start motors, which are relatively expensive and contain a starting switch which could be a source of trouble due to failure or to the presence of flammable gas in the vicinity of the well.

Oil-Well Control. A packaged control unit is available to control individual oil-well pumps. It contains, in a weatherproof enclosure, a combination magnetic starter, a time switch that can start and stop the motor according to a predetermined program, a timing relay that delays the start of the motor following a power failure, and lightning arresters. Push-button control is also provided.

Power-Factor Correction. The induction motors used for oil-well pumping have high starting torques with relatively low power factors. Also, the average load on these motors is fairly low.

Therefore, it is advisable to consider the installation of capacitors to avoid paying the penalty imposed by most power companies for low power factor. They will be installed at the individual motors and switched with them, if voltage drop in the distribution system is to be corrected as well as power factor. Otherwise they may be installed in larger banks at the distribution center, if it is more economical to do so.

21.6.5 Gas-Processing Plants

Natural Gas. Natural gas varies widely in composition and contains undesirable materials such as water and sulfur compounds, which must be removed before the gas enters the transmission pipeline. Various chemical processes are used, and plant capacity ranges from 5 to 1000 million ft^3 of gas processed/day. By-products such as propane, butane, pentanes, and elemental sulfur are produced and marketed.

Power Supply. Purchased power is used where available. Local generation is by reciprocating gas engines or gas turbines.

Electrical installation practice in gas plants is similar to that followed in oil refineries, as described below.

21.6.6 Oil Pipelines

Gathering Systems. These collect crude oil from the individual wells, or from tanks located near them, and carry it to tankage, where shipments may be accumulated.

Trunk Lines. These feed crude oil from gathering systems to the main crude pipeline pumping station.

Crude Lines. Crude lines are generally operated as common carriers. Since they handle crude oil for several companies and because crude-oil shipments vary greatly in quality and composition, storage tanks are necessary at stations along the pipeline so that batch shipments may be handled.

Product Lines. These convey products from a refinery to the market area. Some products lines are operated as common carriers, while others are privately owned and operated.

Operation of Pipelines. Batches of crude oil or products are dispatched through a pipeline and are withdrawn to tankage at the end of the line or at intermediate points. If a batch is being drawn off at an intermediate point, the downstream stations will operate at reduced flow.

Little mixing occurs at the interface between different batches. By careful scheduling and a knowledge of the pipeline it is possible to predict fairly accurately when an interface will arrive at a station. Interface detectors are installed also.

Pumping Stations. A schematic diagram of a typical pumping station is shown in Fig. 21-3.

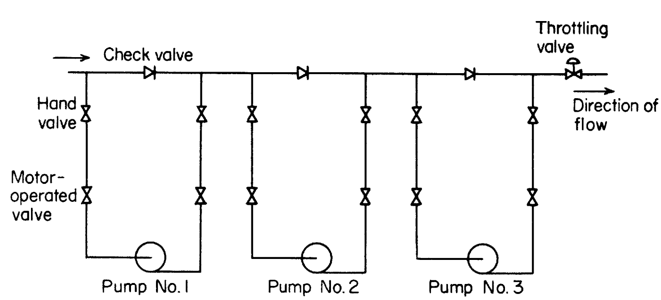

FIGURE 21-3 Pipeline pumping station.

Arrangement of Pumping Stations. These are located at the head of the pipeline and at intervals along the line. Intermediate or booster stations must be capable of operating under varying conditions due to differences in liquid gravity, withdrawals at intermediate points, and the shutting down of other booster stations. Pumping stations often contain two or three pumps connected in series, with bypass arrangements using check valves across each pump. The pumps may all be of the same capacity, or one of them may be half size. By operating the pumps singly or together, a range of pumping capacities can be achieved.

Throttling of pump discharge may also be used to provide finer control and to permit operation when pump suction pressure may be inadequate for full flow operation.

Control of Pumping Station. Pumping stations are often unattended and may be remotely controlled by radio or telephone circuits.

Electrical System. Figure 21-4 is a typical electrical single-line diagram for a pumping station.

Motor Type for Main Pumps. The main pumps are driven by 3600-r/min induction motors having NEMA Design B characteristics. Full-voltage starting is used.

Motor Enclosure. Motor enclosures for outdoor use are NEMA weather-protected Type II, totally enclosed, fan-cooled, or dripproof with weather protection. Motors of the latter type are widely used. Not only are they less expensive than the other types, but they also have a service factor of 1.15. The above enclosure types are all suitable for the Class I, Group D, Division 2 classifications usually encountered.

If the pumps are located indoors, a Division 1 classification is likely to apply. Motors must be Class I, Group D, explosionproof, or they may be separately ventilated with clean outside air brought to the motor by fans. Auxiliary devices such as alarm contacts on the motor must be suitable for the area classification. The installed costs, overall efficiencies, and service factors associated with the enclosures that are available will influence the selection.

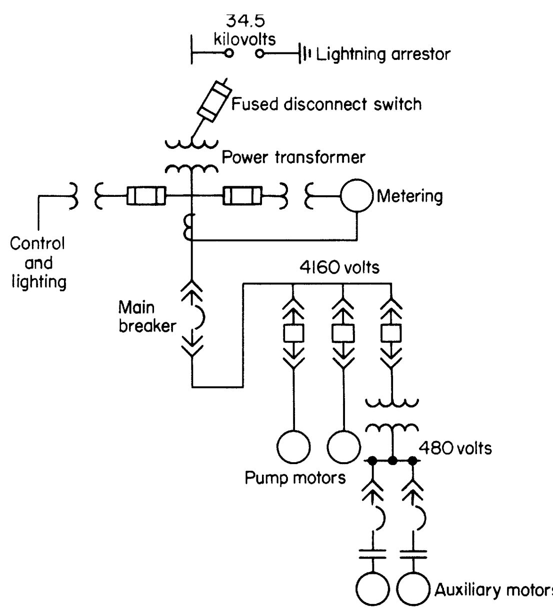

FIGURE 21-4 Single-line diagram of a pipeline pumping station.

Adjustable-Speed Drives. Of the total electricity consumed by petroleum refiners, 80% is for machine-drive applications. Most of this energy is used to drive turbomachinery such as pumps, compressors, and fans. These applications are well suited for adjustable-speed drives. Since the power consumed by turbomachinery is highly dependent on operating speed, the use of adjustable-speed drives to control the output of these machines can provide significant improvements in operating costs and system performance. The most common type of adjustable-speed drive is the *variable-frequency drive* (VFD), which uses rectifiers and inverters to control the frequency of the power supplied to a motor. VFD technology is widely used in industry, providing energy savings up to 70% below conventional flow control options.

Pumping systems are particularly attractive applications for VFDs. Because of the reduced amount of wear on system valves and piping supports that results from minimizing unnecessary pump output, VFDs can improve system reliability and lower maintenance costs.

21.7 THE STEEL INDUSTRY

Industry Description. The domestic steel industry includes blast-furnace integrated steelmakers, nonintegrated minimills, and independent producers of wire, bar, and pipe made from raw steel. Blast-furnace operations use either an open hearth or a basic oxygen furnace, with electric arc furnace used in the minimill. Raw steel is melted increasingly by electric furnaces, and the basic oxygen furnace is still used in a number of mills.

Energy Use. The steel industry is highly energy-intensive. Its aggregated average energy consumption of approximately 19 million Btu per ton of steel shipped represents about 3% of the energy consumed in the United States and 10% of that used by the industrial sector. Approximately 60% of the energy consumed by the steel industry is derived directly from coal, and much of the electricity the industry uses is generated at coal-fired power plants.

Natural gas accounts for nearly 30% of the industry's energy consumption. Energy purchases represent about 15% to 20% of the total manufacturing cost of steel. In response to these significant costs, the industry has sought to improve production efficiency, principally through process modifications, new technology, and the retirement of old or inefficient plants. Since 1975, the steel industry has reduced energy consumption per ton of steel shipped by about 45%. The steel industry blast furnace process lends itself naturally to cogeneration by virtue of the large amount of by-product gases generated. The industry today recycles a high percentage of scrap steel, and uses fuels that are by-products from the cokemaking and ironmaking processes to cogenerate electricity and steam. Additionally, the industry has replaced a number of their open-hearth furnaces with basic oxygen furnaces and has implemented continuous casting on a wide scale.

Electricity as a Cost of Making Steel. The U.S. steel industry is a major consumer of electricity. Energy costs account for 15% to 20% of the total manufacturing cost of producing steel. Electricity on average represents only about 7% of the total energy consumed by the industry, but at some steel plants over half of the purchased energy is in the form of electricity. Costs of electrical energy are disproportionately higher than those for other forms of energy.

Power-Distribution System. Integrated steel mills having blast furnaces and coke plants make use of the combustible gases from these processes by burning them to produce power and process steam. Many older steel plants produce and use power at 25 Hz, utilizing primary distribution voltages of 6.9 to 13.8 kV and secondary systems of 4160 or 2400 V and 480 V. Modern steel plants and modern parts of older plants utilize 60-Hz power exclusively, with primary distribution at 69 or 138 kV and secondary voltages of 13.8 kV, 4160 or 2400 V, and 480 V. Power can be supplied by public utilities, by in-plant generation, or by a combination of the two. Some plants having both 25- and 60-Hz systems have conversion equipment, typically large Scherbius sets or rectifier-inverter systems, for transfer of power from one frequency to the other. Where power is supplied from both a public utility and in-plant generation, there is usually some provision for controlling the maximum demand and improving the power factor of the portion of the load supplied by the utility to avoid high penalty charges.

The presence of numerous cranes and other equipment requiring dc motors with some control over speed has led to the extensive use of 250-V constant-potential dc shop circuits in most steel mills. In older plants the direct current is supplied by rotary converters, motor-generator sets, or mercury-arc rectifiers. In modern plants it is supplied by silicon diode or thyristor rectifiers. The trend is toward the elimination of dc shop circuits by the use of ac cranes and package thyristor power supplies for drives requiring variable speed.

Primary Production. The basic steelmaking areas of an integrated steel plant consist of *coke-oven batteries* for conversion of coal to coke, *blast furnaces* for conversion of iron ore to molten iron, and *steel-producing units* for refining molten iron and other alloy ingredients to steel. Once this basic steel has been produced in ingot (block) form or "continuous cast" into semifinished bars, it is ready for subsequent rolling into a usable size and shape.

Power consumption per ton of steel produced is low in the basic steelmaking areas because the products arc handled in molten or bulk form, compared with the rolling mills, where reheated or cold steel is literally squeezed and stretched to the desired size and shape. Much of the electric power consumption in these primary producing areas is associated with auxiliary drives involved in material handling, water, air, and by-product utilization, and mobile equipment.

The processes of iron reduction and steel refining, with their many, sometimes elusive, variables, do lend themselves to automatic and computer control. Open-loop computer systems have been applied to *blast-furnace* and *basic-oxygen-furnace* (BOF) operations. Raw-material handling and charging functions in *blast-furnace stock houses* and BOF have been automated extensively.

In a minimill, which includes specialty shops, the basic raw material is steel scrap which is melted and refined to produce raw steel and steel products. The steel is melted by an electric arc in which the current passes from one electrode through an arc to the scrap charge, and then from the charge to another electrode. The molten steel is then refined by rapid oxidation and the reaction of impurities with added slag materials.

Rolling Mills. Rolling mills are classified either according to their construction or according to the material processed. Classified according to construction, mills are generally two-high or four-high, with a few existing three-high mills. Four-high mills consist of the usual two work rolls in contact with the product, with two additional "backup" rolls which are much larger and allow high rolling pressure without excessive deflection of the work rolls. A "universal" mill has vertical or edging rolls in tandem with the horizontal rolls. This permits a reduction of width or control of the edges of the product in the same stand where a reduction in thickness is taking place.

The principal types of mills, classified as to product rolled, are as follows.

Blooming Mills. These mills roll ingots into blooms, or slabs. All material rolled in steel mills, except that which is direct continuous cast into slabs, blooms, or bars, first passes through this type of mill, or its equivalent, to be reduced to proper dimensions for handling in the finishing mills. These are generally single-stand, two-high reversing. Slabbing mills are a modification of the blooming mill. They are usually universal mills, which permits convenient rolling of wide slabs by eliminating frequent turning of the ingot. Blooming and slabbing mills may have such automatic features as preset of roll openings and speed synchronization between main and edger rolls. The preset information is sometimes stored on business-machine cards and read into the mill control system by a card reader, or it can be stored in the computer memory in computer-controlled installations. Blooming and slabbing mills are powered by large low-speed dc motors operating from a variable-voltage system. A typical slabbing mill has a total of four 3000-hp motors driving the horizontal rolls and two 2000-hp motors driving the edger rolls at rated motor speeds of 40 to 80 r/min. The dc power for blooming mills has been traditionally supplied by generators using the Ilgner system, but the present trend is toward the use of thyristor power supplies connected in rectifier-inverter configurations.

Hot-Strip Mills. These mills roll sheets, strip, and plate from heated slabs. These mills can be placed in two categories: continuous and semicontinuous. (These terms designate the type of rougher which precedes the finishing train.) The *continuous mill* has two to six mills in line which reduce the slab to a predetermined thickness for subsequent rolling through the finishing train.

The *semicontinuous mill* has a reversing rougher on which reduction is made by running the piece back and forth through the mill, which reduces the slab to a predetermined thickness for subsequent rolling through the finishing train.

The finishing train consists of five to seven stands, closely coupled and synchronized in speed, in which the piece is reduced to the desired gage. As a general rule, the piece is in all finishing stands simultaneously.

Roughing stands of a continuous mill are usually driven by ac motors, since speed synchronization with an adjacent stand is not required. Many existing roughing mills utilize wound-rotor induction motors with flywheels and water-slip regulators, but today synchronous motors predominate. The roughers on semicontinuous mills are driven by dc motors.

Direct-current motors operating from a variable-voltage system have been traditionally used for finishing stands, but ac motors with variable-speed drives are now being used in some applications. Tension between stands must be accurately controlled at a relatively low value, since the hot steel is in plastic form and excessive tension results in "necking," or breaking. Constant-tension "loopers" are used between stands for interstand tension regulation. The looper is pushed up by air, hydraulic pressure, or a torque motor, and the upward movement is restricted by the strip. The looper position is then fed back to the electrical control system, and the speed of individual finishing-stand motors is regulated to maintain the proper looper position.

Various measuring devices must always be in operation, measuring gage, screw position (roll opening), looper position, roll force, and width of strip. With the feedback from these devices, the positioning of the screw-downs, which control gage, and the edgers, which control width, can be regulated during the rolling of the strip. The newer mills make use of digital positioning to set up the mills prior to the entrance of the bar into the mill.

The thread-speed reference is set into the speed controller, and this speed is maintained by utilizing the pilot-generator feedback. When the strip enters the mill, the load increases sharply, bringing the current feedback to the armature controller into effect. By controlling the armature and field, rapid speed changes while complete control is maintained are possible, both with and without load. The acceleration control, when called on, feeds into all the finishing-mill motors for uniform acceleration.

Newer mills now have small digital computers controlling each stand.

As the strip cools during rolling, it becomes harder and the output gage changes. Part of this change in gage can be controlled by accelerating the mill, but much of it must be controlled by changing the position of the screw-downs. The newer hot-strip mills use automatic gage control systems (AGC) to regulate screw-down position while the strip is in the finishing mill. There are two types of AGC in use, a constant-gage system and an absolute system. Both systems work basically the same, by taking a reference either from the head end of the strip in the constant-gage system or from preset switches in the absolute system and maintaining it throughout the length of the strip. This reference is compared with the actual gage of the strip, measured as a function of roll force and screw-down position, or by an x-ray gage, and the screw-downs are moved to bring both these signals to the same value. This is a continuous operation during the period of time the strip is in the finishing mills.

Most modern hot-strip mills are built with computer control. Rolling in a completely automatic or computer-controlled state, the computer provides the position and speed references instead of operators. With a computer-controlled mill, these references can be constantly changed as the computer receives new information from the strip.

The handling of steel between roughing stands and between the finishing stands and the downcoilers is accomplished by roll "tables," which are a series of motor-driven rolls on which the steel lies. In some installations, one large table motor drives a number of table rolls through mechanical gearing and shafting ("line-shaft drive"); in others, each roll is driven by one small motor. Permanent-magnet field dc motors have been particularly successful for this arrangement. Table rolls have been driven by dc motors operating from a variable-voltage system, but newer applications use variable-frequency induction-motor system. As adjustable-frequency power supplies have become more reliable, this system is becoming standard.

Tandem Cold-Strip Mills. These are used to cold-reduce previously rolled hot-strip mill products down to thicknesses as low as 0.002 in. Special "foil" mills have been built which can roll even lighter gages. A cold-strip mill is similar to the finishing stands of a hot-strip mill, except that tension between stands plays a much more important role in reducing the thickness of the steel. Modern cold-strip mills are built for finishing speeds in excess of 5000 ft/min.

Cold-strip mills are generally three- to six-stand mills, four-high, with a coil box or payoff reel on the entry end and a tension reel at the delivery end. Newer cold-strip mills are universally driven by variable speed ac motors. Usually the individual stands are voltage-regulated, and the operator establishes the motor field and, thereby, the stand speed according to the gage reduction and the strip tension desired. Load-cell tensiometers are used to indicate to the operator the interstand tensions.

Some of the most modern mills have each stand speed-regulated, and all major drives incorporate full field acceleration to base motor speed for maximum torque. Above base motor speed, automatic field weakening with constant rated armature voltage is used to attain top motor speed. Payoff-reel tensions, interstand tensions, and winding-reel tensions are accurately controlled by using load-cell tensiometers to measure tension and provide feedback to tension regulators which operate on the appropriate drives (see Fig. 21-5).

Finished steel gage is controlled by utilizing x-ray gages to provide information to AGC regulators. Gage control may be accomplished by operating on interstand tensions only or by a combination of interstand tensions and work-roll openings. Work-roll openings ("screw-down positions") are controlled by digital position regulators which hold the screw-down position constant to within 0.0001 in. To help further in producing constant finished gage, the rolling forces on each stand are held constant by using speed-programmed digital regulators to hold constant rolling force at all speeds. Rolling force is measured and indicated by load cells placed under each stand housing.

Other Types of Rolling Mill. *Billet mills,* used to roll blooms into billets, are frequently of a continuous type with rolling stands in tandem with several sets of passes in the rolls so that different-sized billets can be produced from a given bloom without changing rolls. This type of mill is used for producing only a limited range of sizes, which are further reduced in finishing mills.

Plate mills produce plates from slabs previously rolled by a blooming or slabbing mill. These mills are generally single-stand mills, either two- or four-high reversing or three-high running

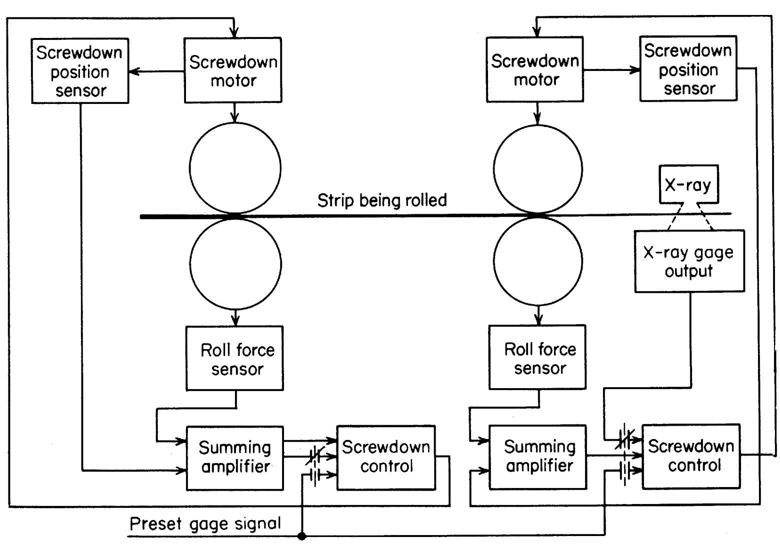

FIGURE 21-5 Cold-strip mill.

continuously in one direction, although some mills are provided with several stands in tandem, one serving as a rougher or breakdown stand. They are sometimes universal mills, provided with vertical rolls for finishing the edges of the plates.

Structural mills are used for rolling beams, heavy angles, channels, etc., from blooms or billets. Such mills rolling the smaller structural sections and miscellaneous shapes are sometimes called "bar mills." They are frequently three-high, with more than one stand in line, and frequently have a separate rougher or breakdown stand. Some also have two-high reversing finishing mills with edger and vertical, as well as horizontal, rolls, to produce wide-flange (H) beams.

Rail mills are special mills for rolling this product only from blooms or billets, although rails are sometimes rolled on structural mills.

Merchant mills are used for rolling small angles, channels, rounds, squares, etc., from billets. This classification is generally applied to mills rolling the smaller sections used for miscellaneous purposes. Most are two-high, in tandem; however, some are arranged for cross-country rolling.

Rod mills are a specialized type of merchant mill for rolling small rounds, usually from No. 5 BWG and upward, which are later drawn into wire. Modern rod mills are arranged to roll a multiplicity of strands simultaneously.

Temper mills are used to produce steel strip of the desired temper, flatness, surface, and luster by using rolling pressure and tension. Reduction in thickness is incidental in the process and is normally very slight. Temper mills generally have one or two 4-high stands and are similar to cold-strip mills, except that they are of lighter construction, have less powerful motors, and have simpler electrical control systems. Temper mills have been built and operated at speeds in excess of 7000 ft/min.

Tube mills are used to produce tubes, for example, pipe and conduit, by either the seamless or the butt- or lap-weld process. Seamless mills pierce a solid billet and then form the pierced billet into tubes of the desired size and thickness. Butt- or lap-weld mills form and weld previously prepared pipe skelp into tubes.

21.8 THE CHEMICAL INDUSTRY

The chemical industry encompasses a broad range of manufacturers that provide essential raw materials for many other manufacturing processes. The largest energy users within the chemical industry are chloralkali facilities, industrial gases, inorganic chemicals, plastics and resins, synthetic rubber, organic fibers, cyclic crudes, nitrogenous fertilizers, and industrial organic chemicals.

21.8.1 Industrial Gases

The industrial gas facilities separate nitrogen, oxygen, argon, and carbon dioxide from air. These gases are then shipped in either liquefied or gaseous form. Some air separation plants build gas pipelines directly into large-volume contract customers.

Industrial gas production is electricity-intensive, accounting for 77% of the total industrial gas energy consumption. The process of separating air is primarily through a cryogenic technique. Air is compressed and cooled to temperatures below –200°F, then sent through turbines where additional energy is removed. After the air is liquefied, it is fractionated so that the component gases can be isolated. The gas products are then purified and reliquefied as required for shipment. The cryogenic technique is largely a mechanical vapor-compression process; consequently, motor drives account for about 87% of all electricity used by the industry.

21.8.2 Industrial Inorganic Chemicals

Industrial inorganic chemicals represents a diverse group of products, including pigments, acids, salts, activated carbons, phosphorus, and sulfur (chlorines, alkalis, and industrial gases are inorganic; they are treated as separate industry groupings). The inorganic chemical industry accounts for about 25% of all chemical products, supplying raw materials to the automotive, paper, packaging, pharmaceuticals, and paint industries.

21.8.3 Manufactured Fibers

The manufactured fiber industry converts polymers such as nylon, acrylonitrile, polyester, polyurethane, cellulose, and cellulose acetate into four primary types of fiber: staple fiber, filament, monofilament, and tow. These products are, in turn, used as raw materials by the textile, apparel, and cigarette industries. The textile industry is the largest industrial consumer of manufactured fibers. Machine-drive applications account for 54% of total electricity use. Energy accounts for between 10% and 18% of the total cost of goods.

In addition to being energy-intensive, the manufactured fiber industry requires highly reliable power. The nature of the manufacturing process makes any interruption in the product flow costly. Since fibers are continuously spun, any disturbance in machine speed or temperature can severely impact product quality. Unexpected downtime can create costly, time-consuming cleanups. Manufactured fiber facilities typically operate 24 h per day, 365 days per year to avoid the cost of restarting the processes. Consequently, power reliability and power quality are high priorities for the industry. Similarly, the industry uses a very conservative approach to investments in electrical equipment.

21.9 THE PULP-AND-PAPER INDUSTRY

21.9.1 Industry Organization

This industry is basically organized into (1) pulp mills and (2) paper and paperboard mills. The pulp-and-paper industry includes the manufacture of pulp from wood products, the production of paper and paperboard from wood pulp, and the conversion of bulk paper and board to finished products. It is sometimes considered part of the larger forest products industry, which includes the agricultural activities of tree farming, as well the conversion of the trees into lumber and wood products.

21.9.2 Pulp Mills

The pulping industry includes the manufacture of wood pulp, which is the input for the entire paper industry. Most of the pulp produced in the United States is for internal use in paper production, but 10% to 15% of the total pulp produced is sold on the open market. Types of pulp include bleached kraft, unbleached sulfite, and thermomechanical products. The "type" refers to the pulp manufacturing process. Pulp types are typically destined for a specific market, such as the use of bleached kraft pulp in higher-quality printing and writing papers. Chemical pulp accounts for approximately 90% of U.S. manufactured wood pulp and is based mostly on the kraft process. In this process, wood chips are mixed with a caustic sulfite cooking liquor at temperatures of 176°C. The wood is then separated into individual fibers with limited mechanical agitation. When the resulting pulp is washed, the waste liquid is processed in a recovery boiler. This boiler generates steam for both process use and power production, and the pulp reduction chemicals are also partially recovered for reuse. Mechanical pulping is very electrically intensive, and essentially applies heat and pressure to convert wood to pulp. Mechanical pulping processes use 1400 to 1700 kWh per ton of pulp produced.

21.9.3 Paper and Paperboard Mills

This industry includes the production of paper, paper products, and packaging materials. The paper industry companies are typically vertically integrated and incorporate most elements of forest products in their businesses. Environmental pressures have increased for the industry since the late 1980s, as in the treatment of the low levels of dioxins in paper-mill sludges. The "cluster rule," passed on April 15, 1998, regulates hazardous air pollutants and chlorinated organics (mostly phenolics). A focus of environmental concern is the continued use of bleaching technology that employs chlorine dioxide in the process. The chlorine dioxide is converted to sodium chlorate with the release of chlorine as a by-product. Mills are now introducing various control measures to deal with this issue.

Papermaking consists of stock preparation and formation of the final paper product in the paper machine. The primary step in stock preparation is refining the cellulose fibers in the pulp to facilitate good fiber-to-fiber bonding. The paper machine removes water from the pulp slurry, proceeding through processes of forming, pressing, and drying. To give an indication of the amount of water removal required in this process, approximately 100,000 gal of water is extracted for each ton of dry paper produced.

Stock preparation and refining requires 1 to 2 million Btu of thermal energy and 150 to 400 kWh of electricity per ton of paper processed. Paper refining requires 6 to 12 million Btu of thermal energy and 250 to 400 kWh of electricity per ton of paper processed. A newer technique of water removal—impulse drying—promises to improve overall efficiency with a lowering of thermal energy needs and an increase in electricity demand.

21.9.4 Power Distribution System

Mills typically use both 480- and 600-V systems for the lower voltage level, although 480 V is predominant. The mill may have its own substation, with distribution system higher voltages at 2400 to 15,000. Most large mills will have multiple 3-phase system voltages at levels including 480, 2400, 4160, or 13,800. Radial distributions are usually preferred because of their simplicity and lower cost.

21.10 DISTRIBUTED GENERATION

Distributed generation refers to small electric generating units located close to load centers. It encompasses onsite generation, self-generation, cogeneration, and any other small-scale power generation that is not considered central-station power. Distributed-generation projects are undertaken by end-use customers, electric utilities, gas utilities, power marketers, and other third parties.

The combination of electric utility deregulation, emerging generation technologies, and the growing worldwide demand for power has renewed interest in distributed generation. Electric utility industries are being deregulated in countries around the world. At the same time, new generation technologies such as fuel cells and microturbines are being commercialized, while conventional small-scale power generation technologies such as reciprocating engines and combustion turbines continue to make evolutionary improvements in performance. At the same time, worldwide demand for electric power has never been greater, and continues to grow, in both developed and developing countries. The combination of these three factors has led to a greatly increased interest in distributed generation.

21.10.1 Why Distributed Generation Is Used

Distributed generation is used for the following traditional applications:

- *Baseload power,* where the unit operates at a high-load factor throughout the year—usually the unit is operated as many hours as possible
- *Intermediate power,* where the unit operates during a specific period during the day, such as 9:00 A.M. to 6:00 P.M., during a specific seasonal or some other time period—usually 500 to 2000 h during the year
- *Peak shaving,* in which the unit operates only during the site's peak electricity demand or during peak electricity price periods—usually less than 500 h per year
- *Cogeneration* where the unit operates for a majority of the time during the year, and supplies both electricity and thermal energy to a site
- *Emergency/backup power,* where the unit is configured to supply power to the site in the event of a grid outage

In addition, a number of new niche applications for distributed generation have emerged, including

- *Premium power*—the unit supplies high power quality, free of interruptions, sags, surges, and spikes.
- *Green power*—the unit supplies power while generating low or zero emissions of pollution.
- *Power used as a hedge by power marketer*— in a deregulated electricity marketplace, strategically located small-scale power generation can be used as a source of power to fulfill contracts when the spot market price of electricity is high.
- *Remote power*—power is supplied where no distribution lines are available.

Various early adopters are currently using distributed generation for a number of reasons. Some use distributed generation purely on the basis of energy economics (distributed generation is cheaper for them than purchasing electricity from the grid). Others use small-scale onsite power generation because of the other benefits, such as increased reliability.

21.10.2 Distributed-Generation Technologies

A number of different technologies are available for distributed generation. Some of these are proven, mature technologies that have been used for decades. Others have been commercialized and have entered the marketplace only recently. Each is described below.

Reciprocating Engines. Otto and diesel cycle reciprocating engines were first developed in the late nineteenth century. They have gained widespread acceptance in almost every sector of the economy, and are used for applications varying from fractional-horsepower units used for small handheld tools to enormous 60-MW baseload electric power plants. Designs have been undergoing evolutionary changes and continue to improve in terms of efficiency, emissions, and other parameters.

For distributed-generation applications, there are two main types of reciprocating engines: Otto (spark ignition) and diesel (compression ignition). For most distributed-generation applications, these engines are of the four-stroke type, and use a piston that reciprocates in cylinders bore with the following cycles: (1) intake, (2) compression, (3) combustion, and (4) exhaust.

The piston starts at the top, the intake valve opens, and the piston moves down to let the engine take in a cylinder full of air and fuel during the intake stroke. Then the piston moves back up to compress this fuel/air mixture. Compression makes the explosion more powerful. When the piston reaches the top of its stroke, the spark plug emits a spark to ignite the fuel (in a diesel engine, the fuel is ignited by the compression alone). The fuel charge in the cylinder explodes, driving the piston down. Once the piston hits the bottom of its stroke the exhaust valve opens and the exhaust leaves the cylinder to go out the tailpipe. Now the engine is ready for the next cycle, so it takes in another charge of air and fuel.

Reciprocating engines are manufactured all over the world. They are currently being used in many distributed-generation applications, for primary power, intermediate power, peak shaving, and cogeneration. They are also used widely for emergency/backup power. They have a fairly low capital cost and reasonable electric efficiency, especially larger, low-speed units. For cogeneration applications, some low-quality steam can be produced, but most applications are for hot water.

Turbines. Combustion turbines are a widely used distributed-generation technology. They range in size from about 500 kW up to large utility-sized units of over 100 MW. Most of the smaller ones (less than 15 MW) are derived from aircraft engines; most of the larger ones are specifically designed for power generation. Combustion turbines are a proven technology that has been used for onsite power generation for many decades.

Combustion turbines consist of a compressor, a combustor, a turbine, and a generator. The compressors and turbines are typically multistage axial-flow designs, and somewhat resemble steam-turbine configurations.

Combustion turbines are used primarily for industrial and large commercial-sector cogeneration. They are also sometimes used for noncogeneration applications, and sometimes smaller units (usually less than 5 MW) are used for backup power. High-quality steam can be produced. Combustion turbines can be run on almost any gaseous or liquid fuel. Electric efficiency is usually poor (less than 35%, but overall efficiency in good cogeneration applications can be as high as 90%). At the time of writing, new combustion-turbine designs, utilizing technologies such as recuperators and ceramic components, with electric efficiencies of over 40%, are expected to enter the marketplace soon.

Microturbines. Microturbines are an emerging class of small-scale power generation technology in the 25- to 300-kW size range. The basic technology used in microturbines is derived from aircraft auxiliary power systems and diesel-engine turbochargers. A number of companies are currently field-testing demonstration units, and commercial deliveries have already begun. Microturbines consist of a compressor, a combustor, a turbine, and a generator. The compressors and turbines are typically radial-flow designs, and look much like automotive engine turbochargers. Most designs are single-shaft, and use a high-speed permanent-magnet generator that uses an inverter to produce ac power.

A number of different microturbine designs and configurations have been tested by manufacturers. The following are some fundamental design and configuration considerations:

Recuperation. Recuperators are air-to-air heat exchangers that use a microturbine's hot exhaust gases to heat the combustion inlet air after it has been compressed. Recuperators are key to the electrical efficiency of microturbines.

Single-shaft with high-speed permanent-magnet generator and inverter versus split-shaft with reduction gearbox and 60-Hz induction generator. Two different ways of producing ac power with microturbines are currently being evaluated in the demonstration units. The first and more common uses a single shaft with a high-speed permanent-magnet generator spinning at the same speed as the turbine. This generator produces very high-frequency ac power that must be converted to 60 Hz using an inverter. The second design uses a two-shaft configuration with a reduction gearbox and a 2-pole, 3600-r/min induction generator that directly produces 60 Hz of power.

Air-bearing versus oil-lubricated. Microturbines are high-speed (≥40,000 r/min) rotating equipment that require high-reliability bearing systems. Two different configurations are currently being used. The first uses air bearings with a compliant foil system that requires no oil lubricant. The second uses a pressurized lube-oil system with a pump, similar to that used by an automobile engine.

Fuel-cell hybrids. Power generation systems utilizing fuel cells combined with microturbines are also being developed by several manufacturers. These systems typically run the hot gas produced by fuel cells through a microturbine to generate additional electricity. Hybrid system are predicted to have exceptionally high electric efficiencies (≥60%).

Gasifiers. Gasifiers produce gaseous fuel from solids, such as coal and biomass. Small-scale gasifiers for use with microturbines are still in the development stage. Gasifiers could help microturbines gain wider acceptance, especially in international markets.

With recuperation, microturbine efficiency is projected in the 26% to 30% (LHV) range. The overall efficiency is projected at 65%. Overall efficiencies may reach 85%, similar to larger turbines. Microturbines can run on natural gas, diesel, gasoline, kerosene, naphtha, methanol, ethanol, alcohol, propane, JP-8 Flair Gas, and other gases with heating values over 500 Btu/lb.

Fuel Cells. Fuel cells are an emerging class of small-scale power generation technology in the ≥25- to 1000-kW size range. The first fuel cells was developed in 1839 by Sir William Grove, although they were not used as practical generators of electricity until the 1960s, when the U.S. space program chose fuel cells for the *Gemini* and *Apollo* spacecraft.

There are a number of fuel-cell types and configurations, but they all use the same basic principle. A fuel cell consists of two electrodes sandwiched around an electrolyte. Oxygen passes over one electrode and hydrogen over the other, generating electricity, water, and heat. Hydrogen fuel is fed into the anode of the fuel cell. Oxygen (or air) enters the fuel cell through the cathode. Encouraged by a catalyst, the hydrogen atom splits into a proton and an electron, which take different paths to the cathode. The proton passes through the electrolyte. The electrons create a separate current that can be utilized before they return to the cathode to be reunited with the hydrogen and oxygen in a molecule of water. A fuel-cell system usually includes a "fuel reformer" that can utilize the hydrogen from any hydrocarbon fuel—from natural gas to methanol, and even gasoline.

Other Technologies. Other technologies that fall under the distributed-generation umbrella include renewables such as photovoltaic (PV) and wind power. PV technologies convert sunlight directly to electric power. Current PV technologies have very high capital costs, but they continue to improve. Wind-power systems use turbines turned by wind to provide torque to a shaft that turns a generator. These technologies also continue to improve, and now can provide electricity at competitive rates, although they obviously operate only under the proper atmospheric conditions.

21.11 ELECTRIC MELTING

21.11.1 Process Overview

Electric Melting Applications. Electricity has been used extensively for industrial process melting applications since the early 1960s, including iron, steel, nonferrous metals, and glass. The most important applications of electric melting are

1. Melting and refining of steel
2. Melting, holding, and casting of most metals, including iron, steel, and nonferrous metals
3. Melting, refining, forming, and annealing of glass

Glass Melting. Electricity has been used in glass production to melt, refine, form, and anneal glass to the desired properties for use in containers, flat glass, pressed and blown glass, and glass fibers. Applications for electrically melting glass were limited until the mid-1950s, and since then its use in either all-electric furnaces or electrically boosted melting has grown substantially.

Technology Applications. The following sections discuss four technologies used for electric melting applications.

Metal melting includes, in addition to the change of state, the further heating of the metal to a specified temperature, known as the "pouring temperature," if the metal is to be poured into a mold or the "working temperature" if the metal is to be used for coating, as in galvanizing, or as a liquid heating bath.

Table 21-1 refers to melting service. An alloy belongs in a group of this table to which its major component belongs. The melting-temperature range of an alloy must be obtained from the constitution diagram of a system to which the alloy belongs.

Metal	Melting point °C	Melting point °F
Group 1		
Tin	232	450
Bismuth	271	520
Cadmium	321	610
Lead	327	621
Zinc	420	788
Antimony	630	1166
Magnesium	651	1204
Aluminum	659	1218

The pouring temperatures of nonferrous metals and alloys range from 100 to 200°C (180 to 360°F) above the melting point. They vary for each metal or alloy with the type of load and the size and type of casting according to the purpose for which the casting is to be used.

Volatilization occurs. In melting metals there is a certain loss by volatilization. This loss of metal is usually negligible except for charges which contain a high percentage of zinc. Another consideration is the poisonous nature of zinc fumes.

Stirring an alloy while it is in the molten state is often necessary to prevent segregation. Stirring is also an aid in bringing about equalization of temperature and is a safeguard against overheating in the surface of the molten mass.

Automatic stirring can be obtained with suitable induction coils or by the use of an induction furnace.

21.11.2 Melting Pots

The melting of the soft metals, or group 1 (see Table 21-1), and their alloys is within the range of the 80 Ni-20 Cr alloy-resistor heating equipment. Containers for these materials are designated as melting pots, solder pots, lead pots, galvanizing kettles, tanks, etc.

Melting pots are made of cast iron or steel and of various nonferrous alloys. The selection of the material for the pot depends on the temperature of the molten metal and the possible reactions of that metal with the material of the pot.

Open-top pots are used in which the molten metal is removed by dipping or pumping and into which metal is dipped for coating. A greater depth than is necessary for the service is desirable as an aid to temperature recovery when cold metal is added.

Closed-top pots are advantageous in reducing the heat loss from the molten-metal surface and in reducing oxidation. Also, space can be provided for a protective atmosphere. Discharge of the molten metal by gas pressure, for example, steam, is incorporated in some designs.

The heat insulation of a metal melting pot should be sufficient to limit the outside surface temperature to a safe value. Otherwise, insulation is a matter of economy. As a rule, a layer of refractory material is unnecessary for temperatures below 600°C (1112°F). A refractory layer is useful as an aid in maintaining an even metal temperature.

Heat loss occurs. The rates of heat loss can be reduced by a layer of insulating material in granular or gaseous form, for example, charcoal or diatomite on the surface of the metal or sulfur dioxide. This layer also reduces oxidation of the metal. When using gaseous layers, adequate ventilation must be provided.

A *cast-in unit* is a self-contained heating unit embedded by casting in a mass of gray iron. This unit is designed for metal-melting services up to 510°C (950°F). The unit is applicable to the melting of all the soft metals with the exception of aluminum and zinc, exceptions because of their alloying action with iron. The rating of the unit should be on the open-air basis.

External heating units supplied to a melting pot should be rated on the basis of 20 to 20 W/in^2 of the side surface of the container. This design of melting pot is suitable for molten-metal temperatures up to 898°C (1650°F).

The temperature-regulating equipment of melting pots is the same as used for resistor ovens and furnaces. As a rule, small melting pots—say, 5 kW and below—have only manual control by a two- or three-point switch.

The melting rate of a melting pot is measured by the time required for the charge of molten metal to regain the pouring or working temperature after the addition of a quantity of cold metal. For example, if 100 lb of cold metal is added and the metal in the pot regains its temperature within 10 min, the melting rate for that metal is $100 \times 6 = 600$ lb/h.

The kilowatts rating of a melting pot is based on the required rate of melting a given metal or alloy. For melting quantities of metal, for example, for castings, the kilowatts rating should be no less than the rate of heat input to the metal plus the rate of heat loss. For melting for coating work, for example, galvanizing, the kilowatts capacity needed is the sum of the capacities required for melting, for heating the base material, and for the rate of heat loss. As a rule, some additional capacity is installed to accelerate heating up and to prevent too large a drop in temperature when cold metal is added. The operating efficiency of the melting range is not affected by its kilowatts rating.

Metals of group 2 and their alloys require either the arc furnace or the induction furnace for melting. Brass and steel are the major alloys of this group.

21.11.3 Arc Furnaces

The two types of arc furnace in common use are (1) the 3-phase furnace and (2) the single-phase furnace. The general field of the 3-phase furnace is the production of alloy steels; that of the single-phase furnace, the production of nonferrous alloys. Both types of furnace can be used for the manufacture of high-quality gray-iron castings. However, the use of large-size induction coreless and core-type furnaces may be preferable.

Three-Phase Arc Furnace. Standard sizes of arc furnaces range from 250 to 80,000 kVA; loading range, 500 lb to 250 tons. Sizes 1000 to 5000 kVA predominate.

The chamber is a steel bowl with a refractory lining. The hearth is a shallow bowl formed in the bottom lining. The roof is a removable dome-shape refractory structure carried on a steel roof ring. The roof has three round ports in equilateral triangular arrangement through which vertical carbon or graphite electrodes travel. Each electrode is carried on a winch-and-rope system, motor-driven.

Refractories. The chemical nature of the slag, acid or basic, determines the required chemical nature of the lining of the hearth and sidewall of the chamber up to a few inches above the top surface line of the slag, that is, an acid refractory (silica) for acid slags, and a basic refractory (magnesia) for basic slags. The roof is usually made of silica brick. Silica has a tendency to spoil during heating and cooling, and furnaces which are in intermittent use often have roofs made of fire-clay brick.

Temperature. The operating temperature of the chamber is limited by the softening point of the refractory, particularly that of the roof, where there is a concentration of heat. A refractory material can be operated with the temperature of its inner face close to its softening point provided that the outer face is exposed to the open air, thus permitting a flow of heat through the refractory body. A temperature gradient is thus established in the refractory so that if its thickness is correctly related to its thermal conductivity the mean temperature of the refractory body will not be high enough to impair its strength materially.

The temperature of molten steels is around 1600°C (2912°F). The melting point of silica is 1713°C (3115°F), but the softening point of a silica refractory is somewhat lower because of impurities in the refractory body. Hence, in a steel melting furnace the temperature of the inner face of the refractory lining is too high to permit the use of heat insulation. Even a thick coat of dust on the roof of the melting furnace is undesirable.

The designation for a 3-phase arc furnace may be given in terms of the holding capacity, the shell diameter, the pouring capacity, the melting rate, or a combination of these. A given diameter of shell can be attached to a range of ratings by varying the thickness of the refractory linings. Sizes are given in Table 21-2.

Charges. The 3-phase arc furnace is primarily a scrap-metal-conversion unit. The two types of furnace with respect to the method of charging are (1) the door-charge type and (2) the top-charge

type. Depending on the character of the scrap, hand charging and chute charging are the usual methods for small furnaces. Large furnace installations are often equipped with side-door-charging machines. Top charging is favored for medium-size furnaces. In this method the roof of the furnace is removed, and a complete charge is placed in the chamber by a drop bucket handled by an overhead crane. This is both a time-saving and a labor-saving method. The charging time is only a few minutes, for example, a reduction from 30 to 5 min. Top charging has the other advantage of a full chamber and a lower heat loss during the charging.

Some 3-phase arc furnaces are used for refining service only. Molten metal from an open-hearth furnace, Bessemer converter, or cupola is the charge.

The weight of scrap metal varies with the degree of its subdivision. The weight of charge that can be placed in a given furnace depends on the kind of scrap. If sufficient scrap metal cannot be placed in the furnace initially to form the weight of molten metal desired, additional quantities can be added later in the heat cycle. This practice affects adversely to some extent both the operating efficiency and the consumption of electrodes.

Electrodes. The arc in each phase is maintained between the tip of the electrode of that phase and the charge (bath after the molten state is reached). The charge thus serves as a common electrode for the three arcs and makes a connection of the 3-phase circuit at that point. The designation "direct-arc furnace" refers to this arrangement.

The trend is toward the general use of graphite electrodes. Carbon electrodes are preferred in some cases. Standard sizes in the corresponding current ratings are given in Tables 21-3 and 21-4.

The consumption of electrodes is caused largely by volatilization and burning. There is some breakage. Graphite begins to oxidize at about 600°C; carbon, at 400°C. Under average conditions the consumption of graphite electrodes is about one-half that of the carbon electrodes. Average values for melting service, pounds of electrodes per ton of metal melted, are graphite 4 to 10; carbon 8 to 15. The corresponding consumption in melting refining service is about 10 lb for graphite and 18 lb for carbon.

Voltamperage. The voltampere characteristic of the arc is negative and a stabilizing element is necessary for circuit stability. Reactance also serves to limit the current in the circuit when an

electrode touches the charge. This reactance is a total reactance of the circuit from the furnace terminals to the point in the power system where the voltage is held constant. Thus a furnace at the end of a long feeder is a different problem from a furnace installed adjacent to a large substation.

The operation of an arc furnace is dependent on the stabilizing element of the circuit only to the extent of ensuring continuity of operation. The limitation of current fluctuations is a problem of power service and is individual for each location. The resistance of the circuit is also a factor, and the actual value of the short-circuit current will be less than that indicated.

Circuit Characteristics. The arc-furnace circuit (containing resistance and reactance) is operated at constant voltage and supplies the unity power-factor load, the arc or arcs. The maximum power of the circuit occurs at 0.707 power factor. The maximum power in the arc occurs at a higher power factor of the circuit, a value dependent on the constant of the circuit.

Electrical Apparatus. The rating of the electrical equipment of a 3-phase arc-furnace installation varies for a given size furnace for the class of service and in some cases according to the power-service conditions. The electrical equipment includes

1. A variable-ratio power transformer
2. Reactors if required
3. An automatic current regulator
4. A control panel for the operator
5. Electrode motors and tilting motors
6. A main-line circuit breaker and disconnecting switches

Transformers. The features which distinguish the arc-furnace transformer from the conventional power transformer are (1) individual service, (2) no requirement of regulation, and (3) a wide range of comparatively low secondary voltages and correspondingly high secondary currents.

Reactance. There are no criteria for stability in current limitations in arc-furnace circuits and hence no standard values of reactance in these circuits. As a rule, 40% to 60% reactance is satisfactory.

The inherent reactance in the circuit of a large furnace—500 kVA and larger—may be, and usually is, sufficient for the need. As the secondary voltage is fixed by conditions other than the kVA rating of the circuit, the smaller installations require more or less supplemental reactance.

The normal reactance of 60-Hz furnace transformers ranges from 5% to 7%. Reactance values higher or lower in each case, within certain limits, than the range noted can be obtained by design but may entail a sacrifice one way or another in the design of the transformer. Hence it is considered better practice to use a normal design of transformer and to add supplemental reactance, if needed, by reactors.

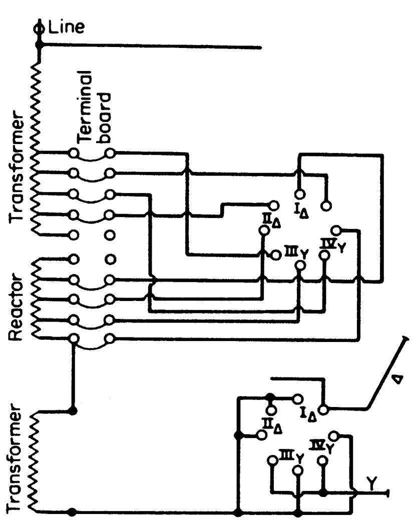

FIGURE 21-6 Diagram for four operating voltages, one phase only of a 3-phase transformer.

Reactors should have a number of taps for adjustment after installation. The transformer taps and reactor taps are connected into a common terminal board arranged so that any combination of transformer taps and reactor taps can be made for each of the selected operating voltages.

The diagram in Fig. 21-6 illustrates a tap arrangement and switching arrangement for operating voltages and the use of reactor windings for both the delta and the Y connection.

An example is the connection of one installation given in the table.

Automatic Current Regulator. A change in current causes a change in the power of an arc-furnace circuit. Within the limits of circuit stability the current with a given applied voltage can be changed by changing the length of the arc. This is the principle of the power regulation of arc furnaces.

The intermittent-type current regulator, which operates within preset limits of current variation, has been superseded almost entirely by the continuous-type current regulator.

A simplified diagram, one phase only of the continuous-type regulator, is shown in Fig. 21-7. The principle of operation is the opposition of a voltage B derived from the circuit of the arc by a reference voltage A. The resultant value of these two voltages determines the polarity of the generator that drives the electrode motor. Thus the length of the arc—and correspondingly the current in the arc—is maintained at a predetermined value.

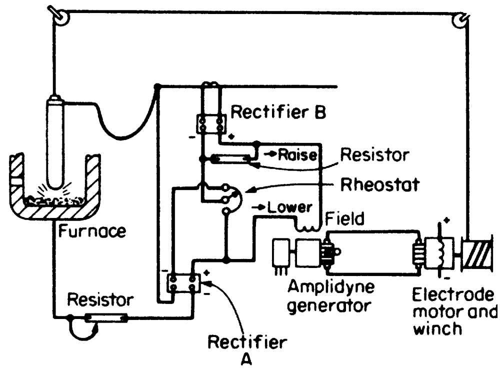

FIGURE 21-7 Simplified circuit diagram of continuous-type automatic current regulator for a 3-phase arc furnace (single phase only).

Each phase in the 3-phase circuit is regulated independently. However, because of the common electrode, the charge, or both, the three elements of a 3-phase regulator work together for the maintenance of equal currents in the three circuits of the power system.

The automatic regulator performs three other functions:

1. The feeding of the electrodes at the rate of consumption
2. The removal of partial short circuits caused by the electrodes coming into contact with the charge
3. The protection of the equipment in case of a failure of the power supply

Operator's Panel. The standard equipment consists of three ammeters, a polyphase wattmeter, a voltmeter, and the necessary rheostats and switches for the operation of the furnace.

The Electrode Drive. This is a reversing service—rapid at certain times—and a motor with a low WR^2 effect is desirable.

The Main-Line Circuit Breaker. This serves both as a protective device and as a switch. The switching service rate is many times per day. In normal operation the arc circuit is opened by raising the electrodes so that the circuit breaker opens the magnetizing part of the power transformer.

All changing of taps is done with a main-line circuit breaker open (no-load tap changing). The tap-changing switch is interlocked with the circuit breaker to prevent incorrect operation. As a rule the tap-changing switch is mounted inside the tank in 3-phase transformers and outside when three single-phase units are used. The tap-changing switch can be motor-operated or hand-operated; the former is the more general practice.

Single-Phase Arc Furnace. The most common single-phase arc furnace is the automatic rocking furnace. This furnace is used extensively for melting both ferrous and nonferrous metals and alloys. Standard sizes extend up to and include 600-kW ratings for melting 4000 lb of cold steel scrap in 90 min.

The load characteristics of a single-phase arc furnace are similar to those of 3-phase arc furnaces. However, as there is no arc between an electrode and the charge, the initial performance of the single-phase furnace is somewhat better than that of the 3-phase arc furnace. The average power factor of the single-phase furnace is 70% to 80%.

Electrical equipment for single-phase arc furnaces is similar to that for 3-phase arc furnaces. Usually only one operating voltage is used.

Gray iron with uniform structure and high engineering properties, namely, tensile, bending, shearing, and impact strength, is produced in arc furnaces. The method of production involves superheating the iron after melting to about 1600°C (2912°F) and holding it at the elevated temperature for a brief period of time. Gray irons with the tensile strength of 40,000 lb/in^2 are produced regularly by this method.

21.11.4 Induction Furnaces

Two types of metal-melting furnace that embody the induction principle are the coreless furnace, which can be used in operation from frequencies of main-line 60 Hz up to many hundreds of kilocycles (the frequency generally depends on the size of the furnace) and the channel furnace, most generally operated from main-line frequencies, principally 60 Hz.

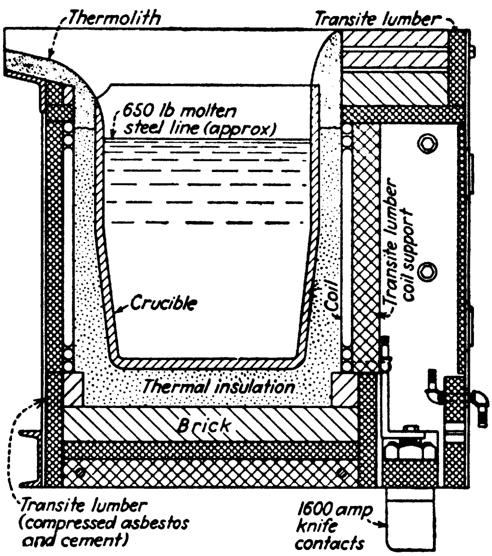

FIGURE 21-8 Coreless induction furnace.

The Coreless Induction Furnace. The general design of this furnace is shown in Fig. 21-8. The assembly consists of three main parts: (1) the primary coil, (2) the refractory container, and (3) the frame, which includes supports and tilting mechanism.

The distinctive feature of this furnace in common with other assemblies for induction heating is the absence of a continuous iron path for the magnetic flux. However, iron laminations are frequently used on the larger sizes, and particularly for line-frequency furnaces, to reduce the reactance for the flux on the back or outside of the furnace. Another feature for comparison with other types of melting furnace is the small quantity of refractory material in the construction.

Standard preformed crucibles are used for the smaller furnaces, up to about 500-lb holding capacity. Over 500-lb capacity rammed linings are employed rather than preformed crucibles. The preformed crucibles are generally used for nonferrous melting.

Standard sizes for steel melting furnaces are 50 up to 60,000 lb. These are often listed in the ratings of 100-lb capacity, 200, 300, 600, 1000, 1500, 2000, 4000, 8000, 10,000, 15,000, 20,000, and 40,000-lb capacity, plus the various intermediate sizes.

Features of operation peculiar to this type of melting furnace are that

1. The refractory container makes necessary a large air gap (loose coupling), with consequent low power factor, 20% to 30%.
2. The charge is cold scrap metal. Thus, initially, the secondary circuit is a current path through a variety of shapes and dimensions of pieces, and contact resistance is a large part of the total resistance. The charge becomes homogeneous as the metal melts, shrinks in height, and thus decreases the coupling of the circuit. At this time, cold metal may or may not be added to the charge. It is a common practice after the first melt to maintain a molten heel in the furnace to expedite the melting of the second load.

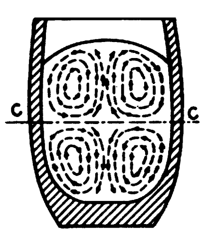

FIGURE 21-9 The stirring effect in a mass of molten metal being heated by induced currents.

3. With charges of magnetic material the effect of the magnetic property is pronounced at the start of the heat cycle.
4. Stirring of the molten metal, as indicated by Fig. 21-9, is characteristic of this furnace. This movement of the bath has much metallurgical significance in the production of homogeneous alloys. The movement is often desirable and can be regulated to a certain extent by the frequency selected for the size furnace involved.

The characteristics of charges vary widely, but the general practice is to vary the capacitance on the circuit during the heat cycle to maintain approximately unity power factor.

Frequency. The primary technical factor in the selection of frequency for a metal-melting furnace is the desired degree of stirring of the molten metal for the size of furnace required. This stirring effect is proportional to the square of the ampere-turns and inversely proportional to the frequency. For a given power value, the current decreases and the voltage increases with increase of frequency.

A second consideration is the fineness of the scrap metal of the charge. If the pieces are very small, there may be difficulty in starting the melting of a cold charge. The frequency must be high enough in a given case to give an electrical efficiency high enough for starting. These conditions and the economics of the service early led to the adoption in this country of 960 Hz for steel-melting furnaces, 100 kW and above, and 3000 Hz for smaller furnaces. As a rule these frequencies are also suitable for melting nonferrous charges. Various frequencies are used for laboratory furnaces. In general industrial practice the trend is to use 60 Hz where large-tonnage furnaces are being used.

Service. The coreless induction furnace is primarily a metal-melting unit. An important use of this furnace is the production of carbon ferrous alloys. The refining of steel, that is, the removal of phosphorus and sulfur, in this furnace has not been developed to a fine art. The deoxidation of the melt, for example, by the addition of aluminum just before pouring, is not here classed as refining. Various special services are duplexing steel, vacuum melting, heating of charges of nonconducting material (with or without melting) by the use of conducting crucibles, etc.

Performance. The melting rate of a furnace, and consequently the power input, is determined in each case by the rate at which the molten metal can be used. Heat cycles of 1/2 h for small furnaces, 1 h for medium-sized furnaces, and 1 1/2 to 2 h or more for large furnaces represent typical practice.

Energy Consumption. This varies for a given material with the size of the furnace, the melting rate, and the idle time between heats. Representative values are 330 kWh/ton (2000 lb) for copper 500 kWh/ton for gray iron, and 600 kWh/ton (2000 lb) for steel. These figures are lower with larger furnaces in continuous operation and somewhat higher with small units and infrequent service.

The Channel (Core-Type) Furnace. The basic feature of this furnace is a single-turn loop of molten metal below and connected to the bath serving as a secondary circuit. A conventional laminated steel core and primary winding complete the transformer feature.

The heat is developed in the loop of molten metal below the body of the charge. Electrodynamic action causes motion of the metal in the loop as indicated. This movement serves to transfer the heat and so stir the molten metal in the chamber above the loop.

Starting the furnace requires sufficient molten metal to close the secondary circuit. In changing from the metal or alloy to another, the furnace must be emptied. For day-to-day melting of the same metal or alloy—the usual practice—the charge, or a portion of the charge, is held molten overnight by using a below-normal voltage.

The V-shaped loop furnace is designed for melting the heavy nonferrous metals and alloys. It is used widely for melting brass. With these metals the slags, or nonmetallic particles, in the melt are much lighter than the metal, so that they tend to float on the surface of the bath and do not interfere with the circulation of the metal in the loop of the secondary circuit.

Standard sizes on these furnaces range from 60 to 1000 kW on single-phase, 60 Hz in the United States, and for standard voltages up to 600 V inclusive.

A design of the channel furnace for melting aluminum and its alloys embodies two or more vertical channels below the bath and connected to the bottom by horizontal channels of larger cross section. The slag particles of the lighter metals have about the same specific gravity or are heavier than the molten metal. Such particles tend to accumulate in the channel of the secondary circuit. The design of the channel noted above provides for its easy cleaning from time to time while the furnace is in operation.

Power and power factor of the channel furnace with constant applied voltage vary with the resistivity of the metal in the loop that forms the secondary circuit.

21.11.5 Resistance Furnaces

Resistance furnaces have a temperature range of 1500°C (2732°F) and above. This type of furnace is generally an open-top heating chamber with electrodes—movable or fixed—buried in the charge. Variations are furnaces with closed tops, furnaces with a resistor buried in the charge, etc.

The general service is heating charges of a refractory nature to bring about chemical reactions or changes in the physical structure of a material. Where the product is obtained by a chemical reaction, for example, the reduction of a metallic oxide, the term *smelting furnace* applies.

The length and cross-sectional area of the path of the current through the charge are proportioned to suit the power characteristic of the material to be heated. Where the buried resistor is used, its design is based on similar considerations. In all cases the load is resistance, that is, the I^2R effect. In some cases where the charge forms a resistor, there may be arcing along the path of the current.

Glass applications require conventional fuel firing initially to melt the glass. Once molten, glass conducts electrically and can be processed using bottom or side electrodes.

There are no standard designs of resistance furnaces. Each application is an individual undertaking, and the furnace is assembled in place. The simplicity of the construction permits a wide range of designs and much latitude in dimensions.

Resistance furnaces are unity-power-factor loads, and the circuit is stable; that is, reactance is not needed as with other furnaces. However, there are reactances and resistances in the furnace conductors, and the circuit characteristics are the same as for arc-furnace circuits. The voltage is low, generally less than 250 V. The corresponding high-current values introduce problems of inductance in the leads to the furnace, particularly with 60-Hz power supply.

Furnaces with Movable Electrodes. There are stationary, vertical, cylindrical, or rectangular structures, single- or 3-phase (see Fig. 21-10). The latter is more common.

The material of the charge, granular in form, is fed, more or less continuously, into open-top furnaces or through chutes into closed furnaces. The product, if molten, is discharged by tapping through a side, usually near the bottom. Vapor products pass out at the top or through the side openings in the chamber. If the product is solid, for example, fused magnesia, the batch method is used and the furnace is disassembled for removal of the product.

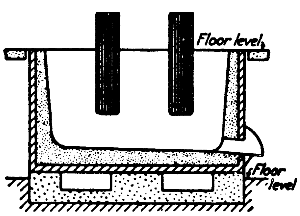

FIGURE 21-10 Open-type resistance furnace with movable electrodes (three electrodes for a 3-phase furnace).

The regulation of movable-electrode furnaces is accomplished by electrode movements to hold constant current, as with arc furnaces. The load is fairly uniform, and the regulating duty is light. Either dc motors or ac motors can be used to drive the electrodes. Direct-current motors are more often employed because of the ease of speed adjustment and the superiority of dynamic braking.

Continuous operation at one voltage is general practice. Transformers for these furnaces have a number of taps in the primary windings for the selection of the secondary voltage to suit operating conditions, which may change from time to time.

Batch Furnaces with Fixed Electrodes. A horizontal rectangular chamber with an electrode at each end is typical construction where the current is passed through the charge.

Refractory materials have negative resistivity versus temperature coefficients. Hence, to maintain constant power in a batch furnace as the temperature of the charge rises, the applied voltage must be varied as expressed by Eq. (21-12) or (21-13). Accordingly the regulation of furnaces of this type is by voltage adjustments, either load-ratio control or no-load tap changing, the latter with or without an induction regulator for intermediate voltages. Generally manual operation is sufficient. Constant power is not the rule. In many cases the power input is varied to correspond to a prescribed heat cycle.

Some of the more common uses of resistance furnaces are for calcium carbide, ferroalloy, ferrosilicon, ferromanganese, ferrochromium silicomanganese, ferrotungsten, ferromolybdenum, silicone oxycarbide, graphite, fused alumina, fused magnesia, fused silica, zinc oxide, and pig-iron applications.

21.12 ELECTRIC HEATING

21.12.1 Principles of Heating

Material is heated for processing purposes either (1) in the open air or (2) protected from the air in a vacuum or a special gas chamber. In comparative terms, in open air the rate of heating is fast and the time short. With enclosures the rate of heating depends on the source. It may be fast; generally it is slow, however, and the time is long. The basic consideration in each case is the correlation of temperature and the time, dictated by the material to be heated and the results desired.

Electric heating has certain unique characteristics:

1. The precision of electric control is extended to the transfer of heat. Uniformity of temperature within a relatively narrow limit is readily attained.
2. Its development does not involve combustion.
3. There is no upper limit to the temperature obtainable except the ability of the materials to withstand heat.

The collateral merits of electric heat vary in value with the conditions in each case. The most important of these are

1. Application at the precise point needed
2. Flexibility, includes easy subdivision, freedom of location, and general adaptability
3. Good working conditions, cleanliness, quietness, ambient temperature minimally affected, etc.
4. Fast response
5. Safety

Heat-Process Engineering. The heating method for a particular process may be selected after consideration of two basic principles of industrial heating: (1) temperature and (2) mode of heat transfer. This narrows considerably the field from which a choice of the heating method should be made. Generally there is more than one possible method. Economic factors must then be taken into account. This, in addition to the relative capital, maintenance, and energy cost, includes a study of the collateral merits of methods that always have a bearing on the overall cost of production.

A convenient temperature classification is

Low temperature—up to 400°C (752°F)

Medium temperatures—400 to 1150°C (752 to 2102°F)

High temperatures—beyond 1150°C (2102°F) (see section on electric melting)

Heat energy is transferred by conduction, radiation, convection, high-density electromagnetic force, and concentrated electrostatic fields. The transfer can be obtained with a combination of these methods.

Heat conduction can take place in all three states of matter, that is, in solids, in liquids, and in gases. Thermal conductivity is defined as the quantity of heat which flows in unit time through unit area of a plate of unit thickness having unit difference of temperature between its faces. There is no generally accepted combination of units for expressing thermal conductivity. Some of the more common combinations of units for this value are:

$$k = \text{Btu/ft}^2 \cdot \text{h for 1-in length of path/°F (British units)}$$

$$= \text{cal/cm}^2 \cdot \text{s for 1-cm length of path/°C (cgs units)}$$

$$= \text{W/(in}^2) \cdot \text{(1-in length of path)} \cdot \text{(°C)}$$

*British units; divide by 2903 to obtain corresponding cgs values of *k*.

Values of *k* for various materials as published are not based on a common method of determination. Hence, agreement in thermal-conductivity data for a given material cannot be expected.

The thermal conductivity of a material is affected by temperature, in some cases increasing, in other cases decreasing with rising temperature. Values representative of the general order of the thermal conductivities of ordinary temperatures of the three states of matter are given in Table 21-5.

An arbitrary standard by which to judge the value of a material as a nonconductor of heat (heat insulator) is $k = 1$ (British unit).

The law of thermal conduction for a constant-temperature gradient is expressed thus:

$$h_c = \frac{Ak_m t'}{l} \tag{21-1}$$

where h_c = rate of heat transfer by conduction, A = area of cross section of path of heat flow, t' = temperature gradient, l = length of path, and k_m = mean value of thermal conductivity of material in which the temperature gradient is established for a given range of temperature.

Shape Factor. Equation (21-1) as written is applicable only to paths of uniform cross section. If the area of the cross section of the path of heat flow varies along its length, the equation is applicable if the logarithmic mean area of the path is used.

For boundary surfaces that are not smooth curves, a shape factor *S* must be substituted for the term *A/l* in Eq. (21-1); thus

$$h_c = Sk_m t' \tag{21-2}$$

Two of the equations for the shape factor *S* are

1. Rectangular enclosures (Fig. 21-20):

$$S = \frac{A}{t} + 0.54\Sigma l + 1.20t \tag{21-3}$$

where A = inside surface area, t = thickness of wall, and Σl = sum of length of all inside edges.

2. Cylindrical enclosures (Fig. 21-21):

$$S = \frac{A}{t} + 0.54\Sigma l + \frac{2\pi h}{2.30 \log (b/a)} \qquad (21\text{-}4)$$

where A = inside area of top and bottom surfaces, t = thickness of wall, Σl = sum of lengths of inside top and bottom edges, h = inside height, b = outside diameter, and a = inside diameter.

Radiation. Radiation is a surface phenomenon. Surfaces emit and absorb radiant energy in various degrees, depending on the nature of the surface.

Average values of radiation and absorption coefficients are given in Table 21-6.

Solids for the most part are opaque to radiation; a notable exception is quartz. Liquids transmit radiation to some extent. Only two gases, water vapor and carbon dioxide, absorb radiation to any marked degree.

The rate of heat transfer by radiation under the conditions usual in heating practice is

$$h_r = \epsilon \times 3.68(T_0^4 - T_a^4) \times 10^{-11} \qquad \text{(Celsius scale)} \qquad (21\text{-}5)$$

$$h_r = \epsilon \times 0.35(T_0^4 - T_a^4) \times 10^{-11} \qquad \text{(Fahrenheit scale)} \qquad (21\text{-}6)$$

where h_r = watts per square inch, ϵ = absorption coefficient of receiving surface, T_0 = absolute temperature of emitting surface, and T_a = absolute temperature of absorbing surface.

Natural Convection. Natural convection is a transfer of heat to or from a surface by the movement of a fluid or gas when this movement is caused solely by a difference in fluid or gas density.

For natural convection in air

$$h_b = 11.70 \times t \times 1.25 \times 10^{-4} \qquad \text{(Celsius scale)} \qquad (21\text{-}7)$$

$$h_b = 6.50 \times t \times 1.25 \times 10^{-4} \qquad \text{(Fahrenheit scale)} \qquad (21\text{-}8)$$

where h_b = watts per square inch, t = temperature gradient. These equations apply to vertical planes more than 12 in high. For heights less than 12 in, multiply the coefficient in Eq. (21-7) or (21-8) by the constant noted below.

Height, in	Constant

6	1.53
4	1.76
2	2.70

The rate of heat transfer by natural convection from a horizontal surface facing upward is about 35% greater and a rate from a horizontal surface facing downward is about 30% less than from a vertical surface. Hence, for average conditions, and on the sides of the body exposed, the average rate of heat transfer by natural convection is well represented by Eqs. (21-7) and (21-8).

If the natural-convection heat transfer is to a surface, the portion affected is the reverse of that stated for transfer from a surface. This does not affect the average rate of heat transfer.

Forced Convection. The velocity of the gas is a dominant factor in the transfer of heat by forced convection. The flexibility of its control, together with the penetrating property of gases, makes forced convection an effective method of heat transfer in many cases. Forced convection can also be applied to fluids.

In electric-heating practice the main limitation on the use of forced convection on gases is the upper limit of operating temperature of fans, about 650°C (1202°F). In some cases the gas can be heated after leaving the fan, and thereby higher temperatures than that noted above can be used.

There is in each use of forced convection a requirement of defined passages for the movement of the gas. This method also entails an investment charge for the fans, ducts, etc., and requires an expenditure of additional energy.

Some of the more common arrangements of surfaces with various conditions of forced convection have been studied, and relate to (*a*) gases flowing in pipes and (*b*) gases flowing past plane surfaces.

Finned Surface. If the heat-transfer coefficient of a surface is less than the heat-transfer coefficient which is the measure of the rate of flow of heat through the body, to or from the surface, the addition of fins or ribs to the surface will increase the rate of heat flow to or from the surface.

As a general rule, a spacing and dimensioning of fins that increase the surface area seven to nine times is good practice. The height of the fins should not exceed 3 to 4 times the spacing.

The principle of increasing the surface area per unit length of the surface by the addition of fins is equally applicable to the transfer of heat by radiation.

Heat Absorption. The rate of heat absorption for given external thermal conditions is determined by the diffusivity coefficient of the substance. This coefficient is defined as the ratio of the thermal conductivity to its heat-storage capacity per unit volume; thus

$$n = \frac{k}{p_c} \tag{21-9}$$

where k = thermal conductivity, p = density, and c = specific heat. This coefficient is but little affected by temperature.

The heat absorbed by a material for a given temperature rise is

$$q = \frac{w \times c_m \times t'}{3.412} + L + R \qquad \text{Wh} \tag{21-10}$$

where w = weight in pounds; t' = temperature rise in degrees Fahrenheit; c_m = mean specific heat over the temperature range; L = latent heat, if any, in watthours; and R = heat of reaction, if any, in watthours.

Heat of reaction here means the quantity of heat that must be added to the charge or subtracted from the charge, depending on whether the reaction is endothermic or exothermic.

The total heat required in a given case is the sum of the heat absorbed by the material, that is, the charge and the heat loss of the operation. The corresponding average power input is the total heat in watthours divided by the time of the heat cycle in hours. The power-time characteristic is individual for each class of heating surface.

Thermal Efficiencies. The conversion efficiency of the heating device is the ratio of the heat absorbed by the material, that is, the charge for a given temperature rise and the corresponding heat input to the device. If the charge is under cover, the heat absorbed by the material of the enclosure (the heating chamber) must be taken into account, along with the heat dissipated from the outer surface of the chamber. With increase in length of heat cycle the heat stored in the materials of the enclosure affects the conversion efficiency less and less, and with continuous operation it is usually negligible.

The operating efficiency expresses the combination of the conversion efficiency and the efficiency of the method of operation. If containers or removable supports for the charge are used, it is necessary to distinguish between net and gross operating efficiencies; the latter includes the heat absorbed by the containers or supports. A much-used rule of thumb for preliminary estimates is an operating efficiency of 50% for many heat applications under cover.

Thermal efficiencies are expressed as watthours per pound, pounds per kilowatthour, kilowatt hours per ton, etc., according to the scale of the operation.

High-Density Electromagnetic Force. Usually utilized to achieve fast heating times in air, vacuum, or gas atmospheres, this method of heating is more commonly known as induction heating. The electromagnetic force is developed at some frequency through the utilization of a suitable conducting coil. The coil is generally made of copper, often it is liquid-cooled, and it is designed to encircle or to be in close proximity to the material (nominally metal) to be heated. The high-density electromagnetic force coupled to the metal load induces current to flow in the load, and this current directly heats the material.

Concentrated Electrostatic Fields. Usually applied to fast heating times in air, vacuum, or gas atmospheres, this method of heating is more commonly known as dielectric heating. The electrostatic field is developed at a very high frequency. Through the utilization of metallic plates (often copper) placed above and below or on either side of the material to be heated (nominally a nonconductor) the electrostatic field causes a rapid reorientation of the molecules in the load, and heat is thereby produced internally.

Industrial Heating. This is classified as follows:

1. The heating of materials to temperatures below the temperature at which a change of state occurs
2. The heating of materials to cause a change of state, that is, evaporation and melting
3. The heating of materials to bring about a chemical reaction

21.12.2 Methods of Electric Heating

The methods of electric heating are

1. Resistance heating = I^2R effect
2. Electric arc
3. Induction heating = special application of I^2R
4. Dielectric heating

The resistance method and the induction method are widely employed. The use of the electric arc is generally confined to high-temperature applications. Dielectric equipment is widely used for the heating and welding of nonconductors.

Alternating current is used in most applications of electric heating. Direct current is required for a thermal process in which electrolysis is involved.

Resistance heating combines the basic attributes of electric heat with the ability to provide efficient temperature control up to 5425°F (3000°C). Apart from mechanical automation for material-handling systems, the trend to automate overall processing will continue.

I^2R effect is expressed by the equation

$$q = i^2rt = \frac{e^2}{r}t \qquad \text{Wh} \tag{21-11}$$

where r = resistance of the path of the current in the load; i = the current in amperes, for varying current, the rms value; e = applied voltage, across load; and t = time, in hours, of the flow in current.

The resistivity-temperature coefficient of metals is positive; that of nonmetals, negative. An exception among nonmetals is graphite.

The relation between applied voltage and change of resistance—a general case in heat applications—for constant power is

$$e_2 = e_1 \frac{z_2}{z_1}\sqrt{\frac{r_1}{r_2}} \tag{21-12}$$

or if the power factor of the circuit is unity:

$$e_2 = e_1 \sqrt{\frac{r_2}{r_1}} \tag{21-13}$$

where e_1 = initial voltage, r_1 = initial resistance, z_1 = initial impedance, r_2 = new resistance, z_2 = new impedance, and e_2 = new voltage.

The rate of heat development, that is, watts, is obtained by dividing the quantity obtained by Eq. (21-11) by the time period in hours or frequencies of an hour.

In indirect resistance heating, the heat is developed in resistors (heating units), a circuit apart from the charge, and is transferred from the surface of the resistors to the surface of the charge by one or more of the modes of heat transfer, namely, conduction, radiation, and convection (natural or forced).

If the heat transfer is by conduction, the resistor must be in contact with the charge. An enclosure for the charge (heating chamber) is required for heat transfer by radiation and convection.

21.12.3 Electric Heating Equipment

Resistors. The materials in general use for resistors for medium- and low-temperature surfaces are the two alloys B82 and B83 designated by the ASTM.

B82 Alloy. Additional data on round wires and rectangular sections are given in Table 21-7. Approximate maximum operating temperature is 1160°C (2100°F).

B83 Alloy. See the footnotes to Table 21-7. Approximate maximum operating temperature is 900°C (1652°F).

The melting ranges of these alloys are narrow. They do not soften if the temperature of the resistor is kept at a reasonable margin below the melting range. The coefficients of expansion are low, and the change of resistance with the change of temperature is small. The resistivities permit the use of reasonable cross sections and lengths at standard low-distribution voltages.

These alloys have the prime requisite of resistance to oxidation and scaling when operated in the air. However, this protection is not perfect, and it decreases in value with increases of resistor temperature. The alloys are susceptible to harm from compounds of sulfur and are affected to some extent by carbon monoxide. Unexpected causes of chemical action on resistors of these alloys are foreign gases or gases evolved from the material being heated.

*For B83 alloy, multiply by 1.037.
†For B83 alloy, multiply by 1.02.

In addition to the B83 alloy, several other similar alloys are listed by manufacturers for low-temperature service.

It is often desirable for low-temperature heating applications to use resistors known as metal-sheath heaters. These devices provide a metal sheath, usually a nickel alloy or a stainless steel, as a protective cover over the resistance device and insulated from it by a magnesia oxide. Sheath heaters are ideal for direct immersion and conductive heating, as the sheath tends to assume the temperature of the resistance element. Direct contamination of the resistance element is thus avoided.

Resistors for operating temperatures above 1150°C (2100°F) are made of silicon carbide, molybdenum, tungsten, and graphite.

Silicon carbide is the basis of a resistor material for operating in air for temperatures up to about 1500°C (2732°F). The material is formed into rods of diameters and lengths for combination into circuits of required electrical rating. The range between the cold and hot resistances is small enough to permit single-voltage operation. The resistance gradually increases with use, and an autotransformer with taps to compensate for this increase of resistance is desirable.

Molybdenum resistors are suitable for temperature up to 1650°C (3002°F). This metal is ductile enough at room temperature for drawing into wire for resistor windings. The wide range between the cold and hot resistances makes multiple-voltage operation necessary. The supports (insulators) of the windings should be of magnesia or zirconia. Molybdenum resistors cannot be operated in air and also must be protected against reactions with silicon and carbon. The metal is immune from reactions with sulfur, nitrogen, hydrogen, and water vapor. A hydrogen atmosphere is ordinarily used for the protection of these resistors. Molybdenum is not suitable for resistors of vacuum furnaces because of its high vapor pressure.

Tungsten resistors can be used for temperatures up to 2000°C (3632°F). The maximum temperature is limited by the refractory supports of the resistor. The metal must be heated for drawing into shapes. The resistivity-temperature characteristic is practically the same as that of molybdenum. The low vapor pressure of tungsten makes it useful for resistors of vacuum furnaces.

Graphite resistors are suitable for any temperature that can be used. The resistors must be protected against oxidation above about 600°C (1112°F). Also because of the chemical activity of carbon, special consideration must be given to the atmospheres surrounding the resistors. The material is available in a wide range of shapes and dimensions.

The *useful life* of a resistor (barring accidents) is dependent mainly on the temperature at which it is operated. That temperature must be high because of the required rate of heat transfer per unit area of the surface. Thus the operating temperature of a resistor is a function of the surface power density (watts per unit area) of the resistor. For a resistor of given shape and dimensions the operating temperature will vary with the watts input, since the surface area remains the same. Hence, watts per unit area is a first consideration in resistor design. This value in practice varies according to the conditions of use.

A rectangular shape for the resistor section gives a greater surface area for a given resistance than the round shape (Figs. 21-11 and 21-12); hence, the frequent use of the ribbon, or strip, form of resistor, particularly for the upper range of temperature. The cast resistor for furnaces also embodies this principle.

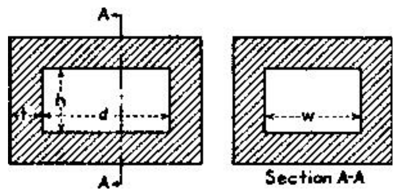

FIGURE 21-11 Shape factor—rectangular enclosures.

The *maximum voltage* of resistor circuits is limited by electrical insulation and elevated temperatures and by safety considerations to 600 V. This value may be exceeded in special cases. Standard distribution voltages and standard frequencies are used. Resistor windings may be in one, two, or more circuits and may be connected either single-phase or polyphase.

As a general rule, the *heat-equalizing effect* of the heat-storage capacity of the charge into the surrounding enclosure (if any) makes permissible voltage fluctuations within reasonable limits. However, the average voltage must be equal to the normal voltage to maintain the normal heating rate. The relation between heating rate and voltage is shown in Fig. 21-13.

The *power input* to resistors supplied from constant-voltage circuits can be varied by the use of multiple circuits and series-multiple-switching combinations. Another method is the use of an autotransformer or transformer with taps. With 3-phase resistor circuits the change from delta connection to wye connection, and vice versa, is available. In each case the power input to the resistor is proportional to the square of the voltage. For example, with the change from delta to wye the power input is reduced to one-third its value with the delta connection.

Other devices are available for power controls such as saturable reactors, regulated or unregulated; variable inductances; and stepless variable autotransformers.

Self-Contained Units, Water Heating, and Steam Generators

Resistor heating equipment includes many small devices such as electrically heated tools, appliances of various kinds, self-contained units, ranges, water heaters, stills, sterilizers, and baths. The larger units include ovens, kilns, lehrs, furnaces, etc. Each of these descriptive terms relates to a field—some more general than others—of electric heating service.

Small devices are often used. As a rule the best design of a resistor for any small device is obtainable only by trial. The space is generally limited, and the conditions which affect heat transfer vary widely. For many devices a useful guide is 20 W/in^2 of resistor surface. Both higher and lower values are used according to the conditions in each case. Metal-sheath heaters can be obtained for operation at many wattages to be operated at specified voltages of 115 or 230 V.

Self-contained units meet manifold needs for localized heat in small quantities within the lower temperature range and extending up to about 815°C (1500°F).

The construction of these units consists of a resistor of the 80 Ni–20 Cr alloy embedded in a heat-resisting material such as powdered fused magnesia and enclosed in a cylindrical metal sheath. In many cases they are applied for direct-contact heating, that is, for heat transfer by conduction.

The forms of the self-contained heating units include insertion (or cartridge) units, straight or curved tubular units in a shape to conform to the method of use, space (or strip) heaters, immersion units for heating liquids, fin-type units for air heating, cast-in units, and a special construction for melting soft metals.

Standard voltages of self-contained units are 115, 230, and 460 V. Space restrictions of the terminals do not permit higher voltages except for special designs. The ratings of these units range from 30 W to 10 kW.

Space Heaters. These are made in two types:

1. With steel sheath; specific rating 10 W/in^2 of surface; maximum operation temperature 399°C (750°F)
2. With porcelain-enameled steel or alloy-steel sheath; specific rating 15 W/in^2 surface; maximum temperature 650°C (1200°F)

Both types are used for ovens, warming tables, process machinery, space heating, etc.

The rating in watts per square inch of affected area of the sheath of the unit is considered in relation to its application: (1) the resistance to oxidation or other chemical action and (2) the rate of heat absorption by the surrounding medium. Immersion units for heating water have comparative ratings, 40 to 50 W/in^2. However, these units should always be installed so as to permit free circulation of water, and they should not be operated unless completely submerged.

Oils in general do not absorb heat as rapidly as water. Also, immersion units in oil accumulate carbon deposits on the sheath. Hence, units for this service have a much lower rating—20 to 25 W/in^2. Steel is a satisfactory sheath material for mineral oils. Other oils must be given individual consideration with reference to the chemical action on the sheath material. The same consideration applies to heating chemical materials in liquid form; for example, a unit with a lead sheath is used for nickel and copper solutions.

The temperature-watts characteristic of the fin-type units is given in Fig. 21-14.

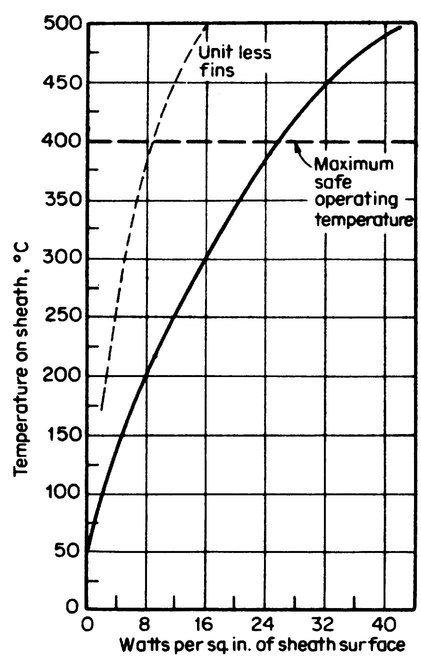

FIGURE 21-14 Temperature-watts characteristics of fin-type unit in still air.

Room Heating. The space heater is well adapted to heating rooms; radiation and natural convection are used for the heat transfer.

An approximate equation for the rate of heat loss from structures or ordinary building construction is

$$\text{kW} = \frac{(0.02NV) + (1.13G) + kA}{3412}(T_r - T_0) \tag{21-14}$$

where N = number of air changes per hour (usually two or three)
V = room volume, ft^3
G = area of windows, ft^3
A = area of ceiling and exposed walls, ft^2
$T_r - T_0$ = temperature difference, °F, between inside and outside
k = heat-transfer coefficient, Btu/h · ft^2 · °F

Average Values of k

Wood construction	0.25
8-in brick wall	0.50
12-in brick wall	0.36
6-in concrete wall	0.79
10-in concrete wall	0.62

The heat-transfer coefficient can be reduced by the addition of proper insulating material in the walls and ceiling of the room. Other heat sources must be considered in determining the actual heating-equipment requirements, such as lighting, appliances, machinery, and people.

A heating cable with a lead sheath for temperatures up to 74°C (165°F) has a variety of uses, for example, warming soil to promote plant growth, prevention of freezing of liquids in pipes, and keeping gutters and downspouts open.

Electric Steam Generators. These are made in three types:

1. With immersion heating units up to 300 kW, single-phase, standard low voltages
2. With 80 Ni–20 Co alloy resistors mounted in the tubes of a fire-tube boiler; sizes up to 1000 kW, single-phase or 3-phase, standard low voltages
3. Electrode type: large units 200 kW and above; all 3-phase, either 2300 or 6600 V

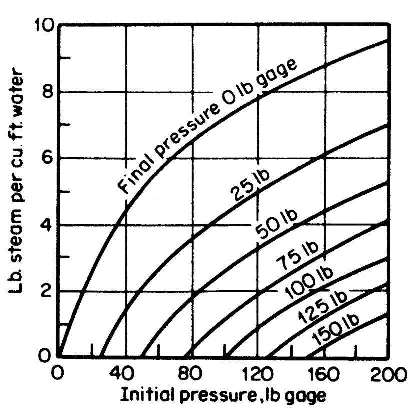

FIGURE 21-15 Flashing capacity of steam generators.

The heat loss from a generator in operation is the sum of the loss through the heat insulation and the loss by conduction through the pipe connections. The time of heating is very short and the total loss within a given time is small compared with the heat output in the steam. Hence, the insulation of the shell can be moderate in amount for a high conversion efficiency—95% to 97% and higher. This efficiency is usually given as 3 lb of steam/kWh. The boiler-horsepower rating is one-tenth the kilowatt rating.

There is little storage capacity in a steam generator, and the power demand cannot be reduced by storage as in water heaters. When a quantity of steam beyond the rating of the generators is required, it cannot be obtained by releasing the steam through a pressure-reducing valve. The amount of steam thus available per cubic foot of water in a generator can be read from Fig. 21-15.

The auxiliary equipment of electric steam generators is the same as that of fuel-fired steam generators. However, full automatic control is more frequently used with the electric steam generator. The main use of the small sizes of electric steam generators is for the supply of steam at points which cannot conveniently be reached by steam pipelines and in locations where the fuel-fired unit is not permissible.

The larger units have been applied mainly for utilization of the excess water capacity of hydroelectric plants and by industrial plants which require large quantities of processed steam, for example, paper mills.

Resistor Ovens

The two types of resistor ovens are convection and radiation.

An *oven* is a low-temperature heating chamber with provision for ventilation.

Oven service is drying and baking. Drying is the removal of liquids by evaporation. The rate of drying is limited by the rate at which the liquid will move from the interior of the mass. This is a limitation on the power input. The effect of a too high power value is skin drying.

Baking is a hardening process which involves chemical and physical changes in the material. If a material contains a solvent, much of that component is removed during the first stage of baking. Air drying preliminary to baking may be advantageous.

The technique of baking is a correlation of temperature and time. The general rule is: The higher the temperature, the shorter must be the heat cycle. The temperature-time relation for each material is individual and must be determined by trial.

Ventilation. As a rule, the ventilation of oven chambers is forced by means of fans. The removal of inflammable vapors is a special procedure.

Convection, Box, and Continuous (Air) Ovens

Convection Ovens. The transfer of heat is by forced convection in gases, mainly air. Steel panels are used for the enclosure of the heating chamber. A double wall with inner heat insulation is general practice. The heat-storage capacity of these enclosures is small.

Box Ovens. Box ovens—batch or stationary heating—are of two designs:

1. Heating chambers with hooks, racks, or shelves for the support of the charge
2. Heating chambers arranged to receive drawers, trucks, or similar removable supports for the charge

Continuous (Air) Ovens. These ovens are flexible in design. The structure may be horizontal, with or without inclined entrance and exit, or vertical. The travel of the charge may be one-way or a U-shape movement. The latter permits the absorption of heat from the outgoing material by the incoming material. The chain conveyer is applicable generally.

Radiation Ovens

In radiation ovens, heat is transferred by radiation. The heating units are tungsten-filament lamps (heating lamps) with self-contained or external reflectors.

Standard heat lamps are 125, 250, 375, 500, and 1000 W, 115 V. The self-contained reflector lamps of the first three ratings are most generally used. The filament temperature around 2500 is low enough to give a comparatively long life, average 5000 h or more. The large part of the radiation from filament lamps is in the infrared region of wavelengths; hence the term *infrared heating.*

Construction of the radiation oven is similar to that of the convection oven. The main difference is the detail incident to the lamp-type heating units. The general arrangement is a bank of heat lamps which surrounds or partially surrounds the charge. In a continuous oven this bank forms a tunnel through which the charge travels. This type of oven is frequently built with metal-sheath heaters as a source of infrared energy. High temperatures are available through the use of quartz-infrared units, used particularly in higher wattage ratings.

General service is drying and baking processes which require temperatures below 315°C (600°F). The method is best adapted to continuous horizontal ovens for heating charges, which present a large surface area in proportion to the mass, for example, sheet metal, textiles, paper, and some plastics, and require only surface heating.

Absorption coefficients of the surface of charges should be reasonably high. Correspondingly, the inner wall surface of the heating chamber should have a low absorption coefficient. Aluminum linings are used in many cases.

Concentration of radiation (power density) on the charge surface depends on the wattage and spacing of the lamps; the efficiency of the lamp reflector units; and, to a limited extent (within the range of practice), the distance between the lamps and the surface of the charge.

21.13 ELECTROMAGNETIC INDUCTION

Classification. Electromagnetic induction is a process used to heat metals for purposes of hot working, heat treatment, welding, and melting.

In the hot-working area, induction is used largely for through preheating prior to forging and extrusion; it has been found to be economically attractive as an alternative to conventional gas-furnace heating processes. The application of induction for slab preheating, although in commercial use, has not attained as high a level of acceptance.

The prime application of induction in the heat-treating field is in the area of surface hardening. It is widely accepted as the principal means of surface hardening for a wide variety of mass-produced parts. In some applications, competition appears to be coming from ion nitriding, laser hardening, electron-beam hardening, and high-frequency resistance hardening. By and large, the first three of these processes do not appear to offer a threat to the induction market. The development of high-intensity induction surface hardening and high-frequency resistance heating and hardening (which employs similar radio-frequency equipment) can be employed to produce the very shallow case-hardened depths achievable by the other three processes.

The use of induction for through heat treatment is less widespread than for surface hardening. This is particularly true for some processes as tempering and annealing. Recent research work has suggested that such applications may indeed be feasible with induction, however.

High-frequency induction and resistance welding are considered to be well-established processes. High production rates and low cost are two of the main factors which make it more attractive than competitive processes such as arc welding in high-volume areas such as pipe and tube production.

Although induction heating is a well-established technology, development efforts in such areas as higher-efficiency equipment, coil design, and automation should enable the process to retain and possibly to enlarge its markets.

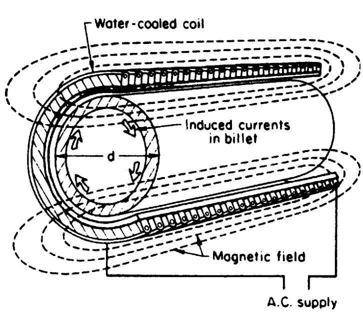

FIGURE 21-16 Basic principle of induction heating illustrated for a tubular conductor heated by a solenoid coil.

Principle of Operation. The material to be heated is exposed to an alternating (or varying) magnetic flux. The material to be heated must be a conductor so that currents are thus induced in the material (or load) and flow wholly within its mass. Generally this type of heating is produced by an electromagnetic field caused by an alternating-current source. It is possible, however, to produce similar results, but at lower current densities, with a high-flux permanent magnet moved at high speed across conductive materials. The term *eddy-current heating* is sometimes applied to the method.

Assemblies. One of the simplest induction-heating setups is shown schematically in Fig. 21-16. Here, the induction coil, or simply inductor, is a helical (or solenoidal) copper conductor carrying an alternating current which surrounds a tubular workpiece. Associated with the ac is a magnetic field whose flux lines pass through the workpiece. The strength of the magnetic field varies with the ac; in so doing, eddy currents are induced in the workpiece. Generally, the induced current path is parallel to that of the currents in the inductor.

For a given workpiece and coil arrangement, the heating rate can be adjusted by increasing or decreasing the induced current in the workpiece. This is done by adjusting the coil current which is controlled by the ac or induction generator. If the workpiece is magnetic (for example, steels at low temperature), additional heat is produced by hysteresis losses. Such heating is usually small but, in some cases involving strong magnetic fields, it can become significant.

Shape of Load. The ideal load shape is a cylinder. It may be a solid, or a tube. Shape alone does not affect the principle involved. It may introduce some complications in geometry. Any shape load can be heated by the inductive method, but not always to obtain the desired results. Special techniques are required for some unusual shapes.

Basic Relations. For a cylindrical load and other loads where the coil encompasses the load, the directions of the magnetic flux are parallel to the longitudinal axis of the load and hence to its lateral surface. The factors which, for a given intensity of longitudinal magnetic flux at the lateral surface of the load, determine the rate of heat development in the load are

1. The electric and magnetic properties of the material
2. The frequency
3. The radius, or one-half the thickness of the charge

Heat Concentration. In considering a solid load, it is necessary to visualize the current subject to skin effect induced to flow in circular paths parallel to the circumference of the load. Each circuit possesses inductance, and there is a subsequent progressive decrease in current strength radially. The rate of decrease changes with frequency.

The Rate of Heat Development. The general equation for the rate of heat development by symmetrical currents in a long load (length much greater than its diameter) of any shape for a longitudinal and sinusoidal alternating magnetic flux at its lateral surface is

$$P = H^2SL \times \sqrt{\mu f} \times \sqrt{p_a \times 10^9} \times 10^{-7} \qquad \text{W} \tag{21-18}$$

$$H = \frac{4\pi N \times \sqrt{2}i}{10L} \qquad \text{Oe} \tag{21-19}$$

where p_a = resistivity of the material of the load in ohm-centimeters cubed
μ = permeability of material of the load
S = shape factor of the load
L = length of the load in centimeters
N = number of turns in the coil around the load
i = current in the coil, A

Magnetic Charges. The ac excitation curve of the magnetic material more or less coincides with the dc magnetization curve as saturation is approached. Hence, the latter curve (usually more readily available) can be used as a reference in induction heating. For values of H higher than that required for saturation, the value of μ corresponds to the saturation values of p of H.

Permeability. Permeability is dependent on frequency up to around 10 kHz. Above that frequency, permeability decreases to some extent with increase of frequency, but this effect is not well defined.

Hysteresis. In induction-heating practice, the rate of heat development by hysteresis in a magnetic material at room temperature is a small percentage of the eddy-current watts. The hysteresis watts decrease rapidly with rise of temperature. Hence, hysteresis is a negligible factor in the inductive method of heating.

Primary Coils. Single-layer coils are standard practice. Tubular conductors—round, oval, or rectangular—provide for water cooling of the coil.

The number of turns is selected with reference to the desired relation of amperes and volts for a given service. The restrictions on this choice are the space required for conductor insulation and the requirement of water cooling.

21.14 ELECTRIC WELDING

21.14.1 Resistance Welding

Resistance welding includes spot welding, projection welding, seam welding, and butt welding. All are based alike on the principle of resistance heating but differ in the details of application.

Spot welding is applied to overlapping sheets. These are clamped between water-cooled electrodes, pressure is applied, and a current impulse is passed through the assembly. The material in the zone of pressure is heated to fusion, and the joint thus made to cool under pressure.

Spot welding is largely employed on sheets 0.025 to 0.125 in thick, although welds on thicker sheets and plates up to 1 in thick are made regularly.

The area of the spot weld is small; weld diameters of 0.25 to 0.625 in are the usual range. The maximum diameter is limited by the area of uniform contact between sheets that can be obtained with practical pressure.

Rapid heating by using high current values is necessary to bring the metal that is to form the joint to the required temperature without more than normal heating of the adjacent metal. Current values range from 5000 A upward. The voltage between the electrodes is usually less than 2 V. The open-circuit voltage is generally less than 12 V. The time period of current flow varies widely, depending on the thickness of the sheets, kinds of material, etc. For thin steel sheets this period is about 1 c ($^1/_{60}$ s) for each 0.010 in of the total thickness of the two sheets to be joined. The pressure, current value, and time are variables that must be correlated in each case.

Spot welding with a single current impulse is limited to sheets not thicker than about 0.125 in. Because of the heating of the electrodes, and consequent short life, with heavier material, thick sheets are welded by using a number of current impulses, for example, 4 c on, 2 c off, repeated as required. The no-current intervals, that is, cycles off, prevent the overheating of the electrodes.

Projection welding differs from spot welding only in the use of the buttonlike projection on one of the sheets to define the path of the current. A number of adjacent welds can be made simultaneously without interference, a useful-method for assembly work.

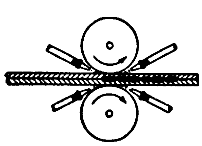

FIGURE 21-17 Seam-welding electrodes with water cooling.

Seam welding can be made by putting a series of spot welds on thin sheets by passing the sheets between two pressure electrodes (Fig. 21-17) and with continuously interrupted current. Speeds range from 10 to 400 in/min; approximately 60 in/min is the most common speed. Twelve welds per inch with 6- to 10-in-diameter electrodes is representative practice.

Sometimes classed as seam welding but otherwise known as edge welding is the type of welding accomplished on continuous tube mills, or continuous butt-welding installations where the edges of metal are brought together and welded as a seam. In this type of welding pulsed currents are not used to obtain the weld, but rather a continuous ac or dc supply fed through rotating electrodes to the abutting edges of the seam produces the electric energy required for the weld.

The *variables* in these three methods of welding which must be correlated are

1. Electrode diameter, material of electrodes, contact area, cooling, and pressure
2. Nature and surface of metal or metals to be welded
3. Timing of current flow
4. Current value and waveform

Timing circuits for resistance welding are either (1) nonsynchronous or (2) synchronous (relating to the welding current zero).

Nonsynchronous timers are of various types, ranging from the simple application of foot pressure to close and open the welding circuit, according to the judgment and skill of the operator, to the combinations of cams, limit switches, etc., the functions of which are independent of the operator.

The synchronous timers are electronic, using thyratrons and ignitions. The most simple of these are those which are adjustable, as regards to current impulse, in 1-Hz steps. When used with an ac supply, the ignitron contractor will pass current each half cycle that the anode is positive. A second ignitron is connected inversely to pass current during each of the other half cycles.

Electronic control for resistance-welding circuits is inherently a precision device. The choice between the two types of control is primarily a matter of the value of exactness in timing, which becomes more important as the welding time is decreased.

Current control in welding circuits, that is, the control of the rate of heat development, is obtained by taps in the primary winding of the welding transformer or by phase control of the welding current, retarding the point at which current starts to flow in each half cycle beyond the power-factor angle. A combination of the two methods is often used.

Percussion welding is a self-timing spot-welding method. A current impulse is obtained by the discharge from a capacitor or from a magnetic field. (This method is usually classified under dc resistance welding.) The capacitor arrangement for percussion welding is used extensively in the manufacture of lamp filaments.

Butt-Welding Upset Method. End-to-end welds, lap welds, and butt welds are included here. The faces of the parts should be prepared for even contact. The parts are clamped and brought together by hydraulic pressure, thus closing the circuit. Plasticity occurs simultaneously over the entire contact area. The joint is cooled under pressure. The method has a wide variety of applications, large and small. In continuous pipe welding, the current is conducted to the work by a pair of rotating electrodes. This, as previously mentioned, is sometimes referred to as the seam-welding technique. Butt welding can be obtained by utilizing induction-heating equipment; how this can be accomplished will be described later.

Flash Welding. No preparation on the face is necessary. One face is stationary, the other movable. Voltage is applied through pressure contacts. A momentary contact establishes current flow and flashing (the melting and vaporization of the minute contact points). The movable face is fed forward continuously at the rate at which the metal is melted. The pressure of the gases developed between faces prevents the access of air to the hot faces and blows out the molten metal. The metal adjacent to the faces becomes plastic, and the joint is made by fusing the parts together by hydraulic pressure. The circuit is opened by a jam relay as the faces make contact. However, if a considerable amount of flashing is required to remove impurities, the circuit is held closed for a predetermined time and may be opened just prior to the application of the last pressure value.

21.14.2 Arc Welding

Welded joint is a union of metal parts made by localized heating, without pressure in arc welding and supplemented by pressure in resistance welding. The technique of welding is built around the methods of concentration of heat and is based on the metallurgy of welds in the mechanics of joints.

Arc-Welding Manual Operation. Methods of arc welding are classified as follows:

1. Direct-current arcs, one electrode—metal or carbon

  a. Unshielded arc
  b. Shielded arc

2. Alternating-current arcs, metal electrodes

  a. Unshielded arc, one electrode
  b. Shielded arc, one electrode
  c. Shielded arc, two electrodes (atomic-hydrogen process)

Joints. The five principal types of arc-welded joints are butt joints, corner joints, edge joints, lapped joints, and T joints. Any length of joint can be made by travel of the electrode; one or more passes may be required.

The position of the joint (see Fig. 21-18), especially for multipass work, is an important factor in the economics of welding. The maximum welding speeds obtained with the flat position are about twice as fast as those with the horizontal position and about 4 times faster than the maximum speeds obtained with the overhead and vertical positions. Welding in the flat and horizontal positions is much easier for the operator than overhead welding—so much so that the arc can be kept in operation about twice as long per hour of overall time. Likewise, vertical welding is less tiresome than overhead welding and represents an increase of about 50% in welding time without an increase in the fatigue of the operator.

The *weldability* of metals and alloys can be stated as easy, intermediate, and difficult to weld. This term, when used with reference to carbon steel, relates to carbon content. Carbon steels up to about 0.30% C are easy to weld. That class of steels is used in a large part of the fabrication of materials by welding. Practically all metals and alloys can be electrically welded, but in many cases an individual study of the metal or alloy, dimensions, and position of the weld is required to develop the particular technique necessary.

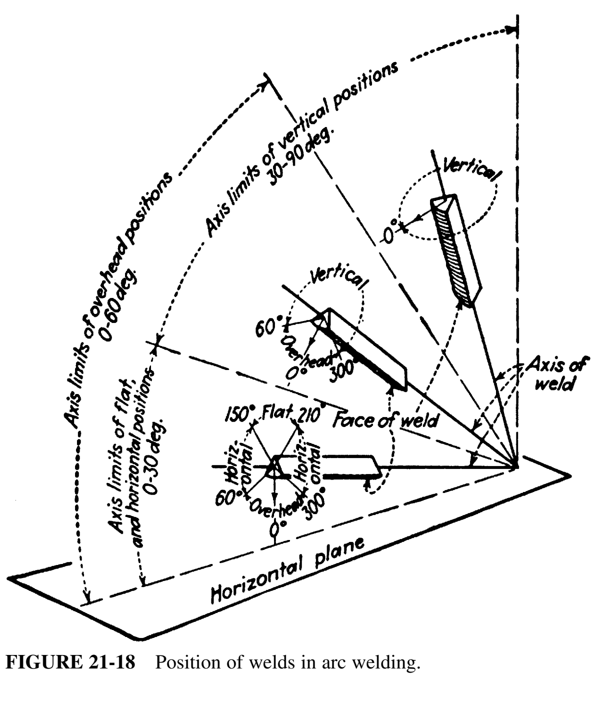

FIGURE 21-18 Position of welds in arc welding.

A characteristic feature of arc welding is that symmetrical sections (I beams and T beams) can be used.

Single-Electrode Welding. The arc is maintained between the electrode and the work. Round steel electrodes, with carbon content suited to the class of work, supply the metal (filler metal) for the joint.

The phenomenon of the transport of the molten metal from the electrode to the work is dependent on the position of the joint. It is, however, a factor in the selection of the electrode for each joint position. The making of a sound weld requires that the filler metal be deposited only on molten-base metal. The depth of the molten-base metal is termed *penetration.*

Metal Electrode Types. There are two basic types:

1. Bare electrodes (or lightly coated electrodes)

2. Coated electrodes

The bare electrode is covered with a film or its oxide to aid in stabilizing the arc circuit. This type of electrode is used mainly for joints which carry only static loads; the coated electrode has a jacket made of either organic (combustible) or inorganic material or a combination of the two types. This coating serves several purposes:

1. The organic material provides the gaseous shield to restrict the access of oxygen and nitrogen (air) to the molten metal.

2. The inorganic material makes a slag to refine the molten metal. (The principle is the same as the refining of steel and the manufacture of steel in an arc furnace.) This slag also serves as an insulating blanket to retard the rate of cooling of the weld metal.

3. The gas envelope and the slag aid materially in the stabilization of the arc circuit.

4. In some cases the coating is used to add alloying elements to the weld metal.

Electrode coatings are of different types, corresponding to the class of weld service (kind of base metal, joint position, etc.). The selection of electrode size, carbon content, and type of coating is a major consideration in welding practice.

Powdered-Metal Electrodes. Some electrodes are available which have powdered iron, which will make up a good portion of the metal to be deposited in the joint, mixed in with the flux coating. This makes the electrodes much larger on the inside for the same-diameter core wire as standard flux-coated electrodes. These electrodes are well suited to down-hand welding and are said to deposit more metal in a given period of time than standard flux-covered electrodes.

Low-Hydrogen-Type Electrodes. Some types of steel welding rods have special treatment during manufacture to reduce the amount of hydrogen in the coating. The reduction of hydrogen in the coating produces a weld with little or no absorbed hydrogen in the base metal and reduces the likelihood of underbead cracking.

Electrode Quantities. The weight of electrode metal required for a given joint is

$$W = \frac{\text{weight of metal deposited}}{l - \text{electrode loss}} \tag{21-20}$$

The weight of metal deposited is calculated from the volume required to fill the joint plus reinforcement, if any. The electrode loss is the sum of the scrap end loss, the spatter loss, and the coating loss. The scrap end loss varies with the diameter and length of the electrode. With 14-in electrodes the loss varies from 10% to 20%. The average value of this loss is about 17%.

The other losses depend on the type and size of the electrode, joint position, welding current, arc voltage, and skill of the operator. With bare electrodes these losses vary from 8% to 15%, average 13%; with coated electrodes, from 15% to 35%, average 27%.

Carbon (Graphitic Carbon) Electrodes. These are used with direct current for arc welding of nonferrous metals and alloys and with the addition of external shielding (gases from material placed adjacent to the arc) for welding steel. The weld metal is supplied by melting a portion of the base metal. If additional metal is required, it is supplied by a filler rod. Carbon electrodes are not suitable for vertical and overhead welding. The use of a carbon electrode is declining.

The DC Arc. The dc arc is adapted to practically any class of welding service. The arc voltage varies with the type of electrode, ranging from 15 to 40 V. Both straight polarity (work positive, electrode negative) and reverse polarity (work negative, electrode positive) are used, depending on the character of the work. (Polarity here relates to the difference in the rates of heat development at the anode and cathode of the dc arc.) Metal electrodes should be selected with reference to the polarity arrangement. Carbon electrodes can be used with either arrangement; straight polarity is more common practice.

The rotating dc-generator single-operator unit, with a drooping voltampere characteristic, driven by any type of prime mover, is made in sizes ranging from 159 to 600 A, usual load-voltage rating 40 V, all sizes. A wide range of adjustments of welding current is provided in each size. The larger part of dc welding is done with this type of equipment.

Multiple-operator equipment and an adjustable series resistor for each arc circuit for operation from constant distribution systems are used to some extent. The special field for this equipment is where the service of each arc-welding circuit is infrequently in use, say, 25% of the time or less. In such cases the loss in the series resistor is less than the no-load loss of the single-operator unit for the same service.

Another type of dc-welding power source is a dry-type rectifier used in conjunction with a multiphase high-leakage-reactance transformer. Many of these rectifier-type welders use selenium rectifiers which are forced-air-cooled.

Rectifier-type welders are said to combine some of the desirable arcing characteristics of dc welding, such as easy arc starting, with those of welding transformers, such as reduced no-load losses. The same range of rating is available in rectifier-type welders used in rotating dc welders.

Alternating-Current Arc Welding. The field of ac arc welding is practically the same as that of dc arc welding.

The standard equipment for single-operator ac arc welding is a single-phase standard frequency transformer, sometimes with a number of voltage taps, and an adjustable reactance. Generally, capacitors are included to correct the power factor of the circuit to about unity between one-half and three-fourths load. The welding leads are limited to about 300 ft radius because of voltage drop.

Standard equipment includes ratings with the range of 150 to 1000 A, 30 to 40 V.

Atomic-Hydrogen Arc Welding. This method uses an ac arc between the tungsten electrodes (not including the work) in an atmosphere of hydrogen (shielded arc). Either commercial hydrogen or disassociated ammonia can be used. The weld metal is supplied by the base metal or, if additional metal is required, by a filler rod.

The method is very flexible. Practically any metal or alloy, ferrous and nonferrous, can be welded. Its greatest usefulness is for the fusion welding of certain ferrous alloys, for example, chrome-nickel steels, aluminum, and duralumin, but it must use flux to weld some of these materials. The welding of thin sheets, the production of tubing, and the repairing of expensive tools and dies are some of the common uses of the method.

Inert-Gas-Shielded Arc Welding. The method comprises the use of a single tungsten electrode, filler rod, and argon or helium as a gas shield. The particular field for the method is the welding of the light metals. No flux is required. The technique varies with the type of work. The following procedures are typical.

Welding aluminum and aluminum alloys—alternating current and argon

Welding magnesium and magnesium alloys—either alternating current and argon or direct current, reverse polarity, and either argon or helium

Welding stainless steel, mild steel, copper, and copper alloys—direct current, electrode negative, and either argon or helium or alternating current, high frequency, stabilized with argon or helium.

Consumable-Electrode Gas-Shielded Welding. This type of welding uses small, bare electrodes in coil forms. The welding is done in gas atmospheres. The 0.020- to 0.125-in-diameter electrodes are fed mechanically into a handgun for manual welding at feed rates up to 1000 in/unit. The voltampere arc characteristics of this type of welding are rising. Standard dc welding generators do not give the best results. Special low-voltage dc welders give better results. The optimum characteristic is one which is rising, to match the arc characteristic.

Argon, argon and 1% oxygen, helium, and carbon dioxide or mixtures of these gases are used. Argon is used for welding aluminum, magnesium, copper alloys, and titanium. Argon-oxygen or carbon dioxide is used for mild-steel welding. Almost all welding is done with the electrode positive.

The automatic consumable-electrode gas-shielded equipment does not require elaborate control systems. With the low-voltage generators the current flow automatically regulates itself to burn off whatever amount of wire is being fed into the arc.

As a result of this type of welding the generator produces the current to make the burnoff of wire rate equal to the wire feed speed.

Direct versus Alternating Current. The considerations that affect the choice between direct current and alternating current are mainly the following:

1. Alternating current has a higher (85%) efficiency. Rotating direct current and rectifier direct current are about 65% under load. Also, no-load losses for rectifier direct current and alternating current are less than the no-load loss of the single-operator dc equipment. The saving is 25% to 30%. A larger saving may be made compared with multiple-operator dc equipment.
2. The power factor of alternating current and rectifier direct current is low (about 40% lagging) and can be corrected by the use of capacitors.
3. The magnetic deflection of the arc (magnetic blowout) is not so pronounced with the ac arc. This phenomenon is often troublesome in working with dc arcs of high current values. The ac arc permits higher current and larger electrodes in such cases, with a consequent higher welding speed.
4. The cost of electrodes must be compared.
5. The cost of equipment must also be compared.
6. Where the range of work in a shop is widely varied, the use of both types of arc welding may be found desirable.

Automatic Arc Welding. Automatic arc welding, either dc or ac, is confined mainly to simple joints which can be placed in the flat position for welding.

The electrode for direct current may be bare or coated. Coated electrodes for alternating current are usual practice except when the flux (in granular form) is applied to the work (submerged-arc method). Coated electrode wire in long lengths for feeding from a reel has a slot in the coating for electrical contact. Coated electrodes in short lengths with end contact are also used by adapting the feeding mechanism for automatic return to the starting position when the electrode is consumed.

The power-supply equipment, dc or ac as the case may be, for automatic arc welding is the same as for the corresponding manual operation.

The automatic regulator controls the rate of feeding of the electrode to match the rate of melting of the metal electrode by controlling the speed of the electrode motor in response to slight changes in the arc voltage so as to maintain a practically constant average arc voltage.

One type of automatic regulator in wide use is an electric device which contains the value and the direction of armature coil of a dc electrode motor. This control uses two thyratron tubes in the armature circuit of the electrode motor, passing current from an ac source in one direction or the other, as required, to feed the electrode up or down. The magnitude of the current passed is controlled by grid-phase shift of the thyratron tubes in response to changes in the arc voltage in comparison with the preset reference voltage.

Automatic arc welding, a method independent of the human element in the operation, has many merits where it is applicable. The most important of these are uniform welds, high production rate, and low electrode loss. Also, a new trend is toward the use of robot welders with solid-state circuitry and logic control that perform repetitive functions and handle heavy production parts.

21.14.3 Induction Welding

Induction Resistance Welding. This method of welding incorporates the use of induction heating principles along with the application of high-frequency energy, usually in a radio-frequency range. It is particularly useful as a method of welding in tube mills. Here energy can be induced into the slit-formed tubing with a single-turn inductor and current caused to flow across the gap between pressure rolls where resistance welding is caused by the I^2R drop across the joint between the weld rolls.

This method of welding has been and is being used effectively for the welding of carbon steels, aluminum, copper, titanium, and mechanical stainless steel. This technique has been applied to portable weld units where it is possible to weld tubing and pipe on site from skelp.

The radio frequencies normally used for this type of welding are in the neighborhood of 200 to 450 kHz. It is possible to weld heavier wall material in this manner, frequencies being used in the neighborhood of 10,000 or even 3000 Hz, although these frequencies will not give as efficient an operating installation as the radio-frequency installation.

High-Frequency Resistance Welding. The application of contacts to line pipe utilizing radio-frequency energy has been successfully accomplished, and a weld similar to that obtained with induction resistance welding is thus secured. In this type of welding installation, high-frequency, preferably radio-frequency, energy is passed through sliding contacts to the V-shaped edges of the tubing. This current is then caused to flow across the contact between the pressure rolls, giving the I^2R heating effect of resistance welding at this point.

This method of welding is also effective on nonferrous materials, as well as carbon steels. It has been adapted to structural shapes and the finned-tube shapes.

Induction Butt Welding. Two properly faced tubular sections or rectangular sections butted together can be induction-heated with a suitable frequency. This work is dependent on the depth of penetration and the size of the part. The work is so heated that when the parts are brought to temperature they can be welded by the application of a suitable pressure. One of the members can be fixed and the other moved.

This method of welding has been particularly suitable for the welding of high-pressure boiler tubing, for the welding of railroad rails in the field, and for the butt welding of certain types of large cylindrical objects. Equipment has been furnished to weld transmission pipe in the field. A weld made in this manner is usually much faster than a weld made by a conventional electrical process.

Longitudinal Butt Welding. The longitudinal butt weld can be accomplished by induction on such mechanical equipment as a tube or pipe mill where hot-rolled skelp can be formed and welded continuously without the necessity of edge cleaning such as is required for conventional resistance welding. Of course, it is also possible to perform this type of welding by either induction resistance or high-frequency resistance welding.

21.14.4 Electron-Beam Welding

A method of welding, particularly in vacuum, has been developed which incorporates the utilization of an electron beam or beams for the welding of very thin and very narrow and unusual metals. This technique has been adapted to thin sections of conventional materials where it is desirable to obtain a weld by heating a very narrow section of the parent metals and obtaining a bond as strong as the parent metal. Commercial units for this type of welding are available, and the units are applicable to certain production operations as well as to laboratory welding.

21.14.5 Electroslag and Plasma Welding

Electroslag welding is a welding process which relies on a molten slag which melts the filler metal and the surface of the work to be welded. The weld pool is shielded by this molten slag which moves along the entire cross section of the joint as welding progresses. The electrically conductive slag is maintained in a molten condition by its resistance to the current which flows between the electrode and the work.

This type of welding appears particularly suitable to replace multipass welding techniques. The process is especially applicable for welding plates ranging in thickness from 1¼ to 18 in.

This method may require welding current of the order of 55 to 65 A for ⅛-in-diameter electrodes; however, the range can vary depending on the material to be welded from 400 to 900 A.

The welding voltage required is normally in the neighborhood of 40 to 55 V for ⅛-in-diameter electrodes.

The electroslag method has been widely used in Europe for some time. Its use should be considered when the welding application involves large structural members, pressure parts in nuclear reactors, and high-pressure boiler downcomer tubes. It could be used for forged crankshaft welding. It would be advisable in some instances to use it on press frames. It is suitable for cylinders for hydraulic presses, for turbines and alternator shafts, for rolling-mill frames, and for ship hulls.

Plasma is a field for electric heating now becoming commerically usable. There are basically two types of plasma heating: (1) arc plasma and (2) induction plasma.

Plasma heating involves the ionization of gases and develops extremely high temperatures.

Arc plasma heating has been used primarily for rapid melting of small quantities of material, both metals and refractories. It can be employed for cutting metals and is being used experimentally in investigations involving extremely high temperatures. A dc arc is generally used in obtaining the plasma.

Induction plasma heating is developed generally at frequencies of about 4 MHz. Experimentally, frequencies of 8 to 10 MHz have been utilized, and investigations are proceeding at many other frequencies. It is reported that plasma temperatures up to 20,000°F have been reached. Various gases are required, depending on the results desired. Gases commonly used are hydrogen, helium, argon, and nitrogen, and some work had involved the use of air.

21.14.6 Pressure Welding

Also called diffusion bonding or diffusion welding, the pressure-welding process is described as an atom-to-atom bond between two surfaces via intimate contact between their oxide-free surface areas. The surfaces must also be free of contaminants. To make the bond effective, the atoms on one surface must be brought, under pressure, within a few angstroms of the atoms of the second surface.

In some cases, interlayers of foil are necessary to achieve an adequate bond, acting as barrier layers between incompatible materials, to allow bonding of materials more readily welded at low temperatures, and to overcome problems with surfaces that have insufficient mobility to come into close contact.

Bonding is done in the solid state, with times and temperatures depending on the materials used. The method is advantageous because (1) it is applicable to a wide variety of joints; (2) many bonds can be made in one operation; and (3) bonds can be made in particularly hard-to-get-at places. At present, the disadvantage of diffusion welding is that joint assessment is difficult to make, but as technology improves, it is thought that, in the future, this type of welding may replace arc welding for major structural components such as nozzle and flange assemblies.

21.15 AIR CONDITIONING AND REFRIGERATION

21.15.1 Air Conditioning

The Air-Conditioning System. As described by the American Society of Heating, Refrigerating, and Air Conditioning Engineers (ASHRAE), an air-conditioning system maintains desired environmental conditions within a space. Air-conditioning systems are categorized by how they control cooling in the conditioned area. Typical central air-conditioning system applications include (1) spaces with uniform loads, (2) small spaces requiring precision control, (3) multiple systems for large areas, (4) systems for complete environmental control, and (5) a primary source of conditioned air for other subsystems. Spaces with uniform loads are generally those with relatively large open areas and small external loads, such as theaters, auditoriums, department stores, and the public spaces of many buildings. Isolated rooms within a larger building with cleanrooms and computer facilities will typically require precision control. Large buildings such as factories, airplane hangers, shopping malls, office buildings, and hospitals require multiple systems.

Environmental Concerns. Owners of many medium-size and most large buildings find it more economical to cool their buildings by distributing chilled water to remote air-handling units than use large space-consuming air ducts from a central air handler. As a result, electric centrifugal chillers are used extensively for cooling commercial buildings. These chillers use chlorofluorocarbons (CFCs) as a refrigerant, and represent a class of extremely stable chemical compounds that are non-toxic and inexpensive. International agreements have been made to phase out use of these chemicals, primarily as a response to the concern that the CFCs may be contributing to the depletion of the ozone layer in the upper atmosphere and to global warming. Other refrigerants are available that limit or eliminate this problem, hydrochlorofluorocarbons (HCFCs), which have one or more hydrogen atoms in their structure and therefore decompose much more readily in the lower atmosphere, and hydrofluorocarbons (HFCs), which contain no chlorine and have little impact on stratospheric ozone.

Substitute refrigerants are available for many CFCs used in chillers. HCFC-123 is the present substitute for CFC-11 (R-11) in chillers, and for CFC-12 (R-12) chillers the substitute is HFC-134a. But neither refrigerant is a "drop in" substitute on existing equipment. Only in cases where equipment is relatively new and is specifically designated "compatible" with the new refrigerants can the substitution be easily made. In most cases, however, new equipment must be purchased that has been designed to use these substitutes. Availability of this equipment is increasing, and the new units can be supplied with performance equal or very close to their CFC counterparts.

Alternatives to electric chillers include steam and gas direct gas-fired absorption chillers, and gas engine-driven chillers. In a specific installation, the engineer must be careful to consider all costs with each alternative and compare options on an equitable, life-cycle cost basis.

Psychrometric Formula. A major step toward the development of air conditioning as a science was made by Willis H. Carrier with the derivation of the rational psychrometric formula (*Trans. ASME*, 1911) which established the relationship between dry-bulb and wet-bulb temperatures, both easily ascertainable, and other important properties of the air such as density, relative and absolute humidity, vapor pressure, and total heat, the exact valuation of which is essential to the solution of problems involving the exchange of heat and humidity between air-conditioning apparatus and conditioned spaces and their contents. The rational psychrometric formula is the basis for numerous psychrometric charts.

Psychrometric Terms

Dry-bulb temperature is the commonly observed temperature of the air as indicated by a conventional thermometer not affected by the relative humidity of the air.

Wet-bulb temperature is the temperature of adiabatic saturation of air or the temperature at which air would normally saturate without any change in its heat content. Wet-bulb temperature is, therefore, also a measure of the total heat content of air; that is, at a given wet-bulb temperature the total heat is constant regardless of changes in the dry-bulb temperature.

Relative humidity within the normal range is the percent ratio of the weight of water vapor actually contained in a unit of space to the weight of water vapor that the same unit of space would contain if fully saturated at the same dry-bulb temperature.

Absolute humidity is the actual weight of water vapor in air at any given condition and is usually expressed in grains per cubic foot or grains per pound of dry air.

Dew point is the temperature of saturation of air, or the point beyond which any further reduction in temperature would result in condensation.

Effective temperature is an arbitrary index of the degree of warmth or cold felt by the human body in response to temperature, humidity, and air motion. Experimentally determined, the scale has been fixed by the temperature of saturated air which reproduces the sensation of warmth felt at other combinations of conditions.

Sensible-heat effect is the exchange of heat between air and its surroundings or apparatus that changes the dry-bulb temperature without affecting the moisture content. It is convenient to consider sensible heat as dry heat.

Latent-heat effect is the exchange of moisture between air and its surroundings or apparatus by evaporation or condensation resulting in a change in the moisture content of the air with consequent change in the total latent heat of vaporization represented by the moisture in the air. It is convenient to consider latent heat as humidity.

Comfort Cooling. Investigations carried on under the auspices of the American Society of Heating and Ventilating Engineers (ASHVE), now ASHRAE, indicate that effective temperatures varying from 70 to 73°F are acceptable inside conditions for peak summer weather depending on length of occupancy and for normally clothed, normally active commercial workers. Table 21-8 gives approximate dry-bulb temperature and relative-humidity combinations within normal range which produce effective temperatures within the stated range with air motion 15 to 25 ft/min.

Inside design conditions of 78 to 80°F dry bulb with 45% to 55% relative humidity, depending on the character of occupancy, are accepted as standard inside design conditions against peak outside conditions for commercial comfort-cooling applications in almost all parts of the United States.

It is seldom desirable to design for inside temperatures in excess of 80°F. It is generally impracticable to reduce the humidity sufficiently to produce effective temperatures within the desired range at dry-bulb temperatures much in excess of 80°F.

Note: $t_{°C} = (t_{°F} - 32)/1.8$.

Industrial-Process Air Conditioning. In industrial or process air conditioning, inside design conditions are frequently dictated entirely by the product requirements. In confectionery plants where chocolate is handled, it is usually not desirable to have temperatures in excess of 65°F (dry bulb), which is far below the comfort range. In chemical or pharmaceutical plants where deliquescent chemicals are handled, lower-than-average humidities may be required for satisfactory production. Many products can be satisfactorily processed at widely varying conditions as long as the condition is maintained constant and the process adjusted to it.

Where conditions are established by product requirement, design is usually directed toward maintenance of satisfactory working temperatures. Investigations to determine the limits for optimum health and efficiency of the industrial workers indicate that conditions should not exceed 80°F effective temperature, that is, approximately 82.8°F, dry bulb at 80% RH, 84.4°F D at 70% RH, 86.2°F D at 60% RH, 88.2°F D at 50% RH, and 90.3°F D at 40% RH. Lower effective temperatures are required where perspiration must be prevented to avoid contamination or staining of products during handling.

There has been a marked increase in the use of complete air conditioning, including refrigeration, even in industrial operations where atmospheric control is not required by the process involved. An example is the trend toward larger manufacturing areas under single roofs, where windows cannot be depended on for light or ventilation. In many cases it has proved less expensive in both first cost and operating cost to provide full air conditioning with refrigeration rather than ventilation.

Winter Heating. Winter heating systems for normally occupied interiors are almost universally designed to maintain 70°F inside, with outside conditions assumed at 10°F above the lowest recorded temperature for the district in question.

Maximum Outside Design Conditions. These are usually taken at values which will not exceed 2.5% of the total hours during June, July, August, and September. Accepted maximum design dry-bulb (D) and wet-bulb (W) temperatures in degrees Fahrenheit for larger cities representative of various climatic divisions of the United States are given in Table 21-9.

Cooling Load. Calculation of the cooling load involves consideration of all possible internal as well as external heat gains not only for transmission and infiltration but also from sunlight radiation.

Solar Heat. Sunlight radiation for 40°N latitude on July 21 attains maximum values in Btu per square foot per hour transmitted by unshaded glass for variously oriented surfaces as follows: east, 200 at 8 A.M.; south, 91 at 12 noon; west, 200 at 4 P.M.; horizontal 258 at 12 noon (*ASHRAE Guide and Data Book*). Major consideration must be given to sun-exposed glass. Of the total impinging radiation, the amount passing through the net area of the window is approximately as follows: unshaded, 100%; half covered by buff shade, 70%; fully covered by light-finish venetian blinds, 70%; equipped with canvas awning, 30%. Although sunlight-radiation effect on walls and roofs can be calculated, allowance is usually made for this effect by calculating heat transmission at a temperature above the design outside temperature. A substantial temperature head (usually 50°F) should be allowed in calculating transmission through the roof surface due to long hours of exposure to the sun. Heat from sunlight contributes only to the sensible-heat load.

Heat Transmission. Transmission of heat through the structural surfaces of buildings or spaces is directly proportional to the temperature difference between the two sides of the surface and to the thermal conductivity of the material or materials forming it. Overall coefficients for a number of common structural elements are given in Table 21-10. The coefficient U is expressed in Btu per hour

per square foot per degree Fahrenheit temperature difference across the surface and is based on an outside-surface coefficient for 15-mi/h wind velocity.

Total heat transmission through any exposed building surface may be computed by the formula

$$H = A \times U(t_o - t_i) \tag{21-21}$$

where H = sensible heat in Btu per hour, A = area of the surface element in square feet, U = coefficient of heat transmission of the surface, and t_o and t_i are, respectively, the outside and inside temperatures in degrees Fahrenheit. This formula is used for computing heat loss from a space as well as heat gain to it.

Heat from Occupants. Every occupant of a conditioned space contributes both sensible and latent heat to the atmosphere; the relative proportions is dependent on the dry-bulb temperature and the total quantity on the state of activity of the individual (see Table 21-11).

Only the sensible heat(SH) fraction affects the temperature of the conditioned space, since latent heat (LH) from evaporation of body moisture appears as vapor at room temperature.

Electrical Heat. The heat equivalent of the electrical input to all lights and electrical heating or power appliances used within a conditioned space contributes to the atmospheric heat which must be removed by the air-conditioning apparatus. In general practice, the approximate heat equivalent of

Note: 1 Btu/h = 0.293 W; $t_{°C} = (t_{°F} - 32)/1.8$.

3400 Btu/h · kW input to lights and appliances and 2500 Btu/h · hp of motor capacity is used in calculating heat gain from this source. In considering heat from appliances and motors, load factor should be carefully investigated, since appliances or motors seldom run continuously at full load. Unless appliances are used for water heating or evaporation, the entire load from electrical sources will be sensible heat.

Process Heat. Heat from gas appliances is the most common form of process heat. Average heat input to common gas appliances in Btu per hour is as follows: 14-in coffee urn, 7500; 12-in coffee urn, 5000 (*ASHRAE Guide and Data Book*). Heat output will be approximately 75% sensible heat and 75% latent heat. Consideration should be given to load factor of appliances.

Ventilation and Infiltration. Air quantity for ventilation purposes is usually based on the number of occupants of the conditioned space. Ventilation is required chiefly to overcome normal odors. Average accepted practice calls for the introduction of at least 10 ft^3/min of outside air for each nonsmoking occupant and 20 ft^3/min for each smoking occupant. For commercial interiors, such as restaurants and drugstores, where moderate smoking occurs, 15 ft^3/min per person is usually allowed. In theaters, where ceiling heights are usually liberal, where there is no smoking, and peak occupancy seldom occurs for long periods, an allowance of 7½ ft^3/min per peak occupant is considered ample. Air positively exhausted from a space must be deducted from the positive ventilation supply in considering possible infiltration. If the exhaust exceeds the supply, infiltration will naturally be induced. Air for ventilation should be first brought to the conditioning apparatus and conditioned before introduction to the conditioned space.

Infiltration varies with the construction, exposure, and size of a conditioned area as well as with door traffic and location of doors. The following quantities are suggested as a general guide for buildings of average construction: cubical contents 0 to 5000 ft^3, one complete change of volume in 30 min; 5000 to 50,000 ft^3, 40 min; 50,000 to 100,000 ft^3, 60 min; 100,000 to 200,000 ft^3, 90 min; over 200,000 ft^3, 120 min. Infiltration in cubic feet per minute for load calculation and comparison with positive supply in cubic feet per minute may be determined by dividing cubical contents of the space by the time factor for that space magnitude.

The sensible-heat component of ventilation or infiltration may be computed approximately from the formula

$$H_s = Q \times 1.07(t_o - t_i) \qquad (21\text{-}22)$$

where H_S = sensible heat in Btu per hour, Q = cubic feet per minute of air, and t_o and t_i = outside and inside temperatures in degrees Fahrenheit, respectively.

The latent-heat component of ventilation or infiltration may be computed approximately from the formula

$$H_L = Q \times 0.675(h_o - h_i) \qquad (21\text{-}23)$$

where H_L = latent heat in Btu per hour, Q = cubic feet per minute of air, and h_o and h_i = outside and inside absolute humidities, respectively, expressed in grains per pound of dry air (see a psychrometric chart).

Only infiltration air entering the conditioned space directly contributes to the internal heat load. Ventilation air-conditioned before introduction to the space contributes to the load upon the conditioner and cooling apparatus only.

The Internal Sensible-Heat Load. This will be the summation of the sensible heat from transmission, sunlight radiation, occupants, lights, electrical devices, process heat, and infiltration. The *internal latent-heat load* will be the summation of the latent heat from occupants, process heat, and infiltration. A factor of safety of 10% is often added to these figures to allow for inaccuracies and, in the case of sensible-heat load, to cover the power input for air circulation. The *total heat load* on the conditioner or cooling apparatus will be the sum of the internal sensible- and latent-heat loads plus the sensible- and latent-heat load of ventilation air. Grand-total heat is usually expressed in tons of refrigeration effect.

Air Quantity for Sensible-Heat Absorption. The sensible-heat load usually serves as the first guide to the selection of proper air quantity. The specific heat of air within the normal air-conditioning range is approximately 0.241 Btu/lb · °F. One Btu will raise 4.16 lb of air 1°F, or approximately 56 ft^3 of air 1°F. The air quantity required to absorb a given sensible-heat quantity may be determined by the formula

$$Q = \frac{H_S}{60} \times \frac{56}{t_i - t_d} = \frac{H_S}{1.07(t_i - t_d)} \tag{21-24}$$

where Q = air quantity in cubic feet per minute, H_S = sensible heat in Btu per hour, t_i = space temperature in degrees Fahrenheit, t_d = delivery temperature of air into the conditioned space in degrees Fahrenheit, 60 = minutes per hour, and 56 = cubic feet per Btu per degree Fahrenheit temperature rise. Modern diffusion-type outlets will permit satisfactory delivery of air into spaces of 10- to 12-ft ceiling at 60°F. With higher ceiling heights and good conditions, air may be introduced at 55 to 50°F.

Latent-Heat Absorption (Dehumidification). For the quantity of air selected to meet the sensible-heat load by the method just suggested, the moisture content at which the air must be introduced into the space to absorb the internal latent-heat load may be approximately calculated by the following formulas:

$$h_r = \frac{h_L}{Q \times 0.675} \qquad \text{and} \qquad h_d = h_i - h_r \tag{21-25}$$

where h_r = humidity deficiency in grains per pound of dry air; h_d and h_i = absolute humidity in grains per pound of dry air at delivery condition and within the room, respectively; H_L = internal latent heat in Btu per hour; Q = air delivery in cubic feet per minute; and the factor 0.675 is calculated from the average density of air, the average latent heat of moisture in Btu per grain, and rate correction. The delivery-moisture condition thus calculated, together with the delivery temperature, will permit graphical determination of the required delivery-air conditions from a psychrometric chart. *Dehumidification* is usually accomplished by condensation of moisture in the process of cooling the air.

Cooling-Dehumidifying Apparatus. Two types of apparatus are used for cooling and dehumidifying: (1) the spray-type dehumidifier and (2) the surface cooling coil. In either, cooling and dehumidification may be accomplished by cold fluid at the proper temperature from any source, for example, cold water from wells or ice tanks or water cooled directly by refrigeration apparatus or by the direct expansion of refrigerants in cooling coils.

Spray Type. In the spray-type dehumidifier, air to be conditioned is passed through a spray chamber into which a large volume of finely divided water is introduced. Spray-type dehumidifiers are of two general types: (1) those in which water cooled externally is introduced at a reduced temperature and (2) those in which water is sprayed over coils cooled by fluid from an external source.

Spray-type dehumidifiers have the advantage of permitting evaporative cooling of cleaning the air of siliceous dust, and of absorbing some gases and odors.

Surface Cooling Coils. Surface cooling coils are widely used for cooling and dehumidification. Cooling of surface coils is usually accomplished by direct expansion of refrigerant though frequently cold water or brine is used.

Common designs include (1) pierced-plate types in which the tubes pass through closely spaced thin metallic plates, (2) helical extended surface in which a ribbon of metal crimped or slit to accommodate curvature is wound in a helix about the central tube, and (3) the type in which fins are extruded directly from the tube body by rolling.

Heating Surface. Heating surface is generally similar to cooling surface in construction. Extended cast-iron surface is still used to some extent. Steam is an accepted heating medium, although the use of hot water is increasing, as it facilitates control.

Humidification and Humidifiers. In many comfort cooling applications and some industrial-process operations which have low winter heat loads and require only moderate humidification during the winter, this is accomplished by small sprays which introduce finely divided water droplets into the air steam usually directly before or after the heating coil so that evaporation is stimulated. Pan-type humidifiers in which water is evaporated into the air steam by steam coils or direct steam sprays may also be employed. It should be noted, however, that these procedures add to the loading within the space and therefore should be employed only where there is a deficiency in heat gain or a heating requirement.

In large commercial or industrial operations employing spray-type air washers for summer cooling and dehumidification, humidity control is usually achieved by maintaining a constant dew-point temperature and then allowing the air to rise to the dry-bulb temperature, resulting in the desired final relative humidity in absorption of heat gains within the space. It should be noted that the majority of industrial and many large commercial applications involve internal loading from power, lights, etc., which require the application of cooling during all seasons of the year when there is normal occupancy or operation. During winter this cooling may be obtained by outside air, as described subsequently for evaporative cooling, but there is no heating requirement during normal service.

The major shortcoming of the dew-point control method for humidity maintenance lies in the fact that there must be a fixed relationship between the maintained dew point and the final dry-bulb condition within the space to achieve the desired relative humidity. Thus there is a fixed relationship between the load and the temperature rise in supply air which may be taken to absorb this load, and this relationship may result in the requirement for excessively high circulating-air quantities, particularly if high relative humidities must be maintained as is common in many textile-mill operations.

Accordingly, in such operations where high relative humidities must be maintained with high continuous internal heat loads, common practice is to employ a *split system* in which the dew point of the circulating air is maintained at an arbitrarily low level which would normally result in insufficient humidification after absorption of the heat load, but the humidity is increased within the space by the direct application of water droplets from compressed-air or motor-operated mechanical atomizers. The atomized moisture introduced directly into the space is in water form and in the process of evaporation not only increases the relative humidity but also absorbs sensible heat from the space in the process of being converted from water to vapor at the room condition. The moisture thus introduced does not add anything to the heat load within the space and further, by the process noted above, increases the sensible-heat-absorbing capacity of the primary supplied air, thus making it possible to perform the required cooling with a substantially lower volume of circulating air than would be needed for the straight dew-point method.

Atomizers are also frequently used as prime means for humidification in areas such as textile mills. Employed in this fashion or with the central-station system, they also afford an excellent facility for direct humidity control in zones within a major area.

Evaporative Cooling. During intermediate seasons in normal climates or in climates such as prevail in dry mountainous country where temperatures are frequently excessive but humidities continuously low, evaporative cooling systems are very effective. Air is saturated adiabatically and thus assumes the wet-bulb temperature. Sensible cooling is thus done at the expense of increased humidity. Calculations for evaporative cooling systems are identical with those for other cooling loads except that 100% outdoor air is used.

Commercial evaporative coolers are similar to spray-type washers or humidifiers or spray-type dehumidifiers. The spray water is continuously recirculated by means of a pump.

Fans for Air Conditioning. Many different types of fan are used in HVAC systems, each of which has certain advantages. Centrifugal fans generate pressure by accelerating air outward from a fan wheel and then converting this kinetic energy to pressure. Centrifugal fans are able to generate relatively high pressures, but tend to be large and heavy with high WR^2 loads. Axial fans, on the other hand, generate pressure using the lift created by the fan blades much like a propeller. Axial fans generate high flowrates at low pressures and have low rotating-mass characteristics. In general, axial fans have to rotate much faster than do centrifugal fans to generate comparable pressures and flow rates. As a result, they tend to generate higher airborne noise levels. However, their lower weight and space requirements make axial fans preferable to centrifugal fans for many ventilation applications. Their high rotating speed requirements are also suitable for direct drive by 4-pole and 6-pole induction motors. By eliminating the belt, these fans are more compact and energy-efficient because of the avoided losses in the belt drive.

In residential applications, the forward-curved-blade centrifugal fan is commonly used because of its ability to generate pressure and flow at relatively low operating speeds. This low-speed operation allows forward-curved fans to generate low noise and structural vibrations. However, in general, forward-curved fans are relatively inefficient, and are not used in larger applications where long operating times can incur high energy costs. Residential HVAC fans are usually powered by single-phase, multispeed motors.

In many commercial applications, backward-inclined centrifugal fans are used to move large amounts of air. When equipped with airfoil-shape blades, these fans can achieve high operating efficiencies. In systems that are distributed over a large floorspace, smaller fans are installed throughout the system ductwork to boost air pressure to the points of delivery.

In many industrial applications, fans also serve to exhaust contaminants and to provide convective cooling by circulating air within a workspace. In simple applications, basic propeller fans are installed without ductwork in rooftops to remove inside air. In more complex applications, fan selection is based on the size, configuration, and pressure requirements of the ventilation system, air properties, contaminant levels, and number of operating hours. Radial-blade and radial-tip centrifugal fans are used in ventilation applications with high particulate levels. The shape of these blades prevents the accumulation of contaminants on the blade surfaces.

In emergency ventilation systems, fan operation is relatively infrequent; consequently, tubular axial fans are often used because of their low starting torque requirements and their space saving features. Most industrial HVAC fans are driven by NEMA Design B polyphase induction motors. Service factors for centrifugal and axial fans are typically 1.10 to 1.15.

Fans are commonly connected to V-belt drives. By using different pulley sizes between the motor and the fan, belt drives allow fans to rotate at slower speeds than their motors. Most fan motors are 2-pole, 4-pole, or—in some cases—6-pole, which rotate at 3600, 1800, and 1200 rpm, respectively. In many HVAC applications, multispeed motors allow the selection of two of these speeds. By using a larger pulley on the fan than the motor, the fan rotates at a lower speed, reducing noise and vibration levels. Speed reduction ratios range between 1–1.5 and 1–4.

Adjustable-Speed-Drive (ASD) Applications. In ventilation systems, the larger opportunities for energy improvement are through the use of variable-speed drive fans and variable-air-volume systems. *Variable-air-volume* (VAV) systems rely on the use of dampers at the point of air delivery to control the amount of heating or cooling air entering a space. VAV systems are improvements over previous system designs such as dual-duct and reheat systems. Dual-duct systems mix cool and warm air streams to achieve a desired delivery temperature. Reheat systems cool air to temperatures between 45 and 60°F, to remove moisture, then reheat it to the desired delivery temperature. Unlike VAV systems, which avoid the unnecessary heating and cooling of air, dual-duct and reheat systems are relatively energy inefficient. Adjustable-speed drives are well suited to operate with the circulating fans in VAV systems, can control the operating speed of a fan to regulate airflow, and can be equipped with feedback instrumentation that matches fan speed to system airflow requirements. By slowing fan speed during periods of low system demand, ASDs minimize the amount of excess flow energy imparted to the system.

Variable-frequency drives (VFDs) are the most common type of ASD. VFDs rely on rectifiers and inverters to adjust the frequency of the power delivered to the motor. VFDs can be combined with direct-drive units to offer attractive advantages in speed control, efficiency, and space savings. VFDs are widely used in commercial and industrial applications, and are included with up to 10% of all new fan installations.

Automatic Control. Most control devices depend on physical, thermal, or hygrostatic force for their operation. For example, thermostats frequently are operated by the distortion of bimetallic strips caused by the unequal expansion of the metals with increase in temperature or by the increase in pressure with rise in temperature of a liquid or gas contained in a closed element. Hygrostats generally depend on the expansion or contraction of human-hair strands with changes in humidity to perform the basic control operation, although silk, paper, or wood is used in certain applications. The thermostatic and hygrostatic elements usually operate other devices to perform the control operation.

Air-Conditioning Control Equipment. This equipment may be divided into three separate classes: self-contained, pneumatic, and electrical.

Self-contained devices are usually composed of thermostatic-fluid elements directly operating steam, water, or brine valves. These devices are not used where close control is necessary or where instantaneous tight shutoff is required. However, they are simple, cheap, and reliable and inherently give modulated control.

Pneumatic-control systems are those in which the thermostatic or hygrostatic element controls the rate of air leakage from a compressed-air system. The air pressure in the control system is used to operate diaphragm motors controlling valves and dampers. The spring loading of these motors can be varied so that within the given control-pressure range a whole sequence of separate valve and damper operations can be accomplished. Various types of relay and compensating arrangements are used to overcome inherent tendencies of such systems to override or "hunt" if set for high sensitivity or to give too wide a control range if set for low sensitivity.

The most common *electric thermostatic or hygrostatic controls* are of the *snap-action type*; that is, the condition change simply serves to cause the device to make or break an electric circuit, which in turn controls the major element or elements to be operated. Because of contact difficulties, line-voltage controllers generally use mercury-tube contactors, which limit the accuracy of control. All wiring to the control must be run in conduit. Low-voltage controls (24 V ac) which operate major motor drives or other elements through relays are more common; the light, open contacts permit accurate control, and open wiring (usually metal-clad) is allowed.

Electric controls employing thermocouples or resistance thermometers for sensing temperature conditions and various electrical leakage devices to determine humidity conditions are finding extensive application for air-conditioning control. However, for large-system work in the actuation of valves and dampers it is hard to find a satisfactory substitute for the pneumatic or hydraulic operator, so that electric or electronic control circuits usually act through other relays to actuate the major system elements by means of such operators. Nevertheless, there is an increase in the use of electric and electronic equipment because of the trend to centralizing main control observation, recording, and actuating points as a result of the complexity and extent of the systems being installed in large commercial and industrial operations.

Air-Conditioning Systems. *Central systems* are usually assemblies of air-conditioning apparatus designed to afford the necessary atmosphere control and may be arranged with (1) a single fan and single apparatus to care for one space; (2) two or more fans and a single apparatus to care for two or more zones; (3) a single fan blowing through warm and cool air chambers with mixing dampers delivering properly proportioned air to two or more zones; (4) a single apparatus and central fan delivering highly conditioned air to individual recirculating fans in two or more zones; or (5) a single central apparatus and fan with supplementary cooling or heating equipment in the ducts leading to two or more zones.

The wide application of air conditioning to multiroom, multistory commercial structures presents a number of problems which have resulted in the development of a number of new systems and techniques. Among systems in common use are the following:

1. The fan-coil system which employs individual units served with hot or cold water from a central circulating system or zone.
2. The high-pressure induction unit system where highly conditioned air at a high velocity is used to aspirate the flow of room air through localized heat-transfer coils supplied with hot or cold water from an external source, the primary air caring for ventilation and dehumidification while the secondary coil cares for the major sensible-heat gain or loss within the zone.
3. The low-pressure hot and cold plenum system in which each zone is supplied from a central unit or apparatus where warm and cold air are mixed as required to meet the zone demand.
4. The high-pressure double-duct system in which warm and cold air from central apparatus served through parallel trunk supply systems are mixed at a local distributing point in each zone through a sound-deadening mixing-valve device subject to control from the immediate zone.
5. The single-effect high-pressure interior system for substantial areas with relatively constant load characteristics with control for various sections by manual or automatic volume regulation, etc.

The Unit Air Conditioner. This is a factory-assembled system within a suitable casing of component apparatus necessary for atmosphere control which may include filters, sprays, cooling or heating coils, fan motor, dampers, etc. Unit air conditioners which include in the same casing the refrigerating system are defined as *self-contained unit air conditioners. Direct units* are those designed for location within the conditioned space. *Indirect or remote units* are those which are designed for location outside the conditioned space. *Free-delivery units* are those with fixed fan characteristics designed for use without air ducts.

Self-contained room air conditioners designed for mounting in a window or special opening through an outside wall have been highly developed as a plug-in appliance requiring only electrical connection. These units consist of filter and cooling coil, conditioned-air fan, and outlet and inlet grilles, together with refrigeration compressor, motor and drive, condenser air fan, and air-cooled condenser, the latter elements located outside the building wall.

These units are available with total heat-removal capacities in Btu per hour ranging from approximately 5000 to 24,000 and with nominal power input approximately 1 hp/10,000 Btu capacity. Units up through 8000 Btu capacity are generally suitable for operation on 115-V single-phase service. Larger units usually require 230-V single-phase service, but this is available for such use in most areas. Units of this type almost universally employ air-cooled condensers.

Self-contained commercial units with the refrigeration system built in as part of the factory assembly are manufactured in various sizes with nominal total heat-removal capacities ranging from 2 tons to in excess of 30 tons. Units in capacities of 2 to 10 tons are frequently employed as direct units within the space, and many employ water-cooled condensers. However, the current trend is to air-cooled condensers located external to the space. A number of designs are available in capacities ranging from 5 to 30 tons designed for roof mounting and complete with air-cooled condensers and in many instances with electric-resistance heating coils or automatic gas or oil-fuel burner systems for heating. Such units are sometimes used in multiple to take care of fairly substantial commercial or industrial areas in single-story construction.

Self-contained and factory-assembled condensing units complete with either water- or air-cooled condensers and suitable for connection to remote air-conditioning units are currently available in capacities of 2 to 75 tons.

Drives for Air-Conditioning Systems. There is no satisfactory substitute for electric-motor drive for the power auxiliaries of air-conditioning systems. Compression-refrigeration systems which are used in conjunction with the large majority of air-conditioning installations are primarily designed for electric-motor drive.

Fuel and Energy Conservation. Because of the rising cost of fuels and energy, and the rapid rate at which fossil fuels are being used, methods of energy conservation are being emphasized. Some of these include

1. *Use of computer programs* to determine the efficient energy use of the building or plant. Massive data relating to constants and variables, such as building occupancy, fuel consumption, and electrical characteristics of the building, are fed into the computer and compared with programs to conserve fuel. An analysis of the comparison shows which proposals are feasible and which are not.
2. *Automated monitoring* of key systems; for example, logic controllers can be set up on boilers to ensure efficient fuel utilization automatically.
3. *Heat-recovery systems*. Heat-recovery cooling units are growing in popularity; typical systems can be water-to-air or air-to-air types. Heat is recovered from areas of a building or plant that requires cooling and transferred to a portion of the plant that requires heating. Some systems recover flash steam for building heating, and still other systems can turn a dust-collection unit into a heating system by filtering the dust and particles through a hopper into drums for disposal, while redirecting the clean filtered air into the plant or building for heating.
4. *Solar air conditioning, heating, and cooling*. Solar collector arrays and reflector panels are located on a building's roof and are capable of regulating and storing the energy received from the sun for equal distribution during the day.

21.15.2 Refrigeration

Refrigeration Cycles. All practical refrigeration cycles produce heat removal by free evaporation in an enclosed chamber (evaporator) of a liquid (refrigerant) under pressure conditions that produce the desired evaporation temperature. The refrigerant liquid absorbs its latent heat of vaporization from the medium being cooled and in this process is converted to vapor at the same pressure and temperature. This vapor is conveyed to another chamber (condenser), in which the pressure is maintained at a level sufficiently high to permit condensation of the refrigerant by water or air at normal temperatures. The heat quantity abstracted in the condenser is the latent heat of condensation (or vaporization reversible) of the refrigerant fluid, together with the heat that has been added to the refrigerant in the process of conveying it from the evaporator pressure level to the condenser pressure level. The condensed refrigerant (liquid) is allowed to flow from the condenser, through suitable throttling valves, back to the evaporator to repeat the cycle.

Unit of Refrigeration. The standard unit of refrigeration is the ton, which is considered as heat removal at the rate of 200 Btu/min or 12,000 Btu/h or 228,000 Btu/24 h. This rate of cooling is about equivalent to the average cooling effect obtained by melting 1 ton of ice in 24 h at 43°F (latent heat of fusion of ice is 144 Btu/lb).

Refrigeration Systems. Practical refrigeration systems differ only in the method used to convey the refrigerant vapor from the evaporator, or low side, to the condenser, or high side. In closed refrigeration systems, three methods are used to accomplish this transfer: (1) mechanical compression or pumping of the refrigeration vapor, (2) chemical absorption of the refrigerant vapor at low pressure with subsequent transfer to the high side as solute in a solution, and (3) physical absorption of the refrigerant vapor at low pressure with subsequent transfer to the high side as adsorbed vapor in a solid. Related to systems (2) and (3) are absorption and adsorption dehumidification systems used in air-conditioning processes requiring drying of air without cooling it.

Compression-Refrigeration Cycle. In the compression-refrigeration cycle a mechanical compressor or pump is used to convey the refrigerant vapor from the (low) evaporator pressure to the (high) condenser pressure. Vapor is drawn from the evaporator, where it has been evaporated in performing the cooling work, and is compressed and delivered to the condenser where it is liquefied, its latent heat of vaporization being absorbed by the condenser-cooling medium, which is usually water or air at normal temperature. The liquefied refrigerant is collected in the bottom of the condenser or in a separate container called a "receiver" and from there is fed back to the evaporator through suitable throttling valves.

There are three types of mechanical compressor in common use: (1) the reciprocating compressor, (2) the rotary compressor, and (3) the centrifugal compressor. To these must be added the jet compressor, which, while not usually considered as a mechanical compressor, is quite similar in operation. The *reciprocating and rotary compressors* are positive-displacement compressors; that is, each cycle of the compressing member definitely opens a fixed volume into which fluid flows and then closes or occupies that same volume, forcibly expelling the fluid. The centrifugal or jet compressors depend for compression on the kinetic or velocity energy imparted to the fluid.

The *reciprocating compressor* is suited to the compression of relatively small volumes of fluid through a high-pressure range. The *rotary compressor* is suited to the movement of moderate fluid volumes through moderate pressure ranges. The *centrifugal compressor* is suited to the movement of large volumes of fluid through small pressure ranges. Ammonia, carbon dioxide, Freon-12, methyl chloride, and sulfur dioxide are almost always used with reciprocating compressors. Freon-21 is used with rotary compressors, while Freon-11, methylene chloride, and water are used with centrifugal compressors.

Refrigerants. The refrigerants which are used commonly enough to merit classification by the National Board of Fire Underwriters are listed in Table 21-12. The Freon group is now among the most widely used of all refrigerants. These halogenated hydrocarbons are chiefly derived from methane (CH_4) by the replacement of hydrogen molecules with chlorine and fluorine molecules and include F-11, F-12, and F-22.

Those listed as inflammable or in toxicity classification groups 1 to 4 (mildly to seriously toxic depending on concentration, exposure, etc.) include ammonia, butane, dichloroethylene, ethane, ethyl bromide, ethyl chloride, methyl bromide, methyl chloride, methyl formate, propane, and sulfur dioxide.

Those listed as nonflammable (or practically so) and less toxic than group 4 (nontoxic in normally possible concentrations) include carbon dioxide, dichlorodifluoromethane (F-12), monochlorodifluoromethane (F-22), dichlorotetrafluoromethane (F-114), monofluorotrichloromethane

Note: Figures are based on standard conditions and dry compression and represent the theoretical performance of the refrigerants for these conditions based on their thermodynamic properties. Figures for carbon dioxide and water are unfavorable under standard conditions, since 86°F condensing temperature is close to the critical temperature of CO_2 and 5°F suction temperature is below the freezing point of water.

(F-11), and methylene chloride (dichloromethane). Water is also used as a refrigerant and is, of course, considered as nontoxic and nonflammable.

Refrigerant Properties. Physical and thermodynamic properties of the nine most commonly used refrigerants and comparison of the performance of these refrigerants with the ideal (Carnot) cycle for standard conditions are listed in Table 21-12.

Ammonia is cheap and easily available; its efficiency is so high that it is the practical standard by which other refrigerants are rated. For these reasons it is widely used for ice manufacture and food processing, for example, ice-cream manufacture, meat packing, cold storage, and brewery refrigeration.

Freon refrigerants, which have satisfactory characteristics with respect to toxicity and flammability as well as stable operation characteristics within the normal range, have largely replaced carbon dioxide for air conditioning, etc., where toxic refrigerants present a public hazard.

Methyl chloride, sulfur dioxide, and Freon refrigerants find broad application in commercial and domestic refrigeration service.

Effect of Operating Conditions on Compressor Capacity and Power Requirement. The capacity of any refrigerating compressor depends on the mass of refrigerant vapor that it can convey from the low- to the high-pressure condition. The power requirement of the compressor depends on the mass of vapor conveyed and the pressure differential between the evaporator and the condenser. For this reason the capacity and power requirement of any given compressor operating at constant displacement vary widely depending on the temperature and pressure conditions of the suction and discharge vapor.

It should be noted that although the unit power requirement is much greater for low suction temperatures, the capacity of a constant-displacement machine is greatly reduced owing to reduced density of the vapor and reduced volumetric efficiency, so that the gross power requirement may be far below that at higher suction temperatures. For this reason it is general practice to operate belt-driven compressors at higher speeds when used at lower suction pressures to obtain greater displacement and capacity within the safe power rating of the machine. Care must be exercised in selecting equipment to be sure that safe power limitations will not be exceeded during start-up periods when abnormally high temperatures may be encountered owing to high refrigerant temperatures. This is a very important consideration in the design of ultra-low-temperature systems, especially those employing multiple compressors in cascade arrangement. Within the normal range of condensing temperatures, the change in vapor density is not so pronounced, and the chief effect of departure above the design condensing temperature is a reduction in the output of the compressor.

Evaporators. The largest classification of evaporators for direct air cooling is surface-cooling coils. For cooling water or brine, simple arrangements of submerged pipe coils or plate surface are sometimes used for small applications, especially where refrigeration storage is desirable. More widely used with reciprocating-compression equipment is the so-called dry-expansion liquid cooler in which refrigerant is expanded into the tube surface within a shell and water passed under forced circulation across the tube surface as directed by baffles. Some larger reciprocating-compressor installations and all large-capacity centrifugal refrigeration systems employ a conventional shell-and-tube surface, with forced circulation of water through the tubes, which are mounted within a pool or evaporating refrigerant within the shell surface.

The majority of such applications employ integrally finned tubing.

Expansion Methods. Two general types of refrigerant expansion are employed: (*a*) dry expansion and (*b*) flooded expansion.

In the *dry-expansion system* the refrigerant is introduced into the evaporator through an expansion valve or pressure-reducing valve and makes one pass through the evaporating surface going to the compressor or absorber suction line. Since any liquid refrigerant which leaves the evaporator represents a loss of cooling effect, care is taken to assure only dry gas leaving the evaporator. The constant-pressure valve has been largely supplanted by the thermal-expansion valve, which through the use of the self-contained thermostatic-valve principle controls the flow of refrigerant to give a constant superheat at the outlet of the evaporator regardless of the load. Dry-expansion systems are widely used with expensive refrigerants, since only a minimum refrigerant quantity is required to feed the evaporator properly. The dry-expansion system also permits feeding evaporators from the top so that any oil carried in the refrigerant will flow through the evaporator and be conveyed back to the compressor.

The flooded-expansion system maintains through float-valve control a constant level of refrigerant in the evaporator. In coil-type evaporators this is accomplished by means of a surge chamber external to the coil, usually located above the top and bottom of the coil. Refrigerant is fed into the surge chamber, which is connected with the top and bottom of the coil and to the suction line. As liquid refrigerant passes up through the evaporator coil, its density is reduced owing to the formation of vapor bubbles, so that the refrigerant circulates rapidly through the coil to the surge chamber, where the gas bubbles are released to the suction line. The major disadvantages of the flooded system are the relatively large refrigerant charge required and the necessity of providing means for oil removal when refrigerants that mix readily with oil are used.

Condensers. The function of the condenser is exactly the reverse of the evaporator, that is, to afford a rapid transfer of heat from the condensing refrigerant to the cooling medium. For this reason there is a great similarity between condensing and evaporating equipment. Air-cooled condensers are frequently used with small compression systems which are located in well-ventilated places and where the difficulty of obtaining water supply and drain connections is not commensurate with the operating economies realized through the use of water cooling. Air-cooled condensers are similar in construction to surface-cooling coils.

Because of the effect that high condensing pressures have upon the economy of operation of refrigeration plants, water-cooled condensers are widely used. It is customary to assume the condensing requirement of the average compression plant to be 15,000 Btu/(ton)(h), of which 12,000 Btu represents the cooling work, and 3000 Btu the energy applied in heat pumping. This amount of heat can be absorbed by 1 gal/min of water rising through 30°F, 2 gal/min through 15°F, or 3 gal/min through 10°F. The design of the condenser and the amount of water required will depend on the available water temperature and the desired condensing temperature and pressure.

Water Conservation. The increased use of tap water for condensing purposes in air-conditioning and refrigeration installations has seriously taxed the *water-supply* and *water-disposal* systems of many cities, with the result that restrictions in the form of increased water rates for condensing purposes, taxes on water disposal, or outright prohibition of the use of water for condensing purposes have been effected by many municipalities. This has resulted in the development of equipment for the conservation of water. The familiar *cooling tower* has been redesigned to meet requirements of downtown buildings as to size and appearance, and the spray pond and atmospheric cooling tower find broader application in the industrial field. With spray ponds and atmospheric towers usually 5 gal/(min) · (ton capacity) is allowed with water temperature entering the condenser at 10°F above the maximum outside wet-bulb temperature. With forced-draft towers usually 3 gal/min · ton will suffice with the same temperature limits.

Thoroughly accepted in this field is the *evaporative condenser*, which consists of an extended-coil condenser over which air is driven by fans and which is continually bathed in a water spray. Efficient condensing effect is obtained by the combined effect of air cooling and evaporation of water by the hot condenser coils. Small sizes for capacities up to 5 tons use propeller fans and direct tap-water connection for spray. Larger sizes (condensers in excess of 250 tons capacity have been built) are quite similar to unit air conditioners and employ centrifugal fans and a recirculating-spray system with a centrifugal pump.

Maintenance difficulties attendant upon the use of either cooling towers or evaporative condensers have resulted in a vast increase in the application of air-cooled condensers for reciprocating refrigeration systems in capacities up to 200 tons and possibly higher. While the use of air-cooled condensers results in a considerable operating-power penalty under maximum temperature condition, the apparatus employed is simple and relatively maintenance-free, factors which frequently justify the power penalty resulting from their use.

Refrigeration Compressors. Three basic types of compressor are used in refrigeration and electric chiller applications: reciprocating, rotary, and centrifugal.

Reciprocating compressors are typically used in applications below 250 tons. Reciprocating compressors are less efficient than other compressor designs, using between 0.75 and 1.0 kW/ton.

The design of reciprocating compressors has been profoundly influenced by development of the production-line internal-combustion engine as offered today for automotive and aircraft service. Multicylinder in-line arrangements of 2 to 8 cylinders are thoroughly accepted, as are V and W arrangements of 4 to 16 cylinders and radial arrangements of 3, 5, and 7 cylinders. Practically all machines are single-acting with enclosed crankcases. With multicylinder design, large capacities are obtainable with good balance and relatively low piston speed, so that it is not unusual for machines of up to 120 tons capacity, with forced-feed lubrication, to operate at speeds as high as 1750 r/min. Speeds below 500 r/min (except with very large machines) are the exception rather than the rule. Capacity variation is obtained by unloading groups of cylinders or by bypass or clearance-pocket arrangements.

The overall application of refrigerated air conditioning to large industrial and commercial buildings requires capacities far beyond the range of the largest ice-making or storage refrigeration installations. These requirements have been met adequately by development in the *centrifugal refrigeration* system, which finds current application in single units from 200 to 1800 tons or over in capacity. Drive motors will vary from a low of 0.85 hp/ton for industrial applications to a high of 1.05 hp/ton for commercial installations.

Rotary compressors are available in a number of different versions, including vane, scroll, and screw designs. Screw compressors are used in applications up to 1200 tons. Rotary-vane compressors are used in a wide range of applications from small residential refrigeration units to large, rugged industrial processing plants.

Scroll compressors are typically used in applications below 15 tons. Scroll compressors have some key operating advantages in terms of efficiency and reliability. Although scroll-compressor designs were developed in the early 1900s, their complicated geometry discouraged mass production and the design was never fully commercialized until the 1970s. Advances in manufacturing techniques have enabled the cost-effective production of scroll compressors. As a result of certain performance and reliability advantages, the use of scroll compressors is increasing. Scroll compressors are typically used in smaller refrigeration units, less than 15 tons. Screw compressors are used over a wide range of system capacities, from 50 to 1200 tons. Versions of screw compressors include single helical screws and double-helical screws. Screw compressors operate between 0.6 and 0.75 kW/ton.

Centrifugal compressors are commonly used in applications as large as 2000 tons and in systems as small as 80 tons. Centrifugal compressors offer many advantages, including high efficiency and good reliability. Centrifugal units operate between 0.55 and 0.8 kW/ton.

The original designs for centrifugal systems employed multistage compressors with shaft seals and operating at speeds from 3500 to 7000 r/min. Standard 4-pole or 6-pole open motors with step-up gears were customarily used for compressor drives. Wound-rotor motors affording 25% speed regulation were frequently employed for capacity control. However, since 1955 design has largely been directed toward hermetic systems in which the drive motor is enclosed in the gas passage with the compressor, and with this arrangement the drive is naturally limited to the use of the squirrel-cage induction motor. Control of compressor capacity is afforded by regulating dampers in the compressor suction connection. Common designs employ either two-stage compressors direct-driven by 2-pole motors at approximately 3500 r/min or single-stage compressors operating at 11,000 r/min or higher and driven through step-up gears by enclosed 2-pole motors. One design employs an external frequency converter providing 300-Hz current for operation of a 2-pole induction motor for direct compressor drive at approximately 17,500 r/min. Centrifugal compressors are still offered without the enclosed motor and with the shaft extended through the compressor housing with a suitable seal; as such they can employ the open-motor or turbine drive. However, the general design and control arrangement of the system is generally the same for either hermetic or open drives for manufacturing standardization. Even with open units induction-motor drives are generally selected, for though motor sizes are large, average experience indicates that even where power- factor penalties are involved, power-factor correction can be obtained more economically by the use of capacitors in connection with induction motors rather than through the use of synchronous motors. Where closed motors are employed for compressor drive, they are cooled either by water jacketing or by an arrangement employing a bypass of refrigerant or refrigerant gas for motor cooling.

Compressor Drives. While conventional open motors and V-belt drives are generally employed for large-capacity, low-speed reciprocating compressors, which are still offered, the bulk of the production of reciprocating equipment is now of the direct-drive design generally employing 4-pole 1750-r/min motors. This design permits an extremely compact arrangement which is well suited to the unit-system combinations now widely offered by the industry.

In both the reciprocating and centrifugal compressor fields there is contention as to whether the use of standard open motors or sealed hermetic arrangements is most acceptable. The use of standard open-motor drives necessitates the shaft seal, which offers some disadvantages. The use of the hermetic arrangement requires careful design of the electrical components and close control of the refrigerant atmosphere, which must be kept absolutely moisture-free if electrical problems are to be avoided. Obviously, if failure occurs, the repair of the hermetic motor is a far more serious problem than the repair of the open motor. On the other hand, if properly designed and installed the fully enclosed motor operates in a controlled atmosphere and may be less likely to give trouble. However, with either arrangement the motor is generally a standard 2-pole or 4-pole induction motor as far as the basic electrical design is concerned.

Reciprocating systems generally employ means of unloading by holding suction valves open to afford capacity control in operation and are similarly arranged to start unloaded. Centrifugal systems employ dampers for capacity control, which are kept closed during the starting cycle so that these units also start unloaded. However, the characteristics of the reciprocating system are such that the starting-torque requirement is fairly high. Accordingly, line start for drive motors is preferred wherever utility-company regulations will permit, and since these units are usually to approximately 125-hp maximum size and are frequently installed in multiple units of smaller capacity, line start is generally permissible. Where reduced voltage starting is required, autotransformer or resistance-type reduced-voltage starters are generally employed, although frequently these may be effective only as a means of reducing inrush, as in many instances full line voltage must be applied before the compressor will actually pick up the load.

Centrifugal refrigeration systems generally represent larger-capacity units than reciprocating systems, with motor sizes ranging from 75 to 2000 hp or occasionally higher. However, their starting-torque requirement is very moderate, and it is entirely practical to place the compressor in satisfactory operation by use of the Y-Δ starting system, in which the compressor drive motor is connected across the 3-phase source in a Y arrangement during the starting interval and switched to the Δ connection when the compressor has reached practically full speed and before the compressor damper is opened, permitting the unit to assume load. With this arrangement the current during the starting period can be limited to approximately 130% of the normal full-load running current, and this arrangement is generally entirely satisfactory to power companies. This starting arrangement is almost universally employed with centrifugal systems except for relatively small units, which may be within a range suitable for line start.

Motor Voltage. All standard equipment is based on the assumption that 60-Hz current is available, although some manufacturers will still list a capacity rating of their units of 60-Hz design when employed on 50-Hz service. All systems involving motors up through 5 hp are generally designed for 230-V 60-Hz 1-phase service, but in sizes 3 hp and above are equally available for 208/220/440-V 60-Hz 3-phase service, which is generally available in most urban areas. Equipment for practically the entire available capacity range is designed for service on 208-V 60-Hz 3-phase current, which is commonly available as urban low-voltage distribution. However, it should be noted that because of the rigorous nature of compressor service it is usually inadvisable to attempt to use 220-V equipment for the compressor drive where only 208 V is supplied. Many feel that good design dictates the use of 200-V motors for such service. For larger commercial or industrial applications which are provided with primary service through independent substations, 440-V 60-Hz 3-phase equipment is generally preferred, as it permits a substantial reduction in wiring cost. Currently a number of systems employ 480/277-V 60-Hz 1-phase 4-wire service, where the higher single-phase voltage may be satisfactorily used for fluorescent-lamp operation. This arrangement affords considerable economy in circuit design but presents complications with respect to the use of standard 115-V 60-Hz 1-phase conventional power or office equipment, for which separate transformers and circuiting must be provided. In the textile industry extensive use is made of 550-V 60-Hz 3-phase service, and equipment is generally available throughout the entire capacity range for this voltage characteristic. In larger plant operations employing plant primary service at either 2300 or 4160 V, these voltages are frequently used for large compressor drives, and most lines make equipment available for this voltage in the range from 200 to 2000 hp, although economics would generally indicate 500-hp drives as being the lowest acceptable size for this voltage.

Reverse-Cycle or Heat Pump. The reverse-refrigeration cycle is for the purpose of heating interiors with electricity. Heat absorbed at a low-temperature level is pumped to a level sufficient to permit satisfactory heating with the expenditure of only the amount of energy necessary to perform the pumping work, which is also reclaimed at the high-temperature level. Under certain circumstances this cycle is entirely practical. Many installations have been made where well water at moderate temperatures (±50°F) is available as a low-temperature heat source, and these installations have shown coefficients of performance up to 400%, that is, 5 Btu of heating effect for 1 Btu of energy applied. However, the performance of the refrigeration machine is sharply limited as the temperature head between the evaporator and the condenser is increased, so that the practical possibilities of this cycle are affected not only by the cost of electrical energy compared with other fuels but by the level of the low-temperature heat source and the temperature that must be maintained within the interior.

Application of air conditioning to residences has accelerated activity in the heat-pump field. Since the basic refrigeration equipment is being installed for summer conditioning, its utility is increased by arranging it to handle at least a part of the winter heating requirements. Most new developments are directed toward the use of outside air as a low-temperature heat source as well as a means for providing condensing effect when the system is on the cooling cycle. Heating capacity of such a system will drop fairly rapidly as outside temperatures drop. However, there is a balance point between the requirement for summer cooling and available capacity for winter heating which will permit a rationally designed apparatus to care for the full heating requirements on the reverse-cycle basis for substantial periods during the heating season. Naturally, the more temperate the climate in which the apparatus is employed, the greater proportion of the total winter heat requirement can be handled entirely by the heat-pump principle. Since peak heating demand is experienced only for short periods, usually during early morning hours, the current procedure is to supplement the available output of the heat-pump device by direct resistance heating. This represents a substantial spot load, but its period of use is relatively short, and under most utility rate schedules the overall economies of the operation are reasonable. However, it presents problems in power distribution. A moderate-sized residence in the South Atlantic area with a basic 6-kW requirement for summer or heat-pump operation may be supplemented with as much as 12 kW of additional resistance heating load for use during peak heating periods. This imposes a maximum load of up to 18 kW per residential unit on the lines of the utility, with little possible diversity.

On the other hand, this load occurs at a time when other urban loads are at a minimum and when outside ambient-temperature conditions are at a very low level, so that distribution circuits, transformers, etc., can handle a substantial overload with no difficulty. Accordingly, utility companies are finding that they can handle this load with no serious problems and feel that it is attractive.

A number of ingenious arrangements employing the heat-pump principle or other heat-recovery systems have been incorporated in designs of installations for large commercial buildings. It is evident that the core sections of these buildings are subject to cooling requirements throughout the entire year, as they are shielded from exterior exposure, but subject to heat gains from lighting and occupancy. A number of systems have been employed which use refrigeration for these interior zones throughout the entire year but during the wintertime take the effluent heat from the condenser of the refrigeration system and apply this as a means of heating the periphery of the building which is subject to normal winter exposure. Thus, in effect, the excess heat from the interior core of the building is transferred to the exterior for heating purposes while affording control of the heat load within the core of the building.

Other arrangements provide for direct cooling of lighting equipment either by circulating water or by exhaust ventilation and transfer the heat thus directly recovered to the periphery of the building for heating purposes. There are obviously many possibilities of this nature which must be studied for each individual project. However, where this means of heating is used, it is dependent on a continued supply of electrical energy to the space as a primary heat source. In some instances arrangement is made to turn on interior lighting during cold periods for the purpose of heating the premises, or where lights are turned off, the equivalent amount of electrical energy may be applied through resistance heating, thus affording a heat source with no increase in electrical demand. These arrangements frequently make full electric heating entirely practical and economical for many large buildings.

Refrigeration Storage: Moderate Temperature. Many refrigeration applications having high peak loads for short periods of time can be most economically handled by the use of relatively small refrigeration machines which are operated over long periods of time to store refrigeration effect to meet the high short-period requirement. Refrigeration effect may be stored in bodies of brine or water, though a relatively large storage volume will be required, since the water or brine can only absorb or give up its sensible heat. A more efficient storage method involves the formation of ice on submerged evaporating coils. Every pound of ice thus formed absorbs and can release, on melting at 32°F, its latent heat of fusion, 144 Btu/lb.

This principle has been frequently used to improve the load factor of refrigeration systems used in conjunction with air-conditioning systems having relatively short use periods (restaurants serving only one meal a day, theaters with only evening showings, and churches or infrequently used auditoriums).

Refrigeration Storage: Low Temperature. A solution of water and salt (or, in general, of any two substances) has a certain concentration which results in the lowest freezing temperature. A solution of this concentration is known as a *eutectic mixture*. A brine with a salt content lower than this concentration will start to freeze above this minimum temperature, and as cooling progresses, pure ice crystals will freeze out, thus increasing the concentration of the brine until the eutectic concentration is reached. At this point freezing will take place at a constant temperature until all latent heat is removed, the resulting crystals being a mechanical mixture of salt and frozen water. If the starting salt concentration of the mixture is greater than the eutectic concentration, salt crystals will first freeze out until the eutectic concentration is reached.

The use of eutectic mixture as a means of storing refrigerating effect, that is, latent heat of fusion, at a temperature below 32°F (the freezing point of water ice) has received wide attention. The eutectic mixture of water 76.7% and sodium chloride (common salt) 23.3% has a freezing temperature of –6°F, and a latent heat of fusion of 101.5 Btu/lb is available at this temperature. Plate evaporators charged with eutectic mixtures are frequently used in refrigerator trucks which are cooled at night to produce sufficient stored cooling effect to meet the next day's operation.

22.1 INTRODUCTION

22.1.1 Role of Power Electronic Converters

Power electronics is an enabling technology that achieves conversion of electric power from one form to another, using a combination of high-power semiconductor devices and passive components— chiefly transformers, inductors, and capacitors. The input and output may be alternating current (ac) or direct current (dc) and may differ in magnitude and frequency. The conversion sometimes involves multiple stages with two or more converters connected in a cascade. The end goals of a power electronic converter are to achieve high efficiency of conversion, minimize size and weight, and achieve desired regulation of the output. Figure 22-1 shows power electronic converters in a generic application.

22.1.2 Application Examples

Power electronic converters can be classified into four different types on the basis of input and output, *dc-dc, dc-ac, ac-dc,* and *ac-ac,* named with the first part referring to the input and the second to the output. The diode bridge rectifier is the front end for most low-power converters. It converts line frequency ac (e.g., from a wall outlet) to an unregulated dc voltage, and the process is commonly called rectification. In a *dc-dc* converter, both the input and the output are dc, and in the simplest case the output voltage needs to be regulated in presence of variation in load current and changes in the input voltage. A computer power supply has a diode bridge front end followed by a dc-dc converter, the combination of which converts line frequency ac voltage to several regulated dc voltages (Fig. 22-2). Electronic ballasts for compact fluorescent lamps consist of a line frequency rectifier followed by a dc to high-frequency ac converter (frequency range of 20 to 100 kHz) whose output is connected to a resonant tank circuit that includes the load. In an adjustable speed motor drive application (Fig. 22-3), the input is a 3-phase ac supply, and the output is a 3-phase ac whose magnitude and frequency are varied for optimum steady-state operation and dynamic requirements of the drive.

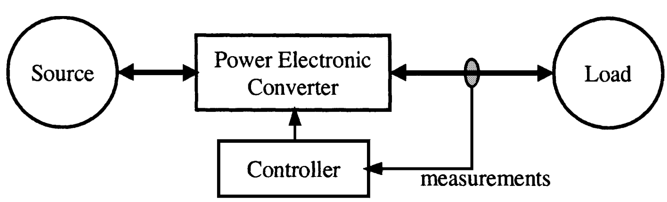

FIGURE 22-1 Application of power electronic converters.

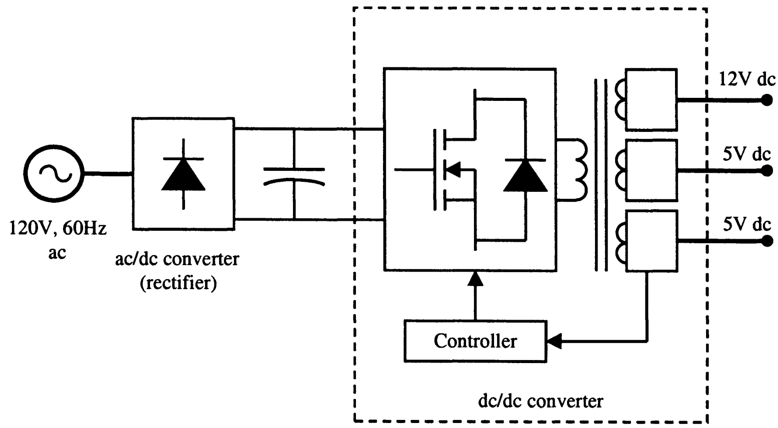

FIGURE 22-2 Computer power supply.

Development of power semiconductors with very high voltage and current ratings has enabled the use of power electronic converters for utility applications. In transmission systems, power electronic converters are being utilized to control power flow, damp power oscillations, and enhance system stability. At the distribution level, power electronic converters are used for enhancing power quality by means of dynamic voltage restorers, static var compensators, and active filters. Power electronic converters also play a significant role in grid connection of distributed generation and especially renewable energy sources; their functions include compensation for steady state and dynamic source characteristics leading to optimal energy transfer from the source, and protective action during contingencies.

Future automotives are expected to have a large number of power electronic converters performing various functions, for example, electric power steering, active suspension, control over various loads, and transferring power between the conventional 14-V bus and the recently proposed *42-V Power Net* [1]. Hybrid electric and all-electric vehicles also utilize controlled power electronic converters for interfacing the battery and motor/generator.

The proliferation of power electronics connected to the utility grid has also led to power quality concerns due to injection of harmonic currents by grid-connected inverters, and highly distorted currents drawn by diode bridge rectifiers. Due to fast transients of voltages and currents within power

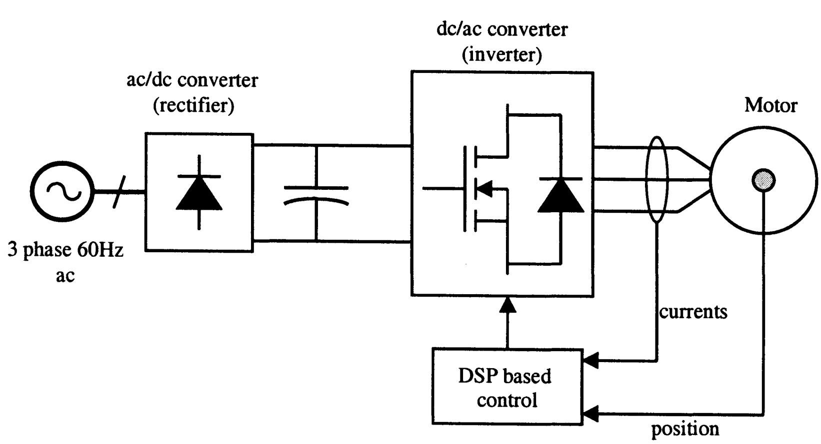

FIGURE 22-3 Adjustable speed motor drive.

converters, they can be a source of electromagnetic emissions leading to electromagnetic interference. Several solutions to limit and correct these effects have therefore been developed.

22.1.3 Scope and Organization

This section gives an overview of power electronic systems. Details of specific converter types and applications have been omitted and only the fundamentals are presented. In some cases, important results are stated without derivation. Mathematical content has been kept to a minimum. In places, empirical aspects have been included, since power electronics is an application-oriented discipline. Design procedures are presented with only those justifications that were deemed imperative. A long list of references consisting of textbooks on the subject of power electronics, reference books on specific areas and applications of power electronics, important research publications, and several online sources has been provided. The reader is expected to use this section as a starting point, followed by the references on the topic of particular interest.

First, the basic principles for analysis and design of power converters are presented in Sec. 22.2. Topology and operating principles of the four types of power electronics converters are described with one section devoted to each. A very simple description of power electronic converter control is presented using the example of dc-dc converters. This is followed by deleterious effects of power electronic converters and precautions necessary to limit or correct them. Applications are described next bringing together the requirements and complete power electronic system realization for some specific examples. Finally, the individual components that constitute a power electronic converter are discussed. Current research initiatives and expected future trends are indicated in each section.

22.2 PRINCIPLES OF SWITCHED MODE POWER CONVERSION

This section presents some basic principles that are common to the analysis of all switch mode power converters. Line-commutated power electronic converters are not, strictly speaking, switched mode converters; they are discussed in Sec. 22.6.

22.2.1 Bipositional Switch

The most basic component of a switch mode power converter is the bipositional switch shown in Fig. 22-4*a*. Nodes 1 and 2 of the switch are invariably connected across a dc voltage source (or across

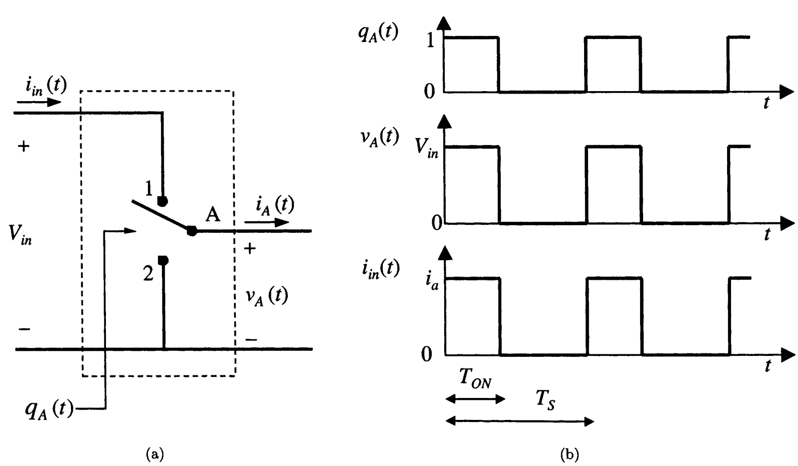

FIGURE 22-4 (*a*) Bipositional switch (*b*) switching waveforms.

TABLE 22-1 States of a Bipositional Switch

$q_A(t)$	Switch position	MOSFET & diode state	Pole voltage & input current
1	1	S1 & D1 ON, S2 & D2 OFF	$v_A = V_{in}$, $i_{in} = i_A$
0	2	S1 & D1 OFF, S2 & D2 ON	$v_A = 0$, $i_{in} = 0$

a big capacitor whose voltage is close to a constant dc), and pole "A" of the switch is in series with a dc current source (or a big inductor whose current is close to a constant dc). This bipositional switch, which is also referred to as a switching power pole, switches at very high frequencies, and is controlled by the signal $q_A(t)$. The switched pole A voltage and the input current based on the control signal $q_A(t)$ are listed in Table 22-1, and the corresponding waveforms are shown in Fig. 22-4*b*.

Figure 22-5*a* shows the electronic implementation of a complete bipositional switch using metal-oxide-semiconductor field-effect transistors (MOSFETs). This implementation can support pole current in either direction and is useful for applications where current direction can reverse. In most dc-dc converter applications, the current through the pole *A* is unidirectional, and hence, the implementation shown in Fig. 22-5*b* is sufficient to realize the bipositional switch.

22.2.2 Pulse Width Modulation

The concept of pulse width modulation (PWM) is central to all switch mode power converters. Pulse width modulation refers to the control of the average value of a switching variable, for example, $v_A(t)$ in Fig. 22-4*b*, by controlling or modulating its pulse width. Some basic concepts and definitions necessary to understanding PWM are presented here.

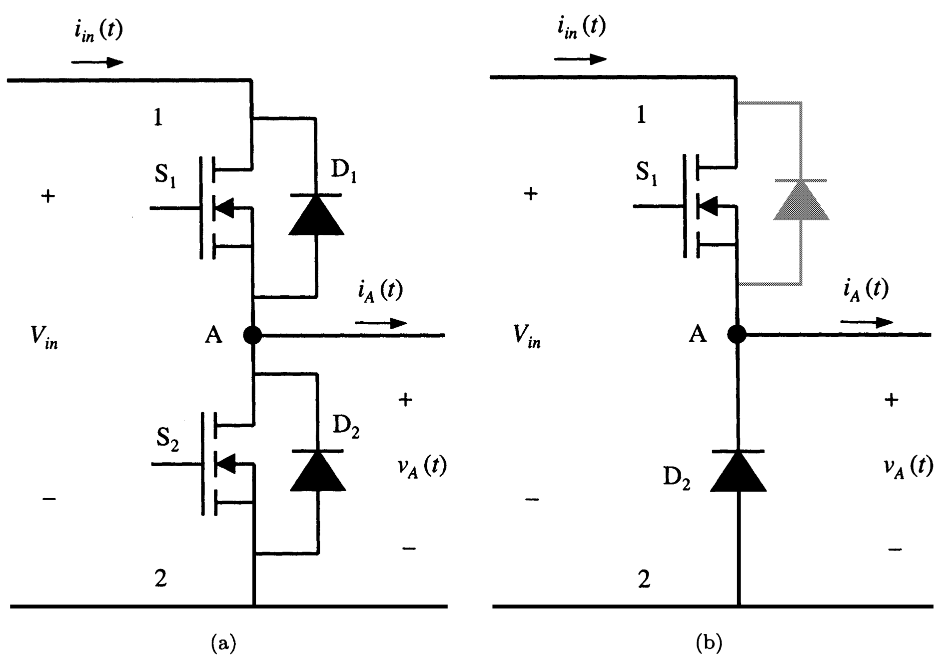

FIGURE 22-5 Electronic implementation of bipositional switch: (*a*) for bidirectional pole current (*b*) for unidirectional pole current.

Duty Ratio. The frequency at which the bipositional switch is switched on and off is denoted by f_s, and the corresponding time period by T_s (= $1/f_s$). The transition between the two states of the switch occurs in a very small duration compared to T_s. The time for which the switch remains in position 1 during a switching period is denoted by T_{on}. The duty ratio d of the bipositional switch is then defined as the ratio of on-time to total time period:

$$d = \frac{T_{on}}{T_s} \tag{22-1}$$

Averaging. Currents and voltages in power electronic converters have (1) high-frequency components corresponding to the switching frequency of the bipositional switch elements, and (2) low-frequency components due to slower variations caused by change in load demand, source magnitude, and changes in reference value of the desired outputs. For dynamic control and steady-state analysis, the low-frequency components are of primary interest. To study these components, it is sufficient to study their averages over one switching time period. It should be noted that the averaging presented here [2] is a very basic form of the general averaging method [3] and has limitations in terms of validity with respect to the switching frequency. However, this simplification is good enough for most practical purposes, and can be confidently used for steady state and dynamics up to one-fifth the switching frequency. Throughout this chapter the averaged variables, that is, averaged over one switching period, are denoted by a "-" on top of the variables. Thus, the averaged value of $x(t)$ is given by

$$\bar{x}(t) = \frac{1}{T_s}\int_{t-T_s}^{t} x(\tau)\, d\tau \tag{22-2}$$

In steady state, the average values of $q_A(t)$ and $\upsilon_A(t)$ are given by

$$\bar{q}_A = \frac{1}{T_s}\int_0^{T_s} q_A(\tau)\, d\tau = \frac{1}{T_s}\int_0^{T_{on}} 1\, d\tau = \frac{T_{on}}{T_s} = d \tag{22-3}$$

$$\bar{\upsilon}_A = \frac{1}{T_s}\int_0^{T_s} \upsilon_A(\tau)\, d\tau = \frac{1}{T_s}\int_0^{T_{on}} V_{in}\, d\tau = d \cdot V_{in} \tag{22-4}$$

In general, the averaged quantities can be time varying, since the pulse widths of the switching waveform can vary with time. Thus

$$\bar{q}_A(t) = d(t) \tag{22-5}$$

$$\bar{\upsilon}_A(t) = d(t) \cdot V_{in} \tag{22-6}$$

As an example of PWM, we can regulate the average value of $\upsilon_A(t)$ in Fig. 22-4*b* by varying the duty ratio d. If $V_{in} = 10$ V, $f_s = 100$ kHz $\Rightarrow T_s = 10\ \mu$s, then $T_{on} = 5\ \mu$s $\Rightarrow d = 0.5$, and $\upsilon_A = 5$ V, etc. By varying the duty ratio sinusoidally a low-frequency ac voltage can be synthesized from a dc voltage, as illustrated in Fig. 22-6.

22.2.3 Concept of Steady State

A converter is said to be in dc steady state when all its waveforms exactly repeat in each switching period, that is, $x(t) = x(t - T_s)\ \forall\ t$, where x is any of the converter variables. With reference to Eq. (22-2), it is clear that in steady state the average value of any variable is constant. Analysis of steady-state operation is essential to determine ratings and design of the power stage components in the converter, viz, power semiconductor devices, inductor, capacitors, and transformers. Important

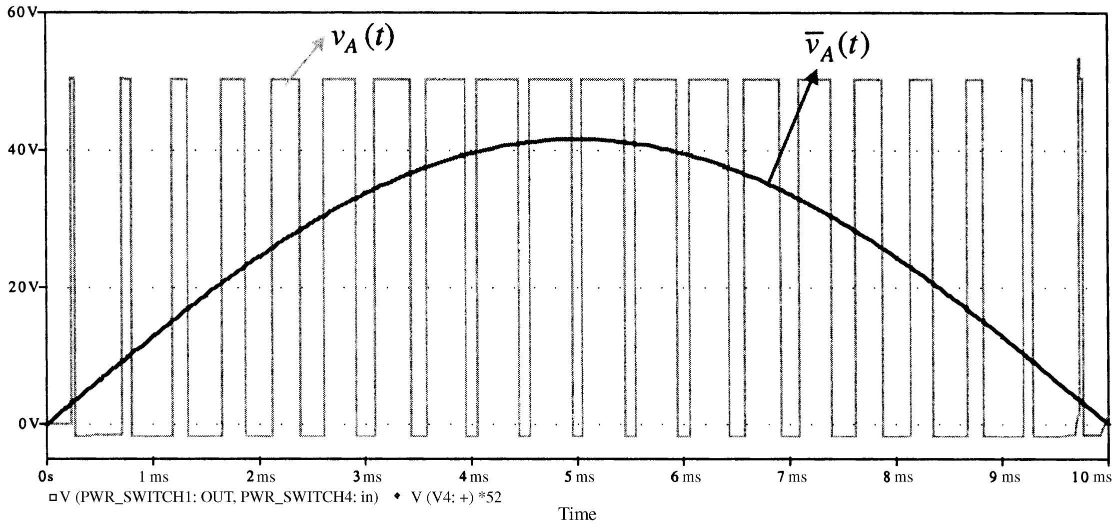

FIGURE 22-6 AC synthesis using PWM.

concepts that enable steady-state analysis from a circuit view point are discussed below. It should be remembered that these are only valid during steady-state operation.

Steady-State Averages of Inductor Voltage and Capacitor Current. The instantaneous v-i relationship for an inductor is

$$v_L(t) = L\frac{di_L(t)}{dt} \quad \text{or} \quad i_L(t) = i_L(0) + \frac{1}{L}\int_0^t v_L(\tau)\,d\tau \tag{22-7}$$

where $v_L(t)$ is the voltage across the inductor and $i_L(t)$ is the current flowing through the inductor. Since $i_L(T_s) = i_L(0)$ in steady state, from the integral form of Eq. (22-7) it follows that

$$\bar{v}_L = \frac{1}{T_s}\int_0^{T_s} v_L(\tau)\,d\tau = 0 \tag{22-8}$$

The above relationship can also be derived directly in terms of the averaged quantities as follows:

$$\bar{v}_L(t) = L\frac{d\bar{i}_L(t)}{dt} = 0 \quad \text{(since } \bar{i}_L(t) \text{ is constant in steady state)} \tag{22-9}$$

This is referred to as *volt-second balance* in an inductor. Figure 22-7 shows a typical steady-state waveform of an inductor voltage for many power converters. The positive area is exactly cancelled by the negative area, making the average value zero. It may be mentioned that during the start-up transient, $\bar{v}_L$ remains positive for several switching cycles, allowing the inductor current to rise from zero to its final steady-state value.

In a similar fashion, it can be shown that in steady state the average current through a capacitor

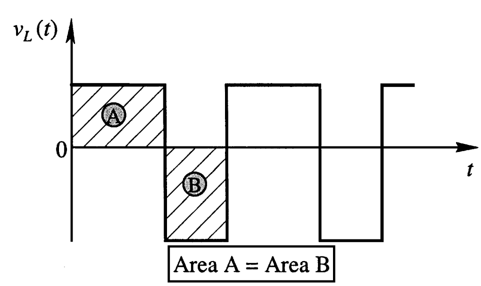

FIGURE 22-7 Volt-second balance for an inductor.

is zero. This is referred to as *ampere-second balance* in a capacitor. Note that though the average value of the capacitor current is zero, its root mean square (RMS) value, which is one of the main selection criteria for a capacitor, can be substantial depending on the converter topology.

Power Balance. For analytical purposes, it is often useful to neglect all losses in the converter and consider input power to be equal to the output power, again in an average sense

$$P_{in} = \bar{v}_{in}\bar{i}_{in} = P_o = \bar{v}_o\bar{i}_o \tag{22-10}$$

This implies that there is no increase or decrease in the energy stored in inductors and capacitors over one switching time period. This is valid for the input-output of the entire converter as well as any intermediate stage.

Kirchoff's Laws for Averages. Just like the instantaneous quantities, the averaged quantities also obey Kirchhoff's current and voltage laws. The sum of average currents entering a node is zero. The proof follows from interchanging the order of summation (for individual currents) and integration (over a switching time period)

$$\sum_k \bar{i}_k = \frac{1}{T_s}\sum_k\left[\int_0^{T_s} i_k\right] = \frac{1}{T_s}\int_0^{T_s}\left[\sum_k i_k\right] = 0 \qquad \left(\text{since } \sum_k i_k \equiv 0\right) \tag{22-11}$$

Similarly, the sum of average voltages in a circuit loop is zero.

$$\sum_k \bar{v}_k = 0 \tag{22-12}$$

22.2.4 Power Loss in the Bipositional Switch

Electronic implementations of the bipositional switch shown in Figs. 22-5*a* and 22-5*b* have significant power loss. The power loss can be divided into two kinds—conduction loss and switching loss.

With reference to Fig. 22-5*b,* when the MOSFET is on there is a nonzero voltage across it. Similarly the diode has a forward voltage drop while it is conducting. Both of these lead to power loss whose sum averaged over one switching time period is called conduction loss.

A finite time interval is required to transition from one state to the other: (MOSFET on and diode off) to (MOSFET off and diode on), and vice versa. While the MOSFET is turning off, the diode cannot conduct until it is forward biased. As the voltage across the MOSFET increases from near zero to the full input voltage V_{in}, it conducts the full output current. Once the diode is forward biased the current starts transferring from the MOSFET to the diode. During the reverse transition, first current is transferred from the diode to the MOSFET, and then the voltage across the MOSFET reduces from V_{in} to the conduction voltage drop. Thus, the MOSFET incurs significant power loss during both transitions. The above description is simplified and there are other phenomena which contribute to loss during the transitions. The diode also has power loss during the transitions. The sum of losses in the MOSFET and diode during the transitions averaged over one switching time period is called the switching loss. Switching power loss increases with increase in switching frequency and increase in transition times. Sum of the conduction and switching loss, computed as averages over one complete switching periods, gives the total power loss Fig. 22-8.

Similar losses occur in the realization of Fig. 22-5*a*. When S_1 is turned off by its control signal, current $i_A(t)$ transfers to D_2, the antiparallel diode of S_2. After this transition, S_2 is turned on and the current transfers from the diode to the MOSFET channel (which can conduct in either direction). A short time delay, called dead time, is required between the on signals for S_1 and S_2. The dead time prevents potential shorting of the input voltage, also known as shoot-through fault.

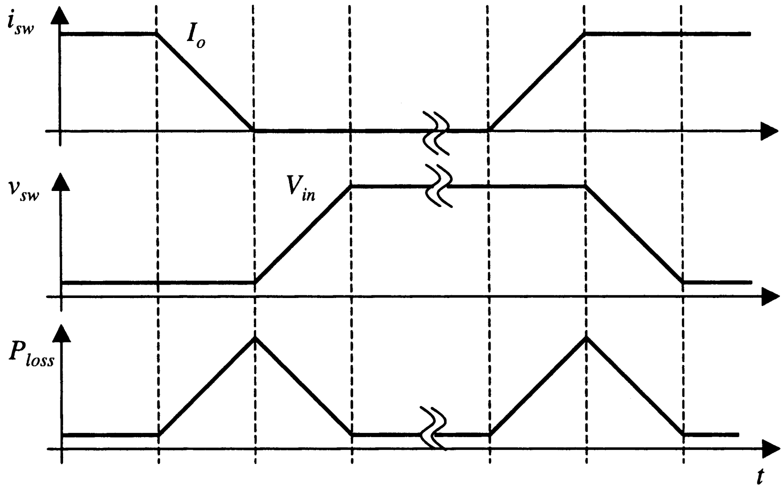

FIGURE 22-8 Switching transients in bipositional switch implementation.

The nonidealities of nonzero voltage drop and switching times will be neglected for analysis of power electronic converters presented throughout this chapter. However, these are extremely important in design and selection of components for a real power converter.

22.3 DC-DC CONVERTERS

DC-DC converters represent one major area in power electronics. In a dc-dc converter, the input and output may differ in magnitude, the output may be electrically isolated from the input, and the output voltage may have to be regulated in the presence of variation in input voltage and load current. In a typical power distribution system (for digital systems), several lower magnitude dc voltages are derived from a common input using a one or more converters. Battery-powered portable devices use converters that boost the input 1.5 V cell voltage to 5 or 9 V. Most of these converters have unidirectional power flow—from input to output. The presentation here is limited to the basic converter types. The interested reader is referred to text books that deal with details of these converters [4–8].

22.3.1 Buck Converter

The buck converter is used to step down an input voltage to a lower magnitude output voltage. Figure 22-9*a* shows the schematic of a buck converter. A power MOSFET and diode combination is shown for implementation of the bipositional switch with unidirectional output current. The bipositional switch is followed by an L-C low-pass filter that attenuates the high-frequency switching component of the pole A voltage and provides a filtered dc voltage at the output. A high switching frequency is desirable to reduce the size of the filter, the higher limit depending on the power level of the converter and the semiconductor devices used. The final choice of switching frequency depends on several factors: size, weight, efficiency, and cost. It is usually above the audible range and frequencies above 100 kHz are very common.

Operation. The input voltage V_{in} is assumed to remain constant within a switching cycle. The inductor L and capacitor C are sufficiently large so that the inductor current i_L and output voltage v_o do not change significantly within one switching cycle. The load is represented by the resistor R_L. Under

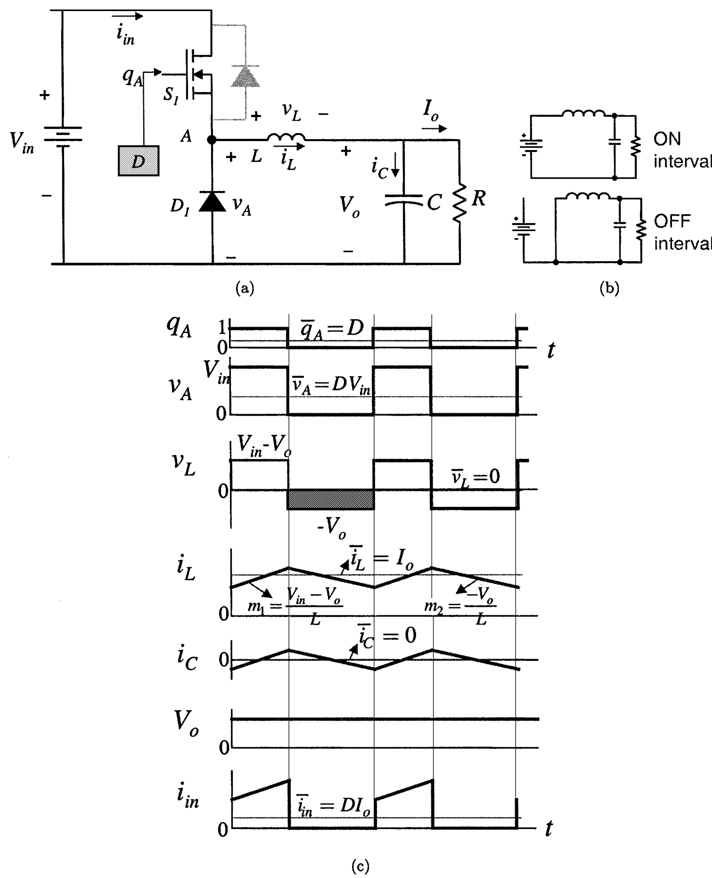

FIGURE 22-9 Buck converter: (*a*) circuit, (*b*) equivalent circuits during ON and OFF intervals, (*c*) steady-state waveforms.

steady-state operation it is assumed that the inductor current is always greater than zero. The MOSFET is turned on in response to signal $q_A(t)$ for $T_{on} = DT_s$, where D represents the steady-state duty ratio. During this time $v_A = V_{in}$ and $i_{in} = i_L$. When the MOSFET is turned off, the inductor current flows through diode D_1 leading to $v_a = 0$ and $i_{in} = 0$. Since the average voltage across the inductor is zero, $\bar{v}_L = 0$, the average output voltage is given by

$$\bar{v}_o = \bar{v}_a = DV_{in} \tag{22-13}$$

The average current through the capacitor C, $\bar{i}_c$, is zero. Thus, $\bar{i}_L = I_o$ and the input current is given by

$$\bar{i}_{in} = DI_o \tag{22-14}$$

From the above equations it is clear that the output voltage is lower than the input voltage and output current is higher than the input current. Also, power balance for averaged quantities can be verified from Eqs. (22-13) and (22-14). Within a switching cycle, instantaneous values of the inductor current and capacitor voltage vary as follows:

$$\begin{array}{lll} \text{MOSFET on:} & L\dot{i}_L = V_{in} - v_o & C\dot{v}_o = i_L - v_o/R_L \\ \text{MOSFET off:} & L\dot{i}_L = -v_o & C\dot{v}_o = i_L - v_o/R_L \end{array} \tag{22-15}$$

Equivalent circuits for the two intervals and instantaneous waveforms are shown in Figs. 22-9*b* and 22-9*c*.

Component Selection. Usually the inductor and capacitor are significantly large so that within a switching period v_o can be assumed constant in computation of i_L. This leads to the linear variation of i_L shown in Fig. 22-9*c* with a *peak-to-peak ripple* ΔI_L given by

$$\Delta I_L = \frac{V_o(1 - D)T_s}{L} \tag{22-16}$$

In most designs, the inductance value is chosen to limit ΔI_L between 10% and 30% of the full load current. Since the average capacitor current is zero, the instantaneous capacitor current is approximately equal to the ripple component of the inductor current.

$$i_C(t) = i_L(t) - I_o \tag{22-17}$$

The peak-to-peak capacitor voltage ripple resulting from the capacitor current can then be derived as

$$\Delta V_o = \frac{\Delta I_L \cdot T_s}{8C} \tag{22-18}$$

Capacitors used for filtering in most dc-dc converters are electrolytic capacitors, which are characterized by significant effective series resistance (ESR) and effective series inductance (ESL). These parasitics also contribute to the output voltage ripple and should supplement Eq. (22-18) in the choice of capacitors. Film or ceramic capacitors, which have significantly lower ESR and ESL, should be used in conjunction with electrolytic capacitors.

The MOSFET has to be rated to block a voltage greater than V_{in}, and conduct an average current greater than I_{in}. Power dissipation and temperature considerations usually require MOSFETs to be rated from 2 to 3 times the maximum input average current. In addition, the peak MOSFET current, equal to the maximum peak of the inductor current, should not exceed its maximum current rating. The diode has to be rated to block V_{in}, and conduct an average current greater than the maximum output current. Diodes are usually chosen with ratings approximately 2 times the expected maximum current.

PWM Control Implementation. As evident from Eq. (22-13) the duty ratio of the switch controls the output voltage. In response to variation in input voltage and load current, the duty ratio has to be changed by a feedback controlled system as shown in Fig. 22-10*a*. The error between the reference and actual output voltage is given to an appropriately designed error compensating amplifier, the output of which is a control voltage v_c. This control voltage is compared with a constant frequency sawtooth waveform. The output of the comparator is the switching signal $q_A(t)$ that determines the on or off state of the MOSFET. When the output voltage is lower than the reference value, the control voltage increases, leading to an increase in the duty ratio, which in turn increases the output voltage. The error amplifier and comparator, and several other features, are available in a single

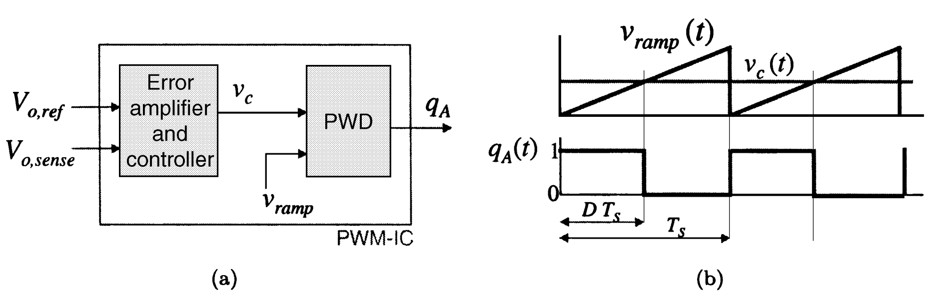

FIGURE 22-10 PWM generation: (*a*) ramp comparison, (*b*) control block diagram.

integrated circuit (e.g., UC3825A) available from several manufacturers (e.g., see Refs. [9–12]). This integration of components leads to reduction in overall size and cost.

22.3.2 Boost Converter

As evident from the name, the boost converter is used to step up an input voltage to a higher magnitude output voltage see Fig. 22-11*a*. In this case, the MOSFET is in the lower position while the diode is in the upper position. The inductor is on the input side and the output has a purely capacitive filter.

Assumptions made for analysis of buck converter are made here as well. When the MOSFET is on in response to $q_A(t) = 1$, diode D_1 is off, and the inductor current increases due to a positive voltage across it (Fig. 22-11*b*). When the MOSFET is switched off, the inductor current flows through diode D_1 and its magnitude decreases as energy is transferred from the inductor to the output capacitor and load. Instantaneous values of the variables during on and off intervals are

$$\begin{array}{lllll} \text{MOSFET on} & v_A = 0 & i_d = 0 & L\dot{i}_L = V_{in} & C\dot{v}_o = -v_o/R_L \\ \text{MOSFET off} & v_A = v_o & i_d = i_L & L\dot{i}_L = V_{in} - v_o & C\dot{v}_o = i_L - v_o/R_L \end{array} \quad (22\text{-}19)$$

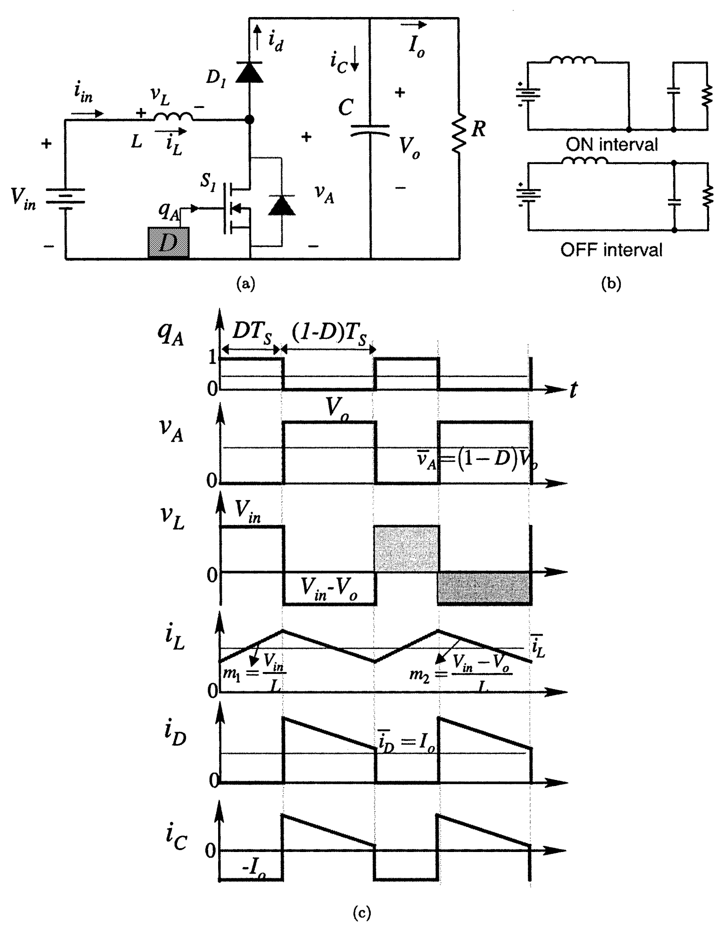

FIGURE 22-11 Boost converter: (*a*) circuit, (*b*) operating states, (*c*) steady-state waveforms.

Noting that $\bar{v}_L = 0$, the averaged pole A voltage is $\bar{v}_A = V_{in} = (1 - D)V_o$. In addition, using $\bar{i}_C = 0$, the steady-state conversion ratios for the boost converter can be obtained as follows:

$$\frac{V_o}{V_{in}} = \frac{1}{1 - D} \qquad \text{and} \qquad \frac{I_{in}}{I_o} = \frac{1}{1 - D} \tag{22-20}$$

From the above equation it is evident that the output voltage is always higher than the input voltage, and conversely, the output current is always lower than the input current by the same ratio. Waveforms of the boost converter variables are shown in Fig. 22-11*c*. The PWM implementation is the same as in the buck converter (Fig. 22-10), with the control objective being regulation of output voltage to a desired value.

The buck and boost converters are capable of either decreasing or increasing the input voltage magnitude, but not both. The buck-boost converter is the third basic converter that can be used to obtain an output voltage both lower and higher than the input voltage; since the output voltage is usually maintained constant, this implies that the input voltage may be higher or lower than the output voltage. A drawback of the buck-boost converter is that the output voltage polarity is inverted with respect to the input voltage return. The SEPIC converter (single-ended primary inductor converter) provides buck and boost gain without polarity inversion but at the expense of additional components. The Ćuk converter, derived from the buck-boost converter using the duality of current and voltage, is another basic dc-dc converter topology [4, 5]. None of the above converters have electrical isolation between the input and the output; however, isolated versions for all of these can be derived.

22.3.3 Flyback Converter

Figure 22-12*a* shows the buck-boost converter circuit. Discussion of this converter in its original configuration is omitted here. Instead, its electrically isolated version known as the flyback converter is described. The flyback converter is very common for low power applications. It has the advantage of providing electrical isolation with low component count. Derivation of the flyback converter from the buck-boost converter is shown in Fig. 22-12*a*. The flyback converter has a coupled inductor instead of an inductor with just one winding. The primary winding is connected to the input while

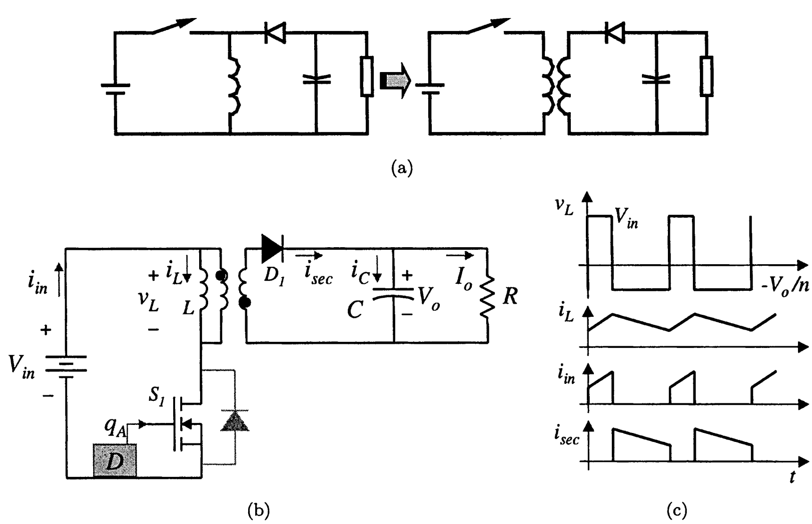

FIGURE 22-12 Flyback converter: (*a*) derivation from buck-boost, (*b*) circuit, (*c*) steady-state waveforms.

the secondary is connected to the output. The circuit diagram is shown in Fig. 22-12*b*. The coupled inductor is represented by an inductor on the primary and an ideal transformer between the primary and secondary. The coupling coefficient is assumed to be 1. Assuming the primary to secondary turns ratio is 1 : *n*, we get

$$\bar{v}_L = V_{in} DT_s - \frac{V_o}{n}(1 - D)T_s = 0 \tag{22-21}$$

$$\Rightarrow \frac{V_o}{V_{in}} = n\frac{D}{1 - D} \tag{22-22}$$

$$\Rightarrow \frac{I_{in}}{I_o} = n\frac{D}{1 - D} \tag{22-23}$$

Although the analysis presented here assumes that the inductor current never goes to zero (called *continuous conduction mode* or CCM), it is very common to design flyback converters so that the inductor current does go to zero within each switching cycle. This operation, known as *discontinuous conduction mode* (DCM), leads to simplification of control design for flyback converters [5]. It should be noted that requirement of electrical isolation is not the only reason that a transformer or (coupled inductor) is used. Another important reason is that the transformer turns ratio leads to better utilization of power semiconductor devices.

22.3.4 Full-Bridge DC-DC Converter

Figure 22-13*a* shows the full-bridge dc-dc converter which is derived from the buck converter. The bridge circuit formed by switches S_1, S_2, S_3, and S_4 converts the input dc voltage to a high-frequency ac ($\geqslant$ 100 kHz), which is applied to the primary of transformer T_1. The high frequency results in a small size for the transformer. After isolation, the high-frequency ac at the secondary of the transformer is rectified by the center-tapped diode bridge rectifier formed by D_1 and D_2, and subsequently filtered by the *L* and *C* as in a buck converter. The topology is very popular for power levels greater than 500 W, when isolation is required.

Steady-state operating waveforms for the converter are shown in Fig. 22-13*b*. With switches S_3 and S_4 off, S_1 and S_2 are turned on simultaneously for $T_{on} = DT_s/2$, thereby applying a positive voltage across the transformer primary $T_{1,prim}$ and secondary $T_{1,sec1}$. During this time, diode D_1 conducts and a positive voltage appears across the inductor. With all the switches off, the transformer primary and secondary voltages are zero and the inductor current splits equally between diodes D_1 and D_2. In the second half of the switching cycle S_1 and S_2 are off, while S_3 and S_4 are simultaneously turned on $DT_s/2$. The rectified voltage waveform is similar to that in the buck converter and is at double the switching frequency of the each switch. The magnetizing flux in the transformer is bidirectional (Fig. 22-13*b*), resulting in better utilization of the core as discussed in *Transformers Design*. The conversion ratio is similar to the buck converter, but scaled by the secondary to primary transformer turns ratio.

22.3.5 Other Isolated DC-DC Converters

Several other isolated converters are based on the buck converter. Figure 22-14*a* shows the forward converter. The operation and conversion ratio is similar to the buck converter. However, the output voltage is scaled by the transformer turns ratio, an additional winding and diode (D_R) are needed to reduce the core flux to zero in each switching cycle, and an additional diode (D_2) is required at the output. The forward and flyback converters have unidirectional core flux and are limited to low-power applications. The push-pull converter (Fig. 22-14*b*), also derived from the buck converter, is better suited for higher power levels, limited by voltage rating of the switches required. Details of these converters can be found in Refs. [4, 5].

22.3.6 Recent Developments and Future Trends

The size of filter components (inductor and capacitor) and isolation transformer reduce as the switching frequency is increased. Thus, a high switching frequency is desirable to minimize size and weight. However, parasitics and other nonidealities in dc-dc converters eventually limit the switching frequency and efficiency. For example, in flyback and forward converters, leakage inductance of the coupled inductor/transformer is a significant problem at high frequencies; in each switching cycle all the energy stored in the leakage inductance at switch turn-off has to be dissipated. Similarly, during turn-on of switches energy stored in parasitic output capacitance of the switch is dissipated inside the switch. These losses increase in proportion to the switching frequency. Thus, thermal or efficiency consideration eventually limit the maximum switching frequency. Besides the ones mentioned above other limiting factors are: switching times of diodes and MOSFETs, reverse recovery of diodes, capacitance of schottky diodes, and capacitance of transformers. To overcome these limitations, several circuits have been developed, which utilize the parasitic inductance and capacitances to advantage. Although the modifications in these sometimes add disadvantages, for specific applications, the advantages outweigh the disadvantages.

Soft-switching converters use resonance conditions between parasitic capacitance and inductance so that either the capacitance of switching devices is discharged before the device is actually turned on, or the current through the leakage inductance is reduced to zero prior to turning off. In some circuits, additional inductors and/or capacitors are added to produce resonance conditions. These converters, generically called *resonant converters*, are widely used in applications such as computer power supplies, electronic ballasts for fluorescent lamps, battery charging, and various portable applications. Details of these converters can be found in Refs. [4, 5].

Reduction in filtering requirements has also been achieved by using *interleaving*. An interleaved converter or multiphase converter has two or more converters called *phases*. These phases operate in parallel with their inputs and outputs being common. They are switched out of phase (180° for a 2-phase case, 120º for three phases, etc.) so that the ripple currents in the individual inductors are also out of phase. This results in lower effective current ripple both at the output and the input, and thus, smaller filter size for a given ripple specification. The lower values of the inductor also lead to faster dynamic response. Hybrid converters combining the benefits of soft switching with lower filter requirements have also been developed [13, 14].

To reduce size and minimize the number of discrete components, there is a significant effort in integrating all the semiconductors in one package. For example, on semiconductors [15] and power integration [16] have developed modules for use in off-line flyback converters; converters whose input is rectified line voltage are called off-line converters. The module contains a high-voltage power MOSFET and control circuit in one standard package. Similar modules are also available for low-power dc-dc converters (e.g., see Ref. [17]). Efforts are also being made to integrate all the magnetic components in dc-dc converters, using one single magnetic component, a concept called integrated magnetics.

22.4 FEEDBACK CONTROL OF POWER ELECTRONIC CONVERTERS

In the last section we saw that the steady-state output of a dc-dc converter, usually the output voltage, is controlled by the duty ratio. To account for changes in load current, input voltage, losses, and nonidealities in the converter, feedback based automatic control is required. Figure 22-15 shows a block diagram of output voltage control for a buck converter. The laplace domain control block diagram is also shown. The sensed output voltage is multiplied by a feedback gain $G_{FB}(s)$ before being compared with a reference value. The error is fed to an appropriate error compensator that generates a control voltage υ_c, which is converted to duty ratio d by the PWM block.

Toward designing a suitable controller, we will first describe a dynamic model of the power converter and then a simple loop-shaping control design method based on input to output bode plots.

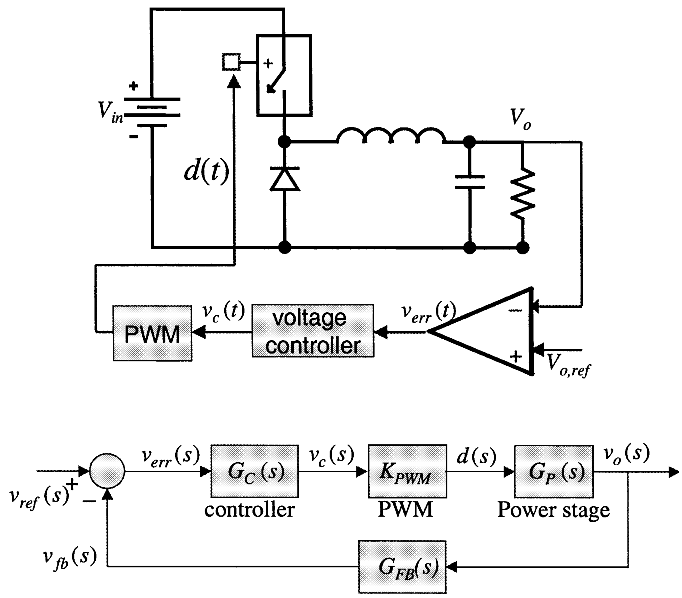

FIGURE 22-15 Block diagram of output voltage control for a buck converter.

It is possible to design more complex controllers in order to meet specific requirements, and the converter topology or operating method may also be modified to make the control design easier (e.g., DCM operation of flyback converters). To keep the explanation simple, it is assumed that the converter operates in CCM.

22.4.1 Dynamic Modeling

The power converter essentially consists of the PWM block and the power stage itself. The feedback gain G_{FB} is usually a constant. The PWM block shown in Fig. 22-10 converts the input control voltage $\bar{v}_c(t)$ to a duty ratio $d(t)$. From geometrical considerations

$$d(t)/\bar{v}_c(t) = 1/\hat{V}_{ramp} = K_R \tag{22-24}$$

where $\hat{V}_{ramp}$ is the peak value of the ramp $v_{ramp}(t)$. The power stage transfer function from $d(s)$ to $\bar{v}_o(s)$ can be derived using one of the methods stated below.

Dynamics of Averaged Quantities. As stated earlier, the bipositional switch approach and averaging are valid for analyzing low-frequency dynamics ($< f_s/5$) of the power converter. Unlike steady-state analysis, under dynamic conditions $\bar{v}_L \neq 0$ and $\bar{i}_C \neq 0$. Averaging the instantaneous state equations [Eq. (22-15)] over one switching cycle, dynamics of the averaged inductor current and capacitor voltage in a buck converter are

$$L\dot{\bar{i}}_L = d(t) \cdot V_{in} - \bar{v}_o \tag{22-25}$$

$$C\dot{\bar{v}}_o = \bar{i}_L - \bar{v}_o/R_L \tag{22-26}$$

Here the time varying duty cycle $d(t)$ is the control input and the averaged output voltage $\bar{v}_o$ is the output that has to be regulated. The situation for the buck converter is simple because the model described by Eqs. (22-25) and (22-26) is linear if V_{in} and R_L are assumed constant, for which case exact transfer functions describing large signal behavior can be derived. For boost and buck-boost converters, the averaged state equations involve terms with multiplications of $d(t)$ with a state variable. Thus, the model has to be linearized, and small signal dynamics obtained at different operating points are utilized for linear control design. It is of course possible to design large signal control based on the nonlinear model at the expense of mathematical complexity [18]. However, ease of design and simple cost-effective implementation has made linear design the preferred method in most power electronic converters in the low-to-medium power range.

Averaged Circuit Representation. Instead of writing averaged state equations explicitly as in Eqs. (22-25) and (22-26), an averaged circuit representation of the bipositional switch can be derived and substituted in different converter circuits Refs. [19–21]. As shown in Fig. 22-16*a* the bipositional switch can be considered as a two-port network with a voltage port (subscript$_{vp}$) at the input and a current port (subscript$_{cp}$) at the output. The average voltage and currents of the two ports are related as

$$\bar{v}_{cp}(t) = d(t) \cdot \bar{v}_{vp}(t) \tag{22-27}$$

$$\bar{i}_{vp}(t) = d(t) \cdot \bar{i}_{cp}(t) \tag{22-28}$$

The relations in the above equations correspond to those of an ideal transformer with turns ratio of $1 : d(t)$. Thus, for analysis purposes, the bipositional switch can be modeled as an ideal transformer whose turns ratio $d(t)$ can be controlled as shown in Fig. 22-16*b*. This representation is extremely useful in conjunction with circuit simulators which can perform operating point (dc bias) calculations, linearization, and ac analysis. Parasitic effects, like series resistances of inductors and capacitors,

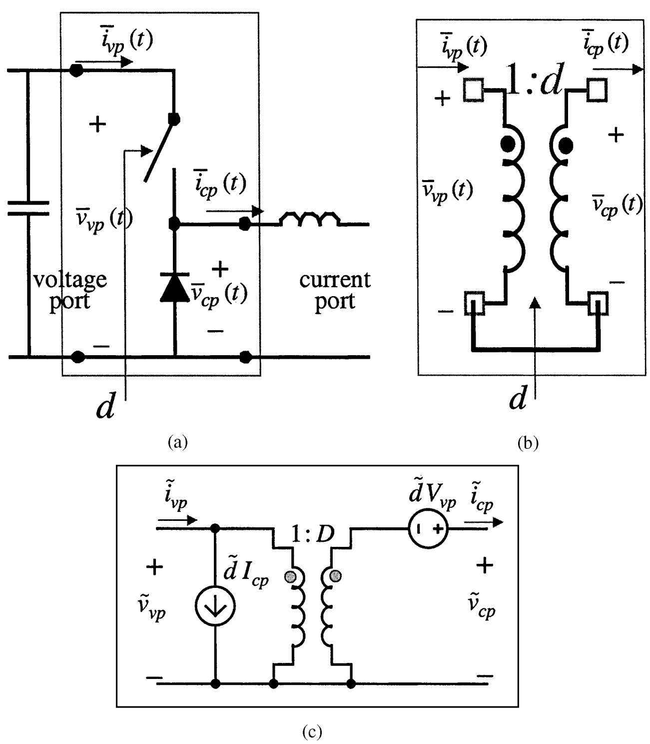

FIGURE 22-16 Bipositional switch: (*a*) two port network, (*b*) average representation, (*c*) small signal model.

can be easily incorporated in the averaged circuit model. Circuit simulators like SPICE [22], Saber, and Simplorer are commonly used for this purpose. The small-signal circuit representation of the averaged circuit obtained via linearization is shown in Fig. 22-16*c*. Quantities in upper case indicate operating point values, while the quantities with a "~" indicate small signal perturbations about the operating point. This representation can be utilized to derive small signal transfer functions using circuit analysis techniques.

22.4.2 Control Design

For a dc-dc converter, the main control objectives are: stability, zero steady-state error, specified transient response to step change in reference and in disturbance inputs (load and input voltage), and robustness to parametric changes. Transfer functions of different components—K_R, $G_{PS}(s)$, and $G_{FB}(s)$—are obtained as described above. The error compensator is then designed so that the open loop transfer function $G_{OL}(s)$ has a specified gain crossover frequency and phase margin. The gain cross-over frequency determines the response time of the controlled converter to changes in reference voltage and load current. Phase margin is usually in the range of 45° to 60° depending on the overshoot tolerable. Details on relation between gain crossover frequency, phase margin, and transient response can be found in any textbook on linear control (e.g., see Ref. 23).

An integrator (pole at origin) is added in $G_c(s)$ to obtain zero steady-state error. Zeroes are added at appropriate locations to obtain required phase margin. The dc gain of $G_c(s)$ is adjusted to achieve the required crossover frequency. Finally, to improve noise immunity, poles may be added for fast roll-off of the gain after the cross-over frequency. A systematic loop-shaping procedure along with implementation suited to dc-dc converters is described in Ref. [24].

Example: Voltage Control of a Buck Converter. A controller has to be designed to regulate the output voltage of a buck converter to a constant value. The specifications, parameters, and control requirements are listed in Table 22-2. Using the methods described above, the duty ratio to output voltage transfer function can be derived to be

$$\frac{\tilde{v}_o(s)}{\tilde{d}(s)} = \frac{V_{in}(1 + sCR_{ESR})}{1 + s[CR_{ESR} + L/R_L] + s^2LC[1 + R_{ESR}/R_L]} \tag{22-29}$$

The transfer function has a complex pole pair due the L-C filter, and a left half zero due to the ESR of the output capacitor. The compensator designed in accordance with the aforementioned considerations is

$$G_c(s) = \frac{K_c(1 + s/\omega_z)^2}{s(1 + s/\omega_{p1})(1 + s/\omega_{p2})} \tag{22-30}$$

where $K_c = 2011$, $\omega_z = 2\pi \times 2556$ rad/s, $\omega_{p1} = 2\pi \times 11.3e3$ rad/s, and $\omega_{p1} = 2\pi \times 80e3$ rad/s.

Representation of the controlled converter using ORCAD PSpice [25] is shown in Fig. 22-17*a*. The bipositional switch has been replaced by a two-port network that models a transformer with

controllable turns ratio. The compensated and uncompensated transfer functions obtained using ac analysis are shown in Fig. 22-17*b*. The gain crossover frequency and the corresponding phase of the compensated transfer function are indicated. Figure 22-17*c* shows dynamic response of the controlled converter when a step change in load is applied at 0.2 ms.

22.4.3 Current Mode Control

In most converters, the inductor current is an *internal* state of the power converter. Changes in the input voltage and duty ratio are first reflected in the inductor current, and subsequently in the output voltage. Thus, controlling the inductor current can lead to better performance. Figure 22-18 shows a cascaded control structure where the internal current controller is about an order of magnitude faster than the outer voltage loop. The average value of the inductor current is controlled to a reference that is generated by the error compensator for the voltage-control loop. The current controller is designed using the transfer function from the duty ratio to the inductor current. For voltage controller, the current control loop is assumed to be ideal, that is, $i_L = i_{L,ref}$; this is justified since the current controller is much faster than the voltage controller. The voltage compensator is then designed, using the inductor current to the output voltage transfer function. In a buck or buck-derived topology, the average inductor current is equal to the load current. Thus, fast control over the inductor current effectively mitigates steady state and transient variations in the input voltage without affecting the output voltage. This current control method is called *average current control*.

Another popular method is *peak current mode control*. In this method, the peak value of the inductor current is controlled to the reference value (generated by the voltage-control loop) in each switching cycle. Peak current mode control has the additional advantage of balancing the positive and negative flux excursions in transformer isolated topologies like full bridge and push pull. However, peak current mode control requires extra precautions to avoid subharmonic and chaotic operation [4, 5, 26].

22.4.4 Other Control Techniques

The basic modeling method described above is applicable to other types of converters (like dc-ac) as long as low-frequency behavior is being studied. Dynamics of the filter elements may of course be different. In dc-ac converters, the control objective is usually to track a moving reference (e.g., sinusoidal control voltage or current). Using a stationary to rotating frame transformation, commonly called the *abc to dq transformation*, the tracking problem can often be reduced to a regulation problem. If current control is implemented in the stationary frame, where the control objective is to track a sinusoidally varying reference, then either average current control or *hysteretic current control* is used. In hysteretic current control, the current is maintained in a band about the reference

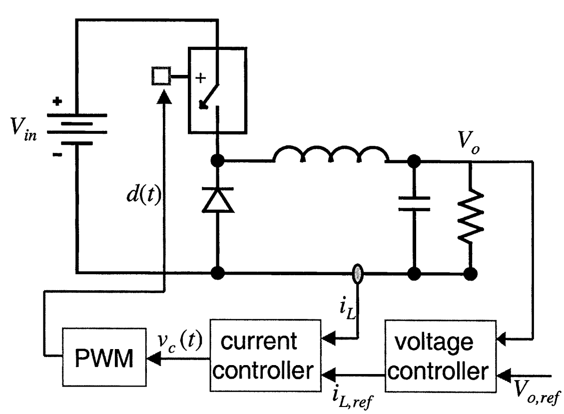

FIGURE 22-18 Average current control of a buck converter.

value. If the current error is below the lower limit of the band, a positive voltage is applied across the inductor (switch on in a buck converter) to increase the current. To reduce the current a negative or zero voltage is applied across the inductor. With hysteretic control, the rise and fall times are only limited by the power components of the converter. However, it has the disadvantage of variable switching frequency, whose instantaneous value depends on a combination of several factors. Several other techniques have recently been proposed for control of power electronic converters: sigma-delta, sliding mode, dead beat, etc. Details of these control techniques can be found in Ref. [27]. In digital implementations, predictive current control is commonly used to reduce the effect of sensing and computational delays. So far, digital control is only used in high power converters, where the overall cost justifies the cost of digital and interface components. However, there is significant effort in extending the benefits of digital control to lower power converters.

22.5 DC-AC CONVERSION: INVERSION

DC-ac converters constitute a significant portion of power electronic converters. These converters, also called *inverters*, are used in applications such as electric motor drives, uninterruptible power supplies (UPS), and utility applications such as grid connection of renewable energy sources. Inverters for single phase ac and 3-phase 3-wire ac systems (without a neutral connection) are described in this section.

22.5.1 Single Phase AC Synthesis

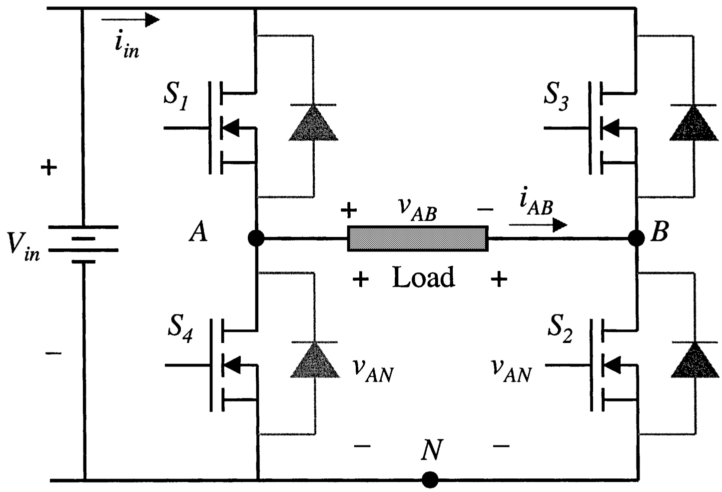
In an ac system both the voltage and the current should be able to reverse in polarity. Further, the voltage and current polarities may or may not be the same at a given time. Thus, a dc-ac converter implementation should be able to output a voltage independent of current polarity. In the full-bridge dc-dc converter shown in Fig. 22-19*a*, the primary circuit consisting of four controlled switches, also called *H-bridge*, has two bipostional switch implementations. Each bipositional switch has bidirectional current capability but only positive output voltage ($v_{AN} >, v_{BN} > 0$). However, based on the duty cycles, the difference of the outputs, $V_{AB} = v_{AN} - v_{BN}$, can reverse in polarity. Thus, the H-bridge is used for synthesizing single phase ac voltage from a dc voltage.

Quasi-square Wave Inverter. The simplest form of dc-ac conversion, albeit with poor quality, is synthesis of quasi-square wave ac instead of a pure sine wave. Diagonally opposite switches in the H-bridge are turned on simultaneously. The pulse width of each pair is controlled to adjust the magnitude of the fundamental component, while the switching frequency is equal to the required output frequency. The synthesized voltage waveform is shown in Fig. 22-19*b*. The peak value of fundamental and harmonic components are

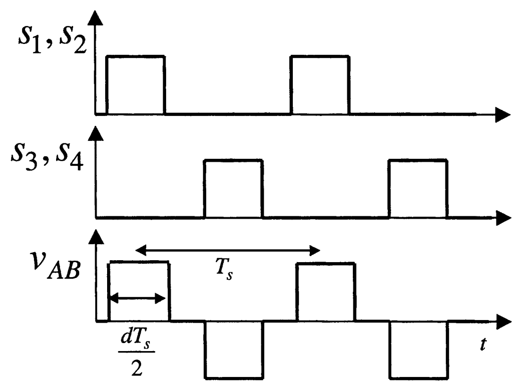
$$V_{AB,n} = \frac{4V_{in}}{n\pi}\sin(n\pi d/2) \qquad n \text{ odd} \tag{22-31}$$

where d is the duty ratio and n is the harmonic number. This converter is widely used for low cost low power UPS applications where the voltage waveform quality is not important. Incandescent lighting, universal input motors, and loads with a diode bridge or power factor corrected front end (discussed in Sec. 22.8.1) are not affected by the voltage waveform quality. The load current, i_{AB}, has harmonics based on the load characteristics. Sometimes an LC filter is added at the output to reduce the voltage (and therefore the current) harmonics.

Single-Phase Sinusoidal Voltage Synthesis. For applications requiring low voltage and current distortion, high-frequency PWM is utilized to generate a sinusoidally varying average voltage. The power converter used is the H-bridge shown in Fig. 22-19*a*. The duty ratio for each bipositional switch, also called one leg of the inverter, is varied sinusoidally. The switching signals are generated



(a)



(b)

FIGURE 22-19 Single-phase inverter: (*a*) circuit, (*b*) quasi-square wave synthesis.

by comparison of a sinusoidally varying control voltage with a *triangle* wave as shown in Fig. 22-20. Equations relating the control voltages, duty ratios, and the averaged output voltages are as follows:

$$v_c = \hat{V}_c \cdot \sin(\omega_m t) \tag{22-32}$$

$$v_{cA}(t) = v_c = \hat{V}_c \cdot \sin(\omega_m t) \tag{22-33}$$

$$v_{cB}(t) = -v_c = -\hat{V}_c \cdot \sin(\omega_m t) \tag{22-34}$$

$$d_A(t) = \frac{1}{2}\left(1 + \frac{v_{cA}}{\hat{V}_{tri}}\right) = \frac{1}{2}(1 + m \cdot \sin(\omega_m t)) \tag{22-35}$$

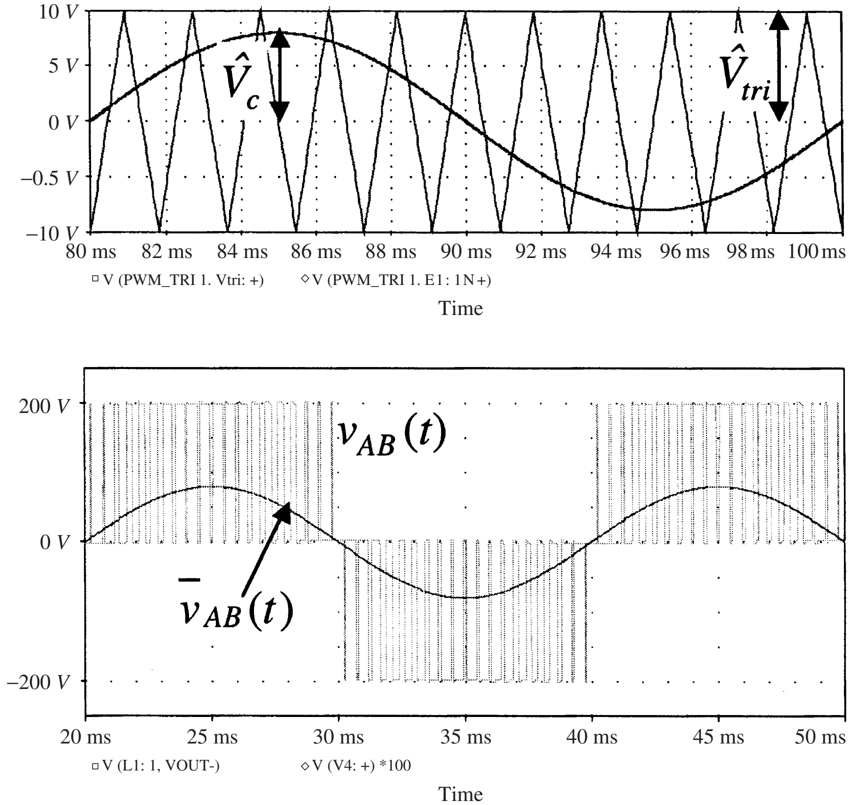


FIGURE 22-20 Single-phase sinusoidal ac synthesis waveforms.

$$d_B(t) = \frac{1}{2}\left(1 + \frac{v_{cB}}{\hat{V}_{tri}}\right) = \frac{1}{2}(1 - m \cdot \sin(\omega_m t)) \tag{22-36}$$

$$\bar{v}_{AN}(t) = d_A(t) \cdot V_{in} = \frac{1}{2}(1 + m \cdot \sin(\omega_m t)) \cdot V_{in} \tag{22-37}$$

$$\bar{v}_{BN}(t) = d_B(t) \cdot V_{in} = \frac{1}{2}(1 - m \cdot \sin(\omega_m t)) \cdot V_{in} \tag{22-38}$$

$$\bar{v}_{AB}(t) = (d_A(t) - d_B(t)) \cdot V_{in} = m \cdot V_{in} \cdot \sin(\omega_m t) = \underbrace{(V_{in}/\hat{V}_{tri})}_{k_{PWM}} \cdot v_c(t) \tag{22-39}$$

Here $\hat{V}_c$ and V_{tri} are peak values of control voltage and the triangle wave, respectively, $m = \hat{V}_c/\hat{V}_{tri} \in [0, 1]$ is the modulation index, $\omega_m = 2\pi f_m$ is the angular frequency of the sinusoid to be synthesized, while $d_A(t)$ and $d_B(t)$ are duty ratios of switches S1 and S3, respectively. In Eq. (22-39) k_{PWM} may be regarded as the gain of the power converter that amplifies the control signal $v_c(t)$ to the average output voltage $\bar{v}_{AB}(t)$. The maximum peak value of the output voltage, obtained for $m = 1$, is V_{in}. This is significantly lower than that obtainable with the quasi square wave inverter ($4V_{in}/\pi$). However, harmonics in the output voltage are significantly reduced and are at much higher frequencies: $k \cdot f_s \pm l \cdot f_m$, where k and l are integers such that $k + l$ is odd [4]. The switching frequency $f_s \geqslant 20$ kHz is significantly higher than the output frequency f_m, which usually has a maximum value of about 50/60 Hz. If the load is inductive, the current harmonics are reduced further, and the current is almost sinusoidal.

Equation (22-37) can be rewritten as

$$\overline{v}_{AN}(t) = d_A(t) \cdot V_{in} = \frac{V_{in}}{2} + \frac{k_{PWM}}{2} \cdot v_c(t) \tag{22-40}$$

This clearly shows that on an average basis the "neutral point" for the output of one inverter leg is $V_{in}/2$ above "N," that is, at the mid-point of the input dc bus. Thus, using the same H-bridge a split-phase ac (two ac voltages 180° out of phase with a common return) can be generated if the center point of the dc bus is available as the neutral connection for the output.

22.5.2 Three-Phase AC Synthesis

The last observation in the previous section leads us to 3-phase inverters without a neutral connection. The circuit consists of three legs, one for each output with a common dc link as shown in Fig. 22-21*a*.

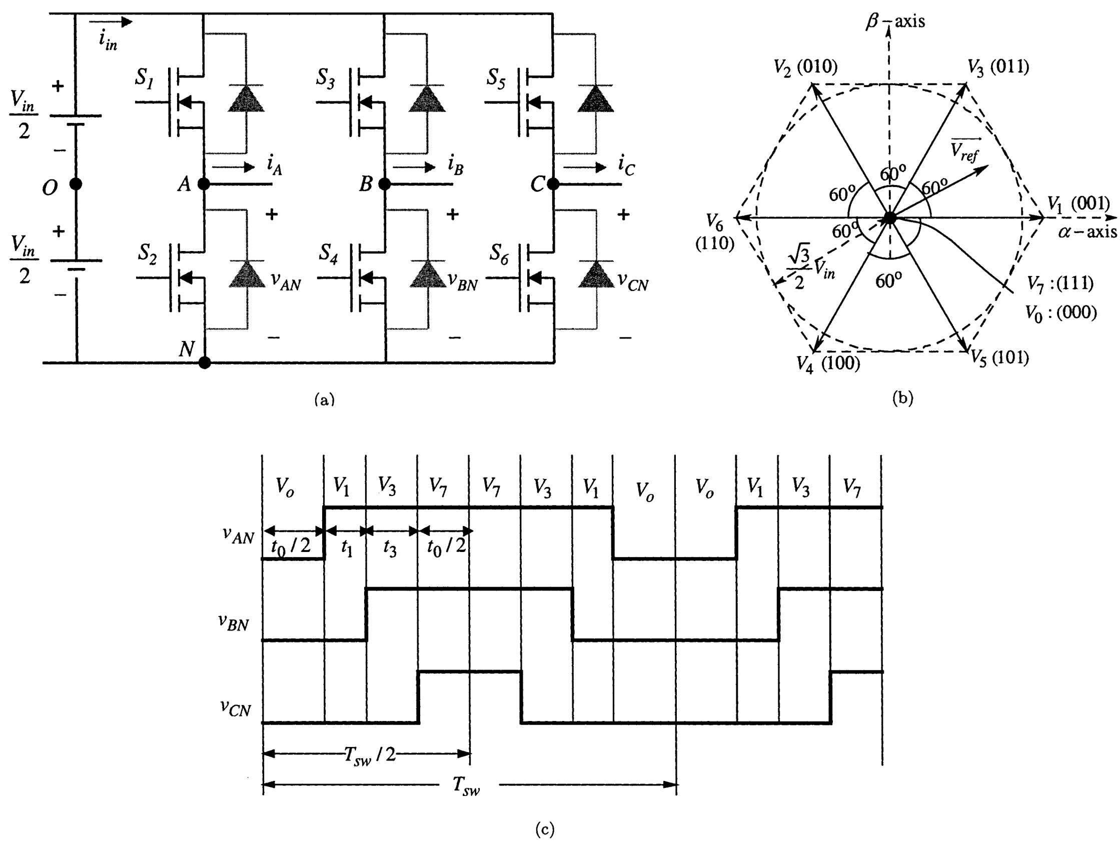

FIGURE 22-21 3-Phase ac synthesis: (*a*) converter, (*b*) output voltage vectors, (*c*) instantaneous waveforms.

Using sine triangle PWM with control voltages offset by 120° (instead of 180° as in the single phase case) we obtain

$$v_{cA}(t) = \hat{V}_c \cdot \sin(\omega_m t) \tag{22-41}$$

$$v_{cB}(t) = \hat{V}_c \cdot \sin(\omega_m t - 2\pi/3) \tag{22-42}$$

$$v_{cC}(t) = \hat{V}_c \cdot \sin(\omega_m t + 2\pi/3) \tag{22-43}$$

$$\overline{v}_{AN}(t) = \frac{V_{in}}{2} + \frac{k_{PWM}}{2} \cdot v_{cA}(t) \tag{22-44}$$

$$\overline{v}_{BN}(t) = \frac{V_{in}}{2} + \frac{k_{PWM}}{2} \cdot v_{cB}(t) \tag{22-45}$$

$$\overline{v}_{CN}(t) = \frac{V_{in}}{2} + \frac{k_{PWM}}{2} \cdot v_{cC}(t) \tag{22-46}$$

The zero-sequence component of the output voltages, $v_z = (v_{AN} + v_{BN} + v_{CN})/3 = V_{in}/2$, does not appear in the line-to-line voltages, and since there is no neutral connection to the inverter zero-sequence currents do not flow.

The maximum peak value of the output line-to-line voltages is $\hat{V}_{LL} = (\sqrt{3}/2)V_{in}$. Using square wave inversion, similar to that for the single-phase case, we can obtain higher magnitude for the fundamental component of the output voltages at the cost of adding harmonics. However, if, instead of all the harmonics, only the fundamental and those harmonics of the square wave that contribute zero-sequence component (triplen harmonics) are retained, the output voltage amplitude increases without adding harmonics to the line-to-line voltages and the line currents. Usually, addition of the third harmonic component is sufficient Refs. [28, 29]. As described in Refs. [30, 31], the most effective method is to add the following zero-sequence component to the control voltages for each phase

$$v_{cz}(t) = \frac{1}{2}[\max(v_{cA}(t), v_{cB}(t), v_{cC}(t)) + \min(v_{cA}(t), v_{cB}(t), v_{cC}(t))] \tag{22-47}$$

In terms of output voltage generation, this is equivalent to space vector modultation (SVM).

22.5.3 Space Vector Modulation

This method has become extremely popular for 3-phase inverters in the low-to-medium power range. A very brief description will be presented here and details can be found in Refs. [27, 28, 30].

For 3-phase systems with no zero-sequence component, that is, $v_z = (v_{AN} + v_{BN} + v_{CN})/3 = 0$, the 3-phase quantities are linearly dependent and can be transformed to a 2-phase orthogonal system commonly called the $\alpha\beta$ system. Quantities in the $\alpha\beta$ system can be represented by complex numbers and as two-dimensional vectors in a plane, called *space vectors*. The transformation from the *abc* to $\alpha\beta$ quantities is given by

$$\vec{v}_{\alpha\beta}(t) = v_\alpha(t) + j \cdot v_\beta(t) = e^{j0} \cdot v_a(t) + e^{j2\pi/3} \cdot v_b(t) + e^{j4\pi/3} \cdot v_c(t) \tag{22-48}$$

With negative sequence components absent, α and β components of steady-state sinusoidal *abc* quantities are also sinusoids with constant amplitude and a 90° phase difference between them. Under transient conditions they are arbitrary time-varying quantities. Thus, for balanced sinusoidal conditions, the space vector $\vec{v}_{\alpha\beta}(t)$ rotates in counter clockwise direction with angular frequency equal to frequency of the *abc* voltages, and describes a circle of radius $(3/2)\hat{V}_{ph}$, $\hat{V}_{ph}$ being the peak of the phase voltage.

The instantaneous output voltages of the 3-phase inverter shown in Fig. 22-21*a* can assume eight different combinations based on which of the six MOSFETs are on. The space vectors for these eight combinations are shown in Fig. 22-21*b*. For example, vector V_4 denoted by (100) corresponds to switch states $\upsilon_{AN} = V_{in}$, $\upsilon_{BN} = 0$, and $\upsilon_{CN} = 0$. The vectors $V_0(000)$ and $V_7(111)$ have zero magnitude and are called *zero vectors*.

Synthesis utilizing the idea of space vectors is done by dividing one switching time period into several time intervals, for each of which a particular voltage vector is the output by the inverter. These time intervals and the vectors applied are chosen so that the average over one switching time period is equal to the desired output voltage vector. For the reference voltage vector $\vec{\upsilon}_{ref}$, shown in Fig. 22-21*b*, the nonzero vectors adjacent to it (V_1 and V_3), and the zero vectors (V_0 and V_7) are utilized as shown in Fig. 22-21*c*. Relative values of time intervals t_1 and t_3 determine the direction, while ratio of t_0 to the switching time period determines the magnitude of the output vector synthesized.

The maximum obtainable average vector lies along the hexagon connecting the six nonzero vectors. As stated earlier, balanced 3-phase sinusoidal quantities describe a circle in the $\alpha\beta$ plane. Thus, to synthesize distortion-free and balanced 3-phase sinusoidal voltages the circle must be contained within the hexagon, that is, with a maximum radius of $\sqrt{3}/2 \cdot V_{in}$. This gives the maximum peak value of line-to-line voltage obtained with SVM as $\hat{V}_{LL} = V_{in}$. This is significantly higher than that obtained using sine triangle PWM: $\sqrt{3}/2 \cdot V_{in}$. Further, the sequence and choice of vectors applied can be optimized to minimize number of switchings and ripple in the resulting currents [32]. There are several variations of SVM, each suited to a different application. Space vector modulation can be easily implemented digitally using microcontroller and digital signal processor (DSPs), and is extremely advantageous in control of 3-phase ac machines strategies using *vector control* and *direct torque control* (DTC) [33–37].

22.5.4 Multilevel Converters

The converter topologies described so far are based on a 2-level converter leg (bipositional switch), where the output voltage of each leg (υ_{AN}) can be either zero or V_{in}. The converters are therefore called 2-level converters. In 2-level converters, all the switches have to block the full dc bus voltage (V_{in}). For high-power applications insulated gate bipolar transistors (IGBTs) and gate turn-offs (GTOs) are used as the semiconductor switches. These have higher voltage and current ratings, and lower on-state voltage drop compared to power MOSFETs, but cannot switch as fast. In some applications like some motor drives and utility applications, even the voltage ratings of available IGBTs and GTOs is not sufficiently high. Simple series connection, to achieve a higher blocking voltage, has problems of steady state and dynamic voltage sharing. Moreover, due to the low switching frequency of high-power switches, the output voltage and current quality deteriorates. These issues are addressed by multilevel converters. In a multilevel converter [38, 39], the output of each phase leg can attain more than two levels leading to improved quality of the output voltage and current. The circuit comprising each leg and its proper operation ensure that voltage blocked by the switches reduces as the number of levels is increased. In addition, multilevel converters are modular to some extent, thereby making it easy to scale voltage ratings by increasing the number of "cells".

Multilevel PWM. For 2-level PWM, comparison of the control voltage with a triangle wave generates the switching signal for the top switch, while the bottom switch is controlled in complement to the top switch. Each of these two states corresponds to the two levels of the output voltage. For multilevel converters, there are more than two effective switch states, each of which corresponds to an output voltage level. For example, in a 3-level converter there are three effective states $q(t) = 0$, 1, 2, corresponding to output voltage levels $\upsilon_{AN}(t) = 0$, $V_{in}/2$, V_{in}. The control voltage $\upsilon_c(t)$ is compared with two triangle waves to obtain two switching signals $q_1(t)$ and $q_2(t)$, and the effective switching signal can be obtained as $q(t) = q_1(t) + q_2(t)$ as shown in Fig. 22-22. The output voltage is then given by $\upsilon_{AN} = q(t) \cdot (V_{in}/2)$. Switching signals for the individual switches are derived using $q(t)$ and the circuit topology. For the waveforms in Fig. 22-22, $f_s = 60Hz$ and $V_{in} = 2\ kV$. Since the

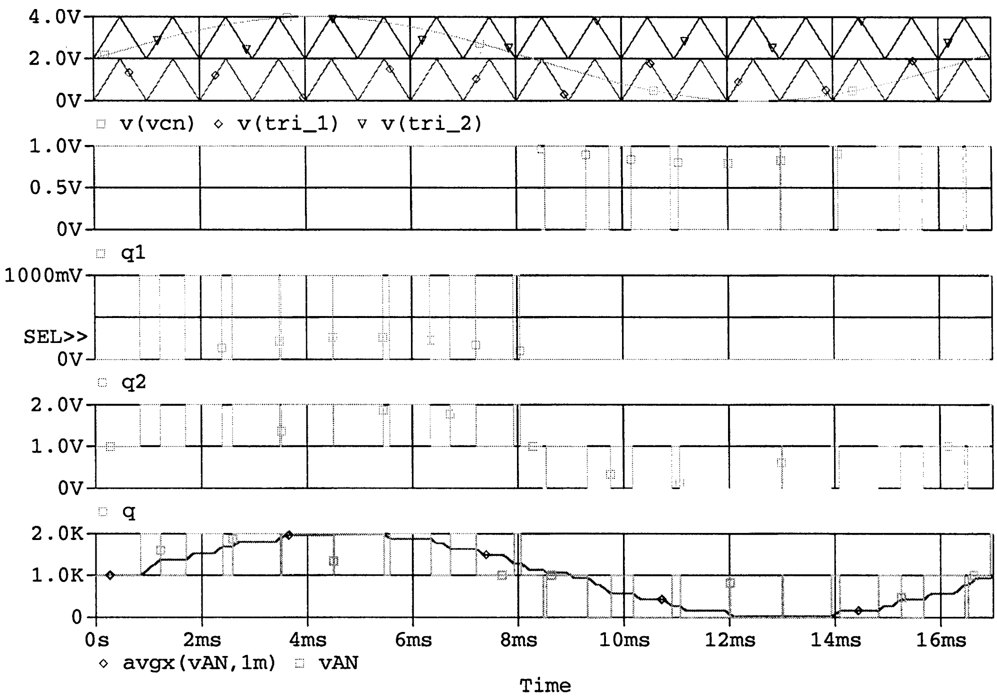

FIGURE 22-22 Multilevel triangle comparison.

v_{AN} waveform is closer to desired sinusoid in the 3-level case, the output voltage has lower total harmonic distortion (THD) even if the switching frequency is low. For 3-phase converters, space vector–based PWM can be used for generating the switching signals (e.g., see Ref. 40), the advantage in the multilevel case compared to the 2-level case being the significantly higher number of output voltage vectors.

Multilevel Converter Topologies. There are three basic multilevel converter topologies—diode clamped, flying capacitor, and cascaded full-bridge converters.

Diode Clamped Converter. Figure 22-23*a* shows 1-phase leg of a 3-level diode clamped converter [41]. The input dc bus is split by means of capacitors. Pairs of switches are turned on to obtain three different voltage levels for the output voltage $v_{AN} = 0$, $V_{in}/2$, V_{in}, as shown in Fig. 22-23*c*. It is evident that this circuit acts like a *tripositional* switch connecting the output to one of three positions of the input dc bus. The minimum voltage at point b_1, and the maximum voltage at point b_2, is clamped to $V_{in}/2$ by the blocking diodes D_{b1} and D_{b2}, respectively. Thus, all the switches have to block $V_{in}/2$ during their off state. This topology can be extended to more number of levels. However, it is eventually limited by the voltage rating of blocking diodes, which have to block increasing voltages as the number of levels is increased. One-phase leg of a 5-level version is shown in Fig. 22-23*b*.

Flying Capacitor Converter. Figure 22-24 shows the topology of a 3-level flying capacitor converter. The basic idea here is that the capacitor *C* is charged to half the input dc voltage by appropriate control of the switches. The capacitor can then be inserted in series with the output voltage—either adding or subtracting $V_{in}/2$, and thereby giving 3-output voltage levels.

Cascaded Full Bridge Converters. In this scheme [42], single-phase H-bridges shown in Fig. 22-19*a* are connected in series at the output to form one single phase circuit. Three separate

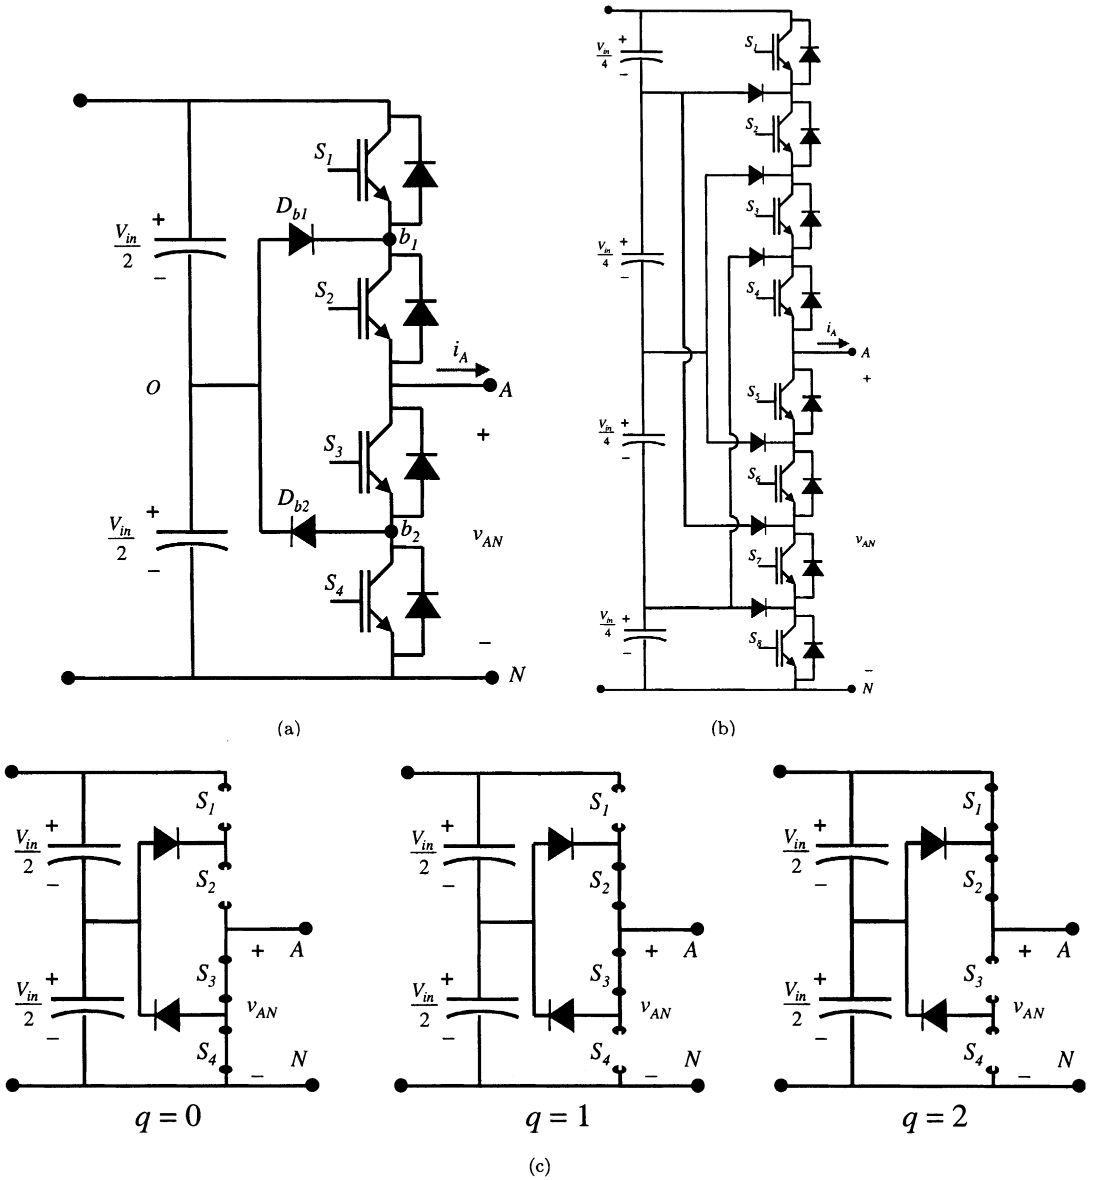

FIGURE 22-23 Diode clamped converters: (*a*) one phase of a 3-level converter, (*b*) one phase of 5-level converter, (*c*) switching states in a 3-level converter.

circuits are required for a 3-phase implementation. Since all the H-bridges are same, the circuit is modular and can be scaled by adding more H-bridges. However, dc sources at the input of all H-bridges have to be isolated from each other. It is also possible to combine different types of H-bridges—IGBT-based fast switching type and GTO-based slower switching type—or have different dc bus voltage magnitudes in different bridges to optimize losses or increase effective number of levels.

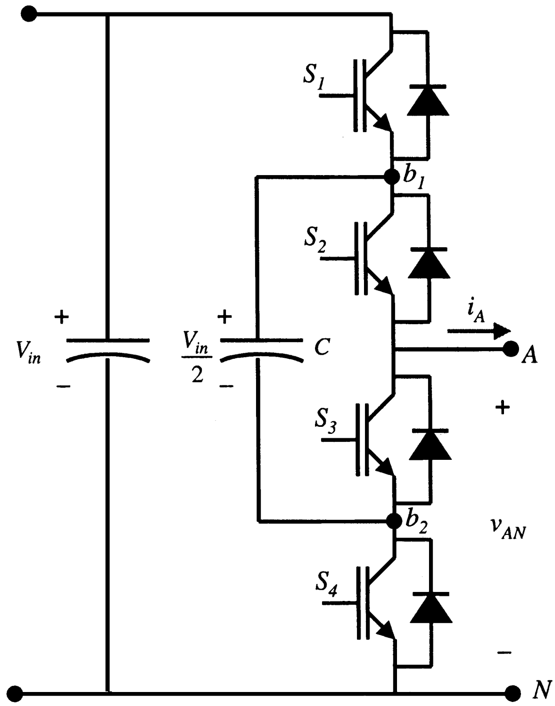

FIGURE 22-24 3-Level flying capacitor converter.

22.6 AC-DC CONVERSION: RECTIFICATION

AC-dc converters, or rectifiers, are used at the input of almost all line connected electronic equipment. Electronic devices that are powered directly from line and do not have regulation requirements use single- and 3-phase diode bridge rectifiers for converting line frequency ac to an uncontrolled dc voltage. For control over the output dc voltage thyristor-based rectifiers are used. Power factor corrected front end converters, discussed in Sec. 22.8, provide output voltage regulation as well as near unity power factor.

22.6.1 Single-Phase Diode Bridge Rectifier

Figure 22-25*a* shows the circuit of a single-phase diode bridge rectifier with a purely capacitive output filter. Due to its simplicity and low cost this circuit is preferred for low-power applications such as input stages of ac-dc adapters and computer power supplies. Diodes conduct in pairs to transfer energy from the input to the output when the input line voltage exceeds the output dc voltage in magnitude. Diodes D_1 and D_4 conduct when $v_s > v_o$, while D_2 and D_4 conduct when $-v_s > v_o$. The capacitor C_d gets charged by high current pulses during these small intervals near the peak of v_s, and discharges with the almost constant load current during the rest of the line cycle, as shown in Fig. 22-25*b*. The output dc voltage is approximately equal to the peak of the line voltage minus the forward voltage drop of two diodes. The capacitor value is chosen on the basis of the maximum load current and allowable output voltage ripple. The line current has significant harmonic content as shown in Fig. 22-25*c*. Source inductance of the line, common for regular utility supply, leads to lower peak input current, larger conduction times for the diodes, and reduced magnitude of the output voltage.

To quantify the line current distortion the following definitions are commonly used.

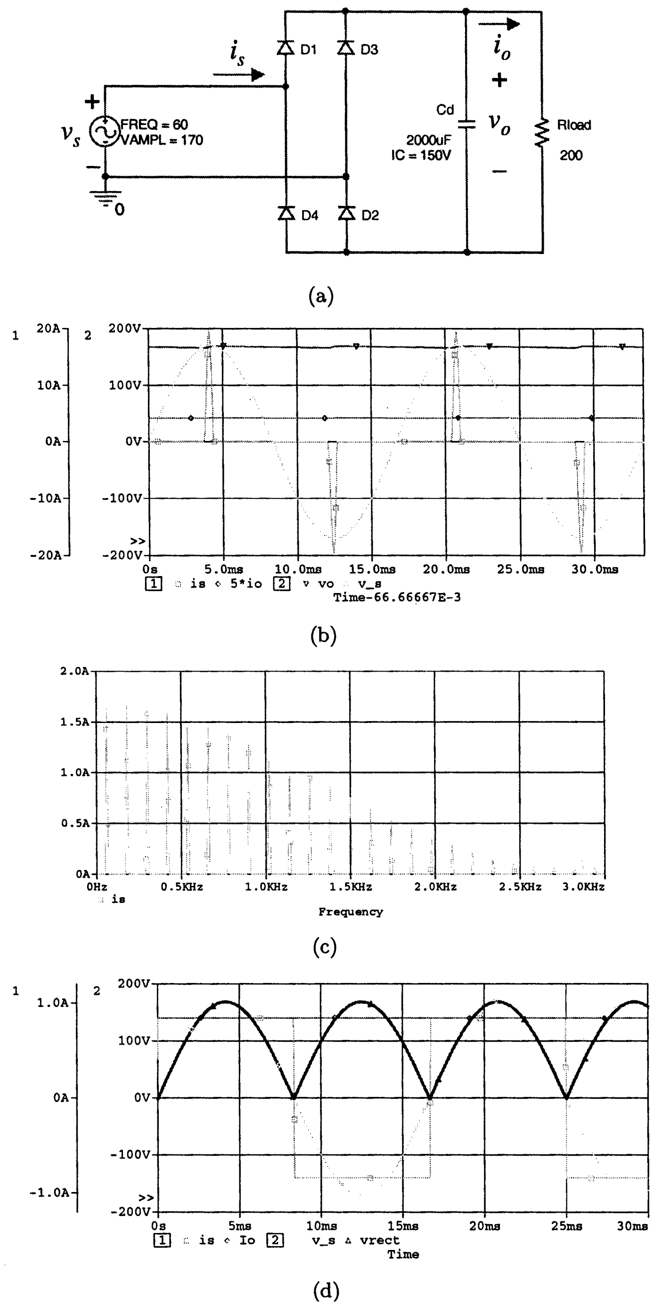

FIGURE 22-25 Single-phase diode bridge rectifier (*a*) circuit, (*b*) waveforms, (*c*) line current harmonics, (*d*) waveforms with inductive filter.

Total Harmonic Distortion. THD is the ratio of rms values of the distortion component to the fundamental component, expressed as a percentage

$$\mathrm{THD} = \frac{I_{dist}}{I_1} \times 100 = \frac{\sqrt{(I^2 - I_1^2)}}{I_1} \times 100 \tag{22-49}$$

Real Power. This is the actual value of power consumed computed as an average over one line cycle

$$P_{real} = \frac{2\pi}{\omega}\int_0^{2\pi/\omega} v_s(t)i_s(t)\,dt = VI_1\cos(\phi_1) \tag{22-50}$$

Apparent Power. It is the product of the rms values of the input voltage and current

$$P_{app} = V \cdot I \tag{22-51}$$

Power factor. Power factor (PF) is defined as the ratio of real power to apparent power.

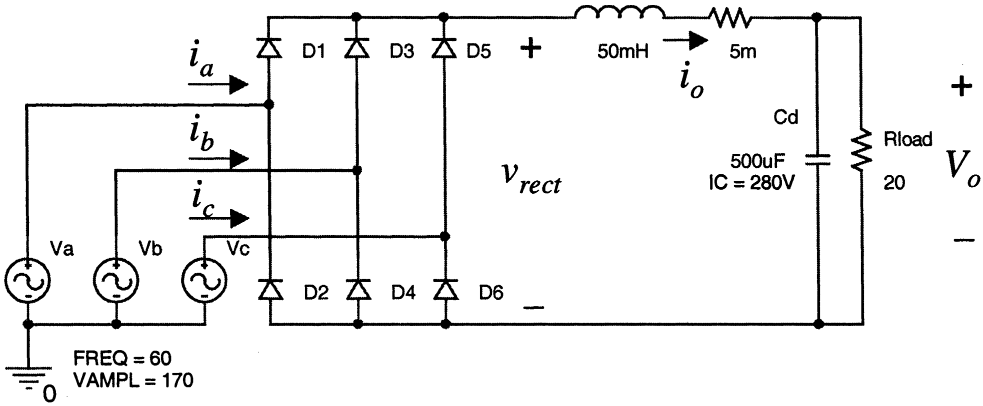
$$PF = \frac{P_{real}}{P_{app}} = \frac{VI_1\cos(\phi_1)}{VI} = \frac{I_1}{I} \cdot \cos(\phi_1) \tag{22-52}$$

where V, I, and I_1 denote the rms value of the voltage, current, and fundamental component of the current, respectively, ϕ_1 is the phase angle of the fundamental component of the current with respect to the input voltage (assumed sinusoidal), and I_{dist} is the rms value of the distortion component of the input current. The term $\cos(\phi_1)$ is called the *displacement power factor*, while the term I_1/I is called the *distortion power factor*.

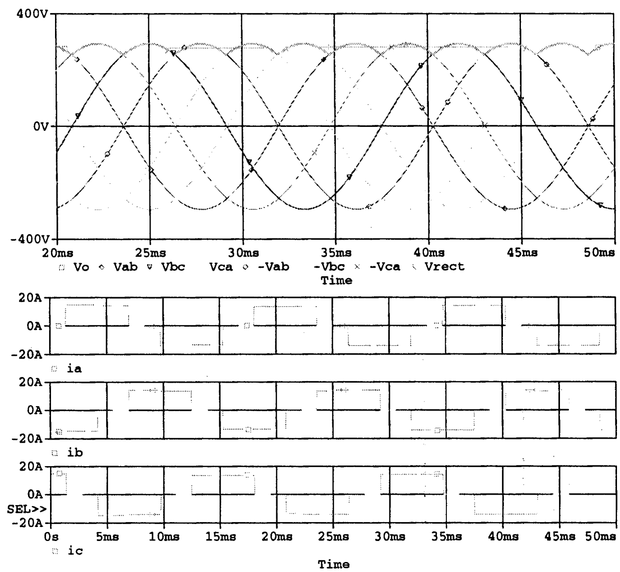
For the circuit values of Fig. 22-25*a*, the load current is 0.84 A, the peak line current $\hat{I}_s = 19.4$ A, rms line current $I_s = 3.8$ A, rms of the fundamental component $I_{s1} = 1.18$ A, $THD = 280\%$, and the PF = (1.18/3·8) · cos(2.0°) = 0.31. The quality of the input current can be improved significantly if an inductive filter is used at the output of the rectifier. With a high enough inductance, the output current can be maintained nearly constant. This leads to a square wave shape for the input current as shown in Fig. 22-25*d*, which has a THD of 48% and a PF of 0.9. With the inductive filter, the output voltage has an average value equal to the average value of a rectified sinusoid, that is, $2\hat{V}_s/\pi$, where V_s is the peak value of the input phase voltage. Inductive output filter is preferable for medium power applications so that the input current has lower harmonic content.

22.6.2 Three-Phase Diode Bridge Rectifier

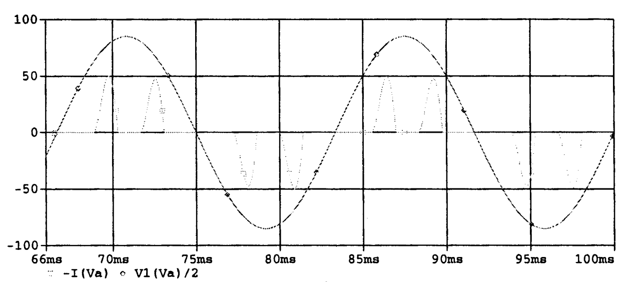
Figure 22-26*a* shows a 3-phase diode bridge rectifier with an inductive output filter. The operation is similar to the single-phase case. Diodes conduct in pairs—one from the upper three and one from the lower three. Cathodes of diodes D_1, D_3, and D_5 are connected together, so the diode with the highest voltage at its anode conducts. The converse holds for diodes D_2, D_4, and D_6. The rectified voltage follows the envelope of the line voltages and their negatives: $v_{rect} = \max(|v_{ab}|, |v_{bc}|, |v_{ca}|)$. This rectifier is also called the 6-pulse rectifier because the voltage at the output of the diode bridge, v_{rect}, has six pulses in every line cycle. The average output voltage across the load is $V_o = \bar{v}_{rect} = (3/\pi)\hat{V}_{LL}$, $\hat{V}_{LL}$ being the peak value of the line-to-line voltage. The input line currents can be derived considering which diodes are conducting at a given time. They have quasi-square waveshapes as shown in Fig. 22-26*b*. The harmonic distortion is lower than in the single-phase case with inductive filter: THD = 31% and PF = 0.955. If the output filter is purely capacitive, the output voltage is equal to $\hat{V}_{LL}$, while the input currents are significantly distorted (Fig. 22-26*c*) and have harmonics at $(6m\pm1)f$, where f is the line frequency and m is an integer. As in the single-phase rectifier with capacitive output filter, THD of the input current depends significantly on the source impedance.



(a)



(b)



(c)

FIGURE 22-26 3-Phase diode bridge rectifier (*a*) circuit, (*b*) waveforms with inductive filter, (*c*) line current waveform with capacitive filter.

The quality of input current and PF generally improve when going from single-phase to three phase, and can be further improved with higher number of phases if voltages with appropriate phase difference are generated from the utility supplied three phases. The output filter requirements also reduce as the number of phases is increased. With six voltage sources phase shifted by 30°, 12 diodes can be utilized to generate a 12-pulse rectifier. Isolated voltage sources phase shifted by 30° can be obtained using a wye-delta connected 3-phase transformer. Other phase shifts are generated by vectorial combination of appropriately scaled and isolated voltages that are obtained from the input 3-phase voltages using line frequency transformers. Rectifiers with pulse numbers 12, 18, and 24 are common for medium- and high-power applications that require good PF and low THD but do not have stringent constraints on size and weight.

22.6.3 Controlled Thyristor Rectifiers

Diode bridge rectifiers do not have any regulation capability and the output dc voltage varies with changes in line and load. This drawback is overcome by controlled thyristor rectifiers. Thyristor rectifiers are primarily used in medium- to high-power applications where regulation of the output dc voltage is required but line current quality and PF are not important (or can be corrected externally). Increasing concerns for power quality have resulted in reduced applications for these converters. High-power dc motor drives, especially those used in traction, battery chargers, and high-voltage dc (HVDC) transmission are the most common uses for these converters.

To understand the operation of thyristor rectifiers it is first necessary to know the basic terminal characteristics of thyristors. Thyristors, also called silicon-controlled rectifiers (SCRs), are high-power semiconductor devices that can block voltage of either polarity and conduct current in one direction (from anode to cathode). They can be switched on by applying a current pulse to their gate terminal when forward biased (positive voltage from anode to cathode), and can be switched off only by reducing the device current to zero.

Single-Phase Thyristor Recitifier. Figure 22-27*a* shows a single-phase *fully controlled* thyristor rectifier. The output has to be inductive for proper operation. For analysis presented here, it is assumed that I_o is constant and that there is no source impedance. During the positive half of the line cycle ($v_s > 0$), T_1 and T_4 are switched on after a delay angle α from the zero crossing of v_s. The angle α is commonly called the *firing angle*. With T_1 and T_4 on, $i_s = I_o$ and $v_{rect} = v_s$. When v_s reverses in

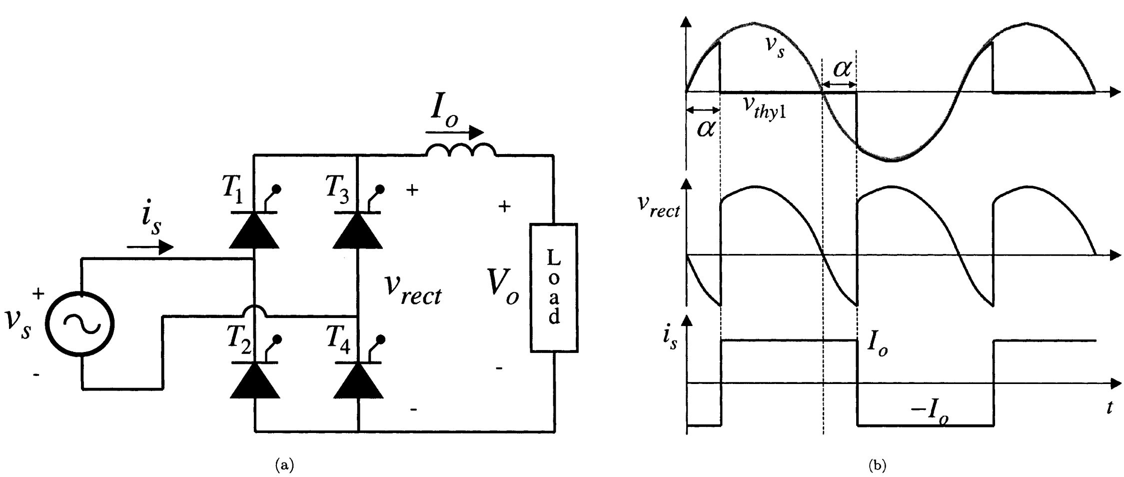


FIGURE 22-27 Single-phase thyristor rectifier: (*a*) circuit, (*b*) waveforms.

polarity thyristors T_1 and T_4 keep conducting since the current through them has not been reduced to zero. During the negative half cycle, T_2 and T_3 are switched on after angle α from the zero crossing of v_s. At this point current is transferred from (T_1, T_4) to (T_2, T_3). In reality there is some finite source inductance, due to which the current transfer takes some time [4]. Once T_2 and T_3 start conducting $i_s = -I_o$, and there is a reverse voltage across T_1 and T_4 that keeps them in the off state. Steady state operating waveforms are shown in Fig. 22-27*b*. The average dc voltage across the load is given by

$$V_o = \bar{v}_{rect} = \frac{1}{\pi}\int_{\alpha}^{\alpha+\pi} \hat{V}_{ph}\sin(\omega t) \quad d(\omega t) = \frac{2\cos(\alpha)}{\pi}\cdot \hat{V}_{ph} \tag{22-53}$$

V_o can be controlled by varying $\alpha \in [0°, 180°]$. It is maximum for $\alpha = 0°$, where the thyristor rectifier behaves exactly like a diode bridge rectifier, and zero for $\alpha = 90°$. For $\alpha > 90°$, $V_o < 0$, and power is transferred from the dc side to the ac side. Where bidirectional power flow is not required, thyristors T_2 and T_4 are replaced by diodes resulting in a *half-controlled* rectifier [43]. Total harmonic distortion of the input current is same as that in the diode bridge rectifier, but the fundamental component of the input current lags the input voltage by angle α, leading to a displacement PF of $\cos(\alpha)$. Thus, regulation of output voltage is achieved at the expense of lower PF.

Three-Phase Thyristor Rectifier. The 3-phase thyristor rectifier is shown in Fig. 22-28*a*. Similar to the single-phase case, each thyristor is switched with a delay of angle α after the anode to cathode voltage across it becomes positive. Each thyristor conducts for 120°, so the input line currents are quasi-square waves with magnitude equal to I_o, as shown in Fig. 22-28*b*. The average output voltage is $V_o = (3\cos(\alpha)/\pi)\hat{V}_{LL}$. For $\alpha > 90°$, power flows from the dc side to the ac side, and the converter acts like an inverter. For unidirectional power flow the three lower thyristors can be replaced with diodes to give a half-controlled version. As with diode bridge rectifiers, thyristor bridges can also be used to obtain 12 (or higher) pulse rectification resulting in lower THD for the input current and reduced size for the output filter. Due to the bidirectional power flow capability of this converter and very high voltage and current rating of thyristors, series connected thyristor rectifiers are utilized in HVDC transmission systems [44].

22.7 AC TO AC CONVERSION

In applications where a controllable 3-phase ac voltage has to be synthesized, the most common strategy is to first rectify line frequency ac to obtain a dc voltage, and then use a 3-phase inverter. The dc link requires a substantial electrolytic capacitor, which filters the dc voltage and also provides energy storage for short duration line voltage sags and interruptions. Capacitors add significant size and cost, and electrolytic capacitors also have the problem of lower reliability. To reduce the number of stages from two to one, and to eliminate the electrolytic capacitor, there has been a significant research effort in direct ac to ac conversion.

Thyristor-based *cycloconverters* [43] have been used extensively for direct ac to ac conversion. In these converters, a low-frequency ac waveform is synthesized by a piecewise combination of the available input ac voltages. These converters have been used for high-power variable frequency ac drives. However, they have limited control over the magnitude, frequency, and quality of the output voltage, and quality of the input line current.

Recently, matrix converters utilizing controllable bidirectional switches and PWM have been developed. As the name suggests, a matrix converter consists of a matrix of switches connecting each input phase to each output phase as shown in Fig. 22-29*a*. All the switches, denoted by square boxes in the figure, need to have bidirectional voltage blocking and current conduction capabilities. So far, a single semiconductor switch with these capabilities has not been invented. Thus, the switch has to be realized using a combination of existing power devices. One implementation is shown in Fig. 22-29*b*.

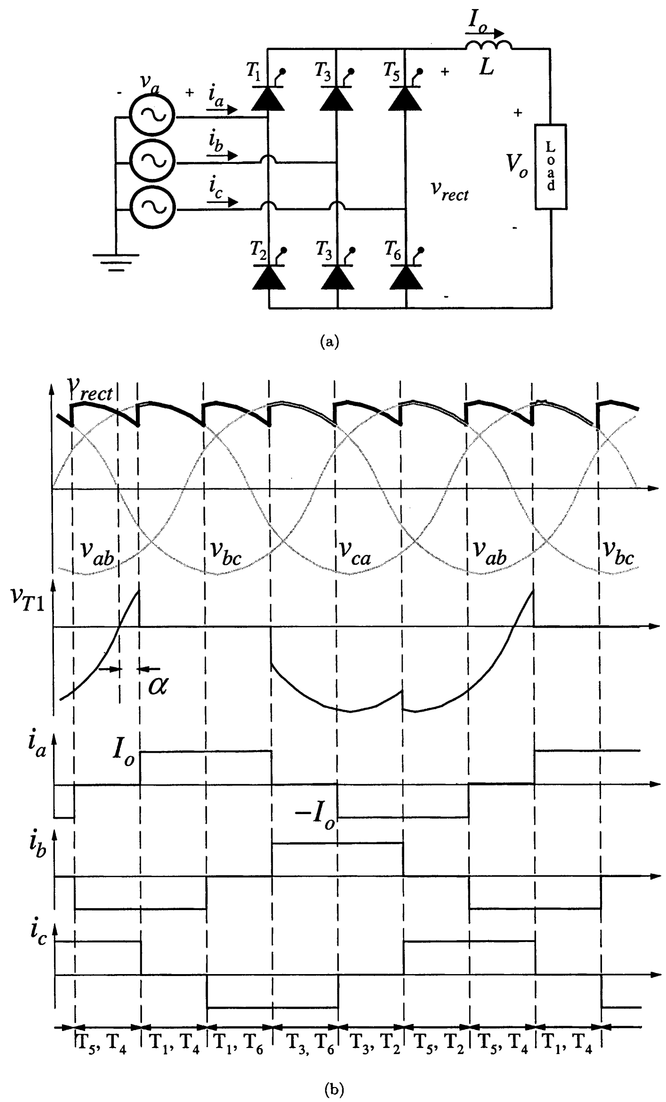

FIGURE 22-28 3-Phase thyristor rectifier: (*a*) circuit, (*b*) waveforms.

At any time instant each of the output phases is connected to one of the input phases, and more than one output phase may be connected to the same input phase. Selecting appropriate switches and using PWM, output voltages with continuously variable amplitude and frequency can be synthesized. The synthesis is most easily understood by means of space vectors [27, 45]. The total number of meaningful switching combinations are 27. Out of these, 6 lead to output voltage space vectors rotating at the input line frequency, 18 lead to stationary output voltage space vectors, while 3 lead to zero vectors. As in the dc to 3-phase ac case, on an average basis, a desired output voltage vector can be synthesized by using a combination of the stationary nonzero and zero space vectors. There is sufficient flexibility to ensure that the input power factor is unity. Considerable research has also

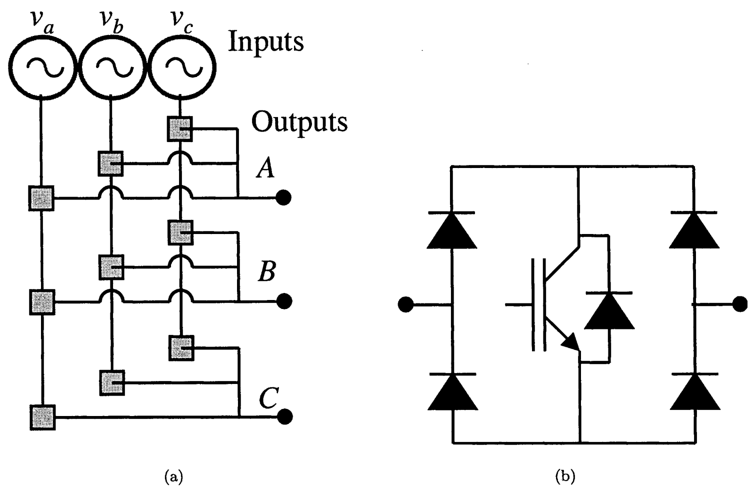

FIGURE 22-29 Matrix converters: (*a*) 3-phase matrix converter, (*b*) bidirectional switch.

been done to ensure proper operation of matrix converters under unbalanced line conditions. However, as shown in Ref. [46] the output voltage of a matrix converter has a theoretical limitation of $V_{LL,op} = (\sqrt{3}/2)V_{LL,in}$, which is considerably lower than that obtainable with an ac-dc-ac configuration ($V_{LL,in}$). In addition, clamping circuits and small input and output filters are required for proper operation.

So far, matrix converters have not been commercially successful. This is chiefly due to the number and cost of bidirectional switches, limitation on the maximum amplitude of the output voltages, and lack of energy storage, which is becoming increasingly important to provide *ride-through* capability during short duration line failures.

22.8 PROBLEMS CAUSED BY POWER ELECTRONIC CONVERTERS AND SOLUTIONS

The two main problems caused by power electronic converters are non-sinusoidal currents injected into or drawn from the utility and conducted and radiated electromagnetic emissions potentially leading to electromagnetic interference (EMI). In addition, power electronic converters have a negative incremental impedance, that is, as the input voltage reduces they draw higher current in order to supply a constant load power. Thus, as the total load supplied by power electronics increases, their effect on power system stability will also increase.

22.8.1 Harmonics and Power Factor Correction

As illustrated in Sec. 22.6, diode bridge rectifiers can inject significant current harmonics, and also result in a lagging power factor for the current. Both harmonics and lagging power factor lead to increased line losses. The harmonic currents in conjunction with the source impedance to the point of common coupling (pcc, where other loads are connected), lead to a distortion in the pcc voltage. Triplen harmonics from single-phase rectifiers contribute to zero-sequence currents when connected in a 3-phase system with a common neutral. If there are several single-phase diode bridge rectifiers connected across different phases and the neutral in a 3-phase system, it can lead to a very significant current flowing in the neutral wire, which is rated to carry only a small current due to load imbalance. Grid connected inverters can also inject currents at the switching frequency unless the switching frequency is sufficiently high or appropriate filters are added.

Due to these concerns, standards have been formulated to limit the amount of distortion in current drawn from and injected into the utility supply. The IEEE 519 [47] specifies the maximum value for individual current harmonics and the overall THD for different applications and power levels. In addition, it also specifies a limit on the distortion in the pcc voltage. However, so far, the IEEE 519 is only a recommendation and not enforced by law. The IEC 1000-3 standard [48] specifies similar limits, and has been made into the EN61000-3-2 European norm. Thus, all electronic equipment sold in Europe has to comply with it. As a result, single-phase and 3-phase unity power factor (UPF) rectification techniques and power factor correction methods have been developed. Unity power factor rectification implies that the rectification technique ensures unity power factor operation. Power factor correction implies that the equipment itself does not draw input current at unity power factor; however, an additional circuit, such as an active, passive, or hybrid filter, is added to ensure that the line current is sinusoidal and in phase with the input voltage. The simplest single- and 3-phase UPF techniques are discussed below. A more comprehensive treatment can be found in Refs. [5, 49].

Single-Phase Boost UPF. The single-phase boost UPF, shown in Fig. 22-30*a*, is the most popular circuit for shaping the input current to be sinusoidal, maintaining it in phase with the input voltage, and regulating the output dc voltage [4, 5].

Basic Operation. The circuit consists of a full-bridge diode rectifier followed by a boost converter. The input voltage to the boost converter, v_{rect}, varies based on the diode conduction; ideally it is a rectified sinusoidal waveform. The output voltage v_o has to be greater than $\max(v_{rect}(t))$ for proper operation; to work with both 120 and 220 V ac inputs (also called universal input voltage range) the output is usually chosen in the range of 380 to 400 V. The boost converter operates so that there is a quasi-steady condition at each point of the input sine wave. Thus, the duty ratio varies as

$$d(t) = 1 - \frac{v_{rect}(t)}{v_o} = 1 - \frac{\hat{V}_s\left|\sin(\omega t)\right|}{v_o} \tag{22-54}$$

The duty ratio is controlled to satisfy two objectives: regulation of output voltage and shaping the inductor current to follow the waveshape of $v_{rect}(t)$. This is done by using the cascaded control structure shown in Fig. 22-30*b*. The error compensator for the outer voltage loop, $G_v(s)$, generates a reference signal for the amplitude of the inductor current (or the rectified input current), $\hat{I}_L$,*ref*. The effect of input voltage magnitude is fed forward by dividing the output of $G_v(s)$ by a signal proportional to square of the rms input voltage. The amplitude reference $\hat{I}_{L,ref}$ is multiplied by the waveshape of the rectified voltage to obtain $i_{L,ref}(t)$, the reference signal for the inductor current. The inductor current $i_L(t)$ is controlled to $i_{L,ref}(t)$ by using average current mode control. Steady-state waveforms are shown in Fig. 22.30*c*.

Control Issues. The current control loop has a bandwidth of the order of 10 kHz, required to follow the rectified sine wave shape accurately enough so that input current has acceptable THD. After each zero crossing of the input voltage, the positive rate of change of inductor current required is very high, while the voltage to effect this change, $v_{rect}(t)$, is close to zero. Thus, there may be a significant error in the current during this time, and the resulting distortion in the input current is called *cusp distortion*. Cusp distortion contributes to harmonics and lagging power factor.

The output voltage necessarily has a 120 Hz ripple component due to variation of power in single-phase systems. The error in the voltage feedback loop also has this ripple component. If this component is compensated by the control loop, it leads to a 120 Hz component in the output of $G_v(s)$, which after multiplication with the rectified voltage waveshape leads to a third harmonic component in the input current. To avoid this, the bandwidth of the voltage control loop is intentionally kept very low—in the range of 5 to 20 Hz. The converter, therefore, has very poor dynamic response with respect to changes in load. The input voltage feed forward signal also has to be filtered heavily to attenuate the ripple component sufficiently. Thus, although the feed forward improves the dynamic performance with respect to line changes, it is still quite slow. Further, to keep the voltage control design simple, a pure integrator is not added in the voltage

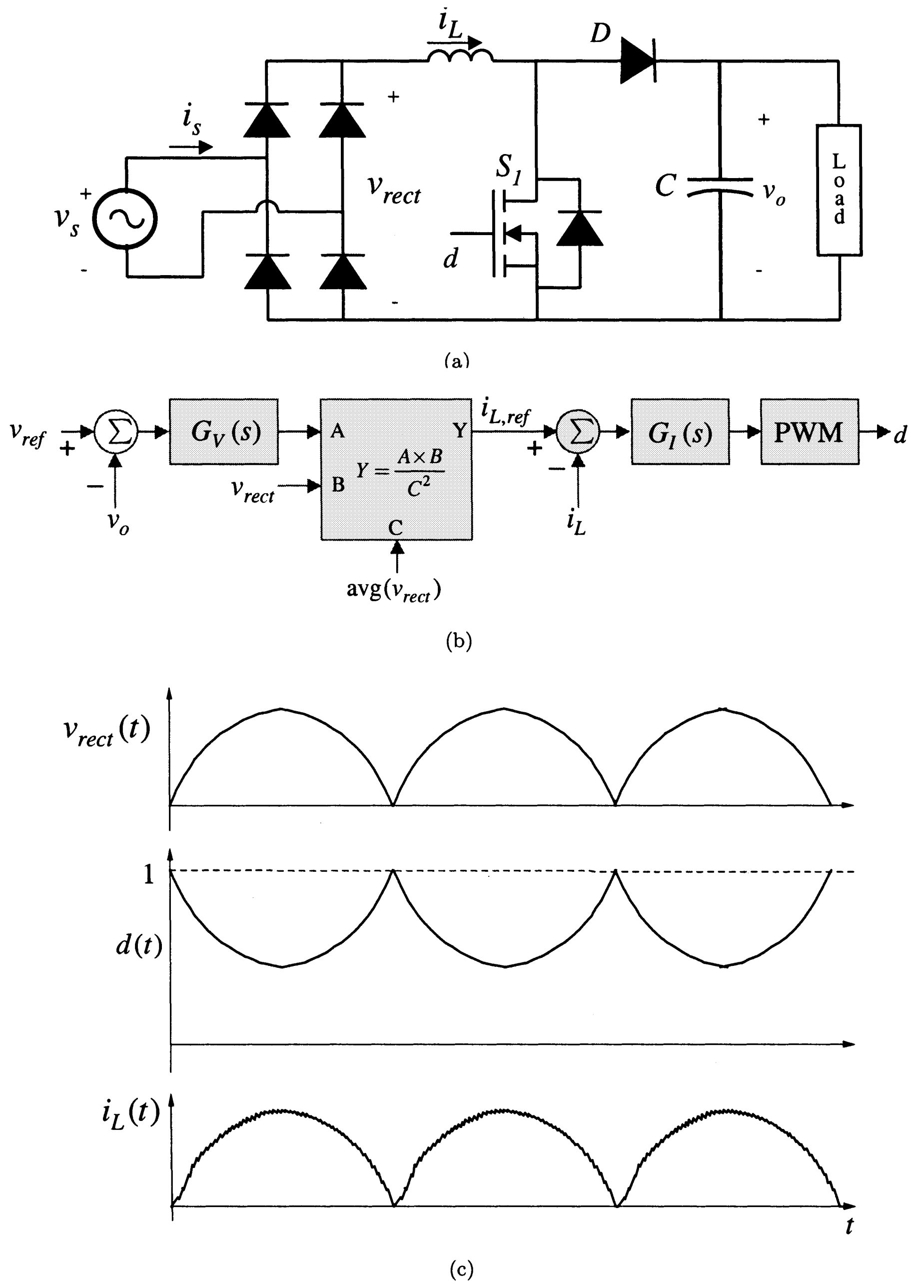

FIGURE 22-30 Single-phase boost UPF (*a*) circuit, (*b*) control block diagram, (*c*) steady-state waveforms.

control loop leading to a nonzero steady-state error. Typically, the output voltage drops by about 10 to 20 V from no load to full load.

The entire control, including the multiplier and divider circuit, can be implemented by means of a single analog integrated circuit (IC) such as the UC3854 [9], although digital implementations are also being explored. The availability of a single chip controller, easy to design power stage, and standardized control design equations (e.g., see the UC3854 application note on TI's website [9]) has made this topology very popular for single-phase applications. However, there are several other topologies that may be suitable for specific applications [5, 49].

The dynamic performance of the single-phase boost UPF is not adequate if the output is directly connected to a load. Usually, isolation of output from input line is a requirement, and the required output voltage may be significantly different from 400 V. Thus, an isolated dc-dc converter stage is required at the output of this UPF. This additional converter takes care of regulation, isolation, and scaling the voltage.

3-Phase UPF. In the 3-phase case, the diode bridge rectifier can be replaced by a 3-phase PWM inverter with external inductances in series with each phase. By appropriate control, this converter can transfer power from the ac side to the dc side. Input currents can be controlled in a manner similar to the single-phase case—waveshape determined by input voltages and amplitude determined by the voltage control loop. The converter operates in boost mode so the output dc voltage is regulated to a value higher than the peak of the input line-to-line voltage. In this case, dynamic response of the voltage control loop is limited by the nonminimum phase nature of the system. This 3-phase rectifier is very expensive compared to its diode bridge counterpart, and its cost is justified only if bidirectional power transfer capability is required. Thus, several alternate solutions for 3-phase power factor correction have been proposed [5, 49].

22.8.2 Electromagnetic Interference

Electromagnetic interference refers to maloperation of electronic equipment due to electromagnetic emissions which originate in the "surroundings". Here, surroundings refer to other electronic equipment that are electrically connected or spatially close. Electromagnetic emissions emanate from transitions in currents and voltages, especially fast transients involving high magnitudes. Thus, power electronic converters can be major source of emissions leading to EMI. Within a converter the main sources are as follows:

- Current transfer between rectifier diodes.
- Switching of semiconductor devices: capacitive coupling between the high voltage switching terminals of the device and heat sink (which is usually grounded) leads to high-frequency common mode and differential mode currents.
- High-frequency inductors and transformers.
- Long wires or printed circuit board (PCB) traces carrying high-frequency currents.

Emissions can be classified into two types: *conducted* and *radiated*. In the conducted case, high-frequency currents produced due to switching transients flow through the parasitics in the power converter, and are manifested as common mode and differential mode currents at the inputs and outputs of the converter. At the output it can cause EMI problems for sensitive loads, and at the input it creates problems for other equipment connected to the utility. To restrict conducted emissions, EMI filters, good circuit board design, and packaging are needed [7, 50]. *Common mode chokes*, which offer high impedance to common mode currents and very low impedance to differential mode currents, are used to limit common mode currents. Differential mode high-frequency currents are attenuated by using capacitors to earth ground; the capacitance values are limited by the maximum allowable ground current specified by safety regulations like UL478 and UL1283. Complete EMI filters that provide both common and differential mode attenuation are commercially available as packaged units from several manufacturers.

Radiated emissions affect high impedance voltage sensitive circuits (e.g., MOS input circuits) that are in close proximity to the converter. To reduce radiated emissions, inductors and transformers are shielded (especially around air gaps), a careful PCB design that minimizes long paths for high frequency and switched currents is carried out, and long wires carrying high-frequency currents are twisted with their return lines. "Twisting" can also be approximately achieved for PCB traces. In addition, the entire converter may be shielded by a grounded metal enclosure.

Depending on the application power converters have to comply with an emissions standard. Emissions standards, formulated by the FCC [51], VDE [52], and the military, dictate the maximum amount of conducted and radiated emissions allowed for different kinds of electronic equipment.

22.9 APPLICATIONS OF POWER ELECTRONIC CONVERTERS

The foregoing sections described the principles and control of different power converters. This section describes the requirements of specific applications, and how power electronic converters are utilized for these. The next section is devoted to utility applications of power electronics.

22.9.1 DC Power Supplies

DC power supplies are required for powering different components in electronic equipment. Their specific features and level of sophistication depend on the application. For example, in a *bias supply*, required for various analog components in a power converter, the main requirements are isolation and a (relatively) large tolerance in the output voltage level. The input to the bias supply may be derived from a regulated dc bus, so line regulation is not required. A simple push-pull converter without an output inductor can be used for this purpose. For use inside a sensitive instrument, the power supply requirements would include strignent regulation with respect to line and load, good dynamic response, compliance with EMI and input power quality standards, and adequate energy storage for normal operation during short duration line failures. Features commonly required in dc power supplies are as follows.

Output Voltage Regulation with Respect to Line and Load. For high-current low-voltage power supplies there may be an additional requirement of regulating the voltage at the load terminals. This requirement, called remote sensing, accounts for voltage drops in the connecting wires. Dynamic requirements of response time and overshoot/undershoot in the output to step change in load current are also specified.

Output Current Limit. This may be a fixed value, or have a *foldback* characteristic [6]. With the latter, once the output current exceeds a certain value, the current limit is varied as a function of output voltage—decreasing as the output voltage decreases.

Isolation. Electrical isolation between output and input.

Soft Start. This is required to limit the inrush current for initial charging of capacitors.

Holdup Time. For line powered applications, there is usually a requirement for holdup time, time for which the power supply should operate normally in the absence of the input voltage. Usually energy storage is provided by adding capacitors; sometimes auxiliary capacitors charged to a higher voltage to store more energy are used.

Sleep Mode. Typically power supplies have a low efficiency at light load. Thus, in battery-powered and portable applications light load condition is detected and the power supply operation is changed to reduce its losses, for example, by reducing the switching frequency.

Power Factor Corrected Front End. For single-phase applications, it also helps in operation with universal input voltage range (100–240V, 50/60 Hz).

EMI Compliance. With a specified standard.

Environmental compliance. For temperature, humidity, and altitude of operation. Some features can be implemented with standard PWM control ICs leading to reduced number of components and design simplification. Commercial availability of low power dc-dc converters modules with standard input and output voltages has increased significantly in recent years. Thus, a custom power converter design may not be required, unless there are special requirements as in space, defense, and some instrumentation applications.

A specific application of dc power supplies is in digital systems. All digital systems need a power electronic converter to provide the requisite supply voltages. With the digital supply voltages going down and the clock frequencies going up, the requirements are increasingly toward low voltages and high currents. For a high-speed microprocessor, the required values are around 2 V and a few hundred amperes. The dynamic requirements are also very demanding since the microprocessor load can go from almost zero current to full load current in a few microseconds. Furthermore, digital components operating at different supply voltage levels may be used in a complete digital system. For these applications, the intermediate bus architecture is used. First, a 12 V (or a lower voltage) bus is derived from the input supply using an intermediate bus converter (IBC); the IBC may also provide isolation from the input. This low-voltage bus is then input to several point-of-load (POL) converters, which are located close to the loads and provide the required steady state and dynamic voltage regulation. Point-of-load converters do not provide isolation between input and output. Intermediate bus converter and POLs with standard input and output voltages are commercially available as modules from several manufacturers (e.g., see Refs. [17, 53]).

22.9.2 Electric Drives

Introduction. Traditionally electric motors have been powered by direct connection to ac line, or to dc voltage obtained from a rectifier. However, this usually results in inefficient operation due to lack of control. Electric motors powered by appropriately controlled power electronic converters lead to significant increase in the overall system efficiency due to the advantages of variable speed operation [54]. Electric motor load has more than half the share of electric power consumption in the United States, of which about half is in industrial applications. Thus, any increase in system efficiency due to electronic controlled motor drives can lead to large savings for the company and overall electricity consumption. Moreover, performance advantages of fast dynamic response and very accurate control over speed and position are obtained.

Squirrel cage induction machines (IMs) are the most widely used electric motors. This is due to the advantages of simple, robust, and low-cost construction, ease of powering, and lower maintainance requirement due to the absence of brushes. Thus, control of induction machines for better performance and improved efficiency has been researched extensively. The invention of vector control [33], and direct torque control [34, 35] have made the dynamic performance of induction machines similar to that of a dc machine. The popularity of vector control was also aided by development of PWM inverters and space vector modulation described in Sec. 22.5.3. Developments in permanent magnets and power electronics, and increasing concerns for size, weight, and efficiency have led to significant interest in permanent magnet synchronous machines (PMSM) and brush-less dc (BLDC) machines. Permanent magnet synchronous machines and BLDC motors have the highest operating efficiency and the highest power density of all the motors [55]. Further, due to development of power electronics, the switched reluctance machine (SRM), the first electromechanical machine invented in the early 1800s, has also been commercialized [56, 57]. This machine has a simple, robust, and inexpensive construction, and is powered from an inherently robust power converter topology. Switched reluctance machines are most popular in the low-to-medium power range and high-speed applications requiring medium performance. Squirrel cage induction, PMSM, Synchronous Reluctance, and BLDC drives require a 3-phase inverter for powering the stator windings and no electrical excitation for the rotor. Switched reluctance machines have a special power converter that has independent sections for individual phases. For illustration, a vector controlled ac drive and an SRM drive are discussed here. Details of these drives may be found in Refs. [28, 30, 36, 37, 54–57].

Vector Controlled AC Drive. Figure 22-31 shows the basic block diagram of a vector-controlled PMSM drive. The structure is identical for the squirrel cage induction motor drive. The input stage is a single- or 3-phase diode bridge rectifier, the output of which is filtered to obtain a dc. The input current during initial charging of the dc bus capacitor is limited using either (1) parallel combination of a controllable switch and a current limiting resistor connected in series with the main power path, or (2) a half-controlled thyristor rectifier. The dc voltage is converted to variable frequency variable magnitude 3-phase ac by means of a 3-phase PWM inverter. During *dynamic braking*, energy stored in the inertia of the machine and load is transferred back to the electrical circuit. If the rectifier has bidirectional power transfer capability, this energy can be transferred to the source. Otherwise, the energy charges the dc bus capacitance. To limit the dc bus voltage, a brake resistor is connected in parallel with the dc bus by means of a controlled switch.

The switching frequency of the inverter in ac drives is usually between 20 and 30 kHz, since the machine inductance is usually sufficient to filter the output current. Thus, IGBTs are commonly used for this application. MOSFETs are used if the dc voltage is below 600 V and a higher switching frequency is required in order to reduce the output current ripple. Intelligent power modules (IPMs) containing all the power semiconductor components along with gate drive and protection circuits in a single package are now available from several manufacturers (e.g., Refs. [58–62]). Use of IPMs results in considerable design simplification, size reduction, and smaller design cycles.

The drive control is carried out using a microcontroller or digital signal processor (DSP), with the use of DSPs becoming more popular due to increased computational requirements. In an industrial application, the DSP controls the machine in response to command signals (for speed or position) obtained over a communication interface bus. AC machines are usually controlled using either vectrol control or direct torque control. From the power electronics point of view, this requires control of the output currents with a high control bandwidth (of the order of 1 kHz). This is done in a cascade manner: the current control algorithm generates reference voltage vectors, which are then synthesized using space vector PWM. Both current control and PWM are implemented on the DSP. The final output of the DSP are switching signals for each of the three inverter legs and the brake switch. These signals are optically isolated and input to the gate drive circuitry for each of the

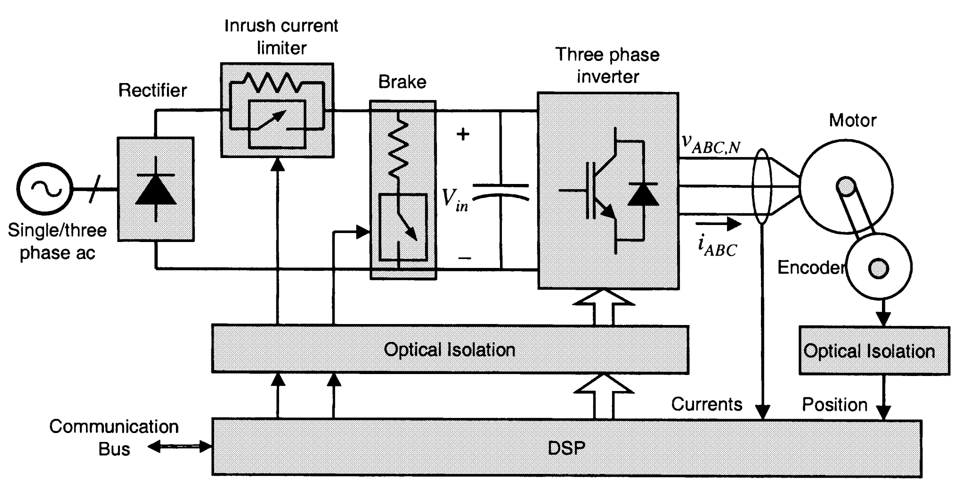

FIGURE 22-31 Vector controlled 3-phase ac drive.

controlled switches. Output currents of the inverter are sensed using either hall effect sensors or sense resistors. The analog current signal is converted to digital form using the internal analog to digital converters (ADCs) of the DSP. The dc bus voltage may also be sensed for feedforward of input line variations and dynamic braking. An optical encoder is used if direct rotor position sensing is required. Since the encoder outputs are already in digital form they can be easily interfaced. However, due to close proximity of the encoder and the machine windings, which are subject to pulsed voltages generated by the inverter, these signals have very high common mode noise. To solve this problem, differential mode line drivers and receivers, and optical isolation of encoder signals are commonly employed.

SRM Drive. The basic structure of an SRM drive is similar to an ac motor drive. However, the power converter is quite different owing to the machine characteristics. Figure 22-32*a* shows the cross-section of a 4-phase SRM. The SRM has saliency on the stator as well as the rotor. Each phase consists of concentrated coils wound on diametrically opposite stator poles. If phase *a* carries current i_a then the closest set of rotor poles are attracted to the stator phase *a* poles. Once the rotor poles are aligned with the stator poles, there is no torque on the rotor and i_a has to be reduced to zero. By energizing and deenergizing phases in sequence a continuous rotation can be achieved.

To build up and reduce winding current, the converter needs to have bidirectional voltage capability. However, since the direction of torque is independent of the current polarity, only unidirectional current capability is required. At low speeds, the back emf of the machine is very low so the winding current has to be controlled usually by hysteretic current control. This is usually done by letting the current freewheel with a zero voltage across the winding terminals, commonly called application of a zero voltage loop (ZVL). To determine which phase needs to be energized or deenergized rotor position information is required, this may be sensed or estimated, and discrete position information is sometimes sufficient [57]. Usually the total torque produced by the machine has significant ripple, and unless instantaneous torque control is a requirement, average torque control is implemented. The average torque depends on the turn-on and turn-off angles (rotor positions with respect to the phase winding where that phase is energized and deenergized, respectively), and the current magnitude if current control is used [56]. The control is usually implemented based on results of numerical simulation and then tuned experimentally.

Ray and Davis published one of the earliest paper on power converters for SRM [63], and suggested the asymmetric bridge converter, which is also known as the classical converter. The circuit topology, shown in Fig. 22-32*b*, is similar to a two-switch forward converter [4] and fulfils all the

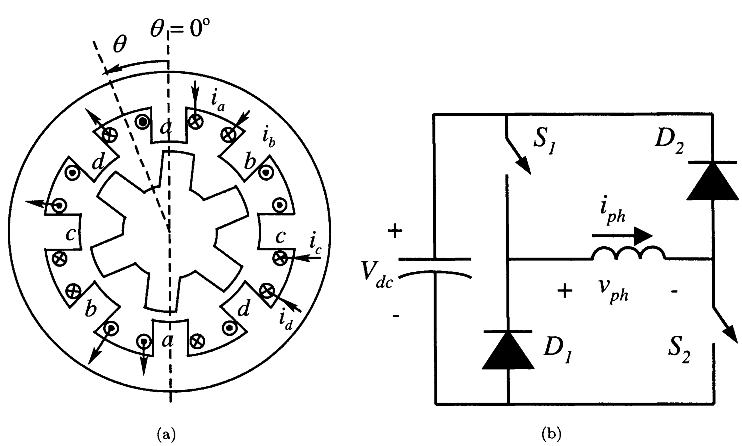

FIGURE 22-32 SRM Drives: (*a*) Cross-section of a 4-phase 8/6 SRM, (*b*) asymmetric bridge converter.

basic requirements. Only one phase is shown, the circuit being identical for the other phases with a common connection to the input dc bus. The basic operating modes of the converter are as follows:

Energization	(S_1, S_2) on, (D_1, D_2) off	$\upsilon_{ph} = V_{dc}$
Deenergization	(D_1, D_2) on, (S_1, S_2) off	$\upsilon_{ph} = -V_{dc}$
ZVL	(S_1, D_2) on, (S_2, D_1) off, or	$\upsilon_{ph} = 0$
	(S_2, D_1) on, (S_1, D_2) off	

where all switches and diodes have been assumed ideal and the winding resistance has been neglected. This converter is extremely reliable and fault tolerant. The problem of "shoot-through" due to spurious turn-on of the two controlled switches in the same leg is avoided, since the phase winding is in series with the controlled switches. Shoot-through can be a major problem in full-bridge dc-dc converters and 3-phase inverters. Although this converter topology has become very popular and a packaged module similar to 3-phase ac inverters is now available, there are several other converter topologies, which may be suitable for specific applications. A detailed comparison of SRM converter topologies can be found in Refs. [56, 64–66].

DC motor drives use a dc-dc converter—buck, buck-boost, or full bridge depending on the requirements—and armature current control for controlling the instantaneous torque. The field current may also be controlled to reduce back emf at high speeds. Their popularity has been decreasing due to maintenance requirements and speed limitations of brushes. As the cost of power electronics reduces, better and low-cost permament magnets are developed, better control and estimation techniques are implemented on lower cost DSPs, and energy efficiency gains priority, it is expected that PMSM and BLDC drives will increase their share in motor drives. Switched reluctance machines are also expected to gain ground in high speed and harsh environment applications where energy efficiency is not very important.

22.9.3 Battery Charging

Battery charging is a very large part of the ac-dc and dc-dc converter applications. The end use for batteries is in telecommunications, electric and hybrid electric vehicles, portable electronics, and energy storage for improving power system stability. For a lead acid battery, there are three standard operating modes for the battery charger: (1) constant current (or bulk) charging during low state of charge, (2) constant voltage charging after about 80% state of charge, and (3) "float" or trickle charge after the battery reaches its open circuit voltage. Thus, the requirement on the power converter is to operate at its maximum current rating over a significant output voltage range with high efficiency. In addition, isolation from input line and power factor correction are usually required.

In recent years, lithium-ion (Li-ion) batteries have gained widespread usage for portable applications like laptop computers, PDAs, and cell phones. They have also been proposed for automotive applications, but so far nickel metal hydride (NiMH) batteries are used in commercially available hybrid electric vehicles (HEV). The advantages of Li-ion batteries are high energy density, higher cell voltage of about 4.2 V, and low self-discharge rate [67]. The disadvantages are high sensitivity to electrical stress and limited temperature range. The cell voltage has to be monitored for overvoltage (which is very close to the nominal open circuit voltage) to avoid catastrophic failure, and undervoltage to maintain battery life. Linear chargers are used for single-cell batteries requiring low charging current, while switch mode converters are used for high-voltage and high-current charging. The charging technique is similar to lead acid—constant current followed by constant voltage. However, pulse charging (alongwith periodic discharge and periodic relaxation pulses) have also been proposed for improving battery life. A further complication with Li-ion is that the dependence of state of charge on open circuit cell voltage is only on a small voltage window (3.2–3.8 V). Thus, in the absence of a detailed cell model, a columb counting technique, which measures the charging and discharging current and estimates the self-discharge rate, is normally used to determine the battery state.

22.9.4 Fluorescent Lamps and Solid State Lighting

About 30% of the total electricity generated in the United States is consumed for lighting [68]. Thus, there is significant interest in increasing energy efficiency of lighting mechanisms. Incandescent lighting, although the most inefficient, is still the cheapest in terms of $/lumens. However, compact fluorescent lamps (CFLs) have gained ground due to their energy efficiency and are now commercially available as replacements for incandescent bulbs. Besides lighting, fluorescent lamps that emit ultraviolet light are used in several industrial applications like sterilization and curing (drying of coatings).

Compact fluorescent lamps and industrial lamps are usually powered using a switched mode converter called an electronic ballast. In one implementation, the converter consists of a full- or half-bridge inverter with its output connected to an L-C-C (all in series) tank circuit. The dc voltage input to the inverter may be obtained using either a diode bridge rectifier or a power factor corrected front-end. The lamp filaments are connected in series with the L-C-C tank, with the two filaments being in parallel with one of the capacitors. The other capacitor provides dc blocking and also tunes the tank operation to a desirable characteristic. When the lamp is off (gas inside not ionized), it acts as an open circuit, so the inverter is effectively connected to a series resonant L-C circuit. To ionize the gas inside the lamp, the filaments have to be heated sufficiently followed by application of a high voltage (~kV) across the lamp for a short time. Once the lamp is on (gas ionized) it acts a resistive load, and the inverter load is then a series parallel tank circuit—series L-C-C with the equivalent resistance of the lamp in parallel with one capacitor. The inverter outputs a high-frequency square wave, typically in the range of 20 to 100 kHz; lamp operation at these frequencies results in increased light output. The switching frequency is varied to control the ballast operation. Initially, the tank circuit and the lamp are excited at a frequency significantly higher than the resonance frequency. During this time, called the preheat time, the lamp filaments increase in temperature. After a suitable delay, the switching frequency is reduced toward resonance so that the voltage across the lamp increases until the gas inside the lamp ionises and the lamp “ignites”. After ignition, the lamp acts like a resistive load, and the lamp output power is controlled indirectly by regulating the phase difference between the inverter current and voltage. The tank circuit also ensures resonant transitions of the converter switches [69] leading to reduced losses. Several ICs that implement full control of a fluorescent lamp including preheat, ignition, and dimming control are commercially available (e.g., see Ref. [62]).

High intensity discharge (HID) lamps have a large share of commercial lighting such as street lighting, sports facilities, etc. They are of three types—mercury vapor, sodium vapor, and metal halide. The ballast requirements of these lamps differ from those of fluorescent lamps. Operation of these lamps at higher frequencies does not improve light output. Further, they exhibit acoustic resonance in the 10 to 100 kHz range. Thus, so far, electronic ballasts for these lamps have not become very popular.

Power supplies for plasma cutting have requirements similar to fluorescent lamp ballasts. Initially, a high voltage (~10 kV) is applied to produce an arc between two high-voltage electrodes. This is followed by *arc transfer*, transfer of the conducting ionized gas between the electrodes to the space between the negative electrode and the metal being cut (workpiece). Once the arc is transfered the cutting procedure requires a current controlled supply (at lower voltage) connected across the negative electrode and the workpiece. Since there are three terminals, two separate power supplies can be used—one for generating the initial high voltage and the other for the actual cutting operation.

The U.S. Department of Energy has identified solid-state lighting as a means to increase lighting efficiencies in the near future [68]. Recent and expected breakthroughs in semiconductor and organic light emitting diodes (LEDs) are the main impetus behind this. Another reason promoting the use of LEDs is the European Union’s directive on removal of hazardous substances (RoHS) in electrical and electronic equipment (Directive 2002/95/EC). The directive aims at phasing out the use of mercury and lead (among other substances), which are chief components of compact fluorescent and HID lamps. LEDs do not use either of these materials. Although the RoHS directive, going into effect in July 2006, makes exceptions for fluorescent and some HID lamps used for lighting, it is expected that these will be covered in future revisions of the directive. Light emitting diodes are already being used for traffic lights, exit signs, and as indicator lights in automobiles. They have the advantages of faster turn-on time, increased efficiency, vibration and shock resistance (required for automotive), and longer operating life. For solid-state lighting, light output of several series connected LEDs, called *strings*, is used. A switched mode converter with a dc current regulated output is used to power the LED string. The output current is regulated to provide dimming control and to avoid failure due to overcurrent [70]. When LEDs start replacing HID lamps, incandescent bulbs, and CFCs for commercial/residential lighting, they will open up a huge market for efficient and low-cost power electronic converters.

22.9.5 Automotive Applications

In recent years, electronically controlled load in automobiles has increased significantly. Further increase is expected due to more comfort features, and potential replacement of some mechanical systems by all electrical systems like active suspension and power steering. The present bus voltage in automotive systems (14 V), decided by the alternator charging voltage, implies very high currents for the expected high power consumption. To keep the current levels manageable, the 42 V power net has been proposed, and adopted by most auto companies and suppliers for future generation automobiles [1]. The choice of 42 V has been made on the basis of safety considerations, load dump overvoltage transients, and optimal utilization of silicon in power semiconductor devices. It is expected that there will be a dual voltage system, with both 42 and 14 V loads, although the exact configuration has not been standardized. Thus, a dc-dc converter, possibly bidirectional, will be required for interconnection between the two system voltages. Furthermore, converters with sophisticated controls will be required for features like active suspension and power steering [71].

Hybrid electric vehicles (HEVs) are now gaining commercial success due to their higher mileage, lower emissions, and tax breaks. The basic ideas in an HEV are:

- Operate engine at optimal efficiency, achieved at high speeds.
- During initial acceleration and at low speeds, power is supplied by a battery powered motor leading to reduced idling losses and emissions.
- For high acceleration, power is derived from both the engine and the battery.
- During high speeds, the battery is charged from a generator connected to the engine. The motor used for generating mechanical power can also be used as a generator.
- During braking, the generator feeds energy back to the battery.

Power electronic converters are required to control the motor (and generator for a separate machine), and for battery charging. In HEVs, the battery has to be maintained at less than full charge to receive regenerative energy during braking. Hybrid and completely electric vehicles with fuel cells as the power source and some means of energy storage are also being developed by several auto manufacturers. These require power converters to interface fuel cell, energy storage element, motor/generator, and other electronically controlled loads.

22.10 UTILITY APPLICATIONS OF POWER ELECTRONICS

22.10.1 Introduction

Power electronics has the potential to change the landscape of power generation, transmission, distribution, and end use. Growing energy demand, coupled with economic, environmental, and political restrictions on newer generation and transmission infrastructure, means that the existing resources operate near their stability limits. As a result dynamic instability, inter-area oscillations, voltage instability cascading to major blackouts have become issues of real concerns today. Power electronic technology is widely considered to be one of the key components of the grid modernization.

Distributed generation is an important energy option for the twenty-first century and is a key element of restructuring of the electric utility. Distributed generation using renewable sources such as solar, wind and tidal energy, and hydrogen, and their interface through power electronic converters, represents one of the most promising paths to sustainable energy. Also, several modern loads such as the processing plants in semiconductor industry or data centers require clean and uninterrupted power. Power electronic-based power quality solutions are essential for these loads to mitigate problems such as voltage sags, harmonics, and flicker in line voltage.

Widespread use of power electronics in power systems is further fueled by dramatic advances in power semiconductor materials and devices, especially those based on silicon carbide (SiC) [72, 73], and advances in the fields of wide area power system monitoring and communication. This section briefly describes the major power electronics applications in power systems, namely, flexible ac transmission systems (FACTS), custom power, and interfacing distributed generation with electric grid. Figure 22-33 shows the interconnected power system network with some of the major power electronics highlighted.

22.10.2 Flexible AC Transmission Systems

Flexible ac transmission systems is a collective term for different types of power electronic devices/converters based systems that are capable of controlling power flow in high-voltage ac transmission systems [74, 75]. With advances in power semiconductor devices, PWM methods, and control theory, the use of FACTS devices has seen a significant increase. Flexible ac transmission systems devices are capable of the following major functions:

- Control power flow along desired transmission corridors, which is critical for a deregulated utility; they can also minimize loop flows.
- Increase transmission capacity without requiring new transmission infrastructure.
- Improve transient, dynamic, and voltage stability, and provide damping for inter area oscillations.

Different types of FACTS devices control different parameters of the transmission system like the effective line impedance, bus voltage magnitudes, or phase angles, to control power flow, and to

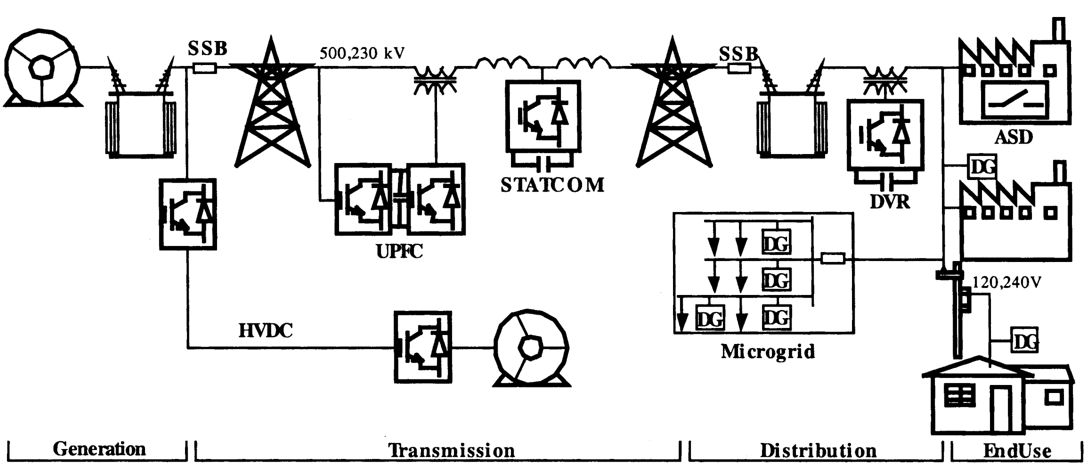

FIGURE 22-33 Power electronics applications in power systems.

increase stability margins. Consider the single line diagram of a 2-bus system shown in Fig. 22-34. The real power flow in the connecting transmission line is given by

$$P = \frac{V_1 V_2}{X} \sin(\delta) \tag{22-55}$$

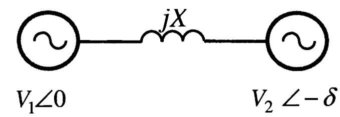

FIGURE 22-34 Single line diagram of a two-bus system.

where V_1, V_2 are the magnitudes of sending and receiving end voltages, respectively, δ is the phase angle between the two voltages, and X is the series line impedance [76]. Flexible ac transmission systems devices control one or more of these three parameters to control power flow and improve stability.

Transient Stability. Flexible ac transmission systems devices have the ability to enhance both transient and dynamic stability of power system networks, thereby enabling increased power flow through existing transmission lines. Transient instability occurs when a major disturbance like fault, line outage, or loss of generation results in large rotor angle deviations leading to loss of synchronism. The rotor angle deviation is governed by the swing equation given in Eq. (22-56).

$$\frac{2H}{\omega_o}\frac{d^2\delta}{dt^2} = P_m - P_e \tag{22-56}$$

where H is the inertia constant in MJ/MVA, ω_o is the synchronous speed, while P_m and P_e are the mechanical power input and electrical power output, respectively. During a fault, the electrical energy drawn from the generator reduces significantly, while mechanical power input remains roughly constant, leading to increasing rotor angle. If the fault is not cleared before a critical time, transient instability occurs. The critical clearing time depends on the electrical power output during the fault and immediately after fault clearance. Since power flow can be controlled continuously using FACTS devices, power during and after a fault can be controlled to improve the stability margin of the system.

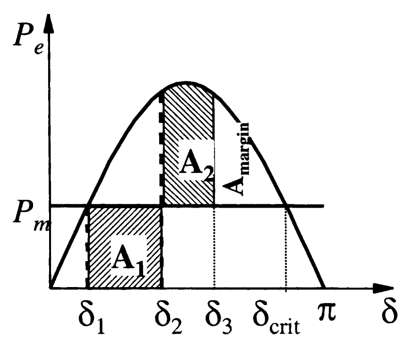

FIGURE 22-35 Equal area criteria for transient stability.

Transient instability is often studied using the equal area criterion as shown in Fig. 22-35 [76]. Initially the mechanical input power input is equal to the electrical power transmitted at an angle δ_1. A fault at the generator makes the electrical power zero while the mechanical input power remains the same, leading to increase in rotor angle from δ_1 to δ_2, at which point the fault is cleared. During this interval, the stored kinetic energy in the machine increases, and increase in kinetic energy is equal to the area A_1 in Fig. 22-35. After the fault is cleared the electrical power transmitted is higher (due to increased phase angle) than the mechanical power input. Hence, the machine begins to decelerate. However, the phase angle increases further due to the stored kinetic energy. The maximum angle is reached at δ_3, when the decelerating energy represented by the area A_2 becomes equal to the accelerating area A_1. If the phase angle extends beyond δ_{crit}, then the system is unstable since decelerating energy cannot balance the accelerating energy. The area A_{margin} between δ_3 and δ_{crit}, represents the transient stability margin of the system. Flexible ac transmission systems devices can improve the margin by dynamically changing the $P - \delta$ characteristics of the system.

Thyristor Controlled Series Capacitor. The earlier FACTS devices were predominantly thyristor based, like the thyristor–controlled series capacitor (TCSC) and static VAR compensator (SVC) [75]. Thyristor controlled series capacitor is a series-connected FACTS device that controls the effective impedance

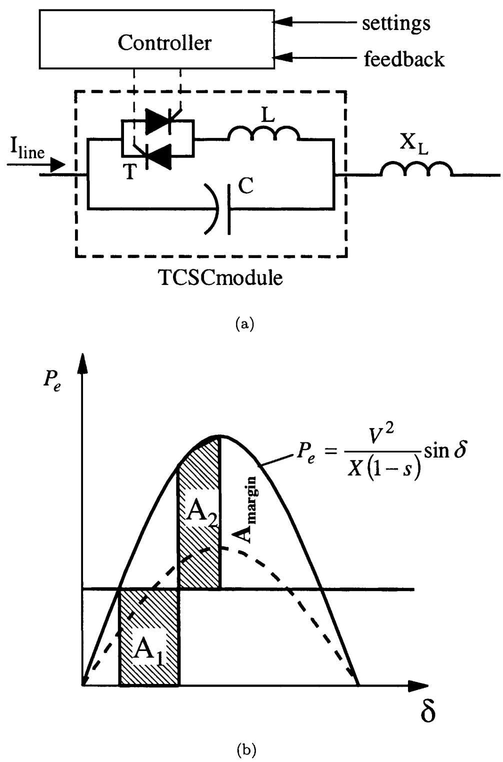

FIGURE 22-36 TCSC: (*a*) schematic (*b*) enhacement of transient stability.

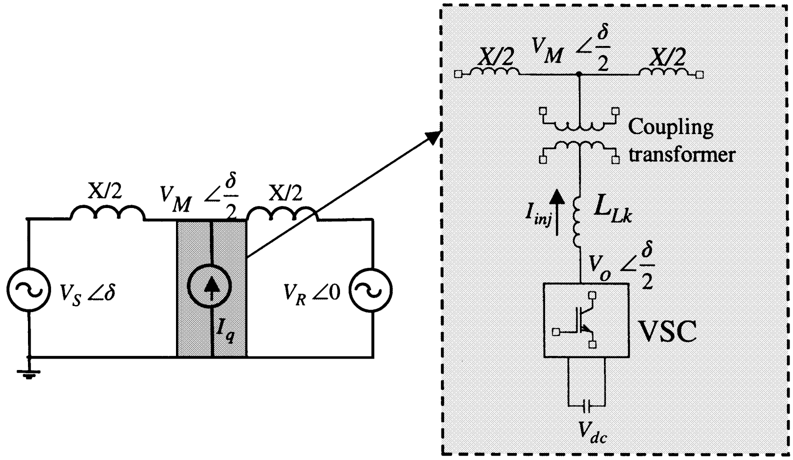
of the transmission line. Figure 22-36*a* shows the basic schematic of a TCSC, which consists of a capacitor in parallel with a thyristor-controlled reactor (TCR). Thyristor controlled reactor is a series combination of an inductor and a pair of phase-controlled thyristors. By suitably controlling the firing angle of the thyristors, the reactance (inductive) of TCR, and therefore, the effective fundamental impedance of TCSC can be controlled continuously. The relationship between the firing angle and the effective TCSC impedance is highly nonlinear. The firing angle α is measured from the zero crossing of the capacitor voltage. As an example, corresponding to an installed capacitive impedance of 0.5 pu (per unit) and inductive reactance of 0.1667 pu, the effective impedance of TCSC can be controlled from about 4 pu capacitive to 2 pu inductive. The effect of TCSC control on the transient stability margin is illustrated in Fig. 22-36*b*. In the figure, *s* indicates the degree of compensation. One of the major advantages of TCSC, when compared with uncontrolled series compensation, is the ability to mitigate sub synchronous resonance (SSR) [75].

Voltage Source Converter Based FACTS. The newer FACTS devices are based on voltage source converters (VSC) implemented using fully controllable devices such as GTO, MCT, IGCT, and IGBT [77]. Within their voltage and current ratings, the VSC-based FACTS devices are capable of injecting any suitable, controlled voltages and/or currents at the line frequency. The main advantages of these FACTS devices, compared to the thyristor-based devices, are the speed of response and the extended control range, which is mostly independent of the line operating conditions. The main VSC-based FACTS devices are the static compensator (STATCOM), the static synchronous series compensator (SSSC), and the unified power flow controller (UPFC).

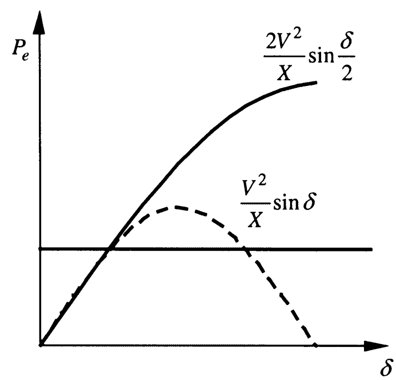
Static Synchronous Compensator (STATCOM). STATCOM is a shunt FACTS device capable of injecting controlled currents at the point of connection with the transmission system [75, 78]. The injected current is usually in phase quadrature (leading or lagging) with the line voltage, so that only reactive power is supplied or consumed by the STATCOM. If real power capability is present, through the use of active energy sources or large energy storage systems, then the injected current can have different phase relationships with the line voltage, thereby extending its control range.

Figure 22-37*a* shows the schematic of a STATCOM connected at the midpoint of a 2-bus transmission system model. The voltage source converter is capable of generating the required fundamental voltage such that the current injected into the system has the desired phase and magnitude to control power flow. The voltage at the dc link is kept constant by large capacitor banks. Losses in the system are compensated, and the capacitor voltage maintained, by drawing a small real power from the transmission system. The voltage source converter is connected to the transmission line through a line frequency coupling transformer, which enables the STATCOM to work with lower voltage switches.

The output voltage of STATCOM (neglecting losses) is controlled to be in phase with the line voltage. Hence, the system can be modeled as two in-phase, line frequency voltage sources,



(a)



(b)

FIGURE 22-37 STATCOM: (*a*) midpoint connection, (*b*) variation of power with phase angle δ.

connected by a reactor (usually the leakage inductance of the coupling transformer), which results in the current I_{inj} being purely reactive. Referring to Fig. 22-37*a*, if the magnitude of V_o is larger than V_m then the STATCOM feeds reactive power into the system, and if V_o is smaller, it absorbs reactive power.

Referring to Fig. 22-37*a*, the amplitudes of the sending end, midpoint, and receiving end voltages are assumed to be equal for simplicity ($V_s = V_m = V_r = V$). The STATCOM compensation at the midpoint effectively segments the transmission line into two independent parts, each with an effective line reactance of *X*/2. Neglecting losses, the real power flow is the same in both parts, and can be derived as given in Eq. (22-57).

$$P = \frac{V^2}{(X/2)} \sin\left(\frac{\delta}{2}\right) \tag{22-57}$$

where δ is the angle between the sending and receiving end voltages. Figure 22-37*b* shows the variation of real power flow with phase angle, as determined by Eq. 22-57. The curve corresponding to no compensation is also shown for comparison. It can be clearly seen that the STATCOM significantly improves the transient stability margin, that is, for a given fault clearing time, STATCOM allows a much higher real power to be transmitted. In the case of power system oscillations, such as inter area oscillations, the shunt compensation is varied dynamically to provide damping.

Static Synchronous Series Compensator. SSSC is a series connected device that injects a synchronous line frequency voltage, normally in quadrature with the line current. The SSSC controls power flow by controlling the line voltage amplitude, phase angle, and effective line impedance.

Unified Power Flow Controller. The UPFC is a versatile FACTS device that combines the functions of a STATCOM and an SSSC, and extends their capability to inject shunt current or series voltage that involve real power flow as well [79]. With UPFC, the real and reactive power can be controlled independently. Unified power flow controller is capable of controlling all the power system parameters such as voltage magnitudes, phase angles, and effective line impedance simultaneously and therefore meet multiple control objectives. Figure 22-38*a* shows the schematic diagram of the UPFC. It consists of two voltage source converters with separate controllers but sharing a common dc link with dc storage capacitors.

In present installations of UPFC, most of the control functions are performed by the series converter by injecting a voltage V_{inj} whose phase is independent of the line current and can vary practically from 0° to 360°. The magnitude of the injected voltage can also be varied continuously within the rating of the series converter. The main function of the shunt converter is to provide the real power exchanged by the series converter with the system. It may be noted that the real power exchanged by the series converter is ultimately derived from the transmission line, but the reactive power is

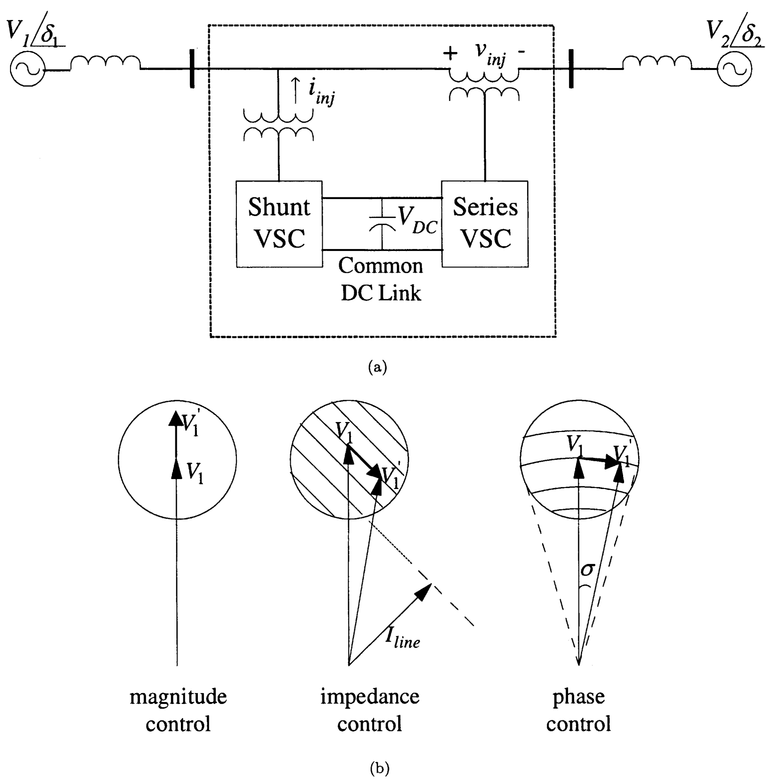


FIGURE 22-38 Unified power flow controller: (*a*) schematic, (*b*) control capabilities.

absorbed or supplied locally by the series converter and does not need to come from the transmission system. The shunt converter can be operated at unity power factor or can be controlled to provide additional functions beyond supporting real power needs of the series converter.

Figure 22-38*b* highlights the capabilities of the series converter of the UPFC, namely, control of voltage magnitudes, phase angles, and impedance [75]. With the injected voltage in phase or antiphase with the line voltage the UPFC provides voltage regulation or magnitude control. For a given voltage rating of the series converter, the in-phase addition provides maximum voltage magnitude control. For impedance control, the magnitude of the injected voltage is proportional to the line current and the phase is in quadrature (leading or lagging). In phase angle control, the magnitude and angle of the injected voltage are controlled such that the sending end voltage has the required phase angle without any change in the magnitude. These three features can be combined to achieve multifunction power flow control.

22.10.3 Custom Power

The digital age loads, for example, processing plants in semiconductor industry and data centers, require clean and uninterrupted power. These loads are highly intolerant to (even momentary) power quality problems such as voltage sags or interruptions, harmonics in line voltage, phase unbalance, and flicker in supply voltage. Power electronic systems that mitigate power quality problems in utility distribution systems (1 to 38 kV) are defined as custom power devices [80–82].

Similar to FACTS, the custom power devices can be connected in shunt or series with the distribution line or a combination of both. The major custom power devices are the dynamic voltage restorer (DVR), distribution static compensator (DSTATCOM) and the unified power quality controller (UPQC). The DVR is a series connected device that injects a controlled voltage to compensate for voltage sags and other momentary disturbances. The DSTATCOM is a shunt-connected device injecting controlled currents at the point of common coupling to compensate for power quality problems in the load current. Unified power quality controller combines the features of DVR and DSTATCOM.

Dynamic Voltage Restorer. Short duration voltage sags are the predominant power quality events, with estimated revenue lost per event of more than $1 million for pharmaceutical industries. Power acceptability curves that quantify voltage disturbances in terms of magnitude of these sags (and swells) and duration of the disturbance have been developed [83]. The most popular of the power acceptability curves is the Computer Business Equipment Manufacturers Association (CBEMA) curve shown in Fig. 22-39. This was developed by the CBEMA, now the Information Technology Industry Council (ITIC). The semiconductor industry has its own standard called SEMI F47, developed by the Semiconductor Equipment and Materials Institute (SEMI).

Dynamic voltage restorers, which are among the most installed custom power devices, protect sensitive equipment against short term voltage disturbances [84]. Figure 22-40 shows the schematic of a DVR. As seen, DVR is a voltage source converter based series connected device that injects a line frequency voltage of appropriate magnitude and phase such that the voltage across the sensitive loads is always well regulated, and any disturbances in the input voltage is not propagated to the load. The voltage source converter is implemented using IGBT switches, which operate at frequencies in the range of tens of kilohertz. They have fairly high control bandwidth and can respond to voltage disturbances in a small fraction of the line frequency cycle.

When the DVR is not connected to an active dc source and cannot handle real power in steady state, the injected voltage is constrained to be in phase quadrature with the load current. With this mode of control, the magnitude of sags that a DVR can correct becomes a function of the load power factor, and at higher power factor (close to unity) only a smaller voltage disturbance can be corrected. Since most of the sag events are of short duration, many of the installed DVRs rely on the large energy storage capacitor to supply real power for a short duration, and not constrain the injected voltage to be in phase quadrature. Several other installations use a separate rectifier to supply real power to the dc link from the distribution system [85].

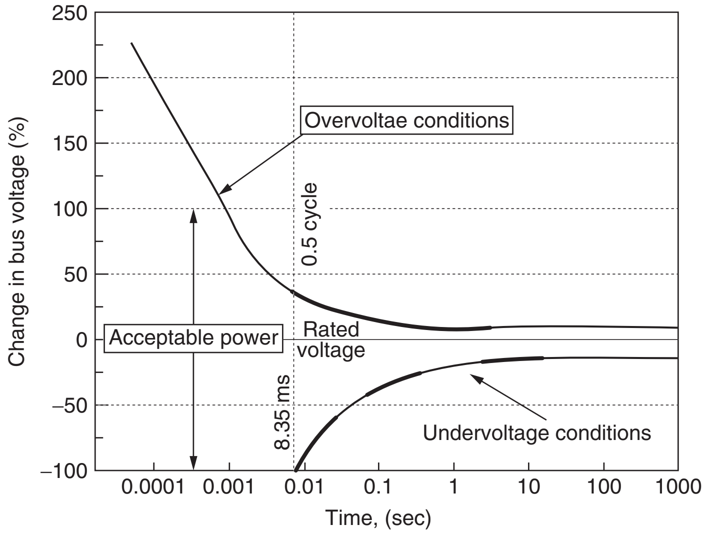

FIGURE 22-39 The CBEMA curve.

Distribution Static Compensator. The Distribution STATCOM has similar structure as that of the STATCOM used in transmission systems, and injects controlled currents. However, the main objectives of DSTATCOM are quite different. The load currents in distribution system can be unbalanced and contain reactive and harmonic components. Standards such as IEEE 519 and IEC 61000 place limits on maximum permissible harmonic currents for various types of equipment and voltage levels [47, 48]. The DSTATCOM with closed loop control injects correction currents such that the compensated load draws balanced, fundamental, unity power factor current.

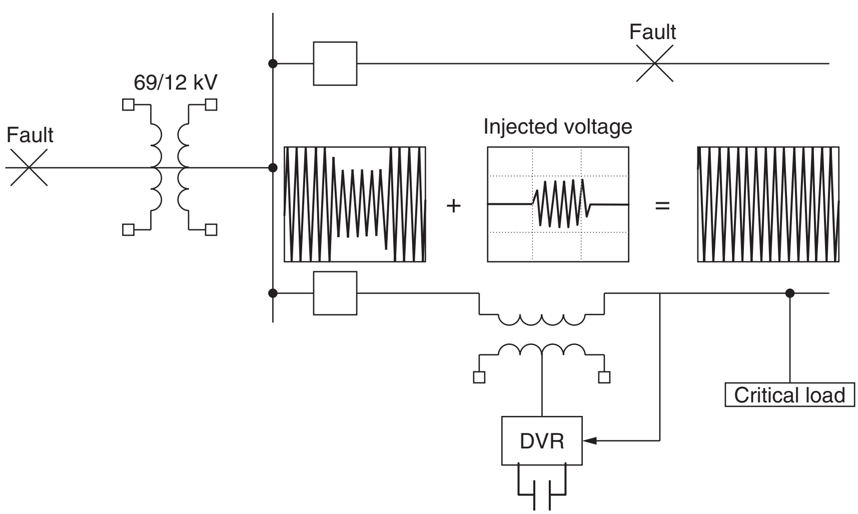

FIGURE 22-40 Application of a DVR.

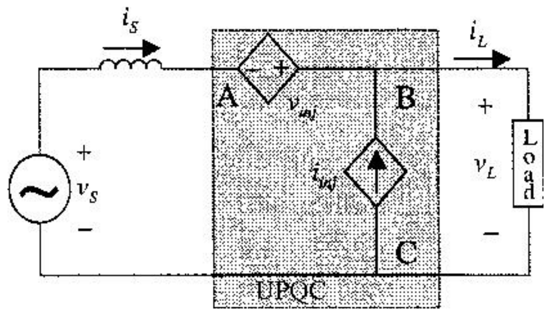

FIGURE 22-41 Unified power quality conditioner.

Unified Power Quality Conditioner. The UPQC combines the features of a DVR and DSTATCOM and can inject current in shunt and voltage in series simultaneously. Figure 22-41 shows the schematic of a UPQC. It has the same structure as that of UPFC used in transmission systems, consisting of two voltage source converters sharing a common dc link. One of the converters is connected in series with the distribution line injecting controlled voltages and the other converter is connected in shunt and injects controlled currents. Therefore, the UPQC can simultaneously correct for unbalances and distortion in line voltage as well as load currents.

Solid-state switches used to connect critical loads to multiple feeders or to break short circuit currents, hence improving power quality, are also considered as custom power devices. These are referred to as network reconfiguring devices and include solid-state current limiter (SSCL), solid-state breaker (SSB) and solid-state transfer switch (SSTS) [80]. These are much faster than the conventional mechanical switches and hence significantly enhance the reliability of the distribution system.

22.10.4 Distribution Generation Interface

Distributed generation (DG) is an important energy option for the twenty-first century and a key element of the restructuring of electric grid. Distribution generation, using renewable sources such as solar, wind, and tidal energy, and hydrogen (with photovoltaics for hydrogen generation) represents one of the most promising paths to sustainable energy.

Fuel cells, photovoltaics (PV), wind energy, and microturbines are among the most promising distributed generation technologies at present. Most of the distributed energy resources (DER) require a power electronic converter to interface with the power system network. Fuel cells and PV require dc-ac conversion, microturbines require high frequency to line frequency conversion, and generators used to capture wind energy are controlled through a rotor side power converter. Further, these DER may also require power electronics controlled energy storage.

Figure 22-42 shows a schematic diagram of the converter that can be used to interconnect photovoltaics with the utility. The input voltage from the solar cell array, typically 52 to 90 V, is converted to a higher magnitude, well regulated and isolated dc voltage through a high-frequency dc-dc converter. The dc link voltage is then converted to the required 60 Hz ac voltage by using a PWM

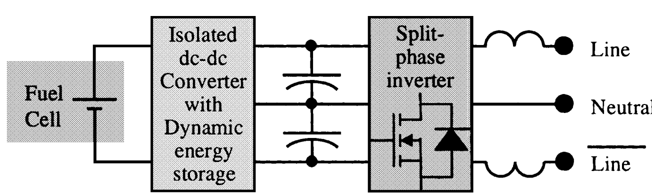

FIGURE 22-42 Fuel cell connection to the grid.

voltage source converter. An important feature of a PV interface is the maximum power point tracking circuitry designed to derive the maximum possible energy from solar radiation by suitably adjusting the current drawn from the solar panel. Fuel cells can also be interfaced to the grid by using a similar configuration as shown in Fig. 22-42. Since fuel cells have very little overcurrent or short-circuit rating, an energy storage capacitor is installed at the input side of the converter.

Wind energy is widely considered to be the fastest growing alternate energy source. The cost of wind energy in large wind farms located in good wind sites, at about 5 cents/kWh, is now competitive with the conventional utility generation, and is expected to reduce further. In 2004, the total installed capacity of wind energy worldwide was above 46,000 MW, with the United States accounting for 7000 MW [86].

Large wind farms consist of several multi megawatt wind turbines that are interconnected with the utility grid through medium voltage collector network. Doubly fed induction generators (DFIG) with a wound rotor and an ac-dc-ac PWM converter, as shown in Fig. 22-43, is becoming the most widely used technology for wind generation. The main advantage of the DFIG based generation is that it allows extraction of maximum energy from the wind at varying wind speeds, with the power converter rated only for about 15% of the total power. The stator winding is connected directly to the utility grid while the rotor is supplied with controlled, variable frequency currents by the PWM converter. By appropriate control of the rotor currents, the machine can generate power from subsynchronous to super synchronous speeds. Another advantage of DFIG is that the grid side converter can generate or absorb reactive power.

Apart from serving as an environment-friendly energy source, the DG systems are expected to provide various other benefits. For example, the concept of microgrids is gaining prominence [87]. Microgrid is a cluster of DER with power converters, energy storage and loads, which can be controlled together and present to the grid as a single entity. With suitably designed power converters, and with coordinated control, the microgrids can enhance stability, provide relief to transmission congestion, and provide reactive power support. Another promising approach is to use distributed micro sources for combined heat and power (CHP) [88]. Due to the various ancillary functions expected, inverter based DG are becoming more widespread compared to traditional reciprocating engines.

The interconnect standards for DG are just being evolved, like the IEEE 1547 standard for interconnecting distributed resources with electric power systems [89]. IEEE 1547 specifies the requirements for the DG to disconnect from the grid under deviations in voltage magnitude and frequency or under grid outages. Much work is still needed to realize a universal interconnect technology (UIT) and to understand the effect of large penetration of DG on fault currents, protection and dynamic interactions with the power system.

22.11 COMPONENTS OF POWER ELECTRONIC CONVERTERS

This section describes the individual components that constitute a power converter. These include power semiconductor devices and passive components (inductors, transformers, capacitors). A detailed description of the structure and physics of power semiconductor devices is beyond the scope of this discussion. The interested reader is referred to standard books on this subject [4, 90, 91]. Details of magnetics, material properties, and capacitors are also omitted. Unlike semiconductor devices and capacitors, very few magnetics are available as standard products from manufacturers, and therefore require custom design. Magnetics design is covered in significant detail in Ref. [92]. For details of capacitors, application notes and datasheets supplied by manufacturers have to be relied on.

22.11.1 Power Semiconductor Devices

Power electronic circuits require high-power semiconductor switches and diodes. An ideal switch should have the following characteristics: full control over switch state (on/off), very low voltage drop during on state, infinite impedance during off-state, and instantaneous transition between states. Diodes should have very low voltage drop during conduction, infinite impedance in off-state, and instantaneous transition. Practical devices have nonideal characteristics, and different devices capitalizing on one advantage while sacrificing some other have been developed. Figure 22-44 shows the circuit symbols of common power semiconductor devices. These are listed below with their voltage, current, and switching limitations.

Diodes: Line frequency, fast recovery, ultra-fast recovery, and schottky—in increasing order of switching speed, and decreasing order of reverse voltage rating.

MOSFETs (metal oxide semiconductor field effect transistor): Good for low voltage ~100s of volts, high switching frequency (> 100 kHz).

IGBTs (insulated gate bipolar transistors): Good from a few hundred Volts to about 6 kV, currents upto 1.2 kA, and switching frequency upto 30 kHz.

Thyristors or SCRs (silicon-controlled rectifiers): Good for very high voltage and current (~kV and kA), and low power moderate performance applications.

GTOs (gate turn-off thyristors): Good for very high voltage (~kV), high current applications (~kA), with switching frequency upto a few kilohertz.

Miscellaneous: IGCT (integrated gate commutated thyristor), MCT (MOS-controlled thyristor), BJTs (bipolar junction transistors), triacs, diacs.

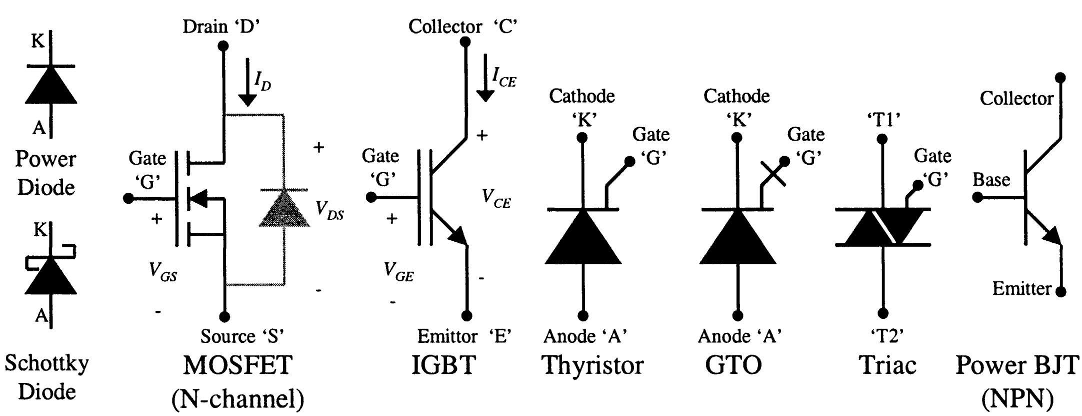

FIGURE 22-44 Circuit symbols of common power semiconductor devices.

Diodes. There are essentially two types of power semiconductor diodes: PN junction, and metal-semiconductor junction (schottky). PN junction power diodes have an additional N^- (lightly doped with N type impurities) drift region, so the overall structure is PN^-N. The depletion layer of the PN junction extends in the N^- region when the diode is reverse biased, and its length determines the maximum reverse voltage the diode can block. Intrinsically, the N^- region has a high resistance. However, when the diode is forward biased there is injection of excess carriers in this region resulting in a low effective resistance. This phenomena is commonly called *conductivity modulation*. The on-state voltage drop across the diode consists of the PN junction drop and the resistive drop in the drift region; typically it ranges from 0.6 to 1 V. There is a small delay in going from off-state to on-state due to the time required for the carriers to build up. During turn-off, the excess carriers in the drift region have to be removed. Thus, for a short time, the diode conducts in the reverse direction with a high voltage across it. This phenomena, known as reverse recovery, leads to significant power loss and becomes one of the limiting factors in high-frequency circuits. PN junction type power diodes are classified as:

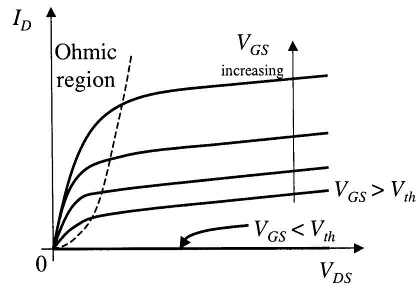
- line frequency rectifiers: for rectification of 50/60 Hz utility input.
- fast and ultra-fast recovery diodes: for high frequency rectification. These have recovery time ranging from a couple of μs to fractions of μs.

Schottky diodes are based on metal-semiconductor junctions. These junctions have a lower junction potential leading to a lower forward voltage drop. Silicon-based schottky power diodes have forward voltage drop ranging from 0.3 to 0.6 V, and can withstand reverse voltages up to 200 V. As opposed to PN junction diodes, schottkys are majority carrier devices, so they do not have any reverse recovery. However, compared to PN junction power diodes, they have significantly higher capacitance. This capacitance, in combination with circuit inductances, can lead to significant oscillations when the diode goes from on-state to off-state. Silicon-based schottky diodes are suited for very high frequency, low voltage, and high current rectification. Recently, SiC-based schottky diodes have been developed and are now commercially available with rating up to 1200 V [93, 94]. Even though SiC diodes have a much higher forward voltage drop (2 to 3 V), the absence of reverse recovery makes them suitable for high voltage high frequency rectification.

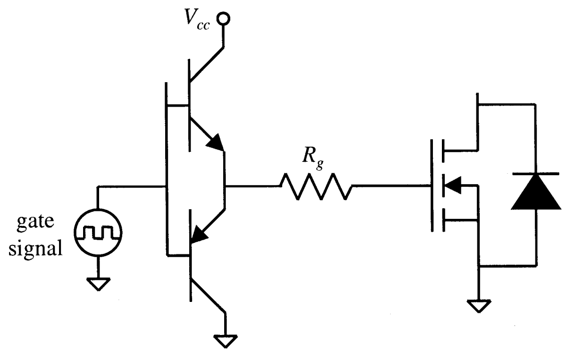
MOSFETs. Unlike signal level MOS devices that are fabricated laterally, power MOSFETs have a vertically diffused structure. For an N-channel MOSFET the doping is of the form $N^+PN^-N^+$. The drain is the N^+ terminal next to the N^- region, while the source is the N^+ region next to the P region. A positive voltage on the isolated gate terminal produces an electron channel in the P-region allowing current to flow from drain to source (or vice versa). Further, the P-type body is shorted to the source terminal resulting in an intrinsic diode with anode at the source and cathode at the drain. Although this diode is not very good in performance, it is useful for most power electronic circuits. Both P and N channel power MOSFETs are available, but N-channel MOSFETs are more prevalent due to their lower on-state resistance. Our discussion will therefore be restricted to N-channel MOSFETs.

The steady-state V-I characterisitcs for an N-channel MOSFET are shown in Fig. 22-45*a*. For $V_{GS} < V_{th}$, the MOSFET acts as an open circuit from drain to source; V_{th}, the threshold voltage, is in the range of 2 to 4 V. For $V_{GS} > V_{th}$, the MOSFET follows the characteristics shown in Fig. 22-45*a*. In amplifier circuits, MOSFETs are operated in their active region, where the drain current I_D is almost independent of the drain to source voltage V_{DS}. Power MOSFETs are operated in the ohmic region where I_D is proportional to V_{DS}, and the MOSFET behaves like a resistance. The effective on-resistance, designated R_{DS}, depends on V_{GS}, I_D, and the junction temperature T_j. For MOSFETs, R_{DS} increases with increasing temperature, a property useful in paralleling of devices to obtain higher current carrying capacity. The maximum value of V_{GS} is usually ± 20 V; for logic level power MOSFETs, it is limited to ± 10 V. For most MOSFETs, increasing V_{GS} beyond 10 V does not have significant effect on R_{DS}. MOSFETs are rated for (1) maximum drain to source breakdown voltage (BV_{DSS}) (2) maximum continuous average current for a specified temperature (e.g., I_{D25} at 25°C), and (3) a safe operating area (SOA) in terms of V_{DS}, I_D, and time duration for which I_D flows. In very high current applications, thermal performance of the device package can also impose an additional constraint.

MOSFET gate drive circuits usually run on a nominal V_{cc} = 15 or 12 V, and switch V_{GS} between V_{cc} and 0 V. For very high current applications and improved noise sensitivity, a negative V_{GS} may



(a)



(b)

FIGURE 22-45 MOSFETs: (*a*) V-I characteristics, and (*b*) simple gate drive circuit.

be applied during the off-time. Since the gate is insulated from the source there is no dc current flow from gate to source. However, depending on their ratings power MOSFETs have a significant input capacitance C_{iss}. Thus, to increase V_{GS} from 0 to 15 V in a very short time (20 to 100 ns) a significant current (order of 1 A) is required. Figure 22-45*b* shows a basic MOSFET gate drive circuit. Several gate drive ICs that can source and sink current upto a few amperes, while providing several other auxiliary functions, are commercially available [9, 12]. For *high-side switches*, switches whose source voltage changes with the switch state, as is the case for the MOSFET in a buck converter, an isolated gate drive is required. The isolation is provided by using either high-frequency transformers or high-speed optocouplers. There are several standard gate drive configurations, each with its own pros and cons. The best source of these circuits are application notes from device manufacturers (e.g., see Ref. [62]).

Power MOSFETs can be used up to a few 100 kHz and in some applications in the megahertz range. To increase operating frequencies further, *RF Power MOSFETs* have recently been introduced [95]. These can be operated in the 10 MHz range and are expected to reduce converter size and weight considerably.

Insulated Gate Bipolar Transistors. The structure of IGBTs is similar to MOSFETs. However, IGBTs have significantly higher voltage and current ratings compared to MOSFETs, and their on-state voltage drop is also lower. In addition, several IGBT chips are paralleled inside one package to form an IGBT module with a significantly higher current rating. Insulated gate bipolar transistors modules are commercially available in voltage rating upto 6.5 kV, and currents up to 1200 A. The gate drive requirements of an IGBT are similar to that of MOSFETs. It is turned on by applying a positive gate source voltage (typically 15 V), and turned-off by applying a smaller negative voltage (about −5 V). Compared to MOSFETs, IGBTs have much longer switching times. Insulated gate bipolar transistors are minority carrier devices, so their turn-off is characterized by a "tail current". Their switching frequencies are generally limited to 30 kHz, and the maximum switching frequency reduces with power level. If resonant power conversion techniques are used, the tail current during turn-off can be avoided and the switching frequency can be pushed higher.

Thyristor and Similar Devices. Thyristors, also called silicon-controlled rectifiers (SCRs), are high-power semiconductor devices that can block voltage of either polarity and conduct current in one direction only (from anode to cathode). They can be switched on by applying a current pulse to their gate terminal (with return path through cathode) when there is a positive voltage from anode to cathode. They can be switched off only by reducing the device current to zero. Thyristors are available in very high current and voltage ratings and have a very low conduction voltage drop. Thyristors are mostly used for ac to dc (or vice-versa) power conversion, where the device current is expected to reduce to zero. Normally, thyristors are switched at or close to the ac system frequency. They are ideally suited for utility applications such as HVDC and controlled reactors.

Gate turn-off thyristors are very high power devices, with their low-end ratings overlapping with the high-end rating of IGBTs. Unlike a thyristor, they can be turned on and off using the gate terminal, although the gate drive is more complex compared to a MOSFET or an IGBT. The switching times for GTOs are of the order of 10 μs so their maximum switching frequency is in the kilohertz range. They are used exclusively in very high power applications like some motor drives, FACTs devices, and active filters. Gate turn-off are commercially available in ratings upto 6 kV and 6 kA. Enhancements to GTO have led to the development of IGCT (integrated gate commutated thyristor) [96] or GCT (gate commutated turn-off thyristor) [97], ETO (emitter turn-off thyristor), and MTO (MOS turn-off thyristor) [91]. At present there is a strong research effort in development of high power devices with high switching speeds. The impetus behind these are high power pulse applications for defence, and the increasing utility applications of power converters.

A "back-to-back connection" of two thyristors (anode of one to the cathode of other) can conduct current in either direction and block voltages of either polarity. Triacs realize the functionality in a single semiconductor device. However, voltage and current ratings of triacs are very low compared to that of thyristors.

Power *bipolar junction transistors* (BJTs) have been almost completely replaced by MOSFETs and IGBTs, due to ease of control and higher switching frequency. However, they are still used in some applications like linear power supplies.

22.11.2 Magnetic Components

In power electronic converters three types of magnetic components are used: single winding inductors (for filtering current and aiding in resonant transitions in some circuits), multi-winding coupled inductors (to provide filtering and isolation), and transformers (for isolation and stepping up/down voltage). Unlike semiconductor devices, these have to be custom designed using available cores, wires, etc. The primary consideration for their design are size/weight and power loss. Design procedures using the common *area product method* is presented here. Another approach is the *core geometry method*, which can be found in Refs. [5, 92]. It is assumed that the reader is familiar with basics of electromagnetism and magnetic circuits. An E-E type core will be used for illustration, but the method is applicable to any core shape. The E-E type core construction, along with relevant definitions of its geometry, is shown in Fig. 22-46. The complete core is formed with two E cores with possibly an air gap between them. The coils are wound over a plastic bobbin placed on the outside of the center leg of the E sections.

Due to high-frequency magnetic fields, significant eddy currents are induced in the magnetic core and windings, and due to high-frequency electric field there can be significant capacitive currents between windings. Eddy currents lead to significant losses and necessitate the use of high-resistivity magnetic core materials and thinner wires (which may be paralleled for high current capacity) for the coils. Loss due to magnetic hysteresis also increases with increase in frequency.

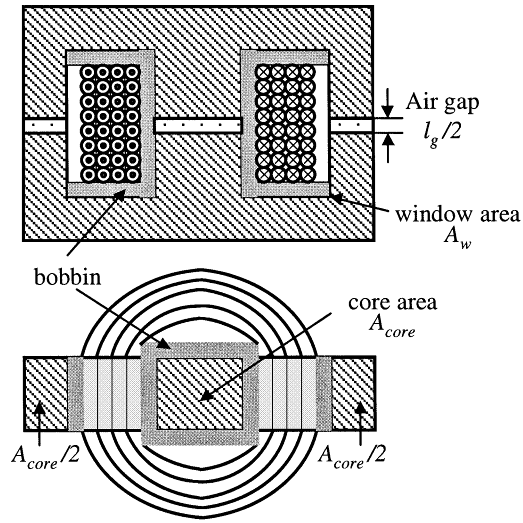


FIGURE 22-46 Vertical and horizontal sections of an E-E core inductor.

Magnetic Core Materials. Inductors use one of three different kinds of core materials, depending on the currents they are supposed to carry. The three core material types are silicon steel for low-frequency filtering, powdered iron for high-frequency filtering, and ferrites for carrying high-frequency currents. Transformers in power converters always carry high-frequency currents and therefore use ferrite cores.

For low-frequency filtering, where the inductor primarily carries a dc component with a 120 Hz ripple (as in line frequency rectifiers), standard silicon steel laminations can be used to form the core. Silicon steel has high saturation flux density (~1.8 Tesla) and high relative permeability (μ_r~ 40,000). This results in a small core size without incurring significant core loss. However, the relative permeability reduces with increase in flux density, so the effective inductance value changes with the dc component of the current.

For inductors that are supposed to carry currents consisting of a large dc component and a small high-frequency ac component (e.g., the inductor used at the output of a dc-dc converter), powdered iron or MolyPermalloy Powder (MPP) cores are used. These cores have high resistivity leading to lower eddy current losses, high saturation flux density (upto 1.4 Tesla) leading to lower core size, and distributed air gap leading to a low relative permeability. As with silicon steel, the relative permeability reduces with increasing flux density. The cores are available in toroidal and E shapes. Toroids are difficult to wind but can be used to make very good quality inductors.

For transformers and inductors that have to carry significant high-frequency current, the powdered iron material has unacceptable loss due to eddy currents and hysteresis. Ferrite materials, with very high resistivity, lower weight, but low saturation flux density (~ 0.4 Tesla) are suitable for these. Common ferrite materials are 3F3 from ferroxcube and PC44 from TDK. Cores made from these materials are available in a wide variety of shapes and sizes: toroids, pot core, E, PQ, RM, etc.

Inductor Design. For inductors, the design requires specified values of the inductance (L), and the peak and rms current ($\hat{I}$ and I_{rms}) it has to carry. The relations between peak current and core area (A_{core}), rms current and window area (A_w), and the expression for the *area product*, $A_p = A_{core} \cdot A_w$, are as follows:

$$\lambda = L\hat{I} = N\Phi = NB_{max} \cdot A_{core}$$
$$\Rightarrow A_{core} = \frac{L\hat{I}}{NB_{max}} \tag{22-58}$$

$$I_{rms} = J \cdot A_{cond} = J \cdot \frac{A_w \cdot k_w}{N}$$
$$\Rightarrow A_w = \frac{NI_{rms}}{Jk_w} \tag{22-59}$$

$$A_p = A_w \cdot A_{core} = \frac{L\,\hat{I}I_{rms}}{JB_{max}k_w} \tag{22-60}$$

Here, λ is the flux linkage, N is the number of turns of the winding, Φ is the magnetic flux corresponding to peak current $\hat{I}$, B_{max} is the maximum flux density (may be different from the saturation flux density), J is the current density in the winding, A_{cond} is the cross-sectional area of one conductor in the winding, and k_w called the winding factor is an empirical factor used to indicate the fraction of window area utilized by the copper of the windings. In the expression for A_p, the numerator consists of specified quantities, while the denominator has quantities which are chosen for design. B_{max} may be chosen close to the saturation flux density depending on allowable core loss; J is chosen in the range of 2.5 to 8 A/mm^2, depending on allowable conduction loss, mechanism for heat removal, and the allowable temperature rise; k_w is in the range of 0.3 to 0.8 depending on space taken by bobbin and insulation, and the method of winding. Once the area product has been calculated, a core with the desired value of A_p can be chosen from manufacturers' catalogs. The number of turns and the air gap required to achieve the desired inductance value are then calculated as

$$N = \frac{L\hat{I}}{B_{max} A_{core}} \tag{22-61}$$

$$L = N^2/\Re = N^2\mu_o A_{core}/l_g \tag{22-62}$$

$$\Rightarrow l_g = N^2\mu_o A_{core}/L \tag{22-63}$$

where $\Re$ is the core reluctance. The above equation assumes that $\mu_r/l_m \gg 1/l_g$, where l_m is the magnetic path length of the core. The conductor size is calculated as $A_{cond} = k_w \cdot A_w/N$. If the current is expected to have significant high frequency component, the radius of the conductors should not exceed the *skin depth* of copper at the expected frequency. Several conductors may then be paralleled to achieve the required value of A_{cond}. Finally, P_{cond}, conduction loss in the windings, and P_{core}, loss in the core, should be calculated. P_{cond} requires an estimate of the winding resistance, while P_{core} is computed using manufacturer supplied empirical loss curves. Core loss in an inductor depends on the operating flux density B (related to the average value of the current), and change in flux density during each switching cycle ΔB (related to the expected current ripple). It is generally accepted that $P_{cond} = P_{core}$ indicates a good design. However, power loss in the core can be dissipated more easily compared to windings (especially if there are several layers). Thus, it may be desirable to have $P_{cond} < P_{core}$. This affects the choice of B_{max} and J values used above.

Powdered iron cores have distributed air gaps and the above procedure is not directly applicable to them. For selection of these cores, the manufacturers suggest a number of cores based on a metric similar to the product $L\hat{I}I_{rms}$. The final core selection can then be made based on allowable losses (P_{cond} relating to J, and P_{core} relating to B_{max}), and temperature rise. The cores have a specified A_L value, the inductance obtained from the core in nH/Turns^2. The number of turns required to obtain the inductance value the can be computed using the specified A_L value. Finally, the inductance variation with dc current should be checked to make sure that the required value is obtained at the maximum operating current.

Transformer Design. For a transformer, the design specifications are the turns ratio, rms current in all the windings, and the maximum volt-second product ([$V\,sec$], the maximum product of voltage and time for which the voltage is applied) expected across the primary winding. The window area can be related to the rms current, the core area to the maximum volt-second product, and the resulting area product calculated as follows

$$\begin{aligned} k_w \cdot A_w &= N_p \cdot A_{cond,p} + \sum_m (N_{sm} \cdot A_{cond,s}) \\ \Rightarrow A_w &= \frac{N_p}{Jk_w} \cdot \left(I_{p,rms} + \sum_m [(N_{sm}/N_p) \cdot I_{sm,rms}]\right) \end{aligned} \tag{22-64}$$

$$\begin{aligned} \Delta\lambda &= [V\,sec] = N_p \Delta\Phi = N_p \Delta B_{max} \cdot A_{core} \\ \Rightarrow A_{core} &= \frac{[V\,sec]}{N_p \Delta B_{max}} \end{aligned} \tag{22-65}$$

$$A_p = A_w \cdot A_{core} = \frac{[V\,sec] \cdot (I_{p,rms} + \sum_m [(N_{sm}/N_p) \cdot I_{sm,rms}])}{J\Delta B_{max} k_w} \tag{22-66}$$

The subscripts "*p*" and "*s*" indicate primary and secondary, respectively, while the index *m* refers to the secondary number. In the above equations, ΔB_{max} is the maximum *change* in flux density; this equals the maximum value of B_{max} for single quadrant operation (as in a forward converter), and twice B_{max} when flux direction reverses (as in full-bridge dc-dc converters). Core loss has more than quadratic dependence on ΔB_{max}. For transformers, the value of B_{max} is therefore chosen much lower than the saturation flux density (about 0.1 to 0.25 T). After a core is chosen by utilizing the computed A_p, the number of primary turns are calculated as

$$N_p = \frac{[V\,sec]}{B_{max} A_{core}} \qquad (22\text{-}67)$$

In high-frequency transformers, the magnetizing current can be a significant part of the primary current and should be accounted for in the above calculations. Conductor selection for transformers is similar to that for inductors. For very high frequency and high current applications use of insulated copper foils and *Litz wire* are alternatives to use of multiple parallel conductors.

It should be noted that the procedures described above are rudimentary and several other factors have to be accounted for in a real design. These include ambient temperature, temperature rise of the core (which affects the saturation flux density and the core loss significantly), *hot-spot* temperature, winding loss due to *fringing fields* near the air gap, and winding loss due to *proximity effect*. In transformers, interleaving primary and secondary windings helps in reducing the proximity loss and leakage inductance at the expense of increased interwinding capacitance. To eliminate the winding process, planar magnetics that use tracks on multilayer PCBs to form the windings have been developed. Planar magnetics also have the benefit of low profile. To reduce the number of discrete magnetic components, there has been significant research in integrated magnetics—realizing the functionality of several magnetic components using a single magnetic component.

22.11.3 Capacitors

There are several types of capacitors each with different advantages and limitations. For power electronic circuits the choice criteria are: capacitance value, voltage rating, effective series resistance (ESR) and effective series inductance (ESL), and the ripple and ac current capacity at different frequencies. All these can be found as specifications in manufacturers datasheets. ESR is either specified as a number at different frequencies (typically 120 Hz and 20/100 kHz), or in terms of the *dissipation factor*, $\tan\delta = ESR/(2 \times f \times C)$. If ESL is specified, it may be either as a number or in terms of the series resonance frequency, $f_r = 1/(2\pi\sqrt{ESL \times C})$. The main capacitor types used in power electronic circuits are listed in the Table 22-3. The list is by no means exhaustive and there are several other capacitor types suited to different applications, for example, tantalum, mica, and high power film capacitors.

22.11.4 Snubber Circuits

As described in Sec. 22.2.4, there is significant energy loss in power semiconductor devices during turn-on and turn-off. In addition to the phenomena described there, reverse recovery in PN junction based diodes and capacitance of schottky diodes, output capacitance of MOSFETs and IGBTs, and leakage inductance of transformers also contribute to power loss during switching. Snubber circuits are used to remove the transient high voltage and high current stress from semiconductor devices. They can be classified into two basic types—*turn-on* and *turn-off* snubbers, depending on the transition where they are active. With a turn-off snubber, an alternate path is provided for the current during turn-off so that the switch ceases to carry current as soon as it is disabled. This does not necessarily imply that the switching loss is eliminated. In low-power applications, the energy may be dissipated in an external resistor and in fact the energy dissipated may be higher. For high-power applications, the energy may be recovered using energy recovery snubbers, resulting in significantly improved

TABLE 22-3 Capacitors Types Commonly Used in Power Electronic Circuits

Capacitor Type	Characteristics	Application
Electrolytic	Polarized (unipolar voltage only) High density, High ESR and ESL Low reliability Voltage ratings up to 500 V Capacitance up to 100s of mF Rated for ripple current capacity	DC input and output filters, very short time energy storage
Ceramic and Multilayer Ceramic	Very low ESL and ESR Low capacitance values (up to ~100 μF) Maximum capacitance value reduces with increasing voltage rating	Paralleled for low voltage output filtering, "bypass" for gate drives, high voltage capacitors (up to 1 kV) used in snubber circuits
(Metallized) Polyester film	Low ESR and ESL Low capacitance values (up to a few μF) High voltage ratings (few kV) Bigger than ceramic and electrolytic	In input and output dc filters: to suppress switching transients, ac filters, snubber circuits
Metallized Polypropylene film	Very low ESR and ESL Low capacitance values (up to a few μF) Very high rms current and high voltage ratings	In resonant converters: for carrying high frequency ac current

efficiency at the expense of increased component count. Another use of snubber circuits is to limit transient overvoltages caused due to parasitics.

22.11.5 Heat Sinks

The main power loss in power electronic circuits occurs in power semiconductor devices, windings, and cores of the magnetic components, capacitors subjected to high-ripple current, and auxiliary circuits like gate drives. The resulting heat has to be removed from the components and eventually transferred to the atmosphere/ambient surroundings due to the following reasons. Power semiconductors have a maximum junction temperature rating beyond which they fail, and on-state resistance of devices like MOSFETs increases with junction temperature leading to reduced efficiency. Electrolytic capacitors can fail when heated beyond their ratings and their expected lifetime reduces with increase in temperature. Increased temperatures in magnetics can lead to higher power loss, poor magnetic core characteristics, insulation breakdown, and shorter lifetimes.

Most semiconductor devices are cooled by mounting their package on a heat sink. A heat sink is essentially a piece of metal designed to dissipate heat by convection and radiation (by maximizing the heat sink surface area). The heat transfer from the device to the heat sink is via conduction. If the package of the device is not electrically isolated from its electrical terminals, an interface material (like Silpads) with good thermal conductivity and high dielectric breakdown voltage has to be used. For magnetics, resins may be used to conduct heat from the windings and the core to the metal heat sink. The heat sink itself may be cooled naturally, by forced convection (using fans to blow air on the heat sink surface), or liquid cooled (by circulating a liquid through the mass of the heat sink, and cooling the liquid by a radiator). Simple steady analysis and design of heat sinks is carried out using specified *thermal resistances*, ratio of temperature difference to heat transferred across the material, of all the materials in the heat transfer path. For pulsed applications, a transient thermal model, usually consisting of first-order lags between two consecutive interfaces, is used.

23.1 PERSPECTIVE ON POWER QUALITY

23.1.1 Introduction

Power quality is about compatibility between the quality of the voltage supplied from the electric power system and the proper operation of end-use equipment. Power quality is also about economics—finding the optimum level of investment in the power system and the end-use equipment to achieve the compatibility. There are two categories of power quality that need to be considered—steady-state (or continuous) power quality and disturbances. Steady-state power quality characteristics include voltage regulation, harmonic distortion, unbalance, and flicker. We can define *compatibility levels* for these characteristics and then the challenge is to maintain performance within these compatibility levels and make sure that equipment can operate with these levels. Power quality disturbances (outages, momentary interruptions, voltage sags, and transients) are much more of a challenge. It is impossible to completely prevent disturbances that may cause equipment disruptions. Therefore, we have to find the best balance between investments to prevent disturbances and investments in equipment and facility protection.

On the technology side, future power quality research will focus on advanced technologies that can be applied at all levels of the system to improve compatibility (both supply-side technologies and end-user technologies) and on the procedures to find the optimum places to make these investments from a system perspective. The result will be guidance regarding expected levels of performance for different types of supply systems that will result in optimum economics if customers also make the associated investments to assure that the required equipment performance. Recommendations from the economic analysis will also require regulatory structures to support the implementation of optimum system designs and solutions. Therefore, the research results must be coordinated with development of regulations and market structures for future power systems.

23.2 CATEGORIES AND CHARACTERISTICS OF POWER QUALITY DISTURBANCE PHENOMENA

23.2.1 General

Power quality is a generic term applied to a wide variety of electromagnetic phenomena on the power system. The duration of these phenomena ranges from a few nanoseconds (e.g., lightning strokes) to a few minutes (e.g., feeder voltage regulations) to steady-state disturbances (harmonic distortions and voltage fluctuations). Due to the extensive variety of the phenomena, many power quality terms have sometimes been applied incorrectly and cause confusion among end users, vendors, and service providers in dealing with power quality concerns. For example, a term *power surge* has been used to describe some kind of power disturbances. However, it is ambiguous and in fact has no technical meaning since power surge does not refer to a surge in power. This term has been used to refer to overvoltage transients in voltage. Power is related to the product of voltage and current. Normally, *voltage* is the quantity causing the observed disturbance and the resulting power will not necessarily be directly proportional to the voltage. The solution will generally be to correct or limit the voltage as opposed to addressing the power. Therefore, the use of ambiguous and nonstandard terms is discouraged.

23.2.2 General Classes of Power Quality Disturbances

The Institute of Electrical and Electronics Engineers Standards Coordinating Committee 22 (IEEE SCC22) has led the main effort in the United States to coordinate power quality standards. It has the responsibilities across several societies of the IEEE, principally the Industry Applications Society and the Power Engineering Society. It coordinates with international efforts through liaisons with the IEC and CIGRE (International Conference on Large High-Voltage Electric Systems). The IEC classifies electromagnetic phenomena into the groups shown in Table 23-1[1].

The U.S. power industry efforts to develop recommended practices for monitoring electric power quality have added a few terms to the IEC terminology [2]. *Sag* is used as a synonym to the IEC term *dip*. The category *short duration variations* is used to refer to voltage dips and short interruptions. The term *swell* is introduced as an inverse to sag (dip). The category *long duration variation* has been added to deal with American National Standards Institute (ANSI) C84.1 limits. The category *noise* has been added to deal with broadband conducted phenomena. The category *waveform distortion* is used as a container category for the IEC *harmonics, interharmonics*, and *dc in ac networks* phenomena as well as an additional phenomenon from IEEE Std. 519-1992 (Recommended Practices and Requirements for Harmonic Control in Electrical Power Systems), called *notching*. Table 23-2 shows the categorization of electromagnetic phenomena used for the power quality community.

23.2.3 Transient—General

The term *transient* has long been used in the analysis of power system variations to denote an event that is undesirable and momentary in nature. Other definitions in common use are broad in scope and simply state that a transient is "that part of the change in a variable that disappears during transition from one steady-state operating condition to another" [8]. Another word in common usage that is often considered synonymous with transient is *surge*. This term should be avoided unless it is qualified with appropriate explanation. In general, transients can be classified into two categories, impulsive and oscillatory. These terms reflect the waveshape of a current or voltage transient.

Impulsive Transient. An *impulsive transient* is a sudden, nonpower frequency change in the steady-state condition of voltage, current, or both, that is unidirectional in polarity (primarily either positive or negative). They are normally characterized by their rise and decay times which can also be revealed by their spectral content. For example, a 1.2 × 50 μs 2000-V impulsive transient nominally rises from zero to its peak value of 2000 V in 1.2 μs, and then decays to half its peak value in 50 μs. The most common cause of impulsive transient is lightning. Figure 23-1 illustrates a typical current impulsive transient caused by lightning.

Oscillatory Transient. An *oscillatory transient* is a sudden, nonpower frequency change in the steady-state condition of voltage, current, or both, that includes both positive and negative polarity values. It consists of a voltage or current whose instantaneous value changes polarity rapidly. It is described by its spectral content (predominate frequency), duration, and magnitude. The spectral content subclasses defined in Table 23-2 are high, medium, and low frequency. The frequency ranges for these classifications are chosen to coincide with common types of power system oscillatory transient phenomena. High- and medium-frequency oscillatory transients are transients with a primary frequency component greater than 500 kHz with a typical duration measured in microseconds, and between 5 and 500 kHz with duration measured in the tens of microseconds, respectively. Figure 23-2 illustrates a medium frequency oscillatory transient event due to back-to-back capacitor energization.

23.2.4 Short-Duration Voltage Variations

Short-duration voltage variations are caused by fault conditions, the energization of large loads that require high starting currents, or intermittent loose connections in power wiring. Depending on the fault location and the system conditions, the fault can cause either temporary voltage drops (sags), or voltage rises (swells), or a complete loss of voltage (interruptions). The fault condition can be close to or remote from the point of interest. In either case, the impact on the voltage during the actual fault condition is of short duration variation until protective devices operate to clear the fault.

*pu = per unit.

This category encompasses the IEC category of voltage dips and short interruptions. Each type of variation can be designated as instantaneous, momentary, or temporary, depending on its duration as defined in Table 23-2.

Interruption. An interruption occurs when the supply voltage or load current decreases to less than 0.1 pu for a period of time not exceeding 1 min. Interruptions can be the result of power system faults, equipment failures, and control malfunctions. The interruptions are measured by their duration since

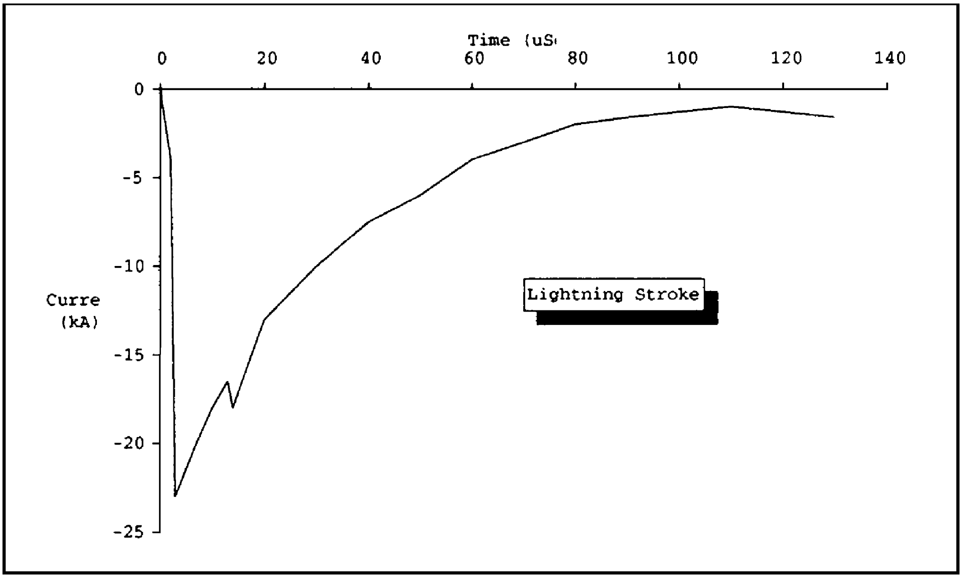

FIGURE 23-1 Lightning stroke current impulsive transient.

the voltage magnitude is always less than 10% of nominal. The duration of an interruption due to a fault on the utility system is determined by the operating time of utility protective devices. Instantaneous reclosing generally will limit the interruption caused by a nonpermanent fault to less than 30 cycles. Delayed reclosing of the protective device may cause an instantaneous, momentary, or temporary interruption. The duration of an interruption can be irregular due to equipment malfunction or loose connections. Some interruptions may be preceded by a voltage sag when the

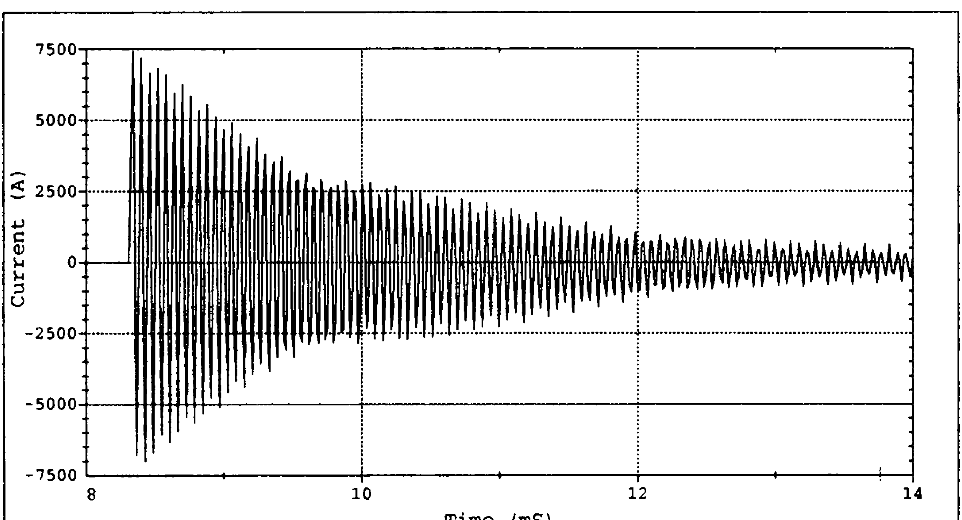

FIGURE 23-2 Oscillatory transient current caused by back-to-back capacitor switching.

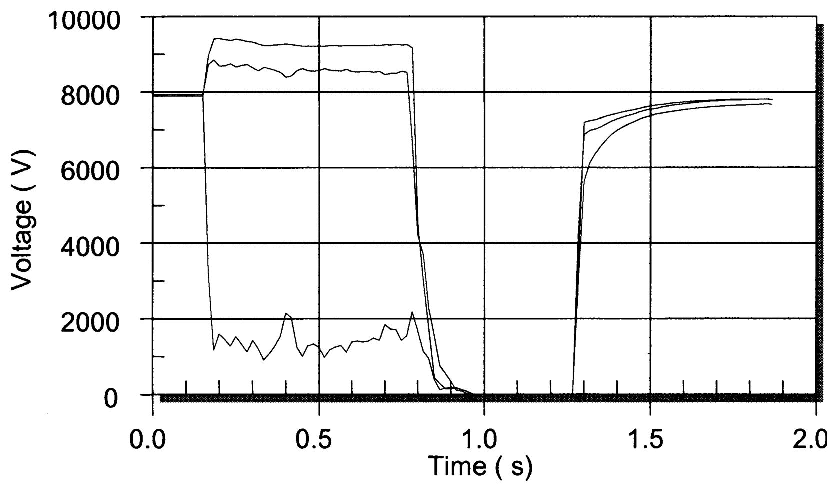

FIGURE 23-3 An instantaneous interruption due to a SLG fault and subsequent recloser operation.

interruptions are due to clearing faults on the source system. The voltage sag occurs between the time a fault initiates and the protective device operates. Figure 23-3 shows a plot of the rms voltages for all three phases for such an interruption. The voltage on the faulted phase initially sags to 15% to 25% for 0.6 s while the fault is arcing. A voltage swell occurs on the other two phases at the same time. The breaker then opens, clears the fault, and recloses successfully 0.4 s later. Utility distribution engineers frequently refer to this as an instantaneous reclose.

Voltage Sags. A sag is a decrease to between 0.1 and 0.9 pu in rms voltage or current at the power frequency for durations from 0.5 cycles to 1 min. The IEC definition for this phenomenon is *voltage dip*. The two terms are considered interchangeable, with sag being the preferred synonym in the U.S. power quality community. Figure 23-4 shows a typical voltage sag associated with a SLG fault on another feeder from the same substation. The voltage sags to 60% for about 5 cycles until the substation breaker is able to interrupt the fault current. Typical fault clearing times range from 3 to 30 cycles, depending on the fault current magnitude and the type of overcurrent protection.

Voltage Swells. A *swell* is defined as an increase to between 1.1 and 1.8 pu in rms voltage or current at the power frequency for durations from 0.5 cycle to 1 min. The term *momentary overvoltage* is used by many writers as a synonym for the term swell. As with sags, swells are usually associated with system fault conditions. One way that a swell can occur is from the temporary voltage rise on the unfaulted phases during a single line-to-ground (SLG) fault. An example is shown in Fig. 23-5. Swells can also be caused by switching off a large load or energizing a large capacitor bank.

23.2.5 Long-Duration Voltage Variations

Long-duration voltage variations encompass rms deviations at power frequencies for longer than 1 min. ANSI C84.1 specifies the steady-state voltage tolerances expected on a power system. A voltage variation is considered to be long duration when the ANSI limits are exceeded for greater than 1 min. Long-duration variations can be either overvoltages or undervoltages. Overvoltages and undervoltages generally are not the result of system faults, but are caused by load variations on the system and system switching operations. Such variations are typically displayed as plots of rms voltage versus time.

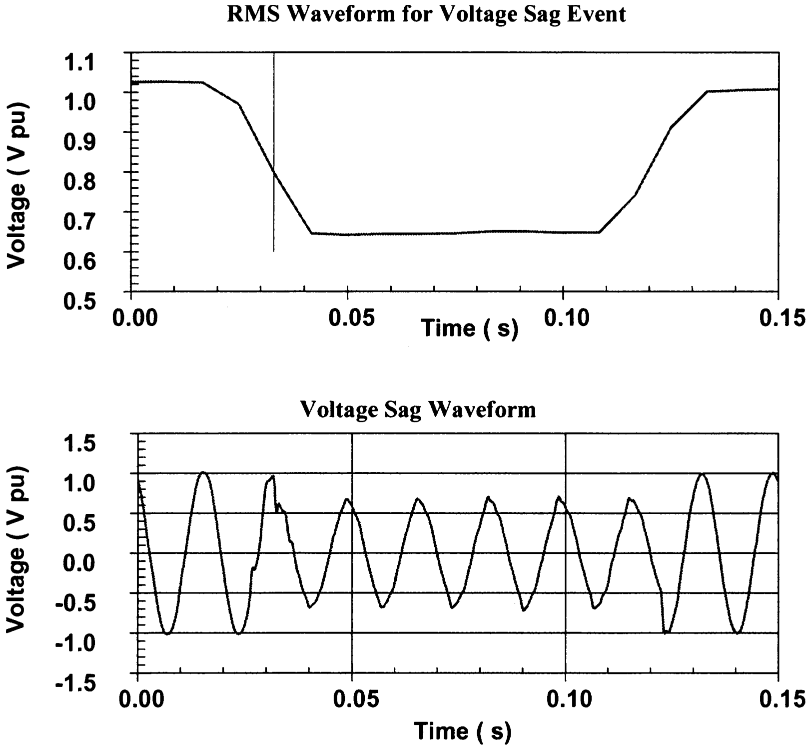

FIGURE 23-4 Voltage sag caused by a SLG fault.

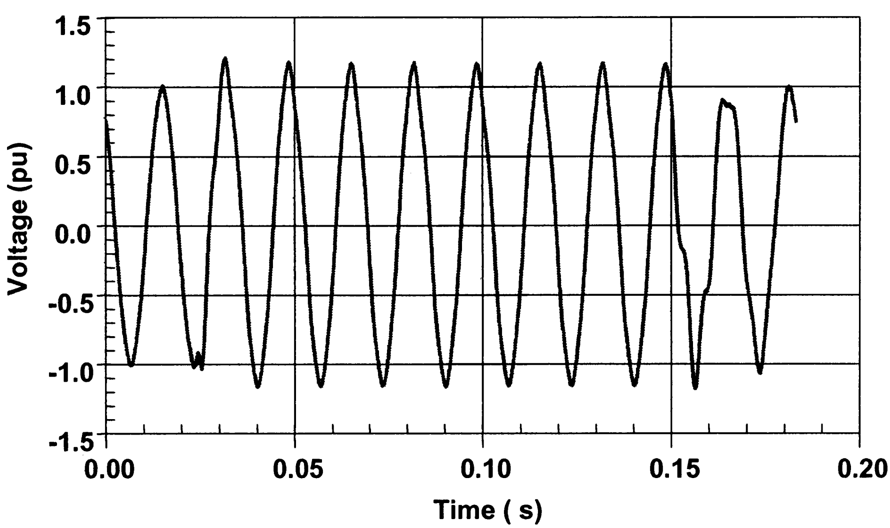

FIGURE 23-5 An 8-cycle voltage swell caused by a SLG fault.

Overvoltage. An *overvoltage* is an increase in the rms ac voltage greater than 110% at the power frequency for a duration longer than 1 min. They are usually the result of load switching (e.g., switching off a large load or energizing a capacitor bank). The overvoltages result because the system is either too weak for the desired voltage regulation or voltage controls are inadequate. Incorrect tap settings on transformers can also result in system overvoltages.

Undervoltage. An *undervoltage* is a decrease in the rms ac voltage to less than 90% at the power frequency for a duration longer than 1 min. They are the result of the events that are the reverse of the events that cause overvoltages. A load switching on or a capacitor bank switching off can cause an undervoltage until voltage regulation equipment on the system can bring the voltage back to within tolerances. Overloaded circuits can result in undervoltages also. The term *brownout* is often used to describe sustained periods of undervoltage initiated as a specific utility dispatch strategy to reduce power demand. Because there is no formal definition for brownout, and it is not as clear as the term undervoltage when trying to characterize a disturbance, the term brownout should be avoided.

23.2.6 Sustained Interruption

When the supply voltage has been zero for a period of time in excess of 1 min, the long duration voltage variation is considered a sustained interruption. Voltage interruptions longer than 1 min are often permanent and require human intervention to repair the system for restoration. The term sustained interruption refers to specific power system phenomena and, in general, has no relation to the usage of the term *outage*. Utilities use outage or interruption to describe phenomena of similar nature for reliability reporting purposes. However, this causes confusion for end users who think of an outage as any interruption of power that shuts down a process. This could be as little as one-half of a cycle. Outage, as defined in IEEE Std 100 [8], does not refer to a specific phenomenon, but rather to the state of a component in a system that has failed to function as expected. Also, use of the term *interruption* in the context of power quality monitoring has no relation to reliability or other continuity of service statistics. Thus, this term has been defined to be more specific regarding the absence of voltage for long periods.

23.2.7 Voltage Imbalance

Voltage imbalance (also called voltage unbalance) is sometimes defined as the maximum deviation from the average of the 3-phase voltages or currents, divided by the average of the 3-phase voltages or currents, expressed in percent. Unbalance is more rigorously defined in the standards [6, 8, 11, 12] using symmetrical components. The ratio of either the negative or zero sequence component to the positive sequence component can be used to specify the percent unbalance. The most recent standard [11] specifies that the negative sequence method be used. Figure 23-6 shows an example of these two ratios for a 1 week trend of imbalance on a residential feeder.

23.2.8 Waveform Distortion

Waveform distortion is defined as a steady-state deviation from an ideal sine wave of power frequency principally characterized by the spectral content of the deviation. There are five primary types of waveform distortion: dc offset, harmonics, interharmonics, notching, and noise.

DC Offset. The presence of a dc voltage or current in an ac power system is termed *dc offset*. This can occur as the result of a geomagnetic disturbance or asymmetry of electronic power converters. Incandescent lightbulb life extenders, for example, may consist of diodes that reduce the rms voltage supplied to the lightbulb by half-wave rectification. Direct current in alternating current networks can have a detrimental effect by biasing transformer cores so they saturate in normal operation. This

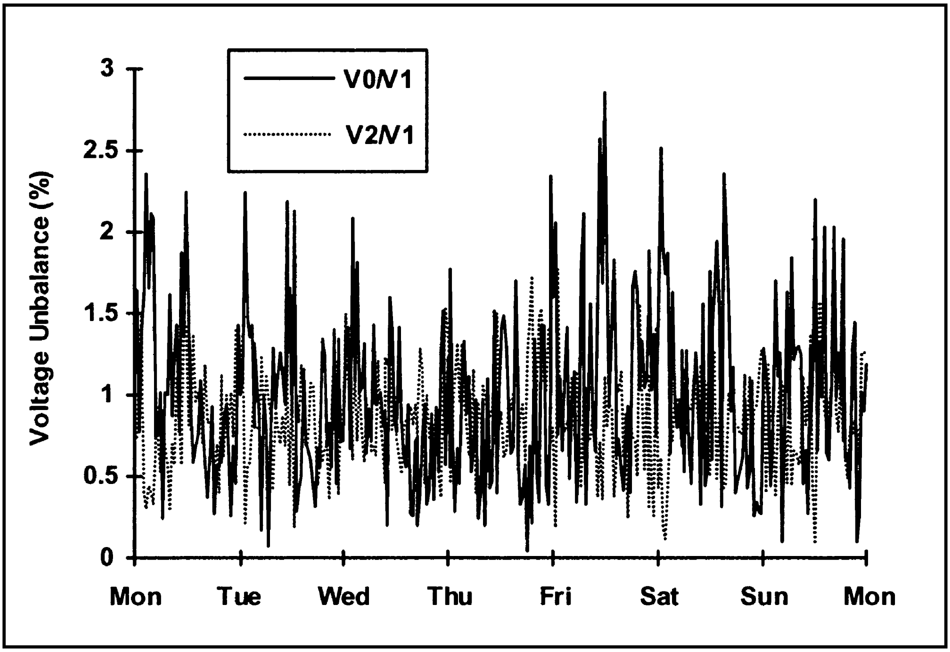

FIGURE 23-6 Voltage unbalance trend for a residential feeder.

causes additional heating and loss of transformer life. DC may also cause the electrolytic erosion of grounding electrodes and other connectors.

Harmonics and Interharmonics. *Harmonics* are sinusoidal voltages or currents having frequencies that are integer multiples of the frequency at which the supply system is designed to operate (termed the fundamental frequency; usually 50 or 60 Hz) [6]. Periodically distorted waveforms can be decomposed into a sum of the fundamental frequency and the harmonics. Harmonic distortion originates in the nonlinear characteristics of devices and loads on the power system. Figure 23-7 illustrates the waveform and harmonic spectrum for a typical adjustable speed drive input current.

Voltages or currents having frequency components that are not integer multiples of the frequency at which the supply system is designed to operate (e.g., 50 or 60 Hz) are called *interharmonics*. They can appear as discrete frequencies or as a wideband spectrum. Interharmonics can be found in networks of all voltage classes. The main sources of interharmonic waveform distortion are static frequency converters, cycloconverters, induction furnaces, and arcing devices. Power line carrier signals can also be considered as interharmonics.

Notching. *Notching* is a periodic voltage disturbance caused by the normal operation of power electronics devices when current is commutated from one phase to another. Since notching occurs continuously, it can be characterized through the harmonic spectrum of the affected voltage. However, it is generally treated as a special case. The frequency components associated with notching can be quite high and may not be readily characterized with measurement equipment normally used for harmonic analysis. Figure 23-8 shows an example of voltage notching from a 3-phase converter that produces continuous dc current. The notches occur when the current commutates from

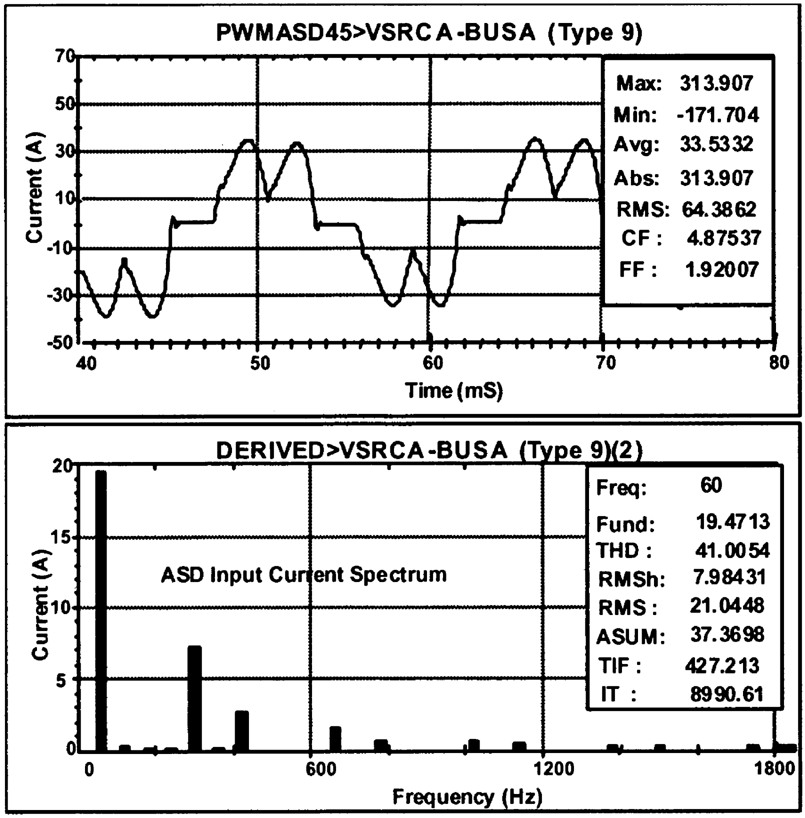

FIGURE 23-7 Current waveform and harmonic spectrum for an ASD input current.

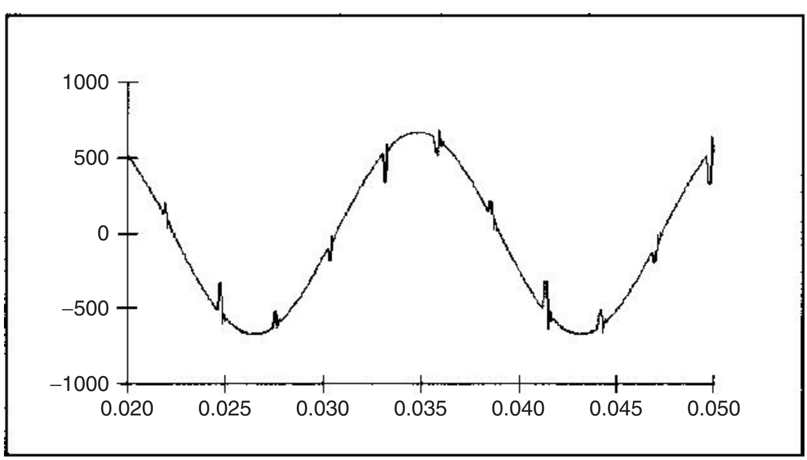

FIGURE 23-8 Example of voltage notching caused by a 3-phase converter.

one phase to another. During this period, there is a momentary short circuit between two phases pulling the voltage as close to zero as permitted by system impedances.

Noise. *Noise* is defined as unwanted electrical signals with broadband spectral content lower than 200 kHz superimposed upon the power system voltage or current in phase conductors, or found on neutral conductors or signal lines. Noise in power systems can be caused by power electronic devices, control circuits, arcing equipment, loads with solid-state rectifiers, and switching power supplies. Noise problems are often exacerbated by improper grounding that fails to conduct noise away from the power system. In principle, noise consists of any unwanted distortion of the power signal that cannot be classified as harmonic distortion or transients. Noise disturbs electronic devices such as microcomputer and programmable controllers. The problem can be mitigated by using filters, isolation transformers, and line conditioners.

23.2.9 Voltage Fluctuation

Voltage fluctuations are systematic variations of the voltage envelope or a series of random voltage changes, the magnitude of which does not normally exceed the voltage ranges specified by ANSI C84.1 of 0.9 to 1.1 pu. IEC 61000-2-1 defines various types of voltage fluctuations. We will restrict our discussion here to IEC 61000-2-1 Type (d) voltage fluctuations, which are characterized as a series of random or continuous voltage fluctuations. Loads that can exhibit continuous, rapid variations in the load current magnitude can cause voltage variations that are often referred to as flicker. The term *flicker* is derived from the impact of the voltage fluctuation on lamps such that they are perceived to flicker by the human eye. To be technically correct, voltage fluctuation is an electromagnetic phenomenon while flicker is an undesirable result of the voltage fluctuation in some loads. However, the two terms are often linked together in standards. Therefore, we will also use the common term voltage flicker to describe such voltage fluctuations. Figure 23-9 illustrates a voltage waveform which produces flicker. This is caused by an arc furnace, one of the most common causes of voltage fluctuations on utility transmission and distribution systems.

23.2.10 Power Frequency Variations

Power frequency variations are defined as the deviation of the power system fundamental frequency from its specified nominal value (e.g., 50 or 60 Hz). The power system frequency is directly related to the rotational speed of the generators supplying the system. There are slight variations in frequency as the dynamic balance between load and generation changes. The size of the frequency shift and its duration depends on the load characteristics and the response of the generation control system

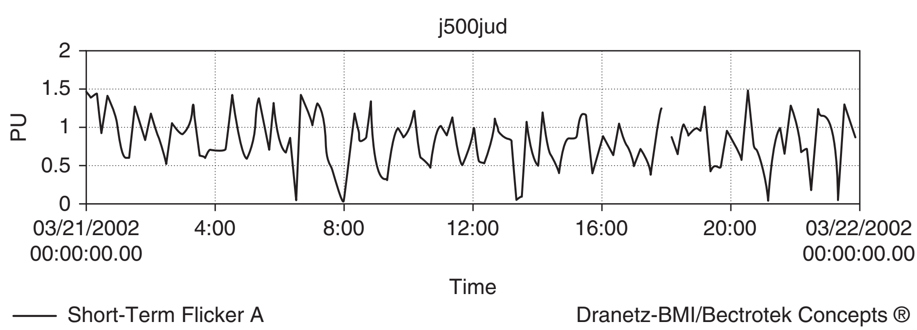

FIGURE 23-9 Flicker (Pst) at 161-kV substation bus measured according to IEC 61000-4-15.

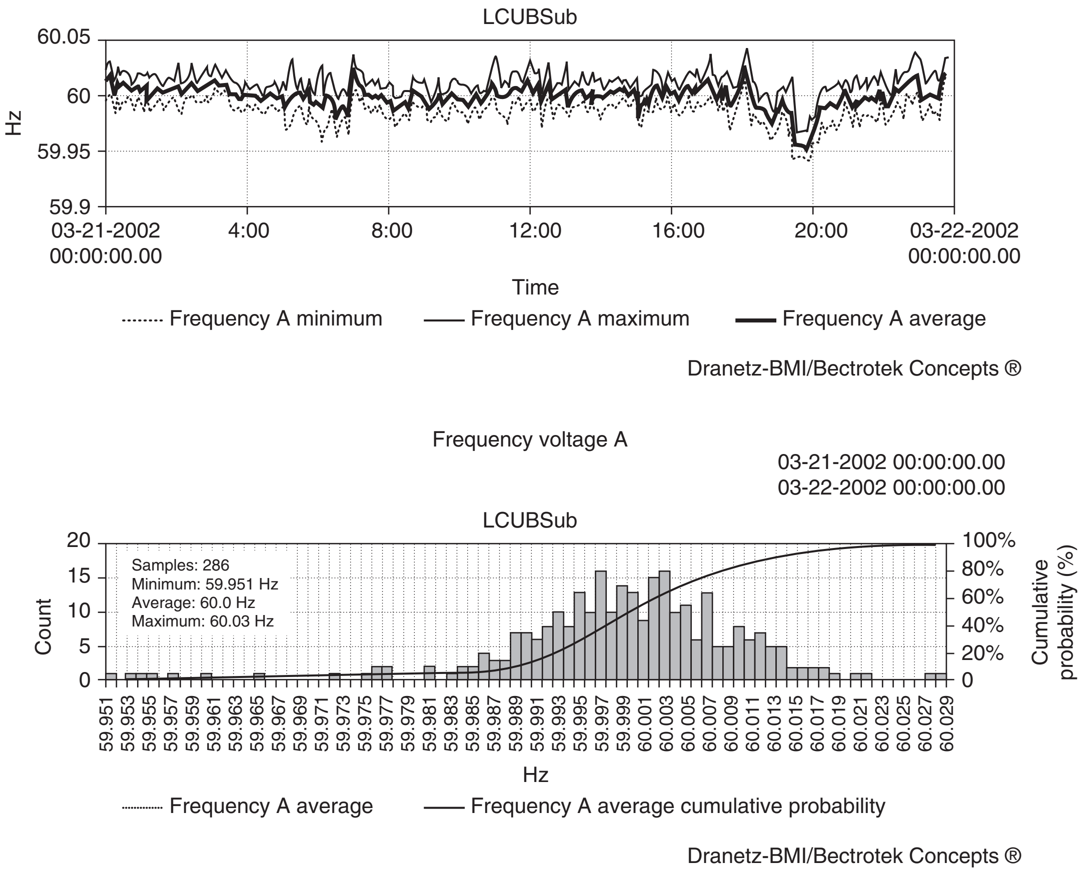

FIGURE 23-10 Power frequency trend and statistical distribution at 13-kV substation bus.

to load changes. Figure 23-10 illustrates frequency variations for a 24-h period on a typical 13-kV substation bus. Frequency variations that go outside of accepted limits for normal steady-state operation of the power system can be caused by faults on the bulk power transmission system, a large block of load being disconnected, or a large source of generation going offline.

23.3 VOLTAGE SAGS AND INTERRUPTIONS ON POWER SYSTEMS

23.3.1 Characteristics

Voltage sags and interruptions are related power quality problems. They are the result of faults in the power system and switching actions to isolate the faulted sections. A voltage sag is characterized by a short duration (typically 0.5 to 30 cycles) reduction in rms voltage caused by faults on the power system and the starting of large loads, such as motors. Momentary interruptions (typically no more than 2 to 5 s) cause a complete loss of voltage and are a common result of the actions taken by utilities to clear transient faults on their systems. Sustained interruptions of longer than 1 min are generally due to permanent faults. Due to the nature of the interconnected power systems and the utility fault-clearing schemes, voltage sags are the most common power quality disturbances.

23.3.2 Sources of Sags and Interruptions

Voltage sags and interruptions are generally caused by faults (short circuits) on the utility system and subsequent operations of protective devices in isolating the faults. Transient or temporary faults on the same or parallel feeders can result in voltage sags. Permanent faults usually result in interruptions. It is also possible that voltage sags are the result of starting of large loads, such as large motors. In some rare circumstances, energizing a transformer in a weak power system can also result in voltage sags. The voltage sag and interruption performance is greatly influenced by the utility feeder design and fault-clearing practices.

23.3.3 Utility System Fault Clearing

A radial distribution system is designed so that only one fault interrupter must operate to clear a fault. For permanent faults, that same device, or another, operates to *sectionalize* the feeder. That is, the faulted section is isolated so that power may be restored to the rest of the loads served from the sound sections. Orchestrating this process is referred to as the *coordination* of the overcurrent protection devices. While this is simple in concept, some of the behaviors of the devices involved can be quite complex. What is remarkable about this is that nearly all of the process is performed automatically by autonomous devices employing only local intelligence.

Overcurrent protection devices appear in series along a feeder. For permanent fault coordination, the devices operate progressively slower as one moves from the ends of the feeders toward the substation. This helps ensure the proper sectionalizing of the feeder so that only the faulted section is isolated. However, this principle is often violated for temporary faults, particularly if *fuse saving* is employed. The typical hierarchy of overcurrent protection devices on a feeder is

Feeder Breaker in the Substation. This is a circuit breaker capable of interrupting typically 40 kA of current and controlled by separate relays. When the available fault current is less than 20 kA, it is common to find reclosers used in this application.

Line Reclosers Mounted on Poles at Midfeeder. The simplest are self-contained with hydraulically-operated timing, interrupting, and reclosing mechanisms. Others have separate electronic controls.

Fuses on Many Lateral Taps Off the Main Feeder. These protective devices have significant implications on power quality issues.

23.3.4 Reclosers

Reclosers are a special circuit breaker designed to perform interruption and reclosing on temporary faults. They can reclose 2 or 3 times if needed in rapid succession. The multiple operations are designed to permit various sectionalizing schemes to operate and to give some more persistent transient faults a second chance to clear. The majority of faults will be cleared on the first operation. These devices can be found in numerous places along distribution feeders and sometimes in substations. They are typically applied at the head of sections subjected to numerous temporary faults. However, they may be applied nearly anywhere a convenient, low-cost primary-side circuit breaker is needed. Figure 23-11 shows a typical pole-mounted line recloser.

In addition to perform interruption and reclosing on temporary faults, reclosers are used for *fuse-saving or fast-tripping* applications. They are some of the fastest mechanical fault interrupters employed on the utility system. While they are typically rated for no faster than 3 to 6 cycles, many examples of interruptions as short as 1.5 cycles have been observed with power quality monitors.

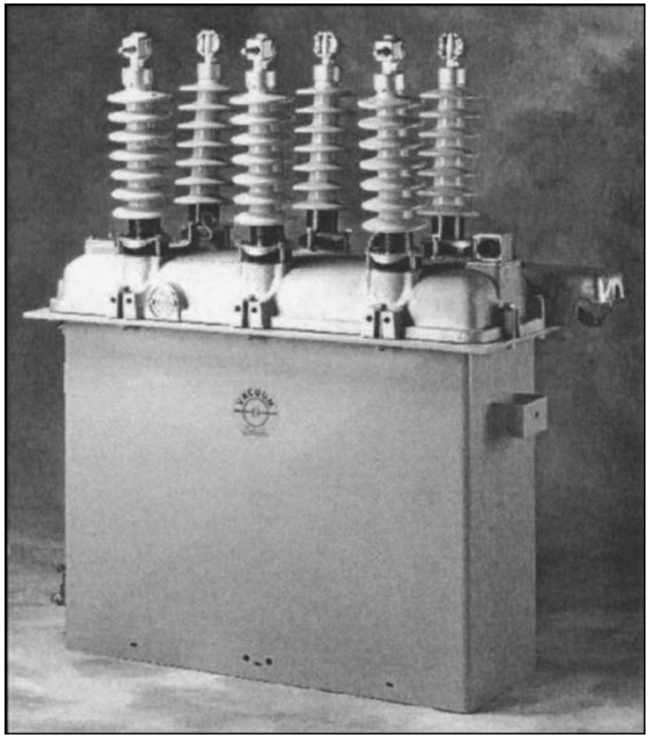

FIGURE 23-11 Typical standard 3-phase oil-insulated line recloser with vacuum interrupters. (*Photo courtesy of Cooper Power Systems.*)

This can be beneficial to limiting sag durations. Where fast tripping is not employed, the recloser control will commonly delay operation to more than 6 cycles to allow time for downline fuses to clear.

23.3.5 Reclosing Sequence

Reclosing is quite prevalent in North American utility systems. Utilities in regions of low lightning incidence may reclose only once because they assume that the majority of their faults will be permanent. In lightning-prone regions, it is common to attempt to clear the fault as many as 4 times. Figure 23-12 illustrates the two most common sequences in use on 4-shot reclosers:

1-fast operation, 3-delayed;

2-fast, 2-delayed.

Reclosers tend to have uniform reclose intervals between operations. The original hydraulic reclosers were limited to about 1 to 2 s and this setting has been retained by many utilities, although modern electronically controlled reclosers can be set for any value. It is common for the first reclose interval on some types of reclosers to be set for *instantaneous reclose*, which will result in closure in 12 to 30 cycles (0.2 to 0.5 s). This is done to reduce the time of the interruption and improve the power quality. However, there are some conflicts created by this, such as with distributed generation disconnecting times.

Substation circuit breakers often have a different style of reclosing sequence as shown in Fig. 23-13. This stems from a different evolution of relaying technology. Reclosing times are counted from the first tripping signal of the first operation. Thus, the common “0-15-45” operating sequence recloses

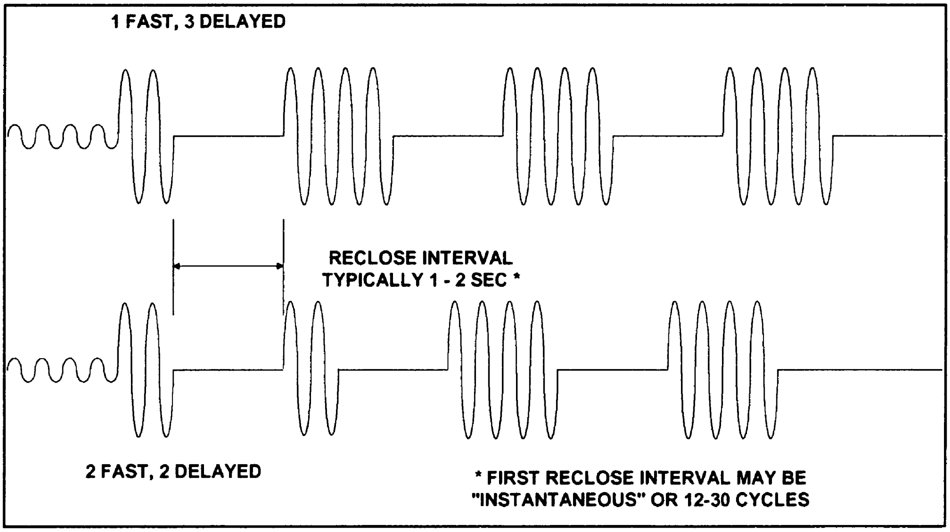

FIGURE 23-12 Common reclosing sequences for line reclosers in use in the United States.

essentially as fast as possible on the first operation, with approximately 15 and 30 s intervals between the next two operations.

Although the terminology may differ, modern breakers and reclosers can both be set to have the same operating sequences to meet load power quality requirements. Utilities generally choose one technology over the other based on cost or construction standards. It is generally fruitless to automatically reclose in distribution systems that are predominantly underground distribution cable, unless there is a significant portion that is overhead and exposed to trees or lightning.

23.3.6 Fuse Saving or Fast Tripping

Ideally, utility engineers would like to avoid blowing fuses needlessly on transient faults because a line crew must be dispatched to change it. Line reclosers were designed specifically to help save fuses. Substation circuit breakers can use instantaneous ground relaying to accomplish the same objective. The

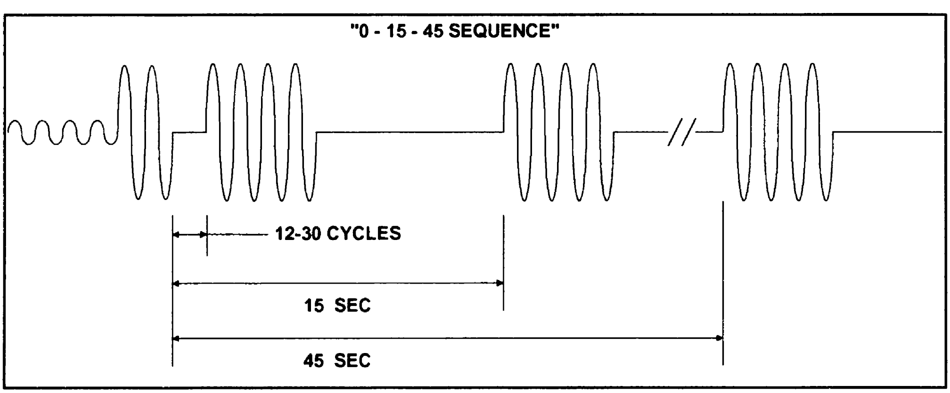

FIGURE 23-13 A common reclosing sequence for substation breakers in the United States.

basic idea is to have the mechanical circuit interrupting device operate very quickly on the first operation so that it clears before any fuses downline from it have a chance to melt. When the device closes back in, power is fully restored in the majority of the cases and no human intervention is required. The only inconvenience to the customer is a slight blink. This is called the fast operation of the device, or the instantaneous trip. If the fault is still there upon reclosing, there are two options in common usage:

1. Switch to a slow, or *delayed*, tripping characteristic. This is frequently the only option for substation circuit breakers; they will operate only one time on the instantaneous trip. This philosophy assumes that the fault is now permanent and switching to a delayed operation will give a downline fuse time to operate and clear the fault by isolating the faulted section.
2. Try a second fast operation. This philosophy is used where experience has shown a significant percentage of transient faults need two chances to clear while saving the fuses. Some line constructions and voltage levels have a greater likelihood that a lightning-induced arc may reignite and need a second chance to clear. Also, a certain percentage of tree faults will burn free if given a second shot.

Many utilities have abandoned fuse saving in selected areas due to complaints about power quality. The fast, or instantaneous, trip is eliminated so that breakers and reclosers have only time-delayed operations.

23.3.7 Fault-Induced Voltage Sags

The majority of voltage sags are caused by faults on the power systems and the subsequent operations of protective devices. Consider a customer that is supplied from the feeder supplied by circuit breaker no. 1 on the diagram shown in Fig. 23-14. If there is a fault on the same feeder, the customer will experience a voltage sag during the fault followed by an interruption when the breaker opens to clear the fault. If the fault is temporary in nature, a reclosing operation on the breaker should be successful and the interruption will only be temporary. It will usually require about 5 or 6 cycles for the breaker to operate, during which time a voltage sag occurs. The breaker will remain open for typically a minimum of 12 cycles up to 5 s depending on utility reclosing practices. Sensitive equipment will almost surely trip during this interruption.

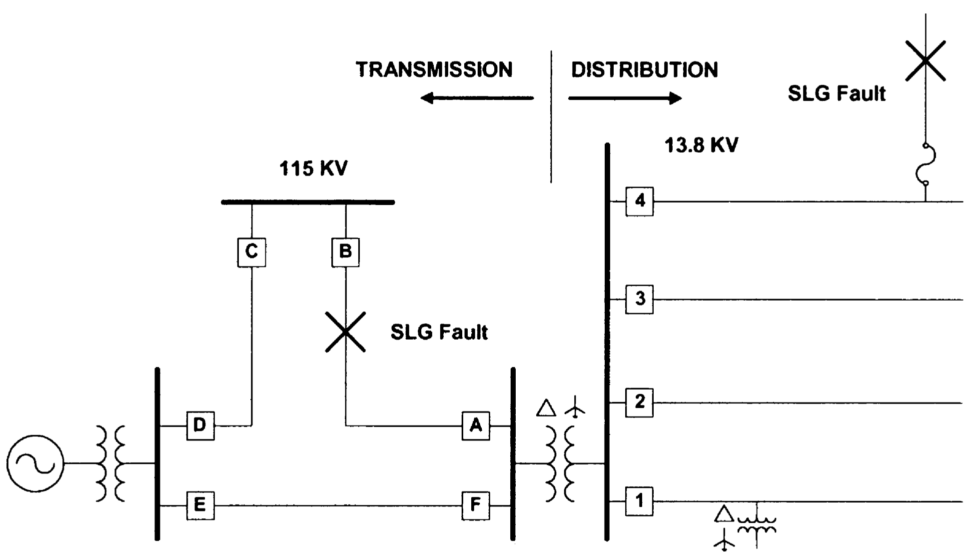

FIGURE 23-14 Fault locations on the utility power system.

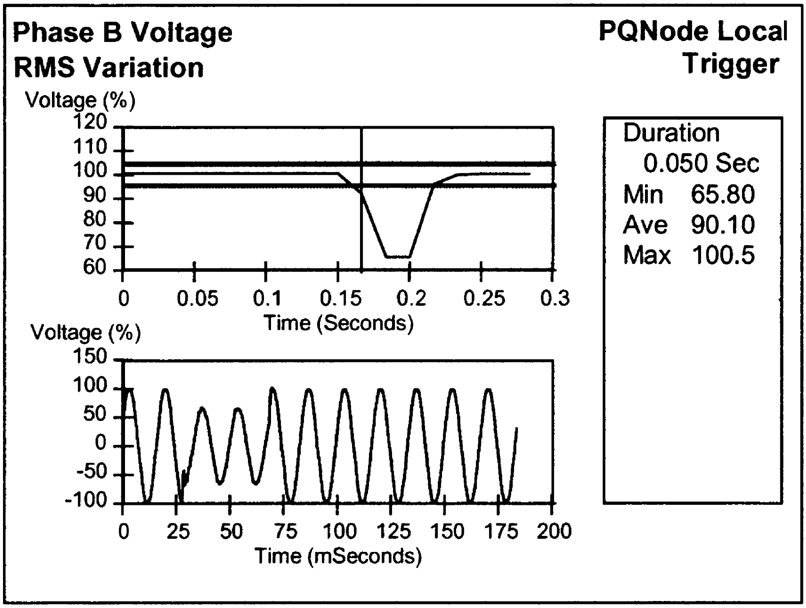

FIGURE 23-15 Voltage sag due to short circuit fault on a parallel utility feeder.

A much more common event would be a fault on one of the other feeders from the substation, that is, a fault is on a parallel feeder, or a fault somewhere on the transmission system (see the fault locations shown on Fig. 23-14). In either of these cases, the customer will experience a voltage sag during the period that the fault is actually on the system. As soon as breakers open to clear the fault, normal voltage will be restored at the customer. Note that to clear the fault shown on the transmission system, both breakers A and B must operate. Transmission breakers will typically clear a fault in 5 or 6 cycles. In this case there are two lines supplying the distribution substation and only one has a fault. Therefore, customers supplied from the substation should expect to see only a sag and not an interruption. The distribution fault on feeder no. 4 may be cleared either by the lateral fuse or the breaker, depending on the utility fuse saving practice. Any of these fault locations can cause equipment to misoperate in customer facilities. The relative importance of faults on the transmission system and the distribution system will depend on the specific characteristics of the systems (underground vs. overhead distribution, lightning flash densities, overhead exposure, etc.) and the sensitivity of the equipment to voltage sags.

Example of Voltage Sags due to a Fault on a Parallel Feeder. This example illustrates voltage sag and momentary interruption events due to a temporary fault on a utility feeder. Figures 23-15 and 23-16 show an interesting utility fault event recorded for an Electric Power Research Institute research project [13,14] by 8010 PQNode instruments* at two locations in the power system. The top chart in each of the figures is the rms voltage variation with time and the bottom chart is the first 175 ms of the actual waveform. Figure 23-15 shows the characteristic measured at a customer location on an unfaulted part of the feeder. Figure 23-16 shows the momentary interruption (actually two separate interruptions) observed downline from the fault. The interrupting device in this case was a line recloser that was able to interrupt the fault very quickly in about 2.5 cycles. This device can have a variety of settings. In this case, it was set for two fast operations and two delayed operations. Figure 23-15 shows only the brief sag to 65% voltage for the first fast operation. There was an

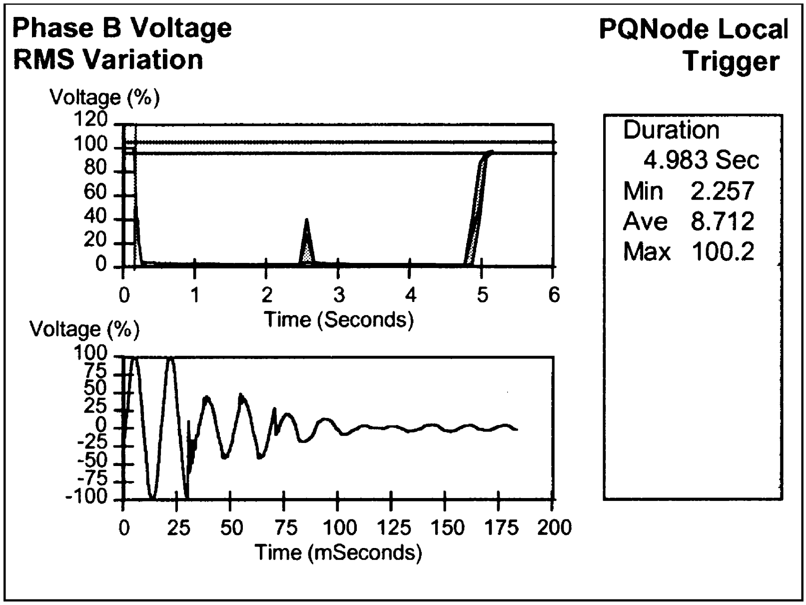

FIGURE 23-16 Utility short circuit fault event with two fast trip operations of utility line.

identical sag for the second operation. While this is very brief sag that is virtually unnoticeable by observing lighting blinks, many industrial processes would have shut down.

Figure 23-16 clearly shows the voltage sag prior to fault clearing and the subsequent two fast recloser operations. The reclose time (the time the recloser was open) was a little more than 2 s, a very common time for a utility line recloser. Apparently, the fault—perhaps, a tree branch—was not cleared completely by the first operation, forcing a second. The system was restored after the second operation.

23.3.8 Motor Starting Sags

Motors have the undesirable effect of drawing several times their full load current while starting. This large current will, by flowing through system impedances, cause a voltage sag which may dim lights, cause contactors to drop out, and disrupt sensitive equipment. The situation is made worse by an extremely poor starting displacement factor—usually in the range of 15%, 30%. The time required for the motor to accelerate to rated speed increases with the magnitude of the sag, and an excessive sag may prevent the motor from starting successfully. Motor starting sags can persist for many seconds, as illustrated in Fig. 23-17.

23.3.9 Motor Starting Methods

Energizing the motor in a single step (*full voltage starting*) provides low cost and allows the most rapid acceleration. It is the preferred method unless the resulting voltage sag or mechanical stress is excessive.

Autotransformer starters have two autotransformers connected in open delta. Taps provide a motor voltage of 80%, 65%, or 50% of system voltage during start-up. Line current and starting torque vary with the square of the voltage applied to the motor, so the 50% tap will deliver only 25% of the full voltage starting current and torque. The lowest tap which will supply the required starting torque is selected.

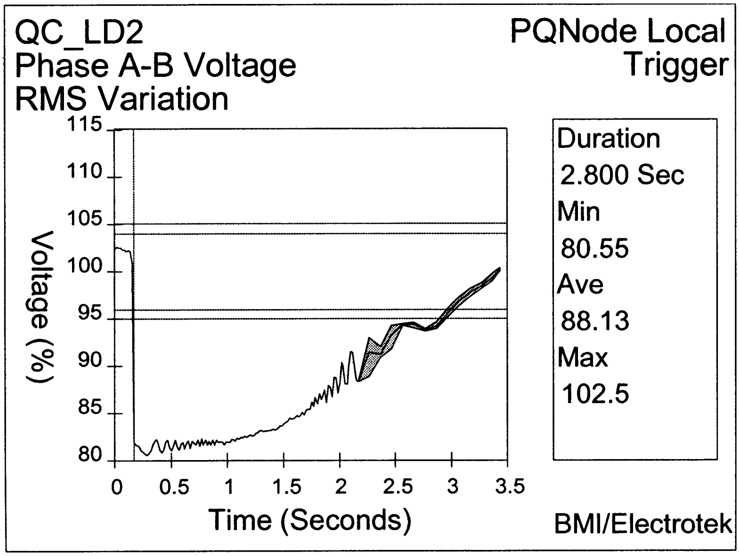

FIGURE 23-17 Typical motor starting voltage sag.

Resistance and reactance starters initially insert an impedance in series with the motor. After a time delay, this impedance is shorted out. Starting resistors may be shorted out over several steps; starting reactors are shorted out in a single step. Line current and starting torque vary directly with the voltage applied to the motor, so for a given starting voltage, these starters draw more current from the line than with autotransformer starters, but provide higher starting torque. Reactors are typically provided with 50%, 45%, and 37.5% taps.

Part winding starters are attractive for use with dual-rated motors (220/440 or 230/460V). The stator of a dual-rated motor consists of two windings connected in parallel at the lower voltage rating, or in series at the higher voltage rating. When operated with a part winding starter at the lower voltage rating, only one winding is energized initially, limiting starting current and starting torque to 50% of the values seen when both windings are energized simultaneously.

Wye-Delta starters connect the stator in wye for starting, then after a time delay, reconnect the windings in delta. The wye connecting reduces the starting voltage to 57% of the system line-line voltage; starting current and starting torque are reduced to 33% of their values for full voltage start.

23.3.10 Estimating the Sag Severity during Full Voltage Starting

As shown in Fig. 23-17, starting an induction motor results in a steep dip in voltage, followed by a gradual recovery. If full voltage starting is used, the sag voltage, in per unit of nominal system voltage is

$$V_{min}(pu) = \frac{V(pu) \cdot kVA_{SC}}{kVA_{LR} + kVA_{SC}} \tag{23-1}$$

where $V(pu)$ = is the actual system voltage, in per unit of nominal
kVA_{LR} = is the motor locked rotor kVA
kVA_{SC} = is the system short circuit kVA at the motor

Figure 23-18 illustrates the results of this computation for sag to 90% of nominal voltage, using typical system impedances and motor characteristics.

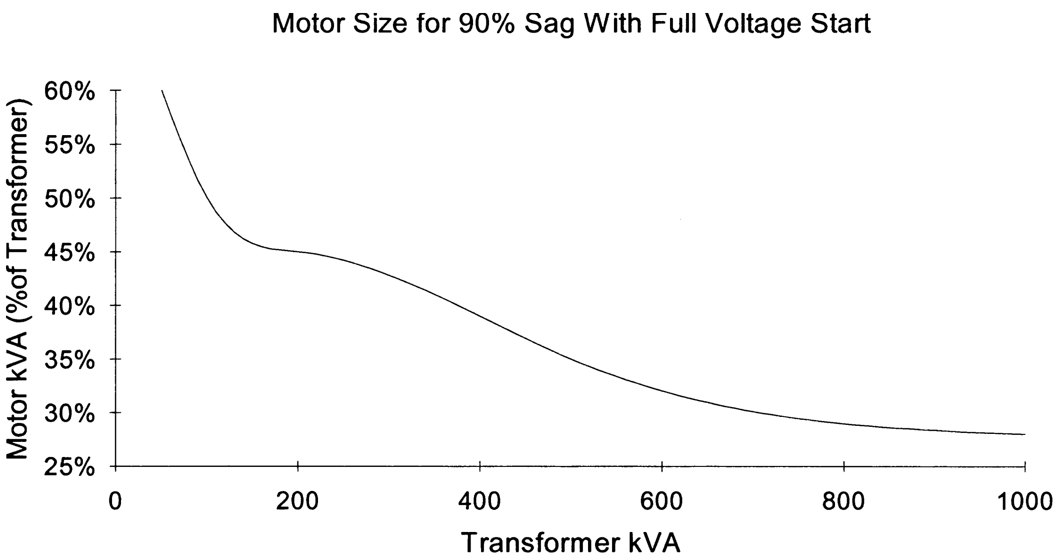

FIGURE 23-18 Typical motor vs. transformer size for full voltage starting sags of 90%.

If the result is above the minimum allowable steady-state voltage for the effected equipment, then the full voltage starting is acceptable. If not, then the sag magnitude versus duration characteristic must be compared to the voltage tolerance envelope of the effected equipment. The required calculations are fairly complicated, and best left to a motor starting or general transient analysis computer program.

23.4 ELECTRICAL TRANSIENT PHENOMENA

23.4.1 Sources and Characteristics

In principle, electrical transient phenomena can be generated due to natural events such as lightning strokes, and switching operations such as capacitor, load, and transformer energizing, and protective device operations. However, two main sources of transient overvoltages on utility systems are capacitor switching and lightning.

23.4.2 Capacitor Switching Transient Overvoltages

Capacitor switching is one of the most common switching events on utility systems. Capacitors are used to provide reactive power (vars) to correct the power factor, which reduces losses and supports the voltage on the system. One drawback to capacitors is that they yield oscillatory transients when switched. Some capacitors are energized all the time (a fixed bank) while others are switched according to load levels. Various control means are used to determine when they are switched including time, temperature, voltage, current, and reactive power. It is common for controls to combine two or more of these functions, such as temperature with voltage override.

Figure 23-19 shows the one-line diagram of a typical utility feeder capacitor switching situation. When the switch is closed, a transient similar to the one in Fig. 23-20 may be observed upline from the capacitor at the monitor location. In this particular case, the capacitor switch contacts close at a point near the system voltage peak. This is common for many types of switches because the insulation across the switch contacts tends to break down when the voltage across the switch is at a maximum

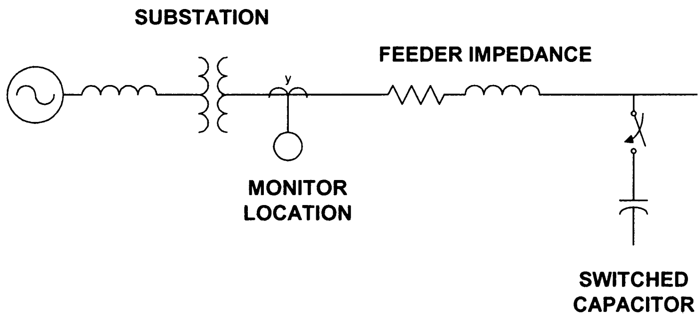

FIGURE 23-19 One-line diagram of capacitor switching operation.

value. The voltage across the capacitor at this instant is zero. Since the capacitor voltage cannot change instantaneously, the system voltage at the capacitor location is briefly pulled down to zero and rises as the capacitor begins to charge toward the system voltage. Because the power system source is inductive, the capacitor voltage overshoots and rings at the natural frequency of the system. At the monitoring location shown, the initial change in voltage will not go completely to zero because of the impedance between the observation point and the switched capacitor. However, the initial drop and subsequent ringing transient that is indicative of a capacitor switching event will be observable to some degree. The overshoot will generate a transient between 1.0 and 2.0 pu depending

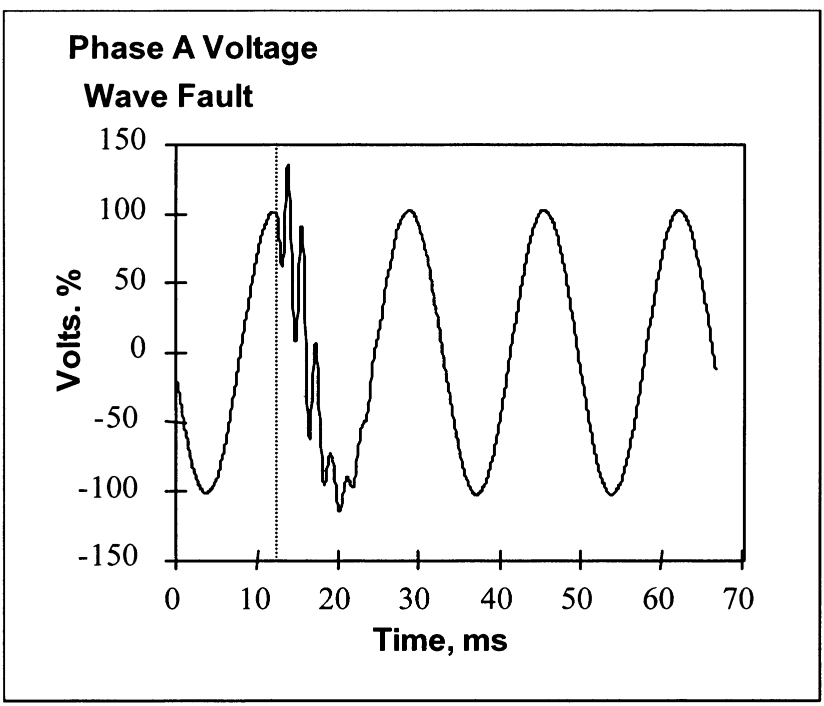

FIGURE 23-20 Typical utility capacitor switching transient reaching 134% voltage, observed upline from the capacitor.

on system damping. In this case, the transient observed at the monitoring location is about 1.34 pu. Utility capacitor switching transients are commonly in the 1.3 to 1.4 pu range, but have also been observed near the theoretical maximum.

23.4.3 Magnification of Capacitor Switching Transient Overvoltages

Capacitor switching transients can propagate into the local power system and will generally pass through distribution transformers into customer load facilities by nearly the amount related to the turns ratio of the transformer. If there are capacitors on the secondary system, the voltage may actually be magnified on the load side of the transformer if the natural frequencies of the systems are properly aligned. The circuit of concern for this phenomenon is illustrated in Fig. 23-21. Transient overvoltages on the end-user side may reach as high as 3.0 to 4.0 pu on the low-voltage bus under these conditions, with potentially damaging consequences for all types of customer equipment.

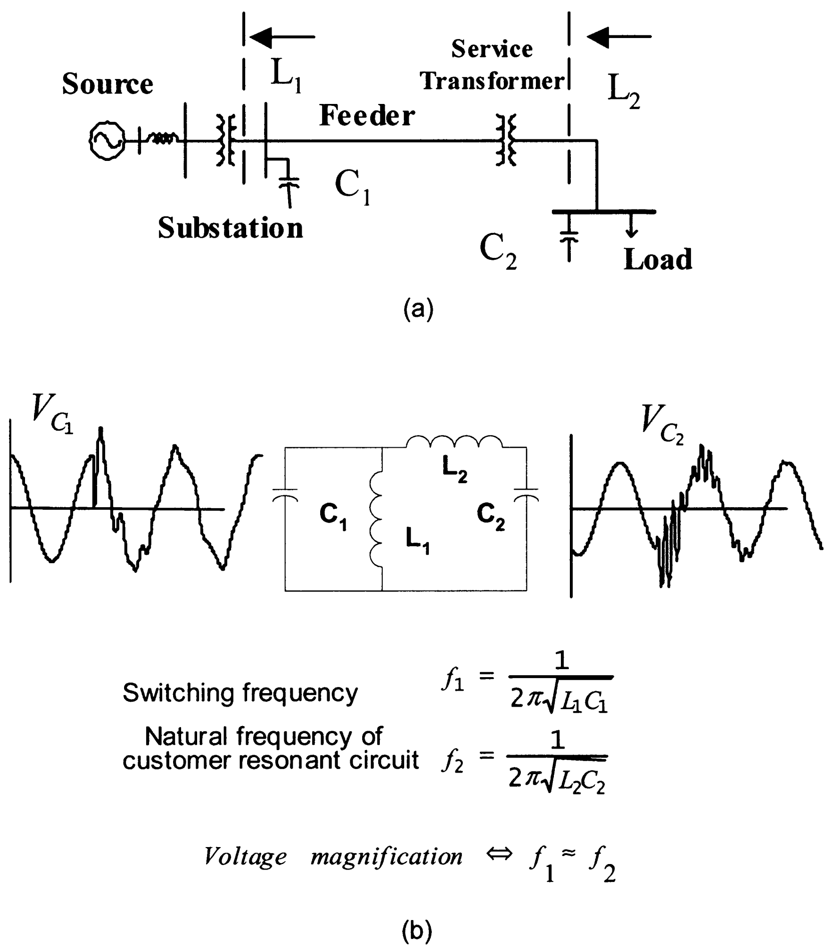

FIGURE 23-21 Voltage magnification of capacitor bank switching. (*a*) Voltage magnification at customer capacitor due to energizing capacitor on utility system (*b*) Equivalent circuit

23.4.4 Options to Limit Magnification

Magnification of utility capacitor switching transients at the end-user location occurs over a wide range of transformer and capacitor sizes. Resizing the customer's power factor correction capacitors or step-down transformer is therefore usually not a practical solution. One solution is to control the transient overvoltage at the utility capacitor. This is sometimes possible using synchronous closing breakers or switches with preinsertion resistors. At the customer location, high-energy surge arresters can be applied to limit the transient voltage magnitude at the customer bus. Energy levels associated with the magnified transient will typically be in the range of 1 kJ. Figure 23-22 shows the expected arrester energy for a range of low-voltage capacitor sizes. High energy MOV arresters for low-voltage applications can withstand 2 to 4 kJ.

While such brief transients up to 2.0 per unit are not generally damaging to the system insulation, it can often cause misoperation of electronic power conversion devices. Controllers may interpret the high voltage as a sign that there is an impending dangerous situation and subsequently disconnect the load to be safe. The transient may also interfere with the gating of thyristors. It is important to note that the arresters can only limit the transient to the arrester protective level. This will typically be approximately 1.8 times the normal peak voltage (1.8 pu).

Another means of limiting the voltage magnification transient is to convert the end-user, power-factor-correction banks to harmonic filters. An inductance in series with the power-factor-correction bank will decrease the transient voltage at the customer bus to acceptable levels. This solution has multiple benefits by providing correction for displacement power factor, controlling harmonic distortion levels within the facility, and limiting the concern for magnified capacitor switching transients.

In many cases, there are only a small number of load devices, such as adjustable-speed motor drives, that are adversely affected by the transient. It is frequently more economical to place line reactors in series with the drives to block the high frequency magnification transient. A 3% reactor is generally effective. While offering only a small impedance to power frequency current, it offers a considerably larger impedance to the transient. Many types of drives have this protection inherently, either through an isolation transformer or a dc bus reactance.

23.4.5 Options to Limit Capacitor Switching Transients—Preinsertion

Preinsertion resistors can reduce the capacitor switching transient considerably. The first peak of the transient is usually the most damaging. The idea is to insert a resistor into the circuit briefly so that the first

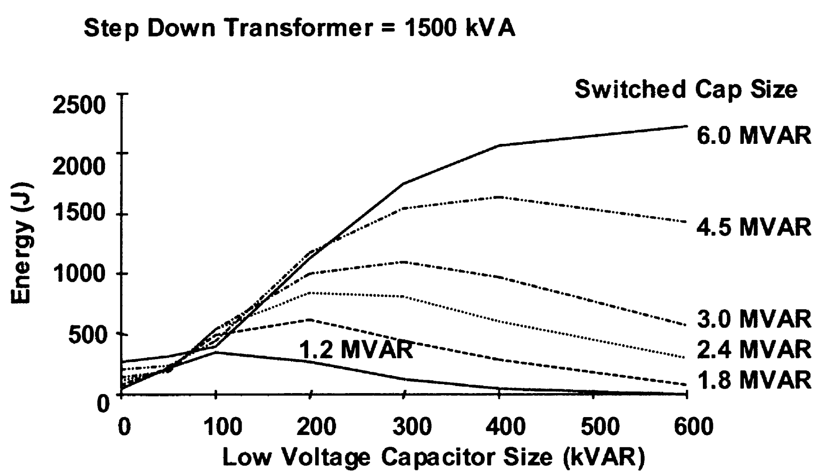

FIGURE 23-22 Arrester energy duty caused by magnified transient.

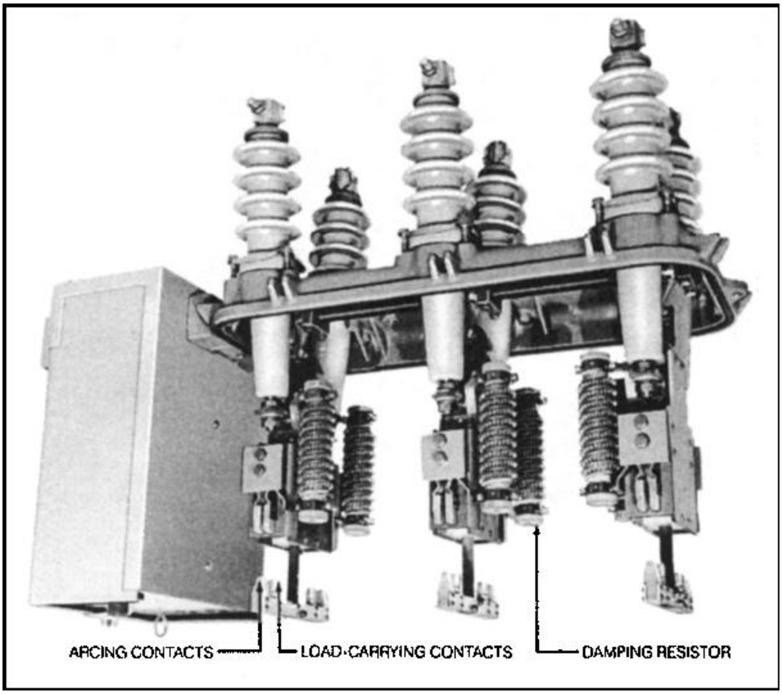

FIGURE 23-23 Capacitor switch with preinsertion resistors. (*Courtesy of Cooper Power Systems.*)

peak is damped significantly. This is old technology, but still quite effective. Figure 23-23 shows one example of a capacitor switch with preinsertion resistors to reduce transients. The preinsertion is accomplished by the movable contacts sliding past the resistor contacts first before mating with the main contacts. This results in a preinsertion time of approximately one-fourth of a cycle at 60 Hz. The effectiveness of the resistors is dependent on capacitor size and available short-circuit current at the capacitor location. Table 23-3 shows expected maximum transient overvoltages upon energization for various conditions, both with and without the preinsertion resistors. These are the maximum values expected; average values are typically 1.3 to 1.4 pu without resistors and 1.1. to 1.2 with resistors.

23.4.6 Options to Limit Capacitor Transient Switching—Synchronous Closing

Another popular strategy for reducing transients on capacitor switching is to use a synchronous closing breaker. This is a relatively new technology for controlling capacitor switching transients. Synchronous closing prevents transients by timing the contact closure such that the system voltage closely matches the capacitor voltage at the instant the contacts make. This avoids the step change in voltage that normally occurs when capacitors are switched, causing the circuit to oscillate. Figure 23-24 shows a vacuum switch made for this purpose. It is applied on 46-kV-class capacitor banks. It consists of three independent poles with separate controls. The timing for synchronous closing is determined by anticipating an upcoming voltage zero. Its success is dependent on the consistent operation of the vacuum switch. The switch reduces capacitor inrush currents by an order of magnitude and voltage transients to about 1.1 pu. A similar switch may also be used at distribution voltages. Each of the switches described here requires a sophisticated microprocessor-based control. Understandably, a synchronous closing system is more expensive than a straightforward capacitor switch. However, it is frequently a cost-effective solution when capacitor switching transients are disrupting end-user loads.

23.4.7 Lightning

Lightning is a potent source of impulsive transients and can have serious impacts on power system and end-user equipment. Figure 23-25 illustrates some of the places where lightning can strike that results in lightning currents being conducted from the power system into loads. The most obvious conduction path occurs during a direct strike to a phase wire, either on the primary or the secondary side of the

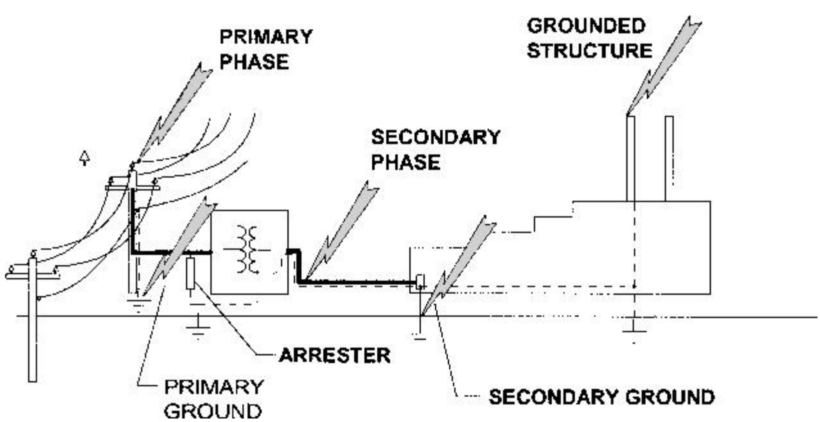

FIGURE 23-25 Stroke locations for conduction of lightning impulses into load facilities.

transformer. This can generate very high overvoltages, but some analysts question whether this is the most common way that lightning surges enter load facilities and cause damage. Very similar transient overvoltages can be generated by lightning currents flowing along ground conductor paths. Note that there can be numerous paths for lightning currents to enter the grounding system. Common ones, indicated by the dotted lines in Fig. 23-25, include the primary ground, the secondary ground, and the structure of the load facilities. Note also that strokes to the primary phase are conducted to the ground circuits through the arresters on the service transformer. Thus, many more lightning impulses may be observed at loads than one might think. Note that grounds are never perfect conductors, especially for impulses. While most of the surge current may eventually be dissipated into the ground connection closest to the stroke, there will be substantial surge currents flowing in other connected ground conductors in the first few microseconds of the strike.

The chief power quality problems with lightning stroke currents entering the ground system are

- They raise the potential of the local ground above other grounds in the vicinity by several kilovolts. Sensitive electronic equipment that is connected between two ground references, such as a computer connected to the telephone system through a modem, can fail when subjected to the lightning surge voltages.
- They induce high voltages in phase conductors as they pass through cables on the way to a better ground.

23.4.8 Low-Side Surges

Some utility and end-user problems with lightning impulses are closely related. One of the most significant ones is called the *low-side surge* problem by many utility engineers. The name was coined by distribution transformer designers because it appears from the transformer's perspective that a current surge is suddenly injected into the low-voltage side terminals. Utilities have not applied secondary arresters at low-voltage levels in great numbers. From the customer's point of view, it appears to be an impulse coming from the utility and is likely to be termed as "secondary surge."

Both problems actually have different side effects of the same surge phenomenon—lightning current flowing from either the utility side or the customer side along the service cable neutral. Figure 23-26 shows one possible scenario. Lightning strikes the primary line and the current is discharged through

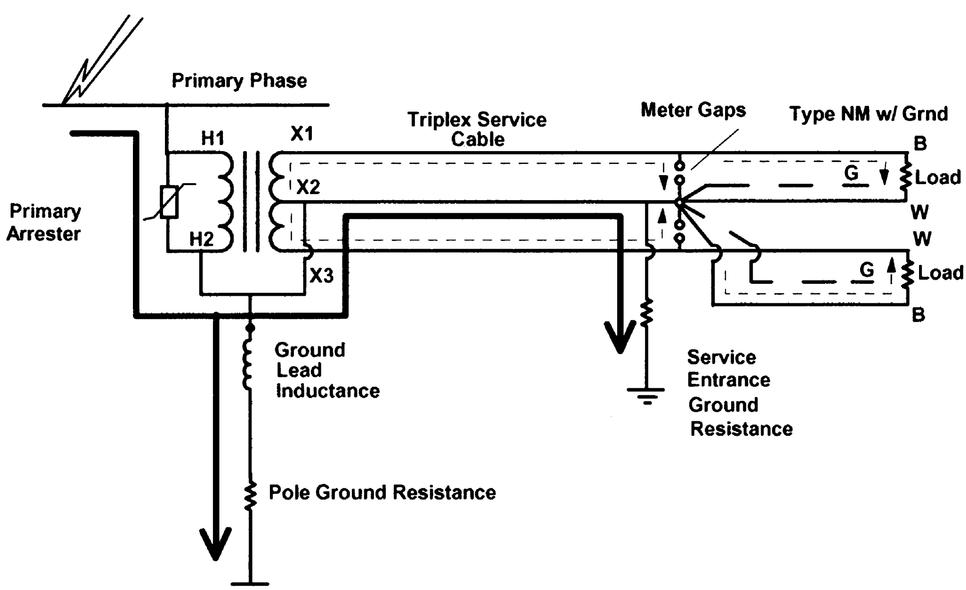

FIGURE 23-26 Primary arrester discharge current divides between pole and load ground.

the primary arrester to the pole ground lead. This lead is also connected to the X2 bushing of the transformer at the top of the pole. Thus, some of the current will flow toward the load ground. The amount of current into the load ground is primarily dependent on the size of the pole ground resistance relative to the load ground. Inductive elements may play a significant role in the current division for the front of the surge, but the ground resistances basically dictate the division of the bulk of the stroke current.

The current that flows through the secondary cables causes a voltage drop in the neutral conductor that is only partially compensated by mutual inductive effects with the phase conductors. Thus, there is a net voltage across the cable, forcing current through the transformer secondary windings and into the load as shown by the dashed lines in the figure. If there is a complete path, substantial surge current will flow. As it flows through the transformer secondary, a surge voltage is induced in the primary, sometimes causing a layer-to-layer insulation failure near the grounded end. If there is not a complete path, the voltage will buildup across the load and may flash over somewhere on the secondary. It is common for the meter gaps to flashover, but not always before there is damage on the secondary because the meter gaps are usually 6 to 8 kV, or higher. The amount of voltage induced in the cable is dependent on the rate-of-rise of the current, which is dependent on other circuit parameters as well as the lightning stroke.

The chief power quality problems this causes are

- The impulse entering the load can cause failure or misoperation of load equipment.
- The utility transformer will fail causing an extended power outage.
- The failing transformer may subject the load to sustained steady-state overvoltages because part of the primary winding is shorted, decreasing the transformer turns ratio. Failure usually occurs in seconds, but has been known to take hours.

The key to this problem is the amount of surge current traveling through the secondary service cable. Keep in mind that the same effect occurs regardless of the direction of the current. All that is required is for the current to get into the ground circuits and for a substantial portion to flow through the cable on its way to another ground. Thus, lightning strikes to either the utility system or the end-user facilities can produce the same symptoms. Transformer protection is more of an issue in residential services, but the secondary transients will appear in industrial systems as well.

23.4.9 Low-Side Surges—An Example

Figure 23-27 shows a waveform of the open-circuit voltage measured at an electrical outlet location in a laboratory mock-up of a residential service [16]. For a relatively small stroke to the primary line (2.6 kA), the voltages at the outlet reached nearly 15 kV. In fact, higher current strokes caused random flashovers of the test circuit, which made measurements difficult. This reported experience is indicative of the capacity of these surges to cause overvoltage problems.

The waveform is a very high-frequency, ringing wave riding on the main part of the low-side surge. The ringing is very sensitive to the cable lengths. A small amount of resistive load, such as a lightbulb, would contribute greatly to the damping. The ringing wave differs depending on where the surge was applied while the base low-side surge wave remains about the same; it is more dependent on the waveform of the current through the service cable. One interesting aspect of this wave is that the ringing is so fast that it gets by the spark gaps in the meter base even though the voltage is 2 times the nominal sparkover value. In the tests, the outlets and lamp sockets could also withstand this kind of wave for about 1 μs before they flashed over. Thus, it is possible to have some high overvoltages propagating throughout the system. The waveform in this figure represents the available open-circuit voltage. In actual practice, a flashover would have occurred somewhere in the circuit after a brief time.

23.4.10 Ferroresonance

The term *ferroresonance* refers to a resonance that involves capacitance and iron-core inductance. The most common condition in which it causes disturbances in the power system is when the magnetizing

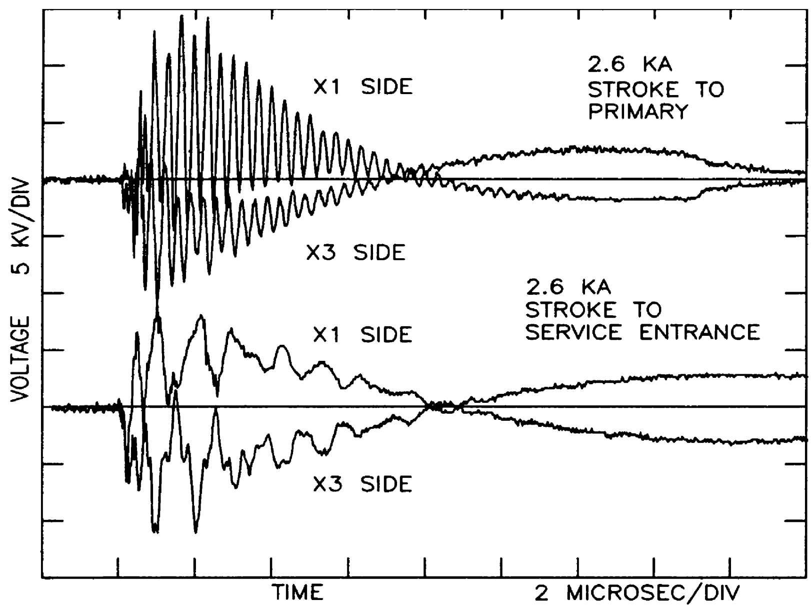

FIGURE 23-27 Voltage appearing at outlet due to low-side surge phenomena.

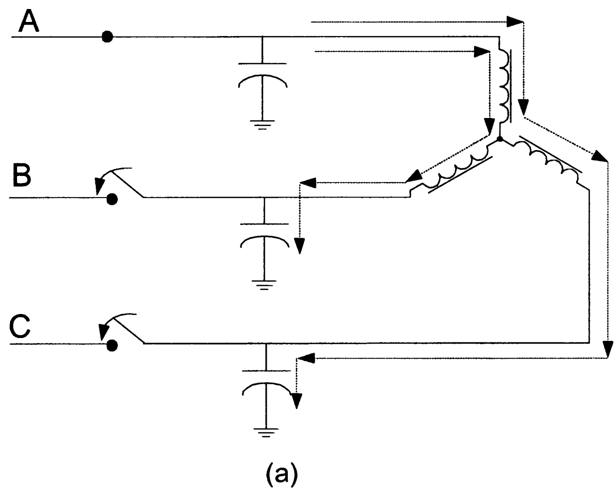
impedance of a transformer is placed in series with a system capacitor due to an open-phase conductor. Under controlled conditions, ferroresonance can be exploited for useful purpose such as in a constant-voltage transformer. In practice, ferroresonance most commonly occurs when unloaded transformers become isolated on underground cables of a certain range of lengths. The capacitance of overhead distribution lines is generally insufficient to yield the appropriate conditions.

The minimum length of cable required to cause ferroresonance varies with system voltage level. The capacitance of cables is nearly the same for all distribution voltage levels, varying from 40 to 100 nF per 1000 ft, depending on conductor size. However, the magnetizing reactance of a 35-kV-class distribution transformer is several times higher (curve is steeper) than a comparably-sized 15-kV-class transformer. Therefore, damaging ferroresonance has been more common at the higher voltages. For delta-connected transformers, ferroresonance can occur for less than 100 ft of cable. For this reason, many utilities avoid this connection on cable-fed transformers. The grounded wye-wye transformer has become the most commonly used connection in underground systems in North America. It is more resistant, but not immune, to ferroresonance because most units use a three-legged or five-legged core design that couples the phases magnetically. It may require a minimum of several hundred feet of cable to provide enough capacitance to create a ferroresonant condition for this connection. The most common events leading to ferroresonance are

- Manual switching of an unloaded, cable-fed, 3-phase transformer where only one phase is closed (Fig. 23-28*a*). Ferroresonance may be noted when the first phase is closed upon energization or before the last phase is opened on de-energization.
- Manual switching of an unloaded, cable-fed, 3-phase transformer where one of the phases is open (Fig. 23-28*b*). Again, this may happen during energization or de-energization.
- One or two riser-pole fuses may blow leaving a transformer with one or two phases open. Single-phase reclosers may also cause this condition. Today, many modern commercial loads will have controls that transfer the load to backup systems when they sense this condition. Unfortunately, this leaves the transformer without any load to damp out the resonance.
- Phase of a cable connected to a wye-connected transformer.



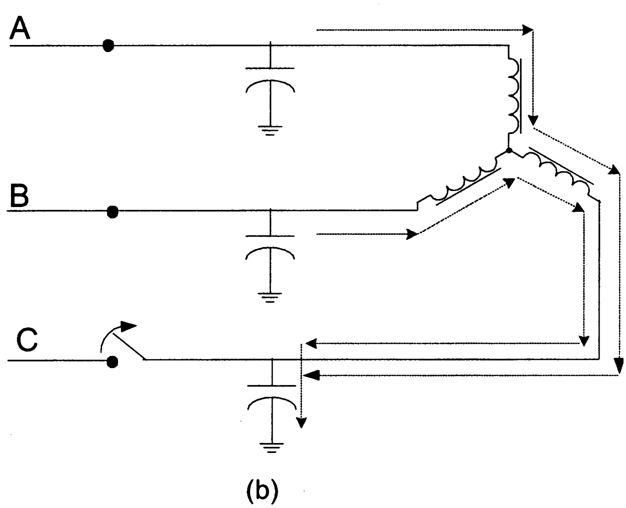


FIGURE 23-28 Common system conditions where ferroresonance may occur: (*a*) one phase closed, (*b*) one phase open.

23.4.11 Transformer Energizing

Energizing a transformer produces inrush currents that are rich in harmonic components for a period lasting up to 1 s. If the system has a parallel resonance near one of the harmonic frequencies, a dynamic overvoltage condition results that can cause failure of arresters and problems with sensitive equipment. This problem can occur when large transformers are energized simultaneously with large power factor correction capacitor banks in industrial facilities. The equivalent circuit is shown in Fig. 23-29. A dynamic overvoltage waveform caused by a third-harmonic resonance in the circuit is shown in Fig. 23-30. After the expected

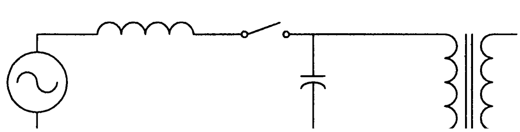

FIGURE 23-29 Energizing a capacitor and transformer simultaneously can lead to dynamic overvoltages.

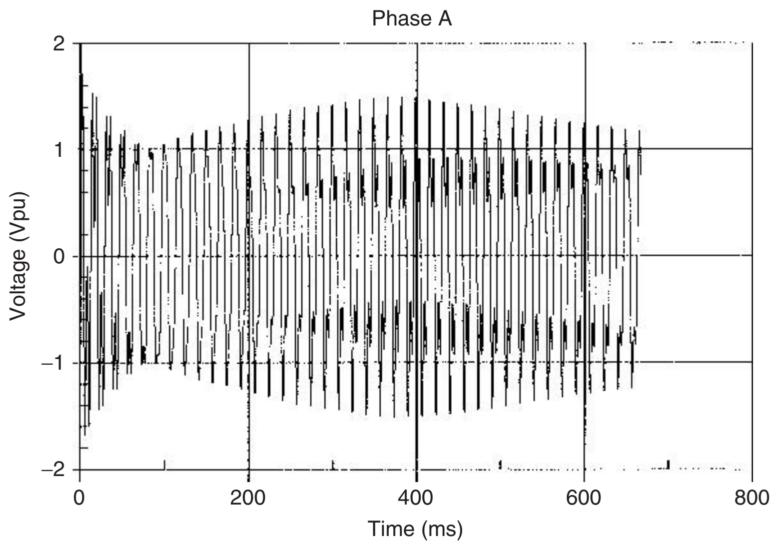

FIGURE 23-30 Dynamic overvoltages during transformer energizing.

initial transient, the voltage again swells to nearly 150% for many cycles until the losses and load damp out the oscillations. This can place severe stress on some arresters and has been known to significantly shorten the life of capacitors.

This form of dynamic overvoltage problem can often be eliminated simply by not energizing the capacitor and transformer together. One plant solved the problem by energizing the transformer first and not energizing the capacitor until load was about to be connected to the transformer.

23.5 POWER SYSTEMS HARMONICS

23.5.1 General

Harmonic distortion is not a new phenomenon on power systems. Concern over distortion has ebbed and flowed a number of times during the history of ac electric power systems. Scanning the technical literature of the 1930s and 1940s, one will notice many articles on the subject. Then the primary sources were the transformers and the primary problem was inductive interference with open-wire telephone systems. The forerunners of modern arc lighting were being introduced and were causing quite a stir because of their harmonic content—not unlike the stir caused by electronic power converters in more recent times.

In contrast, voltage sags and interruptions are nearly universal to every feeder and represent the most numerous and significant power quality deviations. The end user sector suffers more from harmonic problems than the utility sector. Industrial users with adjustable speed drives, arc furnaces, induction furnaces, and the like, are much more susceptible to problems stemming from harmonic distortion.

A good assumption for most utilities in the United States is that the sine wave voltage generated in central power stations is very good. In most areas, the voltage found on transmission systems typically has much less than 1% distortion. However, the distortion increases closer to the load. At some loads, the current waveforms barely resemble a sine wave. Electronic power converters can chop the current into seemingly arbitrary waveforms.

23.5.2 Harmonic Distortion

Harmonic distortion is caused by nonlinear devices in the power system. A nonlinear device is one in which the current is not proportional to the applied voltage. Figure 23-31 illustrates this concept by the case of a sinusoidal voltage applied to a simple nonlinear resistor in which the voltage and current vary according to the curve shown. While the applied voltage is perfectly sinusoidal, the resulting current is distorted. Increasing the voltage by a few percent may cause the current to double and take on a different waveshape. This is the source of most harmonic distortion in a power system. Figure 23-32 illustrates that any periodic, distorted waveform can be expressed as a sum of sinusoids. When a waveform is identical from one cycle to the next, it can be represented as a sum of pure sine waves in which the frequency of each sinusoid is an integer multiple of the fundamental frequency of the distorted wave. This multiple is called a *harmonic* of the fundamental, hence the name of this subject matter. The sum of sinusoids is referred to as a *Fourier series*, named after the great mathematician who discovered the concept.

23.5.3 Voltage and Current Distortion

The term "harmonics" is often used by itself without further qualification. Generally, it could mean one of the following three:

1. The harmonic voltages are too great (the voltage too distorted) for the control to properly determine firing angles.
2. The harmonic currents are too great for the capacity of some device in the power supply system such as a transformer and the machine must be operated at a lower than rated power.
3. The harmonic voltages are too great because the harmonic currents produced by the device are too great for the given system condition.

Clearly, there are separate causes and effects for voltages and currents as well as some relationship between them. Thus, the term harmonics by itself is inadequate to definitively describe a problem. Nonlinear loads appear to be sources of harmonic current in shunt with and injecting

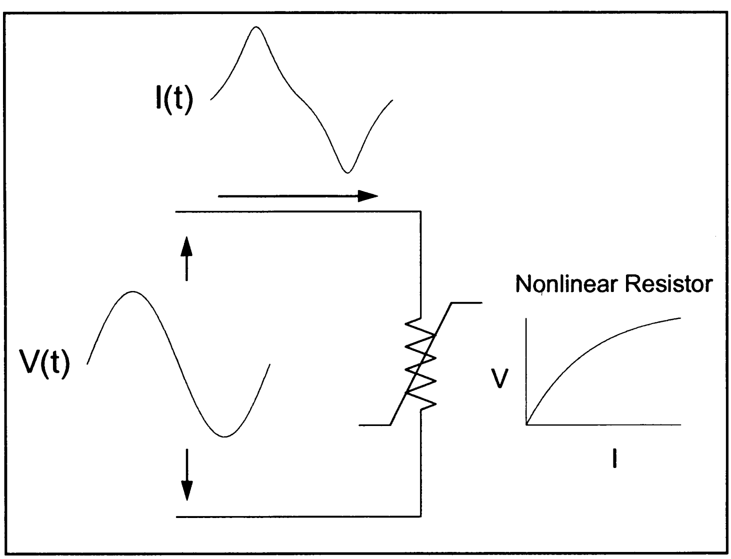

FIGURE 23-31 Current distortion caused by nonlinear resistance.

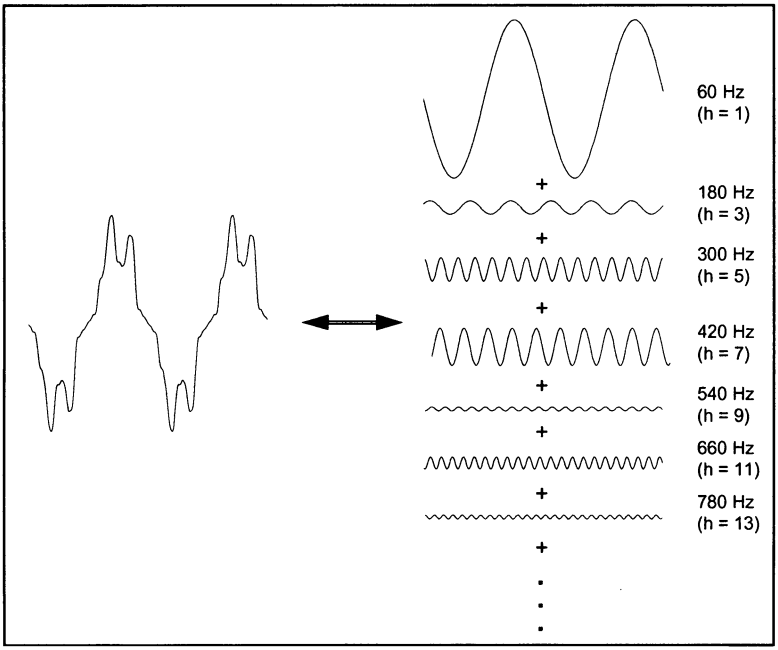

FIGURE 23-32 Fourier series representation of a distorted waveform.

harmonic currents into the power system. For nearly all analyses, it is sufficient to treat these harmonic-producing loads simply as current sources. There are exceptions to this as described later.

Voltage distortion is the result of distorted currents passing through the linear, series impedance of the power delivery system as illustrated in Fig. 23-33. Although, assuming that the source bus is ultimately a pure sinusoid, there is a nonlinear load that draws a distorted current. The harmonic currents passing through the impedance of the system cause a voltage drop for each harmonic. This results in voltage harmonics appearing at the load bus. The amount of voltage distortion depends on the impedance and the current. Assuming the load bus distortion stays within reasonable limits (e.g., less than 5%), the amount of harmonic current produced by the load is generally constant.

While the load current harmonics ultimately cause the voltage distortion, it should be noted that load has no control over the voltage distortion. The same load put in two different locations on the power system will result in two different voltage distortion values. Recognition of this fact is the

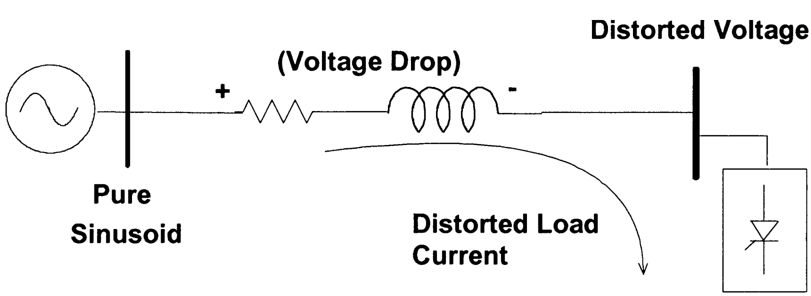

FIGURE 23-33 Harmonic currents flowing through the system impedance results in harmonic voltages at the load.

basis for the division of responsibilities for harmonic control that are found in standards such as IEEE Std 519-1992:

- The control over the amount of harmonic current injected into the system takes place at the end-use application,
- Assuming the harmonic current injection is within reasonable limits, the control over the voltage distortion is exercised by the entity having control over the system impedance, which is often the utility.

One must be careful when describing harmonic phenomena to understand that there are distinct differences between the causes and effects of harmonic voltages and currents. The use of the term harmonics should be qualified accordingly. By popular convention in the power industry, the majority of time the term is used by itself when referring to load apparatus, the speaker is referring to the harmonic currents. When referring to the utility system, the voltages are generally the subject.

23.5.4 Power System Quantities under Nonsinusoidal Conditions

Traditional power system quantities such as rms, power (reactive, active, apparent), power factor, and phase sequences are defined for the fundamental frequency context in a pure sinusoidal condition. In the presence of harmonic distortion the power system no longer operates in a sinusoidal condition, and unfortunately many of the simplifications power engineers use for the fundamental frequency analysis do not apply. Therefore, these quantities must be redefined.

23.5.5 RMS Values of Voltage and Current

In a sinusoidal condition both the voltage and current waveforms contain only the fundamental frequency component, thus the rms values can be expressed simply as

$$V_{\text{rms}} = \frac{1}{\sqrt{2}} V_1 \qquad \text{and} \qquad I_{\text{rms}} = \frac{1}{\sqrt{2}} I_1. \tag{23-2}$$

where V_1 and I_1 are the amplitude of voltage and current waveforms, respectively. The subscript 1 denotes quantities in the fundamental frequency. In a nonsinusoidal condition a harmonically distorted waveform is made up of sinusoids of harmonic frequencies with different amplitudes as shown in Fig. 23-2. The rms values can of the waveforms are computed as the square root of the sum of rms squares of all individual components, that is,

$$V_{\text{rms}} = \sqrt{\sum_{h=1}^{h_{\max}} \left(\frac{1}{\sqrt{2}} V_h \right)^2} = \frac{1}{\sqrt{2}} \sqrt{V_1^2 + V_2^2 + V_3^2 + \cdots + V_{h_{\max}}^2}, \tag{23-3}$$

$$I_{\text{rms}} = \sqrt{\sum_{h=1}^{h_{\max}} \left(\frac{1}{\sqrt{2}} I_h \right)^2} = \frac{1}{\sqrt{2}} \sqrt{I_1^2 + I_2^2 + I_3^2 + \cdots + I_{h_{\max}}^2}, \tag{23-4}$$

where V_h and I_h are the amplitude of a waveform at the harmonic component h. In the sinusoidal condition, harmonic components of V_h and I_h are all zero, and only V_1 and I_1 remain. Equations (23-3) and (23-4) simplify to Eq. (23-2).

23.5.6 Active Power

The *active power*, P, is also commonly referred to as the average power, real power, or true power. It represents useful power expended by loads to perform real work, that is, to convert electric energy to other form of energy. Real work performed by an incandescent light bulb is to convert electric energy into light and heat. In electric power, real work is performed for the portion of the current that is in phase with the voltage. No real work will result, from the portion where the current is not in phase with the voltage. The active power is the rate at which energy is expended, dissipated or consumed by the load, and is measured in units of watts (W). P can be computed by averaging the product of the instantaneous voltage and current, that is,

$$P = \frac{1}{T}\int_0^T v(t)i(t)dt. \tag{23-5}$$

The above equation is valid for both sinusoidal and nonsinusoidal conditions. For sinusoidal condition, $I_{1\text{rms}}$ resolves to the familiar form,

$$P = \frac{V_1 I_1}{2}\cos\theta_1 = V_{1\text{rms}} I_{1\text{rms}} \cos\theta_1 = S\cos\theta_1, \tag{23-6}$$

where θ_1 is the phase angle between voltage and current at the fundamental frequency. Equation 23-6 indicates that the average active power is a function only of the fundamental frequency quantities. In the nonsinusoidal case, the computation of the active power must include contribution from all harmonic components, thus it is the sum of active power at each harmonic. Furthermore, because the voltage distortion is generally very low on power systems (less than 5%), Eq. (23-6) is a good approximation regardless of how distorted the current is. This approximation cannot be applied when computing the apparent and reactive power. These two quantities are greatly influenced by the distortion. The apparent power, S, is a measure of the potential impact of the load on the thermal capability of the system. It is proportional to the rms of the distorted current and it computation is straightforward, although slightly more complicated than the sinusoidal case. Also, many current probes can now directly report the true rms value of a distorted waveform.

23.5.7 Reactive Power

The *reactive power* is a type of power that does no real work and is generally associated with reactive elements (inductors and capacitors). For example, the inductance of a load such as a motor causes the load current to lag behind the voltage. Power appearing across the inductance sloshes back and forth between the inductance itself and the power system source producing no net work. For this reason it is called imaginary or reactive power since no power is dissipated or expended. It is expressed in units of volt-ampere-reactive or var. In the sinusoidal case, the reactive power is simply defined as

$$Q = S\sin\theta_1 = \frac{V_1 I_1}{2}\sin\theta_1 = V_{1\text{rms}} I_{1\text{rms}}\sin\theta_1 \tag{23-7}$$

which is the portion of power in quadrature with the active power shown in Eq. (23-6). Figure 23-34 summarizes the relationship between P, Q, and S in sinusoidal condition.

There is some disagreement among harmonics analysts on how to define Q in the presence of harmonic distortion. If it were not for the fact that many utilities measure Q and compute demand billing from the power factor computed by Q, it might be a moot point. It is more important to determine P and S; P defines how much active power is being consumed while S defines the capacity of the power system required to deliver P. Q is not actually very useful by itself. However, Q_1 the traditional reactive power component at fundamental frequency, may be used to size shunt capacitors.

The reactive power, when distortion is present, has another interesting peculiarity. In fact, it may not be appropriate to call it reactive power. The concept of var flow in the power system is deeply ingrained in the minds of most power engineers. What many do not realize is that this concept is valid only in the sinusoidal steady state. When distortion is present, the component of S that remains after P is taken out, is not conserved—that is, it does not sum to zero at a node. Power quantities are presumed to flow around the system in a conservative manner.

This does not imply that P is not conserved or that current is not conserved because the conservation of energy and Kirchoff's current laws are still applicable for any waveform. The reactive components actually sum in quadrature (square root of the sum of the squares). This has prompted some analysts to propose that Q be used to denote the reactive components that are conserved and introduce

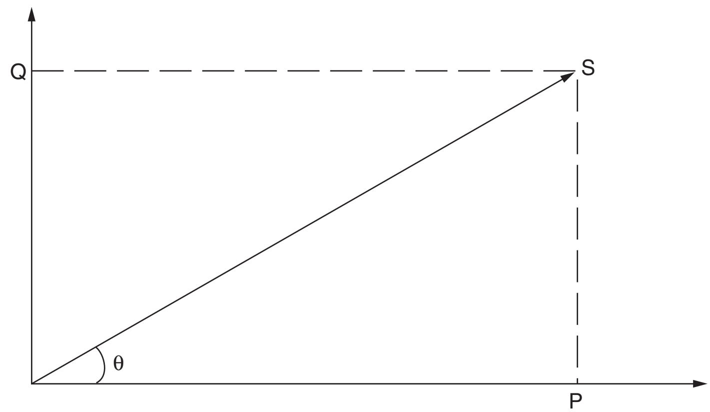

FIGURE 23-34 Relationship between P, Q, and S in sinusoidal condition.

a new quantity for the components that are not. Many call this quantity *D*, for *distortion power* or, simply, *distortion voltamperes*. It has units of voltamperes, but it may not be strictly appropriate to refer to this quantity as *power*, because it does not flow through the system as power is assumed to do. In this concept, *Q* consists of the sum of the traditional reactive power values at each frequency. *D* represents all cross products of voltage and current at different frequencies, which yield no average power. *P*, *Q* , *D*, and *S* are related as follows, using the definitions for *S* and *P* above as a starting point:

$$S = \sqrt{P^2 + Q^2 + D^2}$$
$$Q = \sum_k V_k I_k \sin \theta_k. \tag{23-8}$$

Therefore, *D* can be determined after *S*, *P*, and *Q* by

$$D = \sqrt{S^2 - P^2 - Q^2}. \tag{23-9}$$

Some prefer to use a three-dimensional vector chart to demonstrate the relationships of the components as shown in Fig. 23-35. *P* and *Q* contribute the traditional sinusoidal components to *S* while *D* represents the additional contribution to the apparent power by the harmonics.

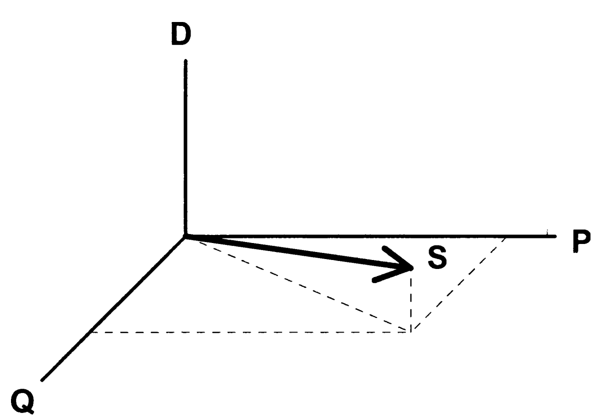

FIGURE 23-35 Relationship of components of the apparent power.

23.5.8 Power Factor

A *power factor* is a ratio of useful power to perform real work (active power) to the power supplied by a utility (apparent power), that is,

$$PF = \frac{P}{S} \tag{23-10}$$

In other words, the power factor ratio measures the percentage of power expended for its intended use. Power factor ranges from zero to unity. A load with power factor of 0.9 lagging denotes that the load can effectively expend 90% of the apparent power supplied (VA) and convert it to perform useful work (W). The term "lagging" denotes that the fundamental current lags behind the fundamental voltage by 25.84°.

In the sinusoidal case there is only one phase angle between the voltage and the current (since only the fundamental frequency is present), the power factor can be computed as the cosine of the phase angle and is commonly referred as the *displacement power factor*,

$$PF = \frac{P}{S} = \cos\theta. \tag{23-11}$$

In the nonsinusoidal case the power factor cannot be defined as the cosine of the phase angle as in Eq. (23-11). The power factor that takes into account contribution from all active power both fundamental and harmonic frequencies is known as the *true power factor*. The true power factor is simply the ratio of total active power for all frequencies to the apparent power delivered by the utility as shown in Eq. (23-10).

Power quality monitoring instruments now commonly report both displacement and true power factors. Many devices such as switch-mode power supplies and PWM adjustable-speed drives have a near-unity displacement power factor, but the true power factor may be 0.5 to 0.6. An ac-side capacitor will do little to improve the true power factor in this case because is Q_1 zero. In fact, if it results in resonance, the distortion may increase, causing the power factor to degrade. The true power factor indicates how large the power delivery system must be built to supply a given load. In this example, using only the displacement power factor would give a false sense of security that all is well.

The bottom line is that distortion results in additional current components flowing in the system that do not yield any net energy except that they cause losses in the power system elements they pass through. This requires the system to be built to a slightly larger capacity to deliver the power to the load than if no distortion were present.

23.5.9 Harmonic Phase Sequence

Power engineers have traditionally used symmetrical components to help describe 3-phase system behavior. The 3-phase system is transformed into three single-phase systems that are much simpler to analyze. The method of symmetrical components can be employed for analysis of the system's response to harmonic currents provided care is taken not to violate the fundamental assumptions of the method.

The method allows any unbalanced set of phase currents (or voltages) to be transformed into three balanced sets. The *positive sequence* set contains three sinusoids displaced 120° from each other, with the normal A-B-C phase rotation (e.g., 0°, –120°, 120°). The sinusoids of the *negative-sequence* set are also displaced 120°, but have opposite phase rotation (A-C-B, e.g., 0°, 120°, –120°). The sinusoids of the *zero sequence* are in phase with each other (e.g., 0, 0, 0).

In a perfect balanced 3-phase system, the harmonic phase sequence can be determined by multiplying the harmonic number h with the normal positive sequence phase rotation. For example, for the second harmonic, $h = 2$, produces 2 × (0°, –120°, –120°) or (0°, 120°, –120°) which is the negative sequence. For the third harmonic, $h = 3$, produces 3 × (0°, –120°, –120°) or (0°, 0°, 0°) which is the zero sequence. Phase sequence for all other harmonic orders can be determined in the same fashion. Since a distorted waveform in power systems contains only odd harmonic components (see Sec. 23.5.1), only odd harmonic phase sequence rotations are summarized below:

- Harmonics of order $h = 1, 7, 13, \ldots$ are purely positive sequence.
- Harmonics of order $h = 5, 11, 17, \ldots$ are purely negative sequence.
- Triplens ($h = 3, 9, 15, \ldots$) are purely zero sequence.

23.5.10 Triplen Harmonics

Triplen harmonics are the odd multiples of the third harmonic ($h = 3, 9, 15, 21, \ldots$). They deserve special consideration because the system response is often considerably different for triplens than for the rest of the harmonics. Triplens become an important issue for grounded-wye systems with current flowing on the neutral. Two typical problems are overloading the neutral and telephone interference. One also hears occasionally of devices that misoperate because the line-to-neutral voltage is badly distorted by the triplen harmonic voltage drop in the neutral conductor.

For the system with perfectly balanced single-phase loads illustrated in Fig. 23-36, an assumption is made that fundamental and third harmonic components are present. Summing the currents at node *N*, the fundamental current components in the neutral are found to be zero, but the third harmonic components are three times the phase currents because they naturally coincide in phase and time.

23.5.11 Triplen Harmonics in Transformers

Transformer winding connections have a significant impact on the flow of triplen harmonic currents from single-phase nonlinear loads. Two cases are shown in Fig. 23-37. In the wye-delta transformer (top), the triplen harmonic currents are shown entering the wye side. Since they are in phase, they add in the neutral. The delta winding provides ampere-turn balance so that they can flow, but they remain trapped in the delta and do not show up in the line currents on the delta side. When the currents are balanced, the triplen harmonic currents behave exactly as zero-sequence currents, which is precisely what they are. This type of transformer connection is the most common employed in utility

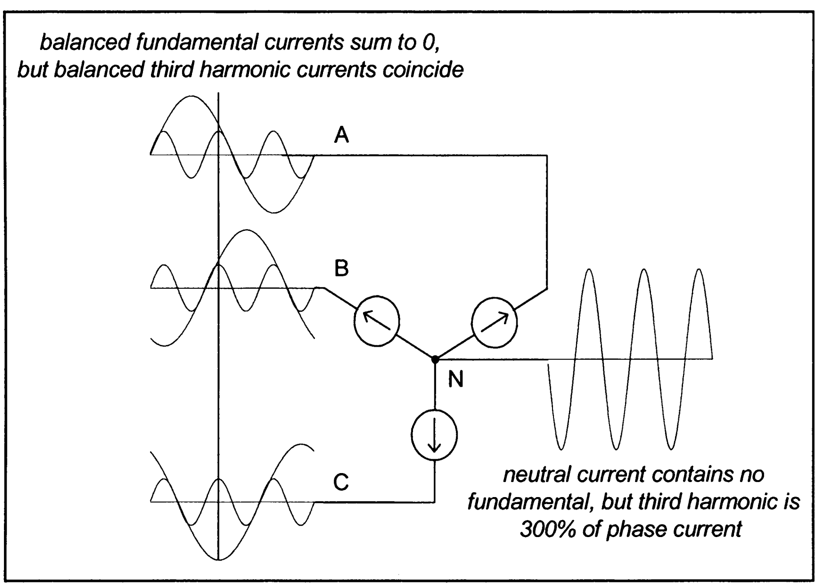

FIGURE 23-36 High neutral currents in circuits serving single-phase nonlinear loads.

distribution substations with the delta winding connected to the transmission feed.

Using grounded-wye windings on both sides of the transformer (bottom) allows balanced triplens to flow from the low voltage system to the high voltage system unimpeded. They will be present in equal proportion on both sides. Many loads in the United States are served in this fashion.

Some important implications of this related to power quality analysis are

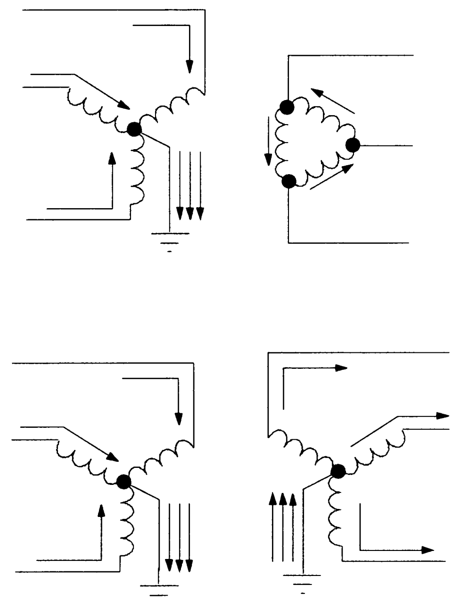

FIGURE 23-37 Flow of third harmonic current in 3-phase transformers.

1. Transformers, particularly the neutral connections, are susceptible to overheating when serving single phase loads on the wye side that have high third harmonic content.
2. Measuring the current on the delta side of a transformer will not show the triplens and, therefore, not give a true idea of the heating the transformer is being subjected to.

   The flow of triplen harmonic currents can be interrupted by the appropriate isolation transformer connection.
3. Removing the neutral connection in one or both wye windings, blocks the flow of triplen harmonic current. There is no place for ampere-turn balance. Likewise, a delta winding blocks the flow from the line. One should note that three-legged core transformers behave as if they have a "phantom" delta tertiary winding. Therefore, a wye-wye with only one neutral point grounded will still be able to conduct the triplen harmonics from that side.

These rules about triplen harmonic current flow in transformers apply only to balanced loading conditions. When the phases are not balanced, currents of normal triplen harmonic frequencies may very well show up where they are not expected. The normal mode for triplen harmonics is to be zero sequence. During imbalances, triplen harmonics may have positive or negative sequence components too.

One notable case of this is a 3-phase arc furnace. The furnace is nearly always fed by a delta-delta connected transformer to block the flow of the zero sequence currents, as shown in Fig. 23-8. Thinking that third harmonics are synonymous with zero sequence, many engineers are surprised to find substantial third harmonic current present in large magnitudes in the line current. However, during scrap meltdown, the furnace will frequently operate in an unbalanced mode with only two electrodes carrying current. Large third harmonic currents can then freely circulate in these two phases just as a single-phase circuit. However, they are not zero sequence currents. The third harmonic currents are equal amounts of positive and negative sequence currents. But to the extent that the system is mostly balanced, triplens mostly behave in the manner described.

23.5.12 Total Harmonic Distortion

The total harmonic distortion (THD) is a measure of the *effective value* of the harmonic components of a distorted waveform. That is, the potential heating value of the harmonics relative to the fundamental. This index can be calculated for either voltage or current:

$$\mathrm{THD} = \frac{\sqrt{\sum_{h>1}^{h_{\max}} M_h^2}}{M_1} \tag{23-12}$$

where M_h is the rms value of harmonic component h of the quantity M. The rms value of a distorted waveform is the square root of the sum of the squares as shown in Eq. (23-3) and (23-4). THD is related to the rms value of the waveform as follows:

$$\text{RMS} = \sqrt{\sum_{h=1}^{h_{max}} M_h^2} = M_1 \cdot \sqrt{1 + THD^2} \tag{23-13}$$

THD is a very useful quantity for many applications, but its limitations must be realized. It can provide a good idea of how much extra heat will be realized when a distorted voltage is applied across a resistive load. Likewise, it can give an indication of the addition losses caused by the current flowing through a conductor. However, it is not a good indicator of the voltage stress within a capacitor because that is related to the peak value of the voltage wave form, not its heating value. The THD index is most often used to describe voltage harmonic distortion. Harmonic voltages are almost always referenced to the fundamental value of the waveform at the time of the sample. Because voltage varies only a few percent, the voltage THD is nearly always a meaningful number.

23.5.13 Total Demand Distortion

Current distortion levels can be characterized by a THD value, as described above, but this can often be misleading. A small current may have a high THD but not be a significant threat to the system For example, many adjustable speed drives will exhibit high THD values for the input current when they are operating at very light loads. This is not necessarily a significant concern because the magnitude of harmonic current is low, even though its relative current distortion is high.

Some analysts have attempted to avoid this difficulty by referring THD to the fundamental of the peak demand load current rather than the fundamental of the present sample. This is called *total demand distortion* (*TDD*), and serves as the basis for the guidelines in IEEE STD 519-1992. It is defined as follows:

$$\text{TDD} = \frac{\sqrt{\sum_{h=2}^{h_{max}} I_h^2}}{I_L} \tag{23-14}$$

where I_L is the peak, or maximum demand load current at the fundamental frequency component measured at the point of common coupling (PCC). There are two ways to measure I_L. With a load already in the system, it can be calculated as the average of the maximum demand current for the preceding 12 months. The calculation can simply be done by averaging the 12-month peak demand readings. For a new facility, I_L has to be estimated based on the predicted load profiles.

23.5.14 System Response Characteristics

In analyzing harmonic problems, the response of the power system is equally as important as the sources of harmonics. In fact, power systems are quite tolerant of the currents injected by harmonic-producing loads unless there is some adverse interaction with the impedance of the system. Identifying the sources is only half the job of harmonic analysis. The response of the power system at each harmonic frequency determines the true impact of the nonlinear load on harmonic voltage distortion.

There are three primary variables affecting the system response characteristics, that is, the system impedance, the presence of capacitor bank, and the amount of resistive loads in the system.

23.5.15 System Impedance

At the fundamental frequency, power systems are primarily inductive, and the equivalent impedance is sometimes called simply the short-circuit reactance. Capacitive effects are frequently neglected on utility distribution systems and industrial power systems. One of most frequently-used quantities in the analysis of harmonics on power systems is the short-circuit impedance to the point on a network at which a capacitor is located. If not directly available, it can be computed from short-circuit study results that give either the short-circuit *MVA* or the short-circuit current as follows:

$$\begin{aligned} Z_{SC} &= R_{SC} + jX_{SC} \\ &= \frac{kV^2}{MVA_{SC}} = \frac{kV}{\sqrt{3}I_{SC}} \end{aligned} \tag{23-15}$$

where Z_{SC} = Short-circuit impedance
R_{SC} = Short-circuit resistance
X_{SC} = Short-circuit reactance
KV = Phase-to-phase voltage, kV
MVA_{SC} = 3-phase short-circuit, MVA
I_{SC} = Short-circuit current, A

Z_{SC} is a phasor quantity, consisting of both resistance and reactance. However, if the short-circuit data contains no phase information, one is usually constrained to assuming that the impedance is purely reactive. This is a reasonably good assumption for industrial power systems for buses close to the mains and for most utility systems. When this is not the case, an effort should be made to determine a more realistic resistance value because that will affect the results once capacitors are considered.

The inductive reactance portion of the impedance changes linearly with frequency. One common error made by novices in harmonic analysis is to forget to adjust the reactance for frequency. The reactance at the *h*-th harmonic is determined from the fundamental-impedance reactance, X_1, by

$$X_h = hX_1 \tag{23-16}$$

In most power systems, one can generally assume that the resistance does not change significantly when studying the effects of harmonics less than the ninth. For lines and cables, the resistance varies approximately by the square root of the frequency once skin effect becomes significant in the conductor at a higher frequency. The exception to this rule is with some transformers. Because of stray eddy current losses, the apparent resistance of larger transformers may vary almost proportionately with the frequency. This can have a very beneficial effect on damping of resonance as shown later. In smaller transformers, less than 100 kVA, the resistance of the winding is often so large relative to the other impedances that it swamps out the stray eddy current effects and there is little change in the total apparent resistance until the frequency reaches about 500 Hz. Of course, these smaller transformers may have an *X*/*R* ratio of 1.0 to 2.0 at fundamental frequency while large substation transformers might typically be 20 to 30. Therefore, if the bus that is being studied is dominated by transformer impedance rather than line impedance, the system impedance model should be considered more carefully. Neglecting the resistance will generally give a conservatively high prediction of the harmonic distortion.

At utilization voltages, such as industrial power systems, the equivalent system reactance is often dominated by the service transformer impedance. A good approximation for X_{SC} may be based on the impedance of the service entrance transformer only

$$X_{SC} \approx X_{tx} \tag{23-17}$$

While not precise, this is generally at least 90% of the total impedance and is commonly more. This is usually sufficient to evaluate whether or not there will be a significant harmonic resonance problem. Transformer impedance in ohms can be determined from the percent impedance, Z_{tx}, found on the nameplate by

$$X_{tx} = \left(\frac{kV^2}{MVA_{3\phi}}\right) \times Z_{tx}(\%) \tag{23-18}$$

where $MVA_{3\phi}$ is the kVA rating of the transformer. This assumes that the impedance is predominantly reactive. For example for a 1500 kVA, 6% transformer, the equivalent impedance on the 480 V side is

$$X_{tx} = \left(\frac{kV^2}{MVA_{3\phi}}\right) \times Z_{tx}(\%) = \left(\frac{0.480^2}{1.5}\right) \times 0.06 = 0.0092\Omega$$

23.5.16 Capacitor Impedance

Shunt capacitors, either at the customer location for power factor correction, or on the distribution system for voltage control, dramatically alter the system impedance variation with frequency. Capacitors do not create harmonics, but severe harmonic distortion can sometimes be attributed to their presence. While the reactance of inductive components increases proportionately to frequency, capacitive reactance, X_c, decreases proportionately:

$$X_C = \frac{1}{2\pi fC} \tag{23-19}$$

where C is the capacitance in farads. This quantity is seldom readily available for power capacitors, which are rated in terms of kvar or Mvar at a given voltage. The equivalent line-to-neutral capacitive reactance at fundamental frequency for a capacitor bank can be determined by

$$X_c = \frac{kV^2}{\text{M}var} \tag{23-20}$$

For 3-phase banks, use phase-to-phase voltage and the 3-phase reactive power rating. For single-phase units, use the can voltage rating and the reactive power rating. For example, for a 3-phase, 1200 kvar, 13.8-kV capacitor bank, the positive-sequence reactance in ohms would be

$$X_c = \frac{kV^2}{\text{M}var} = \frac{13.8^2}{1.2} = 158.7\Omega$$

23.5.17 Parallel and Series Resonance

All circuits containing both capacitance and inductance have one or more natural resonant frequencies. When one of these frequencies corresponds to an exciting frequency being produced by nonlinear loads, harmonic resonance can occur. Voltage and current will be dominated by the resonant frequency and can be highly distorted. Thus, the response of the power system at each harmonic frequency determines the true impact of the nonlinear load on harmonic voltage distortion.

Resonance can cause nuisance tripping of sensitive electronic loads and high harmonic currents in feeder capacitor banks. In severe cases, capacitors produce audible noise, and they sometimes bulge. To better understand resonance, consider the simple parallel and series cases shown in the one-line diagrams of Fig. 23-38. Parallel resonance occurs when the power system presents a parallel

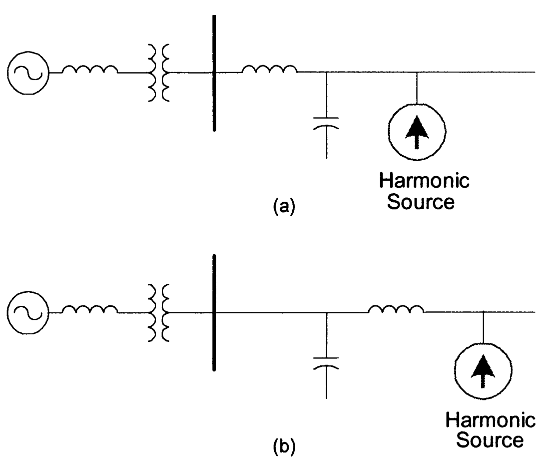

FIGURE 23-38 Examples of (*a*) parallel and (*b*) series resonance.

combination of power system inductance and power factor correction capacitors at the nonlinear load. The product of harmonic impedance and injection current produces high harmonic voltages. Series resonance occurs when the system inductance and capacitors are in series, or nearly in series, with respect to the nonlinear load point. For parallel resonance, the highest voltage distortion is at the nonlinear load. However, for series resonance, the highest voltage distortion is at a remote point, perhaps miles away or on an adjacent feeder served by the same substation transformer. Actual feeders can have five or ten shunt capacitors each, so many parallel and series paths exist, making computer simulations necessary to predict distortion levels throughout the feeder.

In the simplest parallel resonant cases, such as an industrial facility where the system impedance is dominated by the service transformer, shunt capacitors are located inside the facility, and distances are small. In these cases, the simple parallel scenario shown in Fig. 23-38*a* often applies.

23.5.18 Effects of Resistance and Resistive Load

Determining that the resonant harmonic aligns with a common harmonic source is not always cause for alarm. The damping provided by resistance in the system is often sufficient to prevent catastrophic voltages and currents. Figure 23-39 shows the parallel resonant circuit impedance characteristic for various amounts of resistive load in parallel with the capacitance. As little as 10% resistive loading can have a significant beneficial impact on peak impedance. Likewise, if there is a significant length of lines or cables between the capacitor bus and the nearest upline transformer, the resonance will be suppressed. Lines and cables can add a significant amount of the resistance to the equivalent circuit.

Loads and line resistances are the reasons why catastrophic harmonic problems from capacitors on utility distribution feeders are seldom seen. That is not to say that there will not be any harmonic problems due to resonance, but that the problems will generally not cause physical damage to the electrical system components. The most troublesome resonant conditions occur when capacitors are installed on substations buses, either utility substations or in industrial facilities. In these cases, where the transformer dominates the system impedance and has a high X/R ratio, the relative resistance is low and the corresponding parallel resonant impedance peak is very sharp and high. This is a common cause of capacitor failure, transformer failure, or the failure of load equipment.

It is a misconception that resistive loads damp harmonics because in the absence of resonance, loads of any kind will have little impact on the harmonic currents and resulting voltage distortion. Most of the current will flow back into the power source. However, it is very appropriate to say that resistive loads will damp *resonance*, which will lead to a significant reduction in the harmonic distortion.

23.5.19 Harmonic Impacts

Harmonics have a number of undesirable effects on power system components and loads. These fall into two basic categories: short-term and long-term. Short-term effects are usually the most noticeable and are related to excessive voltage distortion. On the other hand, long-term effects often go

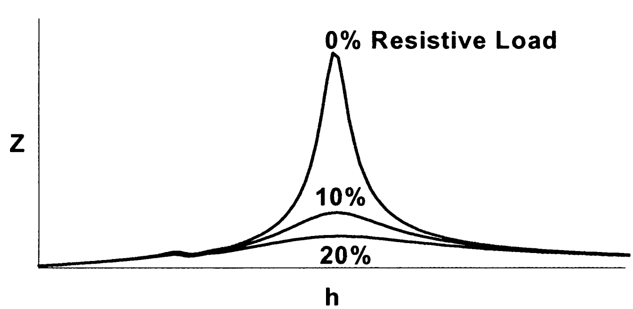

FIGURE 23-39 Effect of resistive loads on parallel resonance.

undetected and are usually related to increased resistive losses or voltage stresses. Short-term effects can cause nuisance tripping of sensitive loads. Some computer-controlled loads are sensitive to voltage distortion. For example, one documented case showed that a voltage distortion of 5.5% regularly shut down computerized lathes at a large pipe company heat treatment operation. While voltage distortions of 5% are not usually a problem, voltage distortions above 10% will almost always cause significant nuisance tripping or transformer overheating.

Harmonics can degrade meter accuracy. This is especially true with common single-phase induction-disk meters. In general, the meter spins 1% to 2% faster when a customer produces harmonic power. However, the greater issue in metering is the question of how active power, and especially reactive power, should be defined and measured when distortion is present. Debate on these definitions continues today.

Blown capacitor fuses and failed capacitor cans are also attributed to harmonics. Harmonic voltages produce excessive harmonic currents in capacitors because of the inverse relationship between capacitor impedance and frequency. Voltage distortions of 5% and 10% can easily increase rms currents by 10% to 50%. Capacitors may also fail because of overvoltage stress on dielectrics. A 10% harmonic voltage for any harmonic above the third increases the peak voltage by approximately 10% because the peak of the harmonic usually coincides, or nearly coincides, with the peak of the fundamental voltage.

Harmonics can also cause transformer overheating. This usually occurs when a dedicated transformer serves only one large nonlinear load. In such a situation, the transformer must be derated accordingly. Derating to 0.80 of nameplate kVA is common.

Overloaded neutrals appear to be the most common problems in commercial buildings. In a 3-phase, four-wire system, the sum of the 3-phase currents returns through the neutral conductor. Positive and negative sequence components add to zero at the neutral point, but zero sequence components are additive at the neutral.

23.5.20 Control of Harmonics

There are two common causes of harmonic problems are

- Nonlinear loads injecting excessive harmonic currents
- The interaction between harmonic currents and the system frequency response

When harmonics become a problem, commonly-employed solutions are

- Limit harmonic current injection from nonlinear loads. Transformer connections can be employed to reduce harmonics in a 3-phase system by using parallel delta-delta and wye-delta transformers to yield net 12-pulse operation, or delta connected transformers to block triplen harmonics.
- Modify system frequency response to avoid adverse interaction with harmonic currents. This can be done by feeder sectionalizing, adding or removing capacitor banks, changing the size of the capacitor banks, adding shunt filters, or adding reactors to detune the system away from harmful resonances.
- Filter harmonic currents at the load or on the system with shunt filters, or try to block the harmonic currents produced by loads. There are a number of devices to do this. Their selection is largely dependent on the nature of the problems encountered. Solutions can be as simple as an in-line reactor (i.e., a choke) as in PWM-based adjustable speed drive applications, or as complex as an active filter.

23.6 ELECTRICAL POWER RELIABILITY AND RECENT BULK POWER OUTAGES

23.6.1 Electric Power Distribution Reliability—General

The term *reliability* in the utility context usually refers to the amount of time end users are totally without power for an extended period of time (i.e., a sustained interruption). Definitions of what constitutes a sustained interruption vary among utilities in the range of 1 to 5 min. This is what many utilities refer to as an "outage." Current power quality standards efforts are leaning toward calling any interruption of power for longer than 1 min, a sustained interruption. In any case, reliability is affected by the permanent faults on the system that must be repaired before service can be restored.

23.6.2 Electric Power Distribution Reliability Indices

Most commonly used reliability indices for utility distribution systems are defined as follows:

- SAIFI: System Average Interruption Frequency Index

  SAIFI represents the average interruption frequency experienced by customers served in the system over a given period of time. It is computed as follows:

$$\text{SAIFI} = \frac{\text{(no. of customer interrupted)(no. of interruption)}}{\text{total no. of customers}}$$

- SAIDI: System Average Interruption Duration Index

  SAIDI represents the average interruption duration experienced by customers in the system over a given period of time.

$$\text{SAIDI} = \frac{\sum\text{(no. of customer affected)(duration of outage)}}{\text{total no. of customers}}$$

- CAIFI: Customer Average Interruption Frequency Index

  CAIFI represents average interruption frequency for affected customers. Customers not experiencing interruption are not included in the calculation.

$$\text{CAIFI} = \frac{\text{total no. of customer interruptions}}{\text{total no. of customers affected}}$$

- CAIDI: Customer Average Interruption Duration Index

  CAIDI represents the average interruption duration for customers experiencing interruptions. In other words, this is the average restoration time for affected customers.

$$\text{CAIDI} = \frac{\sum\text{(customer interruption durations)}}{\text{total no. of customers interruptions}}$$

- ASAI: Average System Availability Index

  ASAI represents the average system availability over a given observation period, which is usually a year (or 8760 hours). The index is given in percent.

$$\text{ASAI} = \frac{\sum\text{ customer hours service availability}}{\text{customer hours service demand}}$$

23.6.3 Major Bulk Electric Power Outages

Since the electric power industry was born in the early twentieth century, there have been several notable major bulk power outages. Most common causes of these outages are errors in protective device system design, overgrown vegetation, loss of system awareness due to failure of alarm systems, and a combination of unexpected events, whether they are natural and man made. Summary of these bulk power outages are complied from various sources and presented in the next paragraphs.

23.6.4 Great Northeast Blackout of 1965

The 1965 power outage started on November 9 at about 5:15 P.M. in Ontario, Canada. It cascaded down through the power system to the majority of New York, Connecticut, Massachusetts, Rhode Island, and some portions of northern Pennsylvania, and New Jersey. They were about 30 million customers out of service for up to 13 h. The power outage left 20 GW of load demand unserved. The outage was triggered by a backup protectively relay in opening one of five 230-kW lines delivering power from the Adam Beck Station No. 2 to the Toronto load area. System operators were not aware that the backup relay was set to take the line out of service when the line loading exceeded 375 MW. This relay setting was below the unusually high line loadings of recent months. Higher than normal line loadings was imposed due to higher than normal import from the United States to cover nearby Lakeview power plant (west of Toronto) outage. Upon opening the 230-kV line, the remaining four 230-kV lines were also tripped out successively within $2^1/_2$ s. Subsequently, two key east–west 345-kV lines between Rochester and Syracuse tripped out due to line instability. Several lower voltage lines tripped open along with 5 of 11 generation units at the St. Lawrence (Massena) Station. Losses of major transmission lines caused 10 generators at Adam Beck Station to shut down due to low governor oil pressure. By 5:30 P.M., the majority of northeast was without power. The service was, however, restored by 4:44 A.M. the next day in Manhattan [18].

23.6.5 New York Blackout of 1977

The event started on July 13 at about 8:37 P.M., when a lightning stroke caused a phase B to ground fault on both of a double-circuit 345-kV transmission line between Buchanan South and Millwood West Substations [18,19,21]. The tripping of circuit breakers at Buchanan South Circuit rings isolated Indian Point No. 3 generating unit without a transmission path to any load. The plant tripped of line and shut down causing a generation loss of 883 MW. A coordination error in the protective system played a critical role in the subsequent chain of events in which a transfer trip signal to Ladentown was initiated to open the 345-kV line from Buchanan South to Ladentown. A subsequent lighting stroke also caused a trip out of two more 345-kV lines between Sprain Brook and Buchanan North, and Sprain Brook and Millwood West. The later was restored to service in about 2 s. However, Sprain Brook to Buchanan North 345-kV was out of service. Losses of key transmission lines eventually forced the electrical system to separate and collapse. The power outage affected 9 million people. However, it was limited to New York City alone. Unlike the 1965 blackout, the 1977 event was marred by violence and looting [20].

Timeline of key events in the total collapse of the ConEd system [19,21]:

- At 8:37:17 P.M., July 13, 1997, two 345-kV lines connecting Buchanan South to Millwood West were each subjected to a phase B fault to ground as a result of a severe lightning stroke.
- The tripping of circuit breakers at the Buchanan South ring bus, isolated the Indian Point No. 3 generating unit from any load, and the unit tripped for a loss of 883 MW.
- Loss of the ring bus isolated the 345-kV tie to Ladentown, which had been importing 427 MW, with a total loss now of 1310 MW.
- At 8:55:53 P.M., about $18^1/_2$ minutes after the first incident, a severe lightning stroke caused the trip-out of two 345-kV lines, which connect Sprain Brook to Buchanan North, and Sprain Brook to Millwood West. These two 345-kV lines share common towers between Millwood West and Sprain Brook. One line (Millwood West to Sprain Brook) was restored to service in about 2 s. The failure of the other line to reclose isolated the last ConEd interconnection to the northwest.
- The resulting surge of power from the northwest, caused the trip-out of the line between Pleasant Valley and Millwood West (a bent contact on one of the relays at Millwood West caused the improper action).
- At 9:19:11 P.M., a 345-kV line, Leeds Substation to Pleasant Valley tripped as a result of a phase B fault to ground (fault probably caused by line sag to a tree because of the excessive overload imposed on the line).

- At 9:19:53 P.M., the 345-kV/138-kV transformer at Pleasant Valley tripped on overcurrent relay and left ConEd with three remaining interconnections.
- At 9:22:11 P.M., the Jamaica/Valley Stream tie was opened manually by the Long Island Lighting Co. system operator after obtaining the approval of the pool dispatcher.
- About 7 min later, the tap-changing mechanism failed on the Goethals phase-angle regulating transformer resulting in the trip of the Linden/Goethals tie to PJM, which was carrying 1150 MW to ConEd.
- The two remaining external 138-kV ties to ConEd tripped on overload isolating the ConEd system.

23.6.6 The Northwestern Blackout of July 1996

This outage occurred on July 2 at about 2:24 P.M. when a tree fault tripped a 345-kV taking power from Jim Bridger power plant in southwest Wyoming to southeast Idaho [17]. Protective devices detected the fault and de-energized the line. However, due to a protection coordination error, a parallel 345-kV line was also tripped. The loss of two 345-kV line severely limited power transfers from Jim Bridger plant causing generator protective devices to trip two 500-MW generators to maintain the system stability. With two generators out, frequency in the entire western interconnection began to decline forcing some customers out of service. This move was not successful and the system disintegrated into five islands. About 2 million customers were interrupted for up to several hours with about 11,850 MW of loss of load demand.

23.6.7 The Northwestern Blackout of August 1996

This blackout occurred on August 10 when Keeler-Allston 500-kV transmission line sagged into a grove of trees [17]. Prior to the disturbance, the Northwest area was importing about 2300 MW from Canada due to excellent hydroelectric conditions that lead to high electricity transfers. This and other conditions, that is, hot weather, maintenance outage of a transformer that connects a static var compensator to a 500-kV line in Portland, and/or failure to trim trees, lead to a cascading outage. A series tree fault disturbances finally broke the western interconnection area into four islands and interrupting services to 7.5 million customers for up to 9 h.

23.6.8 The Great Northeastern Power Blackout of 2003 [22, 23]

This outage on August 14, 2003 is by far the largest and most severe among all major outages. It affected 50 million customers for up to 2 days. The area affected was over 9266-mi [2] covering two Canadian provinces and eight northeastern U.S. states. The outage caused an estimated of \$4 to \$8 billion in lost economic activity.

The outage was preceded by a computer software abnormal operation, a series of generator tripping, and line outages. This series of events is considered as a precursor to the cascading outage. MISO's (Midwest Independent Service Operator) state estimator software solution did not converge and produced a solution with a high mismatch due to an outdated input data in the state estimator. Eastlake No. 5 generating unit tripped along with two other units (Conesville and Greenwood) causing a severe shortage in reactive power supply. Adequate reactive power supply is an important requirement high voltage long distance electric power transmission. At about 2:02 P.M., Stuart–Atlanta 345 kV in southwestern Ohio tripped due to contact with trees causing a short circuit to ground and locked out. This situation was exacerbated by lost of key alarm functions in FirstEnergy's (Ohio) control room. The controller also lost a series of other important computer functions. Unfortunately, FirstEnergy operators were unaware of computer failures thus they lost situational awareness of their system.

Precipitating events that lead to the cascading outage began around 3:00 P.M., when three key 345-kV transmission lines into northern Ohio from eastern Ohio tripped out, Harding–Chamberlain (3:05 P.M.), Hanna–Juniper (3:32 P.M.), and Start–South Canton (3:41 P.M.). They were all tripped out due to tree faults caused by overgrown vegetation. With these three 345-kV line out, power flowed

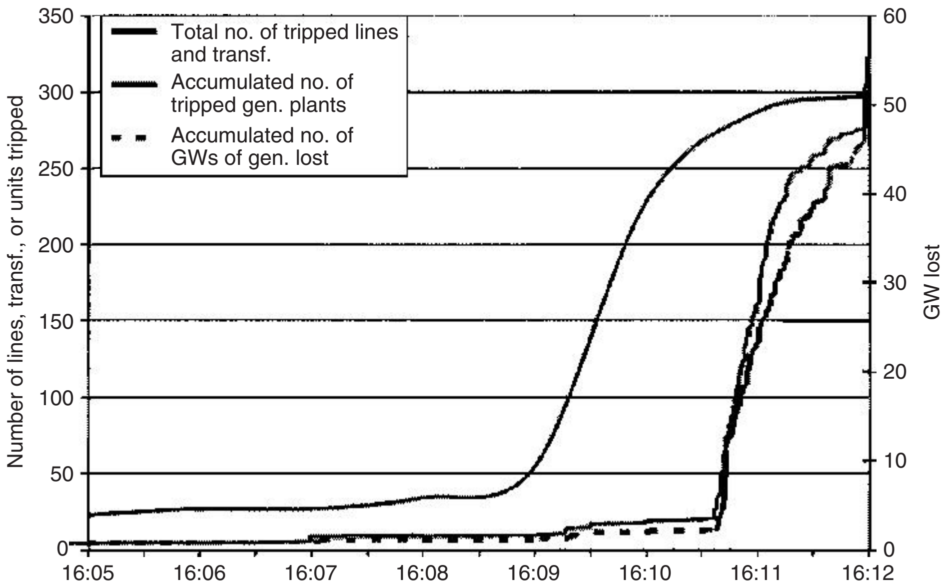

FIGURE 23-40 Accumulated line and generator trips during the cascade [23].

over through other remaining lines including the underlying 138-kV system. This redirection of flow caused severe overloading in 138-kV lines. As a result between 3:39 P.M. and 3:58 P.M., seven 138-kV lines tripped. At 3:59 P.M., West Akron bus tripped due to breaker failure. This event caused another five 138 kV-lines to trip. A few minutes later, between 4:00 P.M. and 4:08 P.M., another four 138-kV lines tripped. Losses of these transmission lines disconnected northern Ohio from Eastern Ohio. The last 345-kV line between Sammis and Star tripped at 4:06 P.M. The loss of this line left northern Ohio without any 345-kV path to eastern Ohio, and initiated a cascading blackout across the northeast U.S. and Canada. Within 7 min after the loss of 345-kV Sammis–Start line, more than 508 generating units at 265 power plants had been lost, and close to 300 lines and transformers tripped.

23.6.9 Power Quality Characteristics in the Great Northeastern Power Blackout of 2003

A major power quality characteristic of the blackout was sagging voltage when transmission lines experienced fault clearing operations (opening and reclosing) due to tree contacts.

An 8-cycle voltage sag was measured at an industrial site in Cleveland at about 3:45 P.M. This was when a series of 138-kV lines experience tree faults and attempted to isolate them (Fig. 23-41). This particular fault was detected and cleared promptly, but the voltage recovery at the site appears to be slow, suggesting that the system was now much weaker than previously. At least one more line was out of service.

Shortly after 4:00 P.M. there was another instantaneous voltage sag recorded (Fig. 23-42). The voltage drops abruptly and remains at the lower level. Phase unbalance develops, suggesting either the presence of a remote fault or that the system has become very weak due to the tripping of another line.

A short time later (accuracy of the time stamp is uncertain), the disturbance in the voltage shown in Fig. 23-43 was recorded in an office building in downtown Manhattan. This waveform is consistent with that of a power system that is going unstable.

Waveforms of this type can be observed in system dynamics simulations for buses in the weaker part of the system as it begins to move relative to a more distant part of the system that remains in

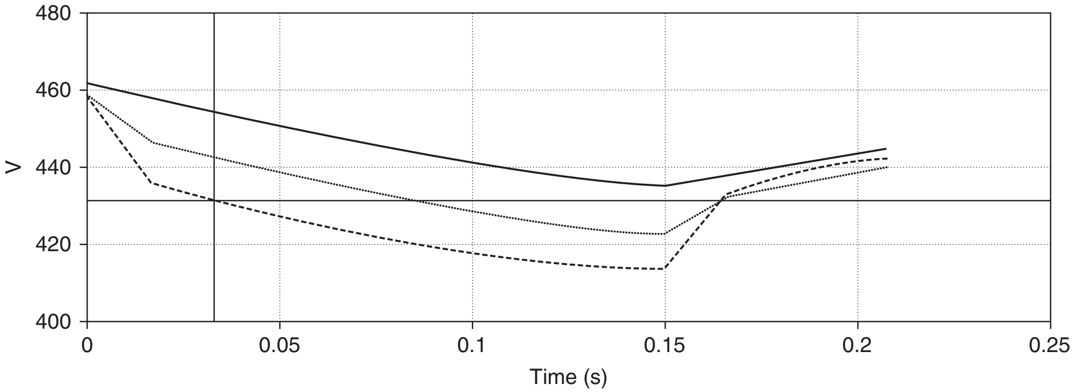

FIGURE 23-41 Instantaneous sag on phase C captured at service entrance of Cleveland industrial facility at around 3:45 P.M. (note time stamp is off by about 12 min) likely due to a fault on a transmission line. Voltage recovers slowly after fault is cleared, suggesting a weakened system. synchronism. A "beating" frequency develops as the two interconnected systems operate at different frequencies. In this case, it would appear that the system containing this power monitor had drifted by approximately 2 Hz from the rest of the system. Once this occurred, the power system supplying Manhattan detected the instability and immediately shut down the generators and separated from surrounding power systems.

Several of the neighboring systems successfully separated and remained stable throughout the blackout period despite briefly experiencing voltage waveforms like this while they were still interconnected with the part of the system that was collapsing.

Once the massive amount of load in the affected areas was lost, the entire eastern interconnection experienced a jump in frequency of approximately 0.2 Hz. This could be seen over a large geographic area (Fig. 23-44). After a few minutes, generator controls brought the average frequency back to 60 Hz and few energy users outside the affected area realized that anything had happened. While large in terms of system dynamics issues, this frequency change is inconsequential to most loads.

Figure 23-45 shows the complete rms voltage trend for the Manhattan site from the beginning of the blackout shortly after 4:00 P.M. on August 14 until the power was restored at 5:30 A.M. on August 15.

24.1 INTRODUCTION

In the last few decades, much has been ascertained about the interaction between the grounding electrode and the earth, which is a three-dimensional electrical circuit. Ultimately, it is the soil resistivity (and special variations thereof) that determines system design and performance. New technology has significantly reduced the resistance between grounding electrodes and the surrounding soil, which is a determining factor in the performance of small electrodes. There are a number of different grounding electrodes in use today. They are the standard driven rod, advanced driven rod, grounding plate, Ufer (concrete encased electrode), water pipes, and the electrolytic electrode.

The National Electric Code (NEC) divides grounding into two distinct areas: *equipment grounding* and *system grounding*. Equipment grounding is the process of connecting above-ground equipment to the earth. In other words, how to properly bond wires to equipment, routing them through conduits, circuit-breaker boxes, etc. System grounding is the process of intentionally making an electrical connection to the earth itself. This is the actual connection of metal to soil, and the minimum standards by which this connection is made. This process is often referred to as *earthing*.

The goal for this chapter is to provide a basic knowledge of system grounding and earthing in an easy-to-read and understandable manner. Above-ground wiring issues, except where needed is not discussed. The topics covered are system grounding, the benefits and features of the available grounding electrodes, and the ground potential rise (GPR) hazards of high current discharges. We also introduce the principles of proper soil testing, resistance-to-ground (RTG) testing, and meter selection.

Both equipment grounding and system grounding are becoming more essential as technology rapidly advances. Many of the latest and most advanced systems have stringent grounding requirements. Understanding the available electrical data through proper ground testing enables the electrical engineer to manage grounding systems that will meet specified grounding criteria.

Our goal is to provide the basic knowledge needed to understand and make the right choices when it comes to electrical grounding. Remember, "To protect what's above the ground you need to know what's in the ground."

24.2 SPHERE OF INFLUENCE

An important concept as to how efficiently grounding electrodes discharge electrons into the earth is called "the zone of influence," which is sometimes referred to as "the sphere of influence." The zone of influence (Fig. 24-1) is the volume of soil throughout which the electrical potential rises to more than a small percentage of the potential rise of the ground electrode, when that electrode discharges current into the soil. The greater the volume compared with the volume of the electrode, the more efficient the electrode. Elongated electrodes, such as ground rods, are the most efficient. The surface area of the electrode determines the ampacity of the device, but does not affect "the zone of influence." The greater the surface area of the electrode, the greater the contact with the soil and more electrical energy can be discharged per unit of time.

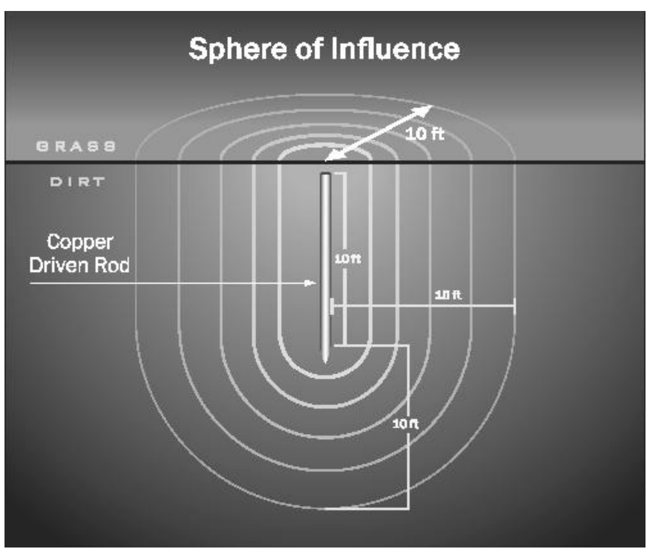

FIGURE 24-1 Sphere of influence of an earth electrode.

The formula for calculating the volume of soil is

$$V = 5\pi L^3/3 \tag{24-1}$$

where V = the volume of soil in the sphere of influence and L = the length or depth of the electrode.

A simpler version of the equation is used when the above formula is modified by rounding π(pi) down to 3 and cross canceling to get the formula:

$$V = 5L3 \tag{24-2}$$

Thus, a single 10-ft driven rod will utilize 5000 cubic ft of soil and a single 8-ft rod will utilize about half the soil at 2560 cubic ft.

24.3 GROUNDING ELECTRODES

Grounding is the process of electrically connecting any metallic object to the earth by the way of an earth electrode system. The *NEC* requires that the grounding electrodes be tested to ensure that they are under 25-Ω RTG (earth).

It is important to know, that aluminum electrodes are not allowed for use in grounding (Table 24-1).

24.3.1 Driven Rod

The standard driven rod or copper-clad rod (Fig. 24-2) consists of an 8- to 10-ft length of steel with a 5- to 10-mil coating of copper. This is by far the most common grounding device used in the field today. The driven rod has been in use since the earliest days of electricity with a history dating as far back as Benjamin Franklin.

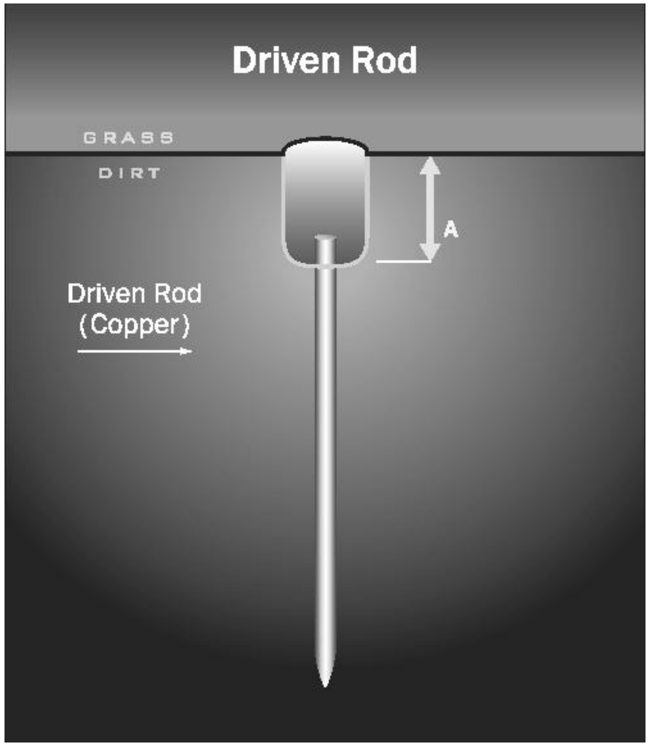

FIGURE 24-2 Copper-clad driven grounding rod.

Driven rods are relatively inexpensive to purchase, however, ease of installation is dependent upon the type of soil and terrain where the rod is to be installed. The steel used in the manufacture of a standard driven rod tends to be relatively soft. Mushrooming can occur on both the tip of the rod as it encounters rocks on its way down, and the end where force is being applied to drive the rod through the earth. Driving these rods can be extremely labor-intensive as rocky terrain creates problems as the tips of the rods continue to mushroom.

Often these rods will hit a rock and actually turn back around on themselves and pop back up a few feet away from the installation point. Because driven rods range in length from 8 to 10 ft, often a ladder is required to reach the top of the rod, which can become a safety issue. Many falls have occurred from personnel trying to literally "whack" these rods into the earth while hanging from a ladder many feet in the air.

The *NEC* requires that driven rods be a minimum of 8 ft in length and that 8 ft of length must be in direct contact with the soil. Typically, a shovel is used to dig down into the ground 18 in before a driven rod is installed. The most common rods used by commercial and industrial contractors are in 10-ft lengths. Many industrial specifications require this length as a minimum.

A common misconception is that the copper coating on a standard driven rod has been applied for electrical reasons. While copper is certainly a conductive material, its real purpose on the rod is to provide corrosion protection for the steel underneath. Many corrosion problems can occur because copper is not always the best choice in corrosion protection. It should be noted that galvanized driven rods have been developed to address the corrosion concerns that copper presents, and in many cases are a better choice for prolonging the life of the grounding rod and grounding systems. Generally speaking, galvanized rods are a better choice in all but high salt environments.

An additional drawback of the copper-clad driven rod is that copper and steel are two dissimilar metals. When an electrical current is imposed, electrolysis will occur. Additionally, the act of driving the rod into the soil can damage the copper cladding, allowing corrosive elements in the soil to attack the bared steel and further decrease the life expectancy of the rod. Environment, aging, temperature, and moisture also easily affect driven rods, giving them a typical life expectancy of 5 to 15 years in good soil conditions. Driven rods also have a very small surface area and that is not always conducive to good contact with the soil. This is especially true in rocky soil conditions where the rod will only make contact on the edges of the surrounding rock.

A good example of this is to imagine a driven rod surrounded by large marbles. Actual contact between the marbles and the driven rod will be very small. Because of this small surface contact with the surrounding soil, the RTG will increase, lowering the conductance, and limiting its ability to handle high-current faults.

24.3.2 Advanced Driven Rods

Advanced driven rods (Fig. 24-3) are specially engineered varieties of the standard driven rod with several key improvements. Because they present lower physical resistance, advanced rods can now be installed in terrain where only large drill rigs could install before and can quickly be installed in less demanding environments. The modular design of these rods can reduce safety-related accidents during installation. Larger surface areas can improve electrical conductance between the soil and the electrode.

Of particular interest is that advanced driven rods can easily be installed to depths of 20 ft or more depending upon soil conditions. Advanced driven rods are typically driven into the ground with a

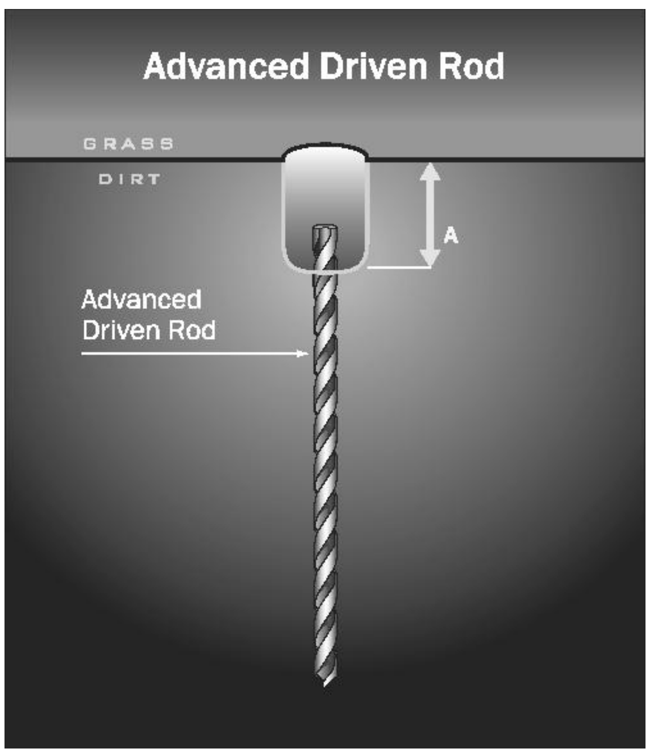

FIGURE 24-3 Advanced driven grounding rod.

standard drill hammer. The tip of an advanced driven rod is typically made of carbide and works in a similar manner to a masonry drill bit, allowing the rod to bore through rock with relative ease. Advanced driven rods are modular in nature and are designed in 5 ft lengths. They have permanent and irreversible connections that enable them to be installed safely while standing on the ground. Typically, a shovel is used to dig down into the ground 18 in before the advanced driven rod is installed. The advanced driven rod falls into the same category as a driven rod and is applicable to the same codes and regulations.

In the extreme northern and southern climates of the planet, frost-heave is a major concern. As frost sets in every winter, unsecured objects buried in the earth tend to be pushed up and out of the ground. Driven grounding rods are particularly susceptible to this action. Anchor plates are often welded to the bottom of the rods to prevent them from being pushed up and out of the earth by frost-heave. This, however, requires that a hole be augured into the earth in order to get the anchor plate into the ground, which can dramatically increase installation costs. Advanced driven rods do not suffer from frost-heave issues and can be installed easily in extreme climes.

24.3.3 Grounding Plates

Grounding plates are typically thin copper plates buried in direct contact with the earth (Fig. 24-4). The *NEC* requires that ground plates have at least 2 ft^2 of surface area exposed to the surrounding soil. Ferrous materials must be at least 0.20 in thick, while nonferrous materials (copper) need only be 0.060 in thick. Grounding plates are typically placed under poles or supplementing counterpoises.

As shown in “A” on Fig. 24-4, grounding plates should be buried at least 30 in below grade level. While the surface area of grounding plates is greatly increased over that of a driven rod, the zone of influence is relatively small as shown in “B.” The *zone of influence* of a grounding plate can be as small as 17 in. This ultra-small zone of influence typically causes grounding plates to have a higher resistance reading than other electrodes of similar mass. Similar environmental conditions that lead to the failure of the driven rod also plague the grounding plate such as, corrosion, aging, temperature, and moisture.

24.3.4 Ufer Ground or Concrete Encased Electrodes

Originally, Ufer grounds were copper electrodes encased in the concrete surrounding ammunition bunkers. In today’s terminology, Ufer grounds consist of any concrete-encased electrode, such as the rebar in building foundations, wire or wire mesh when used for grounding.

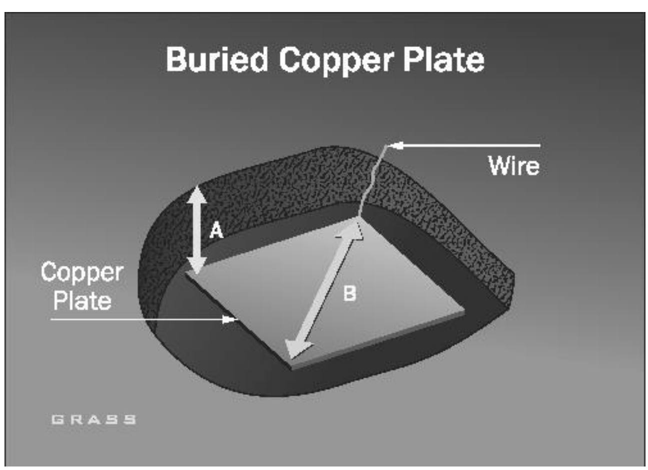

FIGURE 24-4 Buried copper plate.

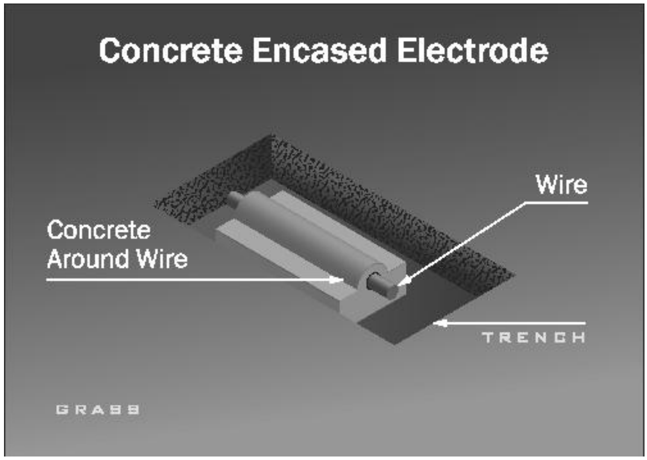

FIGURE 24-5 Concrete encased electrode.

Concrete Encased Electrode. The *NEC* requires that concrete-encased electrodes (Fig. 24-5) use a minimum no. 4 AWG copper wire at least 20 ft in length and encased in at least 2 in of concrete. The advantages of concrete encased electrodes are that they dramatically increase the surface area and amount of contact with the surrounding soil. However, the zone of influence is not increased; therefore, the resistance to ground is typically only slightly lower than the wire would be without the concrete.

Concrete encased electrodes also have some significant disadvantages. When an electrical fault occurs, the electric current must flow through the concrete into the earth. Concrete, by nature, retains a lot of water, which rises in temperature as the electricity flows through the concrete. If the extent of the electrode is not sufficiently great for the total current flowing, the boiling point of the water may be reached, resulting in an explosive conversion of water into steam. Many concrete-encased electrodes have been destroyed after being subjected to relatively small electrical faults. Once the concrete cracks apart and falls away from the conductor, the concrete pieces act as a shield preventing the copper wire from contacting the surrounding soil, resulting in the dramatic increase in the RTG of the electrode.

There are many new products available on the market designed to improve the concrete encased electrodes. The most common are modified concrete products that incorporate conductive materials into the cement mix and are usually carbon. The advantage of these products is that they are fairly effective in reducing the resistivity of the concrete, thus lowering the RTG of the electrode encased. The most significant improvement of these new products is in reducing heat buildup in the concrete during fault conditions, which can lower the chances that steam will destroy the concrete encased electrode.

However, some disadvantages are still evident. Again, these products do not increase the zone of influence and as such the RTG of the concrete encased electrode is only slightly better than what a bare copper wire or driven rod would be in the ground. Also a primary concern regarding enhanced grounding concretes is the use of carbon in the mix. Carbon and copper are of different nobilities and will sacrificially corrode each other over time. Many of these products claim to have buffer materials designed to reduce the accelerated corrosion of the copper caused by the addition of carbon into the mix. However, few independent long-term studies are being conducted to test these claims.

Ufer Ground or Building Foundations. Ufer grounds (Fig. 24-6) or building foundations may be used provided that the concrete is in direct contact with the earth (no plastic moisture barriers); that rebar is at least 0.500 in in diameter; and that there is a direct metallic connection from the service ground to the rebar buried inside the concrete.

This concept is based on the conductivity of the concrete and the large surface area. This will usually provide a grounding system that can handle very high current loads. The primary drawback

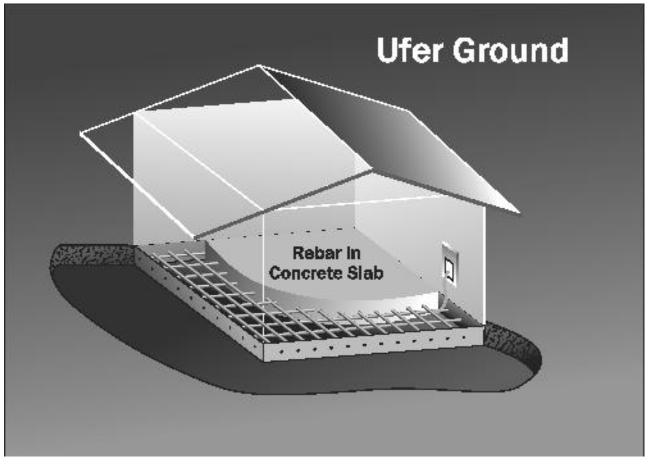

FIGURE 24-6 Building foundation or Ufer.

occurs during fault conditions. If the fault current is too great compared with the area of the rebar system when moisture in the concrete superheats and rapidly expands, cracking the surrounding concrete and threatening the integrity of the building foundation. Another drawback to the Ufer ground is that they are not testable under normal circumstances, as isolating the concrete slab in order to properly perform resistance-to-ground testing is nearly impossible.

The metal frame of a building may also be used as a grounding point, provided that the building foundation meets the above requirements and is commonly done in high-rise buildings. It should be noted that many owners of these high-rise buildings are banning this practice and insisting that tenants run ground wires all the way back to the secondary service locations on each floor. The owners will have already run ground wires from the secondary services back to the primary service locations and installed dedicated grounding systems at these service locations. The goal is to avoid the flow of stray currents that can interfere with the operation of sensitive electronic equipment.

24.3.5 Water Pipes

Water pipes have been used extensively in the past as a grounding electrode. Water pipe connections are not testable and are unreliable due to the use of tar coatings and plastic fittings. City water departments have begun to specifically install plastic insulators in the pipelines to prevent the flow of current and reduce the corrosive effects of electrolysis. Since water pipes are continuous city wide, fault conditions in adjacent neighborhoods could backfeed current into sensitive equipment causing unintentional damage. The *NEC* requires that at least one additional electrode be installed when using water pipes as an electrode. There are several additional requirements including:

- 10 ft of the water pipe is in direct contact with the earth
- Joints must be electrically continuous
- Water meters may not be relied upon for the grounding path
- Bonding jumpers must be used around any insulating joints, pipe, or meters
- Primary connection to the water pipe must be on the street side of the water meter
- Primary connection to the water pipe shall be within 5 ft of the point of entrance to the building

The *NEC* requires that water pipes be bonded to ground, even if water pipes are not used as part of the grounding system.

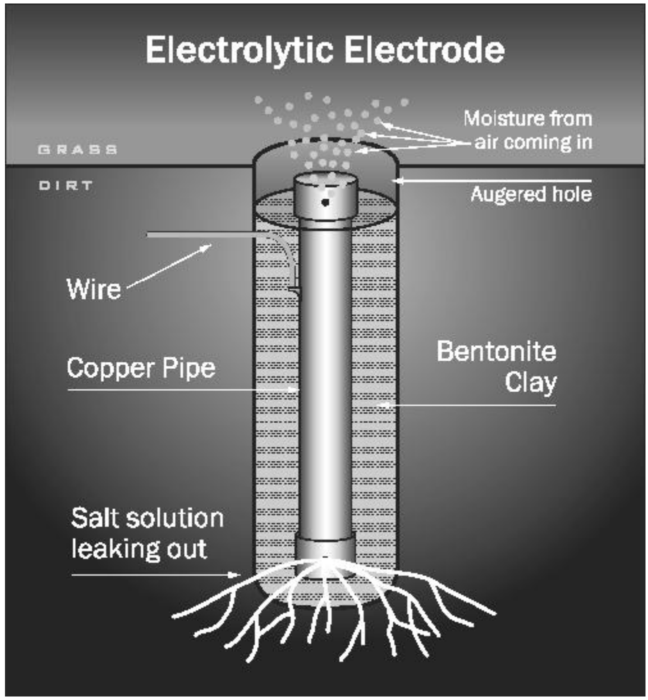

FIGURE 24-7 Electrolytic electrode.

24.3.6 Electrolytic Electrode

The electrolytic electrode (Fig. 24-7) was specifically engineered to eliminate the drawbacks found in other grounding electrodes. This active grounding electrode consists of a hollow copper shaft filled with natural earth salts and desiccants that have a hygroscopic nature to draw moisture from the air. The moisture mixes with the salts to form an electrolytic solution that continuously seeps into the surrounding backfill material, keeping it moist and high in ionic content.

The electrolytic electrode is installed into an augured hole and backfilled with a special highly conductive product. This specialty product should protect the electrode from corrosion and improve its conductivity. The electrolytic solution and the special backfill material work together to provide a solid connection between the electrode and the surrounding soil that is free from the effects of temperature, environment, and corrosion. This active electrode is the only grounding electrode that improves with age. All other electrode types will have a rapidly increasing RTG as the season's change and the years pass. The drawbacks to these electrodes are the cost of installation and the cost of the electrode itself.

24.4 SYSTEM DESIGN AND PLANNING

A grounding design starts with a site analysis, collection of geological data, and soil resistivity of the area. Typically the site engineer or equipment manufacturers specify a RTG number. The NEC states that the resistance-to-ground shall not exceed 25 Ω for a single electrode. However, high technology manufacturers will often specify 3 or 5 Ω depending upon the requirements of their equipment. For sensitive equipment and under extreme circumstances a one ohm specification may sometimes be required.

TABLE 24-2 Surface Materials vs. Resistivity

	Resistivity of sample in Ωm	
Type of surface material	Dry	Wet
Crusher granite w/fines	140×10^6	1,300
Crusher granite w/fines 1.5"	4,000	1,200
Washed granite—pea gravel	40×10^6	5,000
Washed granite 0.75"	2×10^6	10,000
Washed granite 1–2"	1.5×10^6 to 4.5×10^6	5,000
Washed granite 2–4"	2.6×10^6 to 3×10^6	10,000
Washed limestone	7×10^6	2,000 to 3,000
Asphalt	2×10^6 to 30×10^6	10,000 to 6×10^6
Concrete	1×10^6 to 1×10^9	21 to 100

When designing a ground system the difficulty and costs increase exponentially as the target RTG approaches the unobtainable goal of 0 Ω.

24.4.1 Data Collection

Once a need is established, data collection begins. Soil resistivity testing, geological surveys, and test borings provide the basis for all grounding design. Proper soil resistivity testing using the Wenner 4-point method is recommended because of its accuracy. This method will be discussed later in this chapter. Additional data is always helpful and can be collected from the existing ground systems located at the site. For example, driven rods at the location can be tested using the 3-point fall-of-potential method or an induced frequency test using a clamp-on ground resistance meter.

24.4.2 Data Analysis

With all the available data, sophisticated computer programs can provide a soil model showing the resistivity in Ωms and at various layer depths. Knowing at what depth the most conductive soil is located for the site allows the design engineer to model a system to meet the needs of the application.

24.4.3 Grounding Design

Soil resistivity is the key factor that determines the resistance or performance of a grounding system. It is the starting point of any grounding design. As you can see in Figs. 24-10 and 24-11, soil resistivity varies dramatically throughout the world and is heavily influenced by electrolyte content, moisture, minerals, compactness, and temperature (Table 24-2).

24.5 SOIL RESISTANCE TESTING

Soil resistance testing or soil resistivity testing is the process of measuring a volume of soil to determine the conductivity of the soil. The resulting soil resistivity is expressed in Ωm or ohm-centimeter.

Soil Resistivity testing is the single most critical factor in electrical grounding design. This is true when discussing simple electrical design, to dedicated low-resistance grounding systems, or to the far more complex issues involved in GPR studies. Good soil models are the basis of all grounding designs and they are developed from accurate soil resistance testing.

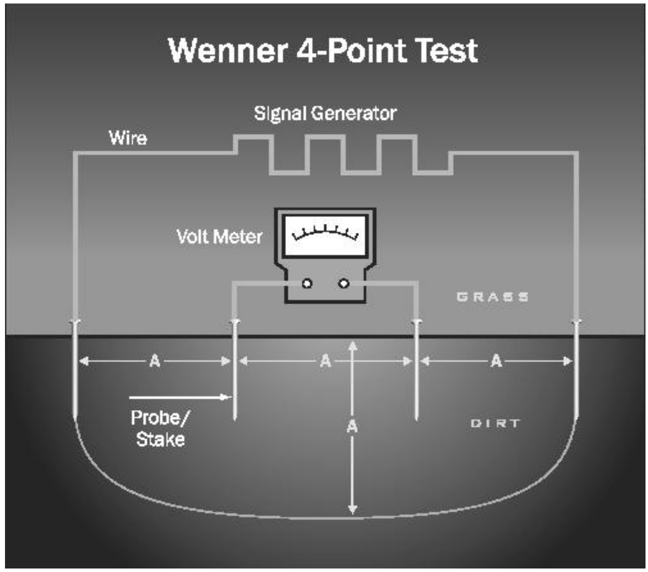

FIGURE 24-8 Wenner 4-point testing pattern.

24.5.1 Wenner Soil Resistivity Test or 4-point Test

The Wenner 4-point method (Fig. 24-8) is by far the most used test method to measure the resistivity of soil. Other methods do exist, such as the General & Schlumberger method, however, they are infrequently used and vary only slightly in how the probes are spaced when compared to the Wenner method.

Electrical resistivity is the measurement of resistance in a unit quantity of a given material. It is expressed in Ωms and represents the resistance measured between two plates covering opposite sides of a 1 m cube. This test is commonly performed at raw land sites, during the design and planning of grounding systems specific to the tested site. The test spaces four probes at equal distances to approximate the depth of the soil to be tested.

Typical spacing will be 1, 1.5, 2, 3, 4.5, 7, 10 ft, etc., with each spacing increasing from the preceding one by a factor of approximately 1.5, up to maximum spacing that is commensurate with the 1 to 3 times the maximum diagonal dimension of the grounding system being designed, resulting in a maximum distance between the outer current electrodes of 3 to 9 times the maximum diagonal dimension of the future grounding system. This is one "traverse" or set of measurements, and is typically repeated, albeit with shorter maximum spacing, several times around the location at right angles and diagonally to each other to ensure accurate readings.

The basic premise of the test is that probes spaced at a 5-ft distance across the earth, will read 5 ft in depth. The same is true if you space the probes 40 ft across the earth, you a weighted average soil resistance down to 40 ft in depth and all points in between. This raw data is usually processed with computer software to determine the actual resistivity of the soil as a function of depth.

Conducting a Wenner 4-point (or four-pin) Test. Figure 24-9 shows how to take one "traverse" or set of measurements. As the 4-point indicates, the test consists of four pins that must be inserted into the earth. The outer two pins are called the current probes, C1 and C2. These are the probes that inject current into the earth. The inner two probes are the potential probes, P1 and P2. These are the probes that take the actual soil resistance measurement.

In this test, a probe C1 is driven into the earth at the corner of the area to be measured. Probes P1, P2, and C2 are driven at 5, 10, and 15 ft respectively from rod C1 in a straight line to measure

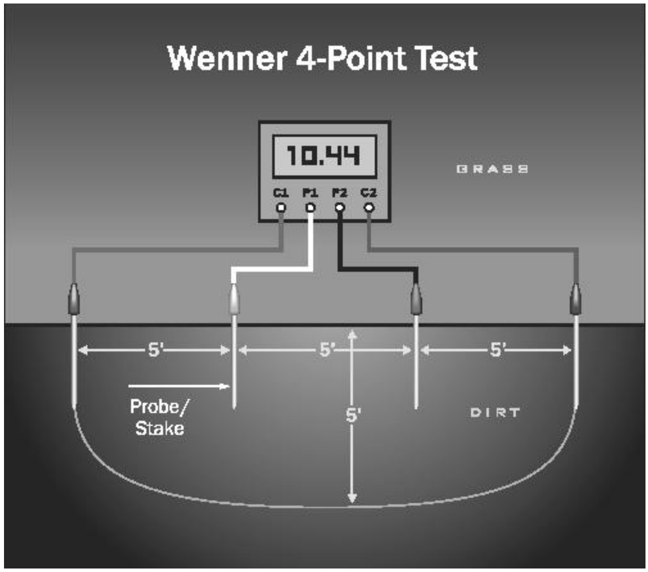

FIGURE 24-9 Wenner 4-point test setup.

the soil resistivity from 0 to 5 ft in depth. C1 and C2 are the outer probes and P1 and P2 are the inner probes. At this point, a known current is applied across probes C1 and C2, while the resulting voltage is measured across P1 and P2. Ohm's law can then be applied to calculate the measured resistance.

Probes C2, P1, and P2 can then be moved out to 10, 20, and 30 ft spacing to measure the resistance of the earth from 0 to 10 ft in depth. Continue moving the three probes (C2, P1, and P2) away from C1 at equal intervals to approximate the depth of the soil to be measured. Note that the performance of the electrode can be influenced by soil resistivities at depths that are considerably deeper than the depth of the electrode, particularly for extensive horizontal electrodes, such as water pipes, building foundations or grounding grids.

Soil Resistance Meters. There are basically two types of soil resistance meters: low- and high-frequency models. Both meter types can be used for 4-point and 3-point testing, and can even be used as standard (2-point) voltmeter for measuring common resistances.

Care should always be given when selecting a meter, as the electronics involved in signal filtering are highly specialized. Electrically speaking, the earth can be a noisy place. Overhead power lines, electric substations, railroad tracks, various signal transmitters, and many other sources contribute to signal noise found in any given location. Harmonics, 60 Hz background noise, and magnetic field coupling can confound the measurement signal resulting in apparent soil resistivity readings that are larger by an order of magnitude, particularly with large spacings. Selecting equipment with electronic packages capable of discriminating between these signals is critical.

High-Frequency meters typically operate at 128 pulses per second or other pulse rates except 60. These high-frequency meters typically suffer from the inability to generate sufficient voltage to handle long traverses and generally should not be used for probe spacings greater than 100 ft. Furthermore, the high-frequency signal flowing in the current lead induces a noise voltage in the potential leads, which cannot be completely filtered. This noise becomes greater than the measured signal as the soil resistivity decreases and the pin spacing increases. High-frequency meters are less expensive than their low-frequency counterparts and are by far the most common meter used in soil resistivity testing.

TABLE 24-3 Soil Types vs. Resistivity Chart

Soil types or type of earth	Average resistivity in Ωm
Bentonite	2 to 10
Clay	2 to 100
Wet organic soils	10 to 100
Moist organic soils	100 to 1,000
Dry organic soils	1,000
Sand and gravel	50 to 1,000
Surface limestone	100 to 10,000
Limestone	5 to 4,000
Shale's	5 to 100
Sandstone	20 to 2,000
Granites, basalts, etc.	1,000
Decomposed gneisses	50 to 500
Slates, etc.	10 to 100

Low-Frequency meters, which actually generate low frequency pulses (on the order of 0.5 to 2.0 seconds per pulse), are the preferred equipment for soil resistivity testing, as they do away with the induction problem from which the high-frequency meters suffer. However they can be very expensive to purchase. Depending upon the equipment's maximum voltage, low-frequency meters can take readings with extremely large probe spacings and often many thousands of feet in distance. Typically, the electronics filtering packages offered in low-frequency meters are superior to those found in high-frequency meters. Caution should be taken to select a reputable manufacturer.

Data Analysis. Once all the resistance data are collected, formula 24-3 can be applied to calculate the apparent soil resistivity in Ωms. For example, if an apparent resistance of 4.5 Ω is at 40-ft spacing, the soil resistivity in Ωms would be 344.7. One refers to "apparent" resistivity, because this does not correspond to the actual resistivity of the soil. This raw data must be interpreted by suitable methods in order to determine the actual resistivity of the soil (Table 24-3).

Soil Resistivity
4-Point Data Interpretation

$$\rho = 1.915AR$$

$$\rho = 1.915(40)(4.5)$$

$$\rho = \frac{4\pi AR}{1 + \frac{2A}{\sqrt{(A^2 + 4B^2)} - \sqrt{(A^2 + B^2)}}}$$

ρ = Resistivity　　A = Spacing of Probes

B = Depth of Probes　　R = Resistance (reading from meter)

If $A > 20B$, then $\rho = 2\pi AR = 1.915\ AR$

Shallow Depth Readings. Shallow depth readings, as little as 6 in deep are exceedingly important for most, if not all, grounding designs. The soil resistivity readings are actually weighted averages of the soil resistivity from the earth's surface down to the specified distance and include all the shallow

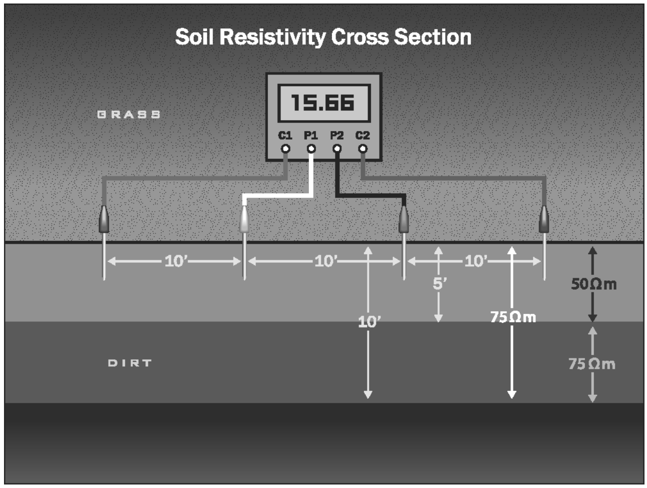

FIGURE 24-10 Importance of shallow readings.

resistance readings above it. The trick in developing the final soil model is to pull out the actual resistance of the soil at depth, and that requires subtracting the top layers from the deep readings.

Figure 24-10 demonstrates how the shallowest readings impact deeper ones below it. If the 5-ft reading shows 50-Ωm soil, and the 10-ft reading shows 75-Ωm soil, the actual soil resistance from 5 to 10 ft is 100-Ωm. The point here is to illustrate a concept that precomputed curves or computer software is needed to properly interpret the data. The same follows true for larger pin spacings. The shallowest readings are used over and over again in determining the actual resistance at depth.

Shallow-depth readings of 6 in, 1 ft, 1.5 ft, 2 ft, and 2.5 ft are important for grounding design. Because grounding conductors are typically buried at 1.5 to 2.5 ft below the surface of the earth. To accurately calculate how those conductors will perform at these depths, shallow soil readings must be taken. These shallow readings become even more important when engineers calculate GPR and step and touch voltages.

It is critical that the measurement probes and current probes be inserted into the earth to the proper depth for shallow soil resistivity readings. If the probes are driven too deep, then it can be difficult to resolve the resistivity of the shallow soil. A rule of thumb is that the penetration depth of the potential probes should be no more than 10% of the pin spacing, whereas the current probes must not be driven more than 30% of the pin spacing.

Deep Readings. Often, the type of meter used determines the maximum depth or spacing that can be read. A general guideline is that high-frequency soil resistivity meters are good for no more than 100-ft pin spacings, particularly in low resistivity soils. For greater pin spacings, low-frequency soil resistivity meters are required. They can generate the required voltage needed to push the signal through the soil at deep distances and detect a weak signal, free of induced voltage from the current injection leads.

24.5.2 Test Location

Soil resistivity testing should be conducted as close to the proposed grounding system as possible, taking into consideration the physical items that may cause erroneous readings. There are two issues that may cause poor quality readings:

1. Electrical interference causing unwanted signal noise to enter the meter.
2. Metallic objects “short-cutting” the electrical path from probe to probe. The rule of thumb here is that a clearance equal to the pin spacing should be maintained between the measurement traverse and any parallel buried metallic structures.

Testing in the vicinity of the site in question is obviously important; however, it is not always practical. Many electric utility companies have rules regarding how close the soil resistivity test must be in order to be valid. The geology of the area also plays into the equation as dramatically different soil conditions may exist only a short distance away.

When left with little room or poor conditions in which to conduct a proper soil resistivity test, one should use the closest available open field with as similar geological soil conditions as possible.

24.6 TESTING OF EXISTING GROUNDING SYSTEMS

The measurement of ground resistance for an earth electrode system is very important. It should be done when the electrode is first installed, and then at periodic intervals thereafter. This ensures that the RTG does not increase over time. There are two methods for testing an existing earth-electrode system. The first is the 3-point or fall-of-potential method and the second is the Induced Frequency test or clamp on method. The 3-point test requires complete isolation from the power utility. Not just power isolation, but also removal of any neutral or other such ground connections extending outside the grounding system. This test is the most suitable test for large grounding systems and is also suitable for small electrodes. The induced frequency test can be performed while power is on and actually requires the utility to be connected to the grounding system under test. This test is accurate only for small electrodes, as it uses frequencies in the kilohertz range, which see long conductors as inductive chokes and therefore do not reflect the 60 Hz resistance of the entire grounding system.

24.6.1 Fall-of-Potential Method or 3-point Test

The 3-point or fall-of-potential method (Fig. 24-11) is used to measure the RTG of existing grounding systems. The two primary requirements to successfully complete this test are the ability to isolate the grounding system from the utility neutral and knowledge of the diagonal length of the grounding system (i.e., a 10-ft × 10-ft grounding ring would have a 14 ft diagonal length). In this test, a short probe, referred to as probe Z, is driven into the earth at a distance of 10 times (10×) the

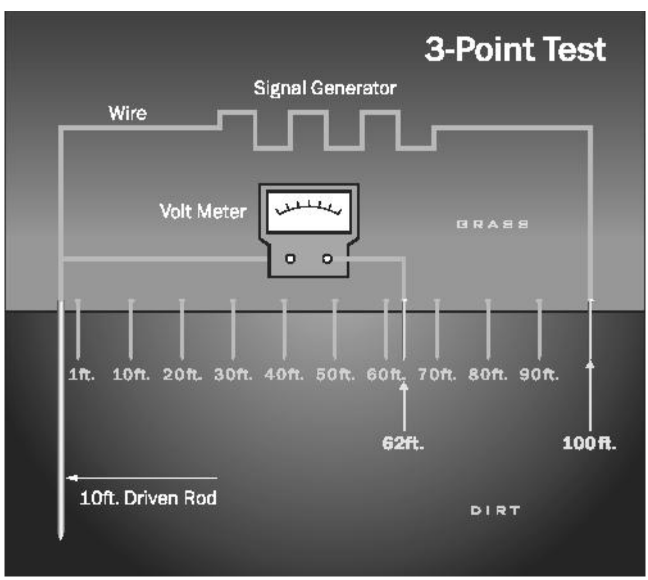

FIGURE 24-11 3-point test method.

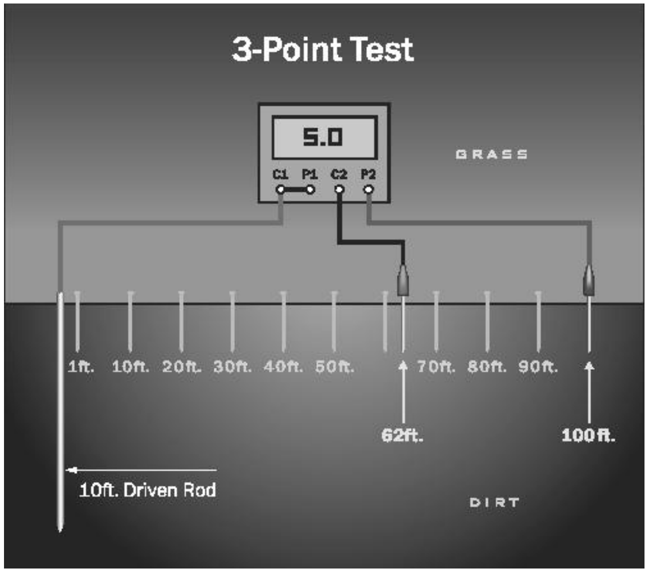

FIGURE 24-12 3-point test setup.

diagonal length of the grounding system (rod X). A second probe (Y) is placed in-line at a distance from rod X equal to the diagonal length of the grounding system.

At this point, a known current is applied across X and Z, while the resulting voltage is measured across X and Y. Ohm's Law can then be applied ($R = V/I$) to calculate the measured resistance. Probe Y is then moved out to a distance of 2x the diagonal length of the grounding system, in-line with X and Z, to repeat the resistance measurement at the new interval. This will continue, moving probe Y out to 3x, 4x, … 9x the diagonal length to complete the 3-point test (Fig. 24-12) with a total of nine resistance measurements.

Graphing & Evaluation. The 3-point test is evaluated by plotting the results as data points with the distance from rod X along the *x*-axis and the resistance measurements along the *y*-axis to develop a curve. Roughly midway between the center of the electrode under test and the probe Z, a plateau or "flat spot" should be found, as shown in the graph. The resistance of this plateau (actually, the resistance measured at the location 62% from the center of the electrode under test, if the soil is perfectly homogeneous) is the RTG of the tested grounding system.

Invalid Tests. If no semblance of a plateau is found and the graph is observed to rise steadily, the test is considered invalid (Fig. 24-13). This can be due to the fact that probe Z was not placed far enough away from rod X, and can usually indicate that the diagonal length of the grounding system was not determined correctly. If the graph is observed to have a low plateau that extends the entire length and only rises at the last test point, then this also may be also considered invalid. This is because the utility or telecom neutral connection remains on the grounding system.

24.6.2 Induced Frequency Testing or Clamp-On Testing

The induced frequency testing (Fig. 24-14) or commonly called the "clamp-on" test is one of the newest test methods for measuring the RTG of a grounding system or electrode. This test uses a special transformer to induce an oscillating voltage (often 1.7 kHz) into the grounding system. Unlike the 3-point test which requires the grounding system to be completely disconnected and isolated

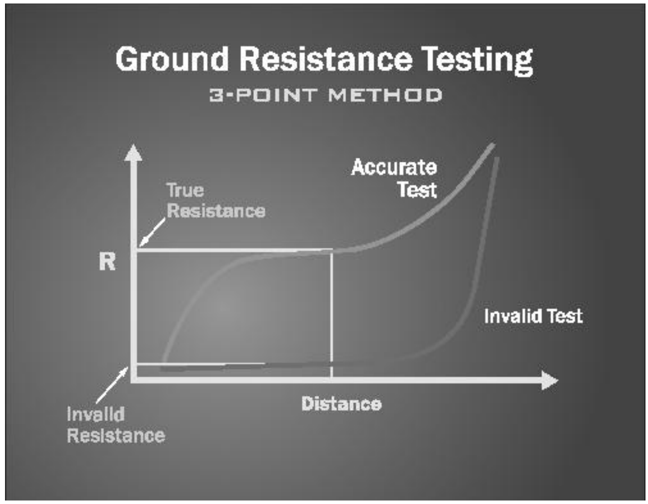

FIGURE 24-13 Comparison of valid vs. invalid 3-point test.

before testing, this method requires that the grounding system under test be connected to the electric utilities (or other large grounding system such as from the telephone company) grounding system (typically via the neutral return wire) to provide the return path for the signal. This test is the only test that can be used on "live" or "hot" systems. However, there are some limitations, including:

1. The amount of current running through the tested system must be below the equipment manufacturers limits.
2. The test signal must be injected at the proper location, so that the signal is forced through the grounding system and into the earth.
3. This instrument actually measures the sum of the resistance of the grounding system under test and the impedance of the utility neutral grounding, including the neutral wiring. Due to the high frequency used, the impedance of the neutral wiring is nonnegligible and can be greater than the

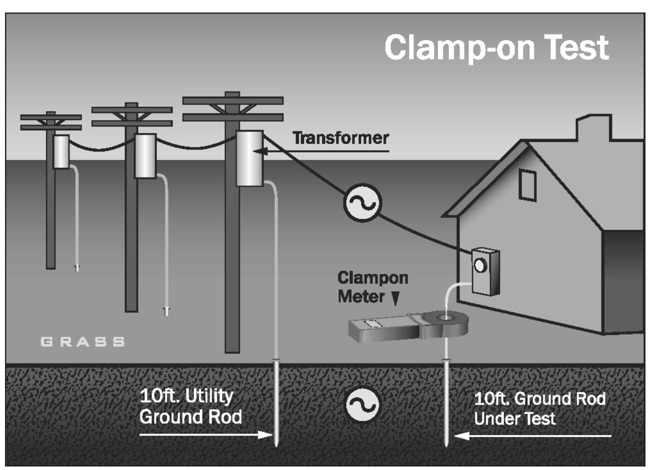

FIGURE 24-14 Induced frequency test diagram.

ground resistance of a very low resistance grounding system, which can therefore not be measured accurately.

4. The ground resistance of a large grounding system at 60 Hz can be significantly lower than at 1.7 kHz.

Many erroneous tests have been conducted where the technician only measured metallic loops and not the true RTG of the grounding system. The veracity of the induced frequency test has been questioned due to testing errors; however, when properly applied to a small to medium sized, self-standing grounding system, this test is rapid and reasonably accurate.

Test Application. The proper use of this test method requires the utility neutral to be connected to a wye-connected transformer. The oscillating voltage is induced into the grounding system at a point where it will be forced into the soil and return through the utility neutral. Extreme caution must be taken at this point as erroneous readings and mistakes are often made. The most common of these occur when clamping on or inducing the oscillating voltage into the grounding system at a point where a continuous metallic path exists back to the point of the test. This can result in a continuity test being performed rather than a ground resistance test. Understanding the proper field application of this test is vital to obtaining accurate results. The induced frequency test can test grounding systems that are in use and does not require the interruption of service to take measurements.

Ground Resistance Monitoring. Ground resistance monitoring is the process of automated timed and/or continuous RTG measurement. These dedicated systems use the induced frequency test method to continuously monitor the performance of critical grounding systems. Some models may also provide automated data reporting. These new meters can measure RTG and the current that flows on the grounding systems that are in use. Another benefit is that it does not require interruption of the electrical service to take these measurements.

24.7 GROUND POTENTIAL RISE

Ground potential rise is a phenomenon that occurs when large amounts of electricity enter the earth. This is typically caused when substations or high-voltage towers fault, or when lightning strikes occur (fault current). When currents of large magnitude enter the earth from a grounding system, not only will the grounding system rise in electrical potential, but so will the surrounding soil as well (Fig. 24-15).

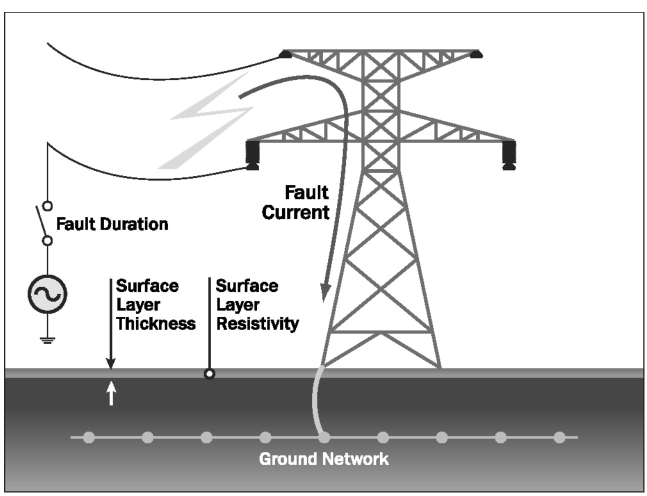

FIGURE 24-15 Electric fault at a transmission tower.

The voltages produced by a GPR event can be hazardous to both personnel and equipment. As described earlier, soil has resistance which will allow an electrical potential gradient or voltage drop to occur along the path of the fault current in the soil. The resulting potential differences will cause currents to flow into any and all nearby grounded conductive bodies, including concrete, pipes, copper wires, and people.

Ground Potential Rise Definitions. GPR as defined in IEEE Std. 367 is the product of a ground electrode impedance, referenced to remote earth, and the current that flows through that electrode impedance.

GPR as defined by IEEE Std. 80-2000 as the maximum electrical potential a substation grounding grid may attain, relative to a distant grounding point assumed to be at the remote earth potential. This voltage, GPR, is equal to the maximum grid current times the grid resistance.

Ground Potential Rise events are a concern wherever electrical currents of large magnitude flow into the earth. This can be at a substation, high-voltage tower or pole, or a large transformer. In cases where a GPR event may be of special concern, grounding precautions are required to ensure personnel and equipment safety.

Electrical potentials in the earth drop abruptly around the perimeter of a grounding system, but do not drop to zero. In fact, in a perfectly homogeneous soil, soil potentials are inversely proportional to the distance from the center off the grounding system, once one has reached a distance that is a small number of grounding system dimensions away. The formula is as follows:

$$\text{Earth potential} = \text{soil resistivity} \times \text{current}/(2 \times PI \times \text{distance})$$

Where earth potential is in volts, soil resistivity is in Ωms, current is the current flowing into the soil from the grounding system, in amperes, *PI* is 3.14159 … and distance is in meters. Probably the most commonly noted GPR event involves the death of cows in a field during a lightning strike. Imagine lightning striking the center of an open field where cows are standing. The current injected into the earth flows radially away from the strike point, in all directions, creating voltage gradients on the surface of the earth, also in a radial direction. All the cows facing the lightning strike would have their fore hooves closer to the strike point than their rear hooves. This would result in a difference of potential between their fore and rear legs, causing current to flow through their bodies, including the heart area, and killing the cow. On the other hand, those cows with their flanks turned towards the lighting strike would have a greater chance of surviving, as the distance between their fore legs and therefore the voltage applied between them, would be relatively small, resulting in a lesser current flow.

GPR studies are typically conducted on substations and high-voltage towers. Substations have relatively large grounding areas, especially when compared to high-voltage towers and poles. Towers and poles represent by far the most potentially dangerous and difficult GPR situations to handle and are often not protected, unless they are located in high exposure areas or have equipment installed at ground level at which service personnel might be required to work.

24.7.1 Ground Potential Rise Analysis

The primary purpose of a GPR study is to determine the level of hazard associated with a given high-voltage location for personnel and/or equipment. When the degree of hazard is identified the appropriate precautions must be made to make the site safe. To do this, the engineer must identify what the minimum grounding system for each location will be. The engineer must also take into consideration all local and federal guidelines including utility companies and other requirements.

For example, many utility companies require at a minimum that a simple ground ring be installed at least 18 in below ground and 3-ft from the perimeter of all metal objects. This ground ring is also referred to as a counterpoise.

Once the minimum grounding system is identified, the engineer can run a GPR analysis and identify the extent of any electrical hazards.

Typically items reported in a GPR study will include the following: The square footage and size of the proposed grounding grid, RTG of the proposed grounding system, the estimated fault current that would be seen at the site, voltage rise of the GPR (in volts) at the site, 300-Vpeak line, the *X*/*R* ratio, and the fault clearing time in seconds. Touch and step voltages are usually computed as well, as these are the primary indicators of safety.

The grounding engineer needs three pieces of information to properly conduct a GPR Study:

1. Soil resistivity data
2. Site drawings with the proposed construction
3. Electrical data from the utility company

Soil Resistivity Data. The soil resistivity data should include apparent resistivity readings at pin spacings ranging from 0.5 or 1 ft to as many as three grounding grid diagonals, if practical. Touch and step voltages represent the primary concern for personnel safety. Understanding the characteristics of the soil at depths ranging from immediately underfoot to one or more grid dimensions is required for a cost-effective and safe grounding system to be designed.

Site Drawings. The proposed site drawings should show the layout of the high-voltage tower or substation, and any additional construction for new equipment that may be occurring on the site, including fencing and gate radius. Incoming power and telco runs should also be included. In the case of high-voltage towers, the height and spacing of the conductors carried on the tower, and any overhead ground wires that may be installed on the tower, need to be detailed during the survey. This information is needed to properly address all the touch and step voltage concerns that may occur on the site.

Electric Utility Data. The electric utility company needs to provide electrical data regarding the tower or substation under consideration. This data should include the name of the substation or the number of the tower, the voltage level, the subtransient *X*/*R* ratio, and the clearing times. In the case of towers, the line names of the substations involved, the amount of current contributed by each substation in the event of a fault, and the type and positions of the overhead ground wires, if any, with respect to the phase conductors installed on each tower or pole. If overhead ground wires are present, tower or pole ground resistances along the line are of interest as well, be they measured, average or design values.

This information is important, as high-voltage towers have small ground area, yet handle very large amounts of electricity. Knowing if a tower has an overhead ground wire is important, because the overhead wire will carry away a percentage of the current, which will depend on the overhead ground wire type and ground resistances of adjacent towers, to other towers in the run, reducing the GPR event. Additionally, towers with overhead ground wires tend to have shorter clearing times. The same holds for substations—overhead ground wires on transmission lines and neutral wires on distribution lines can significantly reduce the magnitude of fault current that flows into the substation grounding system during fault conditions.

The following information is required from the utility company:

1. Phase-to-ground fault current contributed by each power line circuit
2. Fault clearing time
3. Line voltage
4. Subtransient *X*/*R* ratio
5. The make/type/number of overhead ground wires on each tower/pole line and position with respect to the phase conductors
6. Ground wire continuity and bonding configuration back to the tower and substation

7. The average distance from tower-to-tower and tower-to-substation

8. Typical tower/pole ground resistance: measured or design values

As-built drawings are often acquired and are useful for towers with existing grounding systems. They are also useful in the case of modifications and upgrades to existing substations, which will have extensive grounding systems already installed.

24.7.2 Personnel Safety during Ground Potential Rise Events

The grounding engineer will be required to develop safety systems to protect any personnel working where GPR hazards are known to exist. Federal law mandates that all known hazards must be eliminated from the work place for the safety of workers. It is the engineer's choice on which voluntary standards to apply in order to comply with the law. Federal law 29 CFR 1910.269 specifically states that step and touch potentials must be eliminated on transmission and distribution lines that include any related communication equipment.

Substations are always considered workplaces and step and touch potentials must be eliminated. Transmission and distribution towers or poles are not always considered work places and therefore are often exempt from these requirements. Take, for example, a lonely tower on a mountain side or in the middle of the desert—these towers are not typically considered workplaces. However, any high-voltage tower or pole becomes a workplace as soon as equipment is installed that is not related to the electric utility company and requires outside vendors to support the new equipment. Cellular telecommunications, environmental monitoring, and microwave relay equipment are good examples of equipment that, when installed on a high-voltage tower, turns the tower into a workplace. This would make the elimination of step and touch potentials required.

Hazardous Voltages. Fibrillation current is the amount of electricity needed to cause cardiac arrest, from which recovery will not spontaneously occur, in a person and is a value based on statistics. IEEE Std. 80-2000 provides a method to determine the pertinent value of fibrillation current for a safety study, along with a good explanation of how it is derived. Many different methods exist for calculating fibrillation current; however the 50kg-IEEE method is the most commonly used in North America. The formula used shows that the fibrillation current level is inversely proportional to the square root of the fault duration; however, it must be increased by a correction factor, based on the subtransient X/R ratio, which can be quite large for shorter fault durations. If personnel working at a site during fault conditions experience voltages that will cause a current less than the fibrillation current to flow in their bodies, then they are considered safe. If a worker will experience a greater voltage than is acceptable, additional safety precautions must be taken.

The subtransient X/R ratio at the site of the fault is important in calculating the acceptable fibrillation current and to determine the maximum allowable step and touch voltages that can occur at any given site.

Fault duration is a very necessary piece of data for properly calculating step and touch potentials. The fault duration is the amount of time required for the power company to shut off the current in the event of a fault.

Ultimately the engineer must determine two things:

1. The site-specific maximum allowable voltage that a person can safely withstand

2. The actual voltages that will be experienced at the site during a fault

Each site will have different levels of voltages for both of the above. Unfortunately, we cannot simply say that a human being can withstand X-level of voltages and use that value all the time, since this voltage is determined by the surface layer resistivity, the fault duration and the subtransient X/R ratio. Additionally as each site has different fault durations and different soil conditions, it is critical that calculations be made for each and every possible fault location.

Step Potential. When a fault occurs at a tower or substation, the current will enter the earth. Based on the distribution of varying resistivity in the soil (typically, a horizontally layered soil is assumed) a corresponding voltage distribution will occur. The voltage drop in the soil surrounding the grounding system can present hazards for personnel standing in the vicinity of the grounding system. Personnel "stepping" in the direction of the voltage gradient could be subjected to hazardous voltages.

In the case of step potentials, electricity will flow if a difference in potential exists between the two legs of a person (Fig. 24-16). Calculations must be performed that determine how great the tolerable step potentials are and then compare those results to the step voltages expected to occur at the site.

Hazardous step potentials can occur a significant distance away from any given site. The more current that is pumped into the ground, the greater the hazard. Soil resistivity and layering plays a major role in how hazardous a fault occurring on a specific site may be. High soil resistivities tend to increase step potentials. A high resistivity top layer and low resistivity bottom layer tends to result in the highest step voltages close to the ground electrode; the low resistivity bottom layer draws more current out of the electrode through the high resistivity layer, resulting in large voltage drops near the electrode. Further from the ground electrode, the worst case scenario occurs when the soil has conductive top layers and resistive bottom layers; in this case, the fault current remains in the conductive top layer for much greater distances away from the electrode.

Fault clearing time is an important factor to consider as well. The more time it takes the electric utility company to clear the fault, the more likely it is for a given level of current to cause the human heart to fibrillate.

An important note to remember is that most power companies use automated reclosers. In the event of a fault, the power is shut off and then automatically turned back on. This is done in case the faults occurred due to an unfortunate bird that made a poor choice in where to rest, or dust that may have been burned off during the original fault. A few engineers believe that fibrillation current for step potentials must be far greater than touch potentials, as current will not pass through any vital organs in the former case. This is not always true as personnel that receive a shock due to step potentials may fall to the ground, only to be hit again, before they can get up, when the automatic reclosers activate.

Touch Potentials. When a fault occurs at a tower or substation the current will pass through any metallic object and enter the earth. Those personnel "touching" an object in the vicinity of the GPR

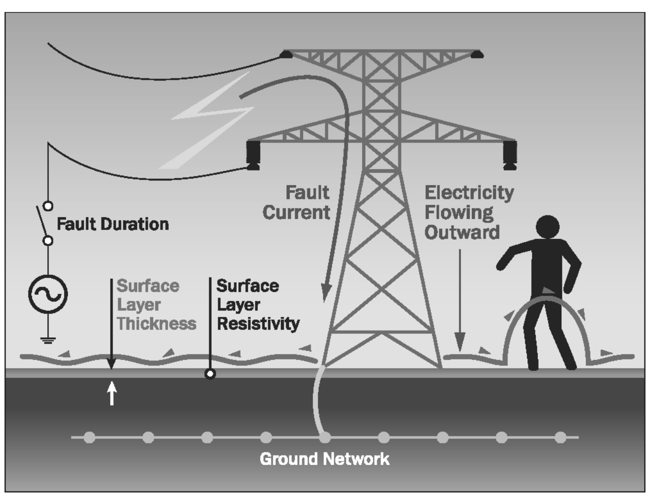

FIGURE 24-16 Step potential at a transmission tower.

will be subjected to these voltages which may be hazardous. For example if a person happens to be touching a high-voltage tower leg when a fault occurs, the current would travel down the tower leg into the persons hand and through vital organs of the body (Fig. 24-17). It would then continue on its path and exit out through the feet and into the earth. Careful analysis is required to determine the acceptable fibrillation currents that can be withstood by the body if a fault were to occur.

Engineering standards use a 1-m (3.28 ft) reach distance for calculating touch potentials. A 2-m (6.54 ft) reach distance is used when two or more objects are inside the GPR event area. For example, a person could be outstretching both arms and touching two objects at once such as a tower leg and a metal cabinet. Occasionally, engineers will use a 3-m distance to be particularly cautious, as they assume someone may be using a power tool with a power cord 3 m in length.

The selection of where to place the reference points used in the touch potential calculations are critical in getting an accurate understanding of the level of hazard at a given site. The actual calculation of touch potentials uses a specified object (such as a tower leg) as the first reference point. This means that the further away from the tower the other reference point is located, the greater the difference in potential. If you can imagine a person with incredibly long arms touching the tower leg and yet standing many dozens of feet away, you would have a huge difference in potential between the feet and the tower. Obviously, this example is not possible—this is why setting where and how far away the reference points used in the touch calculation is so important and why the 1-m rule has been established.

Mitigating Step and Touch Potential Hazards. Mitigating step and touch potential hazards is usually accomplished through one or more of the following three main techniques:

1. Reduction in the RTG of the grounding system
2. Proper placement of ground conductors
3. The addition of resistive surface layers

Understanding the proper application of these techniques is the key to reducing and eliminating any GPR hazards. Only through the use of highly sophisticated three-dimensional electrical simulation software that can model soil structures with multiple layers and finite volumes of different materials, can the engineer accurately model and design a grounding system that will safely handle high-voltage electrical faults.

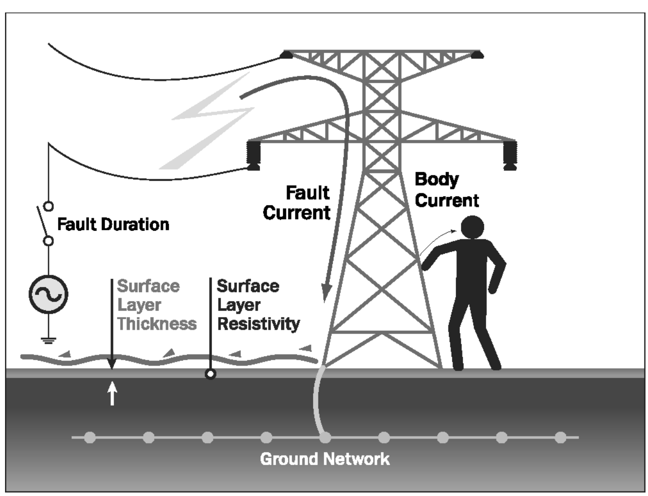

FIGURE 24-17 Touch potential at a transmission tower.

Reduce the Resistance-to-Ground. Reducing the RTG of the site is often the best way to reduce the negative effects of any GPR event, where practical. The GPR is the product of the fault current flowing into the grounding system times the RTG of the grounding system. Thus, reducing the RTG will reduce the GPR to the degree that the fault current flowing into the grounding system does increase in response to the reduced RTG. For example, if the fault current for a high-voltage tower is 5000 A and the RTG of the grounding system is 10-Ω, the GPR will be 50,000 V. If we reduce the RTG of the grounding system down to 5-Ω and the fault current increases to 7000 A as a result, then the GPR will become 35,000 V.

As seen in the example above, the reduction of the RTG can have the effect of allowing more current to flow into the earth at the site of the fault, but will always result in lower GPR values and touch and step voltages at the fault location. On the other hand, further away from the fault location, at adjacent facilities not connected to the faulted structure, the increase in current into the earth will result in greater current flow near these adjacent facilities and therefore an increase in the ground potential rise, touch voltages and step voltages at these facilities. Of course, if these are low to begin with, an increase may not represent a problem, but there are cases in which a concern may exist. Reducing the RTG can be achieved by any number of means as discussed earlier in this chapter.

Proper Placement of Ground Conductors. A typical specification for ground conductors at high-voltage towers or substations is to install a ground loop around all metallic objects, connected to the objects; keep in mind that it may be necessary to vary the depth and/or distance that ground loops are buried from the structure in order to provide the necessary protection. Typically these ground loops require a minimum size of 2/0 AWG bare copper conductor buried in direct contact with the earth and 3-ft from the perimeter of the object, 18 in below grade. The purpose of the loop is to minimize the voltage between the object and the earth surface where a person might be standing while touching the object—that is, to minimize touch potentials.

It is important that all metallic objects in a GPR environment be bonded to the ground system to eliminate any difference in potentials. It is also important that the resistivity of the soil as a function of depth be considered in computed touch and step voltages and in determining at what depth to place conductors. For example, in a soil with a dry, high-resistivity surface layer, conductors in this layer will be ineffective; a low resistivity layer beneath that one would be the best location for grounding conductors. On the other hand, if another high resistivity layer exists further down, long ground rods or deep wells extending into this layer will be ineffectual.

It is sometimes believed that placing horizontal grounding loop conductors very close to the surface results in the greatest reduction in touch potentials. This is not necessarily so, as conductors close to the surface are likely to be in drier soil, with a higher resistivity, thus reducing the effectiveness of these conductors. Furthermore, while touch potentials immediately over the loop may be reduced, touch potentials a short distance away may actually increase due to the decreased zone of influence of these conductors. Finally, step potentials are likely to increase at these locations; indeed, step potentials can be a concern near conductors that are close to the surface, particularly at the perimeter of a grounding system. It is common to see perimeter conductors around small grounding systems buried to a depth of 3-ft below grade, in order to address this problem.

Resistive Surface Layers. One of the simplest methods of reducing step and touch potential hazards is to wear electric hazard shoes. When dry, properly rated electric hazard shoes have millions of ohms of resistance in the soles and are an excellent tool for personnel safety. On the other hand, when these boots are wet and dirty, current may bypass the soles of the boots in the film of material that has accumulated on the sides of the boot. A wet leather boot can have a resistance on the order of 100 Ω. Furthermore, it cannot be assumed that the general public, who may have access to the outside perimeter of some sites, will wear such protective gear.

Another technique used in mitigating step and touch potential hazards is the addition of more resistive surface layers. Often a layer of crushed rock is added to a tower or substation to provide a layer of insulation between personnel and the earth. This layer reduces the amount of current that can flow through a given person and into the earth. Weed control is another important factor, as plants become energized during a fault and can conduct hazardous voltages into a person. Asphalt is an excellent alternative, as it is far more resistive than crushed rock, and weed growth is not a problem. The addition of resistive surface layers always improves personnel safety during a GPR event.

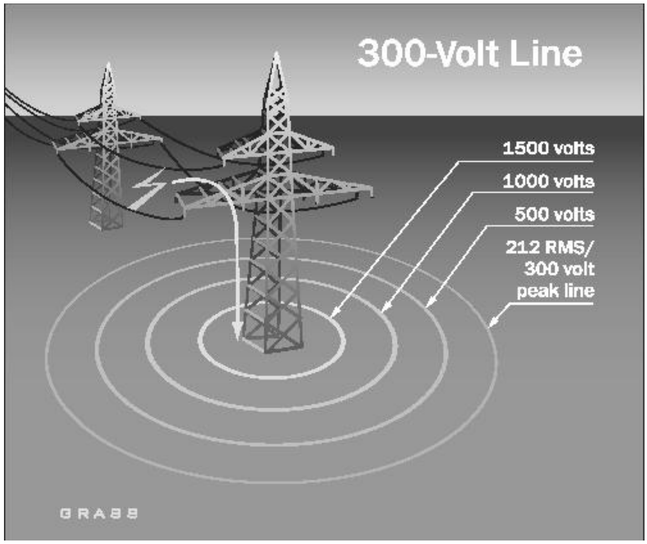

FIGURE 24-18 300-V line at a transmission tower.

Telecommunications in High-Voltage Environments. When telecommunications lines are needed at a high-voltage site, special precautions are required to protect switching stations from unwanted voltages. Installing wires in a substation or on a tower could present a hazardous situation and therefore certain precautions are required.

Industry standards regarding these precautions and protective requirements are covered in IEEE Standard's 387, 487, and 1590. These standards require that a GPR study be conducted so that the 300-V peak line can be properly calculated.

To protect the telephone switching stations, telecommunication standards require that fiber-optic cables be used instead of copper wires. A copper-to-fiber conversion box must be located outside the GPR event area at a distance in excess of the 300-V peak or 212-V RMS line (Fig. 24-18). This is known in the industry as the "300-V line." This means that based on the calculation results, copper wire from the telecommunications company may not come any closer than the 300-V peak distance. This is the distance where copper wire must be converted to fiber-optic cable. This can help prevent any unwanted voltages from entering the phone companies' telecommunications network.

The current formulae for calculating the 300-volt line, as listed in the standards, has led to misinterpretation and divergences of opinion, resulting in order-of-magnitude variations in calculated distances for virtually identical design input data. Furthermore, operating experience has shown that a rigorous application of theory results in unnecessarily large distances. This has caused many compromises within the telecommunications industry. The most noted one is a newer standard, IEEE Std. 1590-2003, that lists a 150-m (~500-ft) mark as a default distance, if a GPR study has not been conducted at a given location.

SECTION 25
COMPUTER APPLICATIONS IN THE ELECTRIC POWER INDUSTRY

CONTENTS

25.1 INTRODUCTION

25.1.1 Growth of Computer Applications

The power industry is engaged in the generation, transmission, and distribution of electrical energy which is obtained by conversion from other forms of energy such as coal, gas, oil, nuclear, water, or other renewable energy. These activities often include mining, rail transport, shipping, slurry pipelines, and storage of energy in many forms. Many electric utilities are also engaged in the transmission and distribution of gas.

In the first 90 years of its history, the industry expanded at a pace nearly twice that of the overall economy, doubling roughly every 10 years. During this period, real prices per kilowatthour

*The author acknowledges the contributions of past authors and reviewers including James V. Mitsche (PTI), M. M. Adibi (IRD), and J. D. Cypert (IBM).

decreased steadily because of generation, transmission, distribution, technical improvements, productivity increases, and stable fuel prices. Throughout the 1970s, increased fuel costs, limits in economies of scale, diminishing returns in technology improvement, and increased regulation costs led to increased kilowatthour costs and reduced demand growth.

The political and economic response to increasing costs has been a movement to smaller generator sizes, minimization of capital investment, and attempts to control costs by fostering competition in generation supply. Incentives were also established to reduce demands and increase load factors. Today power supply is diversifying away from large central station technologies and toward increased use and availability of the transmission system.

In scheduling its day-to-day operation, and in planning for its future growth, the industry has made extensive use of analytical tools and mathematical models which, through optimization and simulation, help in the decision-making process. As a consequence, the industry has long been one of the largest users of computers and among the most sophisticated in its modeling and computational techniques. This use is quite understandable when one considers the high cost of power system equipment, the complexity of power systems, and the severe operational, reliability, and environmental requirements on the electricity supply.

Computer applications have assisted the industry in achieving its objectives: reducing the cost of energy delivered to consumers, improving the quality of service, enhancing the quality of the environment, and extending the life of existing equipment. These objectives have been achieved as follows:

1. Since the industry is one in which capital investment is usually high (over 10% of total spending by the nation's industries), unit costs have been reduced by operating facilities closer to their design limits, allowing better utilization of equipment.
2. Unit costs also have been reduced by automation, allowing operation with fewer personnel, and by optimization, lowering fuel consumption per kilowatthour delivered.
3. Electricity cannot readily be stored; therefore, production and consumption must be simultaneous. Hence enough capacity is required to meet the maximum coincident demand or peak load of all customers. Interconnections between power systems provide important economies arising from different time patterns or diversity of use of the component systems in the network. They allow higher power system reliability at lower capital cost.
4. Quality of service has been improved by reducing the number, extent, and duration of service interruptions, thus providing a more reliable service.
5. Quality of environment has been maintained by operating facilities within acceptable bounds of emission, thermal discharge, waste disposal, and more effective land use.

Today the industry has reached a stage where computer systems are no longer merely an engineering tool. The effectiveness of computer applications is one of the key elements in achieving the basic functions associated with the planning, designing, construction, operation, and maintenance of the power system. In fact, engineering and computers have been integrated. This integration may be viewed as tending toward the construction of a utility industry information system. Such a system is shown in Fig. 25-1. It depicts a typical information system which may be viewed as a combination and integration of several functional information systems.

Such an information system can extend the company capabilities by making relevant and current information accessible to both technical and management personnel. Designs can be refined by using measured data or operations experience, projects can be monitored, revenue requirements can be predicted more closely, and the experience of operations can be reflected in the methods and criteria used in planning and engineering. The information system thus can provide meaningful data at proper times and locations to make decisions and concentrate resources in the most effective manner.

Computers and their applications are ubiquitous in electric utilities. As in most industries, the business and corporate uses are extensive. This section deals with the sophisticated engineering and operations applications of computers, which are often unique and specialized to the industry's goals and technical demands.

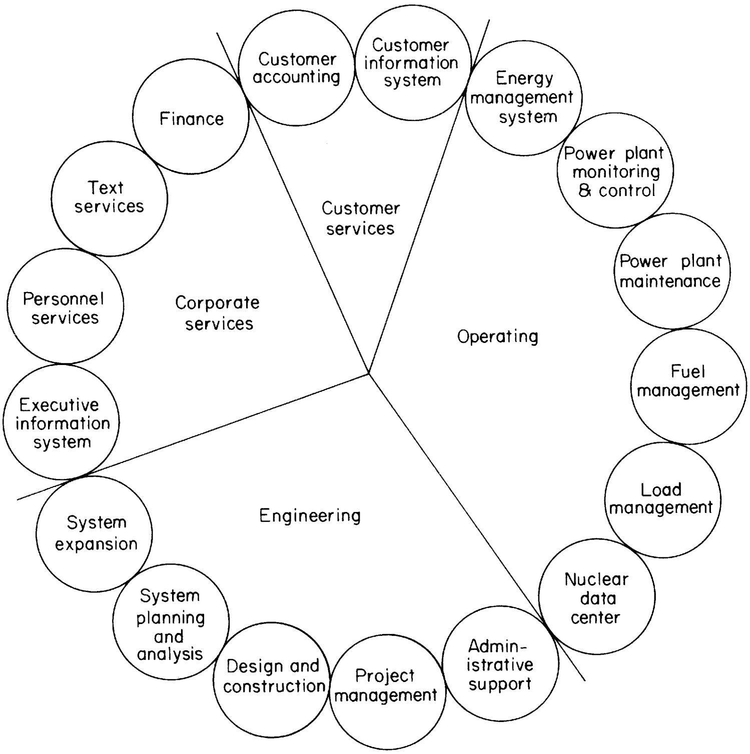

FIGURE 25-1 Electric utility information systems.

25.1.2 Goals of the Power Industry

The industry's purpose is to provide adequate, reliable, environmentally compatible electricity at reasonable cost with the ultimate goal of improving its productivity and net earnings. In spite of the differences between publicly and privately owned utilities, this goal is applicable to each, in different form. This goal is reached by pursuing a number of objectives as described below.

Improved Financial Management

- *Raising new capital*. Traditional electric utility companies and independent power producers are major utilizers of capital to finance and build new capacity, replace or renovate old equipment, and retrofit plants and delivery equipment for environmental and reliability considerations. Projected industry construction in the next decade runs into hundreds of billions of dollars. Competing demands for capital and its high cost encourage and justify precise planning, design, and operations.
- *Plant investment*. Utilities must spend very large sums in generating plants and transmission facilities. Present-day decisions on such additions, together with the proper selection of plant sites and the acquisition of transmission rights of way, have long-range financial implications affecting earnings. At present, the industry is experiencing difficulties in selection of plant sites and obtaining rights of way, licenses, and permits, with the results that the industry seldom obtains new plant sites and is forced to expand existing generating sites. Demand-side options must be properly weighed against generation expansion alternatives. Independent power producers (IPPs) must

make precise investments, and utilities must properly invest in facilities needed to utilize and accommodate IPPs. This situation compounds the problems of system modeling and system losses, and increases transmission system dependency.

- *Long-term contracts*. Fuel constitutes about 35% of the industry's total annual operating expenditures. A typical modern power plant consumes about 500 tons of coal each hour, and its average life is about 30 years. A nuclear power plant of a similar size requires an initial nuclear core costing hundreds of millions of dollars plus a significant annual refueling expenditure for the next 30 years. Independent power producers supply energy under contract for varied periods and conditions. The goal is to procure energy supply and these fossil and fissile fuels through long-term contracts providing a continuous supply of fuel at reasonable cost throughout the plant's 40- to 60-year life.
- *Growth through affiliation*. There have been a significant number of corporate mergers between large and small utilities. The goal in these affiliations is to meet the growth in demand for energy by taking advantage of economy of scale; consolidation of administration, engineering, construction, research, and development; and increasing reliability of bulk power supply.
- *Economy and reliability*. The industry has achieved significant improvement in economy of operations and in reliability of power systems either through direct operational pool functions or with contractual economical agreements.

Increased Revenue. For 30 years (1935 to 1965) utilities were, by lowering costs, reducing their rates and increasing sales. During this period of falling rates, owing to lags in regulatory rate adjustment, utilities enjoyed a higher revenue and were motivated to be efficient. The costs were reduced by the installation of larger generators, higher transmission voltages, lower fuel costs, and shifts to available gas and oil from coal.

From 1973 to 1990, the utilities went through a period of rising costs due to rises in fuel cost, environmental regulation, diminishing efficiency returns in technology (unit sizes and improvements), and investing in new technologies such as nuclear plants. During this rising-cost period, the regulatory lag in rate adjustments had an adverse economic impact, demanding detailed analysis of past and present operations and projection of future requirements by financial modeling, optimization schemes, and simulation techniques.

The expanded list of supply- and demand-side options and the desire to open transmission system access have made electric utility planning and operations much more complex. Construction delays and the desire to minimize capital expenditures have resulted in the electric power system being used in unexpected ways, and design safety margins must be reduced or stressed.

Reduced Cost. Cost reduction can be achieved by reducing investment per kilowatt of installation capacity for generation, transmission, and distribution and reducing operating cost per kilowatthour of energy delivered.

Reduced plant investment can be achieved by proper generation mix and location, increased transmission and distribution voltages, power pooling, interconnection planning, and coordination to gain further advantages of scale. Involved also are improved production and distribution facility utilization (i.e., capacity factor and load factor) through peak shaving, reserve sharing, load diversity, and distribution load balancing. Other means of reducing costs include designing facilities with more precision and reducing the factor of safety, reducing construction and inventory costs, and operating the facilities closer to their design limits.

Reduced operating expenditure can be achieved by adopting new technology that requires lower fuel costs, by improving conventional and established methods of higher energy conversion efficiencies, by reducing energy losses in transmission and distribution facilities, and by interchanging energy with more economical resources and different time zones in different seasons to take advantage of diversity.

Other means are producing and distributing electricity with fewer personnel; minimizing the labor force and material inventory required for maintenance, repairs, and restoration of generation, transmission, and distribution facilities; and reducing customer accounting, general accounting, and administrative expenses.

Improved Quality of Service. Among the requirements in this category are reducing the frequency, duration, and extent of outages in the power supply; reducing voltage and frequency discontinuities and sudden excursions (power-line disturbances) to sensitive electronic loads and digital equipment; and improving customer services through prompt response to inquiries, requests, or complaints. It is also important to maintain the power supply within prescribed ranges and specifications and to restore interruptions in service quickly.

Enhanced Environment. Means of improving environmental impact include reducing thermal discharge to natural bodies of water through the use of artificial lakes, cooling towers, and desalinization processes and advancing direct conversion of heat energy to electrical energy as by magnetohydrodynamics, thermionics, and fuel cells. Also involved in conventional systems are reducing the release of combustion products (sulfur dioxide, nitrogen oxides, carbon dioxide, and particulate matter) in the atmosphere; reducing the frequency, duration, and intensity of pollution concentrates in urban areas; and providing more productive uses for fly ash. Safer storage of nuclear waste is of primary importance.

In the design of systems, selecting remote or underground sites for generating stations, improving aesthetics by the increased use of underground distribution facilities, and beautifying transmission towers and lines in harmony with the countryside are all being urged by environmentalists. Modern transmission- and distribution-line designs reduce magnetic and electric fields in consideration of possible health effects.

Improved Employee Skill

- *Labor.* In earlier years, the power industry had a labor force of about half a million employees, a small force when compared with its very high output. In the 1970s, while the generating capacity doubled, the number of employees remained substantially the same. This was achieved through the operation of larger installations with fewer personnel, centralized control of generation and transmission, unattended substations, and minimizing maintenance and repair crews by automating dispatch procedures. This trend no longer holds.
- *Professional.* The design and construction of large installations such as generating stations and extra-high-voltage lines are often contracted out and are engineered and supervised by consulting firms. Thus, in effect, the consultants provide a common professional pool for all utilities. The electrical manufacturers have been primarily responsible for research and development of the industry, and the practice of accepting turnkey contracts is common. Thus manufacturers also provide a common pool of labor.

However, the advent of nuclear power, extra-high-voltage, and environmental limitations requires significant changes in utility systems and calls for an increase in both the quality and quantity of professional labor. The industry recognizes the need for this rapid increase in in-house skill. This can be provided by (1) improving the productivity and effectiveness of employees, (2) merging and affiliating with neighboring companies forming regional groups, and (3) maintaining aggressive in-house research and development as well as supporting institutions of higher learning and research organizations by sponsoring research and development efforts.

25.1.3 Spectrum of Computer Usage

A review of engineering and operating computer applications indicates that they fall within several broad categories, as shown in Fig. 25-2 and as described below.

System Expansion. These applications are related to 20-, 10-, and 5-year construction programs and cover planning, design, and construction of new facilities. These functions are performed at least once a year and use long-range load forecasts and other predictions as input data. Competitive pressures and complexity of expansion options demand that engineers have sophisticated interactive computer tools, decision-support and communication systems, and report-generating mechanisms.

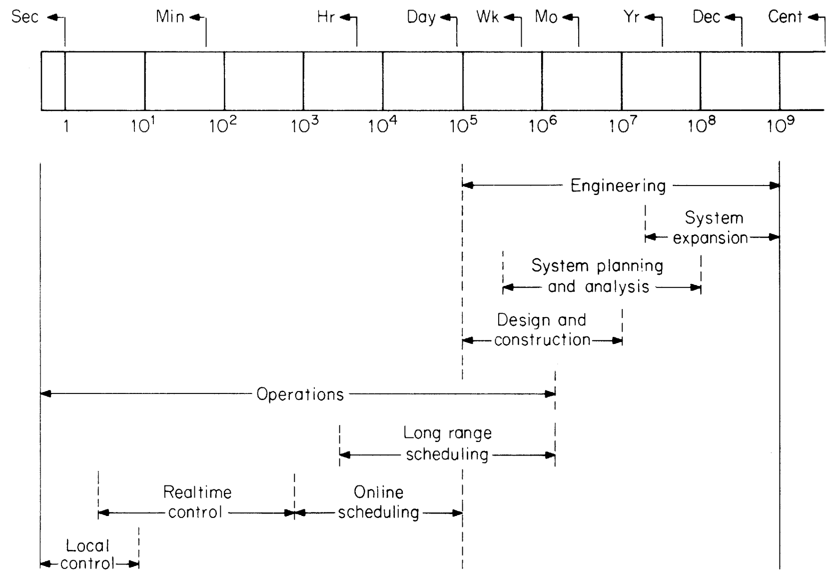

FIGURE 25-2 Spectrum of computer use.

System Planning and Analysis. These applications deal with 3- and 1-year construction of new facilities and the economic and reliable operation of these additions in conjunction with other interconnected power systems. Nuclear fuel management, annual hydrothermal coordination, and coordination for firm transmission and generation planning are among these functions. Because these programs are more frequently called on, they normally reside on disk storage devices. Thus only changes in data and programs need be entered when using specific programs.

Long-Range Scheduling (Operating). These applications are related to annual, monthly, and daily operation of the power system. In this category are transmission and generation maintenance scheduling, unit commitment and withdrawal, and other functions dealing with both reliability and economy of operation. Electric power systems are more complex and stressed than ever before. Maintenance of reliability and cost reduction require fast interactive computation in order to evaluate contingencies, operating options, and limits.

On-Line Scheduling. These applications are related to security monitoring and determination of reserve indexes and hourly data recording. These schedules are performed at least once an hour, although some applications such as pumped storage scheduling are performed weekly and daily. They are based on historical data but also need current power system data such as facilities in and out of operation, generation outputs, and line flows. Therefore, they require direct data flow into the computer. The results, however, are presented to the user for consideration and execution. Because of the scheduling nature of these applications, very fast data acquisition is not a prerequisite; however, accuracy and timeliness of schedules are related to the extent that they include direct data acquisition.

Real-Time Control. These regulating functions are carried out to meet the changing demands on the power system. Power system monitoring, security assessment, and display, rescheduling, and control of system frequency, tie-line flows, voltage conditions, and transmission flows are examples of this category. Other examples are closed-loop automatic control of generating units and interchange scheduling with neighboring companies and pool areas. These functions are performed in a time range of a few seconds to several minutes and therefore not only require direct data flows into the central computer but, in addition, require signals from the computer to the various remote controllers and actuators.

Local Control. These applications require a response speed beyond the capability of central computer control and related communication. Most of these functions are initiated immediately after a fault develops or a variable exceeds certain limits. Their objective is to react quickly and correct the situation or to isolate and contain a disturbance. These functions are performed in the few milliseconds to several seconds range and can best be handled by local computers: (1) by directly sensing variables and controlling through actuators (e.g., direct digital control of boilers or digital relaying of the substations) and (2) by superimposing the computer on the local controllers or protective relays in order to reset their operating positions. The latter applications are in the 1- to 10-s range.

The computational requirements shown in Fig. 25-2 cover both engineering and operating functions. These areas of computer activities are interrelated. From the preceding discussion it is clear that the power system operating functions do not have to be performed necessarily in real time.

25.2 ENGINEERING APPLICATIONS

As the electric utility industry has grown in size and complexity, modifications and additions to existing electric power networks have become increasingly costly. Therefore, it is vital that different design possibilities for additions and modifications to the network be studied in detail to determine their effect on the network, their effect during abnormal operating conditions, and their applicability as a flexible solution to current and future power demands.

The design and construction of planned facilities involves the efforts of a sizable engineering staff and a substantial investment in facilities. To provide support in these activities, computer programs have been developed for analysis of specified designs. The application of these programs contributes to the installation of reliable and economic facilities. The major engineering applications are shown in Fig. 25-1 and summarized below.

25.2.1 System Expansion

The system-expansion applications (Fig. 25-3) support the long-term (5 to 20 years) planning function for generation and transmission of power. The system-expansion application area represents the typical decision support environment in that many cases are produced and a variety of options and strategies are considered in the planning process. This area controls large common data sets from multiple sources. Lengthy reports are produced for internal documentation and regulation approval. In the past, most of the processing was batch-oriented because of the length of computation. Today on-line dialog with the applications is feasible and essential for evaluation of alternatives.

With the current economic outlook, the majority of emphasis in the industry will be to develop more efficient use of existing facilities rather than new construction. Load forecasting and production costing are becoming the most significant items in system expansion to predict load requirements and operating costs. Tradeoffs between expansion and new facilities are increasingly important. The applications in this category are as follows:

Load Forecasting. This application is the basis for all planning functions. It utilizes historical data, trends, economic factors, and residential and industrial projections by geographic area to produce load requirements and load duration plots by area. The effects of demand-side management are incorporated to evaluate the most cost-effective options. It also predicts the load factor.

Generation Mix Analysis. This plans the optimal mix of peaking, base-loaded, or independent power producer units; fuel type; and location of units to meet the future load requirements. It also provides a buy-and-sell analysis and accounts for reliability of generation.

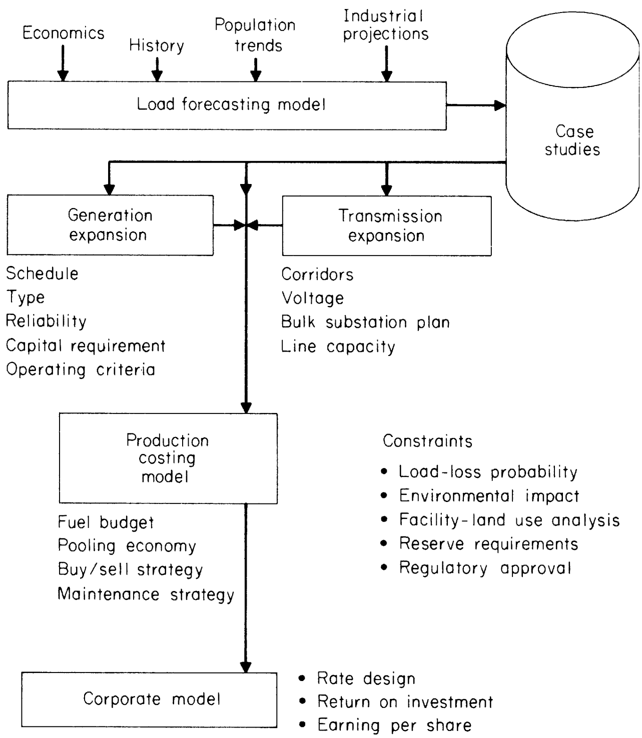

FIGURE 25-3 System expansion applications.

Production Costing. This stimulates the operation of the existing and planned generation facilities for several years in order to predict the fuel budget. It meets the load forecast and accounts for the generation availability and the hour-by-hour dispatch of generation. New techniques use statistical approaches versus detailed models.

Loss of Load Probability. This accounts for unit availability and the reserve requirement to produce a probability of loss of specific loads.

Voltage Level Analysis. This application is a tool to plan voltage levels of existing and planned transmission facilities. It provides tradeoffs of network losses versus capital requirements.

Environmental and Facility Land-Use Analysis. This set of applications assists the planner in locating plants, substations, transmission towers, and lines. Tradeoffs considered are expansion versus new facilities, right-of-way utilization, and environmental impact of planned facilities. Tighter environmental controls are increasingly affecting expansion and operating plans.

25.2.2 System Planning and Analysis

This application area supports the short-term planning process and provides tools for analyzing incremental expansion. System planning and analysis applications are high in floating-point content and represent a significant computational requirement. Many cases are analyzed, and there is a rapid turnaround requirement. While there is on-line dialog with the application and it is common to

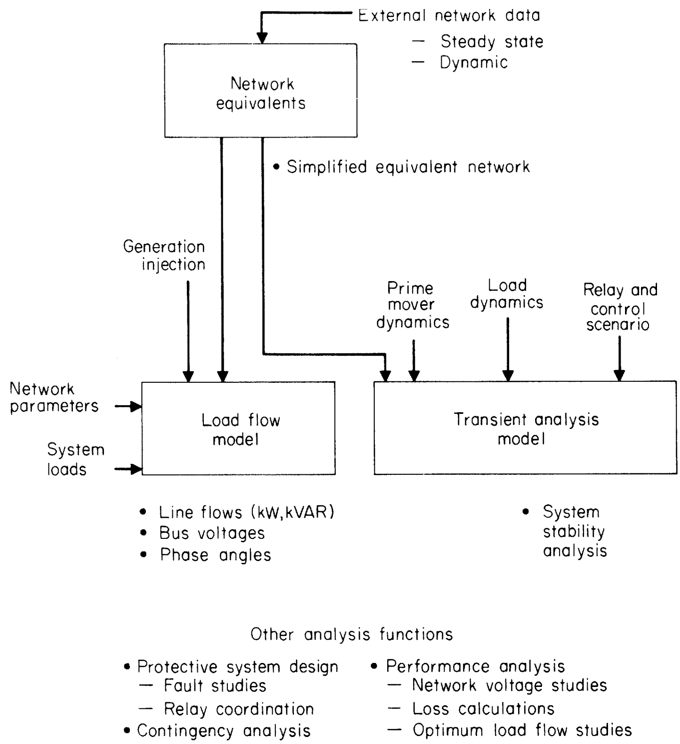

FIGURE 25-4 System planning and analysis applications.

provide on-line display and edit of results, the trend is to use interactive graphics in all phases of this decision support process. The specific applications are shown in Fig. 25-4 and described below.

Load Flow. The load-flow program is one of the major tools of system planning and is utilized extensively. Important to the system planner are that input data errors be minimized and that there be an easy and rapid turnaround for answers when the frequency of program use is high. To accomplish this, interactive capability is provided with the ability to store base cases or numerous power system models on the computer's disks. The storage capability provides many different cases that the planning engineer can access for studying or varying a particular system condition. Load flow enables the power system planning engineer to simulate and solve various power system expansion alternatives in an interactive mode. It utilizes a graphics color terminal specified with a special set of graphic characters that presents results in the form of system on-line diagrams. The multicolor feature of the terminal is used to indicate heavily loaded lines, bus voltages outside normal limits, and open circuit breakers. The engineer working at such a terminal may, with a mouse and alphanumeric keyboard, remove, add, or change elements of the system being studied and request a solution from the host computer.

The simulation programs associated with the load flow program are a system of linked programs that have the following capabilities:

1. Basic programs involving calculation of voltages, power flows, angles, and interchanges between areas of a power system.
2. A network reduction program to represent large networks as equivalents in conjunction with the specified area to be studied.

3. A distribution-factors program that indicates the sensitivity of response of the various circuits to outages of specified transmission lines, used to predict thermal limits with linear (superposition) techniques.
4. The series of programs associated with the stored load flow files which permit accessing a particular case, deleting a case, adding a case, and changing a case.
5. The var allocation program which selects the minimum amount of kilovars of compensation necessary to maintain bus voltages within specified limits under normal and/or emergency conditions. Optimal power flow (OPF) is a versatile alternative for var planning, economic dispatch, and performance improvement.

Transient Analysis. This is a large, dynamic simulation of the generation and transmission network in the transient state. It models the dynamics of synchronous machines after a system fault condition. It produces network stability information that guides the engineer in design of the network and its protective system.

Protective System Design. This application automates the work of the relay engineer in designing the protective system. It includes fault and relay-coordination studies and calculates complex relay settings.

Switching Surge Analysis. This program calculates the voltage and current transients resulting from switching surges and lightning strikes.

Contingency Analysis. This is the off-line analysis of predetermined outages and network contingencies. It is used by planning in design studies. Results are used as input to the operating area for guidance during problem or alert conditions. When combined with OPF, this is referred to as *security-constrained optimization* (SCO).

Performance Analysis. This attempts to satisfy voltage level criteria for the network and specific consumers while minimizing network losses.

25.2.3 Design and Construction

This function includes all routine applications associated with the design and construction of power plants, transmission facilities, substations, service centers, and distribution facilities. Electric utility companies on average spend more for new construction each year than any other industry. Although their primary objective is the usual production and sale of a product, they must be concerned with a large capital investment program. Efficient planning, scheduling, and control of labor and material resources are necessary if customer demand is to be met and at the same time a fair rate of return is to be provided on the investment.

Major Programs. Design and construction is a multidiscipline activity that employs computer applications dealing with electrical, mechanical, and civil engineering functions. A partial listing of specific applications is described below.

The *tower analysis* program provides a summary of the maximum tension and maximum compression for each member of a three-dimensional structure over the entire load range specified. This program also spots structure locations, plots a profile of the transmission line, and calculates sag, insulator swing, and ground clearance.

Line sag calculates sag and tension of conductors under a given situation.

Branch circuit design uses the load, distance, number of cables in a raceway, wire temperature rating, motor-starting, and full-load amps to compute the voltage drops and sizes of breakers, cable, and conduit in a circuit.

Structural design programs are used to design concrete and steel structures using as input the structure configuration and loads such as floor, roof, and impact.

The *structural steel framing* program is used to design the beams, columns, girders, and base-plates of power plant structures.

The *foundation-slab analysis* program is used to design large, complex foundation mats. The results permit evaluation of various slab thicknesses, soil bearing pressures, shears and bending moments, and reinforcement areas.

The *concrete stack analysis* program is used to analyze proposed stacks by determining loadings, resulting stresses, and required steel reinforcement. This program is used extensively in the design of very tall concrete stacks selected for new power plants.

Piping programs are used to perform stress analysis of piping systems and determine hanger design information. The *power plant piping* program analyzes the flexibility of a piping system under the influence of temperature.

The *cable routing* program provides the shortest cable route between nodes, percent raceway fill, and number of cables in a tray or raceway.

Interference analysis resolves the interference between pipe, cable tray, and structures occupying the same space.

The *heating, ventilating, and air-conditioning design* program uses thermal loads and the building configuration to calculate the size of refrigeration equipment and ductwork required.

Fluid dynamics analysis analyzes piping systems for pressure drop, flow distribution, and power requirements.

Hydrologic analysis is used to determine seepage flow networks, underground flow, and rainfall and runoff drainage for culvert and bridge size and design.

Earthwork design is used to design embankments and roadways and perform settlement and embankment stability analysis.

Geotechnical evaluation is used to evaluate soil testing results and determine the strength and swell of soil for dam and foundation design.

Foundation design programs are used to design foundation pile, pier, mat, and spread footing.

A *statistical analysis of equipment failures* means data collected on the frequency and cause of equipment failure is used to determine the likelihood of similar failures in the future based on various changes. The purpose of establishing an equipment operation database is to record and summarize the specific causes of service interruption to generation, transmission, distribution, and communication system equipment as well as to customers. The data provide the basis for designing new systems to specific reliability levels, monitoring equipment and manufacturer adherence to desired availability standards, and carrying out maintenance scheduling activities.

The database consists of a main file for each major equipment category and supplementary files which supply input to a family of programs designed to provide the engineers with periodic statistical reports. Engineers also have the ability to retrieve from this database any combination of data of their own choosing.

Transformer load management consists of a series of programs to process manufacturing performance data for distribution transformers and derive an economic evaluation based on unit cost and expected loss contributions over the expected lifetime. Since distribution transformers represent such a substantial proportion of system investment, it is imperative that they be utilized to their fullest economic capability.

A large percentage of distribution transformers are nominally underloaded; that is, they are oversized for the load being served and hence waste money through overinvestment and excessive core losses. Overloaded transformers also waste money in terms of copper losses, loss of life, fuse and transformer burnouts and replacements, and the investigation of low-voltage complaints.

Drafting includes engineering sketches and standard symbols used to lay out a drawing on a terminal and the results are printed or plotted. Included in this application are computer-aided design and drafting packages.

Economic analysis is used to make economic decisions between alternative sets of system designs or equipment.

Most of the preceding applications require common data. The trend is to treat the data as a corporate resource and to capture and maintain them in a common database. This provides for consistency of data, avoids duplication, and minimizes errors due to entry of the same data in different programs. This common database can then be used by many of the design and construction programs.

Resource-management subsystems that support the design and construction applications are briefly described below. The purpose of resource management is to help utilities in more effective utilization, control, and management of their basic resource (people, equipment, and facilities) in the distribution system.

Distribution Construction Information System. This application supports the management of new investment and maintenance in the distribution area. It provides information for planning, scheduling, and controlling equipment, labor, and material resources and becomes a tool to assist public utilities in providing consistent service and meeting customer demands while realizing fair rates of return on capital investment.

The term *distribution construction* refers to the entire process of work requesting, design, scheduling, reporting, and closing of that portion of the facilities closest in service to customers. New distribution work stems from three types of activity: system maintenance and improvement requirements, customer requests, and inspections or surveys.

For many utilities the distribution system alone represents close to one-third of the total capital investment. Thus it is not surprising to find continuing concern with the process by which facilities are constructed and maintained and by which costs are transferred to property accounts or charged to expense appropriations. This concern is often focused on improving the distribution work process to support the planning, design, scheduling, controlling, and tracking of jobs. Such improvements are undertaken to obtain a more effective and efficient work process leading to an earlier plant-in-service and to improving the utilization of the many resources devoted to distribution construction, maintenance, and operating tasks.

Computerizing the distribution work process is desirable because of the significant capital investment and expense components of utility costs and because the work process has characteristics that lend themselves to a high degree of computerization and to improved productivity and control.

Distribution Facilities Information System. This application provides the information required to plan, control, maintain, locate, account for, and manage the distribution facilities of an electric utility. It is also referred to as an *automated mapping and facilities management system*. When combined with terrain and other landmark information, it is referred to as a *geographic information system* (GIS). It is composed of a graphics system and a database system.

The graphics system provides the interactive functions required to capture information needed to maintain a database for facilities by locations. The user is required to define to the graphics system the facilities and the data elements which are associated with them. This includes its data fields, the pictures that are displayed on a map to represent it, and the connectivity requirements, if it is a network facility.

The graphics system employs a graphics workstation composed of at least one high-resolution display, an alphanumeric display, a keyboard, a mouse, and various hard-copy devices. This workstation is used to enter geographically related data, making it subsequently possible to display the data pictorially (maps), interact with the display (zoom in, window, edit, etc.), display facilities data and alter them, or to make additions or revisions. These are functions that formerly involved manual drafting and filing methods.

Maps or data generated at the workstation may be stored in a common facilities database accessible to many users. The manner in which these data are stored varies. Some systems are able to retrieve only the map facets that were entered; the user must establish the relationship between adjoining facets. In other systems the data exist as a continuous network, and the user requests only the portion and type of data needed. Storage techniques based on the common corporate database management system are becoming prevalent because of the common requirements for facilities data by many departments throughout the company.

The production of maps, diagrams, and pictures is a by-product of this system. Of far greater importance is the network relationship of the facilities data. This allows such applications as feeder analysis, transformer load management, fuse coordination, branch circuit design, and fault current calculations to be executed using the common facilities database.

Material-Management Information System. This system is used to plan for and control the flow of materials in and out of the company. A material items database may be accessed by many departments for multiple purposes. The main subsystems are stores operations, materials planning, and purchasing.

Stores operations relates to all day-to-day activities within the warehouse location. Included in these are functions such as stock inquiry handling, recording of stores transactions (receipts, issues), item location management, order and requisition initiation, and material reservation and allocation control.

Materials planning refers to the control and management of an inventory, both repairable and expendable parts. The functions under this application are acquisition analysis, item forecasting, materials requirements planning, reporting, and stock taking control.

The purchasing area includes the functions of ordering material from the suppliers and transferring to the inventory on receipt of the material. The functions within this are purchase order writing, quotation preparation, receiving, returns, implementation, quality assurance, vendor performance analysis, and invoice matching.

25.2.4 Project Management

The objective of project management is to control project costs and schedules in the maintenance and construction of power system facilities. Power engineers have used manual project information systems for years. Now there is rapid movement to automation of project control with provisions for on-line display and edit of results.

Project management in the engineering departments includes project control, project scheduling, and resource optimization tools. These tools are required to manage small procurement projects. However, they also could be major, long-term projects such as construction of a facility, installation of a major program, or daily tracking of activities within a department. Automated techniques, taking into consideration the control of time, resources, and costs, allow more productive utilization of project management personnel and stricter control of projects than manual methods. There are three major components of a project management system:

1. *Critical-path method*. A network represents a project which consists of a mixture of serial and parallel activities and employs a combination of personnel resources, materials, and facilities. When time is associated with each activity within a network, critical-path methodology can be used to analyze the network and determine the longest time path to completion of the project. All other time paths through the network will then have some slack in terms of the critical path.
2. *Resource management*. Project management and scheduling provides the means to plan and control a variety of projects. These systems permit tasks to be scheduled, resources assigned, costs allocated, and progress reported. Using this process, management can address identified problem areas and adjust its plans accordingly.
3. *Project costing and estimating*. Cost control techniques involve the ability to estimate and assign costs for labor, material, facilities, test equipment, and other resources to all activities comprising the execution of all phases of a project. In addition, some application programs permit extending rates; accommodate matrix and other organization structures; compute general, administrative, and overhead expenses; and summarize project costs over selected parts of projects as well as multiproject groups.

25.2.5 Administrative Support

Administrative functions have been automated to serve the various requirements of engineering departments. Because these requirements are common throughout the company, integrated or common solutions are often used. Administrative support typically falls into the following categories.

Text processing is the preparation, output, and data entry and editing of text using an interactive host-based or stand-alone computer system. This service may be used by a secretary to compose a letter or modify an existing memo. It may also be used directly by an engineer for notes, lists, progress reports, and general documentation. Text processing in a power company is used to prepare and maintain operating standards and procedures, standard material lists, nuclear records, training manuals, maintenance and safety procedures, regulatory reports, and specifications.

Administrative processing allows the user to manage electronic document images. It includes activities such as copying and reproducing, document distribution, records file processing, mailing, and office correspondence. Documents may be filed on disk, searched for, and retrieved. Document search may be by name or by complex search parameters as in nuclear records.

Other administrative services provide a convenient means for writing notes, reminders, messages, and appointment records. Typical functions include calendaring, tickler file (diary), meeting schedule, phone list, and to-do lists.

Text and data integration applications provide the ability to include data created outside of text applications to form reports and letters. These may be used for the creation of manuals which include specification data to reduce redundant keystrokes and increase accuracy.

Communications applications provide an informal and unstructured method of communication within an organization. This provides the means of handling messages that might otherwise require a phone call or memo. It also allows for distribution to multiple locations and receipt acknowledgment.

Personal computing provides engineers with the tools, packages, and techniques that allow them to enter and manipulate data and accomplish in hours what might otherwise take weeks. The intelligent work station provides local processing, user-friendly interfaces, and access to host applications. Many times, all applications programs can be executed on a personal computer.

Presentation graphics applications are used to present data in a pictorial form. The graphics may be displayed on a terminal or converted to a hard copy using a printer, plotter, terminal copier, or an attached camera device. Typical uses include the presentation of engineering or statistical data as line, bar, or pie charts, preparation of foils for a presentation, or drawing sketches or diagrams for inclusion in a publication.

25.2.6 Power Market Computer Simulation

Computer simulation has been a powerful tool for electric power system researchers and operators to study the system behavior under various conditions. The increasing complexity of power systems and interconnections to other infrastructures, vulnerabilities to cascading failures, interactive and large-scale nature of these networks, coupled with advances in modeling, computational methods, software technologies, simulations, control of networks, and economic aspects, have driven the further development of power system computer simulation tools. With the advent of deregulation, unbundling, and competition in the electric power industry, new software tools are needed to improve the efficiency of that network without seriously diminishing its reliability.

Power market simulator is a software tool that helps clients simulate hedging strategies in electricity markets before the strategies are put into practice and account for market contingencies in market operations and production. Capable of modeling complex power market interactions, this software tool will also allow market participants to train their staff to effectively address market scenarios that, until now, could not be handled confidently. The market simulator is useful in helping to perform a variety of functions:

- System contingency analysis to develop hedging strategies for system contingencies
- Market contingency analysis to develop hedging strategies for market contingencies, such as changes in price caps, bidding mechanisms, and new entrants
- Congestion management to develop hedging strategies for congestion charges
- Planning and expansion to demonstrate improved efficiency, reliability, and service from planned generation expansion in specific network locations
- Interregional coordination to simulate seams issues and help test strategies for coordinating production across multiple markets

25.3 OPERATING APPLICATIONS

The prime concern of the electric utility industry is to meet the consumer's power demand at all times and under all conditions. Electric utilities are continually seeking and have been most receptive to every available technique which would reduce the capital investment per kilowatt of installation, reduce the operating expenditures per kilowatthour of energy delivered, and improve the quality of service to the consumer.

Computer systems can be found in use at all levels of operation in power systems. At the generating-plant level, for example, they are used to control and monitor unit startup and operating conditions. In bulk power substations they serve such functions as monitoring, event recording, and switching. And at the system operating center level, they help to improve the economy of operation, improve the quality of service, and simplify system operation. The major computer applications for the operating area of a utility are shown in Fig. 25-1 and briefly described below.

25.3.1 Supervisory Control and Data Acquisition System

The electric utility SCADA (Supervisory Control and Data Acquisition) system is now a mainstay. Most electric utilities have means to monitor their power system activity and control substation equipment from a central location that would be classified as a SCADA system. The long sought improvements in efficiency promised by upgrading manned substations to monitored substations have been largely achieved.

It has taken many decades to get to this point. There has been a long evolution of technology and change that has brought SCADA technology this far. While substation automation is considered current technology, it is valuable to understand the steps in technological evolution and to recognize that some of that history is still in use in utilities today. The evolution in computer technology that helped drive the SCADA systems in their infancy has seen many significant changes. In the substation, microprocessor technology that gave birth to the intelligent electronic device (IED), opened the opportunity to combine functions and has significantly changed the landscape for the substation interface.

The SCADA system connects two distinctly different environments. The substation, where it measures, monitors, and digitizes; and the operations center, where it collects, stores, displays, and processes substation data. A communications pathway connects the two environments. Interfaces to substation equipment and conversations and communications resources complete the system. The substation terminus for traditional SCADA system is the *remote terminal unit* (RTU) where the communications and substation interface interconnect.

SCADA system RTUs collect measurements of power system parameters and transport them to an operations center where the SCADA master presents them to system operators. Predominantly, there are real and reactive power flow (watts and vars) voltages and currents. But other measurements like tank levels—pressures and tap positions are common to SCADA systems. These belong to the class of measurements termed analogs. Almost anything that can be viewed as a continuous variable over a range fits this category. Analog data is refreshed periodically so that the operator can be assured that data on this screen is relevant. The refresh rate is often dependent on the characteristics of the data being viewed and the communications resources available.

SCADA master stations monitor the incoming stream of analog variables and flag values that are outside prescribed limits with warnings and alarms to alert the system operator to potential problems. Data are screened for "bad" (i.e., out of reasonability limits) data as well.

SCADA systems also collect the state of power equipment such as circuit breakers and switches. These data are presented to the system operator, usually on graphical displays, to give the operator a view of the connectivity of the power system at any given moment. Various state change-reporting techniques have been used to report such changes for the system operator. These include flagging momentary changes, counting changes and time tagging them with varying degrees of resolution (sometimes as short as one millisecond).

SCADA systems almost always provide a means for the system operator to control power equipment. This includes circuit breakers, switches, tap changers, and generators. It may include some peripheral equipment in the substation as well.

In the operation center, a SCADA system has at least one computer, communicating to substations and/or generating stations collecting data, issuing control commands, and storing the incoming data. The system operator views data and messages through a set of displays on "view stations." The displays allow the operator to control power equipment and make system changes through a screen dialog.

Besides these basic functions, the operations center computer archives data and displays selected data sets, such as trends and logs in special ways for the operators. More modern systems provide data to other areas of the utility enterprise in any number of different forms and services.

25.3.2 Energy Management System (EMS)

New Development of EMS/SCADA Technology. As the central nervous system of the power network, the control center—along with its energy management system (EMS) (see Fig. 25.5)—is a critical component of the power system operational reliability picture. The market's shift, beginning in the late 1990s, from an investment strategy focused on improving capacity/reliability to one geared toward meeting the needs of a deregulating market impacted not only day-to-day infrastructure investment but also research and development. At the same time, utilities decreased EMS budgets even further because generation scheduling and optimization came to be viewed as a function of the deregulated side of the new market structure. Transmission entities therefore slashed their EMS budgets and staff, thinking that local independent system operators (ISOs) would assume

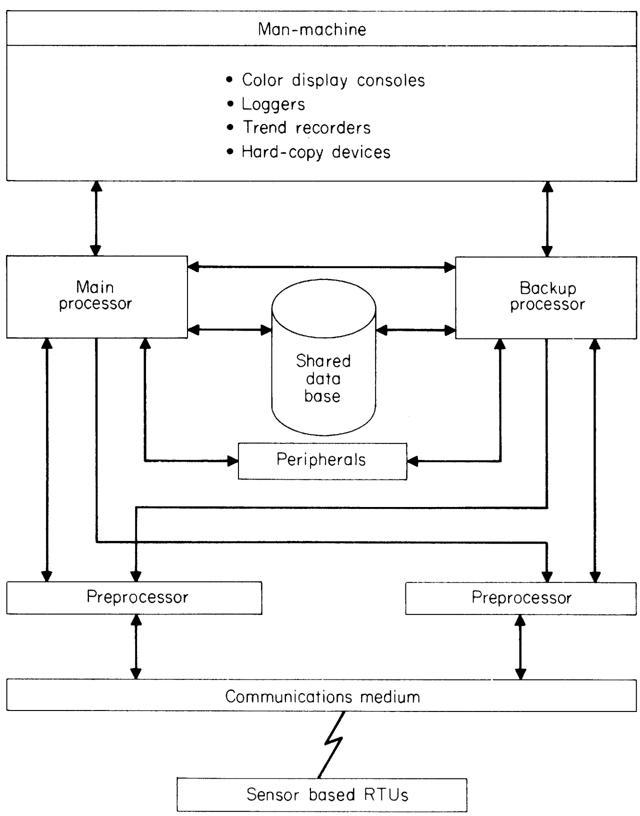

FIGURE 25-5 EMS architecture.

responsibility for grid security and operational planning. Those factors, combined with the fact that EMS technology has historically lagged behind the IT world in general, has created a situation where control room technology is further behind today than it has ever been.

The following important technology trends will come into play in the new EMS/SCADA solutions:

- *Visualization Control.* Control-room visualization today is still limited primarily to one-line diagrams, which are insufficient when it comes to today's needs to understand the availability of electricity at any given time and location and in understanding load, voltage levels, real and reactive power flow, phase angles, the impact of transmission-line loading relief (TLR) measures on existing and proposed transactions, and network overloads.

  Three-dimensional, geo-spatial, and other visualization software will become increasingly indispensable as electricity transactions continue to increase in number and complexity and as power data, historically relevant to a contained group of entities, is increasingly communicated more widely to the ISOs and RTOs charged with managing an open grid. Not only do visualization capabilities enable all parties to display much larger volumes of data as more readily understandable computer-generated images, but they also provide the ability to immediately comprehend rapidly changing situations and react almost instantaneously.

  Three-dimensional visualization is an invaluable tool for using abstract calculated values to graphically depict reactive power output, impacts of enforcing transmission line constraints, line loadings, and voltages magnitudes, making large volumes of data with complex relationships easily understood.

- *Advanced Metering Technology.* In this age of real-time information exchange, automated meter reading (AMR) has set new standards by which the energy market can more closely match energy supply and demand through more precise load forecasting and management, along with programs like demand-side management and time-of-use rate structures. Beyond AMR, however, a host of real-time energy management capabilities are now on the market, which, through wireless communication with commercial, residential, or industrial meters, enables utilities to read meters and collect load data as frequently as once every minute.

  This enables utilities to better cope with dynamic market changes through real-time access to the critical load forecasting and consumption information needed to optimize decision support. The convergence of demand-response technologies and real-time pricing, wireless communications, and the need for more reliable and timely settlement processes are all drivers for enhanced metering capabilities. This, in turn, will create a demand for EMS solutions capable of handling much larger volumes of data and the analytical tools to manage this data.

- *More Stringent Alarm Performance.* The 2003 blackout drew attention to what has become a potentially overwhelming problem—SCADA/EMS has little or no ability to suppress the bombardment of alarms that can overwhelm control room personnel during a rapidly escalating event. In a matter of minutes, thousands of warnings can flood the screens of dispatchers facing an outage situation, causing them to ignore the very system that's been put in place to help them.

  Although distribution SCADA has been able to take advantage of straightforward priority and filtering schemes to reduce the alarm overload, the transmission operations systems have not. This is because transmission systems are networked, and it is more difficult to analyze the alarms to determine what needs to be shown to help the operator reach a conclusion. Also, reaction time is not an issue in distribution, and there is more value in taking the time to locate the fault before taking action; short outages can be tolerated. Other industries, for example, telecom, networking, and refining have had good success with inference engines and other rule-based systems for diagnosing alarm conditions and providing operator assistance. These are worth a second look by the EMS fraternity today.

  New analytical tools are needed in the EMS to enable operators to manage and respond to abnormal events and conditions. See Fig. 25-6.

- *Data Warehousing.* For many years, utilities have been archiving the operational (real-time) and nonoperational (historic) information captured by energy management systems. Today's thought leadership shift is to focus on how this archived operational and nonoperational data can be combined with emerging analytic functionality to meet a host of business needs, for example, to more readily identify parts of the network that are at the greatest risk of potential failure. If integrated

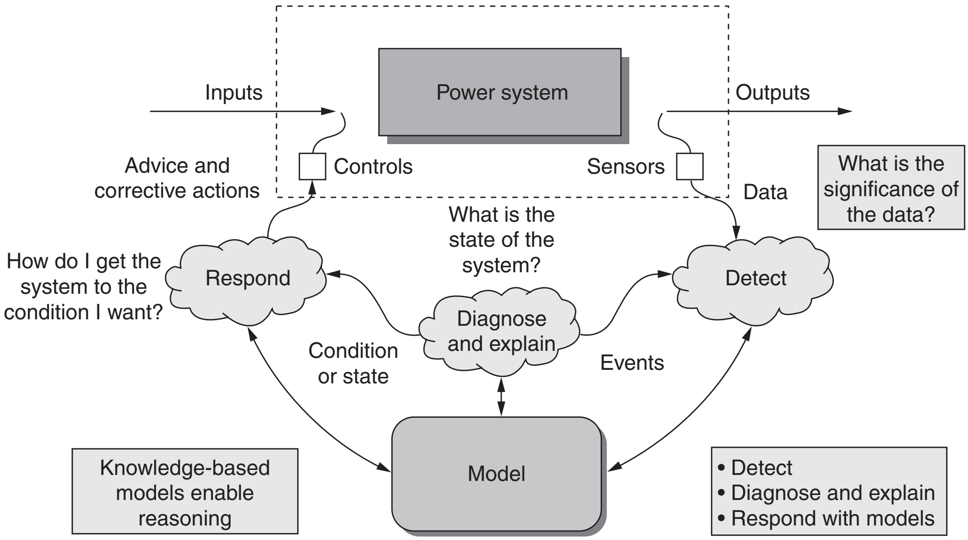

FIGURE 25-6 Real-time event management. (Courtesy of Gensym Corp.)

properly, heads-up information stored by these systems can also aid utilities in proactive replacement or reinforcement of weak links, thus reducing the probability of unplanned events.

A data mart is a repository of the measurement and event data recorded by automated systems. This data might be stored in an enterprise-wide database, data warehouse, or specialized database. In practice, the terms data mart and data warehouse are sometimes used interchangeably; however, a data mart tends to start from the analysis of user needs, while a data warehouse starts from an analysis of what data already exist and how it can be collected in such a way. Desktop access to the data each user needs to perform his or her job functions with an emphasis on business intelligence and knowledge management.

- *Communication Protocols.* EMS systems must have the capacity to talk to "legacy," i.e., preexisting, remote terminal units (RTUs) and, thus, are severely handicapped today in that many still rely on serial RTU protocols that evolved in an era of very limited bandwidth. As a result, most EMS solutions in use today are unable to exploit breakthroughs in communications, in particular, secure communications such as encryption and validation. This will need to change. Eventually, the need for encrypted, secure communications to the RTU, combined with adoption of substation automation and substation computers, may lead to the end of RTU protocols as we know them today and adoption of a common information model (CIM)-based data model for the acquisition of field data.
- *Enterprise Architectures.* To achieve the benefits offered by the technologies described here, EMS solutions need to be able to take advantage of modern enterprise architectures (EAs). EMS systems are typically not included as part of utility EA initiatives, but as their importance becomes readily apparent, this will change. Though EA definitions vary, they share the notion of a comprehensive blueprint for an organization's business processes and IT investments. The scope is the entire enterprise, including the control room, and, increasingly, the utility's partners, vendors, and customers.

  Though no industry-standard technical/technology reference model exists for defining an EA, it is clear that component based software standards, such as web services, as well as popular data-exchange standards, such as the extensible markup language (XML), are preferred, as are systems that are interoperable, scalable, and secure, such as Sun Microsystem's Java 2, Enterprise Edition (J2EE) platform, or Microsoft's.Net framework.

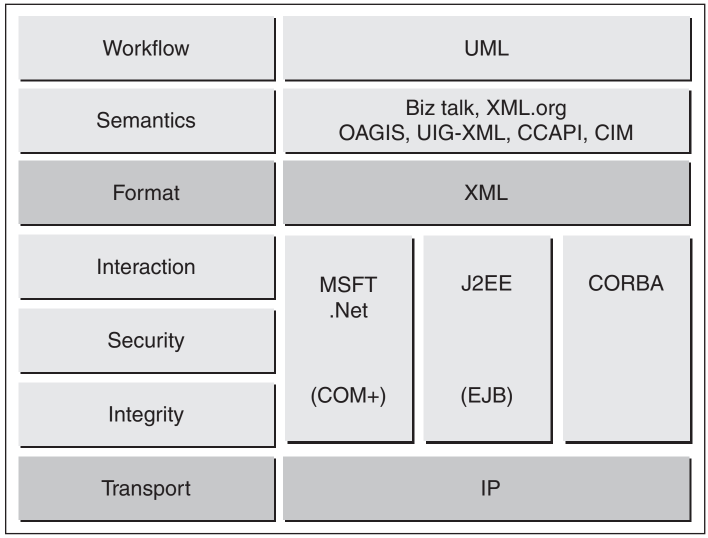

FIGURE 25-7 Integration standards.

It is also clear that frameworks and initiatives, such as the Zachman framework, Federal Enterprise Architecture Framework (FEAF), The Open Group Architecture Framework (TOGAF), and Rational Unified Process (RUP), will strongly impact how enterprise architectures for utility control operations are defined and implemented. See Fig. 25-7. By using shared, reusable business models (not just objects) on an enterprise wide scale, the EA provides tremendous benefits through the combination of improved organizational, operational, and technological effectiveness for the entire enterprise.

- *Web Services Architecture.* There are no EMS deployments today that take advantage of modern Web services architecture, although the architecture is providing tremendous benefits to businesses around the world and holds big promise for control room operations.

Like object-oriented design, Web services encompass fundamental concepts like encapsulation, message passing, dynamic binding, and service description and querying. With Web services architecture, everything is a "service," encapsulating behavior and providing the behavior through an API that can be invoked for use by other services on the network. Systems built with these principles are more likely to dominate the next generation of e-business systems, with flexibility being the overriding characteristic of their success.

As utilities move more of their existing IT applications to the Internet, a Web services architecture will enable them to take strong advantage of e-portals and to leverage standards, such as XML; Universal Description, Discovery, and Integration (UDDI); Simple Object Access Protocol (SOAP); Web Services Definition Language (WSDL); Web Services Flow Language (WSFL); J2EE; and Microsoft.NET.

The dispatcher's interface to the EMS system is through color display terminals used to display on-line diagrams and tabular displays. These displays are updated cyclically or whenever a change is detected. Various data and operating conditions are highlighted with color. The dispatcher uses the displays to interact with the system such as acknowledging an alarm, changing operating limits, controlling devices, determining system status, or executing a program.

The major functions performed by an EMS system are shown in Table 25-1. The types of processing that these functions include are cyclic work that must be completed within a specific cycle, event-driven work that results from random alarms and events that occur on the network, real-time or demand work that has specific response-time requirements, and interactive work which is dispatcher-initiated that also has response-time requirements.

Network Surveillance and Control. This consists of continuous scanning of remote sensor-based units, acquiring all key network and generation data on a 2-s cycle, checking the data for problems, and presenting the status of the network to the dispatcher through displays. The control function allows the dispatcher to take selective control action on power system devices such as circuit breakers. Frequently these functions are called SCADA (supervisory control and data acquisition).

Network data acquisition programs acquire power system data through periodic scanning of local and remote sensors attached to RTUs. The raw data are checked for missing or invalid data before being sent to the central processors by the communications front end. Retransmissions are requested for missing status data.

Data conversion and limit checking programs are used to process the raw data. The data are scaled and converted to engineering units and stored in a database for use by application programs. Reasonability checks are made on the data and values not found to be within limits cause alarms.

Alarm processing programs generate alarms for scanned data and calculated results as changes of network status are discovered, limits are exceeded, or other invalid conditions are encountered.

Logging and reporting programs store selected data in historical log files, where they are available for analysis through displays and reports.

Power device control functions provide for the control of power system devices and for the placement or removal of device tags. Control actions made by the dispatcher to activate power devices are verified, then forwarded through the network to the proper destination.

Load shedding provides rapid access to data for guiding the action of the dispatcher during abnormal operating conditions. Typical of the data that are displayed is the amount of load relief that can be obtained through emergency output of all generating sources, generation requirements, interruptible loads, load curtailment, voltage reduction, and emergency backup through tie lines.

Generation Commitment and Control. This consists of a set of programs used to optimize the production and delivery of power for fuel savings.

Automatic generation control regulates generator output to match the load in order to maintain the frequency in an area and the sum of all active tie-line power exchanges with neighboring power systems. This program executes cyclically every 2 s.

Economic dispatch minimizes the cost of meeting the energy requirements of the system over a period of time and in a manner consistent with reliable service. Desired generator settings are computed and fed to the automatic generation control program. This cyclic program executes every 5 min and also on demand.

Load forecasting computes the total system hourly load for a specified number of days. It provides an adaptive forecasting system based on observed values of demand and estimated weather conditions. The program generally consists of three mathematical models. A load forecasting model uses past load data to compute hourly load forecasts. A weather forecasting model computes hourly weather forecasts based on past weather history. A weather correction model uses telemetered values of load and weather conditions to correct the forecast. The dispatcher may optionally enter these values through a display.

The historical load and weather data are stored and maintained in files which also contain special events that affect load such as holidays or unusual weather phenomena.

Unit commitment determines a schedule for optimal startup and shutdown of thermal units which minimizes unit startup costs subject to generation objectives, predicted area requirements (load forecast), security (spinning reserve requirements and off-system capacity), and operational constraints (unit minimum up and down times, limits, ramp rates, maintenance and derating schedule). It minimizes the operating costs of the dispatchable generating units. The total dispatchable generation is the sum of the load forecast and net scheduled interchange minus the total nondispatchable generation. The operating cost is defined as the sum of production, startup, shutdown, and maintenance costs. Production cost is calculated by the use of input and output curves adjusted by fuel prices. Transmission losses are also considered using one or more sets of penalty factors. Transmission limits are considered with simple approximations.

The output of unit commitment is the hourly unit schedule. Several sets of schedules (or strategies) may be output for operator review and selection. The output is stored and made available to other applications such as transaction evaluation. This program is executed two times a day.

Reserve monitor calculates the available operating reserve necessary to meet company operating policies. Typically, a spinning reserve, 30-min reserve, and 2-h reserve are computed. This program executes cyclically every 4 min or on demand. The dispatcher is alerted when there is inadequate reserve.

Maintenance scheduling assists operating personnel in scheduling generator maintenance in an optimum manner. It generates a maintenance schedule while taking into account constraints and limitations on available resources required to perform maintenance work. The maintenance schedule indicates when particular generating units will be out of service (unit outages). Maintenance is performed routinely at desired intervals or may be required because of unexpected forced outages.

During the maintenance of a given generator, the outage of this unit is compensated for by other capacities in the power system. This is done by maintaining a level of system reserves. The scheduling of generator outages is performed in a manner which maintains a flat megawatt reserve level or a consistent level of probabilistic level of risk, i.e., probability of emergency procedures.

Interchange Management. Formal and informal interchange agreements may exist between neighboring companies. Operating as an interconnected system has economic and security advantages. While many power pools have control centers to manage the interconnection, most companies prefer to manage, or at least monitor, their own interchange of power. The interchange management programs provide the dispatcher with the ability to make good deals with the neighbors. These interactive routines allow the dispatcher to evaluate a buy or sell transaction before being committed to it. Once initiated, the interchange scheduling program automatically schedules the transaction through the automatic generation control program.

Production costing provides the capability to compare a change in interchange with the current schedule. The program always starts by accessing a study file. The calculations are based on current or forecast system load and a proposed interchange schedule entered by the operator.

Transaction evaluation calculates the costs and savings associated with the sale and purchase of power with a selected interconnected company. The program can be used to evaluate past, present, and future operation costs. A production cost calculation is generally included as a part of this program or may be an independent routine.

For evaluating transactions, the transaction evaluation program computes the costs of savings of a proposed transaction by comparing the production costs computed from two economic dispatch calculations: a base economic dispatch calculation for the operating conditions with and without the proposed transaction.

The transaction evaluation program usually can be executed in two modes which specify the starting point for all calculations. These two modes are whether the unit commitment program will be called or not. Essentially, the two options determine how the generation schedule is to be determined. Mode A (also called *economy A*) is executed without unit commitment. Current system load, interchange schedules in study file, and existing unit commitment form the starting conditions. Mode B (also called *economy B*) is executed with unit commitment and is used for transactions in the future.

Interchange scheduling is used to process and display each scheduled transaction with interconnected utilities. It computes the total net scheduled interchange as a function of time for use by the automatic generation control program. This calculation considers the start and stop times, generator ramp rate, magnitude, and direction of each active interchange transaction. Interchange schedules and cost information may be logged and displayed.

Interchange accounting provides the capability to account for electric power in the system. This electric power, in the form of measured, calculated, or scheduled megawatts, includes megawatts which are generated, consumed, lost, passed through, sold, and purchased. It includes functions for logging, displaying, reporting, and updating data recorded by the realtime system.

System Security. These programs help to reduce the chance of a major outage or blackout condition. They operate on a study database which has been cleansed of missing data and metering errors by the network status and state estimation programs.

Network status determines the current configuration of the network based on the status of circuit breakers and disconnect switches obtained from the real-time data and from manually entered status information for devices not telemetered. The program is executed periodically, whenever a status change is detected, or on dispatcher request. In addition, the program develops the corresponding mathematical model of the network using the impedance data for the current base load flow or state estimation case. The model will be used in the subsequent calculation of real-time system conditions using the load flow or state estimation programs.

State estimation determines the current state of the power system, including voltage levels and power flows, and calculates loss factors for use by the economic dispatch program for generation scheduling. It filters real-time measurements to detect and eliminate known errors; estimates expected values of the next real-time measurements; and determines the current network configuration. It corrects the mathematical model of the current network configuration. Thus the state estimation program acts as a filter between the raw real-time data and the real-time data requirements of other security applications. The state estimation program is executed whenever the network status program detects a change, periodically, or on dispatcher request.

Contingency analysis computes the potential effect of contingencies involving the loss of generation and transmission facilities. A specific set of predefined contingencies is analyzed on a cyclic basis. It simulates a contingency and calculates the changes in bus voltages and power flows resulting from the contingency. The base conditions for this calculation are the bus voltages or power flows obtained from the load flow program.

Interactive load flow (ILF) allows the dispatcher to perform load flow studies for a scheduled outage or analyze corrective actions after an unexpected outage. ILF uses real-time data to project bus loads in a network. A bus is a connection where power lines change direction or voltage. A bus load is the load at this point. The ILF program stores mathematical models of the present and planned networks. A color display terminal is used to display one-line diagrams of these models. Colors are used to differentiate voltages, heavily loaded lines, bus voltages outside of limits, and open circuit lines. The dispatcher uses a light pen or mouse together with the terminal keyboard to retrieve previous load flow cases, make modifications, create displays, execute load flow cases, and store them.

Training simulator uses a model of the power network to produce realistic reactions to a dispatcher in training. This function is usually run on the backup central processing unit (CPU). The program can operate in either of two modes: monitor or simulation mode. In monitor or playback mode, the simulator reflects the changing status of the power system during the time period when a playback tape was written. The trainee can view displays, thus monitoring power system changes, but cannot take any control action.

In simulator mode, the trainer can input system changes, and the trainee is allowed to perform control actions. The simulator software will reflect the state of the power system based upon the changes input and control actions taken. In this manner the trainee can operate the control system without affecting the true state of the power system.

Customer response systems control centers are a critical link in responding to customer complaints and reacting to outages. Customer information systems (CIS), used for many business and commercial purposes, are increasingly being combined with the engineering and operations information in order to speed repair crew dispatch and reduce outage times. Work orders, repairs, and inspections are increasingly being merged with inventory, warehouse, and engineering records to reduce costs, speed reaction times, and improve technical performance.

25.3.3 Power Plant Monitoring and Control

This application approaches the traditional process control application. Several applications such as fuel monitoring and performance calculations increase the requirement for the data processing resource. The three major computer systems for fossil power plant monitoring and control are described below.

Process Control System. This is a closed-loop control system which takes its direction from EMS and automatically collects plant data by reading instruments. Physical and electrical parameters associated with the boiler, turbine, and generator are monitored on a continuous cyclic basis. Alarms and events are logged, and control of pumps, valves, and switches for routine functions and for startup and shutdown are provided.

Plant Monitoring System. This is strictly a data-collection system for fuel monitoring, performance calculations, and balance-of-plant calculations; no control actions are performed. Data are stored and retrieved as required to prepare reports and perform analysis. These reports include those required by the plant management, load dispatchers, and planning and engineering groups. Periodic reports are prepared to reflect plant operation. Unit incremental generation cost is determined periodically by collecting data that continuously reflect actual operating conditions. This information is transmitted to the dispatcher for use in load dispatching.

Operational Monitoring System. This is used by plant operators to enter manually collected operational data for record keeping, report writing, and engineering analysis. In addition to these systems, the power plant also may use mini- or microcomputers for security systems, environmental systems, controlled access systems, and chemical analysis systems.

25.3.4 Power Plant Maintenance

Power plant maintenance stores pertinent plant maintenance information for analysis of maintenance costs and evaluation of equipment performance. The interactive portion of the system provides power plant personnel with the capability to enter problem data, planning data, and work execution data. Approval and verification functions are at each step of a work order's progress from problem description through work completion and commitment to history. Interactive functions also are provided for entry and maintenance of an equipment database and for access to equipment history.

The batch portion of the system provides for moving completed and rejected work from the active work database to the equipment history database. Batch functions are also used for work backlogs, scheduled work, and other reports.

Because of its varied data requirements, the maintenance information system also has interfaces to other computer systems in the power company. These are the materials-information system for equipment stocking levels, the personnel information system for labor resources, and the general accounting system for cost tracking. Additionally, text processing services are frequently used.

25.3.5 Fuel Management

Fuel is the single largest expenditure in power-plant operations. Operating support personnel must plan for both short-term (1 year) and long-term (5+ years) fuel availability. Thus control and improvement of fuel cost represent the most substantial contribution to the overall economy of power production. The system is used to administer the procurement of coal and oil. It facilitates the monitoring, reconciliation, and performance of fuel contracts. Accounting functions are used for fuel purchases, transportation costs, fuel usage, and inventory value. Also included are short- and long-term cash flow projections and managerial and regulatory reporting capabilities. The overall fuel management application is an integrated model of the load forecast, generation scheduling and dispatch, and fuel allocation with an objective of optimizing fuel contracts. This application is used routinely with growth and on demand as system perturbations occur.

25.3.6 Load Management

The objective of the load management application is to improve the load factor (ratio of average load to peak load) and to be able to shed selected load during emergency conditions. Most utilities have pilot tested some form of load management. The pilot solutions range from consumer guidance (voluntary) to complete control and metering of the consumer's load.

The benefits of load management have been shown to be enhanced by combining two-way utility to customer communications and control into a distribution automation system. An automated distribution system can have valuable additional functions such as automated meter reading, performance monitoring, and quality-of-service improvement.

Load Curtailment System. This scheme employs one master computer at the power company and several computers at major industrial and commercial load centers. In this scheme there is a limited sensor-based data-acquisition requirement and no closed-loop control. Reduction of load will be manual.

Automatic Meter Reading and Load Management. This hierarchical approach employs the corporate customer information system and the EMS system to direct and receive the meter readings, an intermediate level to serve as a communication concentrator, and an intelligent data control unit to scan remote transponders at the meter locations.

25.3.7 Nuclear Data Center

Functionally, the nuclear data center consists of three systems (Table 25-2), which are described below.

Operational System. This consists of real-time and on-line monitoring of various subsystems in a nuclear plant. The plant process computer system in a nuclear plant is usually provided by the reactor vendor and integrated with the reactor. Additional monitoring facilities are now required by the Nuclear Regulatory Commission (NRC). One specific monitoring system is named the *emergency response information system*, which is now a firm requirement for all operating nuclear plants and a license requirement for plants under construction. It has the following components:

- *Safety parameter display system*. This provides additional monitoring and display facilities to the primary plant control room. The additional facilities provide continuous monitoring of critical parameters.
- *Technical support center*. This is a separate facility and staff within the plant to assist the primary plant control room during emergency conditions.

- *Emergency operations facility*. This is a separate facility and staff located off the plant site but in proximity to the plant. It will manage the overall emergency response and evaluate actual and potential radiological releases.
- *Nuclear data link*. This routes cyclic data from the plant to the NRC headquarters through a communication link. The critical data will be used to monitor an accident, to evaluate emergency conditions, to advise and assist the licensee, and to inform the general public.

Administrative System. This is used for maintenance and backup of the operational system. Storage and information retrieval systems are used for the storage and retrieval of large amounts of data as encountered in nuclear records management. These systems provide interactive direct access to, and fast scanning or searching of, large numbers of articles, reports, contracts, laws, general directives, or abstracts of publications.

Technical System. This is used for large simulation and nuclear fuel management programs. Computer programs simulating nuclear core physics in various levels of detail are presently being used for analysis, leading to continual improvement and enhancement of nuclear plants. These programs are used not only in the design of cores for nuclear reactors but also for the planning and decision making regarding fuel burnup and associated electrical generation for nuclear units. Core refueling schedules are of vital concern. Safety analysis for emergency situations is another area in which the simulation programs are used. Nuclear fuel management programs are used for the design of nuclear reactors and for nuclear fuel management calculations.

25.4 ENGINEERING COMPUTING TRENDS

Costs. Today the cost of the engineering user is 8 to 50 times the cost of the computer that the engineer uses. This range depends on the level of the user and the type of processing: machine-intensive (compiling, executing) or human-intensive (editing, scrolling). It is no longer cost-effective to economize on computing resources required by the engineering user.

Personal Computing. Batch-job and central processing is rapidly being replaced by networked or individual personal computers and workstations. The fast performance and low cost of this equipment are a perfect complement to modern interactive, graphics-oriented software, which combine to greatly improve engineering productivity and effectiveness.

Networks. High-speed networks allow easy communication of data, results, and messages, leading to an integrated set of applications spanning functions and levels of the company. Ethernet and token-ring systems and communication protocols such as TCP/IP provide versatile and very high speed communications between diverse computers.

Languages. Most engineering computer applications are written in FORTRAN because of the long-time popularity of this language. New applications and graphics user interfaces (GUI) are usually written in C or the object-oriented C++ language. Graphics interfaces use special facilities such as Windows, MOTIF, and OpenLook.

On-Line Reporting. This has replaced manual reporting of data. Although text processing systems are used to generate documents, text information can also be transmitted, distributed, and stored electronically to reduce the proliferation of paper documents.

Results Selection and Editing. This is now performed by scrolling a display instead of printing all results and sifting through reams of paper.

Automated Data Flow. The trend is to maintain one set of data that is available to all users. These data are protected by appropriate security features and procedures like any other corporate resource. However, the intent is to make common data available to all users and allow the appropriate users to update the common data. This common database leads to accuracy, avoids duplication, and avoids loss of labor due to the reentry of data.

Productivity Aids. While most of the computer applications that the engineer uses are complex programs, the productivity of the engineer is also increased by simple, direct tools for text processing, graphics, and project control. These tools are interactive and require a minimum of effort to use. These tools help the engineer make notes, drafts, lists, sketches, and establish personal meeting or project schedules.

Computer Configurations. Computer configurations such as shown in Figs. 25-8 and 25-9 are used to support engineering functions. Although the centralized computing approach has traditionally been used, the trend is to a distributed approach in which a separate engineering information center is assigned strictly to engineering work.

Engineering User Service Objectives. Engineering users require three categories of computing support:

1. *Performance requirements.* Less than 0.4-s response time is required for human-intensive work at a terminal. Longer response times reduce concentration and increase frustration. A predictable response time is required for machine-intensive work. Consistent timings for load flow are expected when operating under deadlines. High-bandwidth terminals are required to support Windows graphics user interface (GUI) color graphics applications, which are used to speed work flow and to reduce volumes of data to a presentation of results in a form that can be readily assimilated.

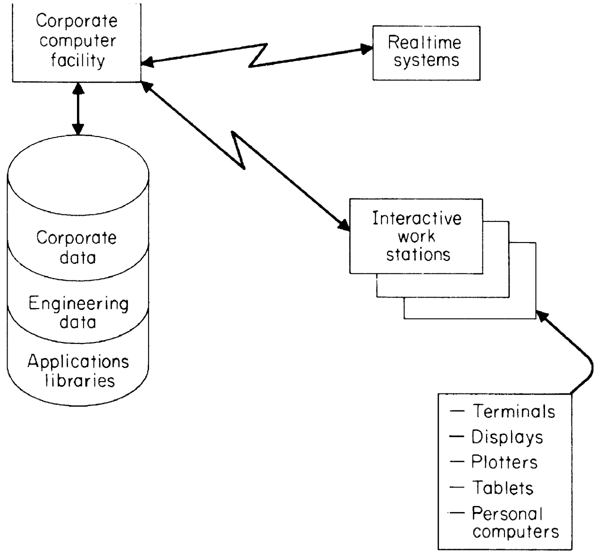

FIGURE 25-8 Power engineering centralized architecture.

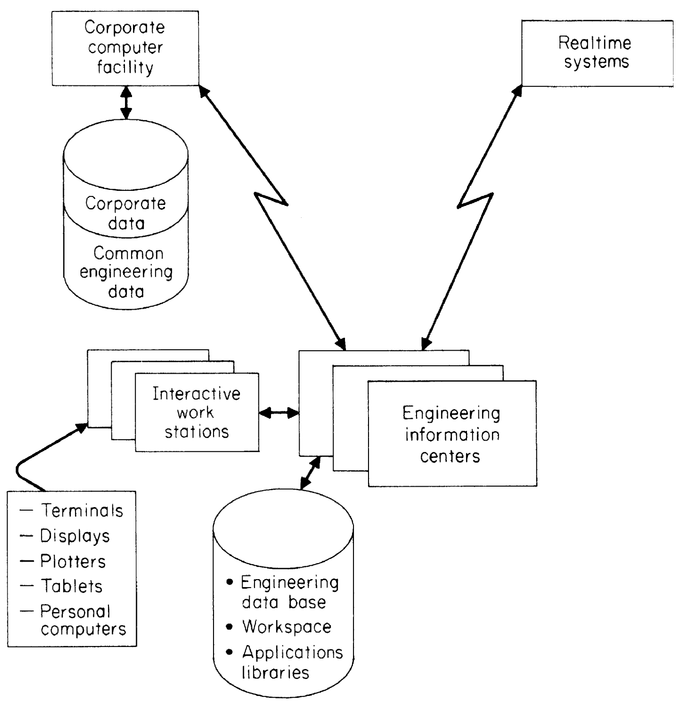

FIGURE 25-9 Power engineering distributed architecture.

2. *Technical support requirements*. The engineering user requires a minimum of system programming knowledge to use the computing system. Included in this are user-friendly selection panels, menus, aids, and help functions; a library of programming tools, languages, and application packages, all of which are maintained by the central data processing department; and training facilities and technical support to assist engineers with the use of computing resources.
3. *Operational support requirements*. Security features and operational procedures are required to protect the user's data and access to the computing system. Included are security features such as password protection of user data files and sign-on's and operational procedures to provide backup of user data and prevent its destruction or loss.

26.1 RADIANT ENERGY AND LIGHT

For the principal purposes of illumination design, light is defined as visually evaluated radiant energy. The visible energy radiated by light source is found in a narrow band in the electromagnetic spectrum (Fig 26-1) approximately from 380 to 770 nanometers (nm). By extension, the art and science of illumination also include the applications of ultraviolet and infrared radiation. The principles of measurement, methods of control, and fundamentals of lighting system and equipment design in these fields are closely parallel to those long established in lighting practice.

26.2 QUANTITIES, UNITS, AND CONVERSION FACTORS[1]

Luminous Flux. This is the time rate of flow of light. See Table 26-1. Radiant energy in the visible region of the spectrum varies in its ability to produce visual sensation, the variation depending upon

the wavelength. The ratio of the luminous flux to the corresponding radiant flux is known as spectral luminous efficacy and is expressed in lumens per watt (lm/W). This varies with wavelength, having a maximum at approximately 555 nm. The data are plotted in Fig. 26-2. At very low levels of illumination the position of the maximum sensitivity gradually shifts to 510 nm as a result of greater use of rod vision.

From the foregoing it is apparent that two sources may radiate equal amounts of energy in the visible region of the spectrum but have different amounts of luminous flux emitted, depending on the spectral distribution of the energy. The luminous flux (ϕ) is the integrated product of the energy per unit wavelength emitted by the source $P(\lambda)$, referred to as the source's spectral power distribution, and the spectral luminous efficacy $V(\lambda)$ as follows:

$$\phi = 683\int_{\lambda=360}^{800} P(\lambda)V(\lambda)d\lambda$$

The lumen is the unit of luminous flux. Light sources (i.e., lamps) are rated in lumens.

Luminous Intensity. This is the luminous flux per unit solid angle in a specific direction. Hence, it is the luminous flux on a small surface normal to that direction, divided by the solid angle (in steradians) that the surface subtends at the source (see Table 26-1). The definition of luminous

*Quantities may be restricted to a narrow wavelength band by adding the word s*pectral* and indicating the wavelength. The corresponding symbols are changed by adding a subscript λ, e.g., Q_λ, for a spectral concentration or a λ in parentheses, e.g., $K(\lambda)$, for a function of wavelength.

†The use of this unit is deprecated.

intensity applies strictly to a point light source. In practice, however, light emanating from a source whose dimensions are negligible in comparison with the distance from which it is observed may be considered as coming from a point.

Candlepower is another term for luminous intensity, since the candela is the unit of luminous intensity. One candela is defined as the luminous intensity of 1/600,000 $m^2$of projected area of blackbody radiator operating at the temperature of solidification of platinum under a pressure of 101,325 Pa. It is also the luminous intensity when one lumen is directed within one steradian of solid angle. A steradian is a unit area on a sphere of radius one, thus there are 12.57 (4π) steradians surrounding any light source. The original definition of luminous intensity was in terms of the strength of a flame source, a standard candle.

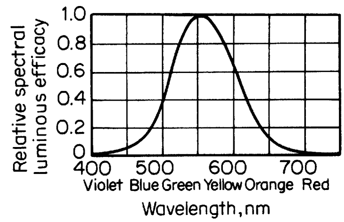

FIGURE 26-2 Spectral luminous efficacy, $V(\lambda)$, for normal human color vision.

Illuminance. This is the density of the luminous flux incident on a surface; it is the quotient of the luminous flux by the area of the surface when the latter is uniformly illuminated. The term illumination is used to designate the act of illuminating or the state of being illuminated. Usually the context will indicate which meaning is intended, but the expression "level of illumination" is a term used to mean illuminance and should be discouraged.

Lux is the unit of illuminance when the meter is taken as the unit of length. It is the illumination on a surface 1 m^2 in area on which there is a uniformly distributed flux of 1 lm, or the illumination produced on a surface, all points of which are at a distance of 1 m form a directionally uniform point source of one candela.

Footcandle is the inch-pound system unit of illuminance where the foot is taken as the unit of length. See Table 26-2 for conversion factors between SI and inch-pound lighting units. Most conversions, like illuminance, involve a 10.76 factor since there are 10.76 ft^2/m^2 (e.g., 1 footcandle = 10.76 lux).

Luminous Exitance. This is the density of luminous flux leaving a surface; it is the quotient of the luminous flux leaving the surface by the area of the surface. It applies to the aggregate flux that is emitted, reflected, or transmitted from the surface and is a nondirectional quantity.

Luminance. This is the quotient of the luminous flux leaving or arriving at an element of a surface and propagated in direction defined by an elementary cone containing the given direction, by the

product of the solid angle of the cone, and the area of the orthogonal projection of the element of the surface on a plane perpendicular to the given direction. More simply, it is the luminous intensity of any surface in a given direction per unit of projected area of the surface viewed from that direction (see Table 26-1).

Candela per square meter is the SI unit of luminance when the meter is taken as the unit of length. Another term for this unit is the nit, which is not commonly used in North America. The candela per square foot is the inch-pound unit of luminance when the foot is the unit of length.

Footlambert is a former unit of luminance, and is equal to $1/\pi cd/ft^2$, or to the uniform luminance of a perfectly diffusing surface emitting or reflecting light at the rate of 1 lm/ft^2, or to the average luminance of any surface emitting or reflecting light at that rate. The term footlambert is now obsolete, and its use is deprecated.

Luminous Efficacy. This is a quantity denoting the energy effectiveness of light sources. It is the ratio of the total luminous flux (lumens) to the total power input (watts). The maximum luminous efficacy of an *ideal* white source, defined as a radiator with constant output over the visible spectrum, is approximately 200 lm/W.

Reflectance. Reflectance ρ is the ratio of reflected flux to incident flux. Measured values of reflectance depend upon the angles of incidence and view, and on the spectral character of the incident flux. Because of the dependence, the angles of incidence and view and this spectral characteristics of the source should be specified.

Transmittance. Transmittance τ is the ratio of the transmitted flux to the incident flux. Measured values of transmittance depend upon the angle of incidence, the method of measurement of the transmitted flux, and the spectral character of the incident flux. Because of this dependence, complete information of the technique and conditions of measurement should be specified.

Absorptance. Absorptance α is the ratio of the flux absorbed by a medium to the incident flux. The sum of reflectance, transmittance, and absorptance is one.

Brightness. This term refers to the intensity of sensation resulting from viewing light source and surfaces. This sensation is determined in part by the measurable luminance defined above and in part by conditions of observation such as the state of adaptation of the eye.

Color. Within the visible spectrum, wavelengths are distinguished one from another by their ability to excite in the human eye various color sensations. Thus the shorter wavelengths excite the color known as violet, and as the wavelengths increase, the color sensation gradually changes through blue, green, yellow, and orange, and finally to red at the longer wavelengths of the visible spectrum. The color of the sensation produced by light of a composite character is determined by its spectral power distribution. Color is defined as that quality of visual sensation which is associated with the spectral distribution of light. Color matching is the process of adjusting the color of one area so that it is the same color as another.

Correlated color temperature (CCT) of a light source is the absolute temperature (in Kelvin) of a blackbody radiator whose chromaticity most nearly resembles that of the light source. CCT refers to the whiteness of the light that a source emits. Low CCT light appears more yellow or red, and is generally considered to be warm in appearance, while high CCT light appears more bluish white. A neutral CCT is generally considered to be around 3500 K.

Color rendering is a general expression for the effect of a light source on the color appearance of objects in conscious or subconscious comparison with their color appearance under a reference light source.

The Color rendering index (CRI) of a light source is the measure of the degree of color shift which objects undergo when illuminated by the light source, as compared with the color of those same objects when illuminated by a reference source of comparable color temperature. Values for common light source vary from about 20 to 99. The higher the number, the better the color rendering

26.3 INCANDESCENT LAMPS

Incandescent Filament Lamps. These are light sources in which light is produced by a filament heated to incandescence by an electric current. Of all commonly used light sources, incandescent lamps have the lowest initial cost, lowest luminous efficacy, and shortest life. As shown in Fig. 26-3, the major parts on an incandescent filament lamp are the filament, bulb, base and fill gas.

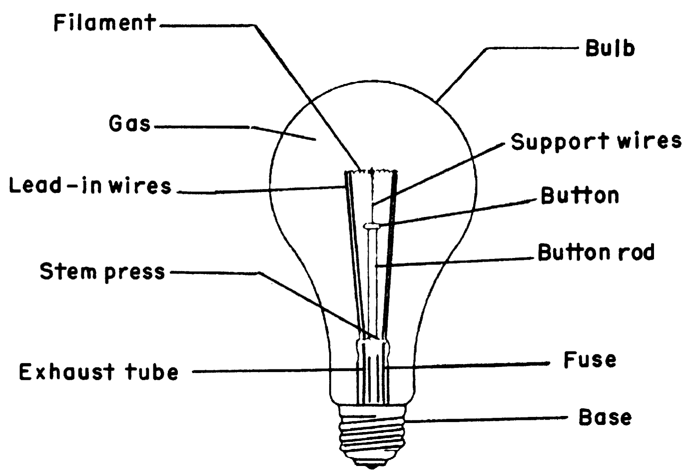

FIGURE 26-3 Incandescent filament lamp construction.

Filament. The efficacy of light production by incandescent lamps depends on the temperature of the filament. Tungsten, because of its high melting point (3655 K), higher than that of all other elements except carbon, is the most common filament material used today. Filament forms, sizes, and support constructions vary with different types of lamps. Most filaments are coiled one or more times to increase the filament temperature, light output, and the lamp's luminous efficacy.

Mechanical problems associated with tungsten filaments make the incandescent lamp an inherently compact, somewhat spherical structure. The filament's length and diameter limit its range of operation between 1.5 and 300 V. At 1.5 V, the filament is very short and thick, and it becomes difficult to heat it without excessively heating its support wires. The lamps in the low-voltage (6-to 12-V) class, however, are relatively rugged and will withstand the shocks of motor-vehicle and similar applications. At voltages near 30 V, the filament is very long and slender; it is fragile and difficult to support.

Bulbs. Bulb shape, size, material, and finish vary finish vary according to application needs. Shapers range from tubular to spherical and from parabolic to flame form. Bulbs are designated by a letter referring to the shape (see Fig.26-4) and by a number which is the maximum diameter in eights of an inch; for example, A-19 designates an A-shaped bulb with a diameter of 19/8 or 2-3/8 in.

Most bulbs are made of lead or lime soft glass, although heat-resisting hard glass is used for high-temperature application, and are frosted on the inside for moderate diffusion of the light without appreciably reducing light output. Clear, unfrosted lamps are used where accurate control of light is needed from a point or line source. Fused quartz and high-silica glass are used for other lamps.

Base Types. These also very according to application needs. They range from screw types for most general-service lamps to bipost and prefocus types where a high degree of accuracy in lamp positioning is important, such as in projection systems. Figure 26-5 shows some typical base shapes. Base size varies with lamp wattage, for heat dissipation, and voltage. For outdoor lighting, use brass-base lamps.

Fill Gas. This is used in incandescent-filament lamps to reduce the rate of evaporation of the heated filament. Inert gases such as nitrogen, argon, and krypton are in common use today, with krypton used where its increased cost is justified by increased efficacy or increased lamp life. For example, the 90-W krypton "energy-saving" lamp produces 4% less light, but one-third longer rated life compared with the standard 100-W lamp.

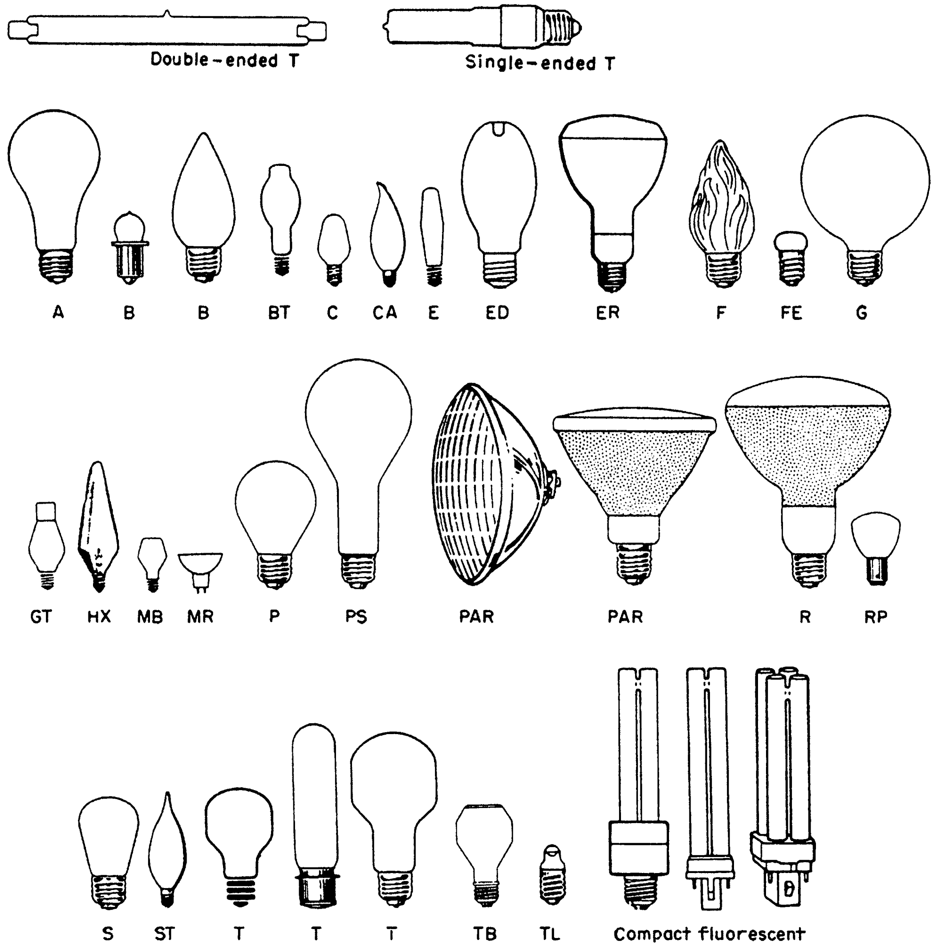

FIGURE 26-4 Typical bulb shapes and designations (not to scale). Most high intensity discharge (HID) lamps use BT-, E-, ED-, PAR-, and R-shape bulbs.

Many regular, tubular, and PAR shaped lamps are available with a halogen fill gas, for better lumen maintenance, improved light output, and/or longer life. Called "tungsten halogen," their filaments operate at temperatures higher than regular incandescent lamps, producing light of greater color temperature, plus longer life for a given light output. For applications justifying the increased lamp cost, a 90-W, 2000-h tungsten halogen lamp, for example, has only 8% less light output rating than the standard 100-W, 750-h lamp, with improved lumen maintenance through its longer life.

Energy Characteristics. Only a small percentage of the total radiation from incandescent lamps is in the visible spectrum, with the majority in the infrared spectrum. As the filament temperature is increased, the luminous efficacy increases with a maximum of 53 lm/W for an uncoiled tungsten wire at its melting point. To obtain life, practical lamps operate at a temperature will below the melting point.

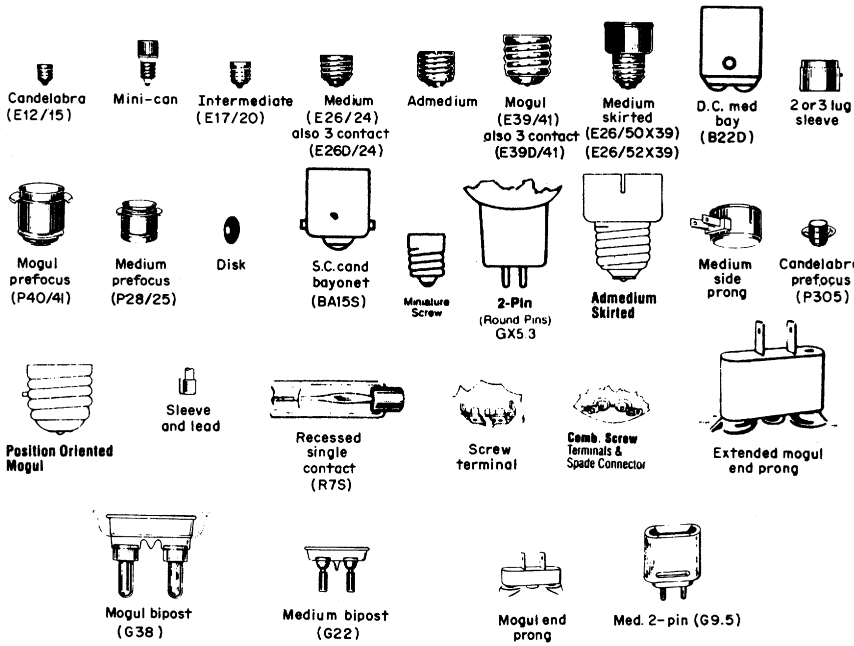

FIGURE 26-5 Common incandescent and HID lamp bases (not to scale). IEC designations are shown where available.

Performance Characteristics. The performance of tungsten-filament lamps is affected by voltage, position of the bulb (if incorrect), size, construction, ambient temperature (if excessive), and quality of manufacture. The voltage characteristics through a range of a few volts above and below design volts may be expressed as simple exponential equations in the following relationships, where capitalized terms represent normal rated values:

$$\frac{\text{Life}}{\text{LIFE}} = \left(\frac{\text{LUMENS}}{\text{lumens}}\right)^a = \left(\frac{\text{LUMENS / WATT}}{\text{lumens / watt}}\right)^b = \left(\frac{\text{VOLTS}}{\text{volts}}\right)^d = \left(\frac{\text{AMPS}}{\text{amps}}\right)^u$$

$$\frac{\text{Lumens}}{\text{LUMENS}} = \left(\frac{\text{volts}}{\text{VOLTS}}\right)^k = \left(\frac{\text{lumens / watt}}{\text{LUMENS / WATT}}\right)^h = \left(\frac{\text{watts}}{\text{WATTS}}\right)^s = \left(\frac{\text{amps}}{\text{AMPS}}\right)^y = \left(\frac{\text{ohms}}{\text{OHMS}}\right)^z$$

$$\frac{\text{LUMENS / WATT}}{\text{lumens / watt}} = \left(\frac{\text{LUMENS}}{\text{lumens}}\right)^f = \left(\frac{\text{VOLTS}}{\text{volts}}\right)^g = \left(\frac{\text{AMPS}}{\text{amps}}\right)^j$$

$$\frac{\text{amps}}{\text{AMPS}} = \left(\frac{\text{volts}}{\text{VOLTS}}\right)^t \quad \text{and} \quad \left(\frac{\text{watts}}{\text{WATTS}}\right) = \left(\frac{\text{volts}}{\text{VOLTS}}\right)^n$$

Exponents *d, k,* and *t* are taken as fundamentals, and other exponents are derived from them. A list of exponents is given in the following table. Values given apply to lamps operated at 90% to 110% rated voltage. Outside that range, use the values from Fig. 26-6.

The theoretical life of lamps calculated by the exponential relationship of life and voltage is seldom realized in practical installations in the case of excessive "undervoltage" burning, since handling, cleaning, vibration, etc., introduce breakage factors which tend to reduce lamp life.

Lamp Lumen Depreciation. Because of filament evaporation throughout life, the filament of a lamp becomes thinner and thus consumes less power. The light output decreases as the lamp progresses through life because of lower filament temperature and bulb blackening. Figure 27-7a shows the change in watts, amperes, lumens per watt, and lumens for a 200-W general-service lamp on constant-voltage service. The minor quantity of bromine or iodine in tungsten-halogen lamps vaporizes during operation, and acts to return particles of tungsten back to the filament. This results in superior lumen maintenance.

Lamp Mortality and Renewal Rate. Lamp life is based on data obtained form lifetesting a large number of lamps. A perfect mortality record would be one in which all lamps reached their rated life and then burned out. However, many factors inherent in lamp manufacture and lamp materials make it impossible for each individual lamp to operate for exactly the life for which it was designed. A typical mortality curve of a large group of lamps is illustrated in Fig. 26-7*b*, where it is superimposed on a lumen depreciation curve from Fig. 26-7*a*.

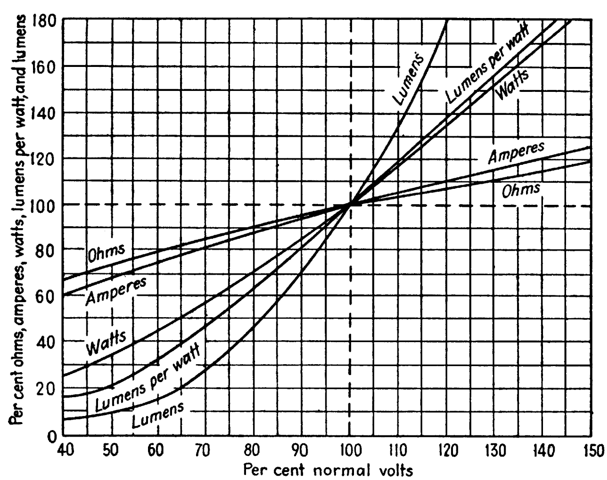

FIGURE 26-6 Characteristic curves for large gas-filled lamps showing the effect of operating a lamp at other than its rated voltage. These characteristic curves are averages of many lamps.

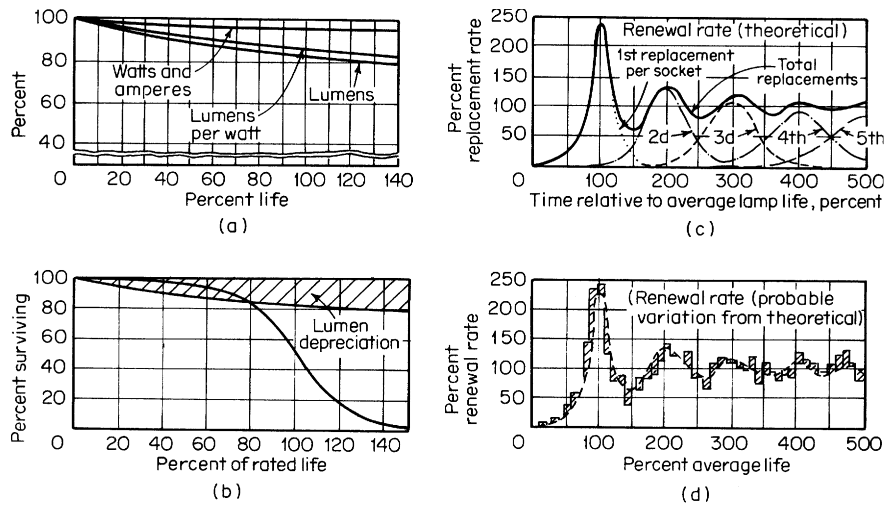

FIGURE 26-7 Life characteristics and renewal rate.

The mortality curve influences the rate of lamp replacements for installations involving a large number of lamps. If individual lamps are replaced as they burn out, the replacement rate is as shown in Fig. 26-7*c*. In a new installation relatively few burnouts would be expected during the first several hundred hours of operation, but as the design life is approached, the rate of burnout increases rapidly. After a burning period of 4 to 5 times the average lamp life, the renewal rate fluctuation finally reaches a steady or normal rate.

The dotted curve in Fig. 26-7*c* showing the theoretical rate of renewals holds only for an infinitely large installation. Departures from this curve in practical installations will, by the law of probability, more likely be represented by the solid block-shaped pattern. The larger the installation, the more closely the two curves tend to coincide. Complaints on life are occasionally encountered during those periods when chance dictates that renewals run higher than average, even though a record of the actual number of renewals over an extended period of time would show average rated life had been obtained.

Rated Lamp Life. The rated life of a lamp is generally defined as the operating hours at which 50% of a representative group of lamp burned under correct operating conditions on a 60-Hz circuit are still burning, and ranges from 750 to 1500 h for the general-service incandescent types. As compared with life in the laboratory under controlled operating conditions, performance in service may differ widely. Lamp breakage and fluctuating line voltage tend to shorten life. Line-potential drop with resultant low-voltage operation often tends to lengthen life. Extended-service lamps with a rated of 2500 h and longer are available in a range of sizes from 15 to 1000 W. They give less light than standard lamps under normal conditions but may be economically justified when labor costs to replace lamps are very high.

Influence of operating Conditions on Lamp Performance. Tests show that ambient temperatures have little effect on performance characteristics. Very high temperatures, however, may cause mechanical difficulties. On direct current, although the mortality rate is lower, the maintenance of light output is poorer than on alternating current. Intermittent operation in general (not sign-flashing service) does not materials affect lamp performance. There is a reason to believe that lamp life is shortened by voltage fluctuations, even though the voltage excess averaged over the life of the lamp is offset by an equal average voltage deficiency.

Except in the case of lamps designed for a particular position of operation, operating position has little effect on lamp performance. Shock and vibration are likely to impair the performance of lamps with filaments of small diameter to a greater extent than in the case of lamps with filaments of large diameter. Special types of lamps are available for use in installations where vibration is likely to be encountered and others, known as "rough-service" lamps, for use where they are likely to be subjected to shock. Neither of these two lamps will function properly in place of the other.

Classes of Incandescent Lamps. Incandescent lamps are divided and cataloged by manufactures into three major groups: large lamps, miniature lamps, and photographic lamps. Large lamps are those normally used for interior and exterior general and task lighting. Miniature lamps are generally used in automotive, aircraft, and appliance applications. Photographic lamps, as the name implies, are used in photography and projection service. Some of the main classes of large lamps are as follows:

General Service. These are for general lighting on 120-V circuits (see Table 26-4). Sizes range from 15 to 1500 W with efficacies of 8 to nearly 23 lm/W. Lamps rated at 130 V and other voltages are also available—consult catalogs or sales representatives of lamp manufactures for specific listings.

High Voltage. High-voltage incandescent lamps are designed for operation directly on circuits of 220 to 300 V. They are less rugged and have a lower efficacy than general-service lamps. There are also general-service incandescent lamps of 277-V circuits. One manufacturer cautions that such lamps be enclosed if used on high-capacity, low impedance electrical distribution systems.

Extended Service. These have a life of 2500 h or more and are intended for use in applications where a lamp failure causes an inconvenience, a nuisance, or a hazard to replace the lamp, or where replacement labor is expensive (see Table 26-5). They are less efficient than general-service lamps.

General Lighting Tungsten-Halogen. These are compact, have better lumen maintenance, and provide a whiter light and a longer life. Some typical lamps for general lighting are listed in Table 26-6.

Reflectorized. These are a group of lamps embodying integral reflecting surfaces. Bowl-silvered lamps are employed in direct-lighting equipment in which it is desired to shield the filament from view in direct or indirect equipment. Initial loss of light output due to the silvering is 6% to 10%; the rate of decline of light output is considerably greater than in clear-bulb lamps of corresponding sizes—60% to 80% greater in the case of 100- and 200-W lamps. However, a luminaire (of similar distribution) with an unprocessed lamp may produce less light because of poorer maintenance.

In projector flood- and spotlight-lamps, the bulb is constructed of a molded bowl-shaped section of parabolic or other suitable profile, on the inner surface of which is a metal-reflecting surface (see Table 26-6). This bowl is fused to a molded-glass cover plate, which may be clear or may consist of a pattern of lenses and prisms, depending on the desired beam characteristics. Reflector-type lamps are constructed with blown bulbs of suitable profiles (usually cylindrical for showcase lighting or parabolic for spotlighting) having parts of the inner surfaces covered with a reflecting metallic film. Their nominal life is usually 2000 h.

The National Energy Policy Act (EPACT) of 1992 prohibited the manufacture after October 31, 1995 of certain standard, general-service 115- to 130-V reflector and projector lamps. Among those obsoleted were 50-, 75-, and 100-W R-40 lamps and 75-, 100-, and 150-W R-40 and PAR-38 lamps. They are replaced by higher-efficiency halogen-capsule lamps.

A number of projector lamps are available with dichroic filters (interference films) to control the spectral quality of the radiation in such a manner as to separate the heat from the light in the beam or to produce colored light without the usual losses due to absorption by filters. From 75% to 80% of the heat can be removed from the beam at a sacrifice of only 15% to 20% of the light. These "cool beam" lamps must be used in luminaires that are capable of dissipating the additional heat that remains within the luminaire. Colored dichroic lamps produce more deeply saturated colors with higher efficacy than is obtainable with color filters.

In certain PAR-bulb lamps, the tungsten-halogen capsule has an infrared coating, enabling a lower power rating by redirecting energy back to the filament (Table 26-7). All applications of reflectorized lamps should follow the recommendations of the manufacturer concerning luminaire

Small Tungsten-Halogen Lamps. Families of 13/8- and 2- in-diameter, 12-V models having internal multifaceted reflectors, providing a range of beam spreads for accent and display lighting, are available. Dichroic reflector coatings reduce approximately two-thirds of the heat in the beam by emitting infrared energy to the rear, thus decreasing fading of color-perishable items that the illuminated. Small changes in applied voltage have large effects on lamp life, and rapid on-off operation will shorten life. Dimmers recommended for the inductive loads of the step-down transformers should be used instead of incandescent-type dimmers. Blackening of the tungsten-halogen capsule which may result from dimming can be cleared up by full 12-V operation.

Rough and Vibration Service. These lamps are for use where lamps are subjected to shock and vibration while in use. filament construction differs. Rough-service lamps are available from 25 to 200 W, while those for vibration service range from 40 to 150 W.

Decorative Lamps. Incandescent lamps in many bulb shapes, bases, and wattages are available for a variety of decorative and architectural lighting applications. Some have specific requirements regarding burning position, shielding from moisture, etc., as covered in technical literature of the manufacturer.

26.4 FLUORESCENT LAMPS

Fluorescent lamps are low-pressure mercury electric-discharge lamps in which a phosphor coating transforms of the ultraviolet energy generated by the discharge arc into light. The major parts of a fluorescent lamp (hot-cathode type) are the bulb (tube), electrodes, fill gas, phosphor coating, and bases, as shown in Fig. 26-8. When the proper voltage is applied across the ends of the lamp, an arc is produced by current flowing between the electrodes through the fill gas (mercury vapor). This discharge generates some visible radiation, but mostly ultraviolet at 253.7 nm, which in turn excites the phosphor coating to emit light.

Fluorescent lamps are available commercially principally in four distinct types, depending upon their operating circuits: (1) hot-cathode, preheat-starting; (2) hot-cathode, instant-starting; (3) hot-cathode rapid-start; and (4) cold-cathode.

Bulb. Fluorescent lamp bulbs are basically tubular of small cross-sectional diameter. The bulb is available in straight, U-shaped, and circular configurations in bulb diameters from1/4 to 21/8 in. In straight lengths, they range from 6 to 96 in (nominal). Shorter lamps, such as the 22-, 34-, and 46-in T-5 lamps, can simplify the design of luminaires for 600-and 1200-mm module ceiling systems. Circular (circline) lamps have nominal overall diameters from $6^1/_2$ to 16 in. U-shaped lamps are 24 in (hot-cathode) and 45 in (cold-cathode) in nominal overall length. Fluorescent lamps are designated by a letter indicating the tube cross section shape and a number indicating the diameter in eighths of an inch. A T-8 lamp has a tubular bulb of 1 in diameter. Smaller diameter lamps and lower height ballasts can result in "thinner" luminaires. See Table 26-8 for a collection of typical fluorescent lamp size and wattages.

U-shaped models employing $^1/_2$- or $^5/_8$- in-diameter bulbs with little separation between the legs are called "compact fluorescent." in lengths below 9 in, they can have one or more twin tubes. Family designations vary. Subminiature hot- and cold- cathode tubular types are 0.25 and 0.266 in in diameter, respectively, and with lengths from 4 to 20 in.

Electrodes. There are two electrodes in each fluorescent lamp, one at each end, designed to operate as either "hot" or "cold" electrodes (or cathodes).

Hot-cathode lamps contain electrodes which are usually coiled-coil (or triple-coiled) tungsten filaments coated with one or more of the alkaline-earth oxides. By suitable circuit arrangements these cathodes can be heated to an electron-emitting temperature before the arc strikes, or they may be required to act momentarily as cold cathodes until they are heated by bombardment after the lamps ha started. Lamps using these cathodes may be designed to carry currents of 1 to 2 A with low-voltage drop (10 to 12 V) at the electrodes. Some energy-saving types of rapid-start ballasts have disconnect elements to discontinue cathode heating after the lamp starts. The power saved is approximately 3 W per lamp. Metal shields can be used to minimize end darkening, improving lamp lumen maintenance.

Cold-cathode lamps are those that use electrodes of tubular form of iron or nickel which may be coated on their inside surfaces with electron-emitting materials. These cathodes operate at temperatures which limit the lamps to low-current densities. The electrode drop in these lamps is relatively high (over 50 V), but they are not subject to short life as a result of frequent instant starting.

Fill Gas. Droplets of liquid mercury are present in the fluorescent lamp and vaporize to a very low pressure during lamp operation. Argon is added to assist ignition of the discharge in standard lamps, while energy-saving types have an argan-krypton mixture. Certain other types use a combination of argon and neon or argon, neon, and zenon.

Phosphors. The chemical composition of the phosphor coating on the bulb interior surface determines the color of the light produced and, in part, lamp efficacy. Those lamps with phosphors producing good overall color rendering are generally of higher efficacy. Figure 26-9 shows typical spectral power distributions for a variety of different phosphor compositions.

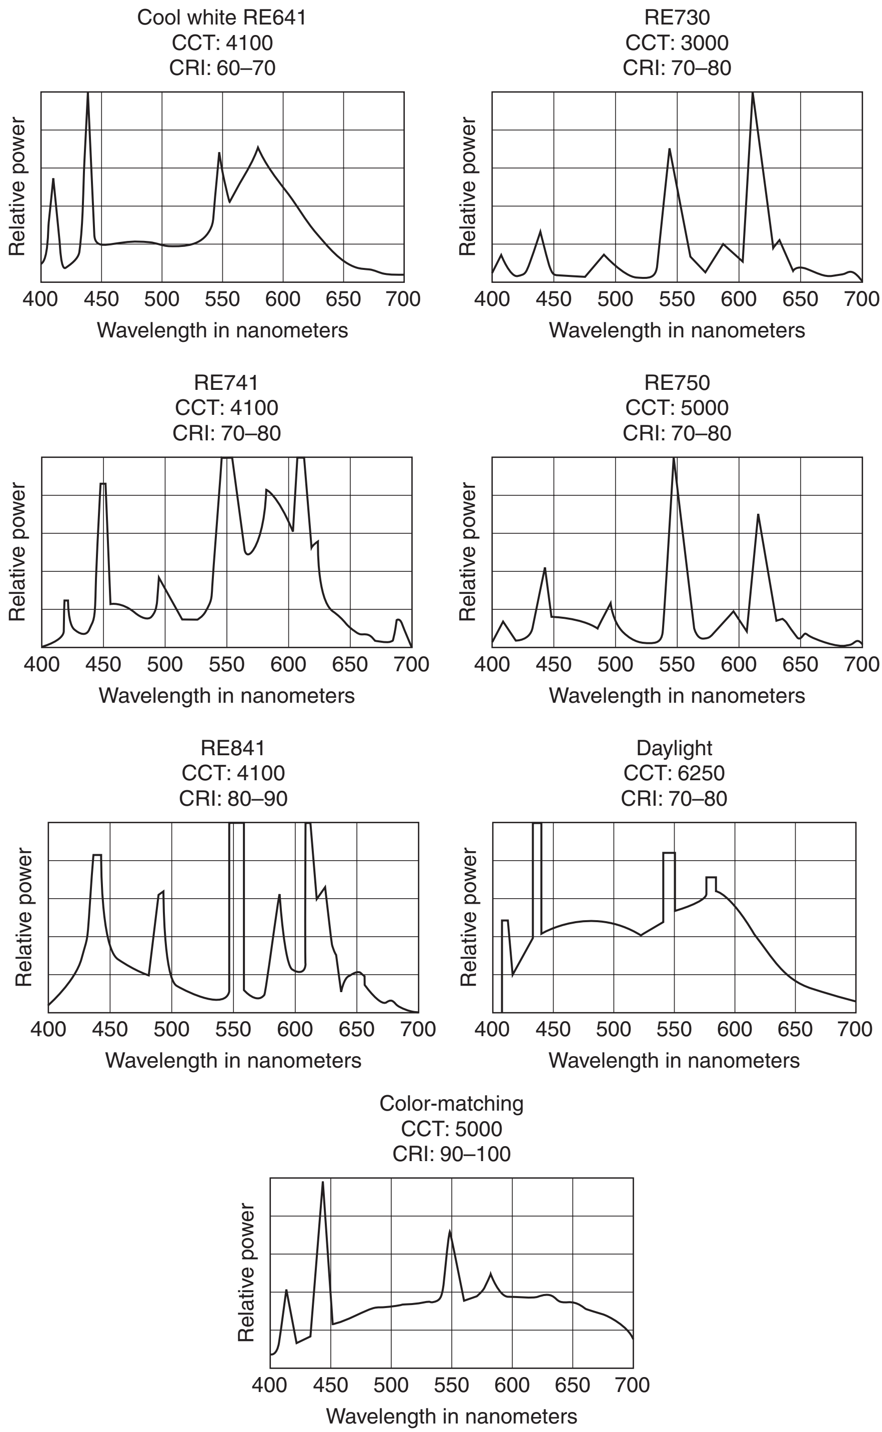

FIGURE 26-9 Spectral distribution curves for typical fluorescent lamps. (*Reprinted from the IESNA Lighting Handbook 9th ed. with permission from the IESNA.*)

The bulbs of some fluorescent lamps have a single, thick inner coat of conventional “halophosphor.” Adding a thin coat of more expensive, rare-earth triphosphors can provide an improved color rendering index (CRI) and increase the efficacy. When a double coat of the triphosphors is used, CRIs are 80 to 90, while retaining the higher levels of lumens per watt. Triphosphor coatings are standard on certain families of fluorescent lamps—check manufactures’ technical literature for current information, and for designations employed with superior-color lamps. Special phosphors are also used in fluorescent lamps designed for plant growth and for black-light effects.

Bases. Lamps designed for instant-start operation generally have a base at each end with a single pin connection. (In some cases instant-start lamps may have two pins at each end electrically connected.) Lamps for preheat or rapid-start operation also have a base at each end, but with two pins (connections) in each. Some manufacturers use a green base finish or print to identify fluorescent lamps which have less mercury and/or pass the toxicity characteristic leaching procedure (TCLP), and therefore are classified as nonhazardous waste in many states. Rapid-start high-output lamps have recessed double-contact bases, and T-2 subminiature fluorescent lamps have axial bases. The circline lamp has a single four-pin connector. Compact fluorescent lamps may have single two-pin or four-pin bases. Four-pin bases are required if the lamps are to be dimmed. See Fig. 26-10 for images of the available fluorescent lamp base types.

Compact Fluorescent Lamps. Energy-conservation activities have focused attention on the relatively low efficacy and short life of general-service 25- to 100-W incandescent lamps widely used in many residential, commercial, institutional, and industrial applications. Compact fluorescent lamps provide significantly higher efficacy and come in a variety of sizes and wattages (see Table 26-9). Shorter models can replace incandescent lamps in existing and new table and floor lamps, in recessed downlights, etc. The $10^1/_2$- and $22^1/_2$-in-long sizes are useful in 1- and 2-ft luminaires, and a three-lamp, 2 by 2 ft recessed luminaire with 40-W twin-tube lamps can achieve so-called “nondirectional” layouts without significant reduction in total luminaire output

compared with 2 × 4 ft units. Designers should check with lamp manufacturers about suitability for dimming.

Medium-screw base adapters are available for installing certain compact fluorescent lamps in 120-V as sockets. Some adapters have integral preheat ballasts, and others contain electronic components. Permanently assembled lamps, starter, and ballast units are also available with medium-screw bases.

Certain adapters can be used with bare compact fluorescent lamps, while other adapters have enclosing globes of various shapes, or reflectors to obtain directional light. Typical input wattages are 5, 9, 13, 18, and 26, considered as replacements for 25-, 40-, 60-, 75-, and 100-W incandescent lamps, respectively.

Energy Distribution. The approximate distribution of energy in a typical cool white fluorescent lamps is shown in Fig. 26-11.

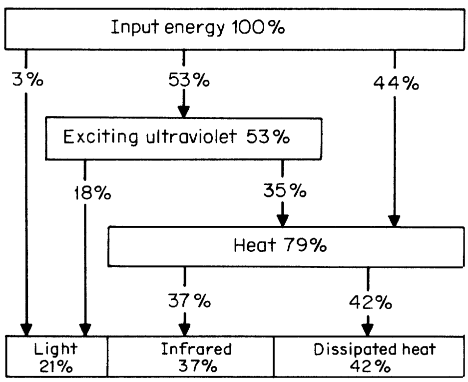

FIGURE 26-11 Energy distribution in a typical fluorescent lamp.

Performance Characteristics. Table 26-8 lists some typical fluorescent lamps for general lighting along with their physical characteristic, rated life, color-rendering index, and rated initial lumen output. Consult ballast manufacturers for input wattage data needed for energy calculations. Table 26-10. contains data for a variety of fluorescent lamp/ballast combinations. Due to the significant savings provided by electronic ballasts, most fluorescent ballasts used today in commercial luminaires are electronic.

The escalation of electronic data-processing equipment and variable-speed motors increased attention given to the harmonic content of electric power systems. Fluorescent-lamp ballasts are known to contribute to total harmonic distortion (THD). Harmonics raise the current in the neutral conductor of 3-phase, 4-wire, wye-connected power distribution systems, even though the phase loads may be reasonably balanced. Some older circuits exist where reduced neutrals are used for fluorescent lighting loads. However, full 100%

capacity neutral conductors have long been recommended for branch circuits serving loads consisting of more than one-half fluorescent lighting. Indeed, some electrical engineers specify cables with single, oversized neutral conductors, cables providing a separate neutral for each phase, transformers designed to handle harmonic loading, etc.

Light output for fluorescent lamps is sensitive to surrounding (ambient) air temperature as shown in Fig. 26-12. Lamp wattage changes in a similar fashion, but not as drastically at ambients below normal. Lamps operated at ambient temperatures below 60°F should be enclosed to conserve their heat. Air movement over the lamp bulb has the effect of lowered ambient temperature. Some CFLs apply a mercury amalgam that provides more stable lumen output over a wider range of temperatures and operating positions.

Fluorescent lamps generally should be operated at voltages within ± 10% of their designed operating points for best performance. Decreased life land uncertain starting may result from operation at lower voltages, and at higher voltages there is danger of overheating of the ballast as well as decreased lamp life. One exception to this is found in the series operation of cold-cathode lamps, where an adjustable voltage supply makes possible operation over a wide range of illumination levels, that is, dimmer operation such as that used in stage lighting.

Failure of a hot-cathode fluorescent lamp usually results from loss of active material from the cathode or cathodes. This loss proceeds gradually throughout the life of the lamp and is accelerated by frequent starting. Depreciation of light output is caused principally by tube blackening and is rapid (as much as 10%) during the first 100 h but very gradual from that point on. For this reason the lamps are rated commercially on the basis of the lumen output after 100 h of operation.

Fluorescent-lamp Operation. Fluorescent lamps are best adapted to operate on ac circuits with reactance ballasts. Typical operating circuits are shown in Figs. 26-13 to 26-17.

Fluorescent lamps are, to a considerable extent, dependent on the characteristics of the ballast equipment. Typical of this is the effect of variations from rated line voltage on the conditions of lamp operation. Certified ballasts made in accordance with industry specifications and periodically field-checked by an independent laboratory are available for the more commonly used fluorescent lamps. They are to be distinguished by the letters CBM on the ballast case. Thermally protected "Class P" ballasts are required for fluorescent fixtures installed indoors, except fixtures with simple reactance ballasts.

The fluorescent lamps, in itself, is inherently a high-power-factor circuit, but the reactive ballast normally used to stabilize the arc is inherently low power factor. Since in the usual circuit the voltage drop across the ballast is approximately equal to that across the lamp arc, the resulting power factor of a single-lamp reactive-ballast circuit is on the order of 50%. For many applications this low power factor is objectionable. In single-lamp ballasts, power factor correction may be obtained by means of a capacitor shunted across the line connections or, where the

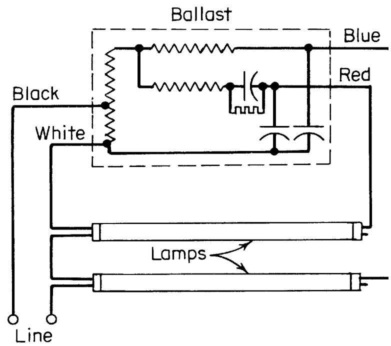

FIGURE 26-15 Two-lamp lead-lag ballast circuit for instant-starting hot-cathode lamps.

lamp requires a higher voltage, by a capacitor across the transformer secondary. The two-lamp ballast, through phase displacement of the lamp currents, or series capacitors, offers a ready means of power factor correction and is usually designed to give a circuit power factor greater than 90%.

All inductive fluorescent ballasts emit a certain amount of noise; the noise increases with the lamp current. A sound rating for ballasts has been developed by some manufactures from A (quietest) of F (noisiest). The amount of cumulative ballast noise, which is tolerable, depends on two sets of principal factors: (1) characteristics of the room and (2) characteristics of the luminaire. Electronic ballasts are generally much quieter than magnetic ballasts and provide an "A" rating.

Where direct current is available at circuit voltages comparable with the open-circuit voltages of the usual ac ballast circuits, fluorescent lamps may be operated from these sources. For such operation, resistance must be added to the usual series reactance ballast (transformer ballasts are not applicable) to limit the operating current to the designed value. This causes a marked reduction in the overall efficacy of the lamp and circuit combination over that obtained in ac operation. Under dc operation, lamps more than a few feet in length will promptly develop a concentration of the mercury vapor at the negative end of the lamps, with the result that only a fraction of the bulb will give

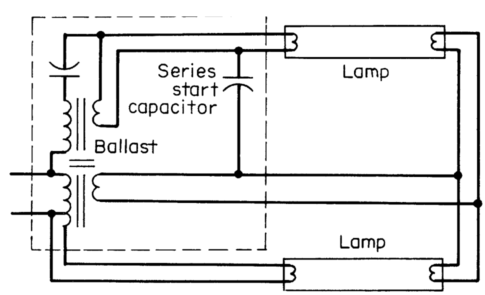

FIGURE 26-17 Two-lamp series rapid-start high-power-factor circuit.

off light. This condition can be overcome through a periodic (about once in 4 h) reversal of the polarity of the lines feeding the lamps. The life of lamps is likely to be shorter on dc.

Dimming. For dimming hot-cathode fluorescent lamps, a number of different arrangements are available. For smooth operation, the lamps on any circuit should be made by the same manufacturer, at the same time, in the same color, and of the same age in use. Group replacement is the most satisfactory procedure. Lamps should be operated free from drafts at 50 to 80°F and should be seasoned 100 h at full brightness prior to dimming. Certain energy-saving lamps are not recommended for dimming applications. Special dimming ballasts are typically required.

Dimming ballasts are available to reduce light output of T-8 and T-12 rapid-start lamps to 1%, 5%, or 10% of full lighting output. Most dimming ballasts are electronic ballasts. Standard T5 lamps can only be dimmed to 5% while T5HO can be dimmed to 1%. Compact fluorescent lamps can be dimmed to either 1% or 5%. Dimming ballasts offer slightly lower lumens per watt than nondimming electronic ballasts. One manufacturer states that dimming from 100% to 1% and to 10% is perceived as 10% and 32% of full brightness, respectively. Various sliding and other types of wall box and wireless dimmer controls are available for dimming control, or in connection with occupant and daylight sensors for automatic energy-conservation systems. Ballasts can be controlled via analog or digital signals, and the controller must be configured to operate the type of ballasts being used. Compatibility with emergency-lighting ballasts should also be explored.

Electronic Ballasts. The use of solid-state electronic elements instead of magnetic components can increase lamp efficacy by higher-frequency operation of lamps, and can reduce input power. This has made electronic ballasts the standard for today's fluorescent lighting systems. Some use a control chip that results in constant light output and energy consumption over a significant range of line voltages. Electronic ballasts are lighter in weight, operate cooler, and can be designed for rapid-and instant-start lamps to meet federal efficacy and FCC EMI/RFI standards. Some models permit dimming of fluorescent lamps, and can be used with appropriate sensors to compensate for changes in daylight illuminance levels. Electronic ballasts cost more than electromagnetic types, but often provide swift payback for the lighting-hours usage and kilowatt-hour rates typical of commercial, institutional, and industrial applications.

Table 26-11 shows the energy-saving potential of electronic ballasts. The annual operating cost values can be adjusted for burning hours other than 4000 h per year, and for kilowatt-hour rates lower or higher than 7 cents. Note that the combination of T-8 lamps and electronic ballasts gives higher system efficacy than other lamp-ballast combinations in the table. Ballast factor is the lumen output of lamps operated on commercial ballasts divided by the lumen output of those lamps operated on a reference ballast.

CBM electronic ballasts have ballast factors of 0.85 or higher, compared with 0.925 to 0.95 for CBM magnetic ballasts. However, fluorescent lamps operate at lower bulb-wall temperatures on electronic ballasts, so a ballast factor of 0.85 will result in approximately the same light output when within enclosed luminaires, compared to magnetic ballasts.

Both electronic and magnetic ballasts generate harmonics in the line current. For electronic types, most modern fluorescent ballasts limit the total harmonic distortion to under 20% or under 10%, neither of which should create problematic current in the neutral conductor. Engineers should check the current ANSI and IEEE 519/587 standards. Reported measurements of compact fluorescent lamps and diode devices for use in incandescent-lamp sockets showed power factors in the 47% to 67% range, and total harmonic distortion (THD) greater than 100%.[1] Although electronic ballasts generally have lower THDs than do magnetic ballasts, check compliance with the requirement of most electric utilities that the THD of electronic ballasts be less then 20%.

Many electronic components are employed in assembling electronic ballasts. Their specific designs are considered proprietary, but Fig. 26-18 gives the block diagram for basic electronic ballasts for fluorescent lamps.*

Most ballasts for T-2, T-4 and T-5 fluorescent lamps sense deactivated-cathode "end-of lamp life" conditions when one or more of the cathodes are depleted. This avoids a potentially hazardous situation when those small-diameter lamps are used with electronic ballasts, which could continue operating a bad-cathode lamp, perhaps causing the glass at that end to melt or crack. Some electronic ballasts for T-8 rapid-start lamps are expected to also incorporate end-of-life shutdown circuits.

Electronic ballasts are classified as rapid-start, instant-start, and programmed start. The latter designation is used for ballasts that contain a microprocessor programmed to preheat the cathodes and increase the starting voltage at an optimum temperature, and to sense end-of-lamp life and disconnect the ballast until the lamp is replaced.

Electronic instant-start ballasts give shorter lamp life than do rapid-start and programmed-start ballasts, but are lower in input wattage. The savings in kilowatt-hours often makes instant-start electronic ballasts the economic choice, unless occupancy sensors (or other causes of frequent lamp cycling) turn the lighting off and on 7 or more times each day. Users should also check with electronic ballast manufacture about level of line inrush current on starting.

26.5 HIGH-INTENSITY DISCHARGE LAMPS

High-Intensity Discharge (HID). This term denotes a general group of lamps consisting of mercury, metal halide, and high-pressure sodium lamps. A mercury lamp is an electric discharge lamp in which the major portion of the radiation is produced by the excitation of mercury atoms. A metal halide lamps is an electric discharge lamp in which the light is produced by the radiation from an excited mixture of a metallic vapor (mercury) and the products of the dissociation of halides (for example, halides of thallium, indium, sodium). A high-pressure sodium lamp is an electric discharge lamp in which the radiation is produced by the excitation of sodium vapor in which the partial pressure of the vapor during operation is of the order of 10^4 N/m^2.

Lamp Construction and Designation. HID lamps consist of a cylindrical transparent or translucent arc tube which confines the electric discharge and the associated gases. That tube is further enclosed in a glass bulb or outer jacket to exclude air to prevent oxidation of the metal parts and to stabilize operating temperatures and significantly reduce ultraviolet radiation emitted by the excitation of the vapors. The mount structure of many HID lamps is anchored to the "dimple top" of the outer glass bulb, assuring greater structural integrity and more accurate alignment of the arc tube. The construction of a typical mercury lamp is shown in Fig. 26-19. The basic elements are the arc tube, fabricated from fused silica and filled with a drop of mercury and a rare gas at low pressure; the electrodes; and the outer envelope, which may or may not have a phosphor coating on the

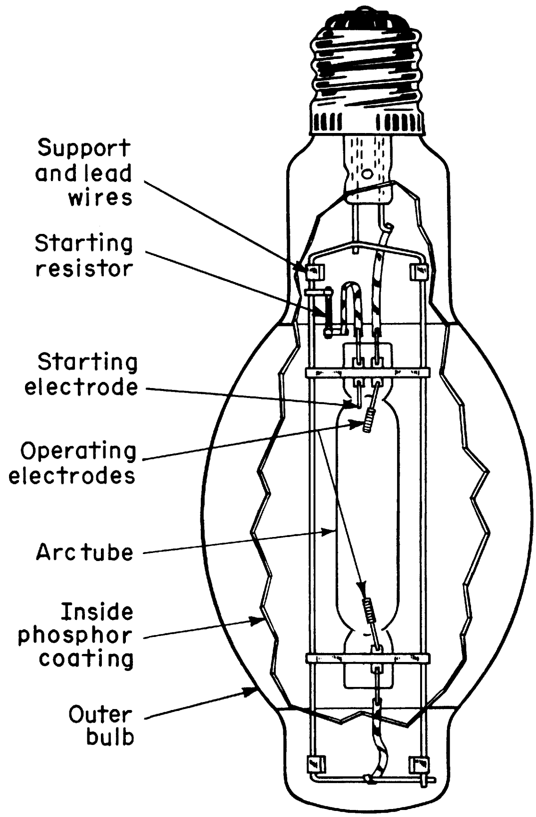

FIGURE 26-19 A 400-W phosphor-coated mercury lamp. Lamps of other sizes are constructed similarly.

interior for improved color rendering. Mercury lamps, due to their relative inefficiency and generally poor color rendering, are rarely, if ever, applied in today's lighting designs.

Metal halide lamps are very similar in construction to the mercury lamp, the major difference being the addition of a metal halide in the arc tube (see Fig. 26-20). The outer bulb may or may not have an inner phosphor coating to improve color rendition, and for lower, more uniform lamp brightness. Special metal halide lamps, with aluminized reflective coatings on the top of the bulb, can reduce glare and help minimize light trespass. There are PAR-and R-bulb mercury and metal halide lamps, xenon metal halide for fiber optic systems, and iodine metal halide to simulate natural daylight.

Metal Halide lamps have historically been susceptible to color maintenance problems due to shifts in their color over time. Recent developments aimed to minimize the occurrence of this problem include special rounded-shape arc tubes, pulse start ignitor technology, and the use of ceramic arc tubes.

The construction of a typical high-pressure sodium lamp is shown in Fig. 26-21. The basic components are the arc tube of translucent polycrystalline or single-crystal alumina, filled with sodium, mercury, and a rare gas (xenon); electrodes; and an outer borosilicate glass envelope. This outer bulb is either clear or contains an inner diffuse coating for more uniform lamp brightness. HPS lamps with twin arc tubes provide quick-restarting when momentary power failures occur. Rated at 40,000-h life, they also are valuable for difficult-to-reach locations.

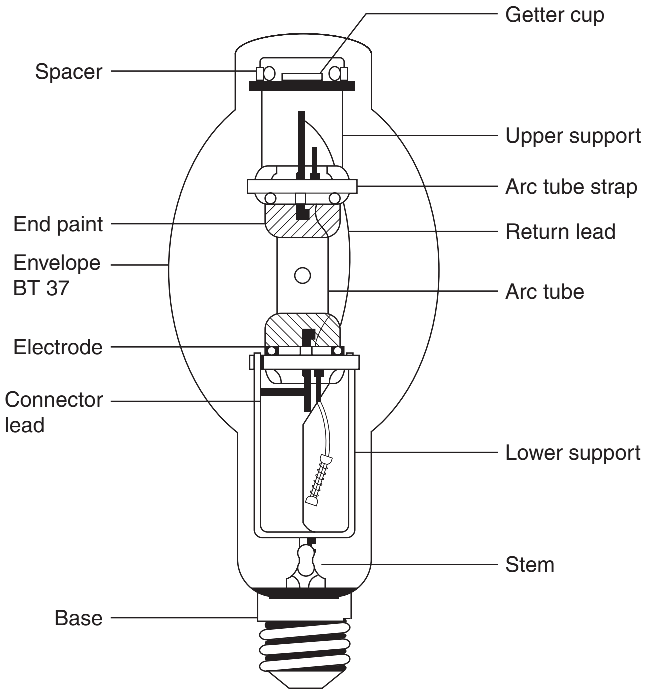

FIGURE 26-20 Construction of a standard metal halide lamp. (*Courtesy of Osram Sylvana.*)

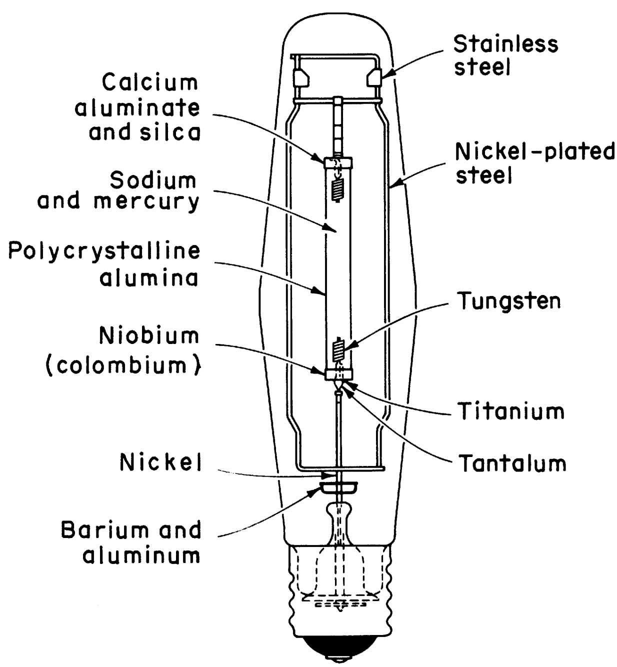

FIGURE 26-21 Construction of a typical high-pressure sodium lamp.

A lamp designation system developed by the American National standards Institute (ANSI) is currently in use.[1] It consists of five groups of letters or numbers: first a letter indicating the type of lamp (H, mercury; M, metal halide; S, high-pressure sodium), followed by an arbitrary number designating electrical characteristics (which relates to the type of ballast required), followed by two arbitrary letters which describe the physical characteristics, then the lamp nominal wattage, and finally letters indicating the phosphor color. An example for a 175-W metal halide lamp would be M57/C/175/U/MED.

Lamp Characteristics. Light output from each of the three types of HID lamps has its own color appearance (chromaticity), and the spectral power distributions vary as shown as in Fig. 26-22. Table 26-12 lists the radiated energy of typical 400-W HID lamps.

Performance Characteristics. Table 26-13 lists some typical metal halide and high-pressure sodium HID lamps for general lighting along with their light output (reference initial and mean lumens). The basis for published data may vary with manufacturer. For a qualitative comparison of HID lamps with incandescent and fluorescent lamps, see Table 26-14.

Many mercury and high-pressure sodium lamps, and some metal halide lamps, can be operated in any position. Other metal halide lamps have restricted narrow ranges of acceptable burning positions, outside of which light output and rated life may be adversely affected. Some metal halide lamps must be used only in enclosed luminaires, or may operate at higher temperatures which would exceed the temperature rating of explosion-proof or other hazardous-area luminaires. Certain metal halide lamps have compact outer bulbs and bases at each end, for smaller display-, sports- and flood-lighting luminaires. Some HID lamps have sufficient ultraviolet output to produce skin burn and/or eye injury, thus requiring specialized luminaires equipped with safety interlocks.

A new family of pulse-start metal halide lamps resulted from studies showing that improved lumen maintenance and color stability of metal halide lamps could result form (1) reducing the

sputtering of tungsten from the electrodes and (2) shortening the starting time.[2] Pulse start metal halide lamps require an ignitor with the proper ballast, and provide increased light output, longer life, quicker warmup, and faster hot restrike as additional benefits.

Another relatively new technology is that of ceramic arc-tube metal-halide lamps. These lamps are generally available in the lower wattages, some in PAR shapes, and provide improved color consistency and very good color rendering. The clear arc tube is replaced with a short translucent ceramic arc tube of similar material to that used in a high-pressure sodium lamp.

HID Lamp Operation. The practical limit of an HID lamp's current-carrying capacity is how high a temperature its enclosing tube can withstand without rupturing. By connecting an impedance in series with the lamp, the current is controlled. In most lamps about one-half the supply voltage is absorbed by a series ballasting device. A variety of ballasts are available for operating lamps, singly or in pairs. Single lamp ballasts may have low (0.50 minimum) or high (0.90 minimum) power factor, 2 lamp ballasts have inherently high power factor. The simplest lamp ballast is the reactor-type used in series with the lamp when line voltage is sufficient for reliable starting. This is not recommended where line-voltage fluctuations exceed 5%. A reactor-type ballast can be used when the line voltage is approximately twice the rated lamp voltage. The autotransformer-type ballast is used on circuits where the line voltage must be changed to suit the lamp requirements. Constant-wattage types of the autotransformer or isolated-secondary design are widely used because of better regulation, low line starting currents, and lower dropout voltage. They are also called *stabilized* or *regulated*. Heavier wiring, oversized circuit breakers, and time-delay relays that may be required by the relatively high starting currents of non-CW and non-CWA ballasts are eliminated with stabilizing ballasts, as the starting current is less than the rated operating current.

One of the limitations of the HID lamp is the effect of power-supply interruptions. In the event of a power interruption or voltage dip lasting for more than 1 cycle, HID lamps extinguish and do not restart for several minutes. The exact magnitude of the voltage drop to cause this condition depends on the ballast design. Regulator ballasts withstand a greater drop than other types. The delay in lamp restarting is caused by the high pressure that develops in the arc tube during operation. The open-circuit voltage of standard ballasts is not sufficient to restart the lamp until the lamp cools and the pressure decreases. In installations where this characteristic might be a safety hazard, the use of a few incandescent or fluorescent luminaires along with the HID units assures emergency illumination until the HID lamps restart. Tungsten-halogen auxiliaries are available for HID industrial luminaires to provide standby illumination in the event of momentary power failure. For indoor and outdoor sports lighting, and other applications where instant restrike is preferable, special ignitor are available, as are special instant-restrike high-pressure sodium lamps. Metal halide lamps with a wire lead (at the end opposite the base) are used with auxiliary ignitors to achieve instant restrike. For aisle lighting in warehouses and other interior and exterior situations where illumination levels for accurate seeing are not needed all of the time, high/low electrical components, combined with occupancy detectors, transmitters, and luminaire-mounted receiver scan provide major energy saving by reducing input wattage 50% to 70% during intervals when the spaces are unoccupied.

26.6 MISCELLANEOUS LAMPS

Low-Pressure Sodium Lamps. These are sodium vapor lamps in which the partial pressure of the vapor during operation does not exceed a few newtons per square meter. Their light output is almost monochromatic, consisting of a double line in the yellow region of the spectrum at 589 and 589.6 nm.

As with other electric discharge sources, a ballast is required. Starting time to full light output is 7 to 15 min, but the lamp will restart immediately after interruption of the power supply. The major application of these lamps is for area lighting and streetlighting where monochromatic yellow light is acceptable and a high luminous efficacy is required. Low-pressure sodium lamps are often applied in the vicinity of astronomical observatories, since the monochromatic light can be filtered out of telescope images.

Glow Lamps. When sufficient voltage is applied to electrodes sealed within a bulb containing neon, argon, or helium, light is produced at the negative electrode. On direct current, one cathode glows; on alternating current, the reversal is so rapid, both electrodes appear to glow. The range of glow lamps is 1/25 W to 3 W. Their useful life varies approximately as the inverse of the cube of the current. A glow lamp has a negative volt ampere characteristic; hence a limiting resistance is used in series with it. In conventional screw-base types, the resistor is concealed in the base. Average lamp life ranges between 7500 and 25,000 h.

Glow lamps have wide use in electronic circuitry, where their action is that of a practically instantaneous switch. At breakdown voltage, the lamp glows, and the switch is closed; at the extinguishing voltage, the lamp current drops to a fraction of its full value and may be considered as nonconducting, or open-circuit in certain circumstances. This on-off characteristic suits the glow lamp to the dichotomy of binary arithmetic as used in computers and logic circuitry in general. Other glow-lamp applications in electronic circuitry include oscillators, pulse generators, voltage regulators, and coupling networks.

Electroluminescent Lamps. This type of lamp is a thin-area source in which light is produced by a phosphor excited by a pulsating electric field. In essence, the lamp is a plate capacitor with a phosphor embedded in its dielectric and with one or both of its plates transparent. Green, blue, yellow, or white light may be produced by choice of phosphor. The green phosphor has the highest luminance. These lamps are available in ceramic and plastic form, are flexible or have a stiff backing, and are easily fabricated into simple or complex shapes. They have been used in decorative lighting, night lights, switchplates, instrument panels, clock faces, telephone dials, thermometers, and aircraft egress marking strips and signs. Their application is limited to locations where the general illumination is low.

Luminance varies with applied voltage, frequency, and temperature, as well as with the type of phosphor. Life is long and power consumption is low. There is no abrupt point at which the lamp fails; the time at which the luminance has fallen to 50% of initial is sometimes used as a measure of useful life. For the ceramic form, this is approximately 20,000 h at 120 V, 60 Hz. Approximate initial current and wattage values per square foot of lamp under these operating conditions are 60 mA and 3.5 W.

Black-Light Lamps.[1] Near-ultraviolet radiant energy (energy not visible to the human eye) causes certain materials to fluoresce or emit visible light. The normal human eye is sensitive only to radiant energy between 380 and 780 nm in wavelength. Thus, lamps that produce primarily near-ultraviolet radiant energy in the 320- and 380-nm range are popularly called *black* lights. This term is quite descriptive, since the ultraviolet energy from the light source cannot be seen by the human eye, but the effects of the radiation on special materials can be visually dramatic.

When black light is directed at a fluorescent material, an energy conversion takes place. The material or chemical sensitive to ultraviolet energy absorbs the energy, then reradiates it at longer wavelengths to which the eye is sensitive.

Mercury lamps with filters to absorb the visible light and transmit the near-ultraviolet are used for fluorescent effects. Called black-light lamps, they are generally enclosed in a red-purple filter glass bulb that looks black. Many materials fluoresce when irradiated by black-light lamps. They are used for theatrical and advertising effects, industrial and food inspection, detection of counterfeits and forgeries, medical diagnosis, insect traps, crime and vermin detection, laundry marking, and copying equipment.

Tubular sources designated as BLB lamps, such as 4-, 6-, and 8-W T-5, 15-W T-8, and 20- and 40-W T-12 lamps, have integral filters and may be operated with the same ballasts as corresponding fluorescent lamps.

The luminance of an irradiated fluorescent material is between 1 and 5 fL with printing inks and between 0.25 and 2.5 fL with interior paints, depending on the color. The apparent brightness increases considerably as the eyes become dark-adapted. Conversely, the effectiveness of black light is greatly reduced or entirely negated by a small amount of visible light.

Short-Arc Sources. Also called "compact arcs," these lamps have glass-enclosed arcs in bulbs containing mercury-argon, mercury-xenon, and xenon, to give the high brightness of carbon arcs, but without their dirty operational and maintenance problems. Principal applications are display systems, optical instruments, projectors, and searchlights.

Sulfur Lamps. Brilliant white light can be produced by using kitchen-grade microwave energy to excite a small quantity of sulfur within an argon-filled quartz sphere of golf-ball size.* The small sphere must be rotated at 300 to 600 r/min to keep the quartz from melting. The light output is said to be 125,000 to 175,000 lumens, and the target efficacy is 110 to 140 lumens per watt, with target input power of 800 to 1200 W.

Induction Lighting Systems. The discharge bulb contains mercury and an inert gas, and the inner surface is coated with phosphor, giving 3000 or 4000 K white light. An axially located power coupler serves as an antenna to radiate 2.65-MHz energy received via coaxial cable from an external high-frequency generator. Light output from the 85 system watts: initial 6000 lumens, mean 4800 lumens, CRI 80+, and rated life 100,000 h. (*Note:* this is the principle used for the 23-W R-25 bulb compact fluorescent lamp listed in Table 26-12.)

26.7 LUMINAIRES AND LIGHTING SYSTEMS

Luminaires. These are complete lighting units consisting of a lamp or lamps together with the parts designed to distribute the light, to position and protect the lamps, and to connect the lamps to the power supply. They are clarified in the CIE.

*Fusion Lighting Inc. Rockville, Md. See also Cook.[2]

(International Commission on Illumination) according to the percentage of light output above and below the horizontal as follows:

Direct	0%–10% upward, 90%–100% downward
Semidirect	10%–40% upward, 60%–09% downward
General diffuse	40%–60% upward, 40%–60% downward
Semi-indirect	60%–90% upward, 10%–40% downward
Indirect	90%–100% upward, 0%–10% downward

This classification system applies to all types of luminaires for general lighting in industrial, commercial, and residential applications.

Lighting systems are installations of one or more luminaires and are classified in a number of different ways. One of these is by CIE distribution type, since these different distributions provide different lighting quality, performance and space appearance.

Direct Lighting. When luminaires direct 90% to 100% of their output downward, they form a direct lighting system. The distribution may vary from widespread to highly concentrating, depending on the reflector material, finish, and contour, and on the shielding or control media employed. Troffers and downlights are two forms of direct luminaires.

Direct lighting units can have the highest utilization of all types, but this utilization may be reduced in varying degrees by brightness-control media required to minimize direct glare. Veiling reflections and shadows may be excessive unless the distribution and location of luminaires are designed to reduce these effects. Large-area units are generally also advantageous since they soften shadows.

Luminous ceilings, louvered ceilings, and large-area modular lighting elements are forms of direct lighting having characteristics similar to those of indirect lighting discussed in paragraphs below. Luminous ceilings may be difficult to apply at low power densities.

Semidirect Lighting. The distribution from semidirect units is predominantly downward (60% to 90%) but with a small upward component to illuminate the ceiling and upper walls. The characteristics are essentially the same as for direct lighting except that the upward component will tend to soften shadows and improve room brightness. Care should be exercised with close-to ceiling mounting of some types of prevent overly bright ceilings directly above the luminaire. Utilization can approach, or even sometimes exceed, that of well-shielded direct units.

General Diffuse Lighting. When downward and upward components of light from surface-mounted and suspended luminaires are about equal (each 40% to 60% of total luminaire output), the system is classified as general diffuse. General-diffuse units combine the characteristics of direct lighting described above and those of indirect lighting described below. Utilization is somewhat lower than for direct or semidirect units, but it is still quite good in rooms with high-reflectance surfaces. Brightness relationships throughout the room are generally good, and shadows form the direct component are softened by the upward light reflected from the ceiling.

Direct-indirect is a special (non-CIE) category within this classification for luminaires which emit very little light at angles near the horizontal. Since this characteristic results in lower luminances in the direct-glare zone, direct-indirect luminaires are often more suitable than general-diffuse luminaires which distribute the light about equally in all directions, especially in spaces involving critical and prolonged seeing.

Semi-Indirect Lighting. Lighting systems which emit 60% to 90% of their output upward are defined as semi-indirect. The characteristics of semi-indirect lighting are similar to those of indirect systems discussed below except that the downward component usually produces a luminaire luminance that closely matches that of the ceiling. However, if the downward component becomes too great and is not properly controlled, direct or reflected glare may result.

Indirect Lighting. Lighting systems classified as indirect are those which direct 90% to 100% of the light upward to the ceiling and upper sidewalls. In a well-designed installation, the entire ceiling becomes the primary source of illumination, and shadows are virtually eliminated. Also, since the luminaires direct very little light downward, both direct and reflected glare will be minimized if the installation is well planned. Luminaires whose luminance approximates that of the ceiling have some advantages in this respect. It is also important to suspend the luminaires a sufficient distance below the ceiling to obtain reasonable uniformity of ceiling luminance without excessive luminance immediately above the liminaires.

Since with indirect lighting the ceiling and upper walls must reflect light to the work plane, it is essential that these surfaces have high diffuse reflectances, but low specular reflectances. Care is needed to prevent overall ceiling luminance from becoming too high and thus glaring.

Control of Light Distribution. This is usually accomplished through reflection, refraction, transmission, absorption, and diffusion using glasses, plastics, metals, and woods, of various shapes, reflectance, transmittance, absorptance, polarization, and finish. Reflector contour shapes include parabolic, ellipsoidal, hyperbolic, and spherical. Refractors (lenses) utilizing prisms, cones, and spherical shapes are commonly used to produce a wide range of light-controlling devices. Flat or contoured diffusers are used to diffuse, color, or polarize the light according to the lighting needs.

Lighting systems are also classified in accordance with their layout or location with respect to the visual task or object lighted—general lighting, localized general lighting, and local (supplementary) lighting.

General Lighting. Lighting systems that provide an approximately uniform level of illumination on the work plane over the entire area are called general lighting systems. The luminaires are usually arranged in a symmetrical plan fitted into the physical characteristics of the area and blend well with the room architecture. They are relatively simple to install and require no coordination with furniture or machinery that may not be in place at the time of the installation. Perhaps the greatest advantage of general lighting systems is that they permit complete flexibility in task location. Since they illuminate the entire space to the same level, they may provide more light than is necessary in certain parts of the room, and therefore consume more energy than needed.

Localized General Lighting. A localized general lighting system consists of a functional arrangement of luminaires with respect to the visual task or work areas. It also provides illumination for the entire room area. Such a lighting system requires special coordination in installation and careful consideration to ensure adequate general lighting for the room. This system has the advantages of better utilization of the light on the work area and the opportunity to locate the luminaires so that annoying shadows and direct and reflected glare are prevented.

Local Lighting. A local lighting system provides lighting only over a relatively small area occupied by the task and its immediate surround. The illumination may be from luminaires mounted near the task (task lighting) or from remote spotlights. It is an economical means of providing higher illumination levels over a small area, and it usually permits some adjustment of the lighting to suit the requirements of the individual. Improper adjustments may, however, cause annoying glare for nearby workers. Local lighting, by itself, is seldom desirable. To prevent excessive changes in adaptation, it should be used in conjunction with general lighting that is at least 20% of the local lighting level; it then becomes *supplementary lighting*. This combination of a local and general system is generally referred to as task-ambient lighting. Task ambient lighting can provide excellent energy efficiency because high illuminance levels are applied only where needed.

Application Considerations. There are many utilitarian, esthetic, energy-efficiency, and economic considerations that influence the selection of light sources, luminaires, and lighting system for interior spaces. The choices are simple for illuminating a janitorial closet, but increasingly difficult for areas requiring reasonably inconspicuous luminaires which provide the quantity and quality of light that enable rapid and accurate seeing of critical and prolonged visual tasks.

Changes in building design and escalating construction costs have combined to lower ceiling heights in typical commercial and institutional spaces. The expansion of computers and word processors containing visual display terminals (VDTs) brought many shiny, curved, near-vertical tasks of relatively low contrast into the visual environment. The parabolic troffer was for many years the lighting solution in office environments. The general environment provided by these luminaires often appears somewhat dark due to the low luminance of the ceiling plane. Appropriately configured pendant-mounted lighting systems with some amount of uplight generally provide higher quality office lighting, since these systems can both limit veiling reflections and provide higher overall space brightness.

Commercial and Institutional Interiors. In such spaces, the need exists to limit direct glare, reflected glare, and veiling reflections by selecting luminaires with appropriate luminous intensity distributions and finishes of furniture and room surfaces, as well as task reflectances, that provide appropriate illuminance levels and achieve luminance ratios within recommended limits (no greater than 3:1 or 1:3 for the task to the near surround and no more than 10:1 or 1:10 between the task and the far surround.)

As discussed above, a widely used luminaire type is the recessed troffer, with prismatic, parabola-shaped or other louvered enclosures. Standard sizes are 1 × 4 ft, 20 × 48 in, 2 × 2 ft, and 2 × 4 ft. The 3- and 4-in deep parabolic louvers are popular when critical and prolonged seeing tasks are involved, or where inconspicuous lighting systems are desired.

Pendant luminaires are available in a variety of distributions, shapes, and sizes. T8 lamps are the most common lamps in these luminaires, but the small diameter of T5 lamps generally provides for better optical control and permits smaller pendant luminaire cross sections.

Hard-metric* recessed luminaires are available as a result of the 1994 policy requiring them in future construction projects of all U.S. federal agencies. Later the 1996 Savings in Construction Act passed in the 105th Congress mandated that hard-metric luminaires must not be more costly than soft-metric[†] models.

Computer monitors are increasingly available with finishes that are less susceptible to reflected glare, and as a result, luminaires such as recessed direct-indirect troffers are being promoted by some manufacturers to provide environments with more vertical illuminance for walls and other surfaces. These large square of rectangular units, with all the components above the ceiling plane, contain shielded fluorescent-lamp luminaire elements positioned to direct all or most of the light to white-finished curved or sloping sides, but are actually a CIE direct luminaire distribution. The tendency of these recessed direct-indirect luminaires to produce direct or reflected glare is similar to that of lensed luminaires, and is a function of their luminance.

Specialized models of small- and large-cell parabolic louvers in recessed and surface-mounted luminaires are designed to meet standards of the Illuminating Engineering Society of North America for spaces with VDTs. Parabolic luminaires expected to be used with T-8, high-lumen compact, and other rare-earth phosphor fluorescent lamps should be equipped with low-iridescence aluminum louvers.

The National Electrical Manufacturers Association provides dimensions to help ensure compatibility with conventional generic systems for ceiling suspension. Dimensions are provided for a variety of different ceiling systems, along with cross-section details showing how the luminaires interface with the ceiling systems[1].

Combining Lighting and Air Conditioning. Families of recessed fluorescent-lamp luminaires (troffers) are designed to provide the additional function of bringing cool or warm air into interior spaces and to take air out of those spaces, thus eliminating or minimizing the need for supply air diffusers and return air grilles. The air-supply function is accomplished by slots along the bottom edge of the luminaire sides, above which sheet-metal air connectors (frequently called *airboots*—see Fig. 26-23*a*) spread out the conditioned air received by 5-, 6-, and 7-in flexible ducts form larger plenum ducts. Air connectors can be above one or both side slots, can be internally insulated or uninsulated,

and can have volume-control dampers. The luminaire side slots can include air pattern-control blades (Fig. 26-23*b*), which are field positioned to be closed (static), at 45° for horizontal air supply, and vertical (fully open) for vertical air supply. Side slots may also be used to return air to the plenum, or to connect directly to a ducted air return system.

Room air can also be pulled through the lamp compartment of troffers by creating negative air pressure in the plenum and building in suitable air entry and air exist openings in the luminaire. By this process, considerable lamp and ballast heat is then expelled through top openings into the plenum. Called *heat transfer* or *heat exhaust*, such luminaires can significantly reduce the heat sent into the occupied space below, increase light output because of the more optimum temperature inside the lamp compartment, and provide a thermal environment for more favorable ballast life.

Air-handling luminaires can combine both the air supply and heat-transfer return air functions, called *combination units* in Fig. 26-23*c*, which shows the top heat-transfer openings, and the two end openings (Fig. 26-23*d*), which allow room air to enter the lamp compartment.

Iuminaire mounting issues. Incandescent- and HID-lamp luminaires for surface and recessed applications are widely used for downlighting, wall washing, etc. Surface or recessed track with suspended, adjustable incandescent luminaires is popular for display and localized lighting in stores, restaurants, art galleries, museums, etc. See the latest edition of the NEC for special requirements, such as thermal protection for incandescent and HID recessed luminaires, minimum clearances for clothes closets, and wattage and temperature markings.

Fluorescent-lamp luminaires designed for surface mounting are of the prismatic wraparound, metal-box, or bare-lamp (strip) types. If such luminaires are to be installed on combustible low-density cellulose fiberboard, they must be listed for that condition, or be spaced at least $1^1/_2$ in from the surface of the fiberboard.

Industrial Interiors. Luminaires with fluorescent lamps are often preferred for low-bay industrial spaces, generally involving mounting heights 12 ft or less above the floor. Eight-foot units with center-V reflectors and 96 in 800 mA "high output" lamps frequently produce lower overall cost of light than slimline and 1500-mA models, although the extra-high-output type normally results in

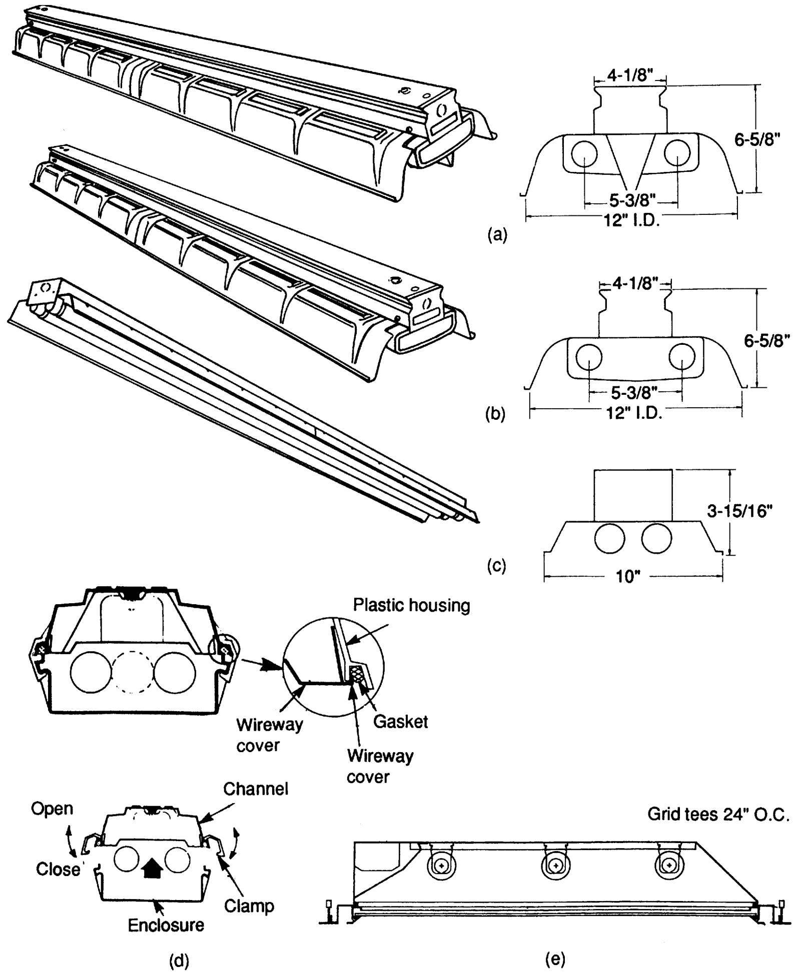

FIGURE 26-24 Industrial fluorescent-lamp luminaire types for nonhazardous areas.

most favorable initial cost. Units with four 4-ft lamps are popular with many plant engineers and maintenance supervisors because of the shorter bulb length. Figure 26-24 shows the wide top slots that give approximately 25% upward light, and the center-V providing greater reflector rigidity and 30° crosswise shielding, which improves visual comfort by reducing direct glare, especially when luminaires are oriented so the long dimension is at right angles to the predominant direction of the worker's line of sight (called *crosswise viewing*). Other models without center-V reflectors frequently have narrower top slots giving approximately 10% upward light and 13° crosswise shielding (Fig. 26-24*b*). Economical luminaires have more shallow 10% uplight or closed-top reflectors (Fig. 26-24*c*). Steel reflectors are most common, with porcelain-or baked-enamel finish.

T5 fluorescent lamps are also applied in industrial lighting where high output linear lamps can be grouped together in a single luminaire to provide sufficient light output for use in high bay applications where HID luminaires are typically applied. Traditional high-bay luminaires with round aluminum, glass, or acrylic reflectors (Fig. 26-25) are also available with multiple compact fluorescent lamps instead of HID lamps. These systems can provide multiple light levels through switching of

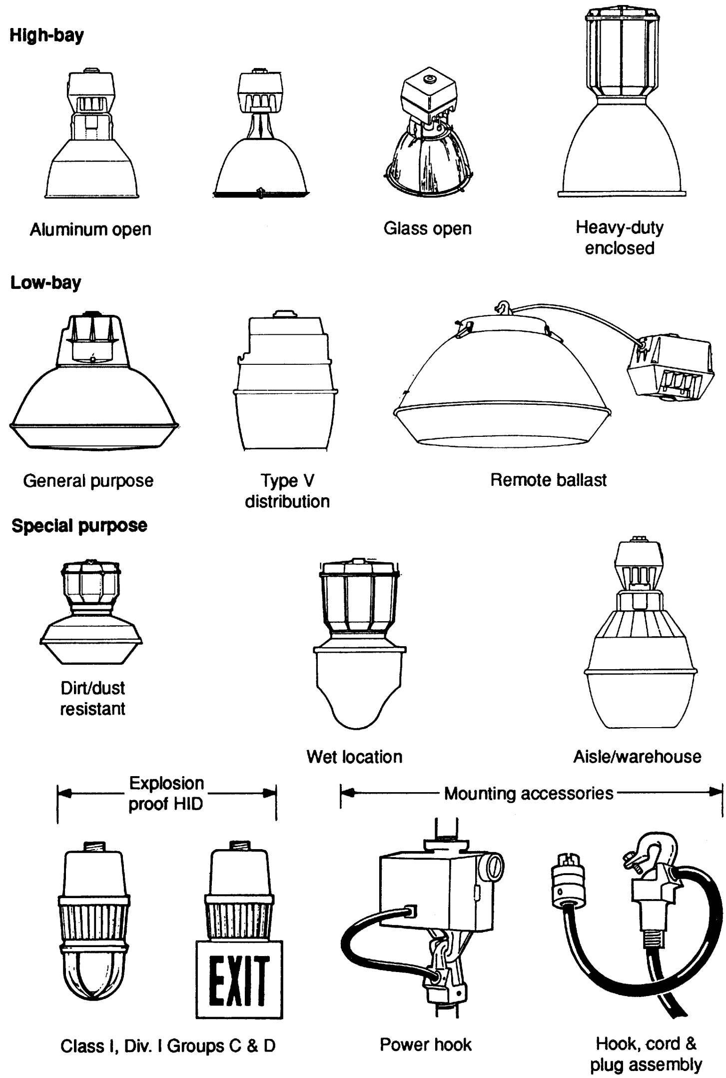

FIGURE 26-25 Industrial HID and incandescent lamp luminaire types and mounting accessories, and two explosion-proof models.

different groups of lamps in the same luminaire, and have been applied in warehouses, stores, gymnasiums and numerous other applications.

Specialized nonhazardous area industrial fluorescent luminaires include enclosed types for dirt- and moisture-resistant applications (Fig. 26-24*d*), recessed troffers for clean rooms (Fig. 26-24*e*), and compact fluorescent supplementary lighting units. Classifications of hazardous areas are defined in the NEC. Advice of the insurance carriers for the hazardous spaces involved is recommended to confirm appropriate classification before installing fluorescent, HID, or incandescent luminaires designed for hazardous areas.

Metal halide and high-pressure sodium industrial luminaires are prevalent for production, warehouse, and other industrial areas. Metal-halide lamps have color characteristics that are superior to high-pressure sodium. High-pressure sodium systems generally result in more rapid payback for situations where minimum energy consumption is the goal and color rendition is an insignificant factor. However, the warm color of high-pressure sodium may be judged undesirable, especially if the visual tasks are such that the high-pressure sodium light would adversely affect seeing speed or accuracy. For example, workers may be less able to see small defects in brass and copper tasks, compared with other light sources.

Figure 26-25 shows typical HID industrial luminaires. High-bay units are generally for mounting heights of 18 ft or more above the floor, where cranes or maintenance catwalks simplify the task of relamping and reflector cleaning. Low-bay models are often selected when luminaires need to be positioned 13 to 18 ft above the floor, and periodic maintenance can be performed with portable scaffolding or lift trucks. Both the high- and low-bay types can employ remote ballasts. Integral or remote, the ballast must be suitable for the ambient temperature involved at the luminaire location.

A variety of HID luminaires are designed for specific purpose, and manufacturers provide mounting and wiring accessories that expedite installation and maintenance. Fuses (single for 120- and 277-V circuits, and double for 208, 240, and 480 V) can be located either in the ballast assembly or inside the power hook. Since regular HID lamps will not immediately restart after a momentary power interruption or a severe voltage dip, a tungsten halogen lamp inside the reflector can provide standby illumination for safety during the few minutes the high-pressure sodium or metal halide lamps are out. A "hot restrike" option is available for metal halide and high-pressure sodium systems. All HID ballasts produce some noise—for quieter operation of HID luminaires, encased and potted ballasts are available.

Merchandise and Display Lighting. Systems achieving the "3 A's" of store lighting (attraction, appraisal, and atmosphere) utilize many luminaire types to (1) call attention to featured items; (2) reveal their inherent characteristics and color; and (3) provide an appropriate, stimulating environment. Some stores may have free-standing racks and open cases, where essentially uniform illuminance is suitable. Or important sales areas may be arranged so that luminaires could be selected or grouped to produce nonuniform illuminance. Still others may have showcases with glass tops and fronts, where certain types or positions of overhead luminaires might cause bothersome reflections that reduce the visibility of merchandise inside the case. Niches can have built-in linear or incandescent lighting, and track, surface, and recessed luminaires are widely employed for vertical displays.

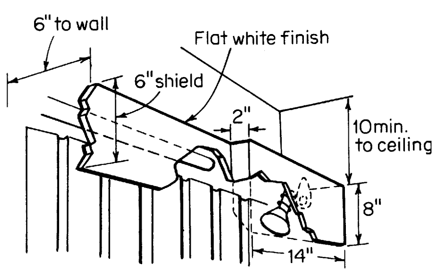

FIGURE 26-26 Valance and spotlight.

Figure 26-26 illustrates a wall-lighting valance that has a spotlight in the end section, which is separately controlled for highlighting. The shelf valance (Fig. 26-27) is useful for books, merchandise, and art objects, and for tasks not affected by veiling reflections. The room divider (Fig. 26-28) is applicable where unobtrusive divisions of space are desirable. Consult other references[2] for additional solutions.

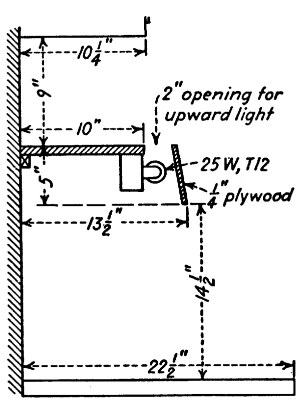

FIGURE 26-27 Shelf valance.

Structural Lighting. Lighting systems that form a substantial part of the structure of a building, as distinguished from individual or groups of luminaires suspended from the ceiling or bracketed to walls, are examples of structural lighting.

A luminous ceiling of suspended plastic or other material is one such form (Fig. 26-29). Luminous ceilings are used less frequently today due to their relative inefficiency. One of the more common forms of structural lighting used today is an illuminated ceiling cove, where a recessed ceiling area is indirectly illuminated from a small shelf around the perimeter through the use of either bare lamp strips, or reflector luminaires designed to direct light out onto the ceiling. In most cove applications, the luminaires or lamps are hidden by the lip of the cove.

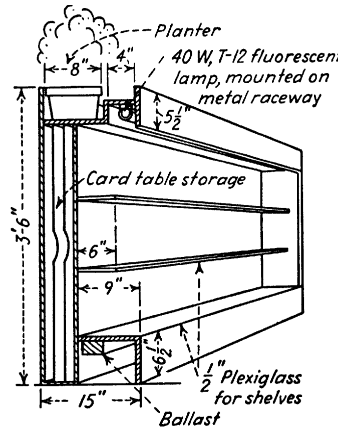

FIGURE 26-28 Room divider.

Codes and Standards. Local codes, national codes, international codes, federal standards, professional standards, and manufacturers' *standards* relate to specific requirements, which must be met in the construction and installation of a luminaire. Standards usually relate to minimum requirements (safety, construction, or performance), which may be exceeded to provide a better product.

Some codes and standards deal with fire and safety (electrical, mechanical, and thermal); others relate to performance (photometric) and construction (materials and finishes). They will vary to some extent depending on geographic location and end use of equipment. Conformance to the appropriate set of specifications is often determined by certified laboratory tests. Certification is often denoted by an identifying label. Local inspection agencies may or may not rely on conformance to national, federal, or industrial codes and standards.

Information regarding local codes may be obtained from electrical inspection departments. Several other code jurisdictions may apply to regional and state codes. The National Electrical Code (NEC) and similar codes in most major countries throughout the world state specific electrical requirements, which must be met by all electrical equipment, including luminaires. They have been developed by safety protection and inspection agencies in conjunction with fire-protection agencies.

The Underwriters' Laboratories, Inc. (UL) and similar groups in other countries publish minimum safety standards for electrical and associated products which are in conformance with the respective electrical codes of their country. They have testing laboratories to which equipment must be submitted for listing. Most manufacturers design luminaires to meet these standards.

The Life Safety Code[3] (National Fire Protection Association 101) covers the requirements of exit signs and emergency lighting. Many models of standard and emergency exit signs are designed to meet NFPA-101 luminance standards, and retrofit kits permit easy conversion to more efficient sources. Signs equipped with battery packs must remain lighted a minimum of 90 min when their normal electric power fails. Engineers are encouraged to check for enactments of specific states regarding the required positions (such as requirements for not only the overdoor location, but also a low-level exit sign) and performance attributes (letter configurations, color, etc.) of exit signs.

Building codes also have requirements for egress lighting. The NFPA-101 *Life Safety Code* identifies occupancies that require emergency lighting. Most codes call for lighting the exit passageways

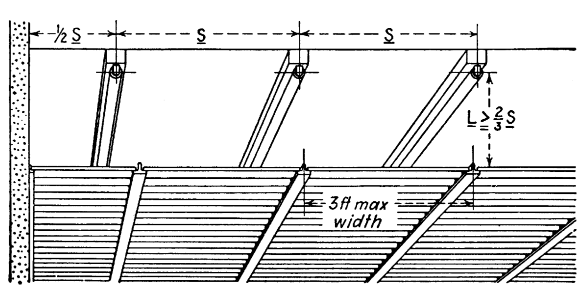

FIGURE 26-29 Luminous ceiling.

to a minimum illuminance of 1 fc on the floor for a period of $1^1/_2$ h after normal power fails. Luminaires containing fluorescent emergency ballasts having suitable, continuously charged battery packs can be positioned to meet requirements with acceptable uniformity. Ballasts providing instant restrike of high-pressure sodium luminaires are also available.

In addition to construction and safety standards, there are national and state energy-efficient lighting regulations which followed the federal Energy Policy Act of 1992. For commercial buildings, provisions of the latest ASHRAE/IESNA Standard 90.1, 2004 may prevail. Except for emergency lighting powered by battery, generator, or other alternate power source, which is automatically off during normal building operation, under this standard the lighting system must adhere to the following.

1. In buildings larger than 465 m^2 (5000 ft^2), automatic lighting shutoff of building lighting is required in all spaces, except for lighting specifically designed for 24-h use. This may be accomplished on a scheduled shutoff basis or through occupant sensors.

An independent schedule must be provided for areas up to 2323 m^2 (25,000 ft^2), but not more than one floor.

Spaces with ceiling-height partitions must have at least one control device to independently control the general lighting within the space, actuated manually by an occupant or automatically by sensing an occupant.

2. Luminaires for one or three fluorescent lamps greater than 30 W each must use two-lamp tandem-wired ballasts instead of single-lamp ballasts, when two or more luminaires are in the same space, and on the same control device. This does not apply to recessed luminaires more than 3 m (10 ft) apart measured center to center, individually mounted surface or pendant luminaires, luminaires with single-lamp electronic ballasts, luminaires with no available pair, or luminaires on emergency circuits.

3. Internally illuminating exit signs shall not exceed 5 W per face.

The 90.1 Standard includes important sections on installed interior lighting power and luminaire wattage. Power limits are computed by either the "building are" or the space-by-space method. Tables give maximum lighting power density (LPD) in watts per square foot for typical interior spaces. For example, enclosed offices are 1.1 W/ft^2, open-plan offices are 1.1 W/ft^2, classrooms/lecture/training spaces are 1.4 W/ft^2, and restrooms are 0.9 W/ft^2, and so on. The standard should be reviewed so that various exceptions can be considered. Other examples are for exterior lighting of a building entrance with canopy, 1.25 W/ft^2; without canopy, 30 W/ft of door width; and 0.2 W/ft^2 for lighting vertical facade area, or 5 W/ft of illuminated wall or surface length.

Legislation requiring adherence to ASHRAE/IESNA 90.1 varies considerably among the states. Engineers are urged to check with appropriate agencies for latest information. Certain states mandate statewide conformance to state-developed energy codes for commercial buildings which meet or exceed ASHRAE/IES 90.1.

The desire of commercial, industrial, and institutional facility managers to reduce costs while maintaining and/or improving the visual environment for occupants also adds to the priority placed on energy conservation in lighting systems. Fortunately, major progress has been made in rating the combined efficacy of luminaires and the lamps and ballasts they contain. Also, modest-cost lighting control devices are available, which quickly pay for themselves by saving energy. See further information, see the subsection on energy conservation later in Sec. 26.9. There are also opportunities and benefits from integrating lighting with other building systems.

26.8 LUMINAIRE PHOTOMETRIC DATA

Types of Photometric Data. Luminaire manufacturers provide laboratory-measured and computed photometric and physical data required for lighting system analysis. The physical data include dimensions, finishes, light-control materials, number of lamps, types of lamps, etc. The photometric data include a luminous intensity (candela) distribution, zonal lumens, luminaire efficiency, coefficients of utilization, luminances, and for some systems, visual comfort probability (VCP) values.

Luminous Intensity (Candela) Distribution. A luminous intensity or candela distribution curve is a graphical presentation of the distribution of light about a lamp or luminaire. Such presentations contribute valuable information to guide the lighting designer in determining the suitability of lighting equipment for application in various fields. As a background for using distribution curves, it is first necessary to understand how they are obtained.

The candelas in any direction from a light source equals the illumination produced on a plane at right angles to the light rays times the square of the distance from the lamp to the point of measurement ($I = E \times D^2$). For accurate measurements the distance should be at least 5 times the largest dimension of the source.

To get sufficient data for a lamp or luminaire, readings are usually taken at a series of horizontal and vertical angles around a luminaire. Vertical angles may range from 0° (straight down) through 180° (straight up) with a spacing of 2.5°, 5° or 10°, while for most indoor luminaires, readings generally have a horizontal angle spacing of 22.5°. Horizontal symmetry and lack of uplight or downlight may limit the number of angles that are needed to fully describe a luminaire's intensity distribution. The luminous intensity values are typically plotted on a polar plot (Fig. 26-30) and may be shown for more than one horizontal angle when the distribution varies across the different axes. The line connecting a series of such points forms the intensity distribution curve. For concentrated light sources such as searchlights and spotlights, photometric readings are often required to be 1° or 2° apart.

The luminous intensity values reported for a particular manufacturer's luminaire apply to a particular lamp and its rated lumen output. If a lamp of identical physical size and light distribution, but having different rated lumens is applied in the luminaire, the luminous intensity values can simply be modified by the ratio of the rated lamp lumens for the new lamp

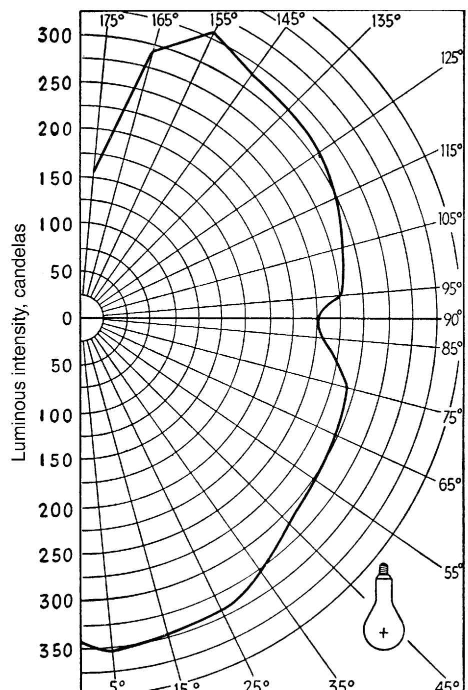

FIGURE 26-30 Distribution curve of a 3700-lm 200-W incandescent lamp. For convenience, the curves of axially symmetrical-type units show a single angle that is repeated at all other horizontal angle (0° or 360°). Luminous intensity in candelas is often referred to as a *candlepower distribution curve*.

versus the photometric test lamp. If the lamp is of different size or different distribution, then a new photometric report is needed to accurately quantify the luminaire's modified intensity distribution.

Zonal and Total Lumens. The total lumens of a light source are obtained by adding the lumens in the various angular zones. The zonal lumen values are readily computed by multiplying the average candelas around a lamp or luminaire at the center of a vertical angle zone by the zonal constant for that zone. For example, in Table 26-15, at 55°, which is the center of the 50° to 60° zone, the 300-cd reading from Fig. 26-37 is multiplied by 0.90, the zonal constant for this zone, giving 270 lm in that zone for the 200-W lamp. Zonal constants for the usual 18 test zones are simply numerical values of the solid angle subtended by that zone, which is the area in square feet within each zone on the surface of a sphere having a radius of 1 ft.

Luminaire Efficiency. The efficiency of a luminaire is expressed in terms of its lumen output divided by the rated lumens of the lamp or lamps. For example, if the 200-W lamp in Fig. 26-30 is placed in a white-glass enclosing globe whose candlepower distribution shows an output of 2960 lm, the efficiency of the luminaire is 2960 divided by 3700, or 80%.

Coefficients of Utilization. A coefficient of utilization (CU) is a number used in general lighting calculations and represents the ratio of the lumens received on the work plane from a uniform layout of luminaires to the lumens emitted by the luminaires' lamps alone. CUs are calculated using a uniform method and are tabulated for various room shapes and reflectances and are applied in the lumen method (discussed later).

Luminance and VCP. Average luminances calculated at various luminaire angles are part of direct-glare evaluations of VCP. Calculated VCP ratings of lighting installations using specific luminaire photometry, for various size rooms of given reflectances and illumination levels, may be reported. These ratings express the percentage of people who, if seated in the most undesirable location

within the installation (4 ft from the center of the back wall and 4 ft above the floor), will be expected to find it acceptable. VCP was developed to quantify the glare of lensed fluorescent troffers, although it is often also applied to parabolic troffers. It cannot be applied to small downlights, HID luminaires, or luminaires with uplight, so its utility is somewhat limited. The CIE provides an alternate glare evaluation system, unified glare rating (UGR), that may apply to a wider range of luminaire types, but it is not widely used in the United States.

Luminaire Spacing Criteria (SC). The maximum permissible spacing for a luminaire is given in the Photometric Report provided by the manufacturer. These spacing limitations are related to the mounting height (usually above the work plane) and apply only to direct and semidirect luminaires. The maximum luminaire spacing center-to-center should not exceed the SC value times the mounting height (MH) and are often listed for the directions along and across the lamps for linear fluorescent luminaires. Observance of such limitations usually will ensure satisfactory uniformity of illumination throughout the major portion of the room so that all parts of the area will be equally suitable for the intended use. Peripheral areas may require special treatment, as indicated below. Illuminance is usually considered uniform if the maximum and minimum values are within plus or minus one-sixth of the average illuminance in the area. Closer spacing than indicated by the spacing criterion improves uniformity and reduces shadows. For luminaires with a large portion of light directed upward, computer software that performs point-by-point calculations can be applied to assess system uniformity.

The distance between luminaires and the wall should not exceed one-half the distance between luminaires. Where desks or benches might be located along the wall, the distance between luminaires and the wall should not exceed $2^1/_2$ ft. Likewise, the ends of continuous rows of fluorescent luminaires should preferably be within 6 to 12 in of the wall, unless this would provide a high luminance "scallop" on the adjacent wall. Additional luminaires or luminaires having a greater number of lamps may be required adjacent to the walls, particularly where walls have low reflectance. Where direct and semidirect luminaires are used under such conditions, the perimeter luminaires should be carefully located to avoid shadows on the task from the worker.

26.9 LIGHTING DESIGN

General Process. The lighting-design process can be broken down into four major parts: (1) determining the project goals, (2) collecting the space criteria and selecting the desired lighting system performance criteria, (3) making design decisions, and (4) evaluating the completed project. The design process may require changes in decisions (3) until the project goals have been satisfied.

Project Goals. These are the conceptual objectives of a whole project. The designer must have knowledge of the appearance requirements of the job, including the style of the architecture; whether a corporate image is to be projected; whether construction is for long life or of a speculative nature; whether young or old persons will be using the facility; and any other objectives of the project which will affect the lighting design.

Space Criteria. These are criteria which originate from outside the engineering discipline. They include identification of visual tasks and their locations and frequency, space dimensions, workplane locations, reflectances, daylight apertures, space temperature and dirt conditions, voltage, operating schedules, cost budgets, power and energy budgets, and codes. These criteria should represent the best available information which can be obtained from the owner, architect, or designer.

Performance Criteria. These are criteria which originate from within the illuminating engineering discipline. They include illuminance levels for task performance and safety, visual comfort data, luminance ratios, other quality considerations. These criteria can be found in various American

National Standards Institute practices (Office,[1] School,[2] Industrial,[3] Roadway[4]), in IES recommended practices and committee reports and in the IES Lighting Handbook.

Lighting design has long been known to involve more than selecting and positioning luminaires to provide recommended illuminances on visual tasks, wherever they are located in horizontal, inclined, or vertical work planes. The Committee on Quality of the Visual Environment of the Illuminating Engineering Society of North America, and that society's application committees, have developed matrices of quality issues for various types of interiors (Table 26-16 and Fig. 26-31). These matrices remind engineers and designers of specific aspects (source/task/eye geometry, color appearance, flicker, direct glare, etc.[1]) which merit very important, important, somewhat important, or no consideration for the areas involved. For example. industrial spaces might have matrices with sections for basic tasks identified as raw-materials processing, materials handling, component manufacture, machining, assembly, warehouse and storage, inspection, service spaces, welding, and manual crafting. Some applications could be subdivided—for instance, the warehouse and storage section might have three rows of criteria ratings, indicating the priority of consideration for inactive, active and active (small items). The assembly section could have rows for simple, moderately difficult, difficult, very difficult, and exacting assembly. These matrices appear in the IES Lighting Handbook.

Design Decisions. All the above criteria along with the project goals need to be evaluated when making major design decisions. These major decisions include light-source selection, luminaire selection and mounting, maintenance-procedure determination, calculation-methods selection, luminaire-layout arrangement, and control planning (switching, dimming). Decisions involving tradeoffs and compromises are often necessary.

Evaluation. No design process is complete until one has evaluated the results to see that the project goals have been met. Computer software and hand calculation methods exist to provide detailed point-by-point work plane or room surface analysis grids or average work plane illuminance for evaluating lighting layouts during the design phase. Many of these programs are also able to provide

informative computer renderings of the luminance patterns across a space. The lighting designer should also evaluate the interior. Battery-powered emergency incandescent-lamp units are widely employed to light aisles and corridors of industrial buildings, and equipping a predetermined portion of fluorescent luminaires with emergency ballasts can provide the prescribed illuminance levels for persons to leave their workstations and follow planned routes of egress. Such ballasts utilize high-temperature nickel-cadmium batteries, which results in fluorescent-lamp light output of sufficient duration to meet life safety code and UL standards (Table 26-17). Models are listed for both magnetic and electronic ballasts, for linear and compact fluorescent lamps, as combination units for both normal and emergency operation. In larger buildings, the emergency power source may be a generator that powers a number of different circuits within the building.

See Sec. 26.5 (paragraph on HID lamp operation) for standby illumination when HID lamps are extinguished by severe voltage dips or momentary power failures.

Veiling Reflections. Substantial losses in task contrast and hence in visibility and visual performance can result when light sources are reflected in such subtly specular (shiny) visual tasks as typing on bond paper. The apparent *veil* that is cast over a task when a light source is reflected in it may be so subtle as to be undetectable by the eye. Many factors contribute to veiling reflections and each of them, individually, has long been known. The problem is to integrate the effects of these interrelated factors. The factors are the visual task and its specularity; the worker's orientation, location, and viewing angles; and the lighting-system layout and luminaire light distribution and polarization.

The following are guidelines for reducing veiling reflections:

1. Where possible, written or printed tasks should be on matte paper using nongloss inks. The use of glossy paper stock and hard pencils should be minimized.
2. Light-source positions on either side and behind the workers are preferred.
3. Where work positions can be determined, substantial gains can be made by not positioning lighting equipment in the general area above and forward of the occupant's position for horizontal tasks, or at a position where veiling reflections would result for tasks of other orientations.
4. The use of luminaires with specific distributions and polarization characteristics for reducing reflections should be considered.
5. Side lighting such as from windows is effective in reducing veiling reflections. From the standpoint of visual comfort, workers should be positioned so their line of sight is parallel to or away from windows—rather than facing them.
6. Any decision on a lighting installation should also include considerations of its efficiency and the visual comfort in the space.

VDT (Computer) Criteria. One of the most common visual tasks that presents special lighting considerations is the visual display terminal (VDT). Although the front of the VDT is self-illuminated and the alphanumeric characters are visible without external lighting, there are typically other paper-background seeing tasks whose visibility are dependant on general or localized lighting systems. In

†Special conditions may require different levels of illumination.

addition, overall environmental luminance considerations call for general (ambient) illumination, which can be provided from a variety of luminaire distributions, all the way from totally direct to totally indirect.

A major specialized consideration involves the location and luminance distribution of luminaires in spaces containing VDTs, and the geometric relationship of the VDT screen to these luminaires and to windows. Luminance ratios should be no more than 3:1 between paper-based visual tasks and an adjacent VDT screen or dark surface, and the same 3 to 1 ratio applies between the VDT screen and an adjacent dark surface. For adjacent light surfaces, the corresponding luminance ratio is 1:3. For remote dark surfaces, the maximum ratio is 10:1, and for remote lighter surfaces, 1:10. To control direct glare, and to largely avoid bothersome reflections in the VDT screen, the average luminance of direct luminaires in the lengthwise, crosswise, and 45° vertical photometric planes at 55° from nadir should preferably not exceed 850 cd/m^2, 350 cd/m^2 at 65°, and 175 cd/m^2 at 75° or more from nadir. The average luminance should never exceed 850, 350, and 175 cd/m^2 at 65°, 75°, and 85°, respectively. Movable task lighting should not exceed 50 fc on the horizontal work plane (see IESNA publication RP-1-04, American National Standard Practice for Office Lighting).

Indirect systems should not exceed 850 cd/m^2 of ceiling luminance at any angle, or more than 8:1 (preferably 4:1) in uniformity. Luminaires with both upward and downward light components should have luminances of 850 cd/m^2 or less at angles between 55° and 90° in the crosswise, lengthwise, and 45° vertical photometric planes.

Visual Comfort. Visual comfort may occur when there are no overly high luminances within a worker's visual field. High luminances can also distract and even reduce visibility. Luminaires and fenestrations which have luminances that are too high for the environment in which they are located will produce discomfort. Discomfort from direct glare is reduced by

1. Decreasing the luminance of lighting equipment or other sources of objectionable glare, such as windows and overhead skylights.
2. Diminishing the area of uncomfortable luminances (with glare zone luminance constant).
3. Increasing the angle between the source and line of sight.
4. Increasing the general luminance in the room.

A rating system based on the degree of freedom from discomfort glare in a proposed lighting installation is called visual comfort probability (VCP). This system is limited to use with direct-lighting fluorescent troffers and cannot be applied to HID luminaires, CFL downlights, and many other direct distribution luminaires. Evaluation is based on the following factors which influence subjective judgments of visual comfort: room size and shape; room-surface reflectances; illumination levels; luminaire type, size, luminance, maximum luminance, and light distribution; number of luminaires; luminance of the field of view; observer location and line of sight; and differences in individual glare sensitivity. Since each of these factors can vary considerably, a standard set of conditions has been established and used as a basis for VCP tables.

Direct discomfort glare should not be considered a problem in lighting installations if all three of the following conditions are satisfied:

1. The VCP is 70 or more.
2. The ratio of maximum to average luminaire luminance does not exceed 5:1 (preferably 3:1) at 45°, 55°, 65°, 75°, and 85° from nadir, crosswise and lengthwise.
3. Maximum luminaire luminances, crosswise and lengthwise, do not exceed the following values:

Angle above nadir, deg	Maximum luminance, (cd/m^2)
45	7710
55	5500
65	3860
75	2570
85	1695

Luminance Distribution. The luminance relationship of the various surfaces in the visual field is important. When the eyes scan a task, an adaptation level is established consisting primarily of the task luminance. As the eyes leave the task and look at an area of a different luminance, there is a sudden loss of sensitivity to see the contrast of the detail in the new area until the eyes can readapt after a short length of time. In order to see the detail of a visual task accurately and quickly, luminance ratios of appreciable areas in the visual environment should be kept low. Table 26-18 is an example of recommended luminance ratios for offices (ANSI/IES RP-1-04, American National *Standard Practice for Office Lighting*). To help achieve these ratios, room surface should be of high reflectance, as recommended for specific applications.

Energy Conservation. In any lighting design it is important to consider the following recommendations for the reduction of energy used for lighting. They are appropriate for designing new construction, in renovation work, and in operating and maintaining existing installations.

1. Design Lighting for Expected Activity (Appropriate Illuminance for Seeing Tasks, with Less Light in Surrounding Nonwork Areas). In some interiors (general offices, classrooms, certain production spaces, etc.) where work stations are in close proximity to each other, the task areas represent a high percentage of the total work plane (length times width), and therefore reasonably uniform task-level illuminance is appropriate throughout the space. In other cases, private offices, for example, the visual tasks may be critical and prolonged for only 20 to 30% of the work plane (such as the tops of the desk and credenza of the single occupant). The lighting designer, thus, has the opportunity to conserve energy by reducing illuminance in the nonwork portions of the room. Such energy savings are in addition to those received by lowered illuminance levels in hallways, other circulation areas, storage spaces, etc.

Open-plan offices often have movable furniture containing linear fluorescent task lighting, and low partitions which subdivide the space to give worker privacy. Luminaires mounted under overhead cabinets or shelves should be positioned if possible to avoid veiling reflections, and a convenient “on-off” switch should be provided. Such supplementary luminaires should be selected to provide illuminances throughout the task area which adequately augment levels of the general lighting system, since the contribution from the general lighting system may be reduced by the height of the shelves, cabinets, partitions, etc.

2. Design with More Effective Luminaires and Fenestration. The goal of both daylight and artificial illumination systems is to produce visual environments which result in rapid and accurate seeing. The goal is achieved in an energy-conserving manner by selecting luminance distributions and luminaire positions which enhance task visibility. For example, desks, drafting tables, and many other types of workstations involve paper-background tasks which use pencil, ink, typed, photocopied, or printed characters which have a specular component of reflection. Such tasks are best lighted from the side. With some acoustical ceiling-suspension systems, recessed fluorescent luminaires can be easily moved as work stations change, especially if the luminaires are powered by plug-in “flexible” wiring cables and connectors (Fig. 26-32). Luminaires for three or four fluorescent lamps can be wired to two wall switches for manual selection of 50 or 100% illuminance if two two-lamp ballasts are involved, and for 33, 67 or 100% if one single-lamp and one two-lamp ballast operate a three-lamp luminaire. Such switching arrangements conveniently permit reduced illuminance

TABLE 26-18 Recommended Luminance Ratios for Offices*

To achieve a comfortable balance in the office and limit the effects of transient adaptations and disability glare, it is desirable and practical to limit luminance ratios between areas of appreciable size from normal viewpoints as follows:

1–√3	between task and adjacent light surroundings
1–√3	between task and adjacent dark surroundings
1–√5	between task and more remote darker surfaces
1–√10	between task and more remote lighter surfaces

*These ratios, 3:1 or 10:1 are recommended as maximums; reductions are generally beneficial.

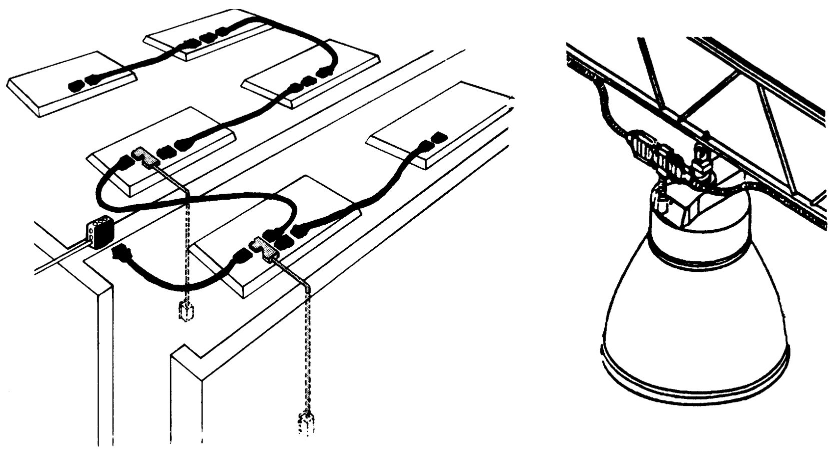

FIGURE 26-32 Flexible (plug-in) wiring systems for (a) commercial/institutional recessed and (b) industrial HID luminaires.

when it is adequate to supplement daylight in spaces with windows, and for the less demanding visual tasks during cleaning operations.

Daylight in areas which include exterior windows can be applied to save electric energy consumed by the electric lighting system. Because the quantity and quality of daylight varies greatly, windows require adjustable shades and blinds to control direct glare. Desks and other work stations should be oriented to minimize body shadows and to minimize veiling reflections (see IESNA publications RP-5, *Daylighting*).

Analysis of owning and operating charges can anticipate the present worth of future expenditures in a method known as "life cycle costing." Periods of 10 to 20 years are usually chosen as the "life" of a typical illumination system. The known or estimated time that future costs are expected to occur are converted to net present values. Such evaluations best show the economic benefits of more efficient, energy-conserving lighting systems.

3. Use Efficient Light Sources (Higher Lumen per Watt Output). Increased lamp efficacy obviously saves energy. Incandescent lamps have lower lumens per watt than any other family of general-service lamps. Also important are the annual hours that lighting is needed in a given space.* Table 26-12 lists many other characteristics that must be considered in selecting lamps. Some lumen per watt (lpw) guidelines:

Incandescent:

For equal life, lpw increases with wattage.

For comparable incandescent lamp options, increased life generally means lower lpw.

Krypton gas fill lamps give energy savings over lamp life.†

Tungsten-halogen capsules can give more lpw, or longer life, or both.

Undervoltage operation lowers lpw and increases life.‡

*Because of its small size and instant starting, and especially because of the low burning hours per year, incandescent lamps are the standard for broom closets even though their efficacy is low.

†Krypton-filled 34-, 52-, 67-, 90-, and 135-W longer-life lamps have lower efficacy than do 40-, 60-, 75-, 100-, and 150-W lamps.

‡For example, a 130-V 1000-h, 150-W argon-filled incandescent lamp operated at 120 V would have average life of approximately 1950 h, and produce initially approximately 2140 lm instead of its 2800-lm-rating if operated at 130 V.

Fluorescent:

32-W T-8 lamps are an obvious choice for 4-ft luminaires—greatly superior to 34-W cool white T-12 lamps in lumens per watt and CRI.

For given tube diameter and lamp current, long lamps have higher lpw than short lamps.

Longer burning hours per start increase lamp life.[§]

High CRI lamps using rare-earth phosphors have improved lpw as well as color rendition.

Compact fluorescent lamps can replace incandescent lamps in downlights, supplementary and adjustable task lights, and residential floor and table lamps.

System efficacy ratings should combine lamp, ballast, and luminaire performance.

High-intensity discharge:

If color is no factor, high-pressure sodium has highest lpw, long life, and good lumen maintenance. Metal halide provides good lpw and color. Since light output can decrease if operated in positions other than designated by the lamp manufacturer, a "tilt factor" is appropriate in design computations.

Standard Metal Halide lamps, in general, have noticeable problems with color consistency. Lamps shift to different shades of white and may not emit a uniform color of white light across all lamps in a system. Ceramic metal halide lamps and specially shaped arc-tube lamps help limit the color shift that occurs.

White high-pressure sodium lamps with 70 plus CRI ratings at 2800 K can be used with incandescent lamps (check for available wattages). 3200-K metal-halide lamps can be considered for retail and other commercial applications where warmer light-source color is desired.

4. Use More Efficient Luminaires. If a lighting system can deliver lumens to the work plane more efficiently, the wattage needed to achieve desired illuminance levels should be reduced, provided the luminaire intensity distribution is appropriate for the application being considered. Luminaire efficacy rating (LER) expresses, to the nearest whole number, the rated lumens per watt of a specific luminaire, equipped with specific lamps and ballasts.

The determination of LER considers luminaire efficiency to the nearest two-place decimal (three-place decimals may be used if desired), ballast factors rounded to the nearest two-place decimal, and input watts rounded to the nearest whole number. NEMA LE 5-2001 provides details on the calculation of LER[6], calling for photometry in accordance with IESNA LM-41, and defines the procedure for calculating ballast factor. Preceding the LER number in manufacturers' literature are two letters, indicating the luminaire category: FL = fluorescent recessed lensed, FP = fluorescent recessed parabolic, FW = fluorescent wraparounds, FS = fluorescent strip, and FI =

A similar NEMA Standard LE 5B-1998 for open (HO) and closed-bottom (HC) HID industrial luminaires[7], considered to have ballast factors of 1.0, gives minimum LERs for these luminaire types. Exempted are luminaires for HID lamps less than 150 W, special-application luminaires such as for hazardous areas, and luminaires using automatically switched quartz-lamp standby circuits.

Since rated ballast(s) input wattage is generated independently of photometric testing, existing photometric tests in compliance with IESNA LM-46 can be used to compute LER values. Because a variety of ballasts can be used with many luminaire designs, the specific ballast type must be reported in conjunction with the LER. See LE5B for further information.

1 Use Thermally Controlled Luminaires. Figure 26-12 shows that the ambient temperature near the luminaire, and the extent to which the heat produced by lamps and ballasts is retained, will have considerable effect on the light output. Tests show that maximum lamp efficacy occurs when the

[§]However, cathode improvements have greatly reduced the life penalty of shorter operating cycles. Combinations of lamp and energy cost may recommend turning off fluorescent lighting even for intervals as short as 10 min or less when the illumination is not needed.

lamp cold-spot temperature is approximately 104F.[8] A four-lamp 40-W troffer 2 ft wide and 4 ft long with a prismatic enclosure can have temperatures up to 120 to 130F inside the lamp compartment, which can account for approximately a 15% reduction in light output. By passing room air through the lamp compartment (called "heat transfer" or "heat exhaust"), a thermal condition more favorable to light production can be achieved, and less of the lighting heat enters the occupied space.

2 Use Lighter Finishes on Ceilings, Walls, Floors, and Furniture. IES recommended practices for various types of interiors list desirable reflectances for room surfaces and furniture. For commercial and institutional interiors these would be 80 to 90% for ceilings, 50 to 70% for walls, 40 to 70% for partitions, 25 to 45% for furniture, 25 to 45% for office machines and equipment, and 20 to 40% for floors. Similar values are suggested for industrial spaces (except not less than 20% for floors), realizing that they are much more difficult to control, and pointing out that some color can be stimulating. Because lower CRI lamps are widely used in factory areas, the colors should be selected while illuminated by the type of lamps under which they will be seen.

Turn Off Lights When Not Needed. Because time is a factor in the formula for electrical energy, programs to conserve energy should minimize the operation of lighting systems when spaces are unoccupied, even for a modest period appropriate for the *traffic* pattern. This is an owner benefit and energy-saving procedure, in addition to varying illuminances to supplement daylight, and to fit tasks that have higher or lower visual demands.

Building codes/standards such as ASHRAE/IESNA 90.1 mandate switches in each space and auto-shutoff. Clock switches can turn luminaires on and off, and can activate either or both of two circuits wired to three- and four-lamp luminaires, as previously mentioned. A central processing unit could provide the capability for preset, digital, and automated control, plus override arrangements when lighting is needed during normal off periods.

Occupancy sensors can also control lighting systems, with adjustable time intervals after infrared or ultrasonic beams sense the presence or absence of people in the space covered. Some take the place of wall light switches for use in private offices and other small spaces. Specifiers should compare features available from different manufacturers.

In warehouses, shipping docks, and many outdoor lighted areas there are numerous times when illuminances can be reduced to save energy if "full output" is provided almost instantly and automatically when needed. High-low components using occupancy detectors of the passive infrared or ultrasonic type can be positioned to sense motion in areas leading to warehouse aisles, for example, which could be operating as low as 30% of normal wattage. A coded signal would be transmitted without control wires to receivers located in metal halide or high-pressure sodium luminaires, resulting in near instant normal light level. A short interval after the motion ends, the luminaires would switch back automatically to the low illuminance level. The infrared occupancy detector/transmitters are smaller and work best outdoors and in low-temperature locations. Ultrasonic models have better sensitivity, can respond to the slightest motion, and are particularly effective over narrow warehouse aisles. General-purpose transmitters permit switches, relays, photocells, or time clocks to operate the high-low system.

8. Keep Lighting Equipment Clean and in Good Working Condition. Early in the design stage, lighting equipment should be selected that will be easy to maintain: to change lamps, to periodically clean reflecting and light-transmitting components, and to easily reach ballasts and other electrical auxiliaries. It is also important to mount luminaires so that maintenance personnel can have access for servicing, or provide means for lowering equipment to more convenient levels. The continuing effectiveness of lighting systems depends on good maintenance. In existing facilities, systematic reevaluations may reveal maintenance procedures which reduce the consumption of lighting energy.

Programs should include considerations of (1) group replacement of lamps at 70% to 80% of expected average lamp life and (2) scheduled luminaire cleanings that help the owner receive the light which the system was designed to provide. Both justify higher light loss factors to reduce the number of luminaires needed. Lighting maintenance companies in metropolitan areas can be engaged to perform relamping, cleaning, and repair functions, and to provide proper cleaning compounds, ladders, scaffolds, etc. In-house maintenance departments should develop and post instructions which cover procedures and frequency of different services, coordinated to minimize disruption of essential activities.

Lighting and the Thermal Environment. Effective building design requires a provision for efficient utilization of dissipation of lighting heat. The benefits of integrating building heat in lighting design are: (1) improved performance of the air-conditioning system, (2) more efficient handling of lighting heat, and (3) more efficient lamp performance if fluorescent lamps are the light source.

The control and removal of lighting heat before it enters the occupied space can reduce heat in that space, reduce air changes and fan horsepower, lower temperature differentials required in the space, enable a more economical cooling-coil selection because of the higher temperature differential across the coil, and reduce luminaire and ceiling temperature, thereby minimizing radiant effects.

The degree to which any of these benefits may be obtained depends on many variables such as the quantity of energy involved, the type of heat-transfer mechanism, the temperature difference between source and sink, and the velocity and quantity of air available for heat transfer.

26.10 QUANTITY AND QUALITY OF ILLUMINATION

Lighting is provided so that people can perform visual tasks. Visual performance is a function of a number of fundamentally important factors. Some of these are the size of the object or detail to be seen, the contrast of the detail with its immediate background, the luminance of the object, the time available to see it, the luminance relation between the object and its surroundings, the visual capability of the human seeing machine, and the level of personal motivation.

The difficulty of the visual task is determined by the size and contrast of the task details. Other factors being equal, small tasks require more illuminance for a given level of visual performance than larger tasks. Similarly, low contrast between the task details and their background justifies higher illuminance levels. The IESNA procedure for selecting illuminance[5] employs seven generic types of interior activity, identified by the first seven letters of the alphabet, as described in Table 26-19, Letter categories A, B, and C, called for modest levels of general lighting throughout the spaces. Categories D, E, and F required minimum illuminances on the task, and G involves higher illuminances on more difficult tasks, obtained by a combination of general and local (supplementary) lighting.

In the past, modifications to these recommended illuminance levels were made based on characteristics of the space, task and age of the occupants. In the current method, the IESNA provides less guidance on when to increase or decrease the recommended values, but suggests that 1/3 increase or decrease to these values be applied if actual conditions or the occupant's age justifies such a change.

26.11 CALCULATING MAINTAINED ILLUMINANCE

Maintained illuminance is the illuminance that will be provided by a lighting system at some future point in time, and generally considers a variety of light-loss factors. Lighting systems are generally designed so that the maintained illuminance prior to cleaning, relamping, etc. is near the target illuminance level. A new and clean lighting system, therefore, will typically provide work plane illuminance levels above the target level to account for the losses that occur over time.

Light-Loss Factor. In calculating maintained illuminance (the lowest level before maintenance procedures are instituted) a light-loss factor (LLF) is used to take into account losses in light output due to temperature and voltage variations, ballast factors, lamp position (tilt) factors, equipment operating factors, thermal factors, dirt accumulation on luminaire and room surfaces, lamp depreciation, maintenance procedures, and atmospheric conditions. The effect of these light losses can be seen in the example shown in Fig. 26-33. It is important that all causes of light loss be investigated and maintenance procedures be established in the lighting-design stage to assure adequate illumination is provided in an economical manner without wasting energy.

LLF Determination. The LLF (formerly called maintenance factor) is mainly the product of the ballast factor (BF), lamp lumen depreciation factor (LLD), the luminaire dirt depreciation factor (LDD), the room-surface dirt depreciation factor (RSDD), and lamp burnout factor (LBO). Other factors such as ambient temperature factor (for fluorescent) and voltage-to-luminaire factor (for incandescent) may also be applied. Data on LLD are available from lamp manufacturers. LBO is the

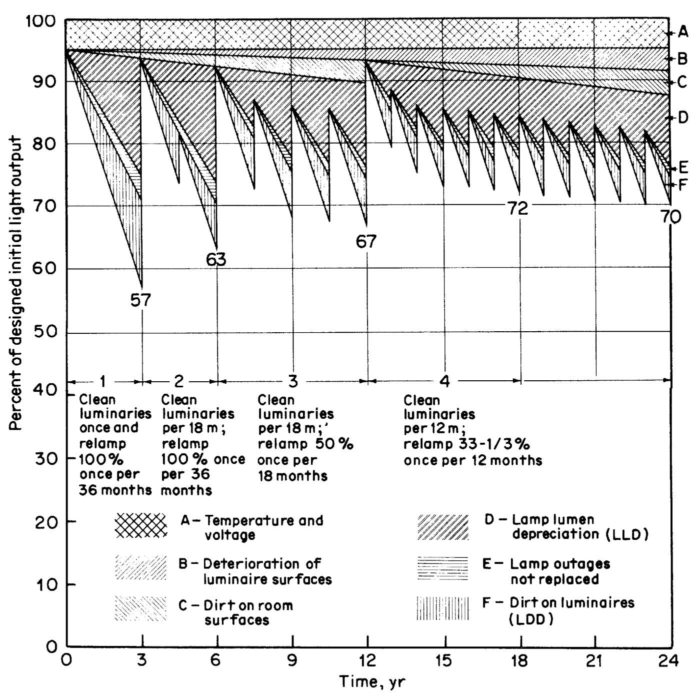

FIGURE 26-33 Effect of light loss on illumination level. Example shown is for enclosed surface-mounted luminaires with 40-W fluorescent lamps, operated 10 h a day, 5 days per week, 2600 h per year. Four maintenance system are shown for comparison purposes.

ratio of lamps remaining lighted to the total in the original installation, if burnouts are not replaced immediately. LDD is obtained from curves, such as shown in Fig. 26-34, a knowledge of the amount of dirt in the room atmosphere, a knowledge of the length of time between luminaire cleanings, and the luminaire maintenance category, a Roman numeral from I to VI, which is based on the luminaire type (see Table 26-20). RSDD is obtained from a curve and table as shown in Fig. 26-35, where room size, luminaire distribution, room atmosphere, and cleaning cycle are known.

Example of calculation procedure. Given a direct type of luminaire of category IV, with 32-W fluorescent lamps (LLD = 0.92. Room atmosphere is very clean and cleaning is performed every 18 months. Room-cavity ratio is 2. Lamps are replaced at burnout.

BF = 0.94 (from ballast or luminaire manufacturer)

LLD = 0.92 (mean lumens/initial lumens form manufacturer's lamp tables)

LDD from Fig. 26-34 5 0.91

RSDD from Fig. 26-35 = 0.98

LBO = 1

$\mathrm{LLF} = 0.94 \times 0.92 \times 0.91 \times 0.98 \times 1.0 = 0.77$

26.12 CALCULATION OF AVERAGE ILLUMINANCE

General Lighting. The design of general lighting systems is governed by room dimensions, structural features, reflectances of room surfaces, mounting height of the luminaires, and the distribution and maintenance characteristics of the luminaire. The choice of the luminaire depends on the service to which it is to be put, which assumes a certain experience in selection, or other aids such as manufacturers' data, which assist the designer in making a selection appropriate from the standpoint of freedom from glare, efficiency, decorative value, and economy. The ultimate "luminance pattern" of the room is an important factor in the design.

The beginning concept of general lighting design is that of delivering a specified average illuminance level to a horizontal plane in a room. The light generated by the lamps in such a system is variously affected and considerably reduced by reflection, diffusion, and absorption as it impinges on reflectors and transmitting media in the luminaires and on ceilings, wall, floors, and on the objects in the room.

The Lumen (Zonal-Cavity) Method.[1] The lumen method is used in calculating the illuminance that represents the average of all points on the work plane in an interior. It is based on the definition of illuminance as luminous flux per unit area, or

where luminous flux is expressed in lumens. If the area is in square feet, the illuminance is in footcandles (lumens per square foot); if the area is in square meters, the illuminance is in lux (lumens per square meter).

Because not all the lamp lumens will reach the work plane owing to losses in the luminaire and at the room surfaces, they must be multiplied by a coefficient of utilization which represents the portion that reaches the work plane.

Since, the design objective is usually to maintain a minimum value of illuminance, factors must be applied to account for the estimated depreciation in lamp lumens, the estimated losses from dirt collection on the luminaire surfaces (including lamps), etc., that occur over time, or due to system components.

The zonal-cavity method considers the actual room as being made up of a ceiling cavity above the luminaires, a floor cavity beneath the work plane, and a room cavity located between the two (see Fig. 26-36).

In the general case, all these cavities are present. In the case of recessed or surface-mounted luminaires, the ceiling cavity is simply the ceiling. When the illuminance on the floor is to be determined, the floor cavity becomes the floor.

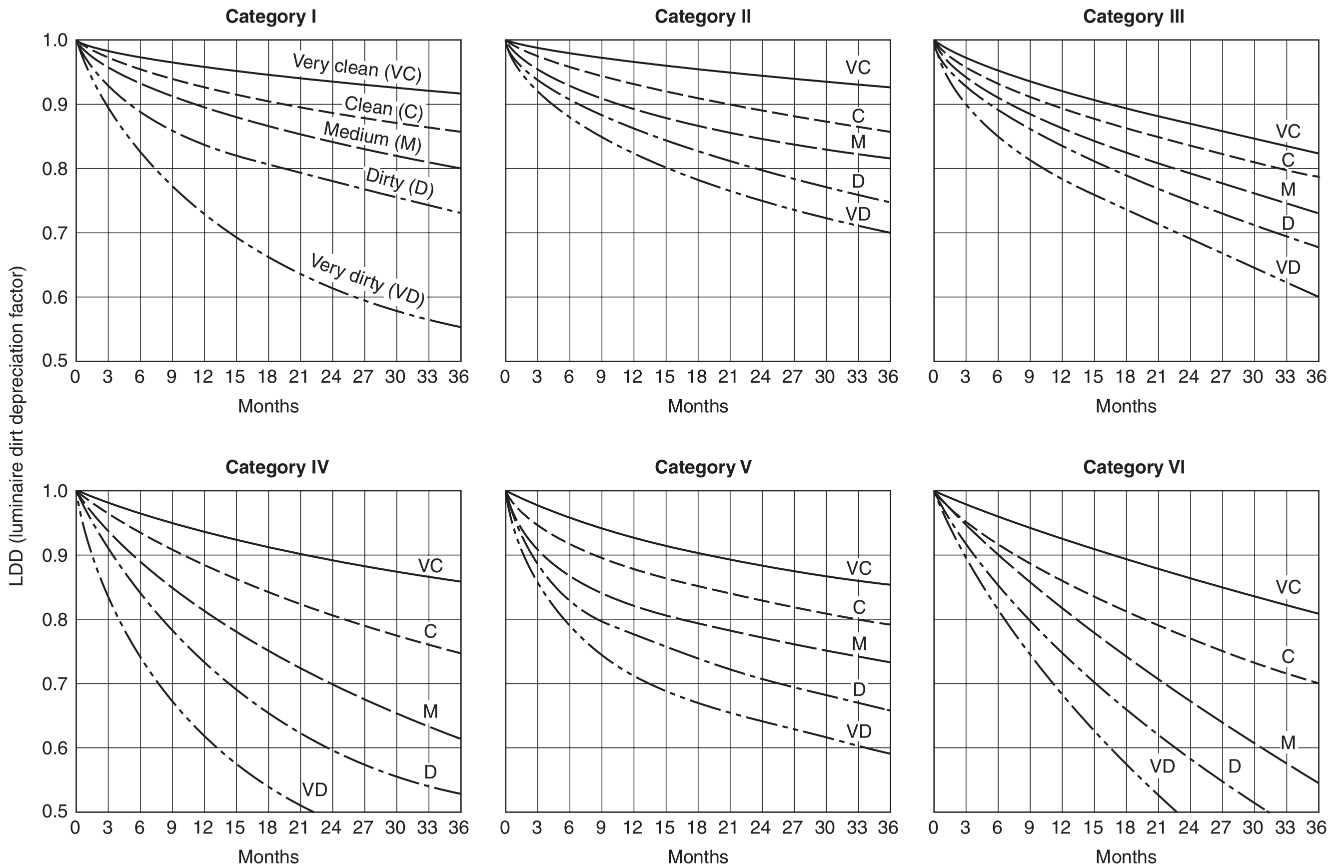

FIGURE 26-34 Luminaire dirt depreciation (LDD) factors for the six luminaire categories and for 5 levels of atmosphere dirtiness. (*Reprinted from the IESNA Lighting Handbook, 9th ed., with permission from the IESNA.*)

TABLE 26-20 A General interpretation of the IESNA Luminaire Maintenance Categories for Luminaires

Maintenance category	Types of luminaires included in this category
I	Bare lamps, bare lamp strips, and globes
II	Open pendant luminaires with >15% uplight through top openings
III	Open pendant luminaires with <15% uplight through top openings
IV	Luminaires with an open bottom and closed top, such as a parabolic troffer or open downlight
V	Luminaires that are completely enclosed, typically with lenses
VI	Uplights with an open top and solid bottom

It is now possible to calculate numerical relationships called *cavity ratios*, which may be used to determine effective reflectance of the floor and ceiling and then to find the coefficient of utilization. The basic steps in the calculation of any average illuminance are as follows:

1. Determine cavity ratios for three cavities shown in Fig. 26-36 as follows:

Room-cavity ratio, $\text{RCR} = 5 \times h_{RC}\,(L + W)/(L \times W)$

Ceiling-cavity ratio, $\text{CCR} = 5 \times h_{CC}\,(L + W)/(L \times W) = \text{RCR}\; h_{cc}/h_{Rc}$

Floor-cavity ratio, $\text{FCR} = 5 \times h_{FC}\,(L + W)/(L \times W) = \text{RCR}\; h_{F_c}/h_{Rc}$

Where h_{RC} = height of room between luminaire plane and work plane; h_{CC} = distance from luminaire plane to ceiling; h_{FC} = height of work plane above floor; L = room length; and W = room width.

2. Obtain the *effective floor-cavity reflectance* (ρfc) for the combination of floor and wall reflectances to be employed from Table 26-22.

3. Obtain the *effective ceiling-cavity reflectance* (ρcc) for the combination of ceiling and wall reflectance to be employed from Table 26-23. Note that, for surface-mounted or recessed luminaires, CCR = 0 and the ceiling reflectance may be used as the effective cavity reflectance.

4. Obtain the coefficient of utilization for the luminaire for a 20% effective floor-cavity-reflectance condition (tables like 26-21), interpolating between tabulated values as required to match room size and ceiling- and wall-reflectance combinations.

5. If the *effective floor-cavity reflectance* (ρfc) obtained in step 3 differs significantly from 20%, obtain a multiplier form Table 26-23 or Table 26-24. Multiply the coefficient of utilization by this multiplier.

6. Determine average maintained illuminance by the following formula:

$$E_{ave} = \frac{(\text{rated lamp lumens / luminaire}) \times \text{CU} \times \text{LLF*}}{\text{area / luminaire}}$$

If initial illuminance is desired, use a LLF factor that considers only the LLF components that will occur when the system is new, such as the ballast factor. When the desired average maintained illumination is known, the formula can more conveniently be expressed as

$$\text{Number of luminaires required} = \frac{E_{desired} \times (\text{room area})}{(\text{rated lamp lumens / luminaire}) \times \text{CU} \times \text{LLF*}}$$

$$\text{Area / luminaire} = \frac{(\text{rated lamp lumens / luminaire}) \times \text{CU} \times \text{LLF*}}{E_{desired}}$$

This area per luminaire when divided by the luminaire length gives the approximate spacing between continuous rows, or it may be divided into the total room area to determine the number of

luminaires required. For direct and semidirect luminaires, spacing between columns and rows should not exceed the maximum spacing as determined by the spacing criterion values for the luminaire.

Example. A room is 28 ft wide and 32 ft long and has a 10-ft ceiling height.

Reflectances are: ceiling 80%, walls 50%, floor 10%. A recessed four-lamp fluorescent luminaire is to be used. Work plane is 2 ft 0 in. Find the coefficient of utilization.

1. In Table 26-21, lookup *effective cavity reflectances* for ceiling and floor cavities. ρcc for the ceiling cavity will be 80%, while ρfc for the floor cavity will be 11%.
2. With the room-cavity ratio RCR known, it is now possible to find the coefficient of utilization for the luminaire in a room having an RCR of 2.7 and effective reflectances as follows (assume luminaire is type described in Table 26-21):

$$\rho cc = 80\% \ \rho w = 50\% \ \rho fc = 20\%$$

Thus CU = 0.65. Note that this is for an effective floor reflectance of 20%, while the actual effective reflectance of the floor ρfc is 11%. To correct for this, locate the appropriate multiplier in Table 26-24 for the RCR already calculated (2.7). It is 0.948 and is found by interpolating between the numbers for 80 ρcc and between RCRs of 2.0 and 3.0. Then

$$\text{CU final} = 0.65 \times 0.948 \times 0.62$$

The average illuminance across the space can now be calculated if we know the lamp lumen rating, and the light-loss factor.

$$E_{ave} = \frac{(\text{number of luminaires}) \times (\text{rated lamp lumens / luminaire}) \times \text{CU} \times \text{LLF}}{\text{room area}}$$

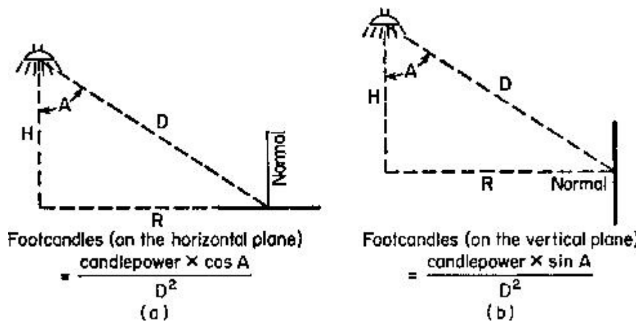
Simplified Design Methods. Buildings may have many individual spaces of different dimensions. If all of the above steps were used to determine the number of luminaires (and/or the number of lamps per luminaire) for each space, the procedure might be too time-consuming or unnecessary accurate or both. Engineers may wish, therefore, to use simplified performance data provided by the luminaire manufacturer in technical portions of catalogs, etc.

One popular method is based on specific illuminance levels for a small group of room proportions (ratios of room width to room or mounting height), and for assumed room-surface reflectances. By using typical light-loss factors, the approximate square footage per luminaire can be calculated using the formula under item 6 of the basic steps in calculating average illuminance.

26.13 CALCULATION OF ILLUMINANCE AT A POINT

Point Calculation Methods. The calculation of the illuminance at a point, whether on a horizontal, a vertical, or an inclined plane consists of two parts—the direct component and the reflected component. The total of these two components is the illuminance at the point in question.

Direct Component Illuminance. Most methods are based on the application of the *inverse-square law* ($E = I/D^2$, where I equals the luminous intensity expressed in candelas obtained from the candlepower distribution curve for the luminaire). In applying this formula to a horizontal surface, the illuminance at any point P is equal to the candlepower directed toward P multiplied by the cosine of the angle A and divided by the square of the distance D from the luminaire [$E = (I \times \cos A)/D^2$]. In this case A is the angle between the axis of the luminaire and a line from the light center to point P.



Reflected Component Illuminance. The reflected component consists of light that strikes the work plane, or any other point of interest after reflection from one or more of the room surfaces. In direct lighting systems and large rooms, this component may be small (less than 20% of the total illuminance at a point), while for indirect lighting systems, all of the light striking the work plane may be reflected. Illuminance calculated with the lumen method includes both the average direct and reflected illuminance on the work plane. For more detailed point-by-point calculations, advanced computer software often apply algorithms that subdivide the room surfaces into smaller patches for analysis of the reflected contribution, providing grids of points at which the illuminance is computed due to both direct and reflected light. Many of these computer programs also provide renderings of how an architectural space might appear. These tools are useful for analyzing lighting systems that do not provide uniform illuminance over the entire space, or to address conditions over a specific area or task location. A survey of lighting software is regularly published in the IESNA's periodical *Lighting Design + Application*.[1]

26.14 FLOODLIGHTING DESIGN AND PROCEDURE

Beam-Lumen Method. All floodlighting-design methods include certain approximations, based on experience. In floodlighting systems containing a large number of luminaires, a detailed computer study of point source calculations with luminaire locations and aiming positions is usually required. A procedure which is useful for designing simpler systems is called the "beam-lumen" method. This method requires the solution of the two formulas (A and B), as discussed in the following paragraphs, and the coordination of the results.

In many locations in which floodlighting is proposed, there are some basic dimensions that can be assumed to be already fixed. For example, in ground-area floodlighting, the designer is usually able to locate points where the equipment should logically be placed, such as on poles/towers or other physical structures. These locations establish the approximate perpendicular distance D from the floodlight to the plane of the surface to be lighted and the average aiming angles. They also guide the choice of floodlight type—narrow, medium, or broad-beam. In like manner the choice of equipment for lighting vertical surfaces can be obtained by taking D as the horizontal distance from the luminaire to the plane in which the vertical surface is located.

The average aiming angle is measured from the perpendicular to the beam-axis line (Fig. 26-37). In a perimeter system in which the floodlights are mounted along or beyond the perimeter of an area, they will, of course, be aimed at various angles, but the average aiming angle used in computation is measured between the perpendicular and the centerline of the area to be lighted. When floodlights are on poles along the centerline of an area, the average aiming angle is measured between the pole (perpendicular) and a point halfway to the boundary (one-fourth of the width of the total area).

Design Formulas and Procedure

$$\text{Formula A} = \frac{(\text{area lighted}) \times (\text{coverage factor})}{\text{floodlights needed for coverage} \times \text{beam-spot area}}$$

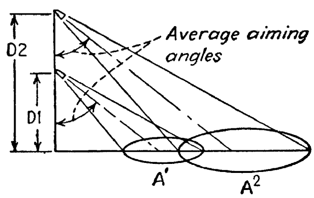

FIGURE 26-37 Spot areas (for the same beam spread and aiming angle) vary as the square of the distance *D*. Spot length *L* and spot width *W* vary as the distance *D*. The spot area may be determined from $\pi LW/4$.

In this formula, the area to be lighted may be either a horizontal surface or a vertical one.

The coverage factor indicates the minimum number of directions from which each point in the area should be lighted, depending on the use of the area. A coverage factor of 1 is acceptable in some applications, although in such systems one or two lamp burnouts might temporarily leave large dark patches. Coverage factors greater than 1 therefore add desirable safety factors. For example, a coverage factor of 2 is necessary for parking spaces and for protective lighting to reduce the effect of shadows between automobiles, rows of freight cars, piles of material, and similar bulky objects (see Table 26-25 for other recommended values).

The beam-spot areas at a (100-ft) distance *D* in formula A are given in Table 26-25 for various beam spreads and aiming angles of usual equipment having symmetrical candlepower distribution. In this table, *D* is the perpendicular distance measured from the floodlight to the plane of the lighted surface. *L* and *W* are the lengths and widths of the ellipses formed when floodlights are aimed at an angle to the lighted surface. At 0° the area is assumed to be circular; at other angles, it is elliptical. At other distances and spreads and for similar beam spreads and aiming angles, the spot areas vary as the square of the distance *D*, while *L* and *W* vary as the distance *D*. For example, if *D* is (24.38 m / 80 ft) and a 30 beam-spread floodlighting unit is aimed at a 50° angle, the elliptical spot areas computed from Table 26-22 will be $(80)^2/(100)^2 \times 9978$, or 6386 ft^2. Likewise, the length *L* of the ellipse will be $80/100 \times 144.4$, or 115.5 ft, and the width *W* will be $80/100 \times 87.96 = 70.4$ ft.

Formula B:

$$\text{Number of floodlights needed} = \frac{\text{illuminance} \times \text{area lighted}}{\text{light-loss factor} \times \text{utilization factor} \times \text{beam lumens}}$$

The light-loss factor allows for dust, dirt, and normal lamp depreciation. This is found under average conditions to be about 0.7. However, it may be as low as 0.3 for extremely dirty locations, where dust, dirt, and smoke are frequently suspended in the air.

The utilization factor, or coefficient of beam utilization, is the ratio of the lumens effectively lighting an area to the beam lumens, and it can be estimated from the following conditions:

1. If half or more than half of the floodlights are aimed so that all their beam lumens fall within an area, the overall utilization factor will be about 0.75.
2. If one-quarter to one-half of the floodlights are aimed so that all their beam lumens fall within an area, the overall utilization factor will be about 0.60.
3. If fewer than one-quarter of the floodlights can be aimed so that their beam lumens fall within an area, the overall utilization factor is likely to be not more than 0.40.

Most floodlights and projector- and reflector-type lamps as listed in the manufacturer's catalog are rated in beam lumens. These lumen ratings usually include only the light flux in that part of the

beam in which the candlepower values are 10% or more of the maximum candlepower of the floodlight.

As a general rule, it is wiser to design a system with a small number of floodlights with larger, more efficient lamps. This makes a simpler system to install, to control, and to maintain. Also from a control-of-light point of view it is desirable to choose a floodlighting unit having as narrow a beam spread as can be used and still maintain the coverage-factor requirements. It should be remembered, however, that large floodlights are hard to conceal; this is important where their daytime appearance may be objectionable architecturally.

To solve formula B, after choosing the desired illuminance and determining the light-loss and utilization factors, a size of floodlight is chosen for trial calculation and its beam lumens are substituted in the equation.

When the dimensions or shape of an area lead to the use of several types of floodlights, with different beam spreads, it is customary to divide the area into sections and plan a system for each of them. Buildings with setbacks are typical examples, also very tall structures such as towers or monuments. In setback buildings, you would design one setback at a time, selecting the type of floodlight most suitable for each. With towers or monuments, a similar approach is in order.

Floodlighting Design Problem. Assume that an area 200 by 200 ft is to be lighted to 5 fc. Also assume that the floodlights will be mounted on poles that are 60 ft high located on opposite sides of this area. By using a scale drawing to represent the luminaires placed 60 ft high and aimed toward the center line of the 200-ft-wide work space, the aiming angle will be about 60°. For trial-computation purposes it is best to start with the assumption that a narrow-beam-spread floodlighting unit will serve the coverage requirements and then change to a wider beam if found desirable. Hence, for this work space the lighting-design procedure is as follows:

1. From Table 26-26 the area which can be lighted for a 15° floodlight mounted 60 ft high at an aiming angle of 60° is

$$\frac{(60)^2}{(100)^2} \times 4720 = 1700 \text{ ft}^2$$

*The spot area for any other distance can be computed by multiplying the area in this table at the selected aiming angle by D^2 and dividing by 10,000.

2. Solving formula A

$$\text{No. of 15° units needed for coverage} = \frac{(\text{area}) \times (\text{coverage factor})}{\text{spot area}} = \frac{40{,}000 \times 3}{1700} = 70$$

3. Solving formula B. A light-loss factor of 0.3 is found for this dirty location, and a utilization factor of 0.7 may be assumed for narrow-beam floodlights in this area. If a 1000-W incandescent unit is selected for a trial computation, and it has 9500 beam lm. Then the number of 1000-W floodlights needed =

$$\text{1000-W floodlights needed} = \frac{(\text{illuminance}) \times (\text{area})}{\text{LLF} \times \text{UF} \times \text{beam lumens}}$$

$$= \frac{5 \times 40{,}000}{0.3 \times 0.7 \times 9500} = 100$$

4. Since the number of floodlights (100) in formula B is greater than the number needed for adequate coverage, it could be concluded that, if 50 floodlight units are conveniently located on either side of the area, a satisfactory 5-fc lighting installation would be provided. On the other hand, if a minimum number of floodlights are desired, formula B can be resolved on the basis of using 1500-W luminaires having 12,300 beam lm. In this case,

$$\text{1500-W floodlights needed} = \frac{5 \times 40{,}000}{0.3 \times 0.7 \times 12{,}300} = 77$$

Hence, this work area can be satisfactorily lighted with 5 fc maintained in serviced if thirty-nine 1500-W 15° floodlights are well distributed along each side of the area at 60-ft mounting heights.

As seen from the foregoing example, it is possible to use a fewer number of higher-wattage luminaires when the number of units (formula B) to provide the required illuminance is considerably greater than the number required for adequate coverage (formula A). On the other hand, when the trial computations show that the number of luminaires to provide the required illuminance is less than those for adequate coverage, it becomes necessary to recalculate formula B by using beam lumens from smaller-sized units, until one is found which brings the answer equal to or greater than that for formula A. In other words, the answer to formula B should preferably never be less than that for formula A in order to provide adequate illumination as well as satisfactory coverage. In all cases, consideration should be given to the use of lamps with the highest luminous efficacy of a color suitable for the application if HID floodlights of appropriate beam spreads are available

A more detailed point-by-point floodlighting design could also be computed using software. In any floodlighting installation, care should be taken to avoid light trespass and light pollution (light directed to the sky). Local outdoor lighting ordinances may restrict illuminance levels or the use of particular types or mounting heights of outdoor lighting equipment.

26.15 ECONOMICS OF LIGHTING

The Value of Lighting. The value of good lighting depends on its use in the various fields of application.

Reports from a variety of industrial plants have indicated that better lighting created more satisfactory working conditions which in many instances meant an increase in production, reduced, spoilage, fewer accidents, and less labor turnover. Likewise, in stores and other selling areas, good lighting properly applied has been recognized as a necessity, not only to permit the customer to properly inspect the merchandise but also to direct his or her attention to displayed items and thereby increase the volume of sales. Moreover, light and lighting are an integral part of many modern buildings where the architect has incorporated luminous elements for their functional use and aesthetic value.

Reduced office productivity can be caused by poor lighting. In addition, workers using computers can experience headaches, eye strains, and other ergonomics-related problems from improper lighting.

For utilitarian installations, which have resulted in an increase in factory production or an increase in sales in a store, a dollars-and-cents value can readily be given to better lighting, but this is rarely something that can be predicted prior to system installation. On the other hand, there is wide acceptance of light and lighting for its humanitarian and decorative aspects, which are of inestimable value.

Cost of Lighting. The overall items for comparing different lighting systems must include both the initial and the operating cost. While one of these may be a dominant factor in the final selection, it is usually desirable to combine the two into some type of "total cost" indicator.

The computation of initial, operating, and total annual cost for various systems considered for a given interior must be based on certain common assumptions, if the systems are to be fairly compared. Some of the important considerations are:

1. Equal illuminance results—since different systems may not produce equal illumination levels in service, all costs should be equated to an equal maintained illuminance basis.
2. Equal rates for amortizing the initial investment and for addressing interest, taxes, and insurance should be used.
3. Equivalent electrical-energy rates and operating conditions (burning hours per year and starting frequency of the lamps) should be applied to different systems.
4. Cleaning schedule should be appropriate to each type of system.
5. Uniform labor rates among systems should be used for estimating the cost of installations, cleaning, and relamping. Some users request life-cycle costs.

Table 26-27 tabulates a cost-analysis procedure for comparing the cost of two or more lighting systems and is self-explanatory. Table 26-27 develops capital expense based on initial costs divided by the assumed year's life, and operating expenses computed from present energy, lamp replacement, cleaning, and repair costs. A simple payback analysis may also be computed from the differential first cost between two systems and the annual savings that a system provides. Life cycle costing is preferred by many owners, because it considers the present value of money, which depends on the rate of interest, and provides the most accurate measure of economic performance (see IESNA publication RP-31-96, *Economic Analysis of Lighting*).

Group-Relamping Costs. The cost of lamp replacement is made up of the cost of the lamp and the cost of labor required to replace the lamp. When the sum of the costs is reduced, of course, the total annual cost of operating the lighting system is reduced. It is difficult to assess the exact overall cost reduction without having all the other facts about the installation, but it should be kept in mind that economical lamp replacement means better overall lighting economics.

With spot replacement, the total replacement cost per lamp is equal to the cost of the lamp plus the labor cost of replacement. Group-relamping cost, to compare with this, is equal to the lamp cost plus group-relamping labor cost plus the cost of any interim spot replacements, divided by the group relamping interval to put both systems on an equal time basis.

26.16 LIGHTING MAINTENANCE

Maintenance of Lighting. Good lighting system maintenance is good economics, that is, good maintenance assures users that they actually get the light they pay for. With a well-maintained lighting system, the user also gets the better conditions that the system was designed to provide. These better seeing conditions contribute directly to higher productivity and improved morale in factories, offices, and schools. In stores, the better lighting that results from good maintenance helps to increase sales. In addition, all areas benefit from a better appearance and fewer work interruptions that come with good maintenance.

Causes of Light Loss. Several factors contribute to light loss, and the effects of these factors vary with the kind of activity that takes place and the location of the establishment. For example, spaces vary as to the amount and type of dirt present in the air. Obviously, the amount of dirt in a machining factory is greater than that in an air-conditioned office. It is important to recognize these variations in considering the light losses which result from dirt on lamps and lighting units and dirt on room surfaces. These two, along with the unavoidable lamp-lumen depreciation, are the principal factors that cause light loss in every lighting installation.

Benefits of Cleaning. A lighting system should not only be cleaned properly, it should be cleaned at the proper time. This combination produces a cleaning program, which is a profitable investment because three principal benefits can be obtained.

1. *Better energy utilization for lighting*. Dirt absorbs light—cleaning removes the dirt and thus helps to maintain the light level. As a result, visibility is maintained, which benefits the user.
2. *Reduced maintenance costs*. A good maintenance program calls for cleaning the lighting system at the most economical time. It makes use of the most efficient methods and equipment. In this way the time and materials required are reduced, thus maintenance costs are lowered.

3. *Better appearance*. Clean lighting systems improve the appearance of the space. This is conducive to improved morale, better housekeeping, and increased occupant satisfaction.

To further improve the appearance of the area being lighted, walls and ceilings should be periodically cleaned and repainted as part of the cleaning program.

Relamping Benefits. The lamps in a lighting system can be replaced individually as they burn out, or the entire installation can be replaced before the lamps reach their average life. Individual replacement is usually called *spot replacement*; mass replacement is called *group relamping*. The labor costs saved by group relamping in large installations and in many small ones more than compensate for the value of the depreciated lamps that are thrown away before they burn out. Other advantages which always accompany group relamping are more light, fewer work interruptions, better appearance of the lighting system, and less maintenance of auxiliary equipment.

There are five principal advantages for group relamping. The first three apply to all lighting systems, the last two chiefly to fluorescent and HID systems.

1. *Reduced labor costs often mean net savings.* Group relamping saves on labor costs, largely because much of the travel and setup time required to change lamps individually is eliminated.
2. *More light delivered*. All lamps depreciate in lumens continually as they burn. The earlier they are replaced, the higher the maintained illumination will be without adding to the use and cost of electric energy since a larger number of luminaires are needed to achieve a target design illuminance.
3. *Fewer work interruptions*. Group relamping can be done at a convenient time—during vacation shutdowns or after working hours, for example, when there will be no interruption of operations. The number of interruptions to report burnouts or to replace tem is greatly reduced.
4. *Better appearance of the lighting system*. Black ends, color variations, and differences in brightness between adjacent old and new fluorescent lamps are common when spot replacement is used. With group relamping, all the lamps are the same age, and appearance is more uniform.
5. *Less maintenance of auxiliary equipment*. Abnormal operating conditions that may occur at the end of lamp life can damage starters and ballasts. When most of the lamps are replaced before they reach the end of life, auxiliary equipment lasts longer.

26.17 LIGHTING MEASUREMENT DEVICES

A variety of light measurement devices are available to a lighting practitioner for use in measuring lighting system performance. The most common devices are meters to measure illuminance and luminance.

Illuminance Meter. An illuminance meter is generally constructed with a silicon or selenium cell placed beneath an integrating white diffuser that may be either flat or round. The cells generate a potential difference when irradiated which bears a relationship to the level of illumination. The cells also have a spectral sensitivity that is chiefly in the visible and near ultraviolet region. Because it is different than that of the human eye, to measure photometric quantities (quantities based on the definition of the lumen) the cell must contain a color-correcting filter to align the detector's performance with that of the CIE luminous efficiency curve (see Fig. 26-38). Illuminance meters must also provide a reading that follows the cosine law of illuminance. That is, that the illuminance is proportional to the cosine of the angle the incident light ray makes with the normal to the measurement surface. Most illuminance meters perform well in this regard, but are less accurate at very high incident light angles (above 75° to 80°). When using an illuminance meter, it is important to properly orient the meter and to avoid shadowing the light arriving at the meter.

Luminance Meter. A luminance meter is used to measure the light leaving a surface in a particular direction. This type of meter must also be color corrected, and is used to record the luminous intensity (candelas) per projected area leaving the surface in the direction of the meter. Luminance meters are typically configured with a lensed optical system and an eyepiece through which the operator views the surface. A circle in the center of the image viewed through the meter indicates the surface area to be measured. The angular extents of this measurement zone may vary, but it is typically on the order of 1° or some fraction of a degree. When using a luminance meter, it is important that the operator focus the image using an adjustable outer lens. Since it may be difficult to hold such a meter steady and achieve a static reading, these meters typically have a trigger that may be pulled to make a reading, then released to freeze the reading.

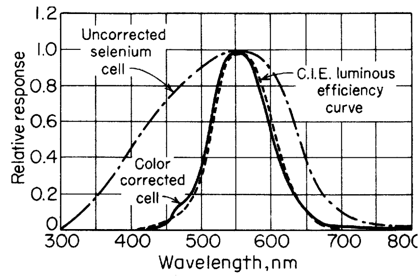

FIGURE 26-38 Average spectral sensitivity characteristics of selenium barrier-layer cells, compared with CIE spectral luminous efficiency curve.

Other more specialized devices for measuring lighting quantities are also available. These are unlikely to be needed by a lighting designer, but may be useful to manufacturers, research laboratories, and other lighting specialists. This list of devices include chromaticity meters, exposure meters, reflectometers, goniophotometers, glossmeters, fluorometers, colorimeters, refractometers, and pyranometers.

References on illumination may be found in texts on the subject of illuminating engineering and in appropriate journals. A few are listed in the bibliography.

SECTION 27
LIGHTNING AND OVERVOLTAGE PROTECTION

A. P. (Sakis) Meliopoulos
Professor, School of Electrical and Computer Engineering, Georgia Institute of Technology

CONTENTS

27.1 INTRODUCTION

Temporary overvoltages in power systems occur for a variety of reasons such as faults, switching, and lightning. By far, the most severe overvoltages result from lightning strokes to the power system. Most likely, lightning overvoltages will be very high, resulting in insulation breakdown of power apparatus with destructive results. It is therefore imperative that power systems be designed in such a way that expected overvoltages be below the withstand capability of power apparatus insulation. Many times, this basic requirement is translated into excessive cost. For this reason, one seeks a compromise in which power systems are designed in such a way that the possibility of destructive failure of power apparatus due to overvoltages is minimized. This procedure is based on coordinating the expected overvoltages and the withstand capability of power apparatus. Two steps are typically involved: (1) proper design of the power system to control and minimize the possible overvoltages and (2) application of overvoltage protective devices. Collectively, the two steps are called *overvoltage protection* or *insulation coordination*.

The importance of overvoltage protection cannot be emphasized enough. First it affects system reliability, which translates into economics. Traditionally, overvoltage protection methods were guided by the objective to maximize system reliability with reasonable investment cost. In this sense, transient overvoltages which do not lead to interruptions are acceptable and short-duration interruptions are tolerable. Recently, however, with the introduction of sensitive electronic equipment, new concerns have been raised. The issue of power quality is important and it is transforming the practices for overvoltage protection. While the application of overvoltage protection devices is pertinent, more and more emphasis is placed on design procedures to minimize the possible overvoltages and control the sources of disturbances. An attempt has been made in this section to provide a balanced treatment of overvoltage protection in view of present-day concerns.

The subject of lightning and overvoltage protection is rather complex. A thorough treatment requires good understanding of many related subjects. First, the mechanisms by which lightning is generated and how its pertinent characteristics are related to power systems must be well understood. Second, the response of power systems to lightning and other causes of overvoltages must be studied. Analysis methods to study the phenomena are indispensable tools, which provide the basis for proper selection of design options. Invariably, overvoltages can be minimized, but they cannot be eliminated. As a result, power systems must be protected against overvoltages using overvoltage protection devices (surge arresters). In recent years, major breakthroughs have occurred in protective device technology. Effective protection requires a deep understanding of the capabilities of present technology as well as its limitations.

27.2 BASIC CONCEPTS AND DEFINITIONS

Electric power systems are subjected to external surges (lightning) as well as internally generated surges (switching), which may result in temporary high voltages. To maintain a highly reliable system, protection against these overvoltages is needed. This need is dictated by the fact that the insulation of power equipment (which may be air, oil, SF_6, etc.) is subjected to breakdown if sufficiently high voltage is applied. This protection involves a coordinated design of the power system itself and placement of proper protection devices at strategic locations for the purpose of suppressing overvoltages and avoiding or minimizing insulation failures.

Coordinated design involves

Effective grounding techniques

Use of shielding conductors

Preinsertion resistors during switching

Switching angle control among breaker poles

Use of surge capacitors

Protection devices include spark gaps and various designs of surge arresters.

The basic objective of overvoltage protection of power systems is to avoid insulation breakdown and associated outages or damage to equipment. The most common insulators used in power system apparatus and their characteristics are listed in Table 27-1.

In general, in terms of potential damage to equipment, the insulation of power apparatus can be classified into external and internal as follows:

- External insulation

  Air

  Porcelain

  Glass

- Internal insulation

  Oil

  SF_6

  Mica

The effects of external insulation breakdown are not as destructive as internal insulation breakdown. The reason is that external insulation is, in general, self-healing (self-restoring) after the cause of breakdown (overvoltage) ceases to exist. On the other hand, internal insulation breakdown generally results in permanent damage to the equipment and possibly catastrophic failure. These facts dictate different approaches for external and internal insulation protection. For external insulation protection, the objective is to minimize the expected number of insulation breakdowns subject to economic constraints. In this sense, many sophisticated approaches have been developed, which

TABLE 27-1 Common Insulators in Power Apparatus

Insulator	Breakdown, MV/m	Resistivity, $\Omega \cdot$ m	Relative permitivity
Air	3	$\rho = \infty$	$\epsilon_r = 1$
Oil	10	$10^4 \times 10^{10}$	2.2
SF_6	15 at 1 atm 59 at 5 atm		
Mica	100	$10^{11} - 10^{15}$	4.5–7.5
Porcelain	10	3×10^{12}	5.7
Glass	…	10^{12}	4–7

balance system reliability (which is mainly related to insulation breakdowns) versus cost. Because many of the exogenous parameters, such as lightning strength and soil parameters are statistical in nature, the methodologies use statistical approaches. For internal insulation protection, deterministic methods are applied where the objective is to design for zero insulation breakdowns.

The above simplistic characterization of external and internal insulation is not always apparent in power apparatus. Specifically, the insulation of a specific power apparatus may be complex. For example, consider a transformer. The windings of the transformer may be submerged in oil (the dielectric is oil) while the terminals are exposed to air through the bushings (the dielectric is the air). When considering withstand capability of a power apparatus, we are not concerned with which dielectric will break first, although this is part of the design process. But rather we are concerned with the question of at what voltage the insulation (any part) will break down. Because insulation breakdown depends on voltage waveform as well as on some other factors, the following definitions, which have been taken from the ANSI Std C92.1, apply:

Withstand voltage. The voltage that electrical equipment is capable of withstanding without failure or disruptive discharge when tested under specified conditions.

Insulation level. An insulation strength expressed in terms of a withstand voltage (typically 10% less than the withstand voltage).

Transient insulation level (*TIL*). An insulation level expressed in terms of the crest value of the withstand voltage for a specified transient wave shape, for example, lightning or a switching impulse.

Lightning impulse insulation level. An insulation level expressed in terms of the crest value of a lightning impulse withstand voltage.

Switching impulse insulation level. An insulation level expressed in terms of the crest value of a switching impulse withstand voltage.

Basic lightning impulse insulation level (*BIL*). A specific insulation level expressed in terms of the crest value of a standard lightning impulse.

Basic switching impulse insulation level (*BSL*). A specific insulation level expressed in terms of the crest value of a standard switching impulse.

Note that two of the most commonly used measures, the basic lightning impulse insulation level and the basic switching impulse insulation level, are the most widely used values to characterize the insulation of power apparatus. Note that they are defined in terms of two specific waveforms: (1) the standard lightning impulse and (2) the standard switching impulse. The definitions of these waveforms are

Standard lightning impulse. A full impulse having a front time of 1.2 μs and a time to half value of 50 μs. It is described as a 1.2/50 impulse. (See *American National Standard Measurement of Voltage in Dielectric Tests,* C68. 1.)

Standard switching impulse. A full impulse having a front time of 250 μs and a time to half value of 2500 μs. It is described as a 250/2500 impulse. (See American National Standard C68.1.)

These waveforms are illustrated in Fig. 27-1.

The standard impulses were introduced because they remotely resemble lightning and switching waveforms, and they can be easily generated in a laboratory via an impulse generator. The basic structure of an impulse generator is illustrated in Fig. 27-2*a*. By stacking many basic structures together, one can create an impulse generator capable of generating an output impulse many million volts in crest.

The impulse voltage withstand of a power apparatus is strongly dependent on the duration of the impulse voltage. The time dependence is mainly due to the fact that arc generation involves an electron avalanche which takes a finite time to form. The full development of an arc across an insulator is classified as a breakdown. The time to breakdown is normally quantified with a volt-time characteristic. This characteristic can be determined by applying impulses across an insulator of increasing magnitude and recording the voltage and time at which breakdown occurred. For self-restoring insulation, this test is relatively simple and is illustrated in Fig. 27-3. In this way, volt-time curves for all insulators in usage have been determined. Unfortunately, the withstand voltage of non-self-restoring insulation cannot be readily determined without destroying the sample. This means that determining

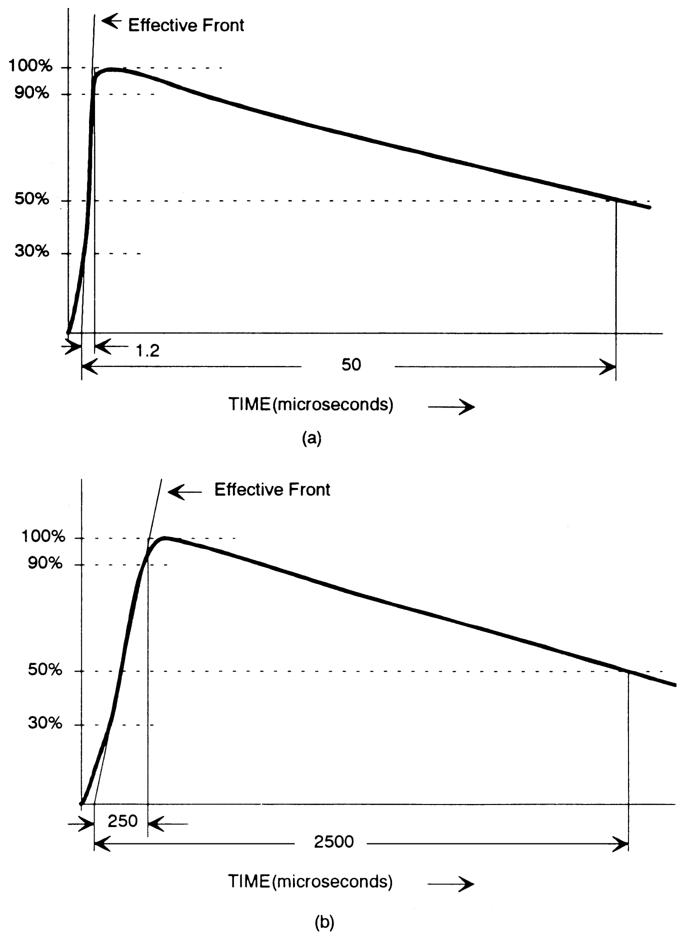

FIGURE 27-1 Standard waveform: (*a*) standard lightning impulse; (*b*) standard switching impulse.

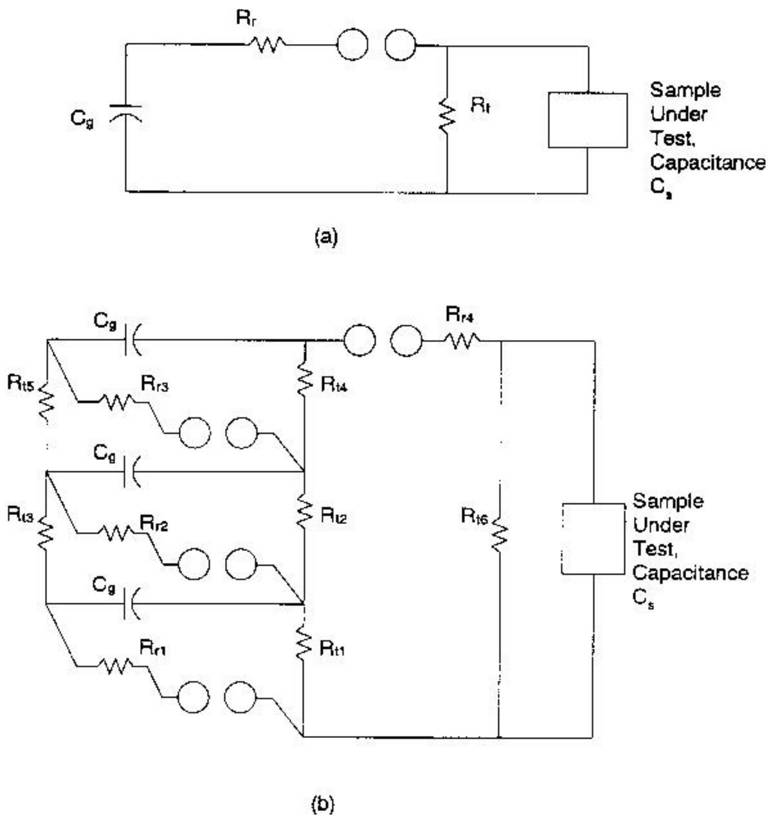

FIGURE 27-2 Impulse generator: (*a*) single-stage; (*b*) multiple-stage.

the volt-time curve of non-self-restoring insulation is a practical impossibility. For this reason, the methods for determining withstand voltage for internal insulation are different. Specifically, internal insulation is designed for a specific withstand capability, the *design withstand*. The manufacturer must guarantee a certain withstand at which the insulation, if tested, will not fail. This is the *tested withstand* and it is normally lower than the design withstand. Apparently, the *actual withstand* cannot be known without destroying the sample. The actual withstand is definitely higher than the tested withstand and probably higher than the design withstand.

There is another issue related to the fact that the withstand voltage depends on many other factors that exhibit random variations. Some of them are

Insulation geometry and smoothness of surfaces

Insulation contamination

Atmospheric conditions

Voltage polarity

It is a practical impossibility to quantify the effects of all variables on voltage withstand. For this reason, voltage withstand is described in statistical terms. In this sense, the following definitions apply with reference to Fig. 27-3:

Critical flashover (CFO) is the crest voltage of an applied impulse wave that will cause flashover on the tail of the wave 50% of the time and no flashover the other 50% of the time.

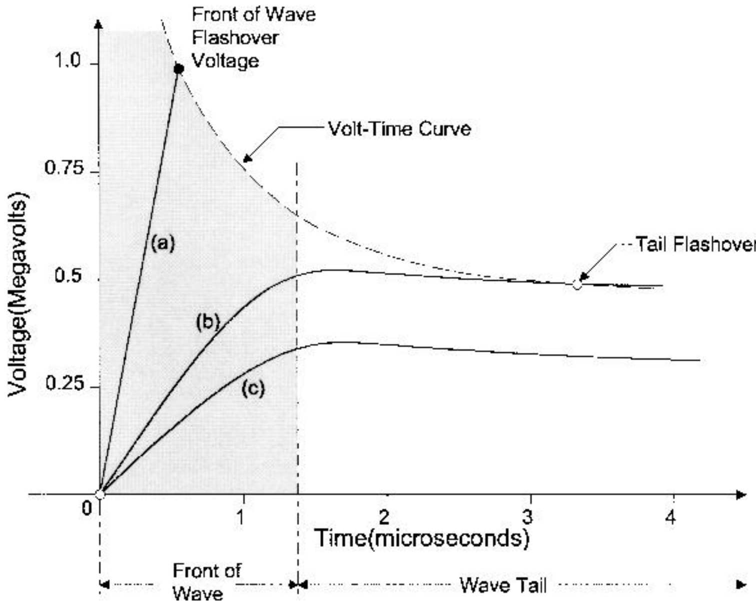

FIGURE 27-3 Determination of the volt-time curve of insulation breakdown.

Critical withstand is the highest crest voltage insulation can take without flashover under specified conditions—usually less than 1% probability of flashover.

Rated withstand is the crest voltage that insulation is required to withstand without flashover when tested by established standards under specified conditions (usually 5% to 10% less than critical withstand).

In summary, in this section we reviewed several basic concepts and definitions, which are useful in the process of designing protection systems.

27.3 MECHANISMS AND CHARACTERISTICS OF LIGHTNING

Introduction. Atmospheric electrical discharges known as *lightning* or *thunderbolts* (from cloud to cloud or cloud to ground) have captured the imagination and fear of the human race since ancient times. The ancient Greeks believed that lightning was Zeus' tool to punish human misbehavior or to demonstrate his anger. It was not until Benjamin Franklin that the first scientific inquiry occurred into the phenomenon of lightning. Since that time, lightning has been extensively studied and many theories have been developed, which reasonably explain the phenomenon. In addition to these theories, there exists an enormous amount of measured data of lightning characteristics. These data are useful for design of protection schemes against lightning.

This section presents a brief overview of the theory of thundercloud formation and lightning, the characteristics of lightning, and describes existing relevant data.

The Electrification of Thunderclouds. The cause of lightning is separation and accumulation of electrical charges in clouds via certain microphysical and macrophysical phenomena. This electrification results in electric field intensities high enough to cause air breakdown and subsequent development of lightning. To explain these phenomena, certain theories have been developed. The most useful are the precipitation and convection theories and later improvements, most notably the charge-reversal temperature theory. Understanding of these theories is helpful in the design of protection systems against lightning. A brief description of the cloud electrification theories is provided in this section.

The precipitation theory, postulated as early as 1885 by physicists Elster and Geitel, is based on the observation that large water droplets accelerate toward ground because of gravity, while smaller water droplets (mist) remain suspended in air or rise as warmer air moves upward. Collisions between large water droplets and mist of water droplets and possibly ice crystals in the colder altitudes result in transfer of a net negative charge to the large water droplets. As they move toward lower altitudes (by gravity), they cause a net negative charge in the lower part of the cloud. Conservation of charge requires that the upper part of the cloud be positively charged, resulting in a dipole structure in the thundercloud. A simplified illustration of the process is given in Fig. 27-4.

The convection theory, which was formulated much later, is based on transfer of charged particles from one location of a cloud to another by the upward and downward drafts in the cloud. The theory suggests that the charged particles are generated by two mechanisms: (1) cosmic rays impinge on air molecules and ionize them, resulting in two ions, one positively charged, the other negatively charged; and (2) high-intensity electric fields around sharp objects on the earth's surface produce corona discharges, which result in positively charged ions. The positive ions are transported to higher altitudes by the upward draft in the cloud. On the other hand, the negative ions attach themselves to water droplets and ice particles, which move to lower altitudes due to gravity or downward drafts. The net result is a dipole structure in the thundercloud. A simplified illustration of the process is given in Fig. 27-5.

Precipitation and convection occur in a thundercloud simultaneously. Yet the two theories are distinct and independent. Both theories postulate that the thundercloud is a dipole with the negative pole near the earth, that is, negative dipole. Measurements made by Wilson and later by Simpson of the polarity of the dipole resulted in conflicting conclusions which generated debate and further research. Specifically, Wilson's measurements indicate that the thundercloud is a negative dipole (negative charge at the lower part of the cloud) while Simpson's measurements indicated a positive dipole. It took five decades of additional experimentation and measurements to resolve this apparent conflict. Today's most complete theory for lightning phenomena has established the fact that the structure of a thundercloud is *tripolar*, not bipolar. This structure allows the understanding of both Wilson's and Simpson's conclusions. Specifically, an electric tripole of the size of a thundercloud observed from a single specific point will appear as a dipole. Depending on the point of observation

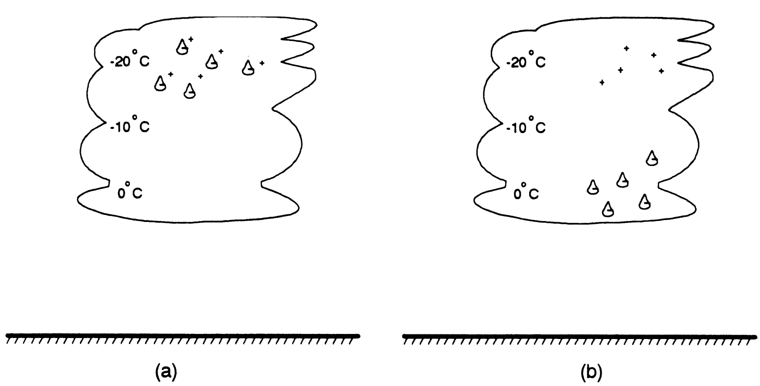

FIGURE 27-4 Illustration of the precipitation theory of cloud electrification: (*a*) separation of the charge due to collisions; (*b*) cloud electrification due to precipitation of charged water droplets.

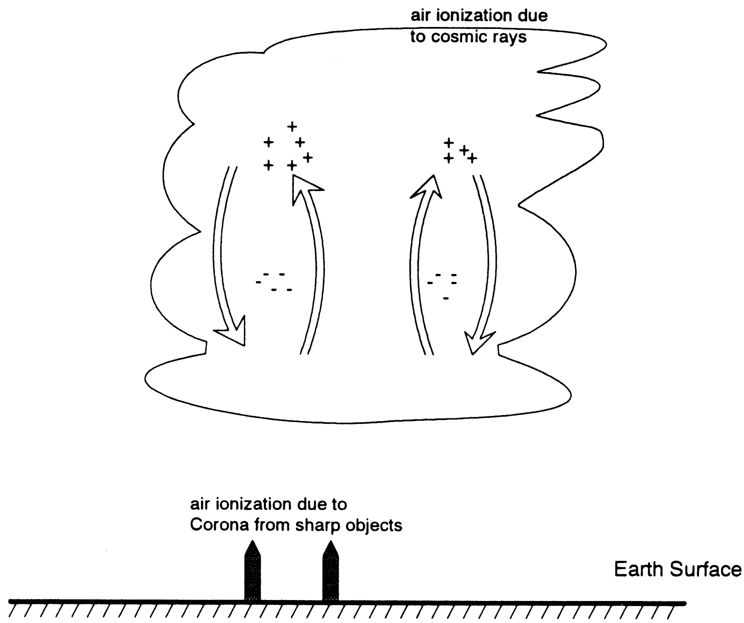

FIGURE 27-5 Illustration of the convection theory of cloud electrification.

one may conclude that it is a negative or positive dipole. Apparently, Wilson and Simpson made their measurements from different observation points. Their measurements were correct but because Wilson made the measurements from a distant point he concluded that the thundercloud is a negative dipole, while Simpson made his measurements from a point underneath the head of the cloud and concluded that the thundercloud is a positive dipole.

Both theories, precipitation and convection, do not completely explain all phenomena occurring in a thundercloud. For example, it has been observed from studies that larger droplets, when they break, acquire positive charge on aggregate. This leads to the hypothesis that the positive charge is due to large droplets that break as they accelerate toward ground. However, this hypothesis is not totally true because it does not explain the fact that precipitation particles below the negative charge carry much greater positive charge than those produced by the droplet fragmentation process. Another hypothesis was based on ice particles accelerating toward ground—as the ice particles reach lower altitudes, they melt and tend to acquire positive charges, which explains the existence of positive charge at altitudes below 4 km. However, this hypothesis still does not explain the existence of positive charges at higher altitudes.

Recent measurements and observations in the past three decades resulted in another hypothesis which explains the tripole nature of a thundercloud. This is the so-called charge-reversal hypothesis, which states that when graupel particles collide with ice crystals, the charge transferred to a graupel particle is dependent on the temperature. At temperatures above a certain value, which is called the *charge-reversal temperature*, the transferred charge is positive. The exact value of the charge-reversal temperature is being debated, but it is believed to be around −15°C. The process is illustrated in Fig. 27-6 in a simplified manner. Considering the fact that the temperature of the atmosphere is −15°C at an approximate altitude of 6 km, this means that due to collisions of graupel particles and ice crystals, the thundercloud will be, on aggregate, negatively charged for altitudes above 6 km and positively charged below 6 km. The situation is illustrated in Fig. 27-7. This hypothesis has been verified in the laboratory and explains the levels of negative and positive charges in a thundercloud. Yet, the exact microphysics of this phenomenon are practically unknown.

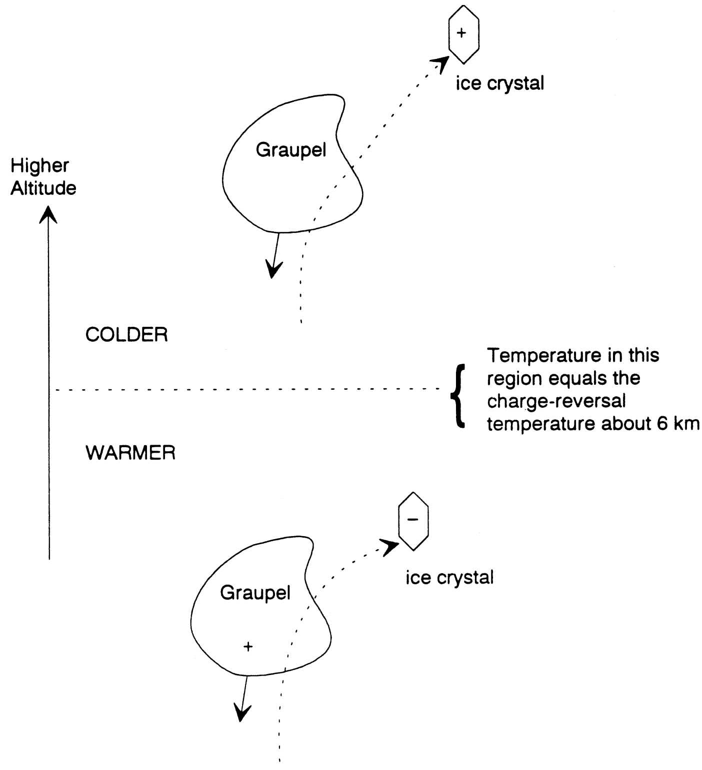

FIGURE 27-6 Explanation of the charge-reversal temperature theory.

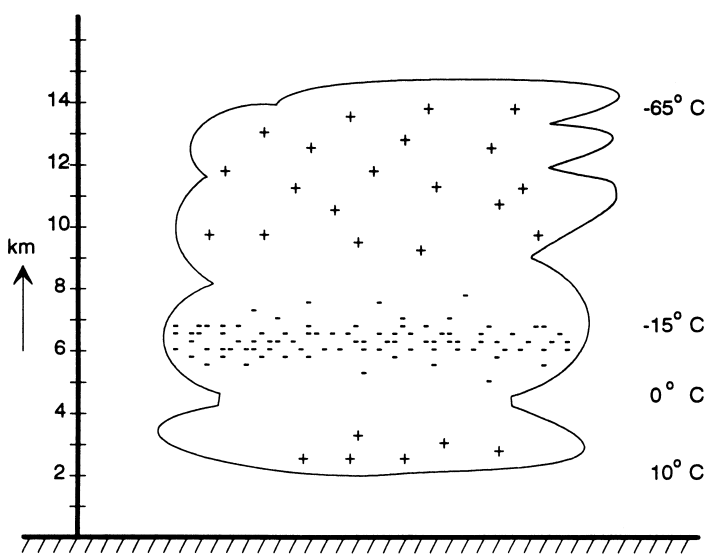

FIGURE 27-7 An electrified thundercloud is typically tripolar.

In summary, the precipitation model with the graupel—ice crystal interaction and charge-reversal temperature best explains most of the behavior of a thundercloud. Yet this model totally ignores the forceful upward and downward drafts within a thundercloud. The convection model considers these drafts but it is unable to explain certain observed phenomena in a thundercloud. Perhaps one day a theory will be developed, which combines the precipitation and convection models and completely accounts for all phenomena related to the electrification of a thundercloud. What has been verified with measurements are the following facts: a thundercloud can be electrified in such a way that positive charge accumulates at the top of the cloud and negative, at the lower part of cloud. A smaller positive charge may be present at lower altitudes of a thundercloud. These charges are responsible for lightning. The mechanism of lightning is explained next.

Mechanisms of Lightning. Lightning initiates whenever the charge accumulation in a thundercloud is such that the electric field between charge centers inside the cloud or between cloud and earth is very high. For power engineering purposes, only cloud-to-earth lightning strokes (ground flashes) are of importance and will be discussed next. An electrified thundercloud will generate an electric field in the space between the cloud and earth as is illustrated in Fig. 27-8. When the intensity of this field is high enough, a discharge will initiate. Typically, the process involves three phases. In the first phase, the high electric field intensity may generate local ionization and electric discharges, which are known as *pilot streamers*. A pilot streamer is followed by the so-called *stepped leader*. The stepped leader is a sequence of electric discharges, which are luminous; they propagate with a speed approximately 15% to 20% of the speed of light, and they are discrete, progressing approximately 50 m at a time. The time between *steps* is few microseconds to several tens of

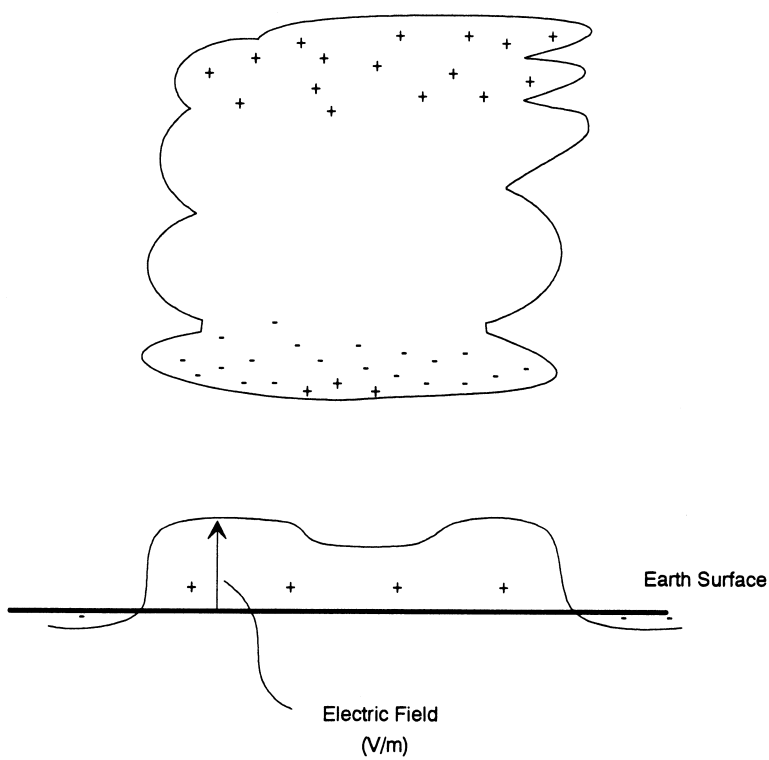

FIGURE 27-8 Illustration of electric field below an electrified thundercloud.

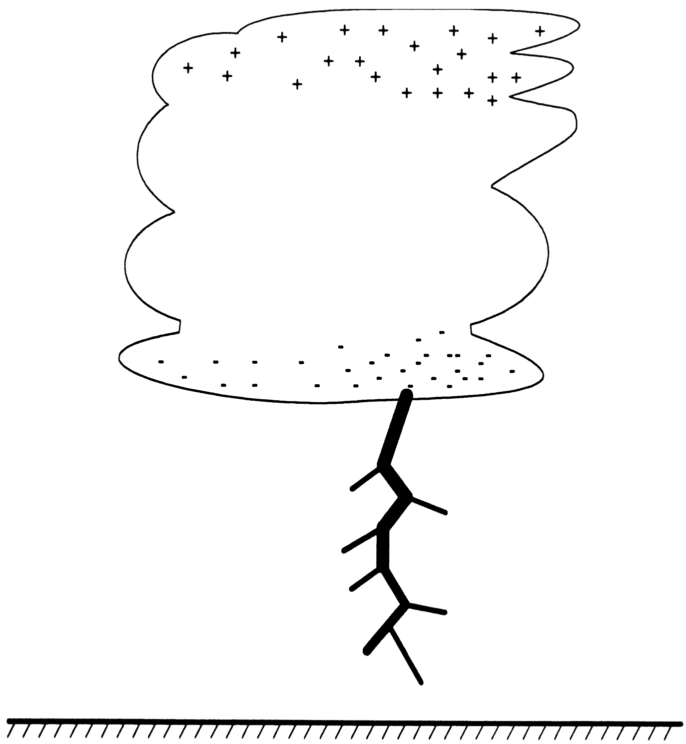

FIGURE 27-9 Illustration of stepped-leader development.

microseconds. A pictorial view of the stepped leader development is shown in Fig. 27-9. The stepped leader will eventually reach the surface of the earth and will strike an object on the earth. However, where it will strike is not determined until the stepped leader is within a *striking distance* from the object. A model for the striking distance will be described in Sec. 27.7. It is possible that a stepped leader or multiple stepped leaders may also initiate from an object on the surface of the earth. In this case, the two stepped leaders may meet at some point. There is also evidence that the initial stepped leader may originate from a tall structure on the earth and not from the cloud.

The second phase initiates when the stepped leader reaches an object on the earth or meets an upward moving stepped leader. Specifically, a high-intensity discharge occurs through the channel established by the stepped leader. This discharge is extremely luminous and therefore visible. It propagates with a speed of about 10% to 50% of the speed of light. The development of the return stroke is illustrated in Fig. 27-10. The return stroke carries an electric current of anywhere from few thousands of amperes to 200 thousands of amperes. The current magnitude rises fast, within 1 to 10 μs, to the peak value and then decreases rapidly. The discharge is known as the *return stroke* or simply the *lightning stroke*. The return stroke transfers a substantial amount of positive charge from the earth to the cloud and specifically to the charge center where the lightning was originated. This transfer results in a significant lowering of the potential of the charge center. This phenomenon initiates the third phase of lightning. In this phase, discharges may occur from other charge centers within the thundercloud to the depleted charge center because of the increased potential difference between them. This discharge will trigger another stroke between cloud and ground through the already established conductive channel with the first stroke. This process may be repeated several times, depending on the electrification status of the thundercloud, resulting in multiple strokes. There is evidence

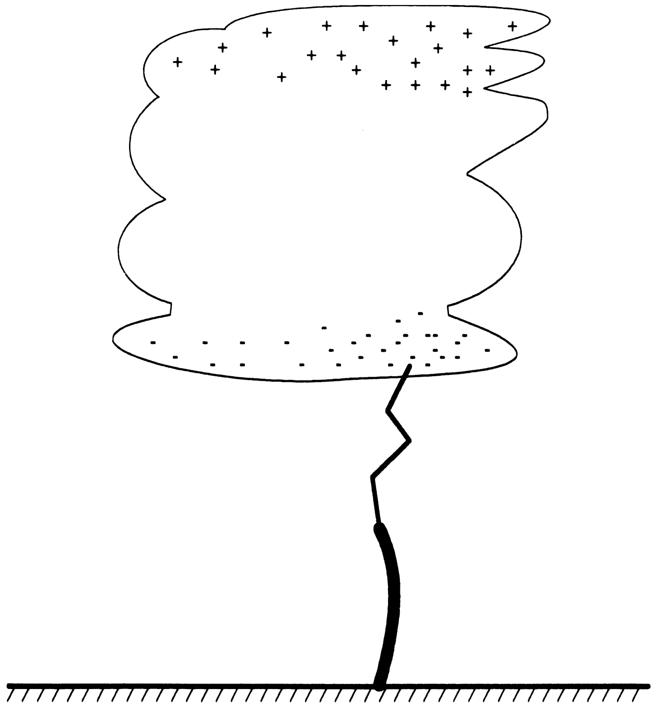

FIGURE 27-10 Illustration of return-stroke development.

that most lightning to ground involves multiple strokes. For example, an analysis of 1430 strokes to the earth by Anderson (1968) resulted in the following statistics:

Single-stroke lightning	36%
Lightning involving six or more strokes	21%
Mean value of multiple strokes	3

It should be mentioned, however, that positive polarity lightning is typically single stroke. Extreme cases have been recorded with a large number of multiple strokes such as 40 or 50 with duration of the entire lightning event approaching 1 s. For example, a 40-stroke lightning event, which lasted 0.624 s is on record. The time interval between successive strokes may be in the order of few milliseconds. However, there is evidence that sometimes the multiple strokes may be so smooth as to appear as a continuous lightning current. This occurs because as long as there is a conductive path between the cloud and ground, electric current will flow until the cloud is neutralized enough for the conductive path to interrupt. The continuous flow of lightning current can be destructive because of its long duration even if the magnitude may be much lower than the crest of a stroke.

Characteristics of Lightning Strokes. The parameters of lightning ground strokes are very important in the design of protection schemes against lightning. The most important parameters are

- Voltage
- Electric current
- Waveform
- Frequency of occurrence

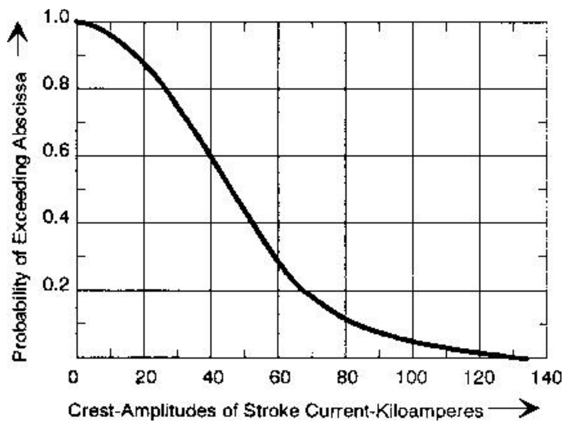

FIGURE 27-11 Distribution of lightning current magnitudes [recorded by Berger (1967) at Mount San Salvatore].

The voltage between a thundercloud and the earth prior to a ground stroke has been estimated from 10 to 1000 MV. For design work, however, the protection engineer is interested in the voltage appearing on the stricken power apparatus. This voltage will be equal to the product of the impedance times the stroke current.

It is generally accepted that the ground-stroke current is independent from the terminating impedance. The reason is that the terminating impedance is much lower than the resistance of the lightning discharge channel, which is on the order of few thousand ohms. Thus, a ground stroke is normally considered as an ideal current source at the point of strike. The crest of the stroke electric current can vary over a wide range: 1 to 200 kA. Data on ground-stroke current magnitudes have been collected by many researchers. Among those, the work of Berger (1967) at Mount San Salvatore in Switzerland has been widely accepted. Statistical representation of these data is shown in Fig. 27-11.

The waveform of the lightning ground stroke current, and especially the rise time, is very important. Again, statistical representation of stroke current rise times data collected by Berger is given in Fig. 27-12.

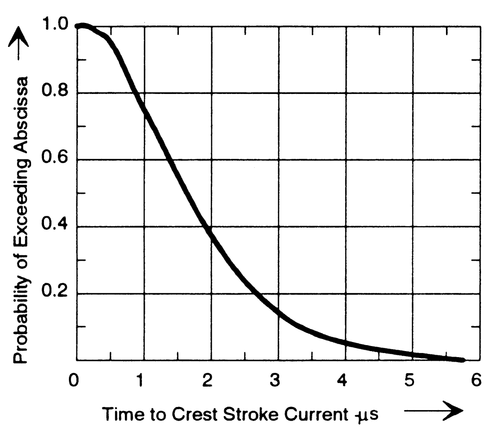

FIGURE 27-12 Distribution of lightning current rise times [recorded by Berger (1967) at Mount San Salvatore].

The frequency of occurrence is also a very important parameter. In order to quantify lightning activity, the crude measure of *thunderstorm day* has been introduced. A thunderstorm day is defined as a 24-h period in which at least one thunder clap has been heard. Collection of historical thunderstorm activity data by the National Weather Service resulted in maps of equi-thunderstorm-day contours. These maps are known as isokeraunic maps, from the Greek word *keraunos*, lightning. Such a map is illustrated in Fig. 27-13. It is important to note that this map, by definition, provides only a crude measure of lightning activity. Specifically, by definition, a thunderstorm day does not provide any information on the frequency of and total lightning activity. Yet, because of lack of better data, the isokeraunic maps have been used for estimation of lightning activity in an area. There are several models, which provide the approximate number

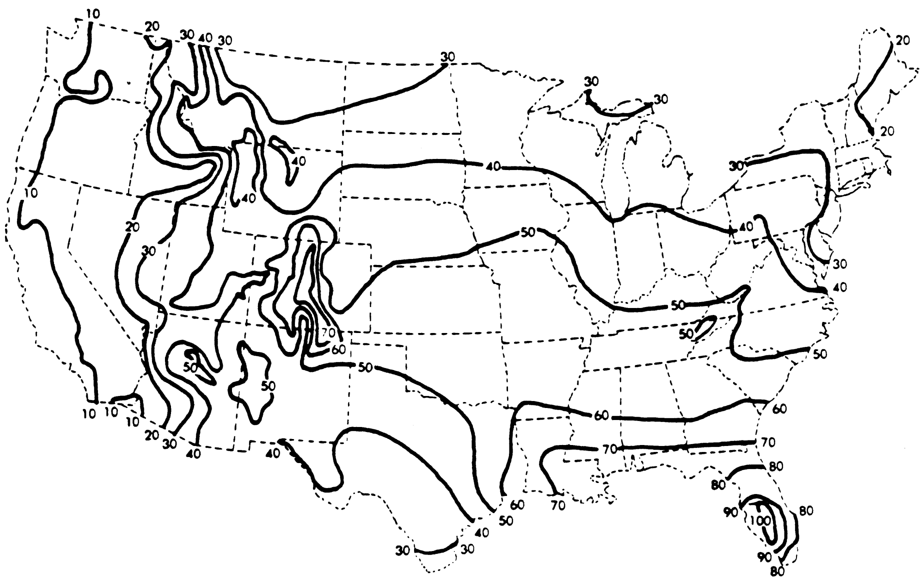

FIGURE 27-13 Isokeraunic curves for the continental United States.

of cloud-to-ground lightning per unit of area as a function of the isokeraunic level. These models will be discussed in detail in Sec. 27.7. As an example, Anderson (1975) has suggested the following

$$N_1 = 0.12T$$

where N_1 is the ground flash density per square kilometer per year and T is the number of thunderstorm days.

Early in the 1980s, the Electric Power Research Institute sponsored a project at the State University of New York at Albany (SUNYA) which resulted in the National Lightning Detection Network (NLDN) records. The system integrated two networks and basically records cloud-to-ground lightning discharges. The objective of the project was to collect lightning data over a period of 10 years, which could be used for lightning protection of power systems. Figure 27-14 illustrates average lightning flashes per square kilometer for the state of Florida. The data were collected over a 5-year period (1985 to 1989). Note that these data correlate reasonably well with the isokeraunic maps data of Fig. 27-13. Similar systems have been installed in many countries.

Summary. This section has described the mechanism of thundercloud formation and electrification and the initiation, mechanism, and characteristics of lightning. Finally, statistical data on lightning parameters were presented. These data are useful for design work.

27.4 POWER SYSTEM OVERVOLTAGES

The causes of power system overvoltages are numerous and the waveforms are complex. It is customary to classify the transients on the basis of frequency content of the waveforms. In this sense, the following three broad categories are defined:

Power frequency overvoltages

Switching overvoltages

Lightning overvoltages

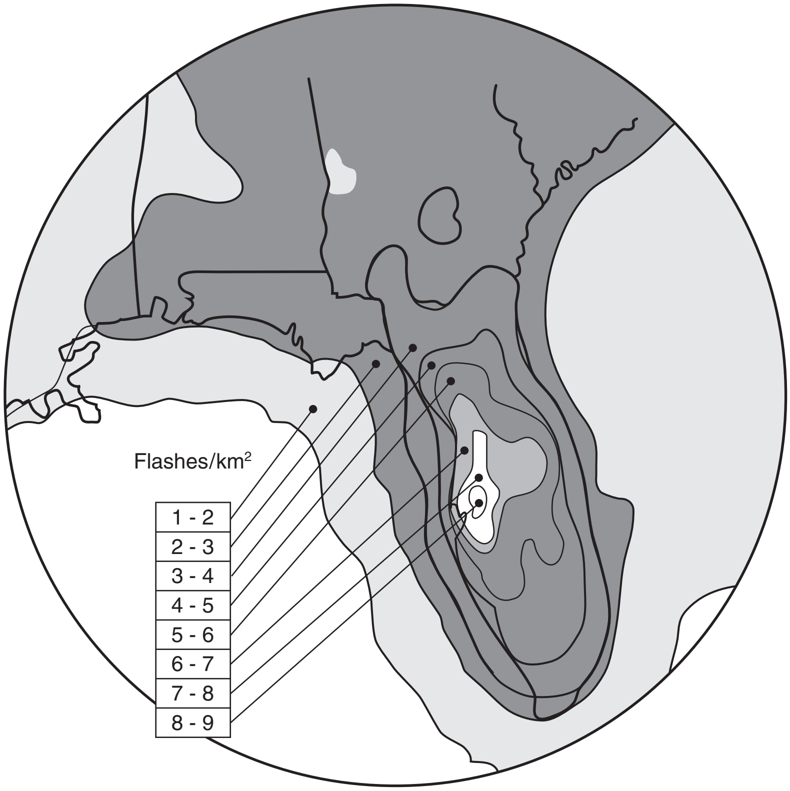

FIGURE 27-14 Average annual flash density data from 1985 to 1989. (*Electric Power Research Institute*.)

Table 27-2 provides brief descriptions and typical causes of the most commonly encountered overvoltages in power systems. The relative level of overvoltages due to these causes is illustrated in Fig. 27-15.

In designing a well-protected electric power system, it is extremely important to thoroughly understand the types, frequency, and magnitude of the expected overvoltages on the power system. For this reason, this section provides a concise discussion of the nature, generation mechanisms, and characteristics of power frequency, switching, and lightning overvoltages in power systems.

Power Frequency Overvoltages. The magnitude of power frequency overvoltages is typically low compared to switching or lightning overvoltages. Specifically, for most causes of these types of overvoltage, the magnitude may be few percent to 50% above the nominal operating voltage. However, they play an important role in the application of overvoltage protection devices. The reason is that modern overvoltage protection devices are not capable of discharging high levels of energy associated with power frequency overvoltages. Thus, it is imperative that protective device ratings be selected in such a way that they do not operate under any foreseeable power frequency overvoltages.

The most common causes of power frequency overvoltages are (1) electric faults, (2) sudden changes of load, and (3) ferroresonance. An electric fault results in voltage collapse for the faulted phase and in a possible overvoltage at the unfaulted phases. The magnitude of the overvoltage depends on the parameters of the circuit, such as positive, negative, and zero sequence impedance, as well as the grounding parameters of the system, such as ground impedance or single- or multiple-grounded

system. Figure 27-16 illustrates a typical case of a single-phase-to-ground fault at the end of a 40-mi-long 115-kV transmission line. Because the electric power system is not completely symmetric, the magnitude of the overvoltage on the unfaulted phases may be different; that is, for the case of Fig. 27-16, the overvoltage on phase B is 28.3%, while for phase C the overvoltage is 31.9%. Many studies have

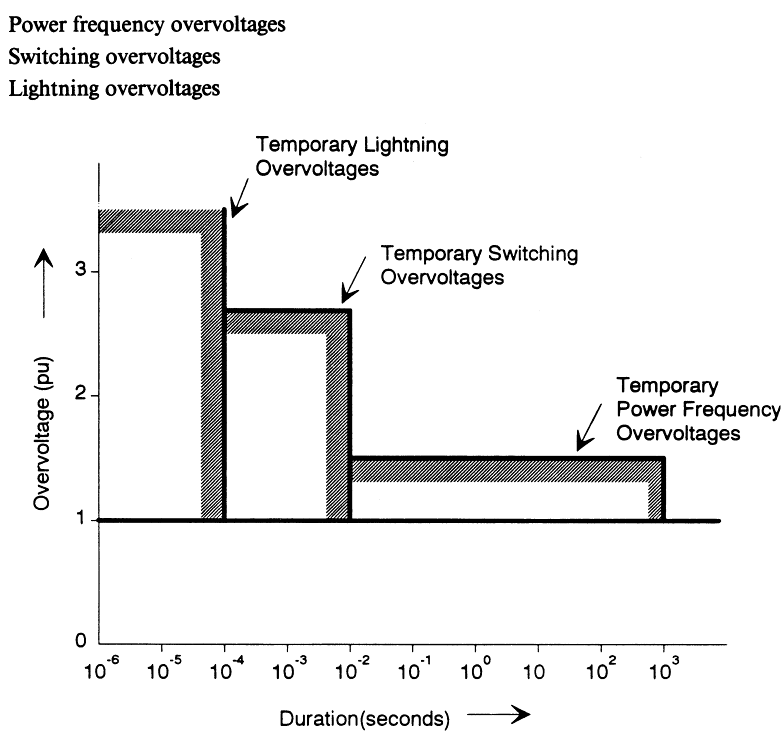

FIGURE 27-15 Typical range of magnitude and duration of power system temporary overvoltages. [*From Regaller (1980).*]

been performed over the years to determine simple techniques for determining the power frequency overvoltages. As a first approximation, one can determine the power frequency overvoltage due to a fault from the sequence parameters (positive-, negative-, and zero-sequence impedances) at the fault location. Figure 27-17, taken from Johnson (1979), illustrates the power frequency overvoltage at the unfaulted phases due to a ground fault in one phase as a function of the ratios (X_0/X_1) and (R_0/X_1).

Computer models for determining the power frequency overvoltage by taking into consideration all relevant factors have been developed. Using these models, one can determine the exact power frequency overvoltage and the effect of grounding practices. As an example, Fig. 27-18, taken from Mancao et al. (1992), illustrates the maximum line-to-ground overvoltage, per unit (pu), on typical distribution circuits versus fault distance from the feeding substation.

Another source of power frequency overvoltages is the so-called Ferranti effect, which occurs when a load is disconnected at the end of a long transmission line. In this case, the line draws a capacitive current from the source, which generates a voltage gradient along the line of such a phase as to increase the voltage at the open end of the line. An approximate expression of the overvoltage at the open end of the line is given by

$$\text{Overvoltage in pu} = \frac{1.0}{\cos(\beta l)}$$

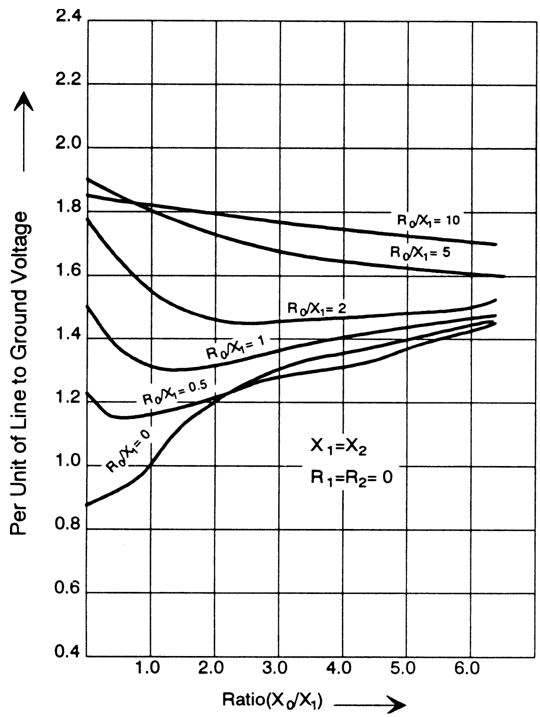

FIGURE 27-17 Overvoltage on unfaulted phase during single-line-to-ground fault. [*From Johnson (1979).*]

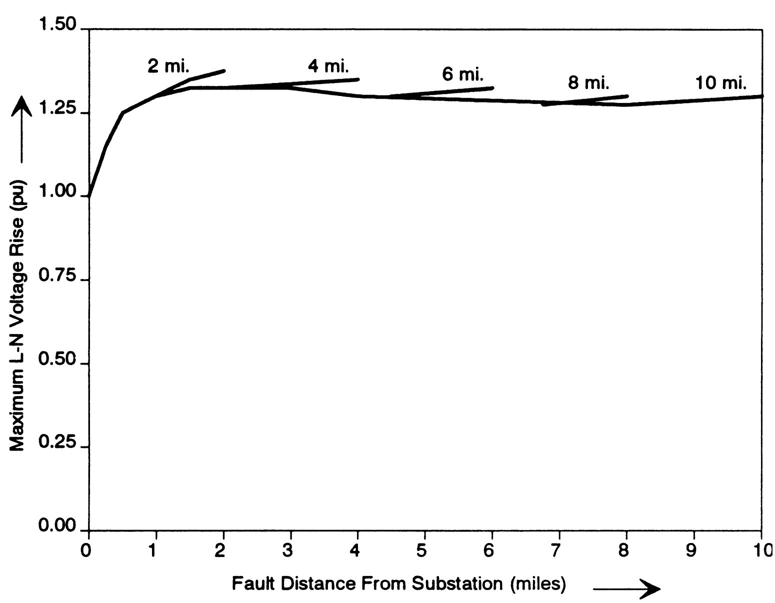

FIGURE 27-18 Overvoltage on unfaulted phases of a distribution circuit as a function of fault distance and circuit length. [*From Mancao et al. (1992).*]

where β is the propagation characteristic of the line ($\omega\sqrt{LC}$) and l is the total length of the line. A typical transmission line of 400 mi may experience an overvoltage of 1.30 pu when one end of the line is open.

Ferroresonance is another cause of power frequency overvoltages but is less frequent. Ferroresonance may occur when energizing long transmission lines and unloaded power transformers, in single-phase switching of a 3-phase transformer, and in other cases involving an iron-core magnetic circuit connected to a substantially capacitive circuit. The overvoltages resulting from ferroresonance can be serious and especially destructive to gapless arresters present in the system. As an example, Fig. 27-19, taken from an IEEE committee report, illustrates the maximum overvoltage due to ferroresonance involving single- or double-phase switching of a 3-phase transformer with an ungrounded primary (delta or wye). The severity of ferroresonance depends on the amount of capacitive reactance present in the system.

Other causes of power frequency overvoltages are (1) generator speedup due to load rejection, (2) generator self-excitation, and (3) malfunction of regulating equipment.

Switching. Switchings in a power system occur frequently. A variety of switchings are performed for routine operations or automatically by control and protection systems. Typical switchings are as follows:

Lines (transmission or distribution)

Cables

Shunt/series capacitors

Shunt reactors

Transformers

Generators/motors

Another class of switching transients are those generated from *insulation flashovers* and breaker *restrikes*. These phenomena are equivalent to the closing of a switch and generate switching surges, which propagate in the system.

Overvoltages resulting from switching operations are typically proportional to the power frequency voltage. For example, energization of a 3-phase line can result in an overvoltage at the open end, which can be as high as 5 pu, depending on the timing of switching with respect to the source. The frequency

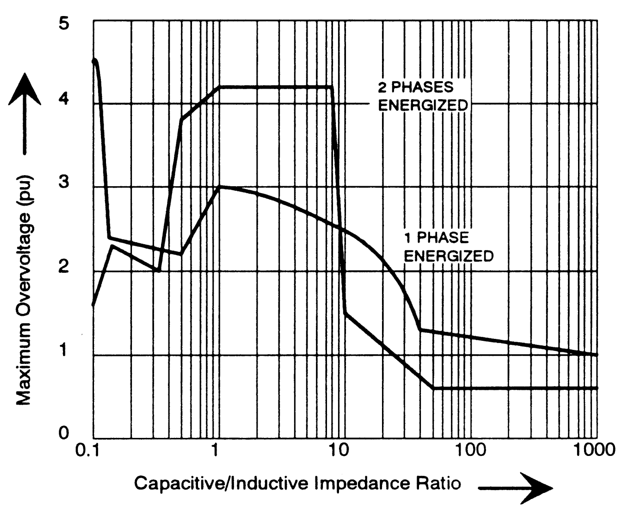

FIGURE 27-19 Maximum overvoltage due to ferroresonance triggered by single-or double-phase switching of a 3-phase transformer with an ungrounded primary.

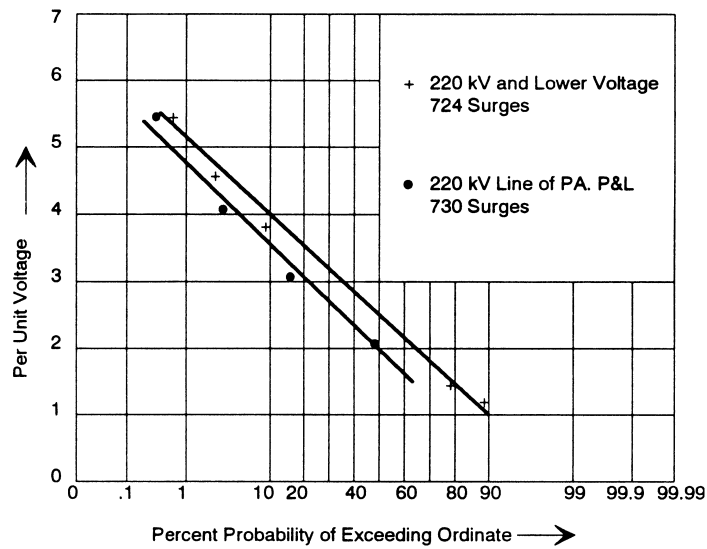

FIGURE 27-20 Probability distribution curves of measured switching overvoltages. [*From Johnson (1979).*]

content of switching transients depends on system parameters. As an example, Fig. 27-20, taken from Johnson (1979), illustrates probability distribution curves of measured line switching overvoltages. Note that there is a substantial probability for overvoltages higher than 5.0 pu.

Switching transients for extra-high-voltage systems, that is, 230 kV and above, can be quite high and must be controlled to avoid the need for higher insulation. There are two methods for controlling the magnitude of switching overvoltages: (1) using breakers with resistor preinsertion and (2) using opening resistors or wound-type potential transformers to discharge trapped charge on lines.

Breakers with resistor preinsertion place a resistor between source and line under energization for a short duration (e.g., 0.8 ms) prior to a direct connection of the source to the line. Proper selection of resistor values and insertion time enables effective control of maximum switching overvoltages. As an example, Fig. 27-21 illustrates the probability distribution curve of switching overvoltages when a resistor preinsertion breaker is used. Note that the maximum switching overvoltage is below 2.5 pu.

Trapped charge on a transmission line can cause excessive switching overvoltages (for specific timing of line energization with respect to source phase). In addition, trapped charge can cause breaker restrike because it contributes to overstressing the breaker insulation. Wound-type potential transformers or opening resistors provide a mechanism for quick drainage of trapped charge on lines.

Switchings can cause other undesirable effects such as inrush currents in transformers and ferroresonance, which has already been discussed.

Lightning Overvoltages. Electric power systems are exposed to weather and therefore are subjected to lightning strikes, which result in overvoltages. Lightning overvoltages are generated by direct lightning strikes on a power system apparatus or indirect strikes to nearby objects, from which subsequent overvoltage is transferred to the system via inductive, capacitive, and conductive coupling.

Unlike power frequency overvoltages and switching overvoltages, which are proportional to the system voltage, lightning overvoltages are independent of system voltage but depend on system impedances. For example, a direct lightning hit to a phase conductor of an overhead transmission line will generate an overvoltage proportional to the characteristic impedance of the line and proportional to the current magnitude of the lightning stroke. This overvoltage may be several million volts. It is a practical and economical impossibility to insulate distribution or lower-kilovolt-level

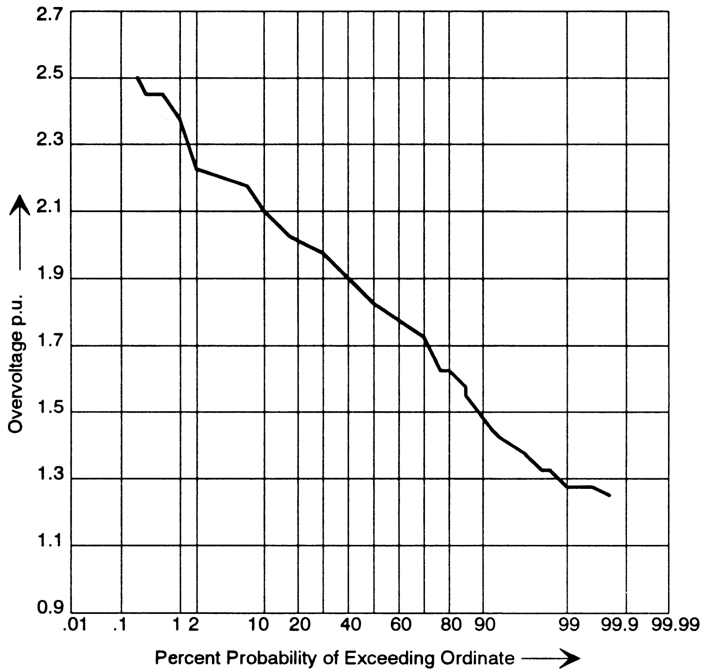

FIGURE 27-21 Probability distribution curves of computed switching overvoltages (switching with a resistor preinsertion breaker).

transmission lines (i.e., 230 kV and below) to withstand this type of overvoltage. As will be discussed in Sec. 27.7, a coordinated design procedure is applied to minimize the effects of lightning; this procedure involves among other things: (1) shielding of lines and equipment, (2) effective grounding, and (3) application of protective devices (surge arresters). The presence of the shielding system ensures that lightning, which otherwise will terminate to a phase conductor, will terminate on a wire, terminal, etc., which is electrically connected to the grounding system. A well-designed grounding system will divert the majority of the lightning stroke current into the soil and thus will minimize the destructive lightning overvoltages. The subject will be further discussed later. Here, a typical example of lightning overvoltages on a 115-kV shielded line is shown in Fig. 27-22. The figure shows the overvoltage at the top of the tower, voltage across insulator of phase A, and the ground potential rise at the tower base. The voltages are given in kilovolts per kiloampere of lightning stroke current. The case shown is for a relatively short tower with effective grounding. The figure shows the effects of nearby towers, which generate reflections of the lightning surge with the end effect of quickly reducing the lightning overvoltages. It should be apparent that the tower-grounding system plays an important role in determining the magnitude of lightning overvoltages, as illustrated in Fig. 27-23. The topic of grounding will be further discussed later.

Lightning strokes to nearby trees, ground, or other objects can result in voltage surges into the power system through coupling. The coupling can be conductive through the conductive soil and the power system grounding structures, inductive, or capacitive. In a typical situation, all the coupling mechanisms may be present, resulting in a voltage surge to the power system. These voltages are called *induced voltage surges* and are generally much lower than those occurring after a direct strike. Specifically, they rarely exceed 400 kV. The induced lightning overvoltages are of concern for distribution lines 35 kV or below. Higher-kilovolt-level lines (i.e., 69 kV and above) have sufficient insulation withstand so that induced lightning voltages do not present the risk of flashover.

27.5 ANALYSIS METHODS

Design of overvoltage protection systems requires a thorough understanding and analysis of transient overvoltages in power systems. Over the years, many analysis methods have been developed for this purpose. All analysis methods require a proper model of the system under study. In this section, we shall discuss modeling requirements for transient analysis and various analysis methods.

Modeling is probably the most important task in a study. There are many modeling choices which must be made in a prudent way and in view of the objectives of the study. Modeling choices are affected by

Phenomenon under study

Period of concern

Model selection of individual system components

For overvoltage analysis, typical phenomena under study will be line switching, capacitor bank switching, and lightning. The period of concern may be seconds, milliseconds, or microseconds. Model selection of individual system components should be guided by the expected frequency content of the transient. The selected models should have the proper frequency response required for the study under consideration. There is a large number of components to be modeled. A representative list is given in Table 27-3.

Three-phase

Underground
Lumped capacitors
Iron-core transformers
Generators

Switches, fuses, etc.

Two other related issues are (1) what to model and (2) how to model. The types of choices to be made regarding the question of what to model may include (1) bus inductance, (2) bus capacitance, (3) transformer winding capacitance, and (4) separation distance between arrester and transformer. The question of how to model is complicated. Typical choices are illustrated in Table 27-4. The task of component model selection is very important. To illustrate the point, consider a 40-mi-long transmission line. The line can be represented as a distributed-parameter model or a lumped-parameter model consisting of a set of cascaded pi sections. Figure 27-24 illustrates the switching voltages computed for this line by using the two models. Note that the solutions are different. Of course, the distributed-parameter model provides the correct answer. Examples of simplified lumped-parameter models and distributed-parameter models are illustrated in Fig. 27-25.

Once the model has been selected, analysis can determine the transient overvoltages for a specific event. Analysis methods can be classified into three categories:

Graphical methods
Analytical methods
Numerical methods

Graphical Methods. The graphical method is based on the observation that the solution for transient voltages and currents in a transmission line can be represented with traveling waves along the line. Under the assumption of an ideal transmission line (zero losses and constant inductance and capacitance per unit length), the waves travel along a line without distortion. Figure 27-26 illustrates the general solution in this sense. Waves are altered when they reach a discontinuity. Specifically, at discontinuity, a wave will be partially reflected and partially transmitted. If the discontinuity involves only resistive elements, the coefficients of reflection and transmission will be constant. This situation is illustrated in Fig. 27-27. The basic relationship among incident (subscript i), reflected (subscript r), and transmitted (subscript t) waves are as follows:

Reflected wave:

$$E_r = \alpha E_i$$

$$I_r = -\alpha I_i$$

$$\alpha = \frac{Z_{\text{eq}} - Z_{01}}{Z_{\text{eq}} + Z_{01}} \quad \text{(reflection coefficient)}$$

$$Z_{\text{eq}} = \frac{R_L Z_{02}}{R_L + Z_{02}}$$

Transmitted wave:

$$E_t = \delta E_i$$

$$I_t = \delta \frac{Z_{01}}{Z_{02}} I_i$$

$$\delta = \frac{2Z_{\text{eq}}}{Z_{\text{eq}} + Z_{01}} \quad \text{(transmission coefficient)}$$

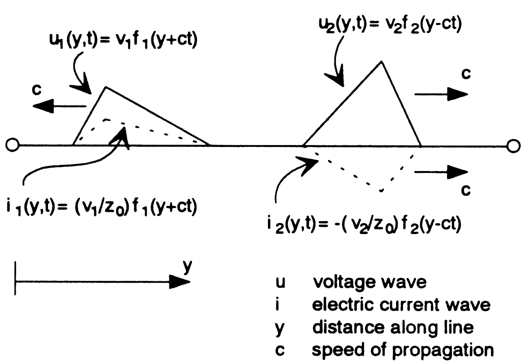

FIGURE 27-26 General wave solution for an ideal distributed-parameter single-phase transmission line.

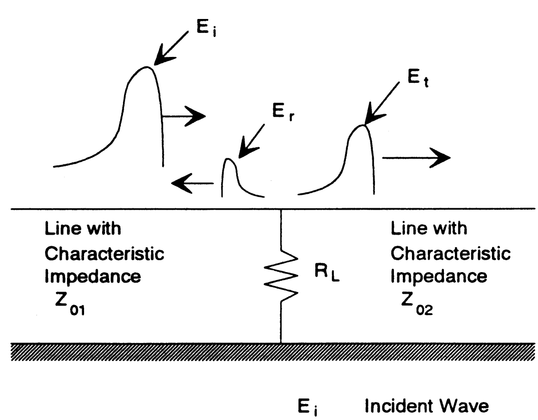

FIGURE 27-27 Transmission and reflection of waves at discontinuity.

If the discontinuity involves storage elements, that is, capacitors or inductors, the coefficients are not constant and the analysis becomes much more complex. The graphical method consists of monitoring all traveling waves on a line with the aid of a diagram, known as the *Bewley diagram*. The Bewley diagram provides, for every point in a system, all the waves present and the time at which they arrive. From this information, the actual voltage waveform at a specific point can be constructed as the superposition of all waves at that point. Such a construction is illustrated in Fig. 27-28.

Analytical Methods. Analytical methods are based on systematic algorithms for solution of the differential equations describing a system. A useful method is based on Laplace transforms. This

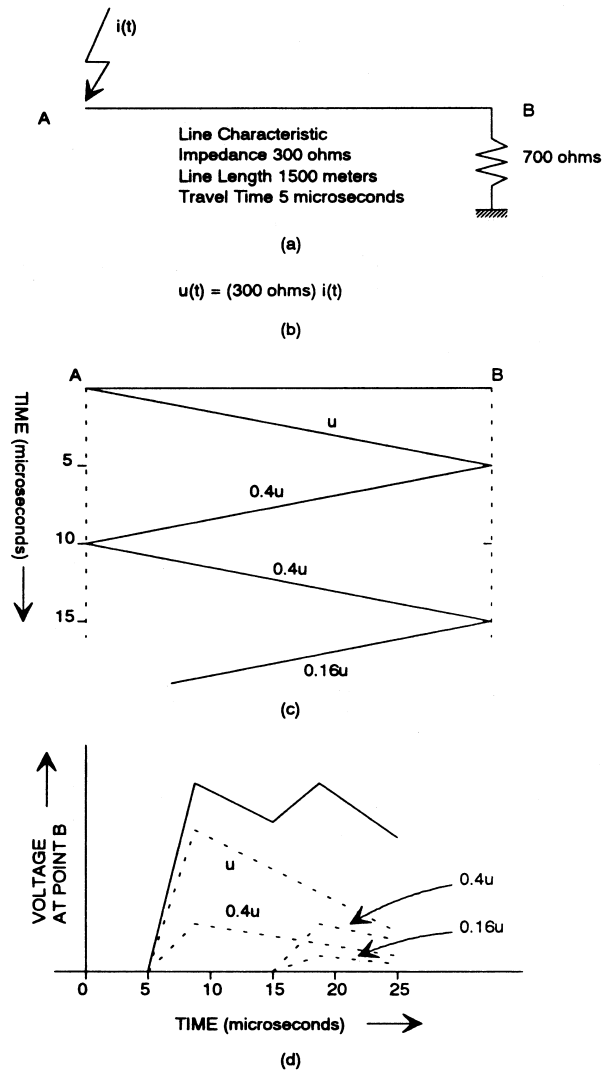

FIGURE 27-28 Illustration of the graphical method: (*a*) system description; (*b*) voltage surge due to lightning *I*(*t*); (*c*) Bewley's diagram; (*d*) construction of voltage at point *B* as the superposition of all surges arriving at point *B*.

method transforms the differential equations describing a component into an equivalent circuit. An example follows. Consider the equation describing an inductor

$$v(t) = L\frac{di(t)}{dt}$$

Application of the Laplace transform on this equation yields

$$V(s) = sLI(s) - Li(0)$$

where $V(s)$ is the Laplace transform of $v(t)$ and $I(s)$ is the Laplace transform of $i(t)$.

The above equation represents the equivalent circuit of Fig. 27-29 (b3). This is known as the Thévenin form of the Laplace domain equivalent circuit. The process can be applied to any power system element described with a set of differential equations. Figure 27-29 illustrates the equivalent circuits in the Laplace domain of typical elements. Note that the equivalent circuits are represented with algebraic equations in complex variables.

Application of the analytical method involves transformation of the differential equations describing individual element with the Laplace transform into an equivalent circuit. Subsequently, nodal analysis (or loop analysis) is applied on the transformed elements to obtain the solution of the voltage at a point of interest as a function of the Laplace variable. Finally, application of the inverse Laplace transform will provide the time waveform of the voltage of interest. Many efficient algorithms were developed during 1975–1995 or so. The details can be found in the literature.

Numerical Methods. Numerical methods are based on transforming the differential equations describing a component into a discrete time equation. This transformation is achieved by proper integration of the differential equations. Many different integration methods can be applied. A very successful method is based on the trapezoidal integration method, because this method is an absolutely stable numerical method. The basic idea is explained as follows. Consider the differential equation

$$\frac{dx(t)}{dt} = ax(t)$$

Integration of this equation in the time interval $(t - h, t)$ yields

$$x(t) - x(t-h) = a\int_{t-h}^{t} x(\tau)d\tau$$

The integral on the right-hand side can be evaluated, *assuming that the function x(t) varies linearly in the time interval (t − h, t)*, yielding

$$\int_{t-h}^{t} x(\tau)d\tau = \frac{h}{2}[x(t) + x(t-h)]$$

This integration is graphically illustrated in Fig. 27-30, which shows that the value of the integral is approximated with the area of the shown trapezoid—thus the name *trapezoidal integration*. Combining above equations and solving for $x(t)$

$$x(t) = \frac{(1 + ah/2)}{(1 - ah)/2} \cdot x(t-h)$$

If $x(0)$ is known, then the above equation can be applied to obtain the value $x(h)$, then $x(2h)$, $x(3h)$, etc. This is a simple algorithm useful for computing the solution at specified times, h, $2h$, $3h$, ...

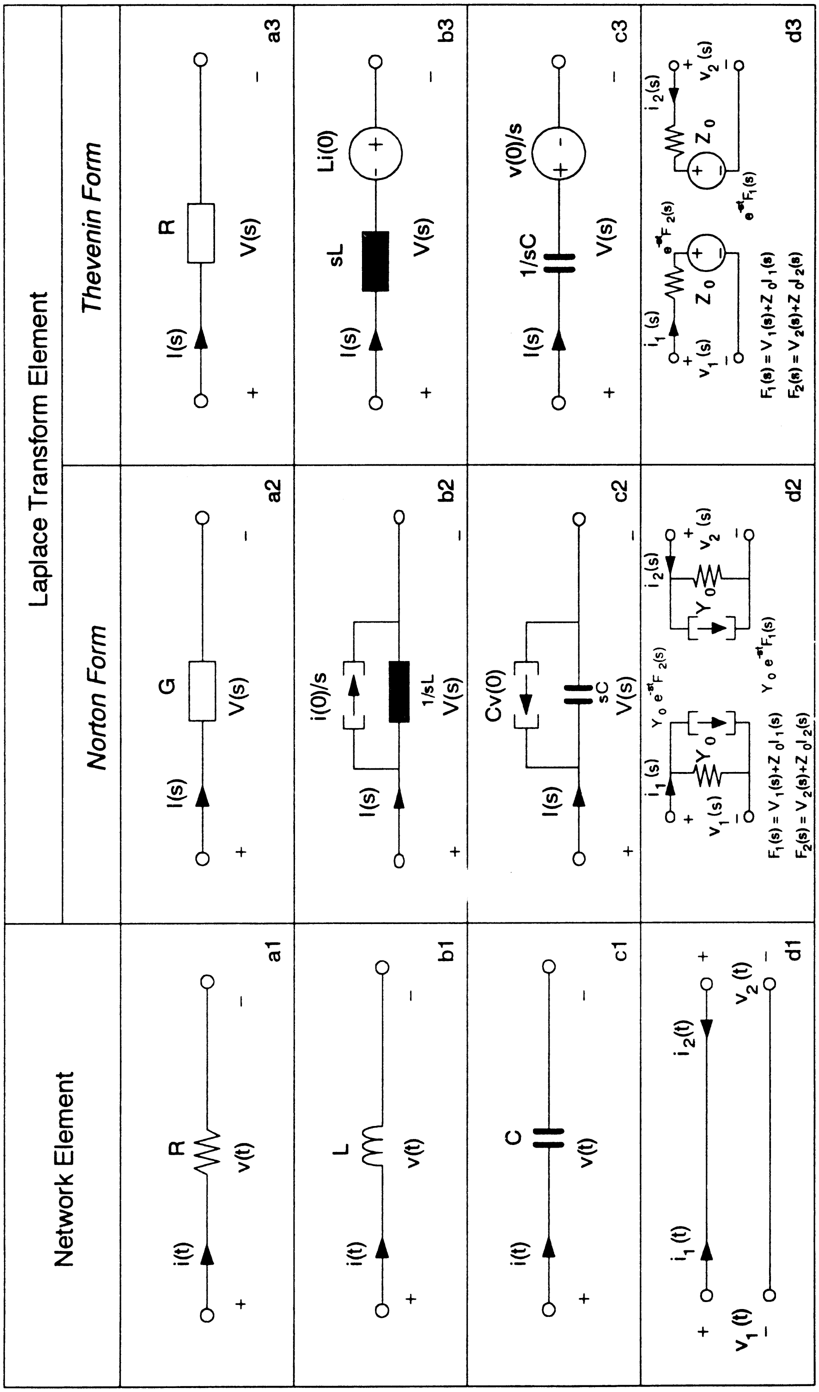

FIGURE 27-29 Equivalent-circuit representation in the Laplace domain. [*From Meliopoulos (1988).*]

The basic idea described above can be applied to the differential equations of any component. The result will be a set of algebraic equations which can be interpreted as a *resistive companion circuit*. The results for simple elements are illustrated in Fig. 27-31. Application of the method requires transformation of each element of the power system into a resistive companion circuit. The process replaces the actual system with a resistive network. This network includes voltage and current sources that depend on the state of the system at times less than t. Application of nodal analysis (or loop analysis) provides the solution for voltages and currents at time t. The process can start at time $t = 0$ and be repeated at times $t = h, t = 2h, \dots$, yielding the values of voltages and currents at times $t = 0, h, 2h, \dots$, etc. Further details can be found in Meliopoulos (1988).

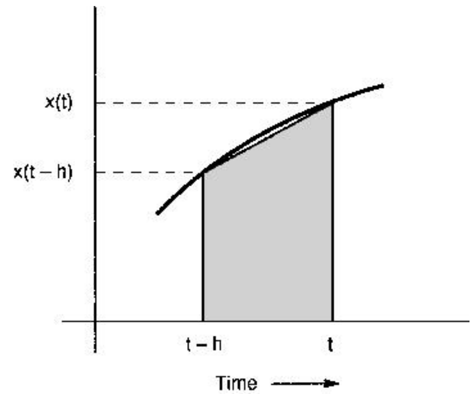

FIGURE 27-30 Graphical representation of the trapezoidal integration.

3-Phase Transmission Lines. 3-Phase transmission is represented with a distributed-parameter model. This model can be derived by considering an infinitesimal length of a 3-phase line as in Fig. 27-32*b*. Assuming an ideal line (zero losses and constant inductance and capacitance per unit length), the model equations are

$$CL\frac{\partial^2}{\partial t^2}v_{abc}(y, t) = \frac{\partial^2}{\partial y^2}v_{abc}(y, t)$$

$$CL\frac{\partial^2}{\partial t^2}i_{abc}(y, t) = \frac{\partial^2}{\partial y^2}i_{abc}(y, t)$$

$$L\frac{\partial}{\partial t}i_{abc}(y, t) = \frac{\partial}{\partial y}v_{abc}(y, t)$$

where

$$v_{abc}(y, t) = \begin{bmatrix} v_a(y, t) \\ v_b(y, t) \\ v_c(y, t) \end{bmatrix}$$

$$i_{abc}(y, t) = \begin{bmatrix} i_a(y, t) \\ i_b(y, t) \\ i_c(y, t) \end{bmatrix}$$

$$L = \begin{bmatrix} L_{aa} & L_{ab} & L_{ac} \\ L_{ab} & L_{bb} & L_{bc} \\ L_{ac} & L_{bc} & L_{cc} \end{bmatrix}$$

is the inductance matrix per unit length of the line and

$$C = \begin{bmatrix} C_{aa} & C_{ab} & C_{ac} \\ C_{ab} & C_{bb} & C_{bc} \\ C_{ac} & C_{bc} & C_{cc} \end{bmatrix}$$

is the capacitance matrix per unit length of the line, y is distance along line, and t is time.

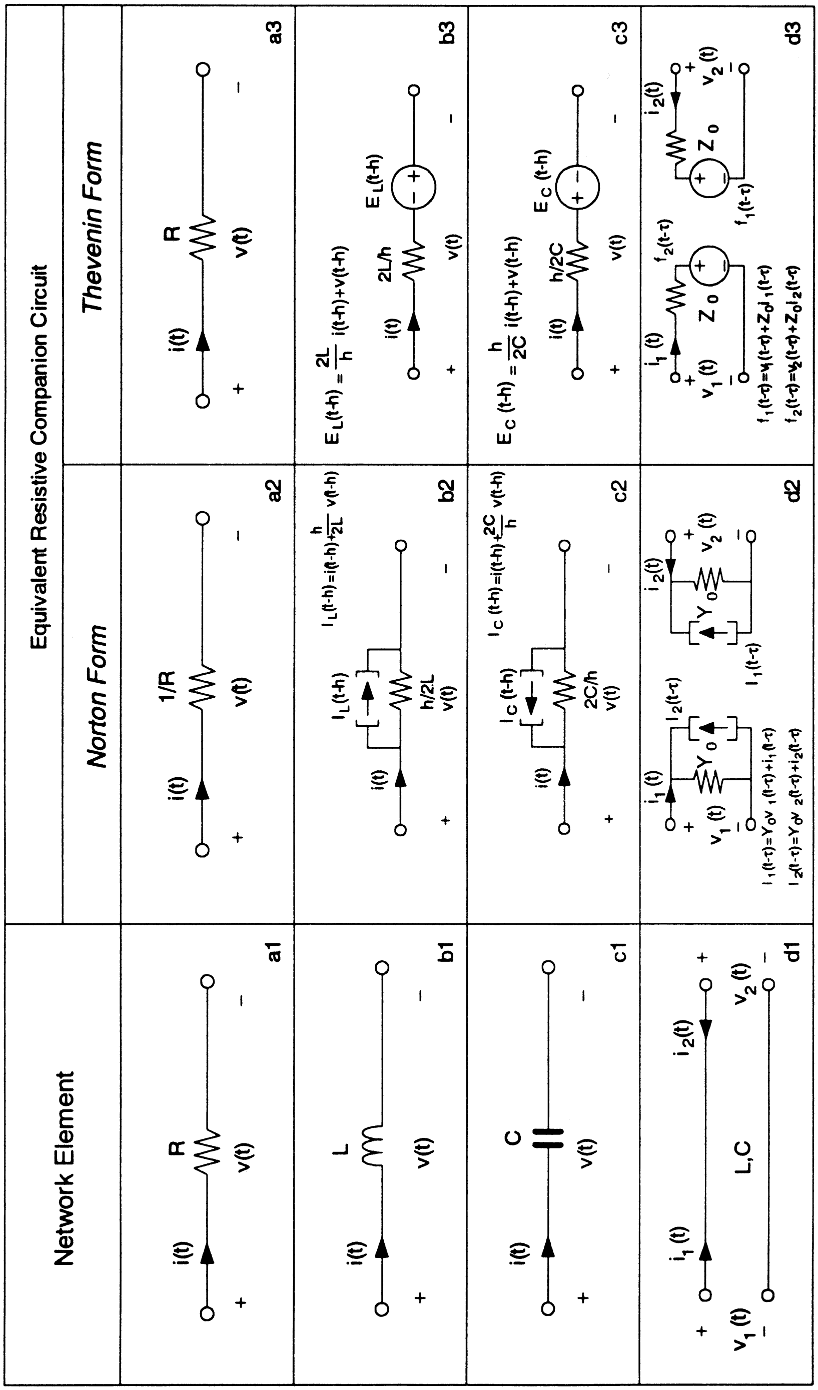

FIGURE 27-31 Equivalent resistive comparison circuits. [*From Meliopoulos (1988).*]

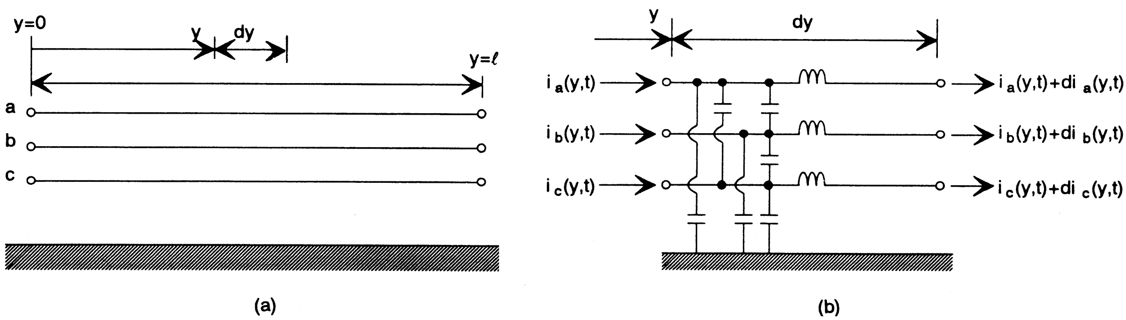

FIGURE 27-32 3-Phase line model: (*a*) 3-phase transmission line; (*b*) equivalent circuit of an infinitesimal length (*dy*) of 3-phase line.

This is a rather simplified model of a 3-phase line and yet very complex. To make clear the behavior of the 3-phase line, the concept of the *ideal continuously transposed line* will be introduced. This concept assumes a perfectly symmetrical line

$$L_{aa} = L_{bb} = L_{cc} = L_s$$

$$L_{ab} = L_{ac} = L_{bc} = L_m$$

$$C_{aa} = C_{bb} = C_{cc} = C_s$$

$$C_{ab} = C_{ac} = C_{bc} = C_m$$

Next, Karrenbauer's transformation is introduced as follows

$$v_{abc}(y, t) = Kv_{gll}(y, t)$$

$$i_{abc}(y, t) = Ki_{gll}(y, t)$$

where

$$v_{gll}(y, t) = \begin{bmatrix} v_g(y, t) \\ v_{l1}(y, t) \\ v_{l2}(y, t) \end{bmatrix}$$

$$i_{gll}(y, t) = \begin{bmatrix} i_g(y, t) \\ i_{l1}(y, t) \\ i_2(y, t) \end{bmatrix}$$

and

$$K = \begin{bmatrix} 1 & 1 & 1 \\ 1 & -2 & 1 \\ 1 & 1 & -2 \end{bmatrix}$$

Replacement of the actual voltages and currents $v_{abc}(y, t)$ and $i_{abc}(y, t)$ with the voltages and currents $v_{gll}(y, t)$ and $i_{gll}(y, t)$ through Karrenbauer's transformation yields the following transformed equations for the 3-phase line (Meliopoulos 1988)

Set 1 (ground-mode equations)

$$(L_s + 2L_m)(C_s + 2C_m)\frac{\partial^2}{\partial t^2}v_g(y, t) = \frac{\partial^2}{\partial y^2}v_g(y, t)$$

$$(L_s + 2L_m)(C_s + 2C_m)\frac{\partial^2}{\partial t^2}i_g(y, t) = \frac{\partial^2}{\partial y^2}i_g(y, t)$$

$$(L_s + 2L_m)\frac{\partial}{\partial t}i_g(y, t) = \frac{\partial}{\partial y}v_g(y, t)$$

Set 2 (line-mode 1 equations)

$$(L_s - L_m)(C_s - C_m)\frac{\partial^2}{\partial t^2}v_{l1}(y, t) = \frac{\partial^2}{\partial y^2}v_{l1}(y, t)$$

$$(L_s - L_m)(C_s - C_m)\frac{\partial^2}{\partial t^2}i_{l1}(y, t) = \frac{\partial^2}{\partial y^2}i_{l1}(y, t)$$

$$(L_s - L_m)\frac{\partial}{\partial t}i_{l1}(y, t) = \frac{\partial}{\partial y}v_{l1}(y, t)$$

Set 3 (line-mode 2 equations)

$$(L_s - L_m)(C_s - C_m)\frac{\partial^2}{\partial t^2}v_{l2}(y, t) = \frac{\partial^2}{\partial y^2}v_{l2}(y, t)$$

$$(L_s - L_m)(C_s - C_m)\frac{\partial^2}{\partial t^2}i_{l2}(y, t) = \frac{\partial^2}{\partial y^2}i_{l2}(y, t)$$

$$(L_s - L_m)\frac{\partial}{\partial t}i_{l2}(y, t) = \frac{\partial}{\partial y}v_{l2}(y, t)$$

Note that the complex equations for the 3-phase line have been replaced with three sets of equations, each set representing an ideal single-phase line. The characteristic impedance and speed of propagation of surges for the three ideal single phase lines are

Ground mode

$$Z_g = \frac{1}{Y_g} = \sqrt{\frac{L_s + 2L_m}{C_s + 2C_m}}$$

$$c_g = \frac{1}{\sqrt{(L_s + 2L_m)(C_s + 2C_m)}}$$

Line mode (1 or 2)

$$Z_l = \frac{1}{Y_l} = \sqrt{\frac{(L_s - L_m)}{(C_s - C_m)}}$$

$$c_l = \frac{1}{\sqrt{(L_s - L_m)(C_s - C_m)}}$$

This model of the line is illustrated in Fig. 27-33. The three sets of equations or three ideal single-phase line models above are known as (1) the ground mode g, (2) line mode 1 l_1, and (3) the line mode 2 l_2. The names become obvious if one considers excitation of the 3-phase line with one mode.

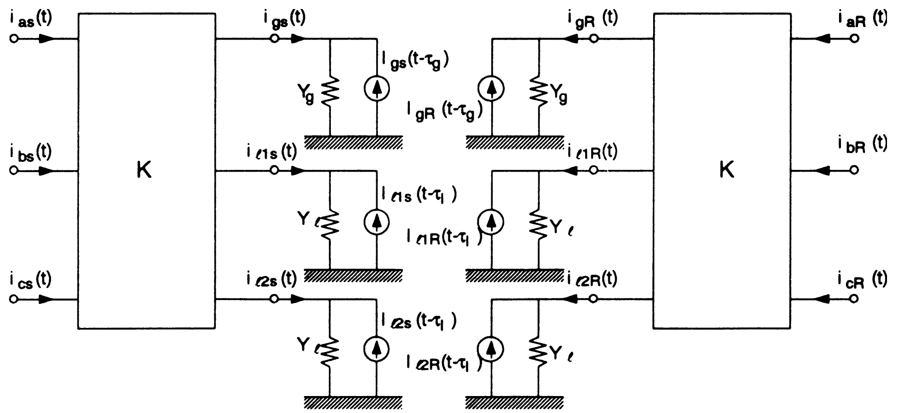

FIGURE 27-33 Equivalent circuit of a continuously transposed line.

For example, consider that the line is excited in such a way that $i_{l1}(y, t) = 0$ and $i_g(y, t) = 0$, $i_{l2}(y, t) = 0$. In this case, the actual phase currents will be

$$i_{abc}(y, t) = Ki_{gll}(y, t)$$

which yields

$$i_a(y, t) = i_{l1}(y, t)$$
$$i_b(y, t) = -2i_{l1}(y, t)$$
$$i_c(y, t) = i_{l1}(y, t)$$

This state of the line is illustrated in Fig. 27-34*a*. Note that there is a positive surge on phases *a* and *c*, which returns through phase *b*. All electric current surges are confined in the line conductors, thus the name line mode.

Consider now excitation with $i_g(y, t) \neq 0$, $i_{l1}(y, t) = 0$, and $i_{l2}(y, t) = 0$. In this case, the equation

$$i_{abc}(y, t) = Ki_{gll}(y, t)$$

yields

$$i_a(y, t) = i_g(y, t)$$
$$i_b(y, t) = i_g(y, t)$$
$$i_c(y, t) = i_g(y, t)$$

This state of the line is illustrated in Fig. 27-34*b*. Note that the surges on all phases are equal. The return current is through the earth, thus the name ground mode. The parameters of the various modes of propagation of surges in a 3-phase line are different. As an example, the following values apply to a 115-kV 3-phase line.

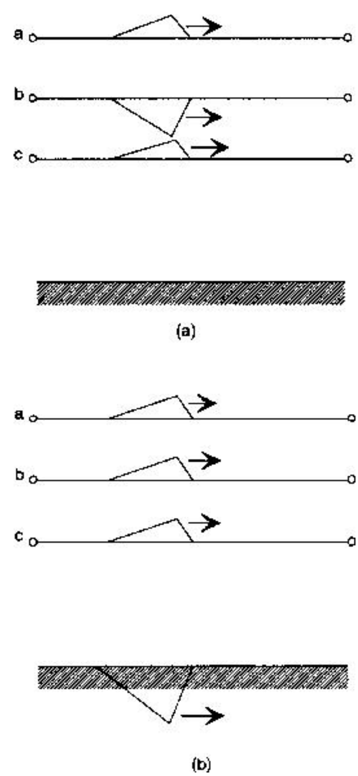

FIGURE 27-34 Modes of propagation along a 3-phase line: (*a*) line mode; (*b*) ground mode.

The inductance matrix is

$$L = \begin{bmatrix} 2.2289 & 1.032 & 0.8935 \\ 1.032 & 2.2289 & 1.032 \\ 0.8935 & 1.032 & 2.2289 \end{bmatrix} \quad \mu\text{H/m}$$

Therefore $\qquad L_s = 2.2289 \quad \mu\text{H/m} \qquad L_m = 0.9858 \quad \mu\text{H/m}$

The capacitance matrix is

$$C = \begin{bmatrix} 7.6737 & -1.9129 & -1.0065 \\ -1.9129 & 8.0184 & -1.9129 \\ -1.0065 & -1.9129 & 7.6737 \end{bmatrix} \times 10^{-12} \quad \text{F/m}$$

Therefore $\qquad C_s = 7.7886 \times 10^{-12}\ \text{F/m} \qquad C_m = -1.608 \times 10^{-12}\ \text{F/m}$

Line mode (1 or 2):

$$Z_l = \sqrt{\frac{(L_s - L_m)}{(C_s - C_m)}} = 363.7\ \Omega$$

$$c_l = \frac{1}{\sqrt{(L_s - L_m)(C_s - C_m)}} = 2.926 \times 10^8\ \text{m/s}$$

Ground mode:

$$Z_g = \sqrt{\frac{(L_s + 2L_m)}{(C_s + 2C_m)}} = 959.1\ \Omega$$

$$c_g = \frac{1}{\sqrt{(L_s + 2L_m)(C_s + 2C_m)}} = 2.283 \times 10^8\ \text{m/s}$$

When lightning hits a 3-phase line, all modes of propagation are excited. The overvoltage of the 3-phase line as a result of the lightning stroke is determined from the parameters of all the modes. Later, examples of these calculations will be provided.

Frequency-Dependent Models. The parameters of power-system elements are frequency dependent. As an example, consider the ground-mode resistance of a 3-phase line. This resistance value may change *several orders of magnitude* in the frequency range 60 Hz (power frequency) to 1 MHz. This increase of resistance is mainly due to skin-effect-type phenomena. The higher resistance values at high frequencies tend to attenuate higher-frequency components of transient overvoltages with the end effect of reducing the maximum overvoltages. Computer models to account for the frequency dependence have been developed for almost all power components. The reader is referred to the literature. Frequency-dependent models are complex, but, on the other hand, they provide a better representation of the real system. As an example, consider Fig. 27-35. The figure illustrates comparison of measured and computed switching transients in a 224.15-mi-long 230-kV line. The single-line diagram of the system is illustrated in Fig. 27-36. The tests were performed by Bonneville Power Administration. The calculated switching transient was performed with a frequency-dependent model (Cokkinides and Meliopoulos 1988). Note that the maximum switching overvoltage is 1.81 pu. It is important to note that simulation of the same system assuming an ideal continuously transposed line results in a maximum switching overvoltage of 2.05 pu. The conclusion is that frequency-dependent models are more realistic.

Grounding Models. Grounding plays an important role in dissipation of lightning strokes and therefore controlling overvoltages resulting from lightning. Yet, grounding has been widely misunderstood and proper analysis models are scarce. Modeling of grounding systems is a rather complex task, and it is strongly coupled to the overall modeling procedure for power systems. Two distinct approaches apply: (1) grounding models for low frequency generally consider grounds as a pure resistance and thus dc analysis models are utilized, based on the method of moments or relaxation methods; (2) grounding models for higher frequencies require complete electromagnetic analysis. For this purpose, finite element analysis or the method of moments can be utilized. Since the grounds are typically complex systems, simplifications are typically introduced. A rule of thumb for selecting dc models or the more complex models is to compare the largest dimension of a grounding system l to the depth of penetration $\delta = \sqrt{2}/\sqrt{\mu\omega\sigma}$. If $l > 0.1\delta$, then a complete model is necessary. In this expression, μ is the permeability of the medium, ω is the frequency in radians per second, and σ is the conductivity.

The choice of the grounding model can be crucial. As an example, consider a grounding system consisting of a counterpoise buried in soil of 100 $\Omega \cdot$ m. The dc ground resistance of this system is 2.29 Ω. The frequency-dependent impedance is much higher for high frequencies and approaches 2.29 Ω for frequencies below 50 kHz. As a result, a lightning discharge through this ground will require a frequency-dependent ground model to accurately predict the transient overvoltages. As an example, Fig. 27-37 shows the differences between the correct model and the dc model for the standard lightning waveform. The example emphasizes the importance of selecting the proper model for the grounding system.

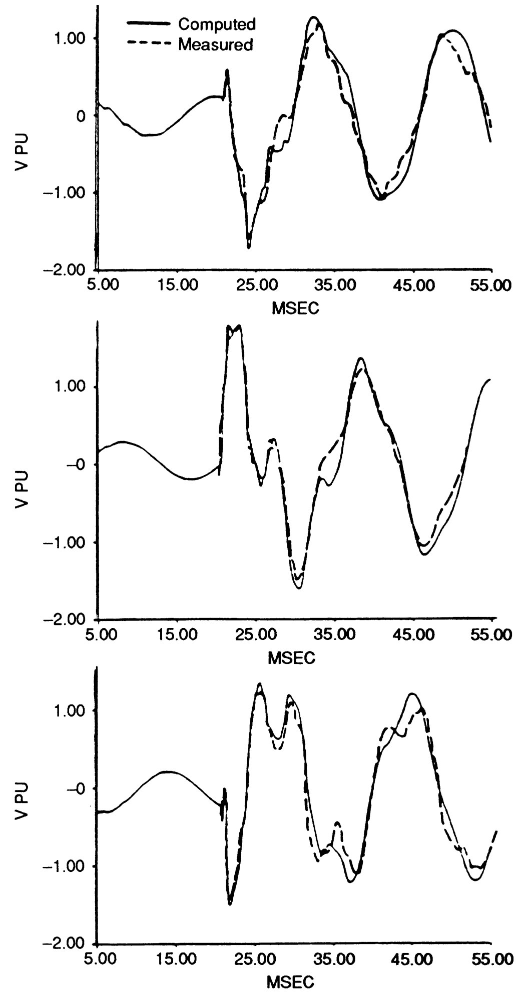

FIGURE 27-35 Comparison of simulation and test results of switching surges: (*a*) phase A transient voltage; (*b*) phase B transient voltage; (*c*) phase C transient voltage. [*From Cokkinides and Meliopoulos (1988).*]

Grounding systems play an important role in propagation of surges from high-voltage power systems to lower-voltage secondary systems. Specifically, transients initiated in the power system can travel through the grounding system and enter the secondary power system of a facility, reaching sensitive electronic equipment. Transformers do not exist in the path of a neutral. Thus, high-frequency transients travel almost unattenuated through the neutral. Attenuation is provided only by the grounds if the neutral is multiply grounded. A proper model of the grounds, neutrals, and the power system can provide a good tool to determine the transient overvoltages reaching a specific piece of equipment. As an example, consider a facility served by a 1-mi (1.6 km) underground distribution cable as in Fig. 27-38. The underground cable is fed from an overhead distribution circuit, which is subject to lightning. At such a service entrance, transients can enter a facility through the cable concentric neutral and the ground conductors.

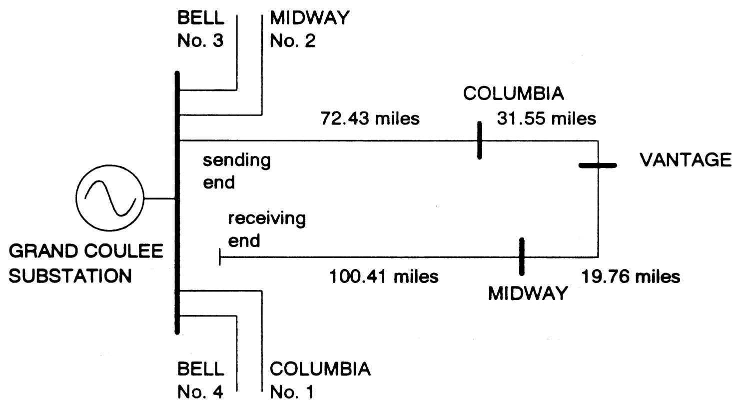

FIGURE 27-36 Illustration of system for switching surge test. *(Bonneville Power Administration.)*

Probabilistic Methods. The objective of these methods is to provide a probabilistic description of overvoltages in a specific power apparatus. The method takes into consideration the uncertainty in parameters affecting the overvoltages. Some of the uncertain parameters are listed in Table 27-5.

The probabilistic methods consist of the following three components:

1. A probabilistic model for the uncertain parameters
2. An analysis model for the system under study
3. A Monte Carlo simulation method

The result of the method is the probability distribution of the overvoltages at the apparatus of interest. Given the probabilistic model for the uncertain parameters and an analysis model for the system under study, the Monte Carlo simulation consists of the following steps:

Step 0: Set count of trial *n* equal to 0.

Step 1: Generate (randomly) a sample of parameters from the probabilistic model of uncertain parameters (crest value of lightning stroke, rise time, fall time, location of incidence, etc.).

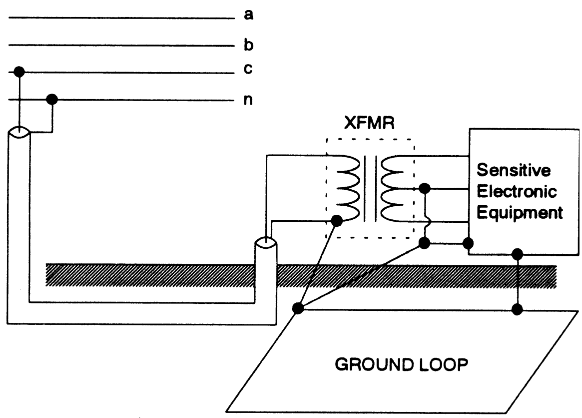

FIGURE 27-38 Illustration of a typical service entrance to a commercial or industrial facility.

Step 2: Use the analysis model and the parameter values determined in step 1 to evaluate the maximum overvoltage at points of interest (or other quantities of interest). Store the computed values.

Step 3: Repeat steps 1, 2, and 3 until the number of trials = n. Then go to step 4.

Step 4: Use the stored computed values of overvoltages (or other quantities of interest) to generate histograms and/or probability distribution functions.

The utility of probabilistic methods is quite obvious. They provide the tool to determine not only the expected overvoltages but also the frequency of occurrence. For external insulation protection practices, probabilistic methods provide an indispensable tool for optimal designs.

27.6 OVERVOLTAGE PROTECTION DEVICES

With certainty, temporary overvoltages on power-system apparatus will exceed their withstand capability. In this case, if the apparatus is left unprotected, insulation failure will occur. Therefore, it is necessary to protect power system components against overvoltages. The philosophy and objectives of this protection vary depending on the type of overvoltages, frequency, effects of insulation failure, and cost of repair. These issues will be discussed later. In this section, we will be concerned with available protection devices, their characteristics, and protection levels. An overvoltage protection device should ideally limit the voltages across the insulation of a power apparatus below a specified value. This specified value is called the *protection level*. The ideal protection device has the voltage-current characteristic indicated in Fig. 27-39. Specifically, if the voltage across the protection device is less than the protection level, then the protection device should have an infinitely large impedance. If the voltage across the protection device is higher than the protection level, then the protection device should allow the flow of electric current through it

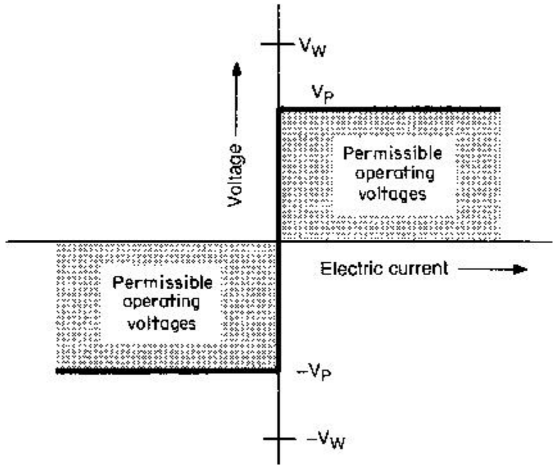

FIGURE 27-39 Voltage-current characteristics of the ideal overvoltage protection device.

in such a way that the voltage is clipped to the protection level value. Such a characteristic can be mathematically described with the equation

$$i(t) = i_0 \left\{ \frac{abs\,[v(t)]}{v_p} \right\}^n \text{sign}\,[v(t)] \tag{27-1}$$

where i_0 = a constant
v_p = protection level
abs $(\cdot)$ = absolute value of the argument $(\cdot)$
$v(t)$ = voltage across the protective device
sign $[v(t)]$ = sign of voltage $v(t)$, + or −
n = a very large number

The protection characteristics of Fig. 27-39 correspond to a very large value of n.

Of course, a protection device with these characteristics does not exist. Research and development has resulted in protection devices which come close to that of Fig. 27-39 to varying degrees. It is important to note that the research and development of protection devices has been evolutionary; over the years the following major breakthroughs have occurred:

Air gaps
Gapped surge arresters
Expulsion arresters
Gapped valve-type arresters
Gapped silicon carbide (SiC)
Metal oxide varistors
Shunt-gapped metal oxide varistors (MOVs)

The most important application characteristics of a protection device are the protection level and the reseal level. These are defined as follows:

Protection level: The maximum voltage, which will be allowed by the device across its terminals.

Reseal level: The maximum voltage below which the protection device will disallow significant electric current through it.

For best results, it is expedient that these two parameters be as close as possible. Observe that for the ideal protection device, the protection level is equal to the reseal level. In order to quantify the protection quality of various technologies of protective devices, the following definition is introduced:

Protection quality index (PQI). The protection-quality index is defined as the ratio of the reseal level over the protection level:

$$\text{PQI} = \frac{V_r}{V_p}$$

Note that the ideal protective device has a protection-quality index of 1. As should be expected, the protective capabilities of protective devices increase with every breakthrough in the technology. Air gaps provide rudimentary protection, gapped SiC surge arresters provide improved protection, and finally MOVs provide even better protection. Within each class of technology, many variations exist. The next paragraphs will discuss the above technologies.

Air (Spark) Gaps. A spark gap was the first protection device to be applied on a power system. It can be constructed with two electrodes placed at a certain distance. The shape of the electrodes varies depending on the application—for example, two wires, a wire and a planar electrode, or two spheres. When the voltage across the air gap exceeds a certain value, an arc will initiate between the electrodes. The voltage across the arc will depend on the current of the arc, the length of the arc, and time. A typical variation of the voltage across the gap is illustrated in Fig. 27-40. The protection level as well as the reseal level, indicated as maximum permissible operating voltage across the gap, are shown. Note that for good protection, the protection quality index (the ratio V_r/V_p) should be maximized. Unfortunately, air gaps exhibit very low protection quality index. In many applications, and in order to improve the protection quality index, the electrodes are shaped in such a way as to force the arc to elongate and therefore increase the voltage reseal value V_r.

Gapped Surge Arresters. Gapped surge arresters consist of a series of spark gaps with or without series blocks of nonlinear resistors, which act as current limiters. The construction of such an arrester is illustrated in Fig. 27-41.

The function of the air gap is to isolate the current limiting block of the surge arrester from the power frequency voltage under normal operating conditions. The air gap is necessary because the current limiting block will fail thermally if subjected to the continuous normal power frequency

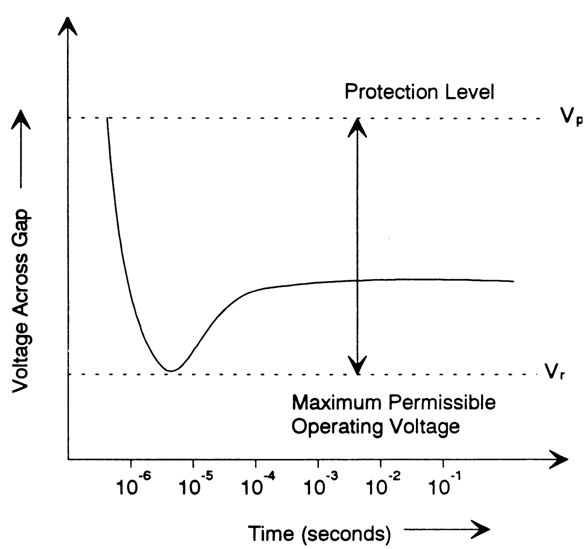

FIGURE 27-40 Typical voltage-time characteristic of a long air gap.

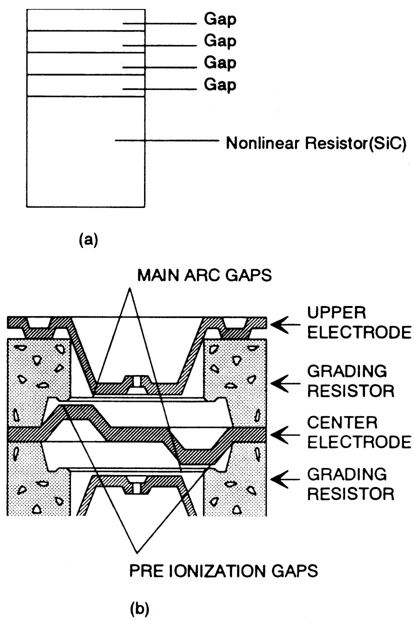

FIGURE 27-41 Construction of a gapped arrester: (*a*) block diagram; (*b*) detail of a gap.

voltage. Elaborate designs of air gaps have been developed, which assure (1) consistent sparkover voltage and (2) arc extinction (resealing) after the overvoltage ceases to exist.

Consistent sparkover voltage is achieved by either a trigger gap or a preionizer. In order to prevent damage of the trigger mechanism, the main current is not allowed to pass through it by use of grading resistors as is illustrated in Fig. 27-41, but through the main arc gaps. To ensure arc extinction and good resealing properties, a mechanism is provided for the control of the arc. Specifically, the main current is passed through a coil. The magnetic field of the coil is established in the space of the arc and is oriented so as to force the arc into a serrated-tooth chamber. The end result of this interaction is that the arc is elongated, cooled, and the voltage across the arc becomes substantial. Figure 27-42 illustrates the buildup of the voltage across the arc due to this mechanism. An illustration of the serrated-tooth chamber is illustrated in Fig. 27-43. The elongated arc improves the capability of the arrester to reseal when the current through it decreases after the overvoltage ceases to exist. It is important to note that the arc control process takes a relatively long time (hundreds of microseconds) to develop full voltage across the gap. This means that for fast transients, that is lightning, almost the entire voltage appears across the current-limiting block.

The current-limiting block in modern gapped arresters is constructed from SiC. The block has nonlinear resistance characteristics that are controlled with the manufacturing process. Specifically, the block is constructed from SiC crystals which are ground into powder form and then are mixed and pressed together with insulating material, forming a block. In this way, an SiC particle partially touches other particles and partially is insulated by the insulating material. The nonlinear properties

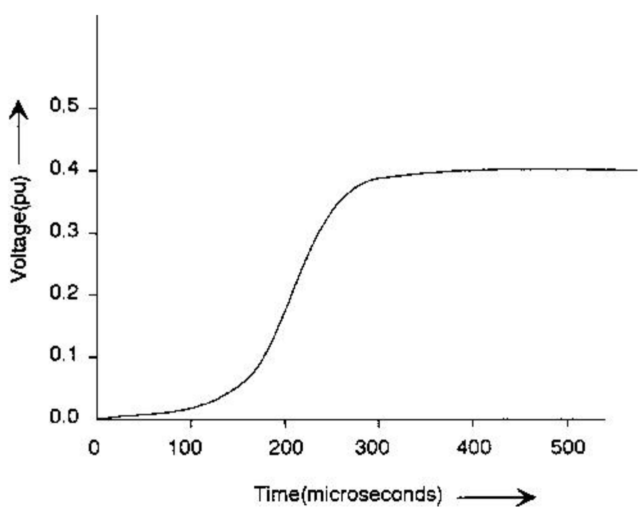

FIGURE 27-42 Evolution of voltage across the arc of a gapped arrester.

are due to the resistance-temperature properties of the junction between the SiC crystals. This relationship is illustrated in Fig. 27-44.

The combined operation of the gap and the current-limiting block result in the voltage-current characteristic illustrated in Fig. 27-45. It is important to note that, while the sparkover voltage V_s is typically consistent, the voltage-current curve depends on the waveform of the electric current, since the gap voltage is time dependent.

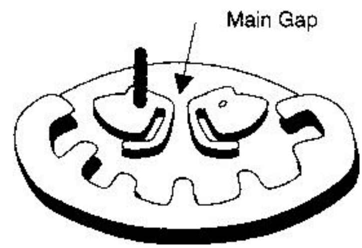

FIGURE 27-43 Illustration of a serrated-tooth chamber of a gapped arrester.

Gapped SiC arresters are subject to power-follow current because of the poor nonlinear characteristics of the SiC block. Specifically, after sparkover and after the temporary overvoltage has subsided, if the power voltage across the arrester is substantial, a relatively high current will continue to flow through the arrester. The reason can be easily visualized if one considers that the arc in the gap is a low-resistance conductor and that the current is primarily determined by the voltage-current characteristics of the SiC block. The situation is illustrated in Fig. 27-46. In the figure, the power-follow current of a SiC gap arrester is also compared to the power-follow current of an MOV arrester, which is discussed next.

Metal Oxide Varistor Arresters. An MOV is formed from a variety of materials via a manufacturing process, which provides the desired electrical properties to the varistor. These electrical properties are not existent in the raw materials. In other words, the electrical properties of the final product are completely dependent on the manufacturing process. Much research effort has been expended to achieve electrical properties of the varistor close to those of the ideal protective device. The typical structure of a metal oxide varistor consists of highly conductive tiny particles of metal oxide (usually zinc oxide, ZnO) suspended in a semiconducting material. This structure is illustrated in Fig. 27-47. The manufacturing process determines the size of the metal oxide particles as well as the thickness and resistivity of the semiconducting material. The key to a good manufacturing process is that the conductive metal oxide particles do not touch each other but are separated by semiconducting material. This structure gives the varistor the properties of a pair of back-to-back-connected zener diodes. A typical voltage-current characteristic of an MOV is illustrated in Fig. 27-46. It should be understood that this function holds for negative voltages and currents.

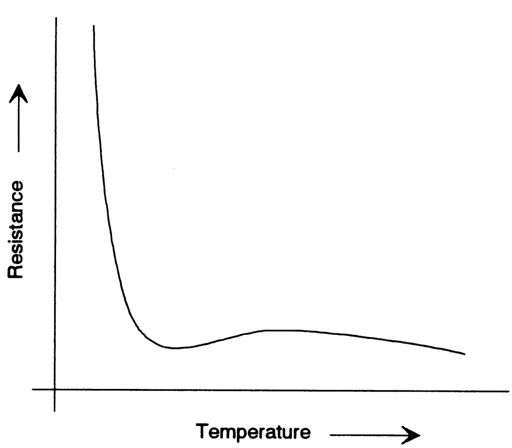

FIGURE 27-44 Typical resistance versus temperature of junction between SiC crystals.

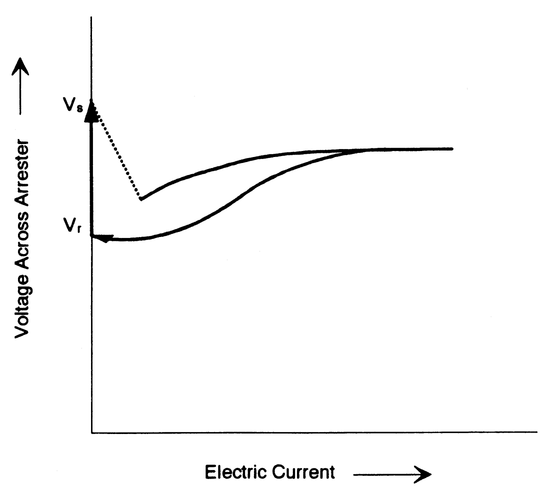

FIGURE 27-45 Typical voltage-current characteristics of a modern SiC gapped arrester.

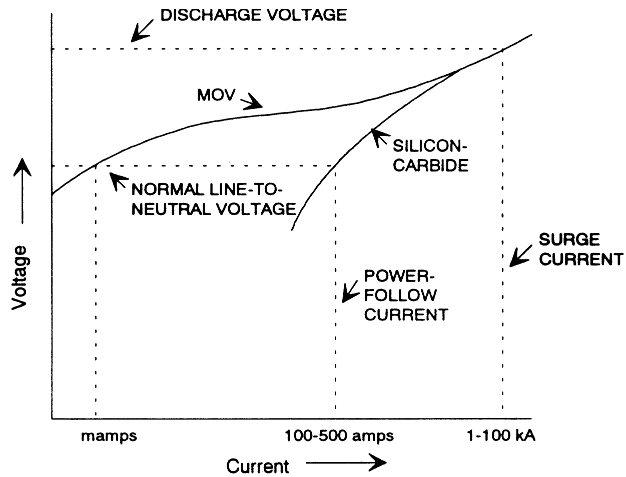

FIGURE 27-46 Illustration of power-follow current for a SiC gapped arrester and an MOV arrester.

In addition to this characteristic, it is necessary that the MOV material be capable of absorbing energy losses during conduction. The average energy absorption capability of a conventional ZnO varistor is about 150 to 200 J/cm^3. Recent advances in MOV technology under Electric Power Research Institute sponsorship resulted in new formulations and manufacturing processes for MOVs. The new MOVs are capable of absorbing 4 to 5 times more energy per volume as above.

The first designs of MOV arresters were subject to problems. The most common were thermal runaway and failures due to moisture ingress causing insulation failures. Thermal runaway can occur because an MOV is typically applied to the energized conductor without a series gap, and a small electric current always flows through the MOV during normal operating conditions. This small current and the associated ohmic losses can potentially raise the temperature of the MOV to the point that its electrical properties deteriorate, allowing more current to flow and further raising the temperature until failure. However, improvements in metal oxide materials and in packaging resulted in robust MOV arresters. The present state of the art and the superior properties of the MOV arresters make them the protection device of choice.

The first commercially available MOV arresters were gapless. As a result, the MOV block is continuously subjected to the power frequency voltage. The performance of the MOV block under this condition is very important for determining the life of the arrester. A deep understanding of these characteristics is essential for the proper application of MOV arresters.

First, observe that the voltage-current characteristic for an MOV arrester in Fig. 27-46 exhibits a knee for small currents (in the milliampere region). The knee is defined to be near the voltage required across the MOV block to cause 1 mA/cm^2 of current to flow through the block. It is important to mention that while the voltage-current characteristic of an MOV block in the protection region (high current flow) is insensitive to the temperature of the block, the voltage-current characteristic near the knee is temperature-sensitive. This is illustrated in Fig. 27-48.

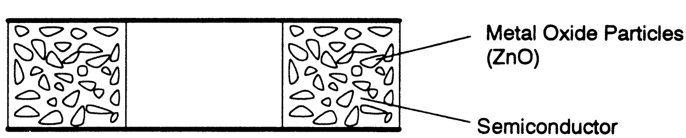

FIGURE 27-47 Structure of a metal oxide varistor (MOV). Size is exaggerated for illustration purposes.

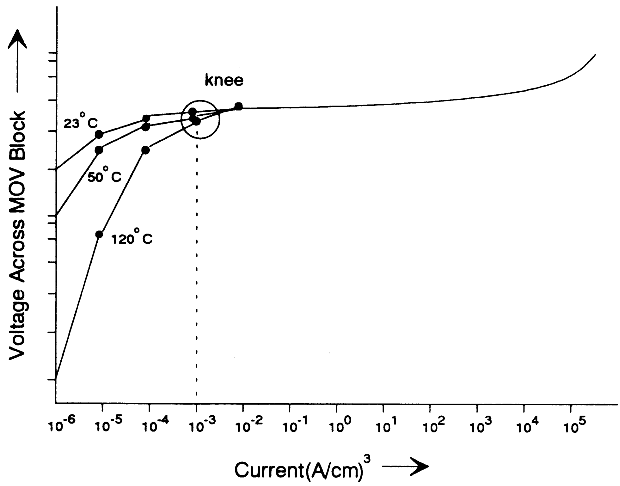

FIGURE 27-48 Voltage-current characteristic is temperature-sensitive near the knee of the curve.

Figure 27-49 illustrates the voltage versus current curves for an MOV arrester for different levels of applied voltage (sinusoidal, 60 Hz) expressed in pu of arrester rating. Note that for an applied voltage near nominal (1.05 pu), the electric current through the arrester is mostly capacitive (voltage and current are approximately 90° apart) and of low value on the order of a milliampere. As the voltage increases, the electric current increases much faster. It can be observed from the figure that the increase of the current occurs in the component, which is in phase with the voltage (resistive current) while the capacitive component remains constant.

The current flow through the arrester is responsible for power loss within the MOV block, which increases the temperature of the block. A typical power loss—applied voltage function is illustrated in Fig. 27-50. Note that as the voltage increases the power loss increases disproportionately. Increased losses and increased operating temperature have a detrimental effect on the MOV arrester life. Figure 27-51 illustrates the expected MOV arrester life as a function of continuously applied sinusoidal voltage.

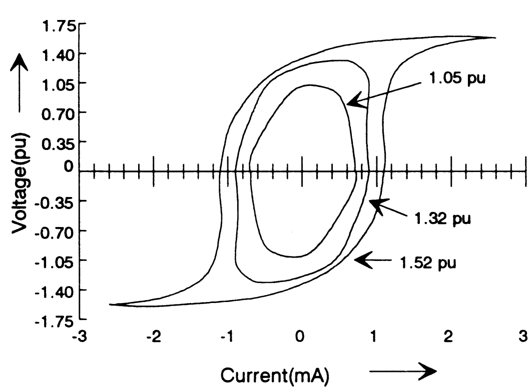

FIGURE 27-49 Illustration of voltage vs. current through an MOV for different levels of a sinusoidal (60-Hz) applied voltage.

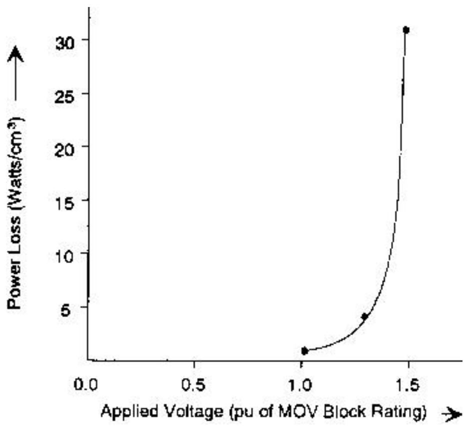

FIGURE 27-50 Typical power loss of an MOV block vs. applied voltage.

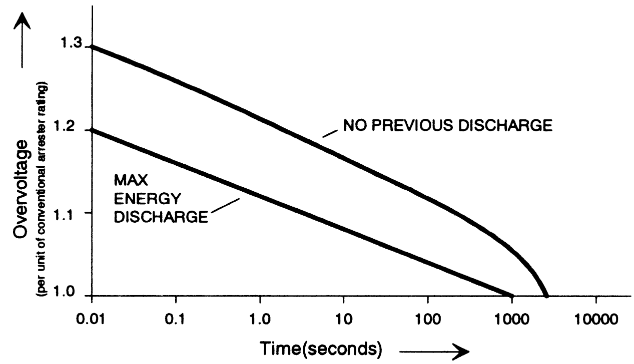

FIGURE 27-51 Expected MOV arrester life as a function of continuously applied power frequency voltage.

An MOV block, because of its dimensions, exhibits a capacitance and an inductance. Both of them are insignificant at low frequencies. However, at higher frequencies they affect the performance of the arrester. This performance is illustrated in Fig. 27-52, which shows the discharge voltage across the MOV arrester as a function of time for specific values of electric current through the arrester. From this figure it is obvious that the protective level of an MOV arrester will depend on the waveform of the overvoltage.

This behavior of the MOV surge arrester can be captured with the model of Fig. 27-53. Note that this model consists of two parallel resistance-inductance (*R-L*) circuits, a parasitic capacitance, and two nonlinear resistors. The nonlinear resistor RN_0, represents the nonlinear characteristics of the arrester to fast front end surges, while the nonlinear resistor RN_1 represents the nonlinear

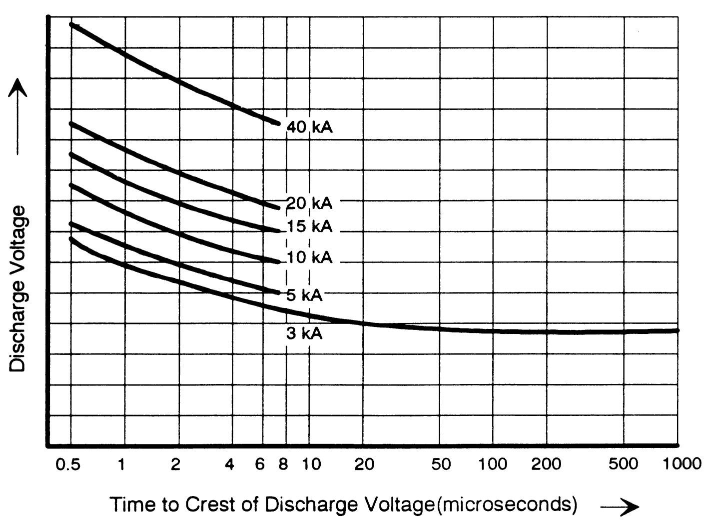

FIGURE 27-52 Discharge voltage across an MOV arrester vs. time for various current levels through the arrester.

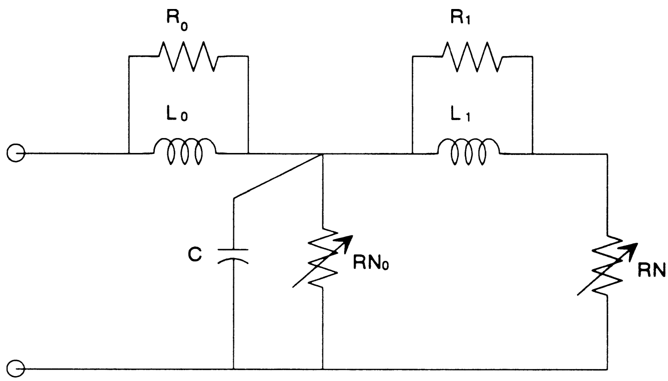

FIGURE 27-53 Nonlinear MOV arrester model.

characteristics of the arrester to slow front-end surges. The parameters of the model are selected to match the measured discharge characteristics of the arrester. Typical parameters are illustrated in Fig. 27-54.

It can be observed in Fig. 27-48 that, as the arrester discharge current increases in an MOV, the desirable nonlinear characteristics are deteriorating. This occurs in Fig. 27-48 at discharge currents above 10 kA. Specifically, the discharge voltage at currents above 10 kA increases, resulting in inferior protection characteristics. In this aspect SiC arresters are superior to MOVs because SiC arresters do not exhibit this abrupt increase of discharge voltage at higher currents. The performance of MOVs at higher discharge currents can be improved by equipping them with a shunt gap (Westrom 1990). Such a construction is illustrated in Fig. 27-55. Specifically, an MOV block in an arrester is equipped with a shunt spark gap. The gap is designed to spark over whenever the discharge current through the arrester exceeds a certain value, for example 10 kA. In this way, when the

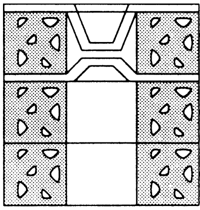

FIGURE 27-55 Typical construction of a shunt-gap MOV arrester.

discharge current increases beyond the value at which the desirable nonlinear characteristics of the MOV block start to deteriorate, the shunt gap sparks over, resulting in reduced discharge voltage and therefore improved protection characteristics.

Protective Margins. Another important concept is the protection margin (PM). The protective margin is related to the properties of the protective device relative to the withstand capability of the power apparatus under protection. For the ideal situation depicted in Fig. 27-39, the protection margin is defined as

$$\mathrm{PM} = \frac{V_w - V_p}{V_p}$$

where V_w is the withstand capability of the power apparatus under protection and V_p is the protection level.

Because both the protection level of a surge arrester and the withstand capability of a power apparatus depend on the rise time of the transient overvoltage, it is expedient to define protective margins for the standard surge waveforms. In this sense, the following protective margins are defined.

1. Equivalent front-of-wave protective margin ($\mathrm{PM}_{\mathrm{fow}}$)

$$\mathrm{PM}_{\mathrm{fow}} = \frac{V_{\mathrm{cww}} - V_{p,\mathrm{fow}}}{V_{p,\mathrm{fow}}} \times 100$$

where V_{cww} is the equipment chopped-wave withstand (cww) voltage and $V_{p,\mathrm{fow}}$ is the arrester protection level for the front of wave (fow).

2. Equipment impulse protection margin (PM_i)

$$\mathrm{PM}_i = \frac{\mathrm{BIL} - V_{p,d}}{\mathrm{BIL}} \times 100$$

where BIL is the equipment basic insulation level and $V_{p,d}$ is the arrester protection level for a full impulse wave.

3. Equipment switching protective margin (PM_s)

$$\mathrm{PM}_s = \frac{\mathrm{BSL} - V_{p,ss}}{V_{p,ss}} \times 100$$

where BSL is the equipment basic switching insulation level and $V_{p,\mathrm{ss}}$ is the arrester protective level for a switching surge.

The definition of these three protective margins is illustrated in Fig. 27-56. In this definition one should bear in mind that the arrester protective levels may be defined differently for gapped and gapless arresters. Specifically, the definition of the protective levels for gapped and gapless arresters follows.

- $V_{p,\mathrm{fow}}$, arrester protection level for front of wave

  Series-gapped arresters—front-of-wave sparkover: standard test dictates the rate of rise of front of wave to be 5.89 pu V/μs

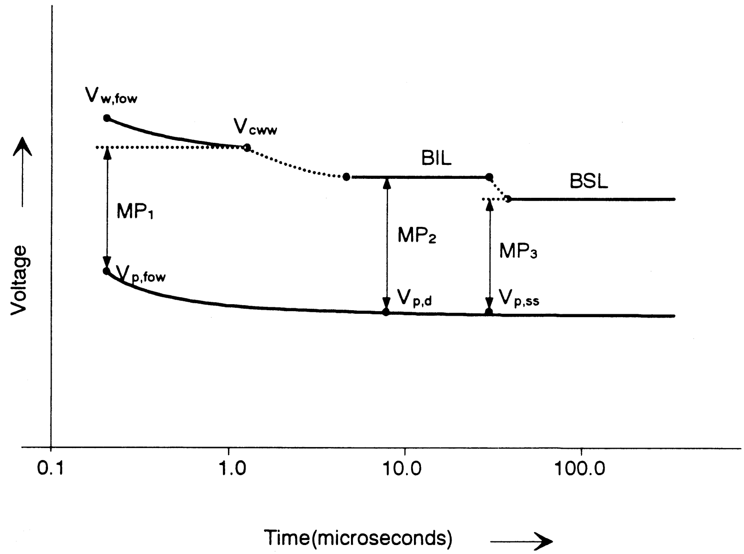

FIGURE 27-56 Illustration of the protection margin definition.

Gapless MOV arresters—front-of-wave sparkover: the highest discharge voltage to a surge-current impulse with 0.5 μs rise time and of specified crest (typically 3 to 40 kA)
Shunt-gapped MOV arresters—front-of-wave sparkover: same as for gapless MOV arresters

- $V_{p,d}$, arrester protection level for a full impulse wave

  Series-gapped arresters—let-through level: the highest full impulse expected to cause sparkover after 8 μs
  Gapless MOV arresters—discharge voltage: the highest discharge voltage to a surge-current impulse (8×20 μs) of specified crest (typically 5 to 20 kA)
  Shunt-gapped MOV arresters—discharge voltage: same as for gapless MOV arresters

- $V_{p,ss}$, arrester protection level for a switching impulse

  Series-gapped arresters—switching surge sparkover: the highest full impulse causing sparkover at a time greater than 30 μs
  Gapless MOV arresters—switching surge discharge voltage: the highest discharge voltage to a current switching impulse of specified crest (typically 3 kA)
  Gapped MOV arresters—switching surge discharge voltage: same as for gapless MOV arresters

Arrester Classification. Arresters can be classified into the following groups:

Station arresters

Intermediate arresters

Distribution arresters

Secondary, industrial, and commercial arresters

This classification is based on kilovolt ratings. Historically, station arresters provide the lowest protective levels relative to their rating (i.e., they have the highest protection quality index) and are capable of discharging the highest amount of energy. Intermediate arresters have somewhat higher protective levels relative to their rating and are capable of discharging somewhat less energy. Distribution and secondary, industrial, and commercial arresters have even higher protective levels and are capable of discharging even less energy. This historical classification and description of arresters may not be valid anymore. For example, there are MOV products that use MOV blocks for secondary arresters of the same quality as station class arresters, and therefore exhibit a very high protection quality index. It is important, however, to adopt this classification for consistency with standards.

Specific voltage ratings, protective levels, and other mechanical characteristics of complete arrester units can be found in the ANSI/IEEE standards. As an example, Table 27-6*a*, taken from ANSI/IEEE C62.1-1989, lists the standard voltage ratings for surge arresters. Table 27.6*b* lists the

MOV arrester ratings taken from ANSI/IEEE std. C62.11-1999. Another example is Table 27-7, taken from ANSI/IEEE C62.2, which provides several important arrester parameters and application data for station- and intermediate-class arresters. More accurate data for specific products are available from the manufacturers.

There are a variety of commercial transient voltage suppression devices based on MOV technology. The quality of some of these products in terms of (1) their nonlinear characteristics, (2) energy absorption characteristics, and (3) current handling capability is very high. As an example, Table 27-8 illustrates the characteristics of a 480-V rated transient voltage suppression device, HA series. Figure 27-57 also illustrates the voltage-current characteristic of this device. By a simple fitting procedure, the nonlinear characteristic of this device in the range 1 to 1000 A is approximately described by Eq. (27-1), where $n \approx 24$. This is a relatively high exponent, suggesting a rather high protection quality index.

27.7 OVERVOLTAGE PROTECTION (INSULATION) COORDINATION

The objective of overvoltage protection coordination, otherwise known as insulation coordination, is to minimize the number of insulation failures and therefore the number of interruptions. This has been a fundamental task of power engineering with a profound effect on the reliability of the system. Insulation coordination methods have evolved from the ad hoc procedures of the past to the highly sophisticated computer methods of today. Yet protection schemes remain an art, and a review of the evolution of methods provides an invaluable insight. By necessity, the methods are based on incomplete data or parameters with substantial uncertainty. As a result, present models are incomplete and interpretation of results is necessary.

The objectives of insulation coordination procedures also depend on the effects of insulation failure. In this respect, power apparatus may be grouped in two broad categories: (1) those that use air as insulation (external insulation) and (2) those that use solid or liquid dielectrics as insulating material (internal insulation). Insulation failure in devices of the first category is not as destructive as insulation failure in devices of the second category. With the exception of secondary effects, failure of air insulation is self-healing, since removal of the overvoltage will restore the insulation. For this reason, the objectives of insulation coordination for external insulation are typically the minimization of insulation failure. It is permissible to tolerate a small probability of insulation failure if this will minimize the cost. Probabilistic methods are pertinent for this purpose. On the other hand, the objective of insulation coordination for internal insulation is to disallow any insulation failure from any known causes. Adherence to this objective is dependent on the cost of the apparatus under protection. As an example, this objective is strictly observed for higher MVA-rating power transformers while for distribution transformers the cost of meeting the objective may not be justifiable. Because of this variability in objectives, the process of insulation coordination is examined separately for transmission lines, substations, overhead distribution systems, undergound distribution systems, and industrial/commercial systems.

Transmission Lines. Overhead transmission lines use air or porcelain as the external insulating material. Flashovers across insulator strings or phase conductor to ground wire do not lead to catastrophic failures but rather to momentary outages. In other words, the insulation strength is quickly restored after arc extinction. For this system, the objectives of insulation coordination are to minimize the momentary outages at minimum cost. This is achieved through a procedure by which the cost of momentary outages is balanced against the cost of providing for overvoltage protection. The procedure is statistical, since many driving factors are statistical, for example, lightning strength and rise time. It is illustrated in Fig. 27-58, where the distribution of overvoltages is plotted as well as the distribution of withstand

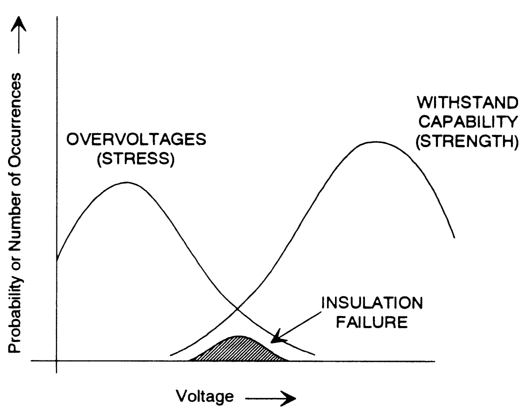

FIGURE 27-58 Statistical evaluation of insulation failures.

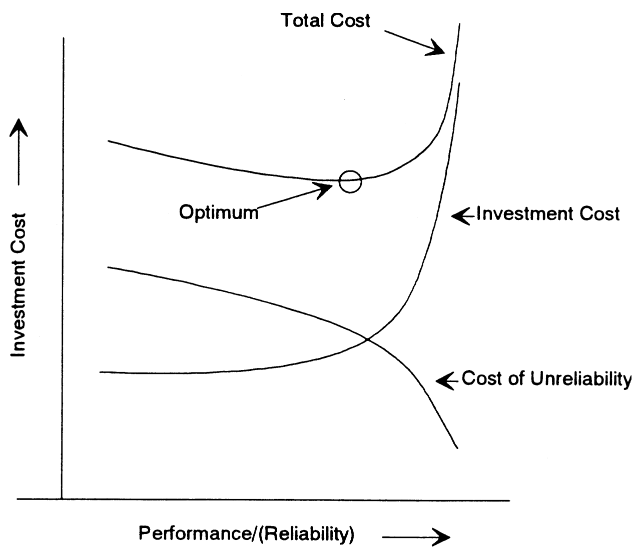

FIGURE 27-59 Optimal design procedures that provide best trade-off between performance (reliability) and cost.

capability. Outages may occur when the overvoltage exceeds the withstand capability. This procedure can be carried one step further, where the performance (reliability) of the system is balanced against cost of designs. This concept is illustrated in Fig. 27-59, where the optimum design is defined at the minimum of the total cost consisting of the investment cost plus the unreliability cost. A drawback of this method is the fact that, while the investment cost can be properly assessed, the cost of unreliability may be elusive and at best subjective. In any case, insulation coordination of overhead transmission lines involves the following basic tasks:

Design of an effective shielding against direct lightning strokes

Design of an adequate insulation strength to withstand power frequency, switching, and lightning overvoltages

Design of an effective grounding system to minimize backflashovers

The design procedure typically consists of selecting a standard design and subsequently estimating the expected number of momentary outages. Design modifications are exercised if objectives are not met. In this section, we will be concerned with estimation of the number of momentary outages. This task involves the following procedure:

Estimation of the number of lightning strokes in the area

Estimation of the percentage of strokes reaching the line

Estimation of number of shielding failures

Estimation of probability of backflashover

Effects of corona

Summary of results

Estimation of the number of lightning strokes in the area. The ground flash density is defined as the number of lightning strokes (cloud to ground) per unit of area. It is preferable to use actual data on ground flash density if available. If not, then, as a first approximation, the ground flash density is taken to be approximately proportional to the thunderstorm activity, measured in thunderstorm days.

Empirical formulas have been developed and are listed in Table 27-9. For the United States, the most commonly used formula is

$$N_1 = 0.12T \qquad \text{or} \qquad N_2 = 0.31T$$

where N_1 = ground flash density per square kilometer per year
N_2 = ground flash density per square mile per year
T = number of thunderstorm days

It must be emphasized that this formula should be viewed as an average and approximate only, since thunderstorm activity may vary from year to year and the lightning activity in a thunderstorm day may vary.

Estimation of the Percentage of Strokes Reaching the Line. The number of strokes reaching the line (shield wire or phase conductor) can be estimated with two basic models:

The geometric model

The electrogeometric model

These basic models have many variations, as many researchers have made improvements to improve their correlation to observed data.

The principle of the geometric model is illustrated in Fig. 27-60. The model postulates that the line casts a shadow around it of width W. Any ground flash which would terminate at the shadow of width W if the line was not present will be intercepted by the line. Assuming that the ground flashes are uniformly distributed over the surface of the ground, the following equation applies for the number of strokes to the line:

$$N_{t1} = 0.00012\ WT$$

or

$$N_{t2} = 0.000193\ WT \tag{27-2}$$

where N_{t1} = number of strokes to the line per kilometer of line length per year
N_{t2} = number of strokes to the line per mile of line length per year
W = width of the line shadow, m
T = number of thunderstorm days in the area

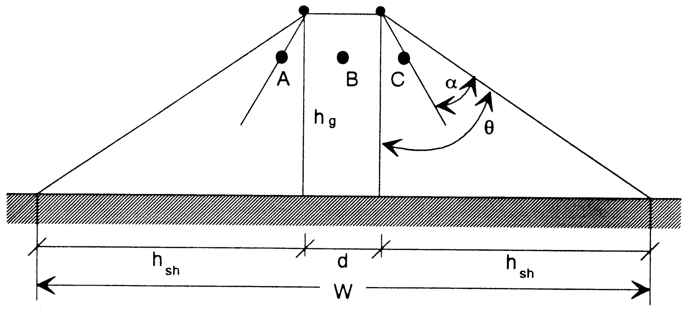

FIGURE 27-60 Illustration of application of the geometric model.

An expression for the shadow width is

$$W = 4h + d$$

where d = distance between shield wires (zero if only one shield wire)
h = effective height of the line, which can be approximated with $h = h_g + {}^2\!/_3\,(h_g - h_{gw})$
h_g = shield wire height at the tower or pole
h_{gw} = shield wire height at midspan

The geometric model is very simplistic. It fails to take into account that the striking distance of lightning is determined by the magnitude of the return stroke as well. An improved method is the so-called electrogeometric model. The principle of this model is illustrated in Fig. 27-61. This model is based on the observation that the point where the stepped leader of a lightning terminates is not determined until the stepped leader is within a striking distance. The striking distance is defined as the length of the final leg of the stepped leader which establishes contact with a ground object. The striking distance was

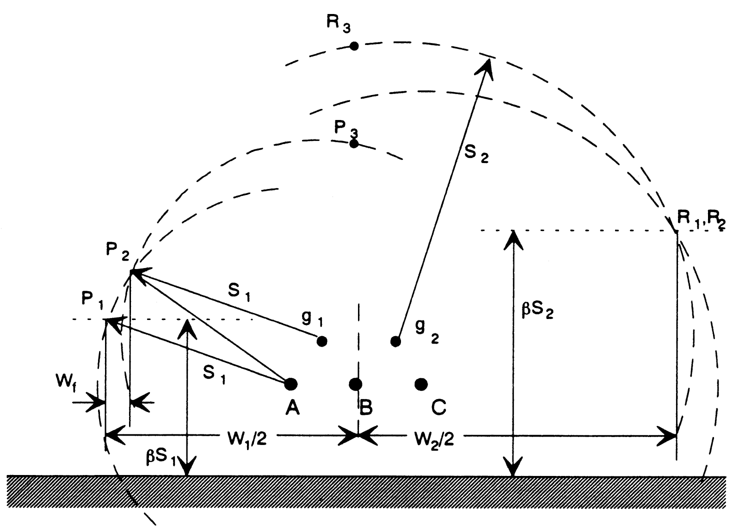

FIGURE 27-61 Illustration of application of the electrogeometric model. [*Note:* The value of β is a function of tower height. Anderson (1975) uses β = 0.67 for ultra-high-voltage (UHV) lines.]

found to depend on the amplitude of the first return stroke. A number of empirical formulas have been proposed for determining the striking distance. Table 27-10 lists the most common ones.

The equation most commonly used in the United States is the second one listed in Table 27-10. Using a striking distance, which depends on stroke magnitude, generates a model, which suggests that the number of strokes intercepted by the line depends on their magnitude. Figure 27-61 illustrates the application of the method to compute the number of strokes terminating at the line for two different stroke magnitudes, 7 and 12 kA. Specifically, for strokes of 7 kA, the striking distance is S_1. For this striking distance, one can construct the width over which the strokes will be intercepted by the line. This width, W_1, is shown in the figure. It is constructed by (1) drawing a line above ground at height βS_1, where $\beta = 0.8$ (from Anderson 1968), (2) drawing a circle of radius S_1 with center at the phase conductor, and (3) drawing a circle of radius S_1 with center at the shield wire. The construction of the width W_2 for strokes of 12 kA is also shown in the figure. The computed widths W_1 and W_2 can be used in Eq. (27-2) to estimate the number of strokes to the line. It should be understood that the process is repeated for several stroke magnitudes, spanning the distribution of lightning current magnitudes; then all the results are utilized to compute the statistical distribution of the expected strokes to the line. The average value can be extracted from this distribution.

Estimation of Number of Shielding Failures. It is important to know how many of the strokes reaching the line will actually terminate on a phase conductor or on a shield wire. The consequences are obvious. A lightning stroke terminating at the phase conductor and of sufficient magnitude will most likely result in a flashover. This is obvious when one considers the magnitude of the overvoltage. When shielding failure occurs and the lighting stroke terminates on the phase conductor, it generates an overvoltage on the stricken phase which is given by

$$v_s(\mathrm{t}) = {}^1\!/_6\,(Z_g + 2Z_t)i(t)$$

and an overvoltage on the other two phases which is given by

$$v_n(\mathrm{t}) = {}^1\!/_6\,(Z_g - Z_t)i(t)$$

where $i(t)$ = lightning stroke current
Z_g = characteristic impedance for the ground mode of propagation of surges along the line
Z_t = characteristic impedance for the line mode of propagation of surges along the line
$v_s(t)$ = lightning overvoltage on the stricken phase
$v_n(t)$ = lightning overvoltage on any one of the other two phases

For a typical transmission line design

$$Z_g \approx 800\ \Omega$$

$$Z_t = 400\ \Omega$$

In this case, the overvoltage is

$$v_s(t) \approx 300i(t)$$

$$v_n(t) \approx 60i(t)$$

Obviously, a shielding failure for a lightning stroke of 20 kA will generate an overvoltage of about 6 MV, which most likely will cause a flashover. On the other hand, a lightning stroke terminating on a shield wire will result in much lower overvoltages, if the transmission line is effectively grounded. It is, of course, possible that the overvoltages resulting from a lightning stroke to the shield wire will be of such magnitude as to cause a flashover from the shield wire or tower to the phase conductor. This event is known as a *backflashover*. In any case, the line shielding must be designed in such a way that the number of times lightning reaches a phase conductor is minimized. Occurrences of such incidents are termed *shielding failure*.

The electrogeometric model provides an adequate tool to determine shielding failure. The basic premise of the method is defined in Fig. 27-61. Consider the striking distance S_1 for a lightning stroke of magnitude I_1. Consider also the line above ground at a height βS_1, the circle of radius S_1 with center at phase A, and the circle of radius S_1 with center at shield wire g_1. The intersections of these circles define the points P_1 and P_2. The electrogeometric model states that any stepped leaders, which reach the arc P_1P_2 and of magnitude less than I_1 will terminate on the phase conductor A, resulting in a shielding failure. Any stepped leader reaching the arc P_2P_3 will be attracted by the shield wire. The percentage of lighting strokes of magnitude I_1 or lower, which will reach a phase conductor, can be estimated by comparing the length of the arc P_1P_2 to the length of the arc P_2P_3. This process can be repeated for various stroke magnitudes. Subsequently, and utilizing the statistics of the stroke magnitude distribution, the probability distribution of shielding failures can be computed. The expected number of shielding failures can also be computed.

For lightning strokes of a certain magnitude, the striking distance will be such that the points P_1 and P_2 may collapse to one point. This condition is illustrated in Fig. 27-61 for a different magnitude of stroke current I_2, where the points R_1 and R_2 coincide. Any stepped leader resulting in stroke current magnitude I_2 or higher and reaching the arc R_2R_3 will terminate on the shield wire. Any other stepped leaders reaching points to the right of points R_2 will terminate to the ground. In this case, the line is shielded for lighting strokes of magnitude greater than I_2. Now assume that the line insulation can withstand the overvoltages resulting from a direct hit on a phase conductor of magnitude I_2. In this case, a shielding failure for lighting strokes of magnitudes I_2 or lower will not result in a flashover. The line is said to be *effectively shielded*.

An extension of this statement results to the concept of the critical striking distance. The critical striking distance is the striking distance for the smallest lightning stroke current magnitude, which, if it terminates on a phase conductor, will cause a flashover. The critical striking distance can be used to define the location of shield wires which will provide an effective shielding.

Estimation of Probability of Backflashover. Backflashover can occur when the transmission tower voltage at the location where the phase insulators are suspended (crossarms) becomes so high as to initiate an arc between the crossarm and the phase conductors. The driving force for initiating the arc is the voltage across the insulator which depends on many factors

Voltage at the crossarm due to the lightning stroke

Induced voltage on the phase conductor due to surges on the shield wire generated by the lightning stroke

Power frequency voltage at the phase conductor

Tower footing impedance

Traveling-wave phenomena along the tower

Lightning strokes to the tower result in the highest overvoltage at the top of the tower as compared to overvoltages from lightning strokes on the shield wire along the span. As an example, consider a lightning stroke of crest 10 kA and rise time 1 μs terminating on the shield wire of a transmission line. For simplicity, neglect the phase conductors. The system is illustrated in Fig. 27-62*a*. All tower ground resistances are 80 Ω. The parameters of the shield wire, for the example under consideration, are

$$L = 2.7\ \mu\text{H/m}$$

and

$$C = 6.58 \times 10^{-12}\ \text{F/m}$$

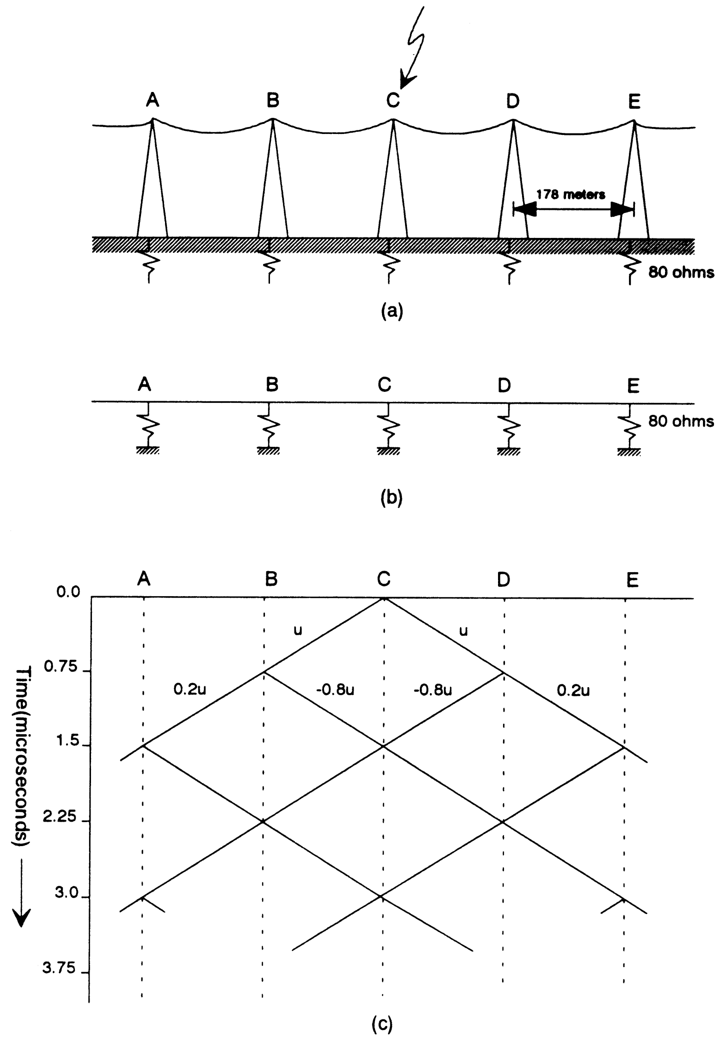

FIGURE 27-62 Simplified calculations of overvoltages resulting for a lightning stroke to a tower: (*a*) schematic; (*b*) simplified circuit; (*c*) Bewley diagram.

The characteristic impedance of the shield wire is $Z = \sqrt{L/C} = 640\ \Omega$, and the speed of propagation of surges is $v = 1\sqrt{LC} = 237$ m/μs. The travel time from one tower to the next is 0.75 μs. To further simplify the computations, traveling-wave phenomena along the tower are neglected, resulting in the simplified circuit of Fig. 27-62*b*. The reflection and transmission coefficients at the tower are $\alpha = -0.80$ and $\delta = 0.20$. The Bewley diagram for this circuit is illustrated in Fig. 27-62*c*, where $u(t)$ is computed as

$$u(t) = R_{eq} i(t) = 64 i(t)$$

Thus, $u(t)$ will have a rise time of 1 μs and crest of 640 kV. By summing up all the waves arriving at point C, the voltage waveform c1 of Fig. 27-63 is obtained. This procedure can be repeated,

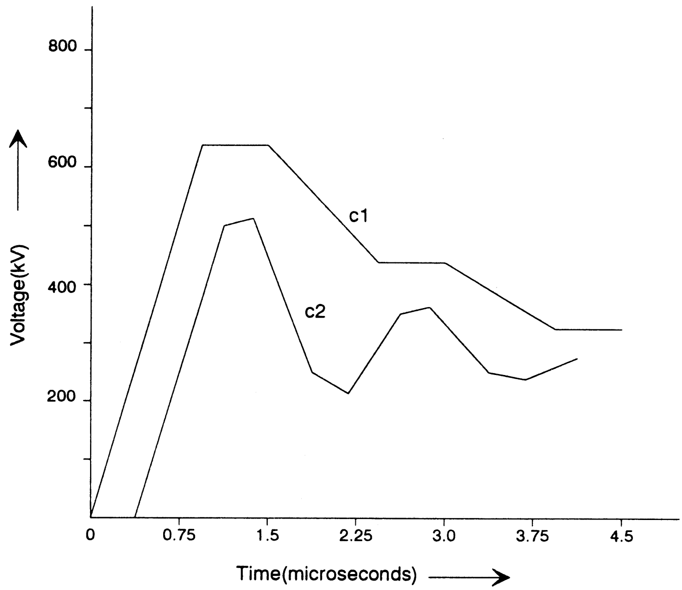

FIGURE 27-63 Lightning overvoltages at top of tower; in c1 the lightning stroke terminates at tower top, and in c2 the lightning stroke terminates at midspan.

assuming that the same lightning stroke terminates at the shield wire in the middle of the span. The resulting overvoltage at the top of the tower C is shown as waveform c2 in Fig. 27-63. Note that the crest of this waveform is much lower. In reality, the tower footing impedance is frequency-dependent and traveling-wave phenomena along the tower affect the overvoltages. Figure 27-64 illustrates a typical voltage waveform across the phase insulators using a rather sophisticated model (Cokkinides and Meliopoulos 1988). Note that reflections from adjacent towers quickly reduce the voltage across the phase insulators. Also, the crossarm voltage is in general lower than the top of the tower voltage. As a result, bottom phase insulators, in general, experience the highest

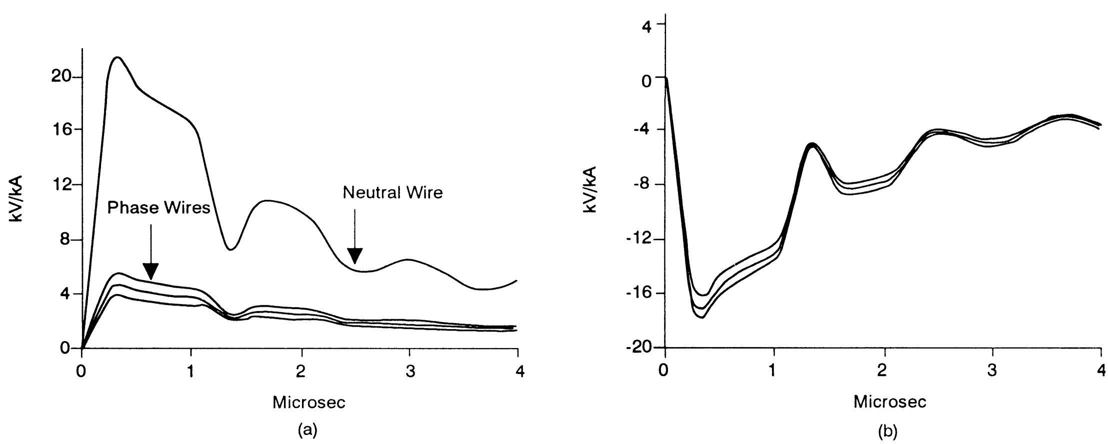

FIGURE 27-64 Typical voltage waveforms across phase insulators due to lightning: (*a*) transient voltage of phase conductors and shield wire; (*b*) transient voltage across insulators.

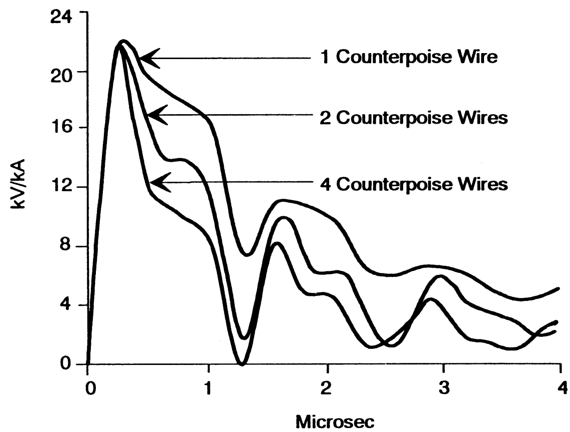

FIGURE 27-65 Illustration of effects of tower grounding on voltage at top of tower due to a lightning stroke at the tower.

overvoltage for backflashover. The tower ground also affects the overvoltage. As an example, Fig. 27-65 illustrates the effect of tower grounding on the lightning voltage at the top of the tower. Note that the voltage at the top of the tower is not affected by tower grounding for the first approximately 0.2 μs after lightning initiation. However, the overall overvoltage waveform is drastically affected by tower grounding. Since the characteristics of arc initiation across the insulator string have a volt-time characteristic, it is very important to examine the effect of voltage waveform on backflashover initiation.

CIRGE has accepted the following volt-time curve for line insulator flashover, which is consistent with the work of Darveniza et al. (1975, 1979) and Whitehead (1977)

$$V_{\bar{f}} = 0.4W + \frac{0.71W}{t^{0.75}}$$

where W = line insulator length in meters
t = time to breakdown in microseconds
$V_{\bar{f}}$ = flashover voltage in megavolts for negative surges

One should compare the volt-time characteristic to the actual voltage across the phase insulators to determine whether a backflashover will occur. Figure 27-66 illustrates such a construction where the insulator withstand capability versus time of a 1-m-long insulator string is superimposed on the actual voltage experienced by the insulator.

Effects of Corona. The overvoltage occurring at a phase conductor or shield wire establishes an extremely high-voltage gradient perpendicular to the conductor. This gradient, wherever it exceeds the withstand capability of air, will generate electric discharges, which will electrify the air surrounding the conductor. This phenomenon is known as *corona*. Corona increases the apparent radius of the conductor while it does not affect the geometric mean radius of the conductor. As a result, it decreases the characteristic impedance of the line and the level of overvoltages resulting from lightning.

The voltage gradient (electric-field intensity) around an energized conductor is approximately

$$E = \frac{V}{r \ln (2h/a)}$$

where V is the conductor voltage, r is the distance from the conductor centerline, h is the conductor height above the earth, and a is the conductor radius.

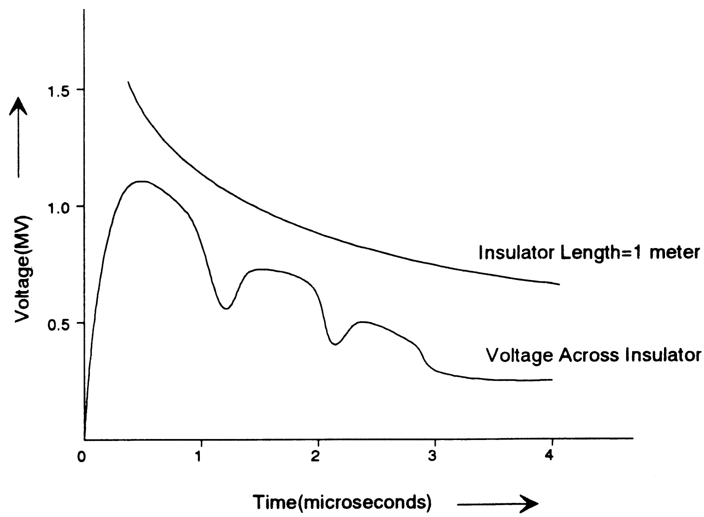

FIGURE 27-66 Insulator voltage-time curve and insulator voltage.

The value of 15 kV/cm is accepted as the electric-field intensity required to establish corona. Thus, corona will exist in a radius a_c such that

$$15 \text{ kV/cm} = \frac{V}{a_c \ln (2h/ac)}$$

As an example, a conductor 50 ft above the earth which experiences an overvoltage of 3.5 MV will establish corona at a radius $a_c = 2$ ft.

Summary of results. In summary, methods have been discussed for design of line-shielding systems, estimation of shielding failure, estimation of overvoltage stresses across insulators, and methods to determine the possibility of flashover across an insulator. There is a considerable uncertainty with almost all parameters and models affecting shielding failure, magnitude, and waveform of overvoltage across insulators, etc. This uncertainty can be dealt with by using probabilistic methods. Monte Carlo simulation is utilized for this purpose and is described in Sec. 27.8.

Substation Lightning Insulation Coordination. Substations typically comprise equipment such as transformers, bus work, breakers, reactors, and capacitor banks etc. This equipment must be protected against lightning overvoltages. As a rule, substations are shielded against direct lightning strikes on phase conductors. Thus, lightning overvoltages in a substation may occur for the following reasons:

1. Backflash due to a strike in the shield of the substation

2. Direct lightning hit due to shield failure

3. Lightning surges from lines (most common)
   a. Line shielding failure
   b. Line backflashover
   c. Induced voltage

The overvoltage protection of substations consists of shielding against direct lightning strikes and application of protective devices (surge arresters) to protect specific power apparatus.

Substation shielding methods are similar to those applied for transmission lines. One can use the geometric model or the electrogeometric model to determine the effectiveness of the shielding wires, masts, etc. The application of the electrogeometric model for substation shielding analysis is more complex since the analysis must be performed on a three-dimensional basis as opposed to a two-dimensional basis for a transmission line. A simplified variation of the electrogeometric model for the three-dimensional problems is the so-called rolling-sphere method. The basic idea of the rolling-sphere method is illustrated in Fig. 27-67*a*. Let S_c be the critical striking distance as defined for transmission lines:

$$S_c = 10 I_c^{0.65}$$

where I_c is the critical stroke current, kA, as defined for transmission lines. The rolling-sphere method postulates that by rolling a sphere of radius S_c over the shield system of the substation, the protected equipment are those which are not crossing the path of the sphere as is illustrated in Fig. 27-67. This method provides a simple procedure to design an effective shielding system for the substation. Figure 27-67*b* provides a visuailization of the application of this method to an actual substation.

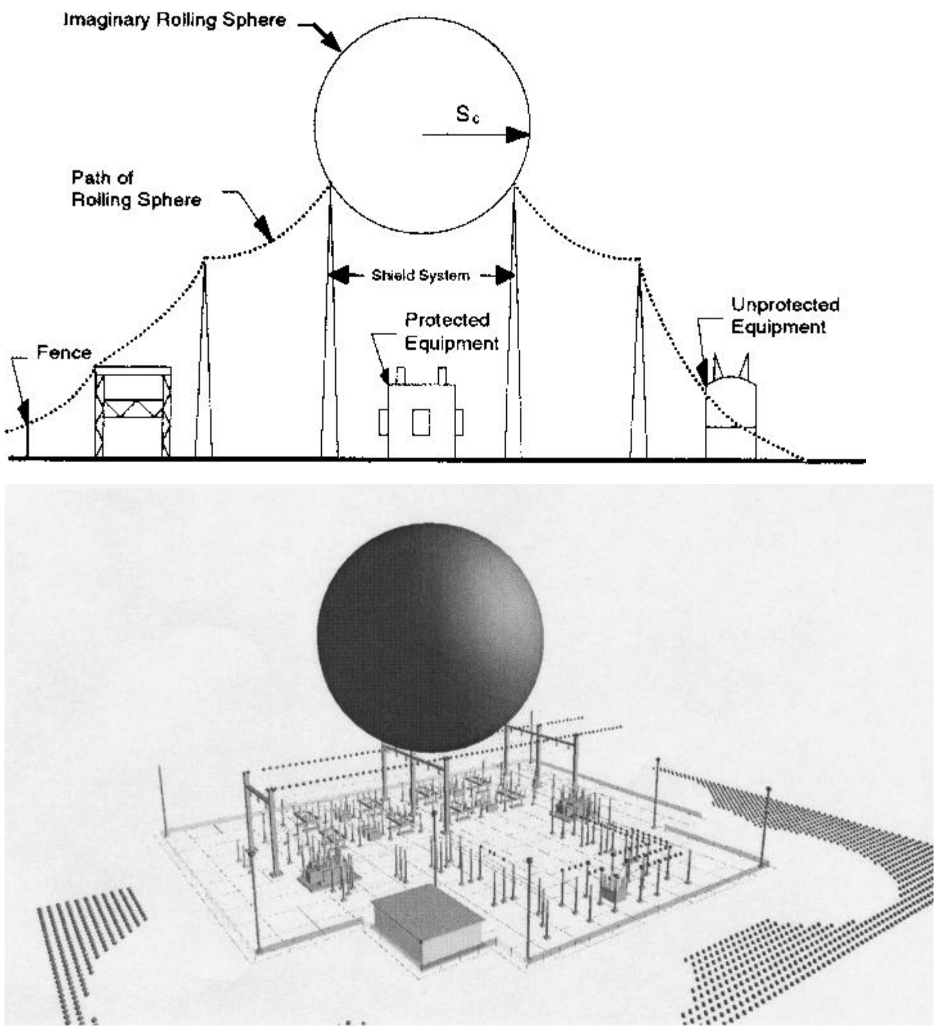

FIGURE 27-67 Illustration of the basic idea of the rolling-sphere method.

In addition to the shielding system, protection must be provided against overvoltages resulting from (1) lightning strikes to the shielding system and (2) surges entering the substation from the transmission lines (which are the most common). The magnitudes of the overvoltages in (1) above depend on the design of the grounding system. On the other hand, the overvoltages from (2) above depend on many factors, such as distance of point of initiation and source of surge (direct hit, induced). These overvoltages are typically limited by the insulation level of the transmission line. Since the usual case is that the substation equipment will have a BIL below the insulation level of the lines connected to the substation, overvoltage protection for the substation equipment must be provided.

The application of protective devices (surge arresters) for the protection of power transformers is illustrated in Fig. 27-68. The application procedure consists of the following steps:

1. Select arrester rating (preliminary).
2. Determine arrester protection levels
   $V_{p,\,\text{fow}}$ = arrester protection level for a front of wave
   $V_{p,d}$ = arrester protection level for a full-impulse wave
   $V_{p,ss}$ = arrester protection level for a switching impulse
3. Determine transformer withstand capability
   V_{foww} = front-of-wave withstand
   V_{cww} = chopped-wave withstand
   BIL = basic insulation level
   BSL = basic switching insulation level
4. Plot arrester protection levels and transformer withstand capability on a common coordinate system, as illustrated in Fig. 27-68.
5. Determine protection margins.
6. If protection margins are not higher than the minimum recommended, select the next-lower arrester rating that is compatible with the normal operating voltage of the system, and go to step 2. Otherwise, go to step 7.
7. Determine whether arrester has adequate energy absorption capability for the application.

This procedure is pertinent for application of surge arresters near the transformer. If there is a separation distance between arrester and transformer, the effects of separation must be accounted for. Specifically, separation results in deterioration of protective margins, as illustrated in Fig. 27-69. The figure shows an application of an ideal arrester 15 m away from the transformer. The ideal arrester

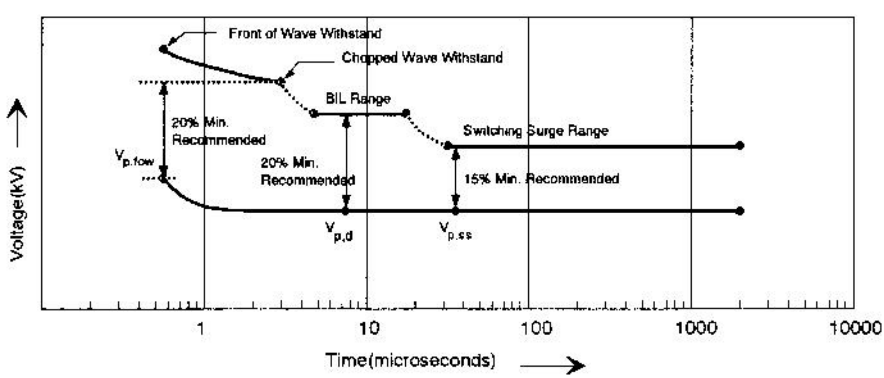

FIGURE 27-68 Application of surge arresters for protection of power transformers.

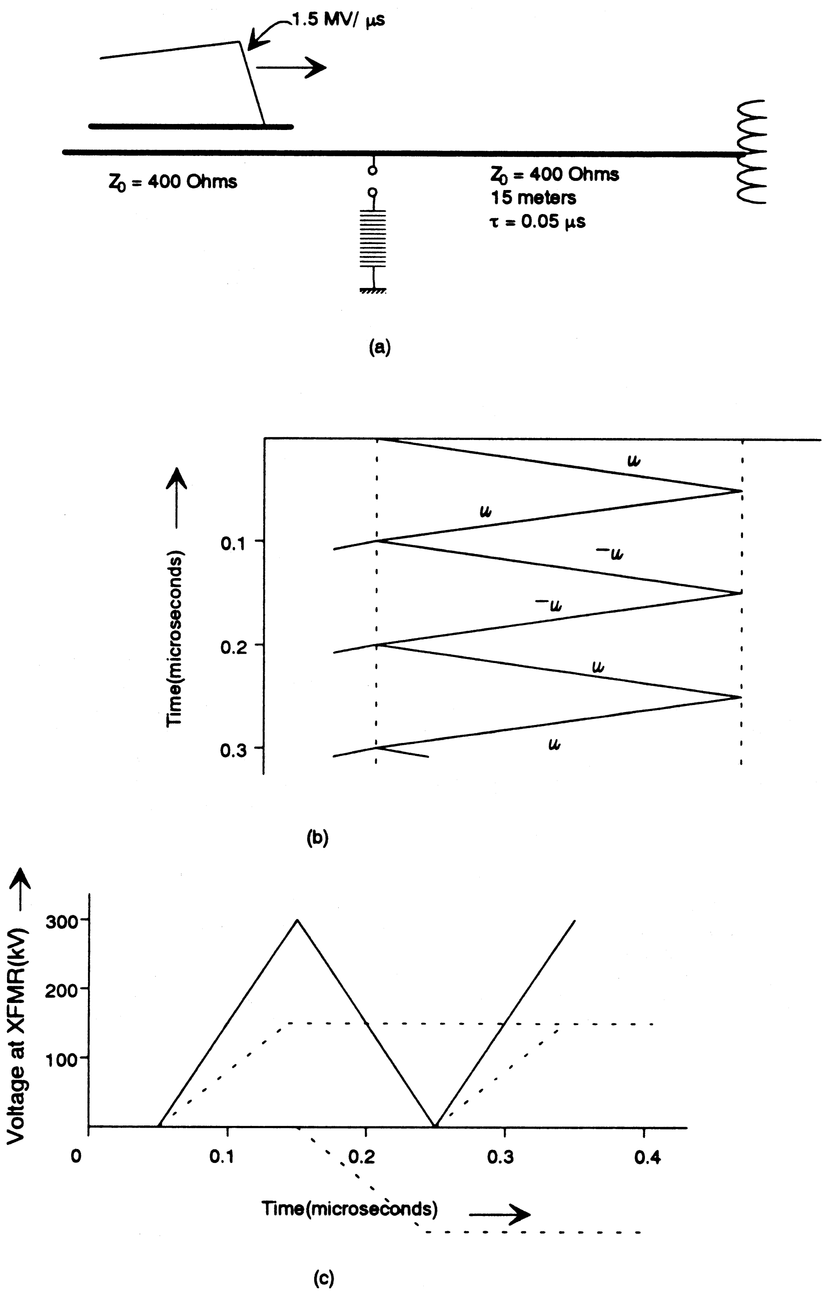

FIGURE 27-69 Example of arrester-transformer separation effects: (*a*) system configuration; (*b*) Bewley diagram; (*c*) voltage at transformer.

is rated 150 kV. Because of the separation distance, the overvoltage reaching the transformer will be 300 kV, double the protective level of the arrester.

Distribution System Overvoltage Protection. Distribution circuits are typically not insulated to withstand direct lightning strokes. As a result, direct strikes will cause a flashover. Direct strikes on distribution lines are not frequent since the poles are not as high and therefore are shielded from trees and structures. On the other hand, distribution lines may be vulnerable to overvoltages resulting from lightning strokes to nearby trees, ground, or other objects. These voltage surges are known as *induced lightning voltages* and are injected into the power system through coupling. The coupling can be conductive through the conductive soil and the power system grounding structures, inductive, or capacitive. In a typical situation, all the coupling mechanisms may be present resulting in a voltage surge to the power system. These voltages are called *induced voltage surges* and are generally much lower than those occurring after a direct strike. Specifically, they rarely exceed 500 kV. The induced lightning overvoltages are of concern for distribution lines 35 kV or below. Higher kilovolt-level lines (i.e., 69 kV and above) have sufficient insulation to withstand induced voltage surges.

The mechanism of induced voltage surges is illustrated in Fig. 27-70. A lightning stroke terminating at a location near a distribution line induces a surge on the line through conductive, inductive, and capacitive coupling. Several models to estimate the level of the induced voltage surges have been reported in the literature (Eriksson et al. 1982; Liew and Mar 1986). A simplified formula suggests the following induced voltage

$$v_p = Z_0 Ih \cdot \left[\left(\frac{1}{2y}\right) \frac{1 + (x + \beta y)}{\sqrt{x^2 + 2y^2 + 2\beta xy - \beta^2 y^2}} + \frac{2\beta x + y}{y^2 + (2\beta x + y)^2} \cdot \frac{1 + 2\beta^2 x + \beta y - \beta x}{\sqrt{x^2 + 2y^2 + 2\beta xy - \beta^2 y^2}} \right]$$

where $\beta = 0.004I^{0.64} + 0.068$ first stroke
$= 0.004I^{0.86} + 0.18$ subsequent strokes
Z_0 = distribution line characteristic impedance
I = stroke current crest

The terms x, y, and h are as illustrated in Fig. 27-70. In addition, many measurements of induced voltage surges have been performed which practically verify the available models.

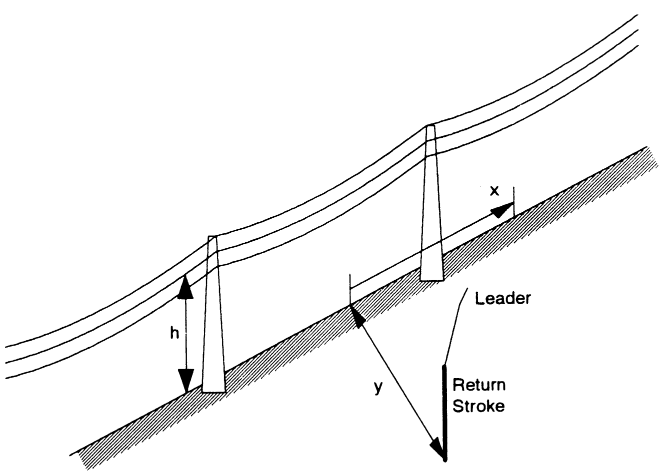

FIGURE 27-70 Illustration of lightning stroke near a distribution line.

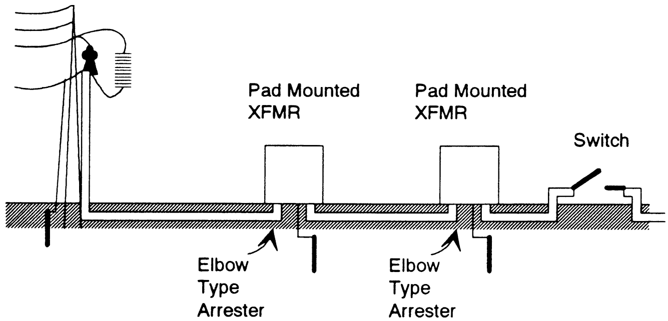

FIGURE 27-71 Typical overvoltage protection scheme for underground residential distribution (URD) systems.

Induced voltage surges on distribution lines are quite frequent. It is therefore necessary to insulate distribution lines to withstand these surges. This translates into the requirement of a 300 BIL for distribution lines. In addition, power apparatus, connected to distribution lines and with BIL lower than the induced voltage surges, such as distribution transformers (typically the BIL of distribution transformers is 100 kV) must be protected. It is practical to protect transformers with surge arresters of appropriate ratings.

Underground Distribution System Overvoltage Protection. A typical configuration of an underground distribution system is shown in Fig. 27-71. Typically a surge arrester will be applied at the riser pole. Underground residential distribution systems present a relatively low characteristic impedance (30 to 50 Ω). When a transient (surge) reaches the URD system through the high-surge-impedance overhead system, and because of the presence of a surge arrester at the riser pole, the surge transmitted to the cable will be of very fast rise time, typically a small fraction of a microsecond. The magnitude of the surge is determined by the characteristics of the arrester. This surge will propagate along the cable and will double when it arrives at an open point or at the end of the cable where a transformer may be present. If this overvoltage is below the BIL level of the URD cable, no additional protection is required. However, the BIL of typical URD cable is relatively low. As an example, Table 27-11 illustrates the typical BIL for the most usual cable classes. In most cases, if a cable is protected with a surge arrester at the riser pole only (of the recommended arrester rating), it is possible that the overvoltage at the open end of the cable exceeds the BIL of the cable with the potential of failure. Use of surge arresters at the open ends, or, better yet, use of elbow type arresters at each transformer, drastically improves cable and transformer protection.

Overvoltage Protection of Industrial and Commercial Systems. Industrial and commercial power systems are subject to overvoltages resulting from lightning or switching operations. By far, lightning overvoltages are the most stressful. Since these systems are interconnected to power systems, disturbances on the power system will be transmitted to them. These systems are also subjected to direct lightning. Therefore, these systems also require shielding against lightning. Typically, a grounding system will be installed as well as a lightning protection system (shielding) to divert any direct lightning strokes to ground. This grounding system is referred to as *external grounding* to distinguish it from the so-called internal grounding, which refers to the grounding system of various equipment in the facility. The external grounding systems of industrial/commercial power systems are interconnected to the power system, as shown in Fig. 27-72. The lightning protection system is basically a shielding system designed to route the lightning surges into the external grounding system for the purpose of minimizing potential differences within the facility. A system like this is subjected to lightning overvoltages which may enter from a number of points. Table 27-12 lists a number of possible points of entry. A coordinated design of the external grounding system, lightning protection system, and internal grounding system can provide a system, which is hardened against lightning and other sources of overvoltages. The effectiveness of the system can be assessed with analysis by using the methods discussed in this section.

27.8 MONTE CARLO SIMULATION–BASED METHODS

In many parts of the globe, the performance of electrical installations is affected by lightning. In this case, it is important to design the system in such a way that outages from lightning are minimized. Typically, transmission lines, substations, and commercial and industrial buildings are the focus of the design process. Because lightning parameters present substantial variability, the effects of lightning must be evaluated on a statistical basis. Other parameters that affect system performance may also present substantial variability. One important parameter is soil resistivity, which affects ground impedances and therefore lightning overvoltages. Monte Carlo simulation methods are well suited to evaluate the effects of these parameters on system performance. A simplified description of a Monte Carlo simulation, given by Moussa and Wehling (1992), considers two parameters with substantial variability, and is illustrated in the following sequence of steps:

1. Generate a sample of lightning stroke described with respect to (*a*) crest magnitude and (*b*) rise time.
2. Generate a sample of soil resistivity.
3. Generate a sample of power frequency voltages.
4. Compute probability of shielding failure.
5. Perform an experiment and determine the lightning termination point (phase conductor, shield wire, etc.).
6. Compute transient voltages in system for conditions described above.
7. Perform effects (failure) analysis (compare voltage stresses on insulation against withstand capability).
8. If number of trials exceeded allowable, go to step 9. Otherwise go to step 1.
9. Generate histograms of maximum overvoltage and backflashover.

It should be understood that this Monte Carlo simulation requires that a good analysis procedure should be available to reliably compute the overvoltages on the insulation. Such models have been developed and are available. Detailed description of these methods is beyond the scope of this text. Instead, some typical results will be presented and discussed.

A typical application of these methods is to evaluate the performance of a specific power line. Figures 27-73 and 27-74 respectively illustrate examples of shielding analysis for two different

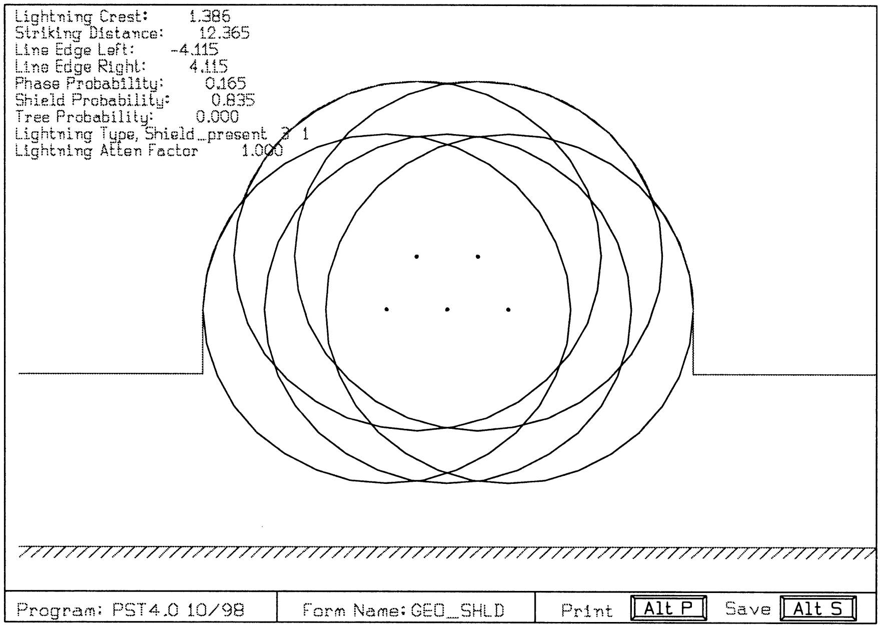

FIGURE 27-73 Example of shielding analysis. Lightning crest is 1.386 kA. There is a finite probability of direct strike on the phase conductor.

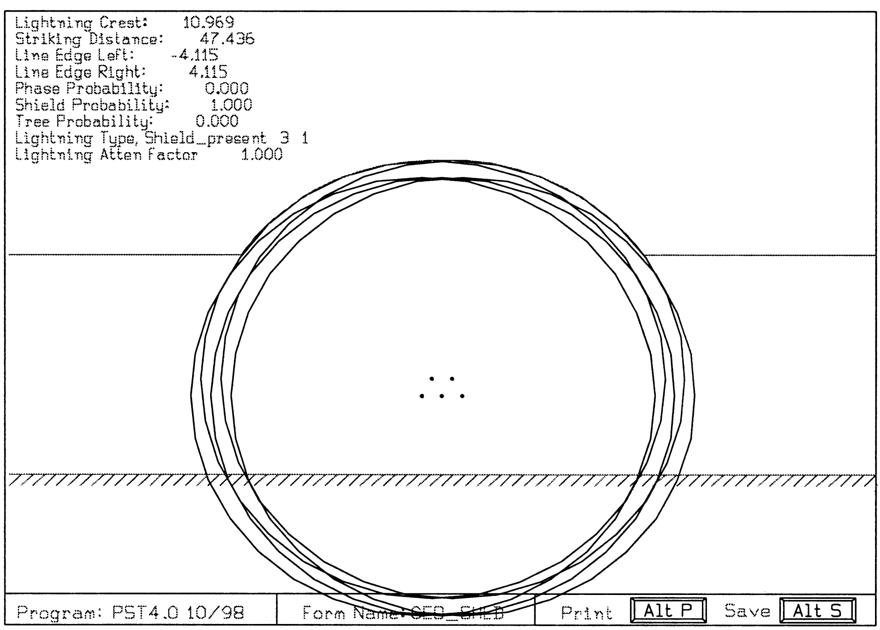

FIGURE 27-74 Example of shielding analysis. Lightning crest is 10.969 kA. The probability of direct strike on the phase conductor is zero.

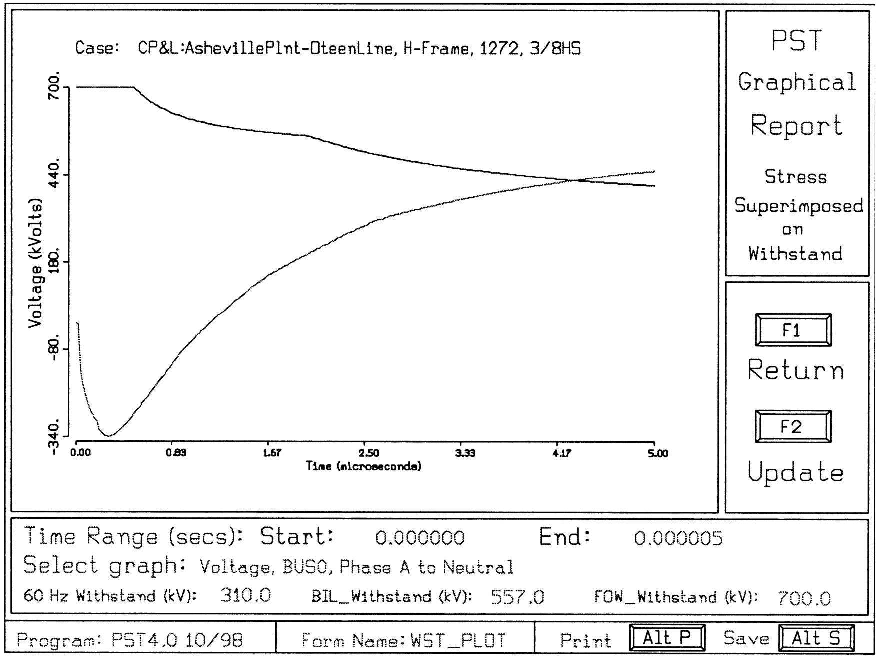

FIGURE 27-75 Example of effects analysis. Overvoltage across insulator exceeds the volt-time withstand curve of the insulator.

samples (trials) of the Monte Carlo simulation. Note that for the same system, when the current is low, there is a probability of shielding failure. As the lightning current increases, shielding failure may be eliminated.

Figures 27-75 and 27-76 respectively illustrate examples of effects (failure) analysis for two different trials of the same system. Note that the conditions illustrated in Fig. 27-75 will lead to insulation flashover, while the system will withstand the conditions illustrated in Fig. 27-76.

The results of the Monte Carlo simulation are illustrated in Fig. 27-77. Note that for this case, which refers to a transmission line, there is a small probability of direct hit to the phase conductor and that the average crest of direct hit is 8.17 kA s. The results are in terms of expected number of flashovers per 100 mi of the line and per year.

27.9 LIGHTNING ELIMINATION DEVICES

It is always desirable to eliminate the destructive effects of lightning on electrical equipment. Benjamin Franklin was the first to invent the lightning rod that provides a sacrificial path for the flow of the lightning current. Professor Moore (1997) has researched Franklin's investigations and points out that, initially, Franklin believed that his lightning rod would eliminate lightning. Experimental observations have shattered this belief and Franklin accepted the fact that the lightning rod does not eliminate lightning but rather behaves as the sacrificial electrode for the termination of lightning so that other structures in the vicinity can be protected. This observation developed into the modern shielding theory we use for design purposes and which was discussed earlier.

The desire to seek a device that prevents lightning did not die. The Czech scientist Prokop Divisch has advocated this goal in 1754. The basic idea in lightning prevention is to provide multiple points of

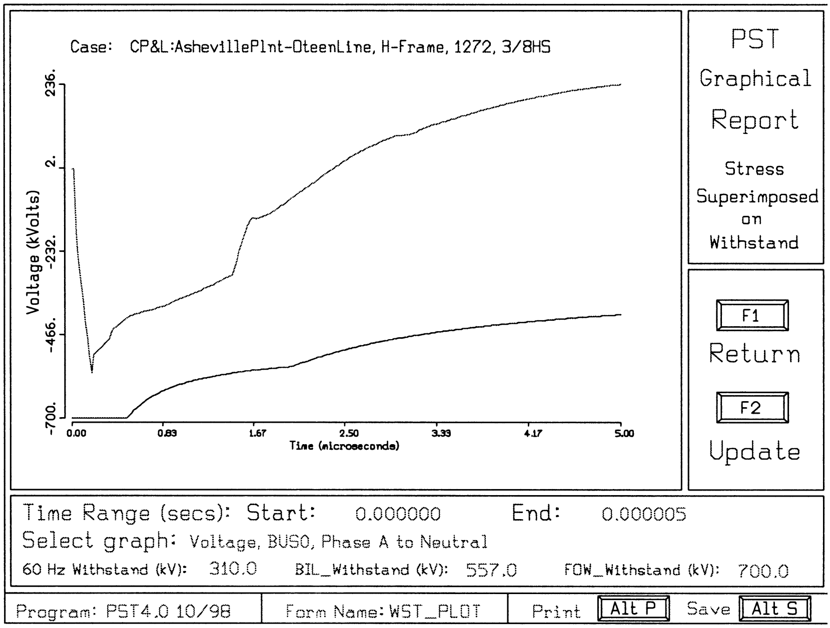

FIGURE 27-76 Example of effects analysis. Overvoltage across insulator does not exceed the volt-time withstand curve of the insulator.

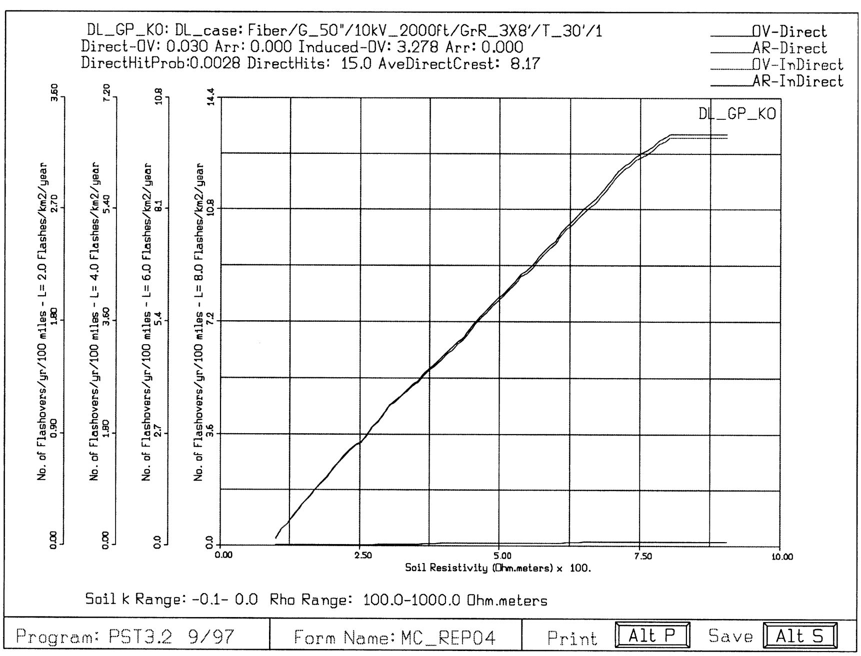

FIGURE 27-77 Example of Monte Carlo simulation results.

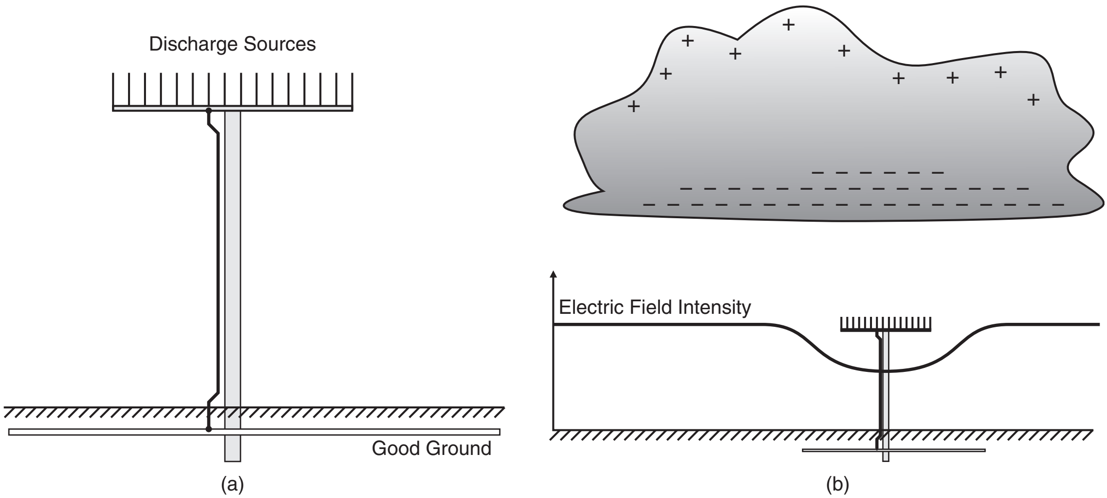

FIGURE 27-78 Conceptual illustration of a lightning elimination system showing (*a*) a good ground with discharge sources and (*b*) the discharge into the electrified cloud.

discharge to neutralize an electrified thundercloud. In theory, these charges can reach the electrified cloud and prevent the initiation of lightning. In fact, in 1930 a patent was awarded to J. M. Cage of Los Angeles for a lightning prevention device consisting of *point-bearing* wires suspended from a steel tower for the purpose of protecting petroleum storage tanks. Later, in 1971, lightning prevention systems were commercialized.

There are many technologies of lightning prevention systems: (a) active air terminal that generate ions which blend into the atmosphere to minimize the electric field around the protected facility, (b) terminals with multiple sharp edges that ionize the air around the terminal for the purpose of minimizing the electric field around the protected facility and (c) umbrella terminals, which provide a smooth surface that minimizes the maximum electric field around the protected facility. As an example the theory of operation of technology (b) is discussed. Specifically, the basic idea of this technology is illustrated in Fig. 27-78. The system consists of sharp objects (discharge sources), which are electrically connected to a good grounding system (Fig. 27-78*a*). The theory is that the discharge released by the discharge sources into the atmosphere will reach the electrified cloud (Fig. 27-78*b*) and will partially neutralize it.

The success of lightning prevention systems has not been as advertised. There is indisputable field evidence that the *lightning elimination devices* cannot eliminate lightning. On the other hand, there are cases in which these devices helped reduce the frequency and extent of damage from lightning (Moussa 1998). The present knowledge and theories of lightning are consistent with this field experience.

ACKNOWLEDGMENTS

A large number of people directly or indirectly contributed to the development of this section. Professor Nikolopoulos of the National University of Athens, Greece, introduced me to high voltage engineering principles. Dr. Roger Webb, Director of the School of Electrical Engineering, introduced and developed a course on power system transients at Georgia Tech and subsequently worked with me in teaching this course. Several folks at the Electric Power Research Institute (EPRI) supported and contributed to my work, namely, John Dunlap, Gil Addis, and Mario Rabinowitz, and numerous

EPRI project advisors contributed in the development of ideas in many different ways. Art Westrom has been an enthusiastic supporter of this work, reviewed the manuscript, and provided valuable suggestions and inputs. Finally, Fan Zhang, a Ph.D. candidate at Georgia Tech, worked with me long hours in typing the manuscript and preparing the drawings.

STANDARDS IN ELECTROTECHNOLOGY, TELECOMMUNICATIONS, AND INFORMATION TECHNOLOGY

28.1 INTRODUCTION

Standards are documents on which agreement has been reached, normally by consensus, that contain specifications or criteria to be used to ensure that materials, products, processes, tests, or services are suitable for their intended purpose.

Standards apply to virtually everything in the world today. The average person is not even aware of their existence, but life would not be the same without them. Engineers, computer scientists, and other scientists, however, are acutely aware of standards and their impact on the work they perform. Development of many of the original standards associated with electrotechnology was a slow process. The products, tests, or specifications being standardized were often in use in industry and had, in reality, become de facto standards before the standards that referred to them were written and approved. In general, most of the standards written were not mandatory, and it was voluntary for users to apply them. In some instances, these voluntary standards became part of government regulations, were adopted by government agencies, or were mandated by companies in specifications. When these types of events occurred, compliance with a specific standard became mandatory. Early standards also became regional to varying degrees. For example, the United States had its electric power standards and European countries had their own electric power standards. Although the two sets of standards had many similarities, there were significant differences between them. Overall, although there were some complaints, the standards development processes remained slow and the differences between standards continued to exist.

The 1980s brought some dramatic changes. The deregulation of the telephone industry, the privatization of government-run electric and telecommunication organizations, the birth of the information age, and the realization of a global market created a huge demand for standards in the fields of telecommunications and information technology. The Internet has, by itself, created the need for standards that govern its use, domain registration, and so forth. Many new players have entered the standards arena and found the traditional methods for developing standards unacceptable, primarily because they were too slow and bureaucratic. New standards in telecommunications and information technology were needed immediately, and the affected industries were moving so fast that many of the standards developed using traditional methods were obsolete before they were issued. Standards developers responded by streamlining processes and adopting fast-track systems. Even these proved too slow for some, and standards saw the birth of consortia whose charters included standards development. The global economy also caused people to take a hard look at existing regional standards. The differences between the standards were viewed as potential "barriers to trade," and harmonization efforts began to make these standards more widely accepted. For example, the United States and Canada are now attempting to harmonize their electrical wiring codes. The global market brought about another significant change in standards. In addition to the traditional standards that dealt with products, tests, and specifications, the protection of intellectual property (e.g., trademarks, inventions, and copyrights) became an important issue. Many standards developers have already begun to make their standards available on the Internet for a fee, although grassroots initiatives have continued to allow free access to standards via the Internet.

Many consortia make their standards and specifications available at no charge. A few standards development organizations have also initiated programs that allow access to a limited number of standards without fee (e.g., the IEEE's "Get 802" program).

28.2 HISTORY OF ELECTRICAL STANDARDS

Early History. The early history of electrical standards stems from activities dominated by the American Institute of Electrical Engineers (AIEE).* In 1884, the institute began actively to develop standard specifications for the growing electrical industry. In 1890, it proposed that the practical unit of self-induction be named the henry. At the same time, the institute appointed its first committee on standardization—the Committee on Units and Standards. The members of this committee were A. E. Kennelly, chairman, F. B. Crocker, W. E. Geyer, G. A. Hamilton, and G. B. Prescott, Jr. The institute also appointed a "Standard Wiring Table Committee" under the chairmanship of E. B. Crocker, to assign linear resistance of standard-conductivity copper wire and at standard temperatures.

A committee was also appointed to prepare a program for the delegates to the International Electrical Congress, held in Chicago in 1893, in regard to units, standards, and nomenclature. As a result of the congress, there were adopted units for magnetomotive force (gilbert), flux (weber), reluctance (oersted), and flux density (gauss). Subsequently, as a result of correspondence with engineering organizations in England, France, and Germany, the term *inductance* was adopted to represent the coefficient of induction (with the symbol *L*) and the present definition of the term *reactance* was proposed by Steinmetz and adopted.

First Electrical Standards. In 1896, a "National Conference of Standard Electrical Rules" was held. The institute's delegate, Professor F. B. Crocker, was made its president, and in cooperation with other national organizations, the conference promulgated the "Underwriters' Rules," which finally resulted in the *National Electrical Code*® (NEC®).**

*In 1963, the AIEE merged with the Institute of Radio Engineers to form the IEEE.
***National Electrical Code* and NEC are registered trademarks of the *National Fire Protection Association (NFPA)*.

In 1897, the Units and Standards Committee recommended adoption of the standard of luminous intensity, or candlepower, as the output of the amylacetate Hefner-Alteneck lamp. It also recommended that the Lummer-Brodhun photometer screen be adopted for measuring the mean horizontal intensity of incandescent lamps.

At the beginning of 1898, a discussion was organized on the subject of "standardization of generators, motors, and transformers." This resulted in the formation of the first AIEE product standards committee, which in 1899 published the first electrical standard under the unique title *Report of the Committee on Standardization*.

National Institute of Standards and Technology. The AIEE was a prime mover in the endorsement of a bill before the U.S. Congress, in 1901, for establishing a national standardizing bureau in Washington, DC, "for the construction, custody, and comparison of standards used in scientific and technical work." This bureau became known as the National Bureau of Standards (NBS) and has had a marked influence on the growth of U.S. technology. In 1988, the mission of the NBS was broadened by The Omnibus Trade and Competitiveness Act and other legislation, to help enhance competitiveness of U.S. industry and speed up the commercialization of new technology. At that time, the NBS was renamed the National Institute of Standards and Technology (NIST).

International Electrical Standards. In 1904, an International Electrical Congress was held in St. Louis which set a precedent for international congresses related to electrical units and standards. The congress unanimously recommended the establishment of two committees. Committee 1 consisted of government representatives and was responsible for legal maintenance of units and standards. This committee has now evolved into the International Conference on Weights and Measures (GPMU). Committee 2, of which Lord Kelvin was elected president, was responsible for standards related to commercial products in the electrical industry and became the International Electrotechnical Commission (IEC) in 1906.

Another international body, the International Commission on Illumination [Commission International de l'Eclairage (CIE)], had its first meeting in 1913. The CIE establishes international units, standards, and nomenclature, in the science and technology of light and illumination.

International Telecommunications Standards. In 1865 the first International Telegraph Convention was signed by 20 countries. This marked the formation of the International Telegraph Union (ITU). After the invention of the telephone in 1876 and wireless telegraphy (the first type of radiocommunication) in 1896, the scope of the ITU was broadened to include these new technologies. In 1906, the first International Radiotelegraph Convention was signed. The International Telephone Consultative Committee (CCIF) was formed in 1924, and the International Telegraph Consultative Committee (CCIT) was formed in 1925. In 1920 sound broadcasting began, and in 1927 the International Radio Consultative Committee (CCIR) was formed. At the Madrid Conference in 1932, the previous conventions were combined into the International Telecommunication Convention. The ITU changed its name in 1934, to the International Telecommunication Union. After World War II, the ITU became a specialized agency of the United Nations in October 1947. In 1956, the CCIF and CCIT merged to form the International Telephone and Telegraph Consultative Committee (CCITT). The year 1963 saw the first telecommunications satellite and the ITU set up a study group on space communications. Most recently, the Plenipotentiary Conference held in 1992 has remodeled the ITU to meet the challenges of the future.

International Standards Outside the Electrical Field. The original standards work in the fields outside electrotechnology was performed under the International Federation of the National Standardizing Associations (ISA), which was formed in 1926. ISA's activities ended in 1942 as a result of World War II. In 1947, the International Organization for Standardization (ISO) was established, as a result of a meeting of delegates from 25 countries that was held in London in 1946. Like the IEC, the ISO is a nongovernmental organization that promotes the development of international standardization and related activities. Its areas of responsibility are fields outside electrotechnology, light, and telecommunications.

International Information Technology (IT) Standards. When the need for international standards in the field of information technology arose, it was clear that both the IEC and the ISO needed to be involved. In 1987, an agreement between the IEC and the ISO created the Joint Technical Committee on Information Technology (JTC-1). The ITU provides input to JTC-1 as an official liasion.

Another organization, The Internet Society (ISOC), was formed in 1992. Its formation came as a result of the INET Conference held in Copenhagen in 1991, where it was decided that a neutral and internationally recognized body devoted to the support of Internet administrative infrastructure was needed.

National Standardization. Although an international standards organization for electrotechnology existed, representation on the IEC was by national committees from its member countries. Many of these countries had their own national standards organizations responsible for their national standards program, endorsement of national standards, participation in international standards development, and so forth. A number of these national organizations later became founding members of the ISO.

In the United States, five professional engineering societies and three government agencies spearheaded by the AIEE organized the American Engineering Standards Committee (AESC) in 1918. The AESC has been aptly described as a "national clearinghouse for industrial standardization." In its early years, this body was organized with 12 divisions, each based on its own area of technology. Few of these became active. The electrical engineering division actually became the strongest, even to the point of having its own bylaws. Today, the AESC is known as the American National Standards Institute (ANSI); however, at times during its history it was also known as the American Standards Association (ASA) and the United States of America Standards Institute (USASI). In 1926, under the auspices of the ASA, engineering abbreviations and symbols were standardized. The AIEE, in cooperation with ASA, sponsored in 1928 the development of a glossary of terms used in electrical engineering. This work was coordinated with the IEC[*]. Over the years, ANSI (and its predecessors) has had many responsibilities in the standards arena, including development of standards. Although many people still believe ANSI develops standards, it has not done so for many years. Standards that become American National Standards (ANSs) are written by one of more than 270 standards developers that can submit their completed standards to ANSI for acceptance as ANSs. It is interesting to note that, in the electrical industry, basic standardization was first in order of development, dating back before 1890. Technical standardization came next, with the formation of the Standards Committee of the AIEE in 1898. Manufacturing standardization came only as a result of World War I and did not take effect until 1920.

In Canada, the Canadian Standards Association (CSA) was formed in 1919. It is a not-for-profit organization supported by its members and develops standards in many fields. In 1970, a new organization called the Standards Council of Canada (SCC) was established by an act of parliament to coordinate voluntary standardization in Canada. The SCC is a federal Crown Corporation. The CSA represents Canada on a number of ISO Committees on behalf of the SCC. Standards may be submitted by accredited standards developing organizations to the SCC for approval as a National Standard of Canada.

Regional Standardization. Once standards began to be developed, it did not take long for regional organizations such as the Organization of American States (OAS), the Pan American Standards Commission (COPANT), or the Pacific Area Standards Congress (PASC), and alliances such as the North American Treaty Organization (NATO), to see the value in having common (or harmonized) standards. For example, in May 1923, the OAS (then known as American States of the Pan-American Union) established the Inter-American Electrical Communication Commission (now known as the Inter-American Telecommunication Commission). However, it was not until the formation of three regional standards organizations by the European Economic Community that the world really took notice. In the area of electrotechnology, the European Committee for Electrotechnical

[*]The 6th edition of the IEC Multilingual Dictionary was published in 2005, with over 19,400 definitions in English and French. Equivalent terms wherever available are included in up to 11 additional languages, including Arabic, Chinese, Dutch, German, Italian, Japanese, Polish, Portuguese, Russian, Spanish, and Swedish.

Standardization (CENELEC) was formed in 1973. Telecommunications standardization is the responsibility of the European Telecommunications Standard Institute (ETSI). All other standardization is the responsibility of the European Committee for Standardization (CEN).

Associations. Many associations have come to exist for various reasons, which may include standards. One of the earliest was the Association of Edison Illuminating Companies (AEIC). It was founded in 1885 to provide guidance to the Edison Illuminating companies that were being formed around the United States. The AEIC became a place where problems facing the growing electric utility industry could be solved by pooling the knowledge and experience of managers, engineers, and operators. Most of the work of the AEIC was technical in nature until 1948; however, in 1948 a committee was formed to deal with load forecasting and end-use management. The AEIC today continues to produce standards for equipment, such as cable, used by electric utilities.

Another example of an early association was Aeronautical Radio, Inc. (ARINC), formed in 1929 by four major airlines. ARINC was incorporated to serve as "the single licensee and coordinator of radio communication outside of the [U.S.] government." Once ARINC was organized, the Federal Radio Commission (predecessor of the Federal Communications Commission), transferred responsibility for all aeronautical ground radio stations to ARINC. ARINC continues to provide services today to the airlines, aviation-related companies, and government agencies.

In the field of telecommunications, the Exchange Carriers Association was formed in 1983 as part of the breakup of the Bell System (i.e., AT&T) in the United States. It has recently been renamed the Alliance for Telecommunications Industry Solutions (ATIS). Its membership is open to those involved in telecommunications in North America and the Caribbean. Committee T1 was formed in 1984 to give exchange carriers a voice in the creation of telecommunication standards, which had previously been developed, de facto, by AT&T. ATIS eventually became the secretariat for committee T1; however, committee T1 was retired in 2004 and its standards work was assumed by ATIS.

Standards in Current Times. The information age and global economy have increased the demand for new standards that are internationally acceptable. The completion of the Uruguay Round of negotiations (1986–1994) of the General Agreement on Tariffs and Trade (GATT) led to the establishment of the World Trade Organization (WTO) in 1995 and a new set of agreements covering goods, services, and intellectual property. It also established a new dispute settlement mechanism. The WTO is the only international agency overseeing the rules of international trade with 148 member nations (as of October 2004). In 2001, the WTO began to host a new round of negotiations under the Doha Development Agency. The formation of the European Commission (EC) along with its regional entities and requirements for compliance with European Norms has had a significant impact on standards. For example, in 1990 the European Organization for Certification and Testing (EOTC) was created under a memorandum of understanding between CEN, CENELEC and the European Free Trade Agreement (EFTA) countries. EOTC was formed to promote the mutual recognition of test results, certification procedures, and so forth throughout the EC and EFTA countries. The North American Free Trade Agreement (NAFTA) and EFTA have had similar effects on the standards community.

Programs intended to harmonize standards to make them more internationally acceptable were instituted by many standards developers. Certification (or registration) began to take on additional importance to those organizations that wanted to compete in the global market. As a result, conformity assessment (which includes both registration and certification) programs began to expand, and in a number of instances certification organizations in one country expanded into other countries or partnered with a certification organization in another country. In 1979, ISO established a technical committee to harmonize the increasing international activity in quality management and quality assurance standards. One product of this committee was the ISO 9000 series of standards, which are internationally accepted and can provide a company that uses them with a route to the world markets. After ISO 9000 the ISO 14000 series of standards on environmental management tools and systems were developed. These standards address a company's system for managing its day-to-day operations as they impact the environment.

Other changes that have occurred in the standards development arena are that the standards developers themselves are changing. Many have been renamed to reflect a more international flavor, and most have reengineered their processes to provide standards in a more timely manner or have begun to introduce new products such as emerging technology standards. For example, the IEC introduced the Industry Technical Agreement (ITA) as a new product in 1997 "in its drive to remain relevant in the field of electrotechnology." The ITAs are not produced within the traditional IEC committee structure, nor are they consensus documents; however, they can be produced in months rather than years. Later, the Technology Trend Assessment (TTA) was introduced. A TTA presents the state-of-the-art or trend in a field of emerging technology that might become an area for standardization in the near-to-medium-term. TTAs are typically the result of research or prestandardization work. Although these programs have met with some degree of success, those in the information technology and telecommunications market want standards in place before, not after, their products are created. These industries are more interested in the anticipatory information provided by the standards process than they are in the final standard. They are also interested in new and more flexible forms of standards development.

As a result, these industries have turned to the formation of trade associations and consortia to develop their standards. In the United States, the number of standards produced in this manner will be greater than those produced by traditional SDOs. In contrast to traditional standards which are typically produced by volunteers, trade associations and consortia use paid professionals and provide them with budgets for expenses, research, legal advice, and so forth. Additionally, international standards organizations such as IEC and ISO have recognized a number of these standards as Publicly Available Specifications (PASs). One example of an industry consortium is the World Wide Web Consortium (W3C). It was founded in 1994 and its mission is "to lead the World Wide Web to its full potential by developing protocols and guidelines that ensure long-term growth for the web.

Other examples are: the Unicode Consortium, established in 1991, to bring together leading software corporations and researchers at the leading edge of standardizing international character encoding; the Open Group, established to answer questions in IT that corporate IT users need answers to by aiding in the development and implementation of a secure and reliable IT infrastructure; the DSDM Consortium, established in 1994 to develop and promote a public-domain rapid application development method; and the Northeast American Electric Reliability Council (NERC), founded in 1968 after the Northeast Blackout to promote reliability of the electrical supply for North America.

28.3 STANDARDS AND THE LAW

Voluntary Standards System. The word *standard* has a number of meanings, but in the context of trade or engineering, it refers to voluntary technical standards that are normally developed by a consensus of experts. Many standards set safety or performance requirements for products or services, for example, standards for workshoes for those involved in electrical work to be "nonconductive with a reinforced toe" for safety purposes. These standards are not normally developed by lawmakers, and because they are outside of the mandatory scope of laws, they are sometimes referred to as *voluntary standards*. In general, standards are developed under a voluntary system. To the extent that their adoption is also voluntary, there is less vulnerability to legal liability. However, many standards are made mandatory, either through reference in purchase specifications and contracts or through adoption by government bodies as regulatory documents. For example, in certain states it may be illegal for a person to drive (or ride as a passenger) a motorcycle without a helmet that meets the requirements of a specific standard. Under such circumstances compliance ceases to be voluntary and the effect of the document is to disqualify or limit the acceptability of certain products or services.

The ability of standards to limit acceptable suppliers is a potential danger of standards and the processes under which they are developed must minimize the possibility of discrimination against specific companies. One can begin to see that standards could be developed that contain absurd requirements that could act as a barrier to trade from a foreign nation, or within the same nation violate antitrust laws. Additionally, once a standard is written into the law, if the law simply states that compliance with standard *xyz* is required, then any revision to the standard (as occurs periodically) has the effect of amending the law.

Legality of Standards. The legality of standards activities is primarily affected by laws related to the fixing of prices, conspiracy in restraint of trade, and intellectual property. Throughout history, standards have been well-known barriers to trade as countries hide protectionism in the veil of an absurd standard. An example would be a standard written by a country that requires the use of a specific material available only in that country for a particular part of the product. Today, however, standards are covered by the GATT, the WTO, and other trade agreements such as NAFTA. The WTO supports the use of international standards developed under the auspices of international standards organization such as IEC and ISO. One reason for this is the belief that it is felt that the international development process will identify and exclude any documents that contain hidden trade barriers. From the users' perspective, certification to international standards should result in greater international acceptance for their product or service.

In the United States, the two key governmental agencies involved are the Federal Trade Commission (FTC) and the Department of Justice. In 1975, the FTC and the Justice Department held hearings on a number of abuses of standards development and certification activities. These abuses involved individuals involved in the standards process who attempted to use standards for market advantage or to deny competitors entrance into an established market. One conclusion of the hearings was that there needed to be some fundamental guidelines and practices that would ensure that the activities related to standards development would be "fair." Those fundamentals were due process, openness, balance, public notice, and the right to participate and appeal. These are the same basic principles that govern standards development around the world; however, they have, in many instances, been interpreted and reinterpreted to the point where they slow down the process. This, as stated earlier, has driven many away from the traditional standards organizations, especially in the areas of new technology.

Since standards activities involve meetings in which representatives of competing organizations make agreements that affect engineering and industrial practices (both of which have economic implications), such meetings must take place under conditions which are subject to carefully regulated procedures. Failing this, participants could be subject to charges of violation of antitrust or conspiracy statutes. Trade associations and consortia are particularly vulnerable in this respect, as meetings restricted to their membership involve participants who tend to be exclusively competitive manufacturers, whereas meetings of committees of professional societies involve technical personnel who are more apt to be representative of the total industry (both manufacturers and users), independent consultants, government personnel, educators, and scientists. Similarly, international standards committees are populated by experts from the national committees from the member countries. These persons individually represent the consensus of experts in their country when developing or voting on standards. However, the degree of liability of participants in standards development activities is virtually negligible when these activities are conducted under the auspices of, and under the strict rules of, an organization experienced in standards development, that is, an organization whose procedures are designed to promote fair and unprejudiced participation by all eligible parties.

Certification. The certification of a product provides additional assurance that a product is reasonably safe and reasonably suited for its intended function. Certification is particularly important for products that are purchased by the general public (i.e., consumers). Legal action against certifying organizations is rare; however, negligence in the certification process could cause a certifying organization to become exposed to a claim for liability.

Patents. The issue of patents as related to their use (or specification) in standards has become something that most standards developers have had to deal with, particularly for new technology standards. Most standards developers have patent policies that require disclosure of patents at the time a proposal for development of a standard is submitted. They further require disclosure at any time in the standards development process that it becomes known that a patent is applicable to a standard. Additionally, the patent holder is normally required to provide a letter stating that (1) the patentee will not enforce any of its present or future patent(s) whose use would be required to implement the proposed standard against any person or entity using the patent(s) to comply with the standard or (2) a license will be made available to all applicants without compensation or under reasonable rates, with reasonable terms and conditions that are demonstrably free of any unfair discrimination. If these conditions are met, the patent may be included in the standard; however, the standards developer normally publishes a disclaimer in the standard making no claims as to the validity of the patent or the reasonableness of rates and/or terms and conditions of the license.

Personal Liability. An area of legal concern for participants in the standards generation or approval process is the question of legal liability. A typical situation deals with the case where an accident occurs under circumstances where potentially negligent parties demonstrate that they faithfully complied with the provisions of the applicable safety standards. The question here is one of the extent of liability of those who participated in the generation or adoption of the standard. A somewhat equivalent situation arises in product liability cases. Any such claim in a legal action turns on allegations of negligence in writing the standard. The general conclusion held by counsel is that members of voluntary standards committees operating under procedures that embody the fundamental principles of due process, openness, balance, public notice, and the right to participate and appeal are not likely to incur significant legal risks.

Some standards developers indemnify those persons who are members of the organization, provided the processes of the organization have been followed during the standards development process. Other standards developers require those participating on its standards writing groups to sign a statement attesting to the fact that they will follow the organization's procedures when participating in standards activities for the organization.

28.4 THE VOLUNTARY STANDARDS PROCESS

Voluntary Development of Standards. There are literally tens of thousands of experts in the fields of electrotechnology, telecommunications, and information technology who participate in standards development worldwide. It should be clear that it is the process by which the standards are developed that is of importance. The process should embody the fundamental principles; however, there are almost as many processes as there are standards developers. Although it would be impossible to describe them all in this section, the information age has made access for interested parties easier than ever before. Today, the World Wide Web allows direct access to a wealth of standards information. A listing of organizations (including their acronyms) and their websites, is provided at the end of this section to enable an interested party begin exploration of the "world of standards." Many of the websites contain the full text of the procedures followed by the standards developer. These can frequently be downloaded.

Although the development processes are designed to enable the broadest possible input to standards, duplicate standards, conflicts between standards, and other problems may exist. The resolution of these problems may be by the standards developers themselves, or by a national or international organization. For example, in the field of electric power cable, conflicts have arisen between standards developed by ASTM and IEEE that had to be resolved by the developers, or by ANSI where resolution was not achieved by the developers. In the case of duplicate standards in a voluntary system, the standard of choice will usually be decided by the market (i.e., the standard referenced by users will become the standard used). Complementary standards for a product are sometimes developed by two or more standards organizations, with each organization responsible for preparing standards within its area of expertise. For example, for power switchgear standards in the United States, IEEE develops those standards related to specifications and tests, while NEMA is responsible for those standards related to ratings. Occasionally, two or more organizations may develop a standard jointly; however, issues related to copyright and reproduction need to be agreed to by each organization before work begins. An example of this is standard IEEE/ASTM S10 which was jointly developed by IEEE and ASTM International and first published in 1976. This standard is intended to give authoritative information on SI and guideance on its application to U.S. citizens and industry. Its use became more important in 1988 when the U.S. Metric Conversion Act was amended to designate "the metric system of measurement as the preferred system of weights and measures for U.S. trade and commerce."

Approval of standards is normally by consensus, with the definition of what constitutes consensus defined by the developing organization's procedures. What this means is that a standard may be made available to users once consensus is reached by the sponsor. A problem here is that some sponsors apply a more rigid interpretation of consensus than intended (some even try to attain unanimity), which ultimately delays the standard. In these instances, the sponsor is doing a disservice to the users that need the standard. Although the sponsor is responsible for the technical content of the standard, the standards developer often has some sort of authority (e.g., a standards board) that is responsible for ensuring the organization's process has been followed. Approval by that authority is the final step in the process before publication. Here, too, interpretation of the process by the authority can cause standards to be returned to the sponsor, resulting in an unnecessary delay of the standard.

Another part of the process that has not been discussed is the maintenance of a standard once it is developed. All standards require periodic review to ensure that the information contained in them is current. Once reviewed, the standard may be reaffirmed (or confirmed), revised, or withdrawn. The standards developers also have the ability to administratively withdraw a standard if it has not been reviewed by its sponsor within some maximum period of time. For example, in the United States, the maximum time a standard can exist without being revised or reaffirmed is 10 years. The IEEE requires its standards to be reviewed every 5 years. The sponsor may request an extension of up to 5 years with a explanation (a 2-year extension is normally granted on request, without explanation). The standard is administratively withdrawn by IEEE after 5 years if no extension is requested and after 10 years with extensions. Internationally, both ISO and IEC require a review of their standards by the responsible Technical Committee (or Subcommittee) at least once every five years. The process for maintenance of standards developed by some consortia may be less than adequate and may be a future issue in standards. This is an area that traditional standards developers are targeting for new work (i.e., to provide standards maintenance services to consortia).

28.5 TERMINOLOGY IN STANDARDS

Standards Terms. The following comprises a partial list of terms used by participants in standards activities. Many of these terms have unique and specialized meaning when used in the context of standardization, and a brief definition is given for each as applied in this context. Some of the terms are specific to the processes of the IEC and are identified by an (IEC) at the end of the explanation of the term.

approval stage The point after the enquiry stage, at which the final-draft international standard (FDIS) is circulated to the National Committees for a 2-month voting period. If the FDIS is approved it is published, and if it is not approved it is referred back to committee for reconsideration (IEC).

balance The characteristic of a standards approving unit (committee, subcommittee, or working group) which assures that all classifications of interests are represented and that no single classification has a representation sufficiently large to enable it to unduly influence the resulting output.

balanced committee A committee so constituted as to maintain a balance among its members. Many committees are balanced among manufacturers, users, and general-interest classifications.

basic standard A standard common to all disciplines, or to an overall technology.

canvass A method used for approval of standards which is dependent on circulation of a draft document to a list of concerned organizations for review and ballot.

*American National Standard for use of the International System of Units (SI): The Modern Metric System.

certification An attestation to the effect that a particular product or service meets the requirements of a relevant standard.

certification mark A special kind of trademark that appears *only* on products that have been certified against a standard.

classification of membership The classification assigned to a participant or member of a standards developing unit which identifies the member's functional relationship or interest in the subject to be standardized. Thus a participant may be a manufacturer of a product being standardized, a user or purchaser of the product, a technically qualified expert with no well-defined functional relationship (classified as general-interest), a labor or insurance representative (in the case of safety standards), or a constructor (one who installs the product for use by others). A variety of other classifications is possible as dictated by the scope of the standards activity.

code (*a*) A body of recommendations of good practice to be followed during design, manufacture, construction, installation, operation, and maintenance to satisfy considerations of safety, quality, economy, or performance in a given application. (*b*) A particular form of identification marking or reference which serves the dual purpose of establishing in a systematic manner the complete identity of an individual product and of identifying its similarity with other products. It may consist of a brief, systematic combination of letters, numerals, and symbols.

committee stage The point at which the document is submitted to the National Committees for comment and ballot if the document is intended to be published as a technical report (IEC).

conformity assessment An activity or set of activities that determines directly or indirectly whether relevant local product requirements have been fulfilled. Typical forms of conformity assessment include testing, inspection, assessment, auditing, certification, registration, and certification.

consensus A substantial agreement of those concerned. It implies that no important interested parties are strongly opposed on substantive grounds, or alternatively, that any opposition is in a small minority and the changes required to effect agreement by this minority would lead to substantive disagreement by the majority. Consensus implies that all disagreements have been given careful consideration and all reasonable attempts have been made for their resolution.

designation A definite and distinguishing name or symbol given to a product or to a group of functionally similar products or to an abstract matter. It emphasizes the group similarity but does not bring out the differences among the various members of the group.

dimensional interchangeability A condition in which the dimensions of two or more products are such that one can physically replace another in a given application.

dimensional standard A standard whose main content is dimensions and sizes of a product or group of products.

e.ballot A "letter ballot" or equivalent that is conducted electronically (e.g., via e-mail).

enquiry stage A point before the approval stage where the bilingual Committee Draft for Vote (CDV) is submitted to P-members of a technical committee for a 5-month voting period. It is the last stage at which technical comments can be taken into consideration (IEC).

functional interchangeability A condition where the characteristics of two or more products are such that they are able to perform the same functions.

guide A standards document that provides alternative information which comprises good engineering practice. Guides may contain application information for use of products and may be tutorial in nature. The user should be cautioned that the use of the word "guide" in the title of a document does not guarantee that the document is in fact nonmandatory. There are many governmental regulatory guides which in fact set forth mandatory requirements. Conversely, many documents that are differently titled are in fact guides.

harmonization The act of coordinating requirements from multiple standards (e.g., multiple countries or multiple SDO's standards) and copublishing the resulting document.

harmonization committee (or task force) A group of individuals responsible for technically developing the proposed draft of the harmonized standard. The group typically consists of a representative of each involved country (or SDO), the secretariat, the chair.

interface standard A standard whose main purpose is to ensure coordination between systems.

international standard A standard that has been adopted by a recognized international standards body (such as IEC or ISO).

joint publication A standard that has been submitted through the standards development process of two or more SDOs and is published separately by all involved SDOs. A joint publication may also be referred to as a harmonized or copublished standard, or if the SDOs represent different countries, as a binational or trinational standard.

letter ballot A ballot used in standards development to determine agreement on a draft standard, or to generate comments that will be instrumental in developing a document on which consensus agreement can be achieved. Such ballots provide for affirmative and negative votes. Negative votes, however, must be accompanied by reasons in sufficient detail to enable the writers of the document to determine what steps need be taken in revision to change the vote from negative to affirmative. The primary advantage of a letter ballot is that it provides adequate time for the recipients to review thoroughly the document which is subject to ballot.

marking The action and the result of stamping, inscribing, printing, or labeling marks, symbols, letters, or numerals on a product or its package for the purposes of identifying the product.

may An operative verb used in a standards document which identifies a possible means for satisfying a requirement. For example, several alternative procedures may be indicated for measuring a particular characteristic or phenomenon, and the selection of the most suitable procedure is left to the user of the document.

national standard A standard that has been adopted by a recognized national standards body (such as ANSI), or a standard that is in effect recognized and used nationally in preference to other documents.

O-member An observer member of a technical committee who has the right, but not the obligation, to vote and attend meetings (IEC).

performance characteristic A characteristic of a product which determines the product's suitability for a specific application.

P-member A participating member of a technical committee who is obliged to attend meetings and vote on a draft international standard (DIS, IEC).

preliminary stage Projects envisaged for the future but not yet ripe for immediate development, or preliminary work, such as better definition of a project for new work, data collection, or round-robin tests necessary to develop standards, which is not part of the standardization process (IEC).

preparatory stage The phase during which a working draft (WD) of a document is prepared (IEC).

product standard A standard containing requirements to be met by a product or group of products, usually including, directly or by reference to other standards, all or some of the following elements: dimensions, performance characteristics, other characteristics, and test methods.

proposal stage A proposal for new work originated from industry via a National Committee, communicated to the members of a technical committee or subcommittee with a form. A simple majority vote takes place within 3 months; if the result is positive and five members agree to actively participate, it is included in the work program (IEC).

rating A characteristic of a product which is determined in an arbitrary, yet consistent, manner, based on the intended function of the product.

recommended practice A standards document that provides information on good engineering practice. Such documents may contain application information for use of products.

safety standard A standard whose primary purpose is to ensure the safety of people and property.

SDO Standards Developing Organization.

secretariat An organization that assumes the responsibility for providing administrative oversight of a standards committee's activities and assures compliance with all applicable procedures.

self-certification An attestation by a manufacturer or supplier of a product or service that it meets the requirements of a relevant standard.

shall An operative verb used in a standards document which indicates a mandatory requirement that must be specifically complied with for conformance to the document.

should An operative verb used in a standards document which indicates a problem area that must be resolved and specifies a requirement, compliance with which resolves the problem. In this sense, the verb "should" can be read as "shall." Alternatively, it is allowable under the document to use some other method which can be proved to resolve adequately the condition or problem area addressed. In some cases, it is also possible to demonstrate clearly that the condition or problem area addressed does not in fact exist, or apply to the product or circumstance in a specific instance.

simplification A form of standardization consisting of the reduction of the number of types of products within a definite range to that number which is adequate to meet prevailing needs at a given time.

specification A standards document that specifies all the characteristics and conditions to be met by a product or service to be supplied to the purchaser. Such a document may refer to other standards, selecting among the specific allowable options. A specification is intended to be a complete purchasing document.

sponsor The group (e.g., a technical committee) that assumes responsibility for the development and/or maintenance of a standard.

standard A documented agreement containing technical specifications or other precise criteria to be used consistently as rules, guidelines, or definitions of characteristics to ensure that materials, products, processes, and services are fit for their purpose.

standardization An activity aimed at an increase of order, giving solutions for recurring problems in the spheres of scientific, technological, and economic activity. Generally it consists of the processes of formulating, issuing, and implementing standards.

terminology standard A standard containing exclusively terms and their definitions.

test standard A standard containing test methods which may be combined with other requirements related to testing, such as sampling, use of statistical methods, and sequence of tests.

third-party certification An attestation by a recognized, technically qualified, independent organization that a product or service supplied by others meets the requirements of a relevant standard. Such certification may be based on inspections and tests conducted by the certifying organization, or on supervision, monitoring, or auditing by the organization of such tests which may be conducted by others. The tests may be performed by the manufacturer or supplier of the service or product while being witnessed or audited by the certifier.

trial-use A publication (standard, recommended practice, or guide) that is effective for not more than 2 years, during which time comments and criticisms from a broad constituency are sought. In the absence of comments during the trial-use period, the document is subject to automatic approval on recommendation of the sponsor.

unification A form of standardization in which two or more specifications are combined into one in such manner that the products obtained are interchangeable in use.

28.6 ISO 9000 AND ISO 14000 STANDARDS

ISO 9000 and ISO 14000 Overview. Unlike the vast majority of ISO standards which are highly specific, ISO 9000 and ISO 14000 are generic families of standards and guidelines relating to management systems. When introduced in 1987 and 1997, ISO 9000 and ISO 14000, respectively, introduced standards to a much broader business community (i.e., beyond organizations in the field of engineering and science only) than did any standards published previously. ISO 9000 is concerned primarily with quality management systems, while ISO 14000 is concerned mostly with environmental management systems. In the context of the standards, *quality management* means what an organization does to conform to its customers' requirements; *environmental management* means what an organization does to minimize harmful effects on the environment caused by its activities. Neither standard is a product standard, and organizations such as law firms, consulting engineers, or standards developers can become ISO 9000–certified. The reason for this is that both ISO 9000 and ISO 14000 are concerned with the way an organization goes about its work (i.e., the process), rather than the direct result of the work (e.g., a product or a service). (For additional information visit the ANSI, ASQ, ISO, and NIST Websites listed at the end of this section.)

ISO 9000 History. In 1959, the U.S. Department of Defense (DoD) established a quality management program designated as MIL-Q-9858, which was later revised to MIL-Q-9858A. NATO essentially adopted the provisions of MIL-Q-9858A in 1968, and published them in Allied Quality Assurance Publication 1 (AQAP-1). In 1970, the U.K. Ministry of Defense adopted the provisions of AQAP-1 when it published its Management Programs Defence Standard DEF/STAN 05-8. In 1979, the British Standards Institution (BSI) developed the first commercial quality management system standard, BS 5750. It was from all of these documents, and BS 5750, in particular, that ISO created the ISO 9000 standards family of documents (the base standards of which are shown below).

When Countries Adopt ISO 9000. By 1992, the European Economic Community (EEC) and 56 countries had adopted ISO 9000. The EEC and other countries assigned numbers to the adopted ISO 9000 standards according to their own national standards numbering system. In the United States, the ISO 9000 series was adopted as ANSI/ASQ Q9000 in 1987. The ANSI/ASQ Q9000 series is essentially identical to the ISO 9000 series with the exception that the text incorporates customary American English language and spelling. Some other examples of adoption of the ISO 9000 series are the EEC as the European Norm (EN) 29000 series, the United Kingdom as BS 5750 Parts 0 to 3, Pakistan as PS 3000-3004 series, Tanzania as TZS 500-504, and China as GB/T 10300.1–10300.5.

Certification. ISO does not itself certify conformity to ISO 9000. This is done by independent certification bodies in different countries. There is also no "official" database of entities certified to ISO 9000.

ISO 9000. This standard, entitled *Quality Management Systems—Fundamentals and Vocabulary*, explains fundamental quality concepts. Additionally, it defines terms and provides guidance on selecting, using, and tailoring the standards in the series.

ISO 9001. This standard, entitled *Quality Management Systems—Requirements*, is the most comprehensive standard in the series. It addresses all the elements in design, development, and so on and provides requirements for quality planning.

ISO 9002. Superseded by the 2000 Edition of ISO 9001.

ISO 9003. Superseded by the 2000 Edition of ISO 9001.

ISO 9004. This standard, entitled *Quality Management Systems—Guidelines for Performance Improvements*, provides guidance for developing and implementing an internal quality system.

Since their introduction, the number of standards in the ISO 9000 and ISO 14000 families have grown to more than 40 documents. In 2004, ISO 90003 was introduced which addresses guidelines for the application of ISO 9001 to computer software.

28.7 INTERNATIONAL ORGANIZATIONS

The International Electrotechnical Commission (IEC). The IEC, a nongovernmental body located in Geneva, Switzerland, is the world organization that develops and publishes international standards for electrotechnology and related technology. Its membership is limited to countries. Today, the IEC membership consists of almost 66 participating countries, including all the world's major trading countries (see Table 28-1). Full membership in the IEC allows the country to participate in all international standardization activities. Participation of a country is by a national committee. Each national committee agrees to open access and balanced representation from all electrotechnical interests in its country (i.e., public and private). A country may also become an associate member, which allows for limited participation in the IEC. Associate members have observer status at all IEC meetings, but have no voting rights.

The mission of the IEC is to promote, through its members, international cooperation on all questions of electrotechnical standardization and related matters, such as the assessment of conformity to standards, in the fields of electricity, electronics, and related technologies, including magnetics and electromagnetics, electroacoustics, telecommunication, energy production and distribution, terminology and symbols, measurement and performance, dependability, design and development, safety, and the environment.

The work of the IEC is carried out by more than 10,000 experts worldwide who participate on more than 200 technical committees and subcommittees, and more than 700 working groups. All IEC publications are bilingual (English and French). Certain documents have also been translated into Spanish. The Russian Federation National Committee develops Russian-language editions of IEC documents. English, French and Russian are the three official languages of the IEC; however, in all bodies of the IEC other than the Council, discussions may be held in English and/or French, following agreement of the delegates. Standards developed by the IEC follow the procedures in the ISO/IEC Directives, published jointly by both organizations and administered by the Joint Technical Program Committee (JTPC). These directives are published in two parts. Part 1 covers the procedures

for the technical work. Part 2 covers drafting and presentation of international standards. These common procedures were adopted by ISO/IEC in recognition of the need to develop timely and cost-effective international standards. The joint ISO/IEC Committee JCT 1, Information Technology develops and maintains its own procedures. All of these procedures may be accessed on each organization's web site.

Figure 28-1 is an organization chart for the IEC. The Council, which is a "general assembly" of committees, is the supreme authority of the IEC and sets policy, financial objectives, and strategy. The Council delegates the management of all IEC work to the Council Board. The responsibility for standards and conformity assessment is assumed by the Standardization Management Board and Conformity Assessment Board, respectively. In the areas of standards and conformity assessment, the IEC works closely with other international organizations such as the ISO, WTO, and ITU. It also has relationships with governmental agencies and regional standardization organizations. For example, an agreement between IEC and CENELEC ratified in 1996, known as the Dresden Agreement, addresses common planning of new work and parallel IEC/CENELEC voting. Other standards organizations may interface with the IEC as liaisons. For example, the IEEE is recognized as a Class D liaison to the IEC.

International Organization for Standardization (ISO). Like the IEC, ISO is a nongovernmental body, located in Geneva, Switzerland, that is a worldwide federation of national standard bodies. ISO is the world's largest developer of standards, publishing approximately 12,000 documents. Its membership is limited to countries, and at present, some 146 countries are members of ISO. The member body of a country to ISO is the national body "most representative of standardization in its country," and only one body in each country can be admitted to membership in ISO. So, for example, ANSI is the ISO member from the United States, Standards Council of Canada is the ISO member from Canada, Standards Australia is the ISO member from Australia, and DIN is the ISO member from Germany. ISO has two other categories of membership for countries. The first is correspondent member, for countries which do not yet have a fully developed national standards activity; the second is subscriber member, for countries with very small economies.

ISO likes to think of its documents as international agreements that are published as international standards. Some might note an apparent inconsistency between the short form of the organization's name, specifically, ISO and its official title. That is because the short form of the name is not an acronym as many believe, but rather a word ISO derived from the Greek *isos* meaning equal. On this basis, the connection between "standard" and "equal" is easy to understand.

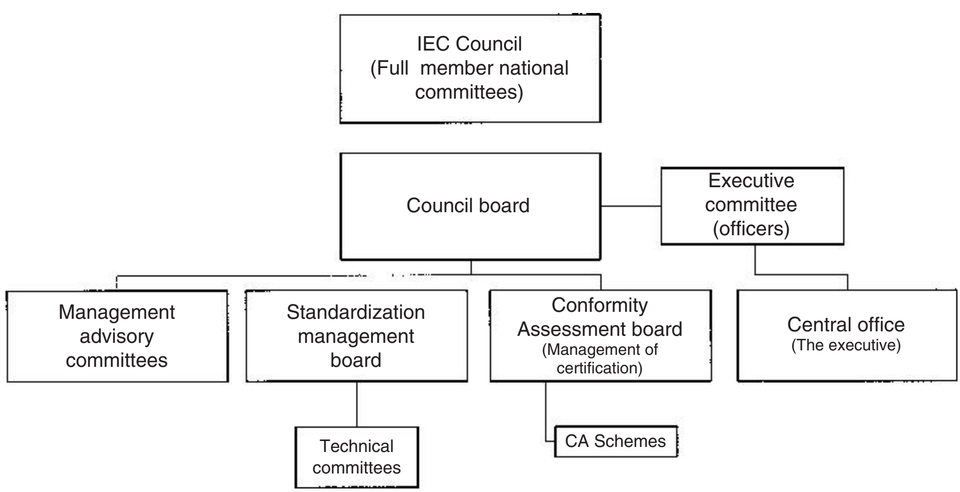

FIGURE 28-1 IEC structure and management.

The mission of ISO is "to promote the development and standards related activities in the world with a view to facilitating the international exchange of goods and services, and to developing cooperation in the spheres of intellectual, scientific, technology and economic activity." The scope of ISO's work is not limited to any particular field, except that electrotechnology is the responsibility of the IEC and information technology is carried out by JTC 1 (a joint committee of ISO/IEC).

Among the documents that affect those in electrotechnology that ISO is responsible for is the universal system of measurements, known as SI (Système International d'Unités) units, which are described in a series of 14 international standards. The work of ISO is carried out by more than 30,000 experts worldwide who participate on more than 700 technical committees and subcommittees, and more than 2000 working groups. An organization chart for ISO is shown in Fig. 28-2. ISO cooperates with other international bodies such as the IEC and ITU, with regional standardization organizations and is building a strategic partnership with the WTO. ISO also has liaisons with almost 550 entities worldwide that are interested in specific aspects of its standardization work. All ISO publications are bilingual (English and French) and are developed following the ISO/IEC directives.

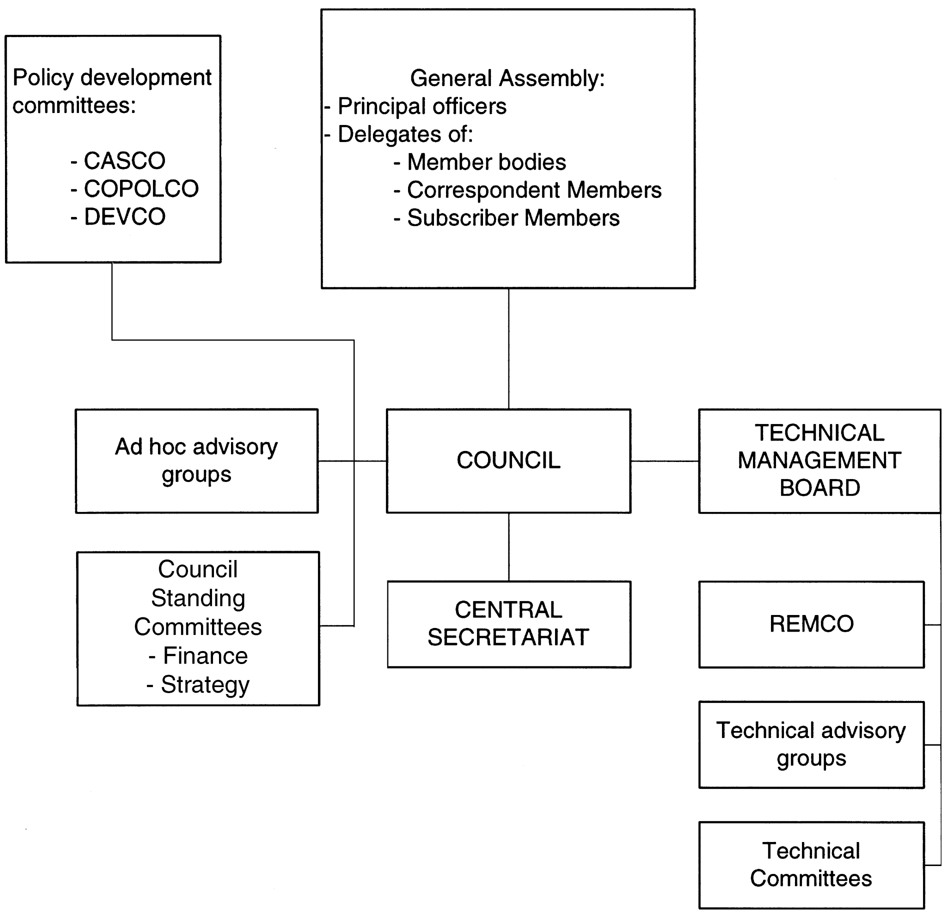

FIGURE 28-2 The ISO organization. (*Legend:* CASCO—Committee on Conformity Assessment; COPOLCO—Committee on Consumer Policy; DEVCO—Committee on Developing Country Matters; REMCO—Committee on Reference Materials.)

The International Telecommunication Union (ITU). The ITU, unlike the IEC and ISO, is part of the United Nations (UN), and its members are governments. It is located in Geneva, Switzerland and has 189 member states (i.e., countries). The ITU is an organization "within which governments and the private sector coordinate global telecom networks and services." It is the leading publisher of telecommunication technology, regulatory, and standards information. The governing bodies of the ITU are shown in Fig. 28-3. The Plenipotentiary Conference has the responsibility to deterrmine the structural and operating changes necessary in the ITU to effectively serve the requirements of the international telecommunications community.

Joint Technical Committee 1 on Information Technology (JCT 1). In recognition of the broad scope and applicability of international standards in the field of information technology, ISO and the IEC approved an agreement in 1987 that formed a joint committee, known as JTC 1 to carry out this work. Membership in JTC 1, like ISO and IEC, is limited to countries; its publications are bilingual (English and French). JTC 1 has 27 member countries (P-members) and 39 observer countries (O-members). It has 17 subcommittees that accomplish its work, and even though it is part of the ISO/IEC, it has its own Website.

The International Committee on Illumination (CIE). The CIE, located in Wien (Vienna), Austria, is "an organization devoted to international cooperation and exchange of information among its member countries on all matters relating to the art and science of lighting." Its short form, CIE, is an acronym from its French title, Commission Internationale de l'Eclairage. The subjects covered by CIE in the fields of light and lighting include vision, photometry, colorimetry, application of light both indoors and out, environmental effects, aesthetic effects, and means for the production and control of light and radiation. The spectrum of light covered is both natural and synthetic over the ultraviolet, visible, and infrared regions. CIE also addresses the optical, visual, and metrological aspects of the processing and reproduction of images using all types of analogous and digital imaging devices, storage media and imaging media. Participation in CIE is like that of other international organizations, by national committee, with 38 countries represented at present. In addition to its own publications, the CIE has published standards jointly with IEC (e.g., the IEC/CIE International Lighting Vocabulary) and ISO.

The Internet Society (ISOC). The ISOC, located in Reston, Va. (U.S.A.), is a nonprofit, nongovernmental, international professional membership organization. It was formed to provide an institution home for the Internet Standards process, as well as to provide financial support for the process.

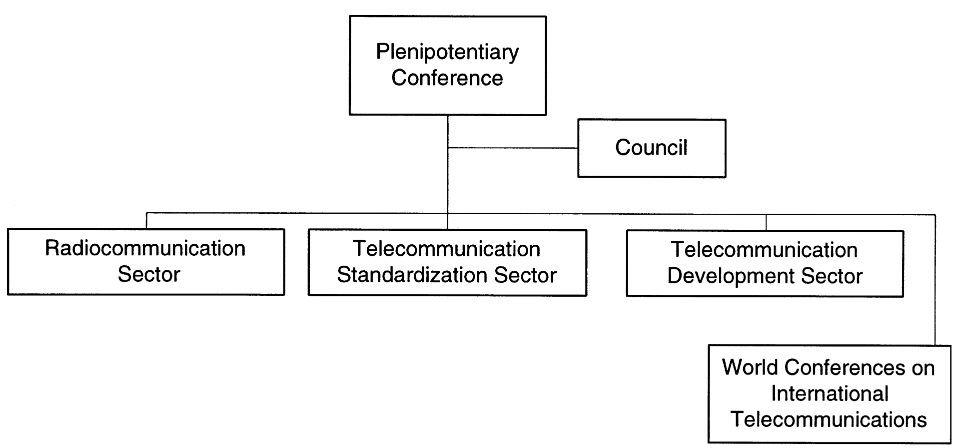

FIGURE 28-3 Governing bodies of the ITU.

It provides the leadership for addressing issues that affect the future of the Internet and it is the organizational home for the groups responsible for Internet infrastructure standards. The combined efforts of the ISOC and IETF have formed and maintain the foundation for all modern networks and Internet products and services. The primary organization supported is the Internet Engineering Task Force (IETF), which since its inception had been supported primarily from research supporting agencies of the U.S. government. The ISOC also charters the Internet Assigned Numbers Authority (IANA) as the central cleaning house to assign and coordinate unique parameter values for Internet protocols. Today, the ISOC has more than 100 organizational and 20,000 individual members in more than 180 countries.

The World Trade Organization (WTO). The WTO, located in Geneva, Switzerland, is an intergovernmental organization and is the only international organization involved in the rules of trade between nations. The WTO is a place where member governments can go to try and resolve trade problems that are between them. The main decision-making bodies are councils and committees consisting of the WTO's entire membership. The authority of the WTO comes from agreements, which are the legal ground rules for international trade and commerce policy. These agreements have three main objectives: "to help trade flow as freely as possible; to achieve further liberalization gradually through negotiation; and to set up an impartial means for settling disputes." Prior to the establishment of the WTO, the GATT had governed international trade and commerce since 1948. The GATT itself was initially an agreement that was provisional. It later became an international organization created to support the agreement but was not recognized in law as an international organization; however, the GATT (i.e., the agreement) has been incorporated into the WTO agreements. Unlike the GATT, which only dealt with trade in goods, the WTO agreements deal with other issues such as copyright, trademarks, patents, industrial designs, and trade secrets. Members of the WTO agree to use international standards (or harmonized standards) to minimize the risk of barriers to trade being introduced by standards. The WTO rules, however, sometimes support maintaining trade barriers when necessary such as in cases where there is a need to protect consumers or to prevent the spread of disease.

The World Intellectual Property Organization (WIPO). The WIPO, located in Geneva, Switzerland, is one of the United Nation's specialized agencies. As such, it is an intergovernmental agency, dedicated to "promoting the use and protection of works of the human spirit." It is responsible for "the promotion and protection of intellectual property throughout the world through cooperation among States, and for the administration of various multilateral treaties dealing with the legal and administrative aspects of intellectual property." The WIPO currently has 182 member states and administers 23 international treaties. Although the WIPO officially became part of the UN in 1974, its "roots" go back to 1883 when the Paris Convention for the Protection of Industrial Property was the first treaty designed to protect intellectual creations through patents and trademarks. Protection of copyrights was added in 1886 with the Bern Convention for the Protection of Literacy and Artistic Works. These groups united in 1893 to form what became the WIPO in 1970.

28.8 REGIONAL ORGANIZATIONS*

European Committee for Electrotechnical Standardization (CENELEC). CENELEC, located in Brussels, Belgium, is a not-for-profit organization and has been officially recognized as the European Standards Organization in its field by the EC in Directive 83/189 EEC. Its membership is made up of national committees from 28 European countries. More than 40,000 technical experts are

Author's note: It is not possible, nor practical, to list all the regional and national organizations, and other standards organizations, that are involved with electrotechnology, telecommunications, and information technology standards. For those readers having additional interest, the World Wide Web provides one with an excellent means of researching these organizations. The reader is also referred to the listing of Websites at the end of this section.

involved in the development of its standards, which are called European Norms (ENs). ENs in the field of information technology are developed and published jointly with the European Commission for Standardization (CEN).

In developing standards, it is the policy of CENELEC to use an IEC standard if it exists (approximately 80% of CENELEC ENs have been developed in this manner). When new work is proposed, it is offered to the IEC with a request that it be undertaken at the international level. CENELEC will develop a standard only if the IEC does not want to undertake the work or if the IEC cannot meet the target dates for the standard. If the IEC assumes the development of a standard, parallel IEC/CENELEC procedures and voting (see Fig. 28-4) designed to result in identical international standards and ENs are used. Once CENELEC has begun work on a standard, or selected an IEC document, all national work (i.e., for CENELEC members) on the same subject is immediately stopped. This suspension of national work for CENELEC members is called "standstill."

Voting in CENELEC is weighted according to the size of the country. Larger countries such as Germany, Italy, France, and the United Kingdom have 10 votes. The smaller countries have one or two votes depending on size. An affirmative vote must meet two conditions. First, a majority of the national committees must vote affirmative and second, at least 71% of the weighted votes must be affirmative. Once an EN is approved it is mandatory that it be adopted as a national standard by CENELEC members (this is unlike most standards processes, e.g., those of the IEC, which allow for

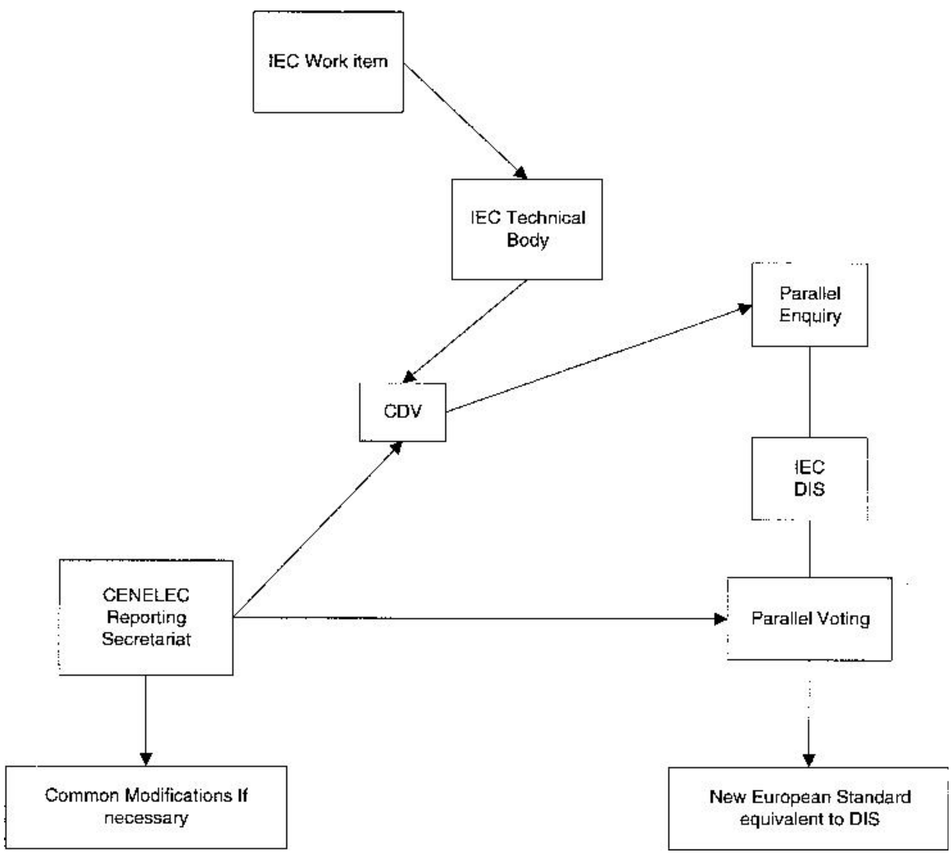

FIGURE 28-4 IEC/CENELEC parallel procedures for standards development. (*Legend:* CDV—Committee Draft with Vote; DIS—Draft International Standard; IEC—International Electrotechnical Commission.)

voluntary adoption). Each CENELEC member is also obligated to withdraw any of its national standards that conflict with an approved EN. On this basis, it is acceptable for a national committee to vote one way in CENELEC (e.g., negative) and another way in IEC (e.g., affirmative).

European Telecommunications Standards Institute (ETSI). ETSI, located in Sophia Antipolis, France, is a nonprofit organization whose mission is "to produce telecommunications standards for use today and the future." It is an open forum (i.e., to European organizations) that brings together some 688 members from 55 countries, representing governments, network operators, manufacturers, service providers, and users. ETSI, unlike CEN and CENELEC, produces voluntary standards, some of which may be adopted by the EC as the technical base for directives or regulations. Promotion of international standardization is favored by ETSI, and as such, it coordinates its activities with international bodies (primarily with the ITU). At present, more than 3500 experts are working in more than 200 groups in ETSI, with more than 13,200 documents already published.

Voting on standards within ETSI is done according to its Rules of Procedure depending on the issue, with only those that are full and associate members allowed to vote. The voting method is weighted individual voting.

28.9 NATIONAL ORGANIZATIONS

The American National Standards Institute (ANSI). ANSI, headquartered in Washington, DC with its operation center located in New York City, is a federation founded in 1918 that has been the administrator and coordinator of the U.S. private-sector voluntary standardization for 88 years. It is a private, not-for-profit organization supported by a number of organizations (i.e., its membership) in the public and private sectors. Today ANSI has approximately 1000 members from companies, organizations, government agencies and institutions.

ANSI's primary goal is "the enhancement of global competitiveness of U.S. business and the American quality of life by promoting and facilitating voluntary consensus standards and ensuring their integrity." ANSI also "promotes the use of U.S. standards internationally, advocates U.S. policy and technical positions in international and regional standards organizations, and encourages the adoption of international standards as national standards where these needs meet the needs of the user country." ANSI is the U.S. member of ISO and, via the United States National Committee (USNC), the IEC.

ANSI does not itself develop standards but functions, rather, as a coordinating body for the purpose of encouraging development and adoption of worthwhile standards as American National Standards. It looks to its organizational members, as well as to other concerned organizations, for accomplishing the task of standards development. These development activities may be performed wholly within one of these organizations, or in accredited committees organized and administered by one of these organizations and operating under a set of rules meeting the basic procedures of ANSI.

A large number of standards (more than 10,000 in 2002) that are processed for adoption by ANSI are developed, approved, and published by any of more than 270 standards development organizations accredited by ANSI. Organizations wishing to become ANSI accredited must develop and maintain procedures (subject to periodic audit by ANSI) that consistently adhere to a set of ANSI requirements or procedures entitled "ANSI Essential Requirements: Due Process Requirements for American National Standards*," that govern the consensus development process. Three of the more commonly used methods are described below:

1. *Accredited organization method*. The organization method is most often used by associations and societies that have, among other activities, an interest in developing standards. Although participation on the consensus body is open to all interested parties, members of the consensus body often participate as members in the association or society. The organization's procedures must

*Available for download from the ANSI Web site.

meet the general requirements of the ANSI procedures. By choosing to use this method, flexibility is provided, allowing the standards developer to utilize a system that accommodates its particular structure and practices.

2. *Accredited standards committee method*. Accredited standards committees are standing committees of directly and materially affected interests created for the purpose of developing a document and establishing consensus in support of this document for submittal to ANSI. The committee method is most often used when a standard affects a broad range of diverse interests or where multiple associations or societies with similar interests exist. The committee serves as a forum where many different interests, without a common membership in an organization or society, can be represented. Accredited standards committees are administered by a secretariat. An accredited standards committee develops and maintains its own operating procedures consistent with the requirements of the ANSI Procedures.
3. *Accredited canvass method*. A standards developer using the canvass method identifies, to the extent possible, those who are directly and materially affected by the activity in question and conducts a letter ballot or canvass of those interests to determine consensus on a document. Although canvass developers provide ANSI with internal procedures used in the development of the draft American National Standard, the due process used to determine consensus begins after the draft standard has been developed. Standards developers using the canvass method must use procedures consistent with the requirements of the ANSI procedures.

Figure 28-5 is an organization chart for ANSI. Standards work is under the Executive Standards Council (ExSC). The ExSC has responsibilities for American National Standards and U.S. participation in those international standards activities in which ANSI participates. ExSC is also responsible for maintaining ANSI procedures for standards development, development and coordination of U.S. position in international standards activities, and establishing and supervising such groups as needed to carry out these responsibilities. The approval and withdrawal of American National Standards has been delegated by the ExSC to the Board of Standards Review (BSR), one of the boards that report to the ExSC.

The Association for Electrical, Electronic and Information Technologies (VDE). VDE, located in Frankfurt am Main, Germany, is a nonprofit, nongovernmental organization founded in 1893 and is one of the largest technical and scientific organization in Europe with more than 33,000 members. In the area of standards in electrotechnology, VDE participates with The German Institute for Standardization (DIN) on the German Commission for Electrical, Electronic and Information Technologies of DIN and VDE (DKE), in both the IEC and CENELEC. The DKE is a joint organization of VDE and DIN; however, VDE is responsible for the administration of DKE. Approximately 4500 persons are involved in the standards process in more than 300 committees and subcommittees, and 300 working groups. The focus of standardization has shifted in the recent past toward the development of European Standards (based on international standards where possible). Pure national standards activity has dropped to approximately 5% of all work done.

VDE also performs certification and testing through the VDE Testing and Certification Institute, which was originally established in 1920 as the VDE Test Center. The VDE Testing and Certification Institute works together with other organizations, such as UL in the United States and CSA in Canada, in approximately 50 countries.

Standards Australia (SA). SA, located in Sydney, Australia, is an independent not-for-profit organization whose primary role is "to prepare Australian Standards through an open process of consultation and consensus in which all interested parties are invited to participate." SA was originally founded in 1922, as the Commonwealth Engineering Standards Association. In 1929, it became the Standards Association of Australia and was granted a Royal Charter in 1950. Its name officially changed to Standards Australia in 1988. SA represents Australia on both the ISO and the IEC. It is also involved in regional standardization activities and was a founding member of the Pacific Area Standards Congress (PASC). It maintains close ties with Standards New Zealand (SNZ) and has a formal agreement with SNZ for developing and publishing joint standards.

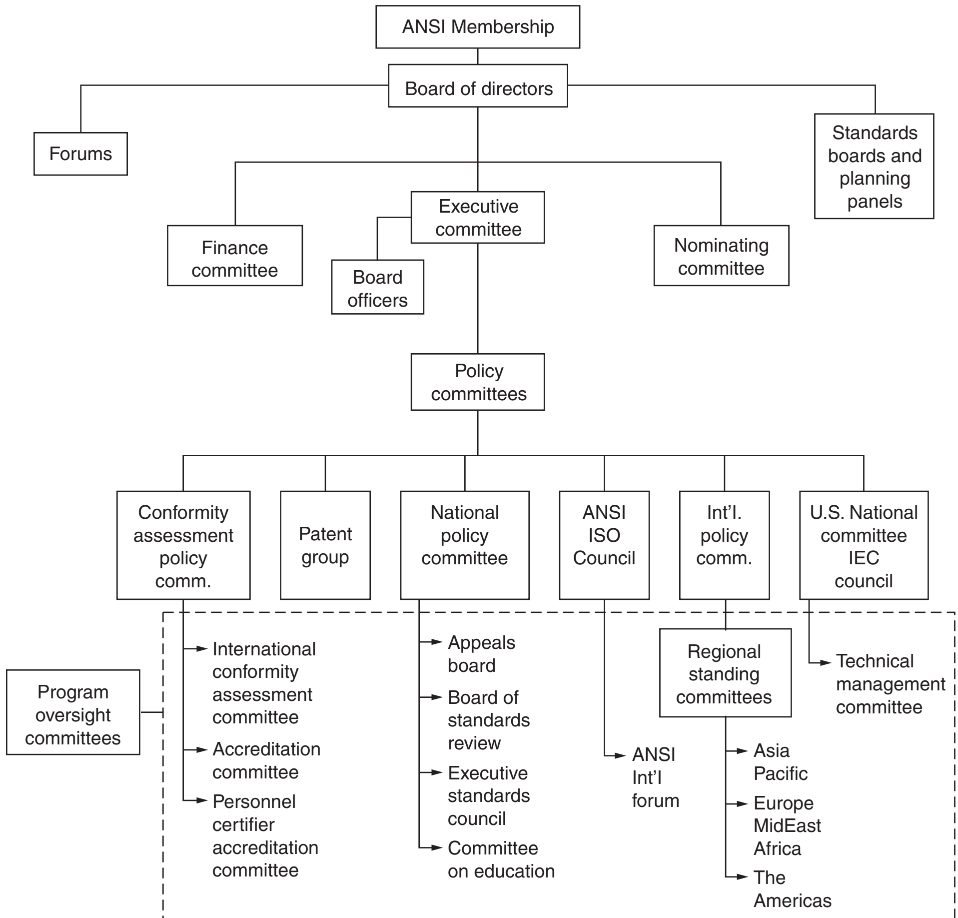

FIGURE 28-5 ANSI organization chart.

At present, approximately 9000 volunteer experts serve on 1500 committees that are responsible for the development and maintenance of approximately 6400 Australian Standards. SA has a subsidiary company, Quality Assurance Services Pty. Ltd., which provides system and product certification services.

Standards Council of Canada (SCC). The SCC, located in Ottawa, Canada, is a federal crown corporation with a mandate to "coordinate and oversee the efforts of the National Standards System, which includes organizations and individuals involved in voluntary standards development, promotion and implementation in Canada." The SCC reports to Parliament through the Minister of Industry. The Governing Council of the SCC consists of 15 members representing a broad spectrum of stakeholder interests. The council is responsible for setting the strategic direction of the organization, ensuring the fulfillment of the SCC's mandate and providing direction on governance matters. Canadian participation in the ISO and the IEC operates under a program under the SCC. The SCC acts as the secretariat for the Canadian National Committee of the ISO (CNC/ISO) and the Canadian National Committee of the IEC (CNC/IEC).

There are more than 15,000 Canadian volunteers involved in standardization activities and some 400 organizations have been accredited by the SCC, as SDOs, certification organizations, testing and calibration, laboratories, registration organizations or auditor certifiers and trainers. Of these organizations, four have been accredited as SDOs. These are Bureau de normalization du Québec (BNQ), Canadian General Standards Board (CGSB), Canadian Standards Association (CSA), and Underwriters' Laboratories of Canada (ULC). These accredited SDOs may submit standards they develop to the SCC for approval as National Standards of Canada (NSC). To become an NSC, a standard must be developed by a process incorporating the fundamental principles, be subject to public scrutiny, be consistent with or incorporate appropriate international and national standards, and be available in the English and French languages. A NSC cannot in any way be presented in such a manner that it will act as a barrier to trade.

28.10 OTHER STANDARDS DEVELOPERS

The Institute of Electrical and Electronics Engineers—Standards Association (IEEE-SA). The IEEE-SA, located in Piscataway, N.J. (U.S.A.), has been responsible for all matters related to standards since its formation in 1998. Actually, the concept of the IEEE-SA was approved by the IEEE Board of Directors in 1996 as part of an overall restructuring of IEEE as it moved into the twenty-first century. Prior to 1998, the IEEE standards program was administered by a Standards Board that reported to the Board of Directors. Under the IEEE-SA, the Standards Board still exists; however, it reports to the IEEE-SA Board of Governors. Standards development in the IEEE, which is the world's largest professional society, with more than 365 000 members in 150 countries, goes back to 1884, when the AIEE began to develop standards. Even today, the IEEE publishes 25% of all of the world's literature in electrotechnology.

The IEEE-SA was formed "to provide a major entity that would offer increased responsiveness to the standards interests of IEEE societies and their represented industries." The IEEE-SA provides services and innovative standards development processes that will keep pace with the needs of users. New classes of membership in the IEEE-SA have been approved, such as corporate membership, which will assist the IEEE-SA in realizing its strategic objectives. At present, the IEEE-SA has more than 30,000 volunteers and more than 70 corporate members participating in its standards activities. The IEEE-SA develops standards in such diverse subjects as broadcasting and communications, electrical practices for large industry (mining, textiles, shipbuilding, transportation, cement plants, and others), instrumentation and measurement, insulators and insulation, magnetics, motors and generators, nuclear power, power apparatus and systems, recording, symbols and units, electrical transmission and distribution, medical devices, electrical practices for commercial buildings and hospitals, emergency power systems, stationary batteries, and information technology. The IEEE-SA also serves as secretariat for a number of accredited standards committees (ASCs), an example of which is ASC C2, the *National Electrical Safety Code*® (NESC®).*

The National Electrical Manufacturers Association (NEMA). NEMA, located in Rosslyn, Va. (U.S.A.), is responsible for the development and maintenance of over 500 standards. NEMA is the largest trade organization for manufacturers of electrical products in the United States, and its 400 member companies are domestic firms varying in size from small companies to large diversified companies. It develops standards in the technical committees of its nine divisions covering

**National Electrical Safety Code*® is a registered IEEE trademark, and its acronym, NESC® is a registered IEEE service mark of the IEEE.

products in such fields as building equipment, power electronics, industrial electrical equipment, insulation, lighting, power equipment, wire and cable, radiation imaging products, and industrial automation.

NEMA technical committees comprise engineers designated to represent member companies who are manufacturers of electrical equipment. Since manufacturers are most knowledgeable in the technology associated with their respective products, NEMA committees are highly competent in developing product standards that realistically take into consideration the economic tradeoffs that are essential to practical standardization. Standards are adopted by consensus with final approval given by the NEMA Codes and Standards Committee.

NEMA Standards are generated in four classifications:

1. NEMA Standard—defines a commercially standardized product subject to repetitive manufacture.
2. Suggested Standard for Future Design—suggests an approach to future product improvement or development.
3. Authorized Engineering Information—included as part of other NEMA standards to explain data or information.
4. Official Standards Proposal—proposed draft for adoption by some other organization such as ANSI.

NEMA is a member of and actively participates in ANSI. It administers the work of a number of ASCs, acting as the secretariat.

The National Fire Protection Association (NFPA).† The NFPA, located in Quincy, Mass. (U.S.A.), has been active in standards development since its founding in 1896. Working under the direction of its Standards Council, the technical committees of NFPA, composed of organization representatives, personal members, and liaison members from other technical committees, develop standards documents that are then subject to public review as a result of advance publication, and are finally approved at a semiannual meeting of the entire NFPA membership. Although dedicated to fire prevention, NFPA is responsible for a series of electrical standards, the most noted of which are the *National Electrical Code* (NFPA 70) and the *Life Safety Code* (NFPA 101).

The NEC covers "the installation of electric conductors and equipment in public and private buildings or other structures (including mobile homes, recreational vehicles, and floating buildings), industrial substations, and other premises (such as yards, carnivals, and parking lots). The NEC also covers installation of optical fiber cable." The NEC is adopted and enforced in all the 50 U.S. states. It is also the basis for electrical codes in several other countries. For example, the Venezuelan electrical code is the 1981 edition of the NEC. The first edition of the NEC was published in 1897. The NFPA took over responsibility for the NEC in 1911. The NEC is produced and maintained by volunteers on 20 codemaking panels and an 11-member correlating committee that oversees the work of the panels.

The *Life Safety Code* "provides minimum requirements for the design, operation, and maintenance of buildings and other structures for safety to life from fire and similar emergencies." The *Life Safety Code* has been adopted by many states. Additionally, all health-care facilities in the United States receiving Medicare or Medicaid funding must comply with the *Life Safety Code*. The groundwork for the *Life Safety Code* began in 1913, when the NFPA appointed its first "Committee on Safety to Life." Its first pamphlet was on exit drills in factories, schools, department stores, and theaters. By 1921, the committee had produced a more comprehensive *Building Exit Code*. The *Life Safety Code* is produced and maintained by members of 15 technical committees.

†*National Electrical Code*®, *Life Safety Code*®, and NEC® are registered trademarks of NFPA.

Underwriters' Laboratories, Inc. (UL).[††] UL, located in Northbrook, Ill, (U.S.A.) is the leading third-party certification organization in the United States and the largest in North America. It is an independent, not-for-profit organization, founded in 1894, whose mark is recognized throughout the world as a symbol of safety.

UL maintains and operates laboratories for testing devices, systems, and materials with relation to public safety. Products so tested and meeting its requirements are eligible for UL "listing." UL maintains an inspection and follow-up program in factories where UL-listed devices are manufactured. UL representatives conduct in-factory and in-the-field inspections of manufacturers' procedures for assuring production compliance with UL requirements. Such requirements appear in appropriate UL Standards for Safety which are developed by UL under procedures that involve consultation with industry and government experts and consumers, among others.

The majority of insurance underwriters in the United States, and many federal, state, and municipal authorities, either accept or require listing or classification by UL as a condition of their recognition of devices, systems, and materials having a bearing upon life and fire hazards.

UL is divided into several engineering departments, each dealing with distinct and separate subjects as follows: electrical heating, air conditioning, and refrigeration; casualty and chemical hazards; burglary protection and signaling; fire protection; and marine. Each department has prepared standards for systems, materials, and appliances.

UL publishes (lists) the names of companies who have demonstrated the ability to provide products conforming to its requirements. Listing authorizes the manufacturer to use the laboratories' listing mark (classification marking, recognition marking, or certificate) on the listed products. UL submits its standards to ANSI for adoption as American National Standards.

UL is active in international standards development and product certification, and is a registrar for quality systems for various systems, including ISO 9000. UL acquired the Danish National Testing and Certification Organization (DEMKO) in July 1996 from the kingdom of Denmark, making it a wholly owned subsidiary of UL. This acquisition provides direct European certification of products to customers worldwide.

UL is responsible for the development and maintenance of more than 800 safety standards, the evaluation of more than 17,000 products, and more than 2500 quality system registrations. In 1998, UL estimated that approximately 14 billion products enter the marketplace each year bearing a UL mark.

28.11 U.S. GOVERNMENT REGULATORY STANDARDS BODIES

The U.S. Consumer Products Safety Commission (CPSC). The CPSC is an independent federal regulatory agency that was created by Congress in 1972, in the Consumer Products Safety Act. The mission of the CPSC is to "protect the public against unreasonable risks of injuries and deaths associated with consumer products." The CPSC has jurisdiction over approximately 15,000 consumer products. Exceptions are motor vehicles, trucks, and motorcycles, which are covered by the Department of Transportation; foods, drugs, and cosmetics, which are covered by the Food and Drug Administration; and alcohol, tobacco, and firearms, which are covered by the Department of the Treasury.

The CPSC works to reduce the risk of death and injury to consumers by developing voluntary standards with industry, and issuing and enforcing mandatory standards. If no feasible standard would adequately protect the public, the CPSC can ban a product. It can also require a recall of products to arrange for their repair. The CPSC also conducts research on potential product hazards and sponsors consumer educational activities (e.g., through the media). All work related to standards or regulations are published in the *Federal Register*. Initially, notice of the proposed

[††]Underwriters' Laboratories, Inc.® and its acronym, UL®, are registered trademarks of Underwriters' Laboratories.

standards or regulation is published for comment. Final regulations are also published in the *Federal Register*.

The U.S. Environmental Protection Agency (EPA). The EPA is an independent federal agency created by Congress in 1970. Its mission is "to protect human health and to safeguard the natural environment—air, water, and land—upon which life depends." The EPA develops regulations and has additional responsibilities for enforcement of these regulations.

The EPA, like other U.S. government agencies, follows a prescribed rulemaking process. The U.S. Congress establishes these requirements to support the development of quality rulemaking and protect the rights of those affected by the rules. Examples of these requirements include the Administrative Procedure Act, the Regulatory Flexibility Act, the Unfunded Mandates Reform Act, the Paperwork Reduction Act, and the National Technology Transfer and Advancement Act. The five stages of rulemaking are

1. *Prerulemaking*—actions to determine whether the agency should initiate rulemaking
2. *Proposed rules*
3. *Final rules*
4. *Long-term actions*—prerulemaking, proposed rule and finals rules expected to be published beyond the next 12 months
5. *Completed actions*—actions that are promulgated and published or actions that are no longer being considered

Comments from interested parties are encouraged during the rulemaking process. All rulemaking activities are published in the *Federal Register*.

The U.S. Federal Communications Commission (FCC). The FCC is an independent U.S. government agency established in 1934 by Congress in the Communications Act of 1934. Its mission is "to regulate interstate and international communications by radio, television, wire, satellite and cable." The FCC's jurisdiction is the 50 states, the District of Columbia, and U.S. possessions. The FCC is organized in bureaus and offices, and the official statement of the FCC actions is called an *order*. Most of the FCC's documents are issued by seven major regulatory bureaus or offices. When the FCC considers a change to its regulations, it issues a Notice of Proposed Rule Making. Essentially all documents issued by the FCC since 1994, can be found on-line through its website.

The U.S. Federal Trade Commission (FTC). The FTC enforces federal antitrust and consumer protection laws and seeks to ensure that the nation's markets function competitively, and are vigorous, efficient, and free of undue restrictions. The FTC has enforcement and administrative responsibilities under 37 separate acts.

The U.S. Food and Drug Administration (FDA). The FDA is one of the oldest federal agencies involved with the protection of consumers. In the area of electrotechnology standards, it is involved with setting standards for medical devices and radiation-emitting products. This work is done under the FDA's Center for Devices and Radiological Health (CDRH). The CDRH is responsible for "ensuring the safety and effectiveness of medical devices and eliminating unnecessary human exposure to man-made radiation from medical, occupational, and consumer products." Products covered in the CDRH's scope include thousands of medical devices (e.g., pacemakers), videodisplay terminals, microwave ovens, medical x-ray machines, and medical ultrasound devices.

National Institute of Standards and Technology (NIST). NIST, which is under the U.S. Department of Commerce, has been involved in the development of standards since its founding in

1901 (then known as the National Bureau of Standards). The documents it produced played a great role in the industrial development of the United States in a broad range of industries, including steel manufacturing, railroads, electric power, and telephone communications. Today it is involved in manufacturing partnerships, quality systems, measurement and testing laboratories, and advanced technology programs. In quality systems, it sponsors the Baldridge National Quality Program and the Malcolm Baldridge National Quality Award.

NIST also develops standards and guidelines for federal computer systems. These documents, known as *Federal Information Processing Standards* (FIPSs), are approved by the Secretary of Commerce. FIPSs are generally developed only when there are no acceptable industry standards available or there are compelling federal requirements (e.g., security). There are also Federal Standards (FED-STDS) developed for telecommunications; however, these are developed by the National Communications System (NCS) and are approved by the General Services Administration (GSA).

The major focus of NIST is on information technologies. Under the National Technology Transfer and Administration Act of 1995, NIST supports the development of national and international voluntary standards as the preferred source of standards for use by the federal government. NIST cooperates with national and international standards organizations, trade associations, consortia, user groups, and so forth to have needed standards developed.

The U.S. Nuclear Regulatory Commission (NRC). The NRC is an independent federal agency established by the Congress under the Energy Reorganization Act of 1974, to "ensure adequate protection of the public health and safety, the common defense and security, and the environment in the use of nuclear materials in the U.S." Its predecessor was the U.S. Atomic Energy Commission. NRC regulations are issued under the U.S. *Code of Federal Regulations* (CFR) Title 10, Chapter 1. Typically, rulemaking is initiated by the NRC's staff; however, any member of the public may petition the NRC to develop, modify, or rescind any regulation. During the rulemaking process, the documents are published in the *Federal Register* and interested parties are allowed at least one opportunity to comment. In some instances, the NRC will hold meetings and workshops before a proposed rule is drafted to obtain a broad range of input from interested parties. Most often in the area of electrotechnology, the NRC will endorse existing industry standards by issuing a regulatory guide (RG). The RG will describe methods that are acceptable to the NRC for applying the standard. The NRC may also use the RG to make recommendations or guides presented in a standard mandatory requirements. The NRC also issues NUREG reports to provide information and expertise to support the NRC's decision making and to assess potential technical issues.

The U.S. Occupational Safety & Health Administration (OSHA). OSHA, which is under the U.S. Department of Labor, was established by Congress in 1970 under the Occupational Safety and Health Act to "save lives and prevent injuries and illnesses in American workplaces." OSHA has responsibilities for developing standards and regulations, and enforcement. OSHA may set standards on its own initiative or in response to petitions from state and local governments, employers, labor representatives, standards organizations, or any other interested party. If it is decided to develop a standard, any one of several advisory committees may be tasked with the development. The process is very similar to that for other U.S. government agencies, including notice and comment period for interested parties.

28.12 CONTACTING STANDARDS ORGANIZATIONS

There are literally thousands of organizations around the world that are involved in standards development. Today, the World Wide Web (WWW) makes contacting these organizations easier than ever. The following listing is just a small sample of what is out on the Web. Many of the websites listed contain links to the websites of other standards developers.
